The polar coordinates of the parent ganglion cell somata in the goldfish retina are reflected by the locations of their axons in the cross-sectioned optic nerve near the nerve head. The distance from the optic disc, r, is mapped on an axis extending from base to base of the roughly trapezoidal cross section. Sectoral origin (θ) is mapped on a second, orthogonal axis. Ventral retinal axons occupy the slanting sides of the trapezoid, axons from dorsal retina occupy the center, and temporal and nasal axons, intermediate positions (Easter et. al., J. Neurosci., 8:739, 1981), similar to the pattern in cichlid fish (Scholes, Nature, 278:620, 1979).

To study whether a similar map also exists more centrally in the optic pathway, we have labeled two groups of axons in the same nerve by punctate application of HRP to 1) fascicles in the retinal fiber layer, labeling axons from a common sector (similar θ), and 2) fascicles in the tectal stratum opticum, labeling fibers of similar age, originating from a common annulus in the retina (similar r). The labeled axons were traced in serial transverse sections from the retina through the tectum.

Axons of similar age remain clustered throughout the optic pathway, whereas axons of common sectoral origin spread over a larger cross-sectional area in the proximal nerve and contract again as they approach the tectum. The precise map observed near the optic nerve head is obscured in the nerve by: (1) this dispersal of fibers of common θ, (2) some ribbon-like folding, and (3) the general increase in diameter of the optic nerve. However, the two labeled populations remain roughly orthogonal to each other throughout the nerve and tract.

Mapping along the two orthogonal axes is obvious in cross-sectioned ventral and dorsal brachia, which carry fibers of dorsal and ventral hemiretinal origin, respectively. The youngest axons (large r) run close to the pial surface, the oldest axons (small r) are located deep, on the opposite side of the brachium. θ is mapped orthogonal to this age axis. Axons of temporal retinal origin run on the central side of the brachium, close to the nucleus rotundus, axons of nasal retinal origin are farthest from it, axons from intermediate retinal locations occupy intermediate positions. This fiber arrangement anticipates the order of exit of the axons from the brachium into the tectum, i.e. the temporal ones exit rostrally, the nasal ones, caudally. Fibers rearrange between the retina and the tectum, but the principle of orthogonally mapping sectoral and radial origin is retained, suggesting that common mechanisms might govern axon topography throughout the optic pathway. 174.4 PROJECTION PATTERNS OF HIPPOCAMPAL TRANSPLANTS IN ADULT HOST HIPPOCAMPUS VISUALIZED BY THY-1.1 IMMUNOHISTOCHEMISTRY. C-F. Zhou*, R.J. Morris*, R.M. Lindsay*, P.J. Seeley*and G. Raisman., Lab. of Neurobiology and Development, National Institute for Medical Research, Mill Hill, London, NW7 1AA, United Kingdom.

Transplantation of neural tissue can be used to shed light on the adult brain's capacity for change and the rules that govern such change. In our transplant experiments, grafts of embryonic mouse hippocampus were placed in the hippocampal formation of host adult mice. Donor tissue, either as primordia or dissociated cell fractions transplanted in a plasma clot, was from the mouse strain A/Thy-1.1 and therefore carried the 1.1 allelic form of the Thy-1 antigen. Host animals were congenic strain A mice expressing the alternative Thy-1.2 allele. Fibres projecting from the transplant could therefore be visualized by Thy-1.1 immunohistochemistry as positive stain against a negative (Thy-1.2) host background.

Two main types of projection were observed: mossy-fibre-like and fimbria-like. Mossy-fibre-like projections generated by transplanted granule cells were visualized as strong staining along the host suprapyramidal layer and weaker infrapyramidal staining along the normal mossy fibre pathway. These projections occurred where transplants interrupted host CA3 and their form depended on transplant position along CA3 and on the location of damage caused by the transplantation procedure. It appeared that deafferentation of neuropil supplied by host mossy fibres was necessary for the transplant projections. Fimbria-like projections from transplanted pyramidal cells occurred either along the commissural/associational band of the dentate molecular layer for transplants positioned at the mouth of the dentate gyrus or along host stratum oriens and stratum radiatum for transplants intersecting host CA3 at its juncture with the fimbria.

Thus projections from transplants appear to invade regions of denervated neuropil and are organized according to rules that are similar to those pertaining to normal fibre projections during development.

This work was supported by an EMBO Fellowship to PJS.

174.5 TRANSPLANTATION OF FETAL LATERAL GENICULATE NUCLEUS TO THE OCCIPITAL CORTEX: CONNECTIVITY WITH HOST'S AREA 17. M. A. MATTHEWS. Dept. Anat., L.S.U. Medical Center, New Orleans, LA. 70119.

The developing lateral geniculate complex was excised from fetal albino rats at 18 days of gestation and implanted into the occipital cortex of host animals at 5 days of postnatal age. Groups of host animals were sacrificed at 10, 20 and 30 days following this procedure. The transplant tissue of selected animals was stereotaxically lesioned two days prior to scheduled sacrifice and their brains subjected to either Fink-Heimer or electron microscopic analysis of the distribution and density of degenerating efferents from the transplant. The remaining animals were analysed by means of Bodian, Golgi-Cox or electron microscopic techniques.

Transplanted neurons displayed typical dendritic branching patterns of geniculate relay neurons by 20 days following implantation. Intrinsic neurons, characterized by a small ovoid soma and two main stem dendrites, only became evident in transplant tissue by 30 days and were much reduced in number. Synapses developed by 10 days and rapidly increased in number by 20 and 30 days. Most complexes were simple axo-dendritic, asymmetric junctions. Multiple serial and reciprocal complexes, as well as the characteristic glomerular complex, failed to appear.

Analysis of Bodian stained material revealed a dense network of fibers coursing about the transplant. Distinct bundles of these fibers were observed extending from the medial edge of the transplant into area 17 by 20 days following implantation. A Fink-Heimer analysis of animals whose transplants were stereotaxically lesioned revealed degeneration in Layers II-VI of the primary visual cortex but the majority of these fibers terminated within the lateral two-thirds of Layer IV. Few degenerated fibers could be found in the underlying white matter indicating that efferents from the transplant found their way to their "correct" target zone by growing through a complex neuropil which provided minimal physical substrates to guide such growth. Most of the contacts formed by these fibers were simple junctions along the shafts of dendrites with a wide range in diameter.

It is concluded that the nearby host visual neurons, which are the correct target cells for the efferents arising in the transplant, induced a directed growth of these fibers.

174.6 TRANSPLANTATION OF LABELED BRAIN CELL SUSPENSIONS BETWEEN SPECIES. J. Wells, B.P. Vietje, D.G. Wells, M. Boucher and R.P. Bodony. Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

Cross-species cell suspension transplants to the hippocampal formation have proven to be successful in restoring function after fornix lesions. In such transplants the cells do not remain aggregated and have been difficult to locate in the host. In order to describe the migration and differentiation of the transplanted cells, the cell suspensions were labeled prior to injection into the denervated host hippocampus. The transplanted cells were labeled with 1% and 5% HRP, 1% HRP conjugated to wheatgerm agglutinin (WGA) and by an antibody to WGA. A variety of fluorescently labeled compounds (WGA/FITC, Lucifer yellow and PHA-L) were also used, but, because there was autofluorescence and phagocytosis of fluorescent particles in the host, the separation of host cells from donor cells could not be made unequivocally. Cells to be labeled and injected were from E15-E17 mouse embryos and were transplanted into adult rat hosts. The hosts were sacrificed 7-11 days after transplantation. Control injections into the dentate gyrus using the same procedures but injecting only 1% HRP with no cells showed only lightly labeled contiguous cell bodies in the dentate granule cell layer.

Labeled neurons and glia survived in the host hippocampal formation. Many cells had migrated away from the injection site and it was rare to see neurons and glia within the injection site. The labeled cells had differentiated and grown to exhibit extensive processes. Some of the labeled processes had structures which appeared to be growth cones and filopodia. The position of the transplanted cells was dependent on the injection site in the hippocampal formation. When the injection was deep, there was a propensity for the cells to be oriented along the dentate granule cells. In those labeled cells which were found in the dentate granule cell layer, the differentiating processes were most frequently oriented toward the molecular layer rather than the hilus. None of the labeled neurons looked like dentate granule cells. If the injection was between hippocampus and dentate, most cells were oriented along the obliterated hippocampal fissure with processes that bridged the fissure. In more dorsal injections, cells were seen oriented along the pyramidal cell layer. Since the HRP reaction product is electron dense, the transplanted cells can be observed ultrastructurally. Distinct synapses on labeled processes were difficult to discern at these survival times, but vesicle-containing profiles were observed in close apposition to labeled membranes. This method will be an important adjunct to the techniques for studying the migration, growth and differentiation of neurons and glia.

174.7 **LIGHT MICROSCOPIC ANALYSIS OF MIGRATION OF SYMPATHETIC PREGANGLIONIC NEURONS IN CHICK EMBRYO.** Anita Prasad* and Margaret Hollyday. Dept. Pharmacol. & Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

We have been looking at the normal development of the Terni Column (TC) in the chick embryo. The TC is comprised of visceral motoneurons in the spinal cord which project to sympathetic ganglia via the ventral roots. From their origin in the ventricular zone these neurons, along with the somatic motoneurons, migrate ventro-laterally. As originally described by Levi-Montalcini (1950) the TC cells subsequently undergo a secondary migration traveling medially and dorsally to their adult position adjacent to the central canal.

As a preliminary study for experiments addressing factors controlling this migration, we have reexamined the migration of these cells using retrograde transport of HRP. HRP conjugated to WGA was injected into the ventral root. The HRP reaction product was visualized by processing the tissue with DAB following a cobalt intensification step. This technique produces Golgi-like staining of the labeled cells which enabled us to study the morphology of the TC cells during migration. We identify Terni cells as those cells positioned medial to the commissural (arcuate) fibers which separate the motor column from the ventricular epithelium and labeled by virtue of having an axon in the ventral root.

Before stage 26, the HRP labeled cells formed a compact, seemingly homogeneous, cluster of cells in the ventrolateral portion of the spinal cord. Some of these cells showed signs of early dendrite formation but the majority were spherical and none of these cells had labeled processes extending medial to the commissural fibers. We interpret this cluster as consisting of both somatic motoneurons and Terni cells prior to their secondary migration. Presumptive migrating Terni cells were first seen at stage 26. These cells had slender processes extending medially, which typically interdigitated with cells of the ventricular epithelium. While some cells were bipolar in shape, the majority of the labeled cells had two or more processes extending medially and/or dorsally to the neuron soma. No growth cone-like specializations were visible at the ends of these processes. The number and complexity of the processes extending from the cell bodies increased in older embryos. Neurons appeared to reach their permanent location and to initiate dendrite formation as early as stage 30. In contrast to the processes extending from labeled cells along the migratory pathway, these incipient dendritic processes were thicker and more irregularly shaped, and commonly ended in enlarged club-shaped specializations. Some of these dendrites extended across the dorsal midline.

Labeled axons were seen in the sympathetic ganglion in stage 26 embryos, the stage when the retrograde migration begins. We are pursuing experiments to determine whether normal migration of the Terni cells depends on the presence of sympathetic ganglion cells.

174.8 WHOLEMOUNT VIEWS OF AXONAL GROWTH CONES IN THE DEVELOPING SPINAL CORD OF XENOPUS. R.H.Nordlander. Dept. Oral Biology, Case Western Reserve University, Cleveland, OH 44106.

Growth cones at the tips of developing longitudinal spinal axons of Xenopus embryos and larvae were filled anterogradely with horseradish peroxidase (HRP) from a number of sites in the brainstem, the spinal cord, and the periphery. After a suitable interval, usually one hour or less, animals were fixed in a solution of 1% paraformaldehyde and 2.5% glutaraldehyde in 0.1 M phosphate buffer at pH 7.3. Spinal cords were dissected free of surrounding tissues, reacted with the reagents of Hanker et al (Histochem.J., 9:789, 1977), and viewed whole in glycerin.

The configurations of the growth cones observed here varied quite widely. Those of primary sensory (Rohon-Beard) neurons were only slightly enlarged and displayed almost no filapodia either at their ascending or descending tips. Those of dorsal root afferents were also generally simple though some filapodia were occasionally observed. Growth cones at the lead of their finer collatral branches, however, were delicate and frilly.

Growth cones of descending axons in the ventral and lateral fasciculi were labeled from sites in the brainstem or spinal cord and belonged to a number of different cell types (Nordlander,R.H., J.Comp.Neurol., 228:117, 1984). These were best seen in lateral views of the cord and were the most variable in shape. Most of these growth cones were bulbus in outline with a few filapodia usually at their apices. Others seemed to be flattened in a plane parallel to the surface of the cord with several webbed filapodia. Still others spread widely over the lateral fasciculus with parallel filapodia reaching into multiple parallel longitudinal tracts.

Axons trailing behind most of these growth cones were straight and constant in dorsoventral position over their entire lengths. In a few cases, however, the trailing axon "hopped" from one parallel course to another and back again as if it had been pulled caudally in the wrong fascicle for a short time and then had corrected its course. Variocosities along the lengths of these developing axons were most common at younger stages.

Growth cone morphology in this system is probably influenced by the same factors that control growth cone shape in vitro (Letourneau,P.C., Devel.Biol. 44:77 and 92, 1975). These include the configuration of the substratum and the adhesiveness of the substratum.

174.9 FUNCTIONAL INTERACTIONS BETWEEN IDENTIFIED GROWTH CONES AND MUSCLES IN EMBRYONIC ZEBRAFISH. Judith S. Eisen, Paul Z. Myers*, and Monte Westerfield. Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Embryonic zebrafish first exhibit spontaneous muscle contractions at about 18 hrs post-fertilization (17 somites at 28.5°C). These contractions begin as localized twitches in individual segments with no apparent coordination between segments or between left and right halves of the same segment. Twitches can first appear in any trunk segment (1-15), and later develop in other segments in no apparent sequence. We have correlated the first appearance of primary motoneuron growth cones with the onset of twitching, and suggest that these early muscle contractions are neurogenic in origin.

Primary motoneurons were identifiable prior to axogenesis by their size and position in the spinal cord. The first primary motoneuron to initiate axogenesis in each segment invariably was located on the ventrolateral aspect of the spinal cord and in the middle of the segment. Within a few minutes after the growth cone of this identified cell left the spinal cord, localized twitches were observed in that segment. These twitches consisted of single contractions that repeated at irregular intervals of 2 sec to 2 min and were restricted to 2-4 muscle fibers at the region of the horizontal septum separating the ventral and dorsal regions of the muscle. These fibers are the first to express mature properties including cross striations and acetylcholine esterase activity. The growth cone was within 20 µm of these fibers when contractions were first observed.

These early contractions appear before primary motor growth cones make obvious contacts with the muscle fibers and certainly before organized neuromuscular junctions are present; this may indicate that subsequent coordinate development of the muscle and motoneurons depends on neuromuscular activity.

174.10 REGENERATING OPTIC NERVES PRODUCE STEADY CURRENTS AT THEIR TIPS. John A. Freeman. Dept. of Anatomy, Vanderbilt Univ. Sch. of Med., Nashville, TN 37232.

Previous studies have shown that growth cones of retinal ganglion cells in culture generate steady inward calcium currents across their tips as they grow (Freeman et al, J Neurosci. Res., 1985). The present study was undertaken to determine whether such currents are also produced during regeneration of the optic nerve in vivo, which would imply that they may play a critical role in the process of nerve growth. Small (1.0-1.5 mm) incisions were made in the medial branch of the optic tract of adult toads (Bufo marinus) on the dorsal surface of the optic tectum. Field potentials evoked by stimulation of the distal portion of the optic tract were recorded to verify which portion of the tract had been severed, and the site of the injury was recorded with a video camera/ frame buffer and stored in a PDP 11/34 computer. Five days later, when the majority of cut optic nerve fibers have developed growth cones and have begun to regenerate, the animals were re-anethetized, and the regions of the optic tract containing the regenerating fibers were mapped with a 2-dimensional vibrating microprobe (Freeman et al, op cit). A consistent pattern of current densities was found at each active site. This consisted of a distribution of positive currents flowing inward at the sites of regeneration, and oriented parallel to the axis of the optic nerve fibers. The current densities ranged in amplitude from 5×10^{-6} A/cm^2 to 7×10^{-5} A/cm^2 at a distance of approximately 100-200 um from the site of the regenerating fiber tips. The video system was used to superimpose the measured current density vectors on the image of the region from which they were recorded, for subsequent microscopic correlation. Application of a Ringers solution containing 0.5mM Ca^{2+} and 100 um La^{2+}, which is known to block calcium currents through calcium channels, abolished the measured currents within 20-30 minutes, suggesting that the regeneration currents are carried principally by calcium ions. Control lesions of the optic tract mapped at the time of injury generated small transient currents, which in contrast to the regeneration currents, decayed rapidly over 1 hour, and were not blocked by La^{2+}. These results complement those of Borgens et al (PNAS, 1980) who found that persistent currents entered the transected lamprey spinal cord. I conclude that regenerating nerve fibers generate substantial steady currents across their tips, which are likely to play a significant role in nerve growth, possibly related to the transport and fusion of membranous vesicles, the electrophoretic transport and alignment of membrane macromolecules, and the release of neurotransmitter, as previously suggested (Freeman et al, op cit).

174.11 SPINAL CORD EXPLANTS CULTURED ON CARBON FILAMENTS AND STIMULATED WITH DIRECT CURRENT: AN EM STUDY. T. Khan, G. Gaik, J. Luberda*, Rehab R&D Center, VA Hospital, Hines, IL

In previous studies, we observed that carbon filaments provided a supporting framework or scaffolding for growing processes in cultures of spinal cord explants. In addition, morphometric techniques demonstrated that direct electric currents applied to carbon filaments enhanced growth of neurites within the cultures. This study focuses on the electron microscopic appearance of the growing explants on non-stimulated and electrically stimulated carbon filaments.

The culture assemblies consisted of approximately 3000 parallelly aligned carbon filaments (8-10 mm diameter) that were attached to the bottoms of 35 mm plastic petri dishes. In electrically stimulated chambers, the ends of the filaments extended through and beyond the dishes and were attached to a direct current source. Two millimeter thick lumbar spinal cord segments from 17 day old rat embryos were prepared under sterile conditions. All explants were grown for three weeks in modified Dulbecco Eagle medium supplemented with 20% fetal calf serum, 0.6% glucose, and 10% penicillin-streptomycin at 37 degrees C in a humidified 95% air and 5% CO2 atmosphere. Specimens for EM observation were fixed at room temperature for 1 hr in 2% glutaraldehyde and 2% formaldehyde in 0.1M phosphate buffer PH 7.4. After rinsing tissues were postfixed in 1% osmium textroxide for 1 hr, dehydrated and embedded in araldite.

Light microscopic observation of living cultures of both non-stimulated and stimulated explants showed that the explants grew between and parallel to the long axis of the carbon filaments. It was noted in the 1 micron plastic sections that some of the cells had migrated along the carbon filaments beyond the boundries of the original explant.

With the electron microscope, the non-stimulated cultures appeared to consist of immature neurons with few neurites and well developed glial cells. The cytoplasm of the neurons contained swollen-appearing golgi and smooth endoplasmic reticular cisternae, scattered fragments of rough edoplasmic reticulum, and some mitochondria. Neurites were few in number, and no synapses were observed. The ultrastructural morphology of the stimulated explants differed in that the neurons were mature in their appearance. The cytoplasm of these cells consisted of a well defined golgi apparatus, nissl material, and mitochondria. Many large dendrites and axons containing well defined microtubules were noted. Axodendritic and axosomatic synapses were frequently observed. The glial cells were well developed.

In conclusion, our electron microscopic data confirmed our previous morphometric observation that growth of spinal cord explants cultured on carbon filaments was enhanced by stimulation with direct current. (supported by VA and PVA Vaughan Chapter)

174.12 NEUROPEPTIDES OR THEIR PRECURSORS ARE PRESENT IN GROWTH CONES OF APLYSIA NEURONS IN VITRO. M. S. Flaster, R. T. Ambron, and S. Schacher. Ctr. for Neurobiol. & Behav., Depts. Anat. & Cell Biol., Columbia Univ., College of P&S, and NYS Psychiat. Instit., New York, NY 10032

Recent in vitro studies indicate presence and release of conventional neurotransmitter at growth cones. Are these findings generalizable to peptide neurotransmitters? Here we report evidence that neuropeptide transmitters or their precursors are present in neuronal growth cones in vitro.

Identified neurons were removed from the abdominal ganglion of the marine mollusc Aplysia californica and placed into cell culture as previously described (Schacher, S., & Proshansky, E., J. Neurosci., 3:2403, 1983). Reagents used for indirect immunofluorescence included anti phe-met-arg-phe-amide (FMRFa) antiserum (Peninsula Laboratories) and 3 anti-R3-R14 peptide antisera of differing sequence specificity (gifts of Dr. R. Scheller).

Anti-FMRFa antisera on cells R2, L2-L6, L12 and L13 yields positively staining cell bodies and intensely staining varicosities and growth cones. All these cells have previously been shown to contain FMRFa-like immunoreactivity in vivo (Brown, R.O. et al., Soc. Neurosci. Abstr., 10:691, 1984). Other cells including L11 and the right upper quadrant (RUQ) cells are non-immunoreactive in vivo and also fail to stain in vitro.

RUQ cells fluoresce intensely and specifically with all 3 anti-R3-R14 antisera as has been previously reported for these cells in vivo (Kreiner, T. et al., J. Neurosci., 4:2581, 1984). Cell bodies stain positively and growth cones and varicosities stain intensely. In all growth cones, fluorescence was more intense in the proximal portion and far less intense in distal regions displaying filopodia. In well spread growth cones, the staining was punctate. RUQ growth cones can be isolated for biochemical analysis (Flaster, M. et al., Soc. Neurosci. Abstr., 10:923, 1984). Following a 24 hr exposure to ^{35}S-methionine, growth cone fractions were collected and compared to RUQ cell bodies, primary RUQ neurites free of growth cones, and the neurites and cell bodies of other identified neurons using SDS-PAGE and fluorography. A prominent band migrating with M_r of 11 kD was found to be uniquely present in all RUQ cell fractions including growth cones. A species of similar M_r has been previously reported to be the R3-R14 propeptide (Kaldany, R-R. et al., Ann. Rev. Neurosci., 8:431, 1985). The presence of the propeptide in the growth cone is consistent with our immunocytochemical results, although smaller, more fully processed peptides may also contribute to the immunocytochemical signal. We also find a prominent peptide species with M_r of 14.5 kD uniquely present in RUQ cell bodies, but absent from other cells and the neurites or growth cones of RUQ cells. The identity of this species remains to be established but it may be related to the R3-R14 pre-propeptide which is similar in size (Nambu, J.R. et al., Cell, 35:47, 1983).

While the presence of neuropeptides in growth cones in vivo remains to be established, the presence of neuropeptide or precursor in the growth cones of neurons in vitro suggests a possible role for these peptides in the earliest interactions between synaptic pairs.

174.13 ULTRASTRUCTURAL LOCALIZATION OF IONS IN NEURONS BY ELECTRON PROBE MICROANALYSIS. D.A. Spero*, K.J. Doane*, I.C. Piscopo* and F.J. Roisen (SPON: G. Krauthamer). Dept. Anatomy, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854 and Philips Electronic Instruments, Mahwah, NJ 07430.

We employed a combination of established morphological techniques in a novel manner to determine the regional distribution of ions in Neuro-2a murine neuroblastoma and primary cultures of dissociated 9-day embryonic chick dorsal root ganglia (DRG). These techniques involved electron probe analysis of quick-frozen, freeze-substituted whole-cell mounts at the ultrastructural level. Neuro-2a and DRG neurons were prepared and grown as described previously (Roisen et al., J. Neurobiol., 4:347-368, 1972; Spero and Roisen, Dev. Brain Res., 13:37-48, 1984). Cells were plated on Formvar-carbon-coated gold grids treated with poly-L-lysine. Cultures were grown for 24-48 h in an atmosphere of 5% CO_2 in air at 35°C. Cultures were drained free of residual medium and quick-frozen by immersing into Freon 22 cooled to its melting point with liquid nitrogen. Samples were freeze-substituted in a mixture containing 1% glutaraldehyde and 0.02 M cacodylate buffer (pH 7.2) in absolute ethanol at -80° C for 2 days. Cells were critical-point-dried in CO_2, coated lightly with carbon and examined with a Philips EM420T equipped with an EDAX 9100 X-ray microanalysis system. Whole-cell transmission electron micrographs were taken of representative cells at 80 kV. Multiple electron probes of 1 um diameter were made in representative intracellular regions including the soma, neurite shaft and growth cone to determine quantitatively the presence of ions in these regions. Background counts obtained from noncellular areas were stored in a microprocessor and substracted from those obtained in cellular regions. The Na, Mg, P, Cl, K and Ca concentrations of the various regions of neurons were not significantly different. However, the concentration of zinc in the neurite and growth cone were increased when compared to the soma in both Neuro-2a and DRG neurons. A comparison of the ion concentration in neurons with non-neuronal cells in DRG cultures revealed higher Ca levels in the non-neuronal cells. These results indicate that the quick-freeze, freeze-substitution method yields high quality ultrastructural preservation, while retaining elements for microprobe analysis. Studies are in progress to determine the developmental changes in the distribution of zinc and its association with a subcellular compartment during neuritogenesis.
Supported by NIH grant NS11299.

174.14 POLARIZED COMPARTMENTALIZATION OF ORGANELLES IN GROWTH CONES FROM DEVELOPING OPTIC TECTUM. T.P.O. Cheng* and T.S. Reese, Lab. of Neurobiology, NINCDS, NIH, at the Marine Biological Lab., Woods Hole, MA 02543.

Computer-assisted reconstructions of continuous serial sections have been used to study the cytoplasmic organization of growth cones in vivo. Optic tecta from 6¼-6½ day old chicken embryos were quick-frozen and then freeze-substituted in acetone-osmium tetroxide (5%) or, for comparison, prepared by conventional fixation (2% glutaraldehyde, 2% formaldehyde and 0.5% acrolein in 0.2M cacodylate buffer, pH 7.2). Ten growth cones were reconstructed from aligned serial electron micrographs. In the freeze-substituted growth cones, numerous lumenless membrane-bound sacs and arrays of multilamellated stacks replaced the abundant smooth endoplasmic reticulum (SER) found after chemical fixation. Microtubule fascicles were well organized in the neurites, but progressively diverged from their typical fascicular organization in the initial segment (transition zone) of the growth cone, and were essentially absent in its varicosity and more distal segment. In contrast, mitochondria were concentrated in the proximal segment of the varicosity while the multilamellated stacks and the endosomal vacuoles were concentrated in the distal segment. Coated pits and vesicles were concentrated near the terminal filopodium in the most distal and organelle-poor domain of the growth cone. Five structural domains are thus delineated along the longitudinal axis of the growth cones on the basis of the spatial distributions of the intracellular organelles: terminal neurite; transition zone; proximal and distal segments of the varicosity; and terminal filopodium.

Measurements were made of the distribution density of coated pits, microtubules, mitochondria, coated vesicles, endosome-like vacuoles, and multilamellated stacks of lumenless membrane-bound sacs (membrane discs) in the structural domains along the growing axis of the growth cone from their serial reconstructions. The polarization of the cytoplasmic compartments, as defined by the distribution of intracellular organelles in the growth cones, was evident when these measurements were pooled, supporting the observed differences in the distribution of various organelles listed above.

In conclusion, the morphological observations suggest that dilation of and fusion among the lumenless membrane-bound sacs, resulting from chemical fixation, may have given rise to the SER network, while the three-dimensional reconstructions suggest that cytoplasmic components of growth cones are polarized along the longitudinal axis of growth, which may reflect their role in membrane recycling.

174.15 RAPID QUANTITATION OF NEURITIC OUTGROWTH WITH A MICROCOMPUTER-BASED IMAGE PROCESSOR. T.A. Dahlberg*, T.S. Ford-Holevinski* and B.W. Agranoff. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

The quantitation of neurite outgrowth in explant culture is typically based on visual estimates of outgrowth density, average length, grid crossings or area of outgrowth which may then be incorporated into a formula determining total outgrowth. These methods tend to be tedious and subject to operator bias. Taking advantage of current microprocessor technology, we have constructed an inexpensive device of commercially available components which will accurately determine the degree of neuritic outgrowth in our explant cultures in 30 sec entirely independent of user input. The components of this system are: an Apple II microcomputer, a black and white video camera, a circuit board to digitize the video signal (Dithertizer II; Computer Stations, Inc., St. Louis, MO) and a 68000 coprocessor board to store and analyze the digital images (Dtack Grande; Digital Acoustics, Santa Ana, CA). Software written in 6502 and 68000 assembly languages allowed this device to be used as an image processor. Interfaced with a Leitz Diavert microscope and utilizing pseudo-darkfield microscopy, the image processor was used to acquire and store images of goldfish retinal explants in culture. The final digital image was composed of a matrix of 280 X 192 picture elements (pixels) each of which was represented by one byte (256 gray levels). At the magnification used, the pixels measured 9 X 10 micrometers in the horizontal and vertical dimensions, respectively. The images were mathematically manipulated by algorithms designed to maximize visualization of the neurites growing out from the explants and to minimize the presence of the explant body itself. Finally, a pattern recognition scheme was used to remove non-neuritic debris as well as to restore the continuity of the digitized neurites. The number of pixels that were "lit" in the final binary image were then counted and used as the measure of growth for the explant at each time point examined. The coefficient of variation for repetitive scans of a single explant is 2.2% while the correlation coefficient is 0.94 when results obtained with this device are compared to those obtained by a visual estimation technique. (Supported by NEI Grant EY 05947. T.F.-H. was a trainee on NIH Training Grant MH 15794.)

174.16 LAMINAR DISTRIBUTION OF MICROTUBULE-ASSOCIATED PROTEIN 2 (MAP2) IN EMBRYONIC MOUSE CORTEX. J.E. Crandall, M. Jacobson* and K.S. Kosik*. Southard Lab., E.K. Shriver Ctr., Waltham and Dept. Neurol., Harvard Medical School, Boston MA

Dendrites of neocortical pyramidal neurons grow and differentiate in the following order: apical tufts, basilar branches and apical collaterals. This growth sequence is correlated roughly with the order in which proliferating axons invade the molecular and subplate layers prior to the cortical plate. Using a monoclonal antibody, 5F9, (Kosik et al., P.N.A.S., 81:7941, 1984) to microtubule-associated protein 2 (MAP2) that selectively stains dendrites and neuronal somata, we have investigated the time and location of appearance of MAP2 immunoreactivity in the embryonic neocortex of the mouse from embryonic day 13 (E13), prior to cortical plate formation, until birth (E19). Embryos were removed from timed-pregnant females and perfused transcardially with or immersed in a 2% paraformaldehyde-lysine-periodate fixative (McLean and Nakane, J. Histochem. Cytochem., 22:1077, 1974). Coronal and tangential 50-70 um vibratome sections were processed for immunocytochemical analysis at both light and electron microscopic levels. The secondary antibody was conjugated to peroxidase and the reaction product was visualized with diaminobenzidine.

Using this staining protocol there was no detectable MAP2 immunoreactivity above background control levels at E13. From E15 to birth the staining pattern of MAP2 immunoreactivity was laminar specific and similar in all neocortical regions surveyed. The molecular layer and subplate of the developing cortex contained the most dense staining of both cell bodies and processes. In these two laminae reaction product was seen in dendrites and cell somata at the ultrastructural level at E17. The cortical plate exhibited weak to moderate staining of single or grouped radial process and cell somata. The ventricular, subventricular and intermediate zones did not stain above background levels in control sections incubated with secondary antibody only or with MAP2- preadsorbed antibody. The laminar pattern of staining may be due to the higher density of differentiating dendrites present in the molecular and subplate layers or to compartmentalization of MAP2 within an individual differentiating neuron. Supported by NIH grants NS12005 and NS20213.

REGENERATION: PATTERNS AND RESPONSES

175.1 SIMULTANEOUS RECORDING OF INHIBITORY INTERACTIONS BETWEEN TWO TASTE NERVES IN ONE PERIPHERAL FIELD. D. R. Riddle*, C. R. Belczynski*, S. E. Hughes*, L. L. Morton* and B. Oakley. Div. of Biol. Sci. Univ. of Mich., Ann Arbor, MI 48109.

The right chorda-lingual nerve will regenerate into the distal stump of the left lingual nerve of gerbils. Subsequent electrophysiological recording from both chorda tympani nerves and histological analysis of the tongue indicated that the left half of the tongue had been supplied with two chorda tympani nerves and the contralateral lingual nerve. In spite of the presence of additional taste axons from the contralateral chorda tympani, no additional taste buds were formed. We conclude that the character of the epithelium, and not the number of taste axons, sets an upper limit to the number of taste buds which can be formed. In these animals it was possible to record impulse discharges from both chorda tympani nerves simultaneously while the tongue was stimulated with 0.3 M NaCl, 0.5 M sucrose, 0.3 M KCl, 0.3 M NH_4Cl, 0.01 M HCl, 0.01 M quinine hydrochloride, 0.3 M $CaCl_2$ and a concentration series of sucrose and of NaCl. The two nerves responded to all chemicals and had similar apparent dissociation constants for sucrose, but the latter values were 2-4 times higher than normal. Responses of the foreign chorda tympani were slower both to rise and to fall from maximal levels. Taste stimulation often inhibited spontaneous activity in multi-unit recording, especially in the foreign chorda tympani nerve. Periods of vigorous activity in the native chorda tympani sometimes coincided with depressed activity in the foreign chorda tympani. Moreover, electrical stimulation of the native chorda tympani frequently suppressed taste responses from the foreign chorda tympani, sometimes for several minutes. We suggest in these hyperinnervated tongues that the sluggish responses to stimulus onset and offset, the inhibition of spontaneous activity, and the inhibitory effects of electrical stimulation reflect inhibitory interactions between taste cells or taste axons that may be similar to the processing of sensory information in normally innervated tongues. Supported in part by NIH Javits Award No. NS07072.

175.2 THE EFFECT ON THE RAT HYPOGLOSSAL AND DORSAL MOTOR NUCLEUS OF THE VAGUS NERVE OF VINBLASTIN APPLIED TO THE INTACT HYPOGLOSSAL AND VAGUS NERVES. H. Aldskogius and M. Svensson (SPON: G. Grant). Dept. of Anatomy, Karolinska Institutet, Stockholm, Sweden.

It has been proposed that axotomy-induced retrograde changes in neurons and their environment develop because the transport of trophic substances from the periphery to the nerve cell bodies is interrupted. Electrophysiological and ultrastructural studies on sympathetic ganglia following application of colchicin to postganglionic axons support this notion (Purves, D., J. Physiol. 259:159, 1976). However, in a recent study using the 2-deoxyglucose technique to evaluate retrograde responses in the hypoglossal nucleus after injection of colchicin in the hypoglossal nerve, the characteristic axotomy-induced increase in 2-deoxyglucose uptake was not observed (Singer, P.A. et al., J. Neurosci. 2:1299, 1982).

In the present study the possible effects of blocking retrograde transport in peripheral nerves with vinblastin have been examined histologically in the hypoglossal nucleus and dorsal motor nucleus of the vagus nerve.

Experiments were performed on anesthetized (chloral hydrate 35 mg/100 g b.w. i.p.) adult, female Sprague-Dawley rats (200-250 g b.w.). Cuffs were prepared by soaking a piece of artificial hemostatic material in a solution of vinblastin (0.05, 0.025, 0.01 or 0.005%) in saline. In control experiments cuffs containing saline alone were used. The cuffs were wrapped around the right hypoglossal and left vagus nerves. A piece of Parafilm was placed under the cuff. After 30 min., the cuff and Parafilm were removed and the area flooded with saline. In one series of experiments, the effects on the retrograde transport of wheat germ agglutinin conjugated horseradish peroxidase from the tongue and pyloric region were examined. Tracer injections were made two days after the cuff application, and the animals were aldehyde-perfused after another two days. Serial, frozen, tetramethyl benzidine processed sections from the brain stem and nodose ganglia were examined. In a second series of experiments, the animals were aldehyde-perfused seven or 12 days after the cuff applications. The brain stem was embedded in paraffin, serial 6 µm sections cut and stained with cresyl violet, and examined qualitatively for the presence of chromatolytic neurons and quantitatively with regard to the number of perineuronal glial cells.

A dose of 0.01% or more blocked retrograde transport of HRP or HRP conjugate almost completely in the hypoglossal nerve and a dose of 0.005% or more in the vagus nerve. At these doses, the majority of neurons ipsilateral to vinblastin treatment were chromatolytic and a perineuronal glial cell reaction was present. These results are compatible with the proposal that interruption of axonal transport of trophic substances from the periphery is a "signal" for the induction of retrograde neuronal and associated non-neuronal changes.

175.3 PATTERNS OF AXONAL REGENERATION AFTER NEONATAL SCIATIC NERVE CRUSH. C.-B. Jeng and R.E. Coggeshall. Marine Biomedical Institute and Depts. of Anatomy and of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

It has been reported that neonatal peripheral nerve damage results in death of primary sensory and/or motor neurons. The present study is an extension of this work in that we present axonal numbers in the distal stump and various tributaries of the damaged nerve. To do this, we crush the sciatic nerve in neonatal rats (< 24 hrs. old). Eight weeks later, all axons in the sciatic nerve distal to the crush (sciatic), the sural nerve (SN), the digital nerve to the 2nd toe (DN), the nerve to the medial gastrocnemius muscle (NMG), the nerve to the lateral gastrocnemius muscle (NLG) and the nerve to the flexor digitorum longus muscle (NFDL) are counted by electron microscopy.

The axon counts are:

	Sciatic		Sural		DN		NLG		NMG		NFDL	
	MY	UN	MY	UN	MY	UN	MY	UN	MY	UN	MY	UN
Operated	5700	8000	460	850	30	160	680	600	480	340	340	330
Normal	8000	16000	1000	3500	142	380	400	660	280	430	400	430

Note that in the regenerated sciatic nerve, there are 25% fewer myelinated and 50% fewer unmyelinated axons than in the normal. This pattern is not repeated in the tributary nerves. For the cutaneous nerves (SN & DN), there is a considerably greater loss of axons, whereas in the muscle nerves (NLG, NMG, NFDL) there is only a slight loss of unmyelinated axons and myelinated axon numbers are increased in NLG and NMG. Further work on mechanisms that lead to these different patterns and to relate these patterns to the sensory and motor cell loss are underway. This work emphasizes the differences in patterns of axon regeneration when a nerve is damaged in a neonate as compared to an adult.

175.4 AXONAL GROWTH AND REGROWTH AFTER SPINAL CORD LESIONS IN NEWBORN RATS. B. S. Bregman, M. McAtee*, and S. Sobhani*, Dept. Anatomy, University of Maryland School of Medicine, Baltimore, Maryland 21201.

After spinal cord lesions sustained neonatally, even late-developing, uninjured axons are unable to grow through the site of a lesion, but can take an aberrant route through adjacent undamaged spinal cord tissue. The current experiments were designed to determine whether transplants of fetal spinal cord tissue could provide a terrain for axonal elongation that is more favorable than that encountered at the glial scar at the lesion site, and serve as a bridge for both injured and later developing pathways to reach spinal cord segments caudal to the lesion. In the current experiments, newborn rats (< 72 hours) received spinal cord transections at a mid-thoracic level. Transplants of fetal spinal cord tissue from fetuses 13-14 days in gestation were placed into the lesion site. Normal littermates and littermates with spinal cord lesion but not receiving a transplant served as controls. We have used peroxidase-antiperoxidase immunocytochemical techniques to examine the descending serotonergic projection from the medullary raphe nuclei to the spinal cord in order to determine: 1) Do the transplants receive serotonergic innervation from the host CNS? and 2) Do the serotonergic axons grow across the transplant and back into the host spinal cord caudal to the lesion?

At the time of transplantation, the fetal spinal cord (E13-14) does not contain serotonergic (5-HT) innervation. The newborn spinal cord contains 5-HT immunoreactive fibers throughout its length. At 1 mo. to 1 yr. survival, there is a moderate to dense 5-HT innervation throughout the transplant and fibers can be observed crossing between host and transplant. No 5-HT immunoreactive cell bodies were identified within the transplants. Neonatal transection abolished the 5-HT innervation of the spinal cord caudal to the lesion by 7 days post-transection. In animals with transplants, however, 5-HT axons were identified both within the transplant and within the host spinal cord caudal to the transection. In the host spinal cord caudal to the transplant, fascicles of 5-HT fibers were often located in an ectopic position (e.g. dorsal column). Despite their abnormal position within the white matter, the 5-HT fibers innervated normal targets within the host spinal cord, e.g. the intermediolateral cell column. Growth was not limited to spinal cord segments immediately adjacent to the lesion and transplant; 5-HT fibers were identified throughout the host cord as far as the lumbar enlargement. The density of 5-HT innervation was far less than that encountered normally. Thus, late-developing or regrowing serotonergic axons were able to cross the site of a neonatal spinal cord transection by growing through the transplant and were able to innervate the host spinal cord caudal to the lesion.

175.5 **Behavioral Analysis of the Recovery of Command System Function Following Spinal Transection in Larval and Adult Sea Lampreys.** D. Kaufman*, L. Margolin* and J. Ayers. (Spon: R. Schatz). Dept of Biology and Marine Science Center, Northeastern University, East Point, Nahant, MA 01908.

We have used a computer algorithm for the analysis of undulatory behaviors (Science 221: 1312-1314) to compare the movement parameters of freely behaving recovered spinally transected larval and adult sea lampreys to the behavioral output evoked in these same specimens by electrical microstimulation of locomotor command tracts located in the rhombencephalon. Experimental animals were fully transected at the ninth myotome caudal to the last gill arch and allowed to recover for 90-120 days until they achieved the criterion for complete recovery of swimming (Brain Res. 279: 238-240). Specimens were prepared for focal extracellular stimulation by exposing the brain and rostral spinal cord. The anterior quarter of the body was pinned to a Sylgard™ lined dish, allowing the caudal regions of the body to undulate freely. Double barreled microelectrodes were used to deliver biphasic stimuli (ammocoete, 10-30 hz., 20-60 μa; transformers, 10-15 hz., 30-60 μa) to the bilateral command tracts .

Stimulation of the command system in recovered ammocoetes elicited swimming which was always shorter in period and increased in intersegmental phase lag when compared to the recovered behavior. As in normal specimens, command tract evoked swimming was bilaterally assymmetrical in curvature (>58% of occurrences). Increasing stimulus current had no direct effect on period and intersegmental delay, but produced a slight decrease in curvature. Increasing stimulus frequency, elicited variable effects on period and intersegmental delay; whereas curvature was slightly decreased. The recovered behavior of transformers, in contrast, was within the range of normal animals except for an increase in curvature In 40% of recovered transformers, microstimulation evoked slight undulations of the body trunk just caudal to the lesion. In contrast to the robust behavioral recovery, total recovery command system evoked swimming has yet to be observed. In 60% of recovered specimens, stimulation elicited tail flicks and flexions of the caudal half of the dorsal fin. In neither case, was the nature of the command system effect related to the quality of the recovered behavior.

175.6 **Behavioral Recovery Results from Spinal Cord Regeneration In Larval Sea Lamprey.** G. Eaholtz. Marine Science Laboratory, Northeastern University, Nahant, MA 01908.

Sea lampreys can recover behaviorally from spinal cord lesions as severe as complete transection. To determine whether the recovery of swimming following spinal cord transection depends upon regeneration of fibers within the spinal cord, I tested specimens for coordinated motor discharge anterior and posterior to a complete transection by electromyographic recording after removing all sources of extero-spinal conduction. Larval lampreys were transected at the level of the 9th myotomal segment and allowed to recover. Specimens which had achieved criterion for recovery of swimming (Brain Res. 279: 238-240), were prepared for electromyographic recording anterior and posterior to the transection site (Soc. Neurosci .Abstr. 10: 631). I eliminated all extero-spinal tissue at the transection site in 4 recovered specimens and found that spontaneous coordinated behavior of the head and the tail persist.

In the first preparation a segment of the body musculature and notocord was removed at the site of the previous transection, but the gut and spinal cord were left intact. Specimens prepared in this fashion can swim spontaneously and exhibit such adaptations as changes in speed and turning. Electromyograms recorded rostrally and caudally to the transection site show coordinated rhythmic bursting activity identical to that observed in intact swimming animals

In additional experiments, specimens prepared by removal of six myotomal segments along with all extero-spinal tissues bridging the transection site were pinned to a Sylgard™ slab. Nose pinch stimulation resulted in undulatory contractions which were coordinated across the site and could propagate rostrally or caudally. Whole mounts of the spinal cords were stained with toluidine blue to confirm the transection site. These findings indicate that the recovery of coordinated swimming in the lamprey results from regeneration across the spinal lesion and not from passive mechanical conduction or plasticity of extero-spinal pathways..

175.7 EPENDYMA-MESENCHYME INTERACTIONS DURING SPINAL CORD REGENERATION: REGENERATION OF LONG DESCENDING AXONS FROM THE BRAIN. S. Pinol-Roma*, K. Pollack*, and S.B. Simpson Jr. Dept. of Biochemistry, Molecular Biology and Cell Biology, and the Graduate Neuroscience Program, Northwestern Univ., Evanston, IL. 60201.

During tail regeneration in the lizard Anolis, ependyma cells regenerate as a continuous epithelial tube and guide hundreds of regenerating central nerve fibers. If however, the lizard cord is injured at mid-back levels, no regenerative response occurs. Histologically the end result is identical to that exhibited by the injured mammalian cord. The neuron cells of origin of the regenerating axons in the tail cord are not known. Obviously, for the lizard cord regeneration system to be of maximal experimental value, at least some of the regenerating central axons should be long descending axons from brain stem neurons.

Using the retrograde transport of HRP and a variety of methods for visualizing the transported marker, we have begun to map both the normal and regenerated long spinal axons in Anolis. We have succeeded in visualizing a large number of neurons in the brain stem that project to caudal levels of the normal anole cord. These neurons are located in the red nucleus, reticular nucleus of isthmus; superior reticular nucleus; vestibular nucleus; nucleus raphe magnocellularis; inferior nucleus of the raphe; and the spinal trigeminal. The projections, so far, appear to be identical to those described for Lacerta by Schwab 1979 in Biology of the Reptilia Neurobiology B., Gans, Northcutt and Ulinski eds. Academic Press.

HRP tracing of regenerated spinal axons in the regenerated tail cord, has to date, identified neurons in the reticular nuclei, the vestibular nucleus and the nucleus raphe magnocellularis as regenerating during tail cord regeneration. We are in the process of refining our maps of both normal and regenerated spinal axons. We are also mapping neurons within the spinal cord that also regenerate during tail cord regeneration.

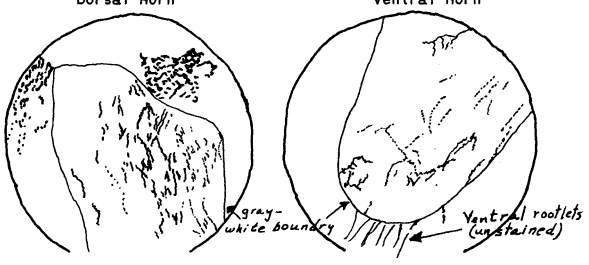
175.8 PATTERNS OF REINNERVATION IN THE ADULT MAMMALIAN SPINAL CORD BY VENTRAL ROOT AXONS ANASTOMOSED TO PROXIMAL DORSAL ROOTS. R. E. Kingsley. South Bend Center for Medical Education, Indiana University School of Medicine, Notre Dame IN 46556.

The right L7 ventral root was cut and anastomosed to the cut proximal limb of the left L6 dorsal root in five cats. Details of the procedure have been published elsewhere (K. K. Messenger & R. E. Kingsley, 1983; R. E. Kingsley, K. K. Messenger & R. H. Seall, 1984). After various reinnervation intervals (6 - 12 months), the grafted dorsal root was sectioned within 2mm of the spinal cord entry point and HRP crystals applied to the central stumps. After allowing 24 hours for transport, the cats were killed, the spinal cord cut into sections 100u thick, and the HRP visualized with TMB (Mesulam, 1982). The sections were stabilized with amonium molybdate (5%), embedded in Araldite-Epon and cured between sheets of Aclar film.

The TMB procedure has proven to be much more sensitive than the DAB procedures we previously used. I observed five types of reaction product. Two forms were artifacts of the chemical process; long slender crystals of reaction product and a dust-link precipitate on the surface of the sections. Another form of artifact was clearly associated with blood and blood vessels. Since these were all easily recognized as artifact, no effort was made to suppress these reaction products in order that more labeled axons could be seen.

Axons were labeled in two distinctly different ways. Most of the axons were labeled with a small fine granular residue. In the dorsal horn, this residue was dense enough to appear continuous, yet still granular. These axons were distributed along the medial side of the dorsal horn, very few were seen in the lateral half. They were not randomly organized, but were distributed in parallel chains running in the dorsal/ventral direction. The TMB procedure has allowed us, for the first time, to see labeled axons in the ventral horn as well. There they are much fewer in number, but their organization is still principally in parallel chains along the medial half of the horn. Deep in the ventral horn they seem to become a little more disorganized, running more independently and they may even run in the medial/lateral direction. These axons were almost never seen in white matter. The second type of labeled axon , seen only in some animals, was large and very densely labeled. They were almost always in white matter. They are probably not derived from the graft but are axons bruised during the second surgury.



175.9 ADULT DORSAL ROOT GANGLION (DRG) NEURONS REGENERATE THEIR CENTRAL PROCESSES INTO TRANSPLANTS OF FETAL SPINAL CORD. A. Tessler, K. Winkler* and B.T. Himes* Philadelphia VA Medical Center and Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129, and J. Houle and P. Reier, Departments of Neurosurgery and Neuroscience, College of Medicine, University of Florida, Gainesville, FL 32160.

After transection of their central axons, adult DRG neurons elongate beyond the site of injury, but regenerating processes fail to re-enter the spinal cord. This failure may be due to inability to penetrate the PNS-CNS interface or to limited capacity for axonal elongation of adult neurons. Either may be affected by implantation of embryonic tissue. Therefore, we have studied the ability of adult DRG neurons to regenerate central axons into grafts of fetal spinal cord. Adult Sprague-Dawley rats (150-250g) underwent laminectomy at the level of the lumbar enlargement. Dorsal roots on one side were cut and a portion of spinal cord approximately 3mm in length was resected. Spinal cord taken from E14 or E15 Sprague-Dawley donors was implanted into the cavity, and the cut dorsal root stumps which remained attached to the DRGs were placed on top of the graft. 2-7 months later WGA-HRP conjugate was applied to the sciatic nerve in order to test the possibility of transganglionic transport of HRP into the transplants. Reaction product was observed within grafts located in lumbar segments. Reaction product generally consisted of finely granular punctate staining or clumped deposits and less commonly had the appearance of axons. Its characteristics resembled the staining found in normal adult spinal cord labeled by the same method. These results indicate that the cut central processes of adult DRG neurons are able to regenerate into transplants of fetal spinal cord. Either or both of two conclusions therefore follow: (1) the regenerative capacity of adult DRG neurons suffices to permit elongation into CNS terrain which is conducive to growth; or (2) embryonic transplants increase the capacity of these neurons to regenerate after axotomy.

175.10 RESTITUTION OF DESCENDING SPINAL PATHWAYS AFTER SPINAL TRANSECTION IN XENOPUS OCCURS DURING, BUT NOT AFTER, METAMORPHOSIS. G.L. Lopate*, M.S. Beattie, and J.C. Bresnahan, Dept. of Anatomy and Div. of Neurosurgery and Neurosci. Res. Lab. , Ohio State Univ. College of Med., Columbus, OH 43210.

The regenerative capacities of vertebrate axons vary widely between species, between systems within species, and in some cases may be dependent upon the developmental status of the organism. Forehand and Farel (J. Neurosci. 2:654, 1982) showed anatomical and behavioral recovery after spinal transections in the bullfrog, but only if transections were made in larval stages and the animals were allowed to complete metamorphosis. We have examined the question of long tract restitution during metamorphosis in **Xenopus laevis**, and find that in this species also, the process of metamorphosis is accompanied by behavioral recovery and restitution of some descending spinal tracts. In addition, we found that fibers crossing the lesion site were located preferentially in the lateral funiculi, a finding like that reported by Bunt and Fill-Moebs (Dev. Brain Res., 16:307, 1984) in the teleost spinal cord. No recovery occured in juvenile, post-metamorphic spinal frogs, and no fibers were seen crossing the lesions, which showed frank discontinuity.

Spinal cord transections between the fifth and sixth or sixth and seventh vertebrae were made in larval tadpoles (stages 50-61) or juvenile froglets under MS-222 anesthesia, using a knife contructed from a tungsten microelectrode. Animals were allowed to survive for 4-5 weeks (juveniles), or until tail resorption was complete (tadpoles). Behavioral observations were made throughout the post-operative interval. In order to label descending spinal axons, HRP was either injected into the caudal brainstem, or was placed in a spinal transection rostral to the initial lesion to label fibers descending into the lesion area. In additional animals, HRP was placed in a second transection made just after the first and rostral to it in order to assess the completeness of the lesion. These animals were sacrificed 4-8 hrs later, and their spinal cords processed for visualization of HRP-filled fibers at the lesion site. These controls showed complete disruption of descending fibers in most cases. In a few cases, a few axons were spared in the ventral funiculus, but never in the lateral funiculus. In recovered animals, fibers could be traced into the lumbar enlargement after either brainstem or spinal placements of HRP.

These results suggest either that brainstem spinal systems regenerate during metamorphosis, or that new fibers cross the lesion and support behavioral recovery. The study of cellular and systemic events during metamorphosis may provide insights into mechanisms which promote axonal growth and regeneration.

175.11 PATHWAY CONSTRAINTS ON REGENERATING MOTOR AXONS IN BULLFROG TADPOLES. M.T. Lee and P.B. Farel. Dept. Physiol., Univ. N. Carolina Sch. of Med., Chapel Hill, NC 27514.

Following ventral root (VR) transection at early stages of development, motoneurons of the bullfrog's lumbar lateral motor column are capable of specifically reinnervating appropriate regions of the hindlimb (Farel & Bemelmans, submitted). This specificity is largely lost if the VRs are transected in more advanced tadpoles or juvenile frogs. In an attempt to understand the factors that influence the selection of targets by these regrowing axons, we have begun to examine the paths they follow between the spinal cord and the muscles of the limb.

The three VRs (8, 9, & 10) that innervate the hindlimb were transected on one side of bullfrog tadpoles (Rana catesbeiana) at various stages. After post-operative periods sufficient to allow motor axon regeneration, horseradish peroxidase (HRP) was applied to one of the previously severed VRs and to the corresponding root on the unoperated side. These orthograde labeling studies were complemented by retrograde labeling of particular muscle nerves in other operated animals. At 3-8 days after labeling, the lumbar spinal nerves and major hindlimb nerves were dissected free of surrounding tissues, intensified with cobalt, reacted with diaminobenzidine, and examined in whole-mount.

At stages XII-XIV, when reinnervation is nonspecific, HRP applied to VR 10 on the unoperated side labels axons that contribute to many of the major nerves of the limb; however, those axons that enter the profundus posterior nerve of the thigh are restricted to 2 of its 4 main branches. On the operated side, motor axons regenerating from VR 10 are also found only in these 2 branches, even though they pass close by the points at which the other branches arise. Conversely, retrograde labeling of one of the other branches shows that none of its axons are supplied by VR 10, on either the operated or the unoperated sides. These results, combined with those of previous studies, imply that axons regenerating from a particular VR to inappropriate targets are nonetheless constrained to enter only those nerves normally supplied by that VR.

These findings are consistent with the concept that regenerating axons are channeled down preformed pathways, which may consist of denervated Schwann tubes of the distal nerve stump (Gutman & Young. J. Anat., 78: 15, 1944). One way to test the strength of this channeling influence would be to misdirect regenerating axons into the wrong Schwann tubes at stages when reinnervation is specific following simple transection. Such misdirection might be accomplished by transecting and then cross-joining the lumbar spinal nerves. These experiments are now in progress.

175.12 ALTERATION OF NERVE FIBERS IN MINOR SPINAL CORD INJURY OF GUINEA PIG. Yutaka Naka*,Kunio Nakai,Toru Itakura*,Kazuo Nakakita*,Ichiro Kamei*,Harumichi Imai* and Norihiko Komai*. Dept. of Neurological Surgery,Wakayama Medical College, Wakayama 640 Japan.

Alteration of various nerve fibers in the spinal cord was studied by morphological methods following minor spinal cord injury. Under gas anesthesia with nitrous oxide and halothane, the spinal cord of guinea pigs weighing 250-300g were pinched by 50% of its original size for ten seconds using a custom-made device(2mm in width). Following this mild spinal cord injury the animals showed a temporary paraplegia and sensory disturbance. After this brief period of spinal shock the animal behaved almost normally for up to six hours. Then they again started to show paraparesis and hypalgesia of bilateral lower extremities that lasted for 2-3 days. About 80% of thus treated animals behaved normally by the fifth postoperative day. After various survival period from the injury, the animals were perfused through ascending aorta with 2% paraformaldehyde and 0.2% picric acid in cold phosphate buffer(PH=7.4). Parasagittal sections of the injured spinal cord were then processed for peroxidase anti-peroxidase immunohistochemistry using antisera against dopamine beta-hydroxylase(DBH),substance P(SP) or vasoactive intestinal polypeptide(VIP) as primary antibodies. Immediately after the lesioning of spinal cord we did not observe any change in immunohistochemistry except the directly damaged area by mechanical compression. The size of this primary mechanical lesion was 0.3-0.5mm in width rostrocaudally. In 6 hours after the lesioning swollen fibers immunoreactive to above three antisera began to appear in the white matter near the primary lesion. At this moment immunopositive nerve fibers in the gray matter around the primary lesion seemed to be unaffected. In 24 hours only SP fibers within the gray matter began to decrease its density in the vicinity of the primary lesion. By 72 hours the number of immunopositive fibers to DBH and VIP began to decrease. Numerous immunopositive swollen fibers to all three antisera had appeared in the white matter of three day-survived animal. Interestingly, those swollen fibers showed significantly elevated cytochrome oxidase activity especially near the primary lesion. In a week after the lesioning, the area without immunoreactive nerve fibers was 1.3-1.5mm in width. In two weeks each nerve fiber already began to reappear within the area whose immunopositive fibers had almost disappeared in one week.

In summary, among three types of neurotransmitter system tested, SP fibers seemed to be more vulnerable to mild spinal cord injury. And the swollen nerve fibers with elevated cytochrome oxidase activity following the injury suggest that swollen fibers within the white matter may have high metabolic activity to promote regenerative process.

175.13 REGENERATION OF SEVERED CNS AXONS IN LARVAL CRAYFISH.

K. R. Seshan* and G. D. Bittner (SPON: José P. Segundo), Department of Zoology, The University of Texas, Austin, Texas.

A single abdominal ganglion of the ventral nerve cord was removed or the ventral nerve cord was severed between two adjacent ganglia in larval crayfish Procambarus clarkii, 4-8 weeks old and measuring 1-5 cm in length. In contrast to results obtained using juvenile or adult crayfish in which very few axons regenerate (Bittner, G.D., Ballinger, M.L.,& Larimer, J.L., J. Exp. Zoology,189:13-36(1974), a substantial number of nerve fibers regenerated and established morphological contacts between the lesioned stumps. The outgrowing nerve fibers were grouped together into several small bundles which in cross section showed ultrastructural characteristics of normal axons with axoplasmic organelles. Glial cells and connective tissue elements occurred in close association with the outgrowing axons. Horseradish peroxidase (HRP) injected into axons 1-5 mm away from the lesioned site was readily taken up by the regenerating axons and transported in both rostral and caudal directions across the lesion site to adjacent ganglia. The appearance of HRP reaction product in axons across the lesion site and in adjacent ganglia suggests that at least some of the severed axons may restore functional connections in larval crayfish. Identifiable severed medial and lateral giant axons grow into the lesion site but do not appear to establish morphological contact with their severed surviving segments within our three month period of experimentation. Severed CNS proximal and distal stumps that do not exhibit any significant axonal regeneration are often covered with glial cells. These axonal stumps end blindly and show accumulation of axoplasmic organelles.

Combined with previous results cited above, our present data show that the CNS of immature crayfish retains its capacity for axonal regeneration but that property gradually decreases with increasing age of the organism.

175.14 REINNERVATION OF THE RAT URINARY BLADDER WITH SOMATIC NERVES. C. L. Lee, L. Monti-Bloch* and E. R. Perl. Dept. of Physiology, University of North Carolina, Chapel Hill, NC 27514.

We have examined the effects of using somatic nerves (femoral, genitofemoral, and obturator nerve) to reinnervate the denervated rat urinary bladder (UB).

Female Sprague-Dawley rats were denervated by unilateral or bilateral isolation and excision of the pelvic nerve (PN) and pelvic ganglia (PG). In bilaterally denervated animals, one somatic nerve was sutured to the detrusor muscle at a site just above the uretrovesicular junction. In the unilaterally denervated animals, the somatic nerve was sutured to the PG or PN. The animals were allowed to survive from 31 to 448 days (total N = 64 animals).

Intrabladder pressure was measured while stimulating the rerouted somatic nerve. Physiological evidence of reinnervation was found in two groups of animals. One-half of the animals (22 out of 44) that had direct femoral nerve to UB detrusor muscle connections responded to the somatic nerve stimulating with transient bladder contraction. Two-thirds of the animals (6 out of 9) with PG connected by a somatic nerve exhibited a pressure response. Only one out of six animals with the genitofemoral nerve connected to the UB detrusor showed a response. None of the animals that had a genitofemoral nerve connection to the PN (2 animals) or obturator nerve connection to the UB detrusor (3 animals) showed a response. The pressure change due to stimulation of the somatic nerve ranged from 0.1 to 7.6 mm Hg; however, none of the animals showed functional spontaneous voiding.

In most animals, the pressure change evoked by somatic nerve stimulation was potentiated by eserine (0.35 mg) and in every case atropine (0.35 mg) abolished the response.

This evidence suggests that physiologically effective reinnervation of the denervated rat urinary bladder by a somatic nerve is feasible, although the functional effectiveness of such reinnervation is yet to be established. Thus the possibility exists of alleviating bladder paralysis secondary to peripheral nerve or spinal injury by using motor outflow from spinal levels above the injury. (Supported by grant NS 14899 from the NIH of the USPHS.)

175.15 **SELECTIVE NEURONAL INVOLVEMENT IN MOTOR NEURON DISEASE (Wobbler Mouse)** H. Mitsumoto, A. Boggs* and N. Sunohara*, Department of Neurology, The Cleveland Clinic Foundation, Cleveland, OH 44106

The reason(s) why certain groups of motor neurons are selectively affected while others are not in motor neuron disease is unknown. The wobbler mouse offers a unique opportunity to study this issue since the disease affects almost exclusively the forelimbs but not the hindlimbs. Morphologically vacuolar degeneration develops in the anterior horn cells, and the spinal ventral root motor axons undergo secondary axonopathy including active axonal regeneration (Mitsumoto and Bradley, Brain, 1983). The difference was analyzed by histometry comparing the C7-C8 ventral roots and the L4-L5 ventral roots. The most distinct differences between these two anterior horn cell groups occurred from 3 to 6 weeks of age: at the cervical level large myelinated fibers (>6 um) were diminished in number by nearly 50% ($p<0.01$) in this period, but regained their prior number by 3 months of age; In contrast, those in the lumbar ventral roots were increased in number parallel to those in the controls in this period, but then diminished in number by 3 months. The absolute number of small myelinated fibers (<6 um) was increased in lumbar ventral roots as compared to control lumbar ventral roots as well as cervical ventral roots ($p<0.05$). These histometric findings suggest that axonal regeneration was more active in lumbar roots. Therefore, we compared the regenerative capacity after nerve crush of the forelimb nerves (cervical anterior horn cells) and sciatic nerves (lumbar anterior horn cells). Our previous study of the regenerative capacity of cervical anterior horn cells by means of radiolabeled axonal transport technique clearly showed at 7 days a diminished rate of axonal elongation ($p<0.01$) and an absence of the distal peak representing a large cohort of growth endings in the cervical anterior neurons (Mitsumoto: Muscle and Nerve, 1985). The same test for lumbar anterior horn cells showed the presence of a normal distal peak at 7 days, identical to controls. Therefore, lumbar anterior horn cells of wobbler mice have a better regenerative capacity compared to cervical neurons, suggesting that the overall neuronal function is better in "unaffected" lumbar anterior horn cells. The difference in the regenerative capacity is perhaps closely associated with the mechanism(s) of selective neuronal involvement in this motor neuron disease (Grant support by NIH, NS-21742).

175.16 HISTOLOGICAL AND HISTOCHEMICAL CHANGES FOLLOWING AXONOTMESIS IN NON-HIBERNATING AND HIBERNATING RODENTS. G. Chaban*, C. Barrett*, E. Donati* and L. Guth*(SPON: J. Krikorian). Dept. of Anatomy, University of Maryland Medical School, Baltimore, MD 21201.

Axonal regeneration in the mammalian CNS may be influenced by microenvironment at the lesion site. We attempted to develop a method of axotomy that minimizes vascular injury and prevents ischemic necrosis (PIN) of neural tissue. We investigated the effect of graded crushes of the optic nerve in rats and crushed optic nerves in non-hibernating and hibernating ground squirrels; in the latter because of depressed adventitial and glial reaction to injury (Guth et al., J.Comp.Neurol., 203: 297, 1981). Retinae and nerves were studied by light microscopy using histological (HOGE, PTAH, protargol) or histochemical (ACHase, acid phosphatase, NADH dehydrogenase, G6PDH and G3PDH) procedures. We crushed rat optic nerves at different points (0,1,4,7,9 mm retrobulbarly) using three levels of force (weak, intermediate, strong) at each position. Blood vessels bridging the site were massaged to reestablish blood flow. Three days postoperatively (dpo), the extent of lesion increased with the severity of crush. However, significant PIN did not result following weak crushes but it frequently did occur when greater forces were used. Presumptive "watershed" area was found (1 mm retrobulbarly), where even strong crushes did not produce PIN. Chromatolytic retinal ganglion cells were seen in the non-hibernators after 3 dpo. Viable tissue bordering the lesion site showed numerous terminal axonal varicosities (TAVs) which were much more prevalent centrally. In the retinal stump, most TAVs occurred at 10 dpo and were morphologically variable, some with thin, sprout-like appendages. Several had reversed direction. Postoperatively, the neurons and their processes diminished in number, however more than 50% of neurons and 20% of optic nerve fibers remained after 90 dpo. This is a greater survival rate than that following neurotmesis (Richardson et al., J.Neurocyt., 11: 949, 1982). The excess of neurons over nerve fibers indicates that many are amacrines. Gliosis was weak and localized in the retina, but strong and disseminated in the optic nerve. In hibernation, the reactive and degenerative changes slowed down by 4 to 30-fold. Between 15 and 30 dpo, uncommonly large and abundant TAVs were seen at the tip of retinal stump, later becoming smaller and denser. Numerous convoluted axons with TAVs recurved in the direction of retina, often in vicinity of macrophages. The lesion site remained loosely organized but changes evident in the non-hibernators soon followed arousal. Histochemical results indicated that significant enzymatic activity persisted in surviving neurons, however, except for acetylcholinesterase, it increased only in glia. Successful axonal regeneration was not observed. It seems that constructive events at the axon tip were not supported by similar changes in the perikaryon. These results support the potential usefulness of this model in studies on CNS regeneration.

175.17 A BIOASSAY FOR THE ANALYSIS OF NEURITE-PROMOTING FACTORS IN THE EXTRACELLULAR MATRIX OF RAT PERIPHERAL NERVE. A. W. Sandrock* and W. D. Matthew, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

In mammals, severed neuronal axons residing in peripheral nerves regenerate readily, whereas axons of the central nervous system fail to regrow effectively. Studies performed in the laboratory of Albert Aguayo have demonstrated that the limited regenerative capacity of central axons is the result of the relative inability of the CNS tissue milieu to support effective axonal elongation, and that the PNS environment contains the necessary ingredients for successful axonal regeneration--even for many CNS axons. What are these ingredients? In the wake of peripheral nerve injury, neuronal axons regenerate within the confines of the persisting Schwann cell basal laminal tubes of the distal stump. The possibility exists, then, that the extracellular matrix (ECM) constituents of these tubes play an important role in promoting axonal regeneration.

We have developed an in vitro bioassay that is sensitive to the substrate-bound factors of peripheral nerve which influence the elongation of regenerating axons. In this assay, rat superior cervical ganglion explants are plated onto longitudinal sections of fresh-frozen sciatic nerve. Twenty-four to forty-eight hours later, the regrowing axons are visualized by catecholamine histofluorescence. The axons always regenerate along the long axis of the nerve in a parallel array, remaining within the boundaries of the tissue section. The rate of elongation is sensitive to the inhibitory effects of INO, a monoclonal antibody which recognizes and inhibits the neurite-promoting activity of a heparan sulfate proteoglycan-laminin complex derived from PC12 cell conditioned medium (Matthew and Patterson, 1983). Interestingly, INO appears to stain the Schwann cell basal lamina of peripheral nerve, but not CNS fiber tracts. In contrast, the rate of axonal regrowth over sciatic nerve sections is virtually unperturbed by an antiserum which recognizes purified laminin, inhibits this molecule's neurite-promoting activity, and stains the Schwann cell basal lamina of peripheral nerve. Finally, when ganglia are similarly explanted onto longitudinal sections of adult rat optic nerve, axonal regeneration is minimal.

In summary, we report the development of an in vitro axonal regeneration assay which (1) reflects the differential ability of PNS versus CNS tissue to support effective axonal regeneration as observed in vivo, and (2) is sensitive to antibodies which interfere with the neurite-promoting activities of ECM constituents in peripheral nerve. We plan to use this assay system to further probe for molecules affecting axonal regeneration.

175.18 ACUTE EFFECTS OF GM1 GANGLIOSIDE ON CNS INJURY: ASSESSMENT OF DOSING SCHEDULE FOR OPTIMAL FUNCTIONAL RESPONSE. Y.S. Li*, M.M. Rapport, & S.E. Karpiak. Div. Neuroscience, NYS Psychiat. Inst., Depts. of Psychiatry, and Biochemistry & Molecular Biophysics, Coll. of Physicians & Surgeons, Columbia U., N.Y., N.Y. 10032.

Since we reported that systemic injections of GM1 ganglioside limit the edema associated with CNS trauma, we are studying the short-term (24-48hrs) effects of ganglioside treatment on CNS injury. We hypothesized that this limitation of damage contributes to facilitated recovery. An experiment was designed to assess when ganglioside treatment produces the greatest functional recovery after injury. Sabel [1] reported that in rats injected with GM1 ganglioside, amphetamine-induced rotation is markedly reduced as early as 48hrs after a unilateral hemitransection of the nigro-striatal pathway (NSP). Using this model, we assessed the effects of GM1 ganglioside (20mg/kg i.p.) administered at various intervals: PRE: daily, for 2 days before surgery; POST: 1 day after surgery, with individual groups receiving their 1st injection at 0,2,4,8 or 12 hrs after hemitransection; PRE&POST: daily, 2 days before surgery, day of surgery [8-12hrs after hemitransection] & day after surgery. Ipsiversive rotation was determined in automated rotometers, 48hrs after hemitransection, for 60min starting 30min after s.c. amphetamine [2mg/kg]. Each experimental group was tested in parallel with a saline control group. The average number of ipsiversive turns for all saline controls was 520 (SEM=49.5;N=34). Rats PRE treated with GM1 showed a 25.7% decrease ($p<0.05$) in rotational behavior. Rats POST treated with GM1 at 0 or 2hrs after surgery showed 38.6% & 49.4% decreases in rotation respectively ($p<0.025$ & $p<0.005$). However, rats POST treated at 4,8 & 12 hrs showed respective reductions in rotation of 21.3%, 27.4% & 27.7%, which were not statistically significant. A significant reduction [47.5%] in rotations was seen in the PRE&POST treated group ($p<0.005$). Our data show that the greatest reduction in rotations was achieved when rats were either treated with GM1 PRE&POST surgery, or treated within 2hrs after surgery. GM1 treatments 4hrs or more after surgery failed to reduce rotation significantly. Limiting dosing to the 0-2hr post-surgical period is equally as effective as a PRE&POST injection protocol, where the 1st post-surgical injection is 8-12hrs after hemitransection. The reduction seen in the PRE&POST group must be due to GM1 dosing prior to injury. Effects of GM1 present at the time of surgery may have been sufficient, so that it was not required to dose animals at 0-2hrs after surgery in order to achieve optimal results. Although all GM1 injected rats showed a trend toward reduced levels of rotation after surgical transection of the NSP, the 0-2hrs post-surgery may be a critical time period when GM1 treatment leads to the greatest reduction in functional impairment.

175.19 EFFECT OF CRUSH LESION ON GANGLIOSIDE AND NEUTRAL GLYCOLIPIDS IN RAT SCIATIC NERVE. M. Guzman-Harty*, J. Warner*, M. Mancini*, D. Pearl* and A. J. Yates. Division of Neuropathology and Statistics Laboratory, The Ohio State University, Columbus, OH 43210.

Exogenously administered gangliosides promote axonal sprouting in crushed rat sciatic nerve. If gangliosides are involved in nerve regeneration, alterations in ganglioside metabolism may occur following nerve trauma. However, little is known about the role of neutral glycolipids in nerve regeneration. Because of the structural and metabolic relationships between gangliosides and neutral glycolipids, we studied the effects of crush injury on the synthesis and accumulation of these compounds in peripheral nerve. Left sciatic nerves (SN) of male Sprague-Dawley rats were crushed and allowed to recover for 0, 1, 2, 4, 7, and 14 days. At each time point, both L-5 dorsal root ganglia (DRG) were injected with 100 μCi of [^{3}H]-glucosamine. Two days later, both DRG, lumbosacral trunk (LST), and SN were removed. Ganglioside and neutral glycolipid of each tissue were purified and radioactivity measured (Ledeen, et.al. Soc. Neurosci., Abstr. 71.PO, 1983). The amounts of ganglioside in crushed LST were consistently higher than the controls with the largest difference occurring within 2 days after crush. At Day 0, there was a significant difference between control and crushed nerve ganglioside in the LST. This difference fell off roughly exponentially with time, with the difference in later days significantly less than that in Day 0. The largest difference between crushed and control SN occurred later than that of LST (2-7 days after crush). The ganglioside in crushed and control SN was nearly the same at Day 0 and Day 1, but became significantly different at later times. There was no consistent difference between the DRG values of control and crushed nerves at any of the times studied. There was a slight but consistently higher radioactivity values in the whole crushed nerve (DRG + LST + SN) than the control tissue at all times studied. The neutral glycolipids followed a similar pattern of synthesis and accumulation as the gangliosides in crushed nerves. Preliminary HPTLC studies of DRG gangliosides showed no observable difference in pattern between the left (crushed) and right (control) tissues. These findings indicate that gangliosides and neutral glycolipids are synthesized at normal or slightly elevated rates after nerve crush but accumulate proximal to the distal end of the crush site. This accumulation may increase ganglioside concentration in the growth cone at this site which may lead to axonal regeneration. Supported by NIH Grant NS 10165 and 5T32 N507091.

175.20 ANATOMICAL AND BIOCHEMICAL CHANGES IN CELL BODIES OF AXOTOMIZED AND CONTRALATERAL INTACT MOTONEURONS. G. Ring*, F. Reichert* and S. Rotshenker. Dept. of Anatomy and Embryology, Hebrew Univ.-Hadassah Med. Sch., Jerusalem, Israel.

The interruption of motor axons is followed by significant anatomical, and biochemical changes in the cell bodies of the axotomized motoneurons. Some of these changes (chromatolysis, nuclear and nucleolar size, and RNA metabolism) are believed to reflect a modification in gene expression that may be an important event in nerve cells' attempt to regenerate their axons. In the present study, we examined some aspects of cell body morphology (cell, nuclear and nucleolar size) in axotomized motoneurons and intact motor nerve cells situated on the opposite side of the spinal cord. The same cells were also examined by quantitative autoradiography for the incorportion of H^3-Uridine into the rapidly labelled pool of RNA molecules.

Significant increases in cell body, nuclear and nucleolar sizes were observed in axotomized motoneurons cell bodies 4 to 34 days after axotomy. Increase above normal was first observed in nucleoli (2 days), cell body (4 days) and nuclei (7 days), all peaked at 14 days and remained elevated for the duration of the experiment (34 days). A small, but significant, increase in nucleolar size was also observed in contralateral intact motoneurons on days 10 and 26.

The incorporation of H^3-Uridine into cell bodies of axotomized motoneurons was complex: it increased 2 days after the operation, reached two peaks (days 4 and 14) and then declined below normal (day 34). The incorporation of H^3-Uridine into cell bodies of contralateral intact motoneurons increased on days 14 and 16 and declined below normal on days 26 and 34.

In axotomized motoneurons, the time course of changes in H^3-Uridine incorporation differed from the time course of changes in cell body, nuclear and nucleolar size. Especially surprising is the dissociation of the time courses of H^3-Uridine incorporation and nuclear size (the organelle into which most H^3-Uridine was incorporated). In contralateral intact motorneurons, the timing of the increase in nucleolar size (10 days) and the increase in H^3-Uridine incorporation (14 and 21 days) correlates with the appearance of contralateral sprouting (about 14 days) (e.g. S. Rotshenker, J. Neurosci. 2:1359, 1980).

175.21 THE RELATIONSHIP OF ORNITHINE DECARBOXYLASE ACTIVITY TO CHANGES IN CHROMATIN STRUCTURE IN AXONAL REGENERATION. M. R. Wells. Neurochemistry Research Lab., V. A. Hospital and Dept. of Physiology, George Washington Univ., Washington, D.C. 20422.

Autoradiographic techniques were used to qualitatively characterize the possible relationship between structural changes in chromatin and ornithine decarboxylase (ODC) levels in rat dorsal root ganglion neurons after crush lesions of the sciatic nerve. Changes in chromatin structure were examined by [^{3}H] Actinomycin D binding to neuronal nuclei in tissue sections (Wells, M.R., Exp. Neurol.,86:303-312, 1984). Alterations in ODC were examined by an autoradiographic technique using [^{3}H] difluoromethylornithine (Wells, M.R., Anat. Rec.,211:212A, 1985). All measurements were made on the L5 DRG after a crush lesion of the sciatic nerve as it emerged from the sciatic notch. The time periods examined included 0,0.5,1,2,3,4,5,7,8,9,11,14, and 30 days postoperation. Counts of autoradiographic grains were made over neurons and/or nuclei and compared statistically to the contralateral ganglion and normal sections on the same slide. ODC levels incresed significantly 0-3 days after injury compared to the contralateral side or normal with a maximum at 0.5 days. This change occurred in the absence of detectable alterations in actinomycin D binding to nuclei. An early increase of actinomycin D binding occurred at 3-4 days postoperation with a peak at day 4. During this time, ODC levels decreased to normal levels at day 4 and began a significant increase from days 5 to 8. Actinomycin D binding decreased at day 5 to normal, dropped to to below control at day 7, and then increased significantly above control levels at day 8. At day 8, both ODC and actinomycin D binding were significantly above control values. From days 9-30, changes in both measures occured in parallel. The pattern observed suggests that increases of ODC occur just prior to increases in actinomycin D binding to nuclei and associated increases in RNA synthesis (Langford, C.J., J. Neurochem.,34: 531-539, 1980). The relationship of ODC and actinomycin D binding appears different in the early phases of the response to axotomy compared to the second week. This may indicate that different mechanisms for ODC regulation are occurring in the early phase of the reaction, perhaps related to injury, as compared to the later response which may be more closely linked to the effort of the neuron to regenerate its axon.

Supported by the Veterans Administration.

175.22 QUANTITATIVE CYTOCHEMICAL (RNA) AND CYTOLOGICAL OBSERVATIONS ON THE AXOTOMIZED RAT RED NUCLEUS. EFFECT OF GANGLIOSIDE INJECTION. K.D. Barron, M. Banerjee* and M.P. Dentinger*. Neurology Service, VAMC and Dept. of Neurol., Albany Med. Col., Albany, N.Y. 12208.

Unilateral rubrospinal tractotomy was performed at C3 in 250-300 g female Sprague-Dawley rats which were sacrificed by perfusion with 3:1 ethanol:acetic acid 3,7,10,14,28 and 60 days later. Operates were paired except that there were 4 subjects for each of the 14 and 28 days postoperative intervals. Additionally, 8 rats were injected daily intraperitoneally with chromatographically homogeneous GM_1 ganglioside, 30 mg/kg body weight. Four of the ganglioside-treated group were killed 14 and four 28 days after surgery. Tissues were embedded in paraffin and, after verification of adequacy of the cord lesion, 6 um sections were cut serially through the red nucleus (RN) from the caudal pole for 300 um rostrally. Counts of neurons and neuroglia and areal measurements of neuronal somas were compared with control data obtained from 4 unoperated rats matched for age and sex. Cytophotometric assay for RNA was by an azure B technic (Barron, K.D. et al, Brain Res. 130:469, 1977). In untreated, tractotomized animals, loss of cytoplasmic RNA from axotomized neurons approximates 20% at three days, 50% at 7-14 days and 65% at 28-60 days postoperative. Nucleolar RNA falls more slowly and is reduced by 41,49 and 58% 14,28 and 60 days after surgery. Somal areas of axotomized neurons averaged 63,50 and 43% of normal 14,28 and 60 days postoperatively. However, counts of neurons in serial sections did not show a significant cell loss in the axotomized RN. Neuroglial proliferation did not occur, in contrast to observations made after axotomy of rat peripheral neurons. The effects of ganglioside treatment are under statistical assessment. In ganglioside-injected rats, neuronal areas were 73 and 65% of normal 14 and 28 days after operation while somal RNA content was 58 and 54% (53 and 36% in untreated animals) and nucleolar RNA 73 and 63% of normal values (59 and 51% in untreated rats). Nucleolar shrinkage also was retarded in ganglioside-treated animals 14 and 28 days after operation (83 and 74% of normal vs 69 and 61%). Light microscopic study of cord lesions did not yield evidence of axonal regeneration in any animals. However, ganglioside treatment may retard the atrophy and loss of RNA that occurs in rubral nerve cells after axotomy.

175.PO "DE MEDINACELI" VERSUS MICROSUTURE: A CRITICAL APPRAISAL OF NERVE REPAIR. J. K. Terzis. Microsurgical Research Center, Norfolk, VA 23501.

Microsurgical nerve coaptations utilize microsutures to maintain close apposition of the cut nerve ends. However, the return of function is typically less than perfect. A new method aimed at circumventing the shortcomings of current techniques has been introduced by de Medinaceli and claims to provide superior results: we have therefore compared the results of nerve repair using the new technique with those using established microsurgical techniques. Results are compared with those after nerve crush, an injury considered to give near optimal conditions for full recovery.

The sciatic nerves of 99 rats were exposed under Nembutal anesthesia and either crushed between watchmakers forceps, or cut and repaired using the standard suture method or the new de Medinaceli method. All operations were performed in random sequence by one surgeon, except for 10 rats in which the nerves were reparied by Dr. de Medinaceli. The rats were coded and their recovery over 3 months evaluated under double blind conditions using the following four methods:

(1) determination every 3-7 days of the twitch tension developed by the middle toe upon supramaximal sciatic stimulus;

(2) analysis of walking tracks obtained every 3-7 days;

(3) measurement of the compound action potentials in response to proximal sciatic stimulation, recorded above and below the lesion in a terminal acute experiment;

(4) histological examination of transverse sections of the sciatic nerve above and below the lesion, and in longitudinal sections through the site of nerve injury.

Examination using the first two methods were hampered by the strong tendency of the rats to mutilate their anesthetic foot (94% of rats in the suture group; 70% of de Medinaceli; 16% of crush).

Preliminary findings suggest that the results obtained with the de Medinaceli method are superior to those obtained with established micro techniques: both techniques yield a result inferior to that obtained with simple nerve crush. The detailed studies will be presented which will reveal any clear advantages of the new method.

DRUG EFFECTS ON RECEPTORS

176.1 SUBSTANCE P AND ITS ANTAGONISTS SHORTEN THE OPEN LIFETIME OF NICOTINIC RECEPTOR CHANNELS IN BC3H-1 CELLS. D.P. Walton* and R.E. Sheridan. Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

The effects of Substance P and a synthetic antagonist of Substance P were examined at nicotinic receptors in the continuous cell line BC3H-1. BC3H-1 cells were grown for 2-4 days in DMEM with 20% fetal bovine serum. The cells were then transferred to DMEM containing either 2% or 0.5% fetal bovine serum to slow cell growth and initiate acetylcholine receptor synthesis. Patch clamp recordings were made on the cells from 4 to 10 days following the change to low-serum media. Single nicotinic receptor channel currents were recorded from intact and excised, inside-out patches of cell membrane exposed to 0.1 to 0.6 micromolar acetylcholine or 1 to 7 micromolar carbachol contained in the patch electrode. Either Substance P or the Substance P antagonist, D-pro^2, D-trp^{7,9} Substance P, were added in micromolar concentrations to the patch electrode. The experiments were conducted in HEPES-buffered saline at 20°C.

Both Substance P and the D-pro^2, D-trp^{7,9} Substance P analog shortened the mean open lifetime of the nicotinic receptor channel. At -125 mV, 20 micromolar Substance P roughly halved the mean open time for receptors opened by either acetylcholine or carbachol. The Substance P antagonist was actually more potent than Substance P and at 20 micromolar reduced the mean open lifetime of carbachol-induced membrane channels by about 5 fold. This "channel shortening" effect of the peptides increased linearly with concentration and increased exponentially with membrane hyperpolarization. However, there was no change in the open-channel conductance of the nicotinic receptors in the presence of either peptide.

The reduction in the mean open lifetime of nicotinic channels in the presence of both Substance P and a Substance P receptor antagonist suggests that this effect is not mediated by a Substance P selective receptor site on the nicotinic receptor. Both the linear dose-response relationship for channel shortening and the strong, exponential dependence on membrane voltage suggest that Substance P interacts with the nicotinic receptor ion channel in a manner analogous to local anesthetics and other channel-blocking drugs at the nicotinic acetylcholine receptor.

176.2 THE OPTICAL ISOMERS OF THE BENZOMORPHAN DERIVATIVE, SKF 10047, HAVE EQUIVALENT EFFECTS ON THE IONIC CHANNEL OF THE PERIPHERAL NICOTINIC RECEPTOR. N. Kapai*, Y. Aracava*, and E.X. Albuquerque. (SPON: Dr. R.G. Grenell) Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

SKF 10047 (N-allynormetazocine) is considered to be the prototype drug for the putative σ opiate receptor. The dextro stereoisomer (+)- and the racemic mixture (±)-SKF 10047 are reported to possess psychotomimetic properties, and the levo (-)-SKF 10047 to have analgesic effects (Martin et al., J. Pharmacol. Exp. Ther. **197**:517, 1976). Binding studies performed on Torpedo membranes have revealed that (-)-SKF 10047 interacts with a site on the acetylcholine receptor-ionic channel (AChR) complex that is distinct from the agonist site as well as that for phencyclidine (PCP) (Oswald et al., Proc. Natl. Acad. Sci. **82**:940, 1985). In light of these findings we attempted to study the effects of the above two steroisomers of SKF 10047 on the nicotinic AChR of the frog (Rana pipiens) neuromuscular junction. The electrophysiological studies were performed using sciatic nerve-sartorius muscle preparations for endplate current (EPC) and isolated fibers from interosseal muscles for single channel current recordings. Our studies revealed that both the stereoisomers (10-60 μM) produced a similar depression of the peak EPC amplitude with a resultant nonlinear current-voltage relationship at increasing hyperpolarized potentials. In addition, the decay time constant of the EPCs (τ_{EPC}) was shortened with an apparent loss in the voltage dependency (10-40 μM) as observed under control conditions. The blocking effects were therefore pronounced at more hyperpolarized potentials. At low concentrations (< 5 μM), only the (+)-isomer produced a slight prolongation of τ_{EPC} with a significant increase in the peak amplitude of the EPC, suggesting the possibility of an anticholinesterase action similar to that observed for psychotomimetic drugs such as PCP. Single channel recordings performed in the presence of both (+)- and (-)-SKF 10047 revealed short channel openings without bursting activity. The increased channel activation and prolongation of the channel open times seen with low concentrations of (+)-SKF 10047 on EPCs were not observed at the single channel level, most likely due to the absence of cholinesterase in the single fiber preparations. The channel open times reached a saturation level at concentrations higher than 20 μM only with the (+)- and not with (-)-SKF 10047. Based on these studies, both stereoisomers of SKF 10047 appear to interact with the neuromuscular AChRs blocking the ionic channel in its open conformation while the (+)-isomer may have in addition other effects. (Supported by USPHS Grant NS-12063 and U.S. Army Med. Res. and Develop. Command Contract DAMD-17-84-C-4219.)

176.3 AGONIST EFFECTS OF NEOSTIGMINE ON SINGLE NICOTINIC ACETYLCHOLINE CHANNEL CURRENTS RECORDED IN RAT MYOTUBES. J.F. FIEKERS, Dept. Anatomy and Neurobiology, University of Vermont Coll. Med., Burlington, Vermont 05405.

The carbamate anticholinesterase agent, neostigmine, in addition to its inhibitory action on acetylcholinesterase, has direct actions on the acetylcholine (ACh) receptor-channel complex (Fiekers, J. Neurosci.5:502-514, 1985). In the present study the direct actions of neostigmine were studied on single channel currents using the gigaohm patch clamp technique. Rat myotubes were cultured in DMEM and 10% horse serum using standard cell culture conditions. Single channel currents were recorded at 20°C on cell attached and inside-out recording configurations. Neostigmine in concentrations ranging from 0.1 nM to 100 uM activated channels in the absence of agonist. The amplitude, duration and frequency of opening of neostigmine-activated channels were increased with membrane hyperpolarization. These currents reversed at approximately zero mV. The frequency of channel opening also increased with increasing concentrations of neostigmine. Concentrations above 10uM exhibited channel openings with abrupt closures similar to effects observed with channel blocking agents. Following a period of increased channel frequency, concentrations above 50uM produced a steady decrease in the frequency of channel opening with complete cessation of channel activation occurring at a rate inversely related to the neostigmine concentration. With high concentrations of neostigmine bursts of channel activity were followed by prolonged silent periods. The half time for onset of this desensitized state was approximately 3 min. for 100uM neostigmine at -100mV.

The frequency of activation of single channel currents was markedly increased above control levels when both neostigmine and ACh (1nM-1uM) were present in the patch electrode. This was followed by a decrease in channel opening frequency which was more rapid than either agent alone. Single channel currents were frequently interrupted by brief closures, i.e. flickering within the open channel and the noise present during a channel opening was increased. Single channel currents recorded in the presence of neostigmine, ACh or both were blocked by prior addition of d-tubocurarine. Similar results were also obtained with experiments on ACh receptor channel complexes in the end-plate regions of adult neuromuscular junctions of snake twitch fibers following enzyme treatment. These results demonstrate that direct actions of neostigmine include (1) agonist effects on the nicotinic receptor, (2) the production of a desensitized state of the receptor and (3) the establishment of an altered state of the receptor in the presence of agonist. (supported by MDA).

176.4 DIRECT INTERACTIONS OF REVERSIBLE AND IRREVERSIBLE CHOLINESTERASE (ChE) INHIBITORS WITH THE ACETYLCHOLINE RECEPTOR-IONIC CHANNEL COMPLEX (AChR): AGONIST ACTIVITY AND OPEN CHANNEL BLOCKADE. Y. Aracava* and E.X. Albuquerque. Dept. Pharmacol. & Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

New aspects of the molecular pharmacology of the classic ChE inhibitors have recently been revealed. Carbamates and organophosphate anti-ChE agents have been shown to have direct effects on the AChR behaving either as a nicotinic agonists or as noncompetitive blockers interacting with sites located on the ionic channel. The current development of a method for obtaining isolated fibers from interosseal muscles of the adult frogs and their suitability for patch-clamp recordings have allowed studies of the kinetics of drug interactions with the nicotinic AChR at the single channel current level. Thus, this biological model was used to evaluate the effects of the carbamates neostigmine and edrophonium, and of the organophosphate agent VX on the neuromuscular AChR. Single channel currents activated by ACh (0.3-0.4 μM) had conductance of 33 pS and mean channel open times of 10-12 msec at -100 mV membrane potential with very few fast closures during the open state. In contrast, neostigmine (1-100 μM)and edrophonium (1-50 μM) when present together with ACh inside the patch electrode produced bursts of very short open events (5-7 openings per burst) with 33 pS conductance as well as of low-conductance channel openings. The individual openings within a burst had a mean duration of 2.8 msec and 0.5 msec in the presence of edrophonium 5 and 50 μM, respectively. Similar effects were observed with neostigmine (50 μM) which decreased the mean lifetime of these conductive intervals to 1.0 msec. The duration of the short closures within a burst (the reciprocal of the backward rate constant of the blocking reaction) were also analysed. In the presence of these carbamates, the mean of these short closed times showed a strong voltage dependence and a prolongation at more hyperpolarized potentials (1.8 msec and 0.52 msec at -100 and 200 mV, respectively). VX (1-50 μM) produced bursts composed of more prolonged open events (3.6 msec at 20 μM). The analysis of the short closed times revealed a slow component (15 msec at 100 mV membrane potential) which suggested a more stable blocked state. In addition, neostigmine and edrophonium showed an agonistic effect, activating bursts of channel openings similar to those observed in the presence of these agents together with ACh. VX, however, did not have such a property. These results indicated that in addition to the well known antiChE activity, these agents possess marked and distinct effects on the post-synaptic receptors of the neuromuscular junction either altering the ACh-activated channels or opening channels as nicotinic agonists. (Supported by U.S. Army Res. & Devel. Command Contract DAMD-17-84-C-4219.)

176.5 COMPARISON OF TWO POTENT, SEMIRIGID NICOTINIC AGONISTS AT THE FROG NEUROMUSCULAR JUNCTION. C.E. Spivak, T.M. Gund*, R.F.-Liang*, and J.A. Waters*. Neuropharmacology Lab., Addiction Research Center, NIDA, Baltimore, MD 21224 and Dept. Pharmacol. & Exptl. Ther., Univ. of Maryland School of Med., Baltimore, MD 21201; Dept. Chem., & Chem. Eng. New Jersey Inst. Technol., Newark, NJ 07102; NIADDK, Bethesda, MD 20205.

Little is known about the relationship between structure and activity of nicotinic agonists. This deficit is due in part to the scarcity of potent, rigid or semirigid representatives. The two agonists described here are cyclic semirigid structures that nearly superimpose. However, they differ greatly in potency. Our objective was to evaluate potency in terms of thermodynamic constants and to relate these to the small differences in structure.

Isoarecolone methiodide (1,1-dimethyl-4-acetyl-1,2,5,6-tetrahydropyridine iodide) (ISO) and 1,1-dimethyl-4-acetylpiperazine iodide (PIP) were synthesized. Potencies were evaluated by isotonic contracture of frog rectus abdominis muscles in assays using carbamylcholine (carb) as a standard. ISO was 50 times more potent than carb (95% confidence interval: 45-56x), making it one of the most potent nicotinic agonists known. PIP was 2.6 times more potent than carb (95% confidence interval 2.4-2.8x). Thus ISO was nearly 20 times more potent than PIP. Intracellular recording of frog sartorius muscles corroborated this finding. For example a 20 mV depolarization was produced by 0.3μ M ISO or by 4.9 μM PIP. Patch clamp studies showed that channel open times could not account for this difference in potency.

Minimum energy conformations of the two agonists were calculated by molecular modeling using a modified version of MM2 with ammonium parameters. The distance from the van der Waals extension of the carbonyl oxygen to the quaternary nitrogen was 6.1Å for both compounds. PIP, however, was more chair-like. Consequently, when the quaternary nitrogens and their alpha substituents were superimposed, the carbonyl oxygen of PIP was displaced upward (on the axis perpendicular to the plane of the rings) by 1.18Å relative to its postion in ISO. Differences in electrostatic potential contours were located using the MNDO method for partial charge distributions. For example, the axial N-methyl group of ISO had a more extended high energy isopotential surface than did the corresponding group of PIP. This finding is noteworthy because this position seems vital for establishing the coulombic bond to the recognition site.

These studies help map the recognition site and the bond types in the nicotinic receptor in both its native and activated conformations.

176.6 GEPHYROTOXIN INTERACTION WITH HISTRIONICOTOXIN BINDING SITES ON THE NICOTINIC ACETYLCHOLINE RECEPTOR COMPLEX OF TORPEDO ELECTRIC ORGAN. L. Narayanan*[1], R.S. Aronstam[1], E.X. Albuquerque[2] and J.W. Daly[3]. (SPON: S.H. Hobbs). [1]Dept. Pharmacol. & Toxicol., Med. College of Georgia, Augusta, GA 30912, [2]Dept. Pharmacol. & Exp. Ther., Univ. of Maryland Sch. Med., Baltimore, MD 21201, & [3]Lab. Bioorganic Chemistry, NIADDKD, NIH, Bethesda, MD 20205.

Gephyrotoxins are a class of tricyclic and bicyclic alkaloids isolated from the skin secretions of the Colombian frogs Dendrobates histrionicus and Dendrobates occultator (Daly, Prog. Chem. Org. Nat. Prod. 41:205, 1982). Gephyrotoxin (GyTX) interferes with neuromuscular transmission through blockade of the receptor complex in the open state and by stabilization of a desensitized conformation of the receptor (Souccar et al., Mol. Pharm. 25: 384-400, 1984). In the present study, we determined the ability of 10 natural and synthetic gephyrotoxins to inhibit [^{125}I]alpha-bungarotoxin (BGT) binding to the acetylcholine receptor of Torpedo electroplax and to inhibit [^{3}H]perhydrohistrionicotoxin ([^{3}H]HTX) binding to sites associated with the receptor-gated ion channel in the presence and absence of receptor ligands.

None of the gephyrotoxins inhibited BGT binding by more than 15% at 50 uM (Carb IC50=2.8 uM). The Ki values associated with GyTX inhibition of [^{3}H]HTX binding are listed below. The natural 1 and synthetic d enantiomers (1 and 2) did not differ in their ion channel affinity, and in the presence of Carb their affinity was increased 3 fold. Structure-activity considerations suggest an important contribution of hydrophobic interactions (e.g., 5 vs 7 or 8 vs 10), although the precise stereoconfiguration was not critical for activity. The data suggest that a GyTX analogue with a longer alkyl chain at C_6 would be very active as an ion channel blocker but would be relatively insensitive to allosteric regulation by receptor agonists.

		Ki, uM		
	Compound	[3H]HTX	[3H]HTX+Carb	R
1	1-gephyrotoxin	2.5	0.79	3.2
2	d-gephyrotoxin	2.0	0.74	2.7

176.7 PHENYTOIN INHIBITS VOLTAGE-DEPENDENT AND DIHYDROPYRIDINE-STIMULATED CALCIUM UPTAKE BY NG108cc15. R.G. Ribares* and R.J. Miller (SPON: C. Houser) Dept. of Pharmacological and Physiological Sciences, The University of Chicago, Chicago, IL 60637.

Decreases in extracellular Ca++ in the cortex are known to accompany and often precede the onset of seizures in various models of epilepsy. Agents that block postsynaptic Ca++ entry have been shown to prevent seizure activity elicited by various convulsants. Several lines of evidence indicate that diphenylhydantoin (DPH) inhibits Ca++ dependent cellular processes. The present study was undertaken to determine whether DPH can block voltage-dependent Ca++ entry in cultured neuronal cells and to test the possibility of an interaction with the dihydropyridine site.

NG108cc15 were grown as monolayers in EMEM with 10% FBS and 2mM glutamine. After 3 days media was replaced with EMEM supplemented with 10 μM PGE1 and 50 μM IBMX. On the fourth day of this treatment cells were assayed for 45Ca++ uptake by timed incubations with Hepes/EMEM containing 45Ca++, either 5.4mM or 50mM K+, and selected drugs (DPH, carbamazepine, phenobarbital, primidone, valproate, ethosuximide, clonazepam, BAY K8644, lidocaine, 4-aminopyridine). Cells were solubilized and protein content and 45Ca++ were measured. All time course assays and dose response curves were run under both low and high K+ conditions. Low K+(basal) 45Ca++ uptake was subtracted from the high K+ uptake to determine depolarization-dependent Ca++ uptake.

Basal 45Ca++ uptake increased linearly at approximately 300cpm/mg protein/min. High K+ augmented 45Ca++ uptake by 3 to 5 fold within the first 5 to 7 min. DPH had no effect on low K+ uptake but selectively inhibited depolarization-stimulated 45Ca++ uptake with an IC 50 of 4.5 μM, which lies within therapeutic CSF levels. Time course assays showed markedly diminished slope within the first 5 min. Elevated extracellular Ca++ (from 1.3mM to 3.0 and 10.0mM) raised the IC 50 of DPH inhibition from 4.5 to 8.1 and 24 μM, respectively, while its maximal effect decreased only slightly. The dihydropyridine BAY K8644 selectively stimulated voltage-dependent Ca++ uptake in a dose related manner, with maxima of 4 to 5 times control high K+ levels. In the presence of DPH, the dose-response curve for BAY K was shifted to the right and the maximal effect was reduced (to 50% by 10 μM DPH), indicating a non-competitive interaction. None of the other antiepileptic drugs tested inhibited Ca++ uptake at concentrations within their therapeutic range. For those that did inhibit Ca++ uptake, albeit at supratherapeutic levels, inhibitory potency correlated with lipid solubility and differed from DPH in their response to changes in extracellular Ca++, selectivity for depolarization-induced Ca++ uptake, and ability to inhibit BAY K stimulated uptake. Clonazepam showed a biphasic dose-response. In conclusion, DPH appears to inhibit the same voltage-sensitive calcium channels with which the dihydropyridines interact in NG108cc15 cells.

176.8 **INFLUENCE OF AGE ON THE RESPONSE OF BENZODIAZEPINE AND GAMMA-AMINOBUTYRIC ACID RECOGNITION SITES TO DIAZEPAM EXPOSURE.** **Harold L. Komiskey, Kathe L. Mundinger* and Atiqur Rahman*. Department of Biomedical Sciences, University of Illinois, College of Medicine at Rockford, Illinois 61107.**

The effect of age on specific binding of ^{3}H-benzodiazepines and ^{3}H-Gamma-aminobutyric acid (^{3}H-GABA) in the brain has been previously examined in naive animals. In the present experiments, rat brain tissue above the cerebellum was examined for age-dependent changes in ^{3}H-flunitrazepam ex vivo binding and ^{3}H-GABA in vitro binding after an acute injection of a low dose of diazepam. Young (3-4 mo.old), mature (12-15 mo. old) and old (29-31 mo. old) male Fischer 344 rats were injected intravenously with diazepam 180 ug/kg or the vehicle five minutes prior to decapitation.

The acute diazepam injection decreased ^{3}H-flunitrazepam ex vivo binding in only senescent rats. ^{3}H-flunitrazepam (6.3nM) binding at both the BZ_1 and BZ_2 receptor or receptor conformation were significantly reduced in the old rats. In contrast,^{3}H-flunitrazepam binding was unaltered with age in rats injected with the vehicle. The concentration of diazepam, desmethyldiazepam and oxydiazepam in the brain tissue above the cerebellum did not differ significantly among the three age groups at the time of sacrifice.

The in vitro binding of ^{3}H-GABA in well washed brain homogenate showed age-related changes. The affinity of the $GABA_A$ recognition site was significantly less in the old rats compared to either the young or mature after vehicle injections. An acute diazepam injection increased the affinity of the $GABA_A$ recognition site in the senescent rats.

The present findings indicate that a low dose of diazepam elicits within minutes an age-dependent alteration in benzodiazepine and GABA binding. Therefore, age-related modifications in the response of benzodiazepine and GABA recognition sites to diazepam exposure may be involved in the increased sensitivity of the elderly to diazepam.

176.9 DIAZEPAM REVERSES THE ATROPINE-RESISTANT SECOND POPULATION SPIKE (PS) CAUSED BY DIISOPROPYLFLUOROPHOSPHATE(DFP) IN RAT HIPPOCAMPAL SLICES. A.M. Williamson and J.M. Sarvey. Dept. of Pharmacology, USUHS, Bethesda, MD 20814-4799.

The irreversible organophosphate acetylcholinesterase (AChE) inhibitor, DFP (10 uM), has been shown to produce a second PS in field CA1 in response to stimulation of fibers in stratum radiatum (Williamson and Sarvey, Neurosci. Abst. 10:167.12). While the second PS produced by iontophoretic application of ACh was blocked by bath application of atropine (1-10 uM), the second PS elicited by DFP was resistant to atropine as well as the nicotinic antagonists, hexamethonium, gallamine and dihydro-B-erythroidine (all 10 uM). Additional experiments have shown that when responses to bath applied carbachol (20 uM), muscarine (20 uM) and ACh (200 uM) were blocked by the irreversible muscarinic antagonist, quinuclidinyl benzylate (1 uM), DFP can still produce a second PS. Therefore, a study was conducted to characterize further the nature of the atropine-resistant second PS.

Experiments were performed on rat hippocampal slices (350-400 uM thick) using standard extra- and intracellular techniques.

Intracellular recordings from CA1 pyramidal cells showed that DFP (10 uM) blocked spike afterhyperpolarization (AHP) and accommodation of action potential generation to depolarizing current pulses. These effects were consistent with an increase in the local concentration of ACh following inhibition of endogenous AChE. Both the loss of the AHP and the loss of accomodation were reversible upon exposure to atropine (1 uM). However, the second PS, as measured extracellularly and the corresponding second action potential measured intracellularly, were not affected by atropine.

Extracellular experiments were then performed to evaluate the ability of the anti-convulsant, diazepam, to affect the second PS. Superfusion of diazepam (1 uM) for 20 minutes significantly reduced the amplitude of the second PS elicited by previous exposure to DFP (10 uM) from 56.5 ± 6.2% (mean ± SEM) to 6.4 ± 2.2% (n=8, $p<.05$). Intracellular recordings revealed that diazepam had no effect on the loss of the AHP and accommodation, but did increase the magnitude of the orthodromically generated early IPSP.

Further experiments are now being performed to delineate the origin of the second PS elicited by DFP, but the second PS does not appear to be an indirect effect resulting from inhibition of AChE.

176.10 EFFECTS OF THE WATER-SOLUBLE DERIVATIVE OF DELTA-9-TETRAHYDROCANNABINOL ON ^{3}H-DIAZEPAM AND ^{3}H-FLUNITRAZEPAM BINDING TO RAT BRAIN MEMBRANES IN VITRO. S. C. Sung and A. Jakubovic. Division of Neurological Sciences, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Over the past several years various biochemical and cellular responses to cannabinoids have been reported. The interference of cannabinoids with the uptake of neurotransmitters into synaptosomes has been ascribed to their action on receptors. Some of the pharmacological activities of the psychotomimetic compounds of cannabis including tranquilizing properties appear to be associated with their affinities for biological membranes. In the present study, the interference of the psychoactive water-soluble derivative of delta-9-tetrahydrocannabinol (1-[4-morpholino)butyryloxy]-3-n-pentyl-6,6,9-trimethyl-10a,6a,7,8-tetrahydrodibenzo[b,d] pyran hydrobromide) (SP-111A) with the ^{3}H-diazepam and ^{3}H-flunitrazepam binding to rat brain membranes was examined. It was found that SP-111A reduced, in a concentration-dependent fashion, the specific binding of ^{3}H-diazepam and of ^{3}H-flunitrazepam to membrane preparations of rat brain cortex. The inhibition of the specific binding of ^{3}H-diazepam by SP-111A was found to be competitive with a K_i value of 3.1 μM. In the presence of 7.5 μM SP-111A the apparent K_d of ^{3}H-diazepam binding increased from 4.3 nM to 12.5 nM, without affecting the B_{max}. The degree of inhibition by SP-111A was dependent on both the concentration of ^{3}H-diazepam as well as the amount of membrane protein. With 6.2 nM ^{3}H-diazepam and 0.082 mg of membrane protein in a final volume of 0.2 ml, the IC_{50} of SP-111A was found to be about 7.5 μM. The inhibition of the specific binding of ^{3}H-flunitrazepam by SP-111A was also competitive; however, the IC_{50} was higher than with ^{3}H-diazepam. Similar inhibition was observed when brain membrane preparations were preincubated for 20 min at 0°C or or 37°C with SP-111A, then repeatedly washed with buffer before incubation with either ^{3}H-diazepam or ^{3}H-flunitrazepam. Comparable concentration-dependent inhibition of specific binding of both ^{3}H-diazepam and ^{3}H-flunitrazepam by SP-111A was observed with membrane preparations either from rat brain cortex or cerebellum or brainstem. Present results indicate that the psychoactive delta-9-tetrahydrocannabinol and other cannabinoids could be competing ligands for benzodiazepine receptors and perhaps other receptor sites in the CNS.

176.11 INTERACTION OF AMINOPYRIDINES WITH [^{3}H]PCP RECEPTORS IN RAT BRAIN. W.S. Lai* and E.E. El-Fakahany. (SPON: A.P. Leccese). University of Maryland School of Pharmacy, Baltimore, MD 21201.

The behavioral effects of phencyclidine (PCP) have been attributed to its ability to block certain potassium channels in brain synaptosomes (Albuquerque et al., Proc. Natl. Acad. Sci. U.S.A. 78, 7792, 1981 and Blaustein and Ickowicz, Proc. Natl. Acad. Sci. U.S.A. 80, 3855, 1983). This hypothesis prompted us to test the ability of 4-aminopyridine, a prototype potassium channel blocker, to interact with [^{3}H]phencyclidine ([^{3}H]PCP) receptors in the brain.

Three analogs of aminopyridine (AP) were tested for their effect on specific [^{3}H]PCP binding in whole rat brain homogenates. For the binding experiments, brain homogenates were incubated with [^{3}H]PCP in 5 mM Tris-HCl buffer (pH 7.4) for 60 min at 4°C. Nonspecific binding was defined using 10 µM PCP and the incubation mixture was filtered over GF/B filters presoaked in 0.05% polyethyleneimine. The rank order of potency in displacing [^{3}H]PCP binding was 4-AP > 3,4-AP > 3-AP. 4-AP displaced [^{3}H]PCP binding with a Hill coefficient close to unity, however, it showed a ceiling effect around 80-85% displacement. When increasing concentrations of [^{3}H]PCP were used in the binding assay, the ability of 4-AP to inhibit the binding was decreased. Dixon plots of such displacement experiements showed an intersection point above the abscissa, suggesting an apparent competitive interaction. In addition, the effects of both 4-AP and unlabeled PCP on the dissociation kinetics of [^{3}H]PCP binding were investigated. Although excess unlabeled PCP failed to alter the rate of dissociation of [^{3}H]PCP-receptor complex induced by dilution, 1 mM 4-AP enhanced the dissociation rate by a factor of three. Our present data suggest that the effect of this class of potassium channel blockers on [^{3}H]PCP receptors in rat brain might not be due to a simple competitive interaction.

176.12 **DOWN-REGULATION OF BETA-ADRENERGIC RECEPTORS (B-AR) WITHIN 24 HR AFTER INTRAVENOUS INFUSION OF ANTIDEPRESSANTS.** V.H.Sethy and J.S.Day, CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

The down-regulation of B-AR in the cerebral cortex is achieved after chronic administration of antidepressants by either the intraperitoneal or oral route (F.Sulser, J. Clin. Psychiat. 44:14, 1983). The delayed appearance of a reduction in the density of B-AR correlates with the latency of therapeutic effects of antidepressants in patients with depression. However, Saletu et al. (Prog. Neuropsychopharmacol. 1:125, 1977) have reported a significant decline in the Hamilton Depression Score at 48 hr after i.v. infusion of antidepressants to patients with depression. Therefore, investigations were carried out to determine the effect of 24-hr infusion with various antidepressants on B-AR in the cerebral cortex of female rats. Desipramine (1, 3, 10, 60 mg/kg), imipramine (10, 30, 100 mg/kg/day), amitriptyline (3, 10, 30, 60, 100 mg/kg/day), zimelidine (3, 10, 30, 60, 100 mg/kg/day), iprindole (3, 10, 30, 60, 100 mg/kg/day), and U-48753E (1, 3, 10, 30 mg/kg/day) dose-dependently down-regulated B-AR at 24 hr. The lowest dose (mg/kg/day) which produced a significant reduction in B-AR was as follows: desipramine = 3, imipramine = 30, amitriptyline = 3, zimelidine = 10, iprindole = 10, and U-48753E = 3. The time-course studies comparing U-48753E with imipramine, each 10 mg/kg/day, demonstrated that U-48753E significantly down-regulated B-AR at 16 hr, whereas a significant effect with imipramine was observed at 48 hr. Treatment with these antidepressants did not modulate pre- or post-synaptic alpha-adrenergic receptors consistently. The results of these investigations suggest that i.v. infusion of antidepressants rapidly down-regulate B-AR, and this procedure may be of clinical utility for providing a rapid therapeutic effect in patients with depression.

176.13 THE NOVEL ANXIOLYTIC BUSPIRONE ELICITS A SMALL HYPERPOLARIZATION AND REDUCES SEROTONIN RESPONSES AT PUTATIVE 5-HT$_1$ RECEPTORS ON HIPPOCAMPAL CA1 PYRAMIDAL CELLS R. Andrade and R.A. Nicoll. Depts of Pharmacology and Physiology, Univ. of California in San Francisco, San Francisco, CA 94143.

Two main types of serotonin receptors, 5-HT$_1$ and 5-HT$_2$, have been proposed to exist in the central nervous system based upon binding studies. The 5-HT$_1$ type would correspond to binding sites exhibiting high affinity for serotonin agonists and low affinity for antagonists, while the 5HT$_2$ type would correspond to those sites exhibiting high affinity for serotonin antagonists but low affinity for agonists. While this classification has been well established in binding studies, there is at present a paucity of reports concerning the possible functional significance of these binding sites in the brain. In the rat hippocampus, serotonin binding appears to be predominantly of the 5-HT$_1$ type. Therefore we have examined the pharmacology of serotonin responses in this area for possible functional correlates of the postsynaptic 5-HT$_1$ binding site.

Rat hippocampal brain slices were prepared and maintained as previously described. Intracellular recordings were obtained from pyramidal cells of the CA1 region using standard electrophysiological techniques. Serotonin administered either in the bath (300nM - 20µM) or by microiontophoresis elicited a dose dependent hyperpolarization which could be as large as 20 mV and was accompanied by a reduction in input resistance. Administration of the selective 5-HT$_{1A}$ agonist 8-OHDPAT (200nM - 4µM) also hyperpolarized these cells. No depolarizing responses to serotonin were ever observed. The classical serotonin antagonists cyproheptadine and cinanserin were weak at antagonizing responses to iontophoretically applied serotonin with IC50s of 50µM and 100µM respectively, while the selective 5-HT$_2$ antagonist ketanserin did not reduce serotonin responses in concentrations up to 200 µM. The ergot methysergide was found to elicit a small hyperpolarization and to effectively reduce serotonin responses with an IC50 of 30µM. Similarly, the novel non-benzodiazepine anxiolytic buspirone, which has been reported to be a potent and selective ligand at displacing serotonin from hippocampal membranes, was also found to elicit a small hyperpolarization (1-4mV) and to reduce serotonin responses (IC50 = 3µM).

These results are consistent with the suggestion that serotonin receptors in the hippocampus might conform to the 5-HT$_1$ classification and indicate that buspirone behaves as a weak partial agonist at these postsynaptic receptors. Such actions of buspirone could play a role in the mechanism by which this compound exerts its anxiolytic action. Supported by grants MH-38256, MH-00437 and MH09180.

176.14 BUSPIRONE: EFFECT ON BRAIN DOPAMINE AND SEROTONIN RECEPTORS. Tyrone Lee and Gloria Su*, Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Canada M5T 1R8.

Buspirone, a non-benzodiazepine compound lacking the usual benzodiazepine side effects such as sedation, anticonvulsion or muscle relaxation, has been found to be an effective antianxiety agent in humans. It has also been reported that buspirone possesses some in vivo anti-dopamine actions in animals such as blockage of apomorphine-induced stereotypy, enhancement of striatal dopamine metabolites, elevation of rat plasma prolactin levels and disruption of conditioned avoidance behaviour (Wood et al., Life Sci. 33, 269, 1983). In order to determine if the antipsychotic action of buspirone bears similarities among classical neuroleptics (haloperidol) or atypical neuroleptics (loxapine), its effect on brain dopamine and serotonin receptors was investigated.

Adult male Wistar rats (200 gm) were divided into 6 groups of 8 rats each with daily injection of buspirone (10 mg/kg i.p.) for 1, 2, 3, 5, 7, and 14 days. Another 6 groups of rats received 1 ml of saline i.p. daily for similar duration. All animals were sacrificed 24 hours after the last injection. Brain striatal dopamine (D_2) receptors were measured using ^{3}H-spiperone and frontal cortex serotonin (S_2) receptors were measured using ^{3}H-ketanserine. Scatchard analyses permit the determination of receptor density (B_{max}) as well as receptor affinity (K_d) in saline- and buspirone-treated animals. The results were as follows:

	Buspirone Treatment (Days)					
	1	2	3	5	7	14
B_{max} for D_2	104	101	101	102	126*	130*
B_{max} for S_2	92	94	98	102	105	120

B_{max} values were expressed as % of respective saline-treated group.
*$p < 0.01$, Student's t-test (two-tailed).

Repeated treatment with buspirone for duration of 7-14 days elicited a significant increase in dopamine receptor density with no apparent change in receptor affinity. However, buspirone did not alter serotonin receptors significantly in the rat frontal cortex.

In our present study, buspirone increased dopamine receptor numbers without affecting the serotonin receptors. Atypical neuroleptics such as loxapine or clozapine, however, have been demonstrated to have rapid and potent effect on serotonin receptors but rather weak effect on dopamine receptors (Lee and Tang, Psychiat. Res. 12:277, 1984). Thus, buspirone seems to act more like a classical neuroleptic such as haloperidol. However caution must be taken to interpret these data as buspirone does not cause catalepsy in rats. (Supported by the Clarke Institute of Psychiatry Research Fund.)

176.15 ^{3}H SCH 23390 BINDING IN VIVO: INHIBITION BY ATYPICAL NEUROLEPTIC DRUGS. Peter H. Andersen[1], Erik B. Nielsen[1], Claus Braestrup[1] and Frederik C. Grønvaldt[2] (spon M. Treiman) [1]Depts. of Pharmacology and [2]Med. Chemistry I, NOVO Pharmaceuticals R&D, Novo Allé, 2880 Bagsvaerd, Denmark.

4 µCi of ^{3}H-SCH 23390 was injected into the tailvein of mice. 15 minutes later, the animals were decapitated and within 30 sec the brain (-cerebellum) was homogenized in 14 ml of 25 mM K_2HPO_4 and filtered through Whatman GF/c filters. The binding of ^{3}H-SCH 23390 was saturable, reversible and highly stereospecific. Pharmacological characterization revealed binding of the ligand to D1-receptors since low ED_{50}-values were obtained for drugs known to exhibit D1 affinity: SCH 23390 (0.017 mg/kg), cis-flupentixol (0.4 mg/kg), (+)-butaclamol (0.3 mg/kg), fluphenazine (2.8 mg/kg) and chlorpromazine (7.3 mg/kg). Typical neuroleptics, known to be D2-specific, were almost inactive: haloperidol (72.5 mg/kg), spiperone (168 mg/kg) and pimozide (194 mg/kg). Surprisingly, atypical neuroleptics exhibited high potency in displacing ^{3}H-SCH 23390 in vivo, despite of the fact that most of these compounds were inactive in vitro (below).

	K_i (nM) D1 (in vitro)	ED_{50} (mg/kg) D1 (in vivo)	AMPH cue
SCH 23390	0.14	0.017	0.014
clozapine	600	10.3	1.22
fluperlapine	400	0.8	-
(±)-sulpiride	10.000	90.6	-
(-)-sulpiride	-	-	53.0
thioridazine	21	8	15

Further, the ED_{50}-values obtained for the atypical neuroleptics and SCH 23390 correlated well with ability to block the amphetamin cue in rats. The selectivity of the ^{3}H-SCH 23390 binding was less apparent when applying agonist as inhibitors. These data indicate that ^{3}H-SCH 23390 binds to D1 receptors or a closely associated site. The results obtained with the atypical neuroleptics were striking and indicate that ^{3}H-SCH 23390 binding in vivo, may be a screen for atypical neuroleptic activity.

176.16 BEHAVIORAL EVIDENCE THAT SK&F 38393 IS A PARTIAL AGONIST AT DOPAMINE RECEPTORS. Erik B. Nielsen[1,2] and Peter H. Andersen[1] [1]NOVO Industri A/S, Pharmaceuticals R&D, DK-2880 Bagsvaerd and [2]Sct. Hans Hospital, DK-4000 Roskilde, Denmark.

Rats were trained to discriminate d-amphetamine sulphate (1 mg/kg; AMPH) from saline in a two-lever water-reinforcement operant task. The specific, partial dopamine (DA) agonist SK&F 38393 (5-40 mg/kg) produced only a modest substitution (~50%) for AMPH's cueing effect. The specific DA_2 agonist pergolide (0.2-1 mg/kg) substituted completely for AMPH; on the converse both D-2 specific antagonists (sulpiride, spiroperidol and haloperidol) and the specific D-1 antagonist SCH 23390 blocked completely the AMPH cue.

Partial agonists can sometimes, depending on efficacy, antagonize the effects of agonists. However, SK&F 38393 failed to antagonize the AMPH cue although only low doses (1-5 mg/kg) could be administered due to behavioral disruption. That SK&F 38393 has DA-antagonistic effects was, however, indicated by the ability of the drug (40-80 mg/kg) to antagonize (~80% blocking effect) the unconditioned gnawing behavior elicited by a high dose (60 mg/kg) of methylphenidate in mice. In comparison, low doses of SCH 23390 blocks completely the gnawing behavior induced by methylphenidate. Further, in reserpinized mice, the ability of SK&F 38393 to cause behavioral activation (locomotion, grooming) was increased; indeed, the drug reversed the reserpine-induced behavioral syndrome. In contrast, SK&F 38393 had no consistent effect in normal mice.

The results indicate that SK&F 38393 behaves like a partial agonist; consequently, caution should be exercised when using the drug in studies aimed at determining the role of D-1 receptors in behavior.

BIOCHEMICAL AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT I

177.1 ACETYLCHOLINE SYNTHESIS BY CULTURES OF MATURE ADRENAL CHROMAFFIN CELLS. P. Boksa. Douglas Hospital Research Centre, Depts. of Psychiatry and Pharmacology, McGill University, Montreal, Quebec H4H 1R3 Canada.

Adrenal chromaffin cells normally synthesize and release catecholamines. However recent electrophysiological studies (Ogawa, M. et al, Nature 307:66, 1984) have shown that neonatal rat adrenal chromaffin cells in culture can form functional synapses that are blocked by cholinergic receptor antagonists, suggesting that these cells may be able to synthesize and release acetylcholine (ACh). In the present study, I have shown that cultures of isolated chromaffin cells from the adult bovine adrenal can take up ^{3}H-choline from the extracellular medium and synthesize ^{3}H-ACh. On incubation with 10 µM ^{3}H-choline for 1 h, day 6 cultures synthesized about 4 pmol ^{3}H-ACh/mg protein. The rate of ^{3}H-ACh synthesis was constant in cells maintained in culture from 6 to 15 days and increased from day 19 to day 28, such that ^{3}H-ACh synthesis in day 28 cultures was 2.4 times that in day 6 cultures. Total protein content/culture was constant between days 15 and 28, indicating that there is a relatively specific induction of ACh synthesizing capacity in the cultures. Depolarization of the cells with 60 mM K^+ increased the subsequent synthesis of ^{3}H-ACh, suggesting that ^{3}H-ACh synthesis may be regulated by neuronal activity in a manner similar to that observed in cholinergic neurons. The ability for K^+ to stimulate ^{3}H-ACh synthesis only developed by day 28 in culture.

In cholinergic neurons, choline is known to be taken up by a specific high affinity uptake mechanism that is Na^+-dependent and hemicholinium-sensitive, and choline is then acetylated by choline acetyltransferase. In chromaffin cell cultures, ^{3}H-choline was taken up by a single mechanism with a K_T of 8-18 µM. ^{3}H-choline uptake was enhanced by Na^+ omission in day 14 cultures but was 50% Na^+-dependent in day 29 cultures. Hemicholinium-3 (IC_{50} <10 µM) inhibited ^{3}H-choline uptake. Acetyltransferase activity in homogenates of chromaffin cell cultures increased 5-fold after 28 days in culture. Only 5% of the acetyltransferase activity was inhibited by an inhibitor of choline acetyltransferase; however this 5% of acetyltransferase activity was 20 times the amount necessary to produce the observed rates of ^{3}H-ACh synthesis in the intact cell. It is concluded that bovine adrenal chromaffin cells, maintained in culture, are able to exhibit cholinergic properties and this capacity is retained even by the mature cell. Supported by the Medical Research Council of Canada.

177.2 Control of acetylcholine production and release in cultured avian retina cells. F.G. de Mello*, M.C.F. de Mello* and W.L. Klein. Dept. of Neurobiology and Physiology, Northwestern University, Evanston, Il. 60201.

The differentiation of the cholinergic system of the retina has been investigated in cultured cells from chick embryos. Cells were prepared from 8-day-old embryos and maintained under conditions that favored either monolayer or aggregate cultures. The expression of Acetyl-CoA:choline O-acetyltransferase, EC 2.3.1.6 (CAT) during differentiation of cultured neurons was compared in both culture conditions. CAT activity in monolayer cultures was approximately 1100pmoles/min.mg protein after 4 days of incubation, remaining stable until culture day 6. Thereafter, a 4 fold drop in the activity of the enzyme was observed. When CAT activity was measured in aggregates we observed that after 5 days of incubation the enzyme activity was the same as that observed in monolayer. However,the enzyme activity in the aggregates remained stable in subsequent days. After 12 days in culture CAT activity in aggregates increased further, reaching levels as high as 1500pmoles/min.mg protein. In contrast the enzyme activity of cells in monolayer was less than 400pmoles/min.mg protein after the same incubation period.

The exposure of cultured cells to ^{3}H-choline resulted in the synthesis of ^{3}H-acetylcholine which accumulated in a pool available for release when cells were pulse stimulated either with K^+ (44mM) or L-glutamate (0.5mM). The acetylcholine released by K^+ stimulation was entirely dependent on Ca^{++} ions in the incubation medium, and the L-glutamate promoted Ach release was only partially affected by the absence of Ca^{++}.

The appearance of the evoked release of acetylcholine from cultured neurons followed the same temporal pattern observed for the expression of CAT activity. Moreover, in monolayer cultures that had low CAT activity, the evoked release of acetylcholine was either low or undetectable. Our results indicate that the presynaptic component of the retinal cholinergic system is expressed early during development and suggest that appropriate cellular interaction may be an important factor in maintaining the differentiated state of cholinergic neurons.

177.3 PHENOTYPIC EXPRESSION OF NEUROTRANSMITTER LEVELS IN 3 TYPES OF DOMESTIC DOGS

W.J. Shoemaker, C. Arons* and B.E. Ginsburg*, Dept. of Psychiatry, University of Connecticut Health Center, Farmington, CT 06032

Domestication and continuous selection by man has resulted in the development of many types of dogs that vary along behavioral, tempermental, physiological responsiveness and anatomical scales. The opportunity to correlate certain behavioral differences with neurotransmitter level, and eventually with transmitter receptor levels, may help assess whether such behavioral diversity is reflected in populations of specific brain neurons. Three types of dogs, whose behavioral responses towards a variety of natural stimuli including livestock animals and other "prey" species are being studied to determine the specific behavioral differences among the types and the development of these behaviors. The three types of dogs are: a) Shar Planinetz, a livestock guarding dog that is non-aggressive toward prey; b) Border Collies, a livestock herding dog that displays components of predatory behavior but does not attack livestock; and c) Siberian Husky, a northern type dog that shows full predatory behavior toward livestock and other prey. Besides possible correlation with specific behavioral differences in the three strains, the comparisons of brain neurotransmitter levels will provide an indicator of the variability permitted by natural selection in brain neuronal populations, while still retaining reproductive identification as the same species. Dogs from each type are anesthetized, their brains removed rapidly, and dissected. Brain regions chosen for catecholamine assay were frozen and homogenized later in 0.1 N $HClO_4$ for HPLC separation with electrochemical detection of norepinephrine, dopamine, epinephrine, DOPAC, and 5-hydroxytryptamine. Brain regions chosen for neuropeptide assay were placed immediately into boiling acid, after 20 min. samples were cooled, homogenized and extracts prepared for RIA of enkephalin, B-endorphin, and vasopressin. Region by region comparisons of neurotransmitter content and concentration will be presented, as well as some suggested relationships of particular brain systems to the observed behavioral differences.

177.4 ALTERATIONS IN PRO-OPIOMELANOCORTIN PROCESSING IN THE RAT MEDULLA OBLONGATA DURING DEVELOPMENT. Norman E. Alessi. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Pro-opiomelanocortin (POMC) related peptides Beta-endorphin (B-END) and ACTH have been identified utilizing immunohistochemical techniques in neurons of the nucleus tractus solitarious (NTS) of the rat from embryonic day 17 through the postnatal period into adulthood (Khachaturian et al., Life Sciences, 33 (Suppl. I):61, 1983). Biochemical studies though have been limited to the determination of the alterations in the levels of B-END immunoreactivity (i.r.) in the medulla oblongata during the postnatal period (Alessi and Khachaturian, Neuropeptides, 5:473-476, 1985). No biochemical studies have investigated the processing of POMC in the medulla oblongatas of developing rats. In the present study, levels of B-END i.r. and the processing of POMC were determined in the medulla oblongata during pre- and postnatal development and compared to the adult.

Pregnant (gestation day 21-22) Sprague-Dawley rats were sacrificed by cervical dislocation. The uterus was dissected and placed in a saline-ice bath. The embryonic (E) rats were dissected from the uterus, decapitated, the caudel medulla oblongatas were dissected in block and immediately frozen at -80°C. Also, tissue was collected from postnatal (P) day 1 and adult male rats. B-END i.r. was measured using a previously characterized antibody (Cahill et al., J. Clin. Endocrinol. Metab., 56:992-997, 1983). For molecular sizing the medulla tissue from E21 (65 regions), P1 (55 regions) and adult (15 regions) rats were chromatographied using a 15 mm x 900 mm column with G-50 superfine gel (Sephadex G50-50), and an eluent buffer of 10% formic acid, 0.1% BSA, and 0.1% 2-mercaptoethanol. Percentages of POMC, Beta-Lipotropin (B-LPH), B-END (1-31) and B-END (1-27) were determined for each age group using the results of the chromatography.

Significant changes were noted in the levels of B-END i.r. during development. From E21 to P1 the level of B-END i.r. ($\bar{X} \pm$ S.E.M.) dropped from 14.1 $\pm$ 2.57 fmol/mg to 7.64 $\pm$ 1.30 fmol/mg of protein. Subsequently, B-END i.r. levels increased significantly to 169.3 $\pm$ 19.9 fmol/mg of protein. In addition, chromatographic alterations were noted. At E21, 21% of the total B-END i.r. was demonstrated to be POMC/B-LPH in size, 64% B-END (1-31), and 15% B-END (1-27) increasing to 32%. In the adult POMC/B-LPH concentration decreased to less than 1%, B-END (1-31) increased to 65% and B-END (1-27) remained at the same concentration.

This report demonstrates not only significant changes in the levels of B-END i.r. during development, but changes in the percentages of POMC and related peptides. This data suggests age specific shifts in the processing of POMC in the medulla oblongata with resulting forms of POMC related peptides with markedly different opiate properties. The physiological significance of these changes remain unknown and in need of further study.

177.5 EXPRESSION OF TYROSINE HYDROXYLASE BY CHOLINERGIC CILIARY GANGLION NEURONS IN CULTURE IS REGULATED BY TARGET STRUCTURES. J. Lee*, L. Iacovitti, G. Teitelman, T.H. Joh, V. Albert and D.J. Reis (SPON: J.M. Carroll). Dept. Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

We have previously reported that a few neurons of the parasympathetic ciliary ganglion (CG) of chick embryos contain tyrosine hydroxylase (TH), the first enzyme in the catecholamine (CA) biosynthetic pathway, during pre- and postnatal development in vivo; and that, in vitro, all CG neurons express the enzyme (Teitelman et al., J. Neurosci. 5: 29-39, 1985). In contrast to TH, L-amino acid decarboxylase (AADC), the next enzyme in the CA pathway, is expressed by all CG neurons during development in vivo and in vitro. In this study, we sought to determine whether the expression of TH but not of AADC in CG neurons is regulated by muscle, their target organ. To test this, hearts removed from chick embryos at day 6 of development (E6) were dissociated and plated on collagen-coated dishes at a density of 1 heart/dish. After 24 hrs. in culture, contracting fibers were already abundant. The following day, CG removed from stage 31-34 (E8) embryos were dissociated and added to myocardial cultures. Cultures were grown in media containing horse serum and eye extract as described previously. After 5 days in vitro, the cultures were fixed and processed for immunocytochemical staining. It was found that CG neurons did not contain TH immunoreactivity when cocultured with heart muscle. In these cultures, however, the neurons were easily visualized with antibodies to AADC or to the housekeeping enzyme, neuronal specific enolase (NSE). Sister cultures containing only CG neurons stained darkly with TH antisera as well as with antisera to AADC and NSE. Similar results were obtained when CG neurons were cocultured with skeletal muscle from E11-E12 chick. The effect of muscle on TH expression was tissue specific since CG neurons did not contain TH immunoreactivity when cultured with E7 kidney, E7 lung or E5 liver cell layers.

To test whether the effect of muscle on the appearance of TH in CG neurons was produced by a) a diffusable substance or b) a cell exudate, E8 CG neurons were maintained in vitro either in the presence of heart conditioned medium or in culture dishes containing a substrata of lysed muscle cells. Under both conditions, CG neurons express TH and AADC immunoreactivity after 5 days in vitro.

We conclude that the expression of TH, but not AADC, by CG neurons in culture is regulated by muscle and that this effect is tissue specific. Moreover, the factor(s) controlling the appearance of TH do not diffuse into the media. These results suggest a) that an interaction between CG neurons and living muscle cells is required for the regulation of TH expression and b) that a similar mechanism may exist in vivo. (Supported by NIH Grant HL18974 and NSF Grant PCM-8303019.)

177.6 THE DEVELOPMENT OF PERIPHERAL SEROTONIN-IMMUNOREACTIVE SYSTEMS IN THE CHICK EMBRYO. R.M. Mondragon* and J.A. Wallace (SPON: G. Ballam). Dept. of Anatomy, Univ. of New Mexico School of Medicine, Albuquerque, NM 87131

Serotonin (5-HT) immunoreactive cells have been shown to differentiate from quail neural crest derivatives grown under in vitro culture conditions (Sieber-Blum et al., Dev. Biol., 99:352,'83). In the present investigation we studied the in vivo distribution of peripheral 5-HT immunoreactive cells that appear during development of the chick embryo. 5-HT immunocytochemical staining patterns were examined in chick embryos taken on days 3,4,5,7,9,12,17 and 21 of incubation. A minimum of two embryos at each daily interval were fixed with 4% paraformaldehyde and processed for routine paraffin-embedding. Anti-5-HT immunostaining was visualized on paraffin sections by the peroxidase ABC staining method. The earliest 5-HT immunoreactivity was observed within APUD cells located in the early forming dorsal pancreas of embryos at 3 days of incubation (E3). By E5, stained cells were also found in all primary and secondary sympathetic ganglia, particularly at more rostral embryonic levels. The immunoreactive cells in each ganglia were relatively small in number comprising approximately between 5 and 10% of the ganglionic cell population and were located primarily in clumps at the periphery of the ganglia. By E7, 5-HT-stained cells were observed in all secondary sympathetic (paravertebral) chain ganglia throughout the length of the embryos. In addition, at E7 staining was noted in various developing prevertebral ganglia, especially in positions ventral and lateral to the dorsal aorta. At this age, intense anti-5-HT staining was also observed in numerous cells of the adrenal medulla and within the forming carotid bodies. From E9 to E12 there was a gradual loss of immunoreactive cells found in the sympathetic chain ganglia starting rostrally and progressing caudally to ganglia found in the lumbro-sacral region. At E17 and E21 (hatching) 5-HT-stained perikarya were only rarely found in sympathetic chain ganglia in caudal portions of the embryos, although stained varicose fibers were occassionally encountered in ganglia at all embryonic levels. In contrast to this decrease in immunoreactivity that occurs in sympathetic chain ganglia, intense staining was found in cells of the carotid bodies, adrenal medulla, pancreas and in numerous scattered prevertebral ganglia throughout the period of embryonic development in the chick. At this point, it is impossible to discern whether the loss of anti-5-HT staining in the sympathetic chain ganglia represents cell death, the switching of transmitter phenotypes or the migration of the cells to other embryonic locations. Supported by NSF BNS 82-08433 and NIH NS 20039 and RR 08139.

177.7 TYROSINE HYDROXYLASE MESSAGE LEVELS INCREASE DURING INDUCTION OF CHOLINERGIC PHENOTYPE. K.L. O'Malley*, A. Maniotis* and M. I. Johnson, Dept. of Anat. & Neurobiol., Washington Univ. School of Medicine, St. Louis, MO 63110.

Previous studies have shown that the adrenergic neurons of the neonatal rat superior cervical ganglion (SCG) can be induced in vitro to develop cholinergic traits. It has been a matter of debate whether they do so at the expense of their adrenergic properties (i.e., whether catecholamine pathway enzymes are still maintained after the cells develop the cholinergic phenotype). We decided to re-examine this issue using a cloned cDNA for rat tyrosine hydroxylase (TH). Dissociated SCG neurons were prepared from neonatal rats and non-neuronal cells were eliminated. Dishes of 40,000 neurons were treated with either 20 mM K^+ in order to maintain an adrenergic phenotype, or human placental extract and chick embryo extract to induce a cholinergic phenotype (Iacovitti et al., 1981). At 1, 3 and 5 weeks in vitro, cultures were harvested and used to prepare total RNA and to determine TH and choline acetyltransferase (CAT) enzyme activities. Three dishes of neurons were pooled at each time point and 10 µg of total RNA recovered, electrophoresed in a formaldehyde gel and transferred to nitrocellulose by blotting. Filters were then probed with a high specific activity TH RNA probe. The medium used here to induce cholinergic function resulted in the persistance of TH mRNA at equal or greater levels than that seen in starting ganglia or cultures treated for 10 days with high amounts of K^+. TH enzyme activity followed suit with a 2-3 fold increase over starting ganglia in cholinergically induced cultures. In contrast to the de-sheathed E_{21} ganglia and the cultures treated with 20 mM K^+, a steady linear increase in CAT activity was measured over the 5-week time course in cholinergic inducing medium. These results demonstrate that SCG cultures are capable of maintaining and expressing both adrenergic and cholinergic phenotypes. Moreover, there is a 2-fold increase of TH message levels and enzymatic activity during the cholinergic induction.

Iacovitti et al., J. Neurosci. 1: 685, 1981.

177.8 THE EFFECT OF VARYING NUMBERS OF STRIATAL TARGET CELLS ON DOPAMINE AXONAL PROLIFERATION IN ROTATION-MEDIATED REAGGREGATE TISSUE CULTURE. P. Kontur, A. Heller and P.C. Hoffmann, Dept. of Pharmacological and Physiological Sciences, The University of Chicago, Chicago, IL 60637

Rotation-mediated reaggregate tissue cultures containing embryonic mouse dopamine neurons of the rostral mesencephalic tegmentum show a developmental increase in dopamine levels with increasing time in culture which is associated with the increasing development of axonal processes revealed by fluorescent histochemistry (Kotake et al., J. Neurosci. 2, 1307, 1982).

We have now investigated the effect of varying the proportion of target cells to which dopamine neurons project in such reaggregates upon the extent to which dopamine axonal processes develop as assessed by quantitative measurements of dopamine levels. The ratio of rostral mesencephalic tegmentum cells to striatal target cells was varied over the range of 1:2 to 1:20 in 5 step increments. This was accomplished by varying the number of rostral mesencephalic tegmental cells (between 0.5×10^6 and 5×10^6) added to cultures containing a constant number (10×10^6) of striatal target cells. A constant total number of cells per flask (15×10^6) was maintained by adding an appropriate number of non-target tectal cells. After 14 days in culture, random pairs of flasks of similar combinations were pooled. Dopamine levels were measured by high performance liquid chromatography in 0.1N perchloric acid extracts from sonicated aggregates.

Dopamine levels were found to be linear functions of the increasing number of rostral mesencephalic tegmental cells present in the cultures (r=.99). This linear relationship held for aggregates maintained in culture for an additional 7 days as well.

These results suggest that increasing the relative target cell numbers for dopamine neurons does not result in an increase in dopaminergic axonal proliferation as estimated by dopamine levels. Rather the axonal field per added dopaminergic neuron appears to be relatively constant. (Supported by MH-28942 and the Brain Research Foundation. P.K. supported by MH-14274 Training.)

177.9 NEUROPEPTIDE DEVELOPMENT IN STRIATE AND PRESTRIATE CORTICES. L. A. Benevento and S.K. Itaya. Dept. of Anatomy, University of Illinois College of Medicine, Chicago, Il 60680.

We compared the neuropeptide development of striate and prestriate cortices and attempted to correlate transient neuropeptide distribution with the development of cortical extrinsic vs. intrinsic connections. Here we report on vasoactive intestinal polypeptide (VIP) and somatostatin (SRIF) immunoreactivity (Immunonuclear lot nos. 8403015 & 8344015) determined with fluorescent (Rhodamine) and Avidin-Biotin peroxidase techniques in the rat. Each animal also received true blue retrograde tracer (TB) injections in one parieto-occipital cortex. On postnatal days 3 to 4 (PND=3-4), areas 17, 18a & 18 contained a sparse number of VIP cells in suplate layer V which was heavily labeled with transported TB from contralateral cortex. By PND=6-7 VIP cells and processes were found in layers II to V (mainly II-III) where ipsilaterally (III) and callosally (III & V) projecting cells are now well labeled with TB. This VIP pattern remains in the adult. Although VIP and TB were in the same layers, there were no double labeled cells. Since the onset and location of VIP intrinsic neurons conincides with those of developing corticocortical projecting neurons, the relationship may be due to VIP cells becoming active when "local regulation of energy metabolism" (Peptides 5:213-8,'84) is required by cortical layers which are forming axonal circuitry. The distribution of VIP cells in areas 17, 18a & 18 was similar at each age. This was not true for SRIF containing cells. By PND=3-4, the heaviest SRIF immunoreactivity was noted in in layers V and VI of area 18. In area 17 there were a few cells in layer VI which were somewhat more numerous at the borders with 18a and 18. Area 18a appeared like 17, but had a few more cells in VI . As development continued this relative pattern of SRIF cell density between 17, 18a & 18 persisted. By PND=6-7 area 18 had a large number of SRIF cells in layers V and VI and a moderate amount in III-IV. A moderate number of SRIF cells was seen in layers V and VI in both 17 and 18a with an occassional cell in layer IV. Again, SRIF cells in area 17 seemed more concentrated at the borders with 18 and 18a. By PND=11-12 SRIF cells increased noticeably in layers II-III of areas 18 and 18a and moderately in II-III of area 17. Area 18 still contained the most cells. This is the developmental pattern which continues into adulthood. In the adult there is a decline in SRIF cells; prestriate and striate areas are no longer as noticeably different as during the first two postnatal weeks. Double labeling revealed some SRIF neurons belong to corticocortical systems. However, the diversity of SRIF cell types and layers indicate that SRIF cells can belong to a number of cortical systems, both intrinsic and extrinsic. The different rates and patterns of SRIF cell development among areas 17, 18a & 18 may refect the different types of connectional organization developing within each area's cortical layers. (Supported by NS21021 and BRSG 8309).

177.10 SPECIFIC BINDING OF ^{3}H-SPIROPERIDOL IN POSTHATCH CHICK BRAIN. S. A. McDougall*, J. L. Neisewander*, M. T. Bardo, and J. F. Zolman. Dept. of Psychology and Dept. of Physiology and Biophysics, University of Kentucky, Lexington, KY 40506.

Previous studies have shown that dopamine agonist and antagonist drugs produce age-dependent differences in the young chicks' behavior during the first posthatch week. Since little is known about the distribution of receptors which are activated by dopaminergic drugs in chicks, we assessed specific binding of the dopamine antagonist ^{3}H-spiroperidol in different regions of 1-, 4-, and 16-day-old chick brain.

Chicks were decapitated and their brains were dissected and frozen at -70° C until assay. Tissue samples were homogenized in 50 mM Tris buffer and washed twice by centrifugation (40,000 x g, 10 min). The samples were then suspended in 100 vols of 50 mM Tris containing 120 mM NaCl, 5 mM KCl, 2 mM $CaCl_2$, 1 mM $MgSO_4$, 10 µM pargyline and 0.1% ascorbic acid (pH 7.7). Brain tissue, preincubated at 37° C for 5 min, was then incubated with 4 nM ^{3}H-spiroperidol (NEN, 23 Ci/nmol) for 15 min in either the presence or absence of 1µM haloperidol. Following incubation, samples were washed under vaccuum pressure onto a Whatman GF/B filter and the radioactivity was counted by liquid scintillation spectrometry.

Specific binding of ^{3}H-spiroperidol in 1-day-old chick cerebellum was 1.38 fmol/mg wet weight. At 4 and 16 days of age, cerebellar binding of ^{3}H-spiroperidol was increased by 26% and 96%, respectively. Specific binding of ^{3}H-spiroperidol in the roof of the chick forebrain was minimal at 1 and 4 days of age (< 1 fmol/mg wet weight), but increased significantly by 16 days posthatch (1.37 fmol/mg wet weight). In contrast, specific binding of ^{3}H-spiroperidol in the base of the chick forebrain, where the paleostriatum is located, was 1.18 and 1.95 fmol/mg wet weight at 1 and 4 days, respectively. A Scatchard analysis of ^{3}H-spiroperidol binding (0.1 - 40 nM) indicated that the age-related increase in binding in the 1- and 4-day-old forebrain base may reflect an increased number of low-affinity receptors (K_d > 10 nM).

177.11 FUNCTIONAL SENSITIVITY OF DORSAL RAPHE NEURONS DURING POSTNATAL DEVELOPMENT: EFFECTS OF 5HT, GABA AND THE BENZODIAZEPINES. D. A. Smith and D. W. Gallager, Depts. of Psychiatry and Neuroanatomy, Yale Univ. School of Med., New Haven, CT 06508 and Dept. of Psychology, Oberlin College, Oberlin, Ohio 44074

To assess potential differences in the functional responsiveness of serotonergic (5HT) and GABAergic receptors during postnatal development, extracellular recordings were made in in vitro midbrain slices cut through the dorsal raphe nucleus (DRN). Slices were superfused with artificial CSF containing 2.5μM phenylephrine which induces pacemaker activity analagous to spontaneous activity in vivo. GABA (.001M) and 5HT (.004M), made up in .1M NaCl, were applied microiontophoretically. Only those cells that showed inhibitory responses to both 5HT and GABA were included for analysis. Drugs were ejected for one minute at regularly spaced intervals. Dose-response relationships were determined by measuring the mean rate of firing during the minute of drug ejection and comparing it with the mean rate during the preceeding minute. Logit and regression procedures were used to obtain the IC_{50} for current. No significant changes in sensitivity to 5HT were observed at any time during postnatal development; (Mean IC_{50}: Adults, 15.0 ± 3.6nA; 8-30 days old, 18.0 ± 3.6nA; 1-7 days old, 11.0 ± 1.7nA; $F(2,30) = 1.25$, $p<.30$). Similarly, a comparison of the sensitivities of DRN neurons to GABA at 4 different ages (1-7 days old, 8-15 days old, and 16-30 days old, adults) showed no significant differences in GABA sensitivity between the age groups ($F(3,78) = 1.43$, $p<.240$), (Mean IC_{50}: 1-7 days of age = 6.4 ± 1.6nA; 8-15 days= 3.6 ± 0.8nA; 16-30 days 3.9 ± 0.9nA; adults= 5.7 ± 1.0nA).

In contrast, preliminary data suggests that cells in slices obtained from new born rats (1-11 days of age) are more sensitive to benzodiazepine mediated enhancement of GABAergic inhibition. The application of the benzodiazepine, clonazepam, in the perfusion fluid at doses between 10^{-8} and 10^{-7}M, produced a 50% increase in GABA inhibitory effects (ED_{50}) at a lower dose in tissue from young animals (1-11 day old: ED_{50} 3.18×10^{-8}M) as compared to adult tissue (7.32×10^{-8}M; $F(1,9) = 11.80$, $p<0.01$). This increased potentiation of GABA effects by benzodiazepines is consistent with previous literature showing enhanced coupling of the GABA-BZ complex at early postnatal ages.

177.12 PRENATAL EFFECTS OF 5 METHOXYTRYPTAMINE AND FLUOXETINE ON SEROTONIN UPTAKE AND BEHAVIOUR IN THE NEONATE. A. Shemer*, A. Ramirez*, P. Whitaker-Azmitia, E. Azmitia (SPON: I. Fand, MD). Department of Biology, New York University, New York, NY 10003.

Serotonergic neurons are one of the first CNS systems to form. It has been proposed that serotonin (5HT) plays a role in development and in the regulation of growing neurons. Furthermore, in tissue culture, it has been demonstrated that 5 Methoxytryptamine (5MT, a 5HT agonist) can inhibit the outgrowth of serotonergic neurites. For these reasons we looked into the in vivo effects of drugs affecting the 5HT system by administering them to pregnant rats and looking at behaviour and high affinity uptake of 5HT in the offspring.

Pregnant Sprague Dawley rats were injected i.p. daily from day 12 of gestation until the day of birth. They received either 5MT 1 mg/kg, or Fluoxetine FL (an uptake blocker specific for 5HT) 10 mg/kg, or saline. On day 1 and 2 after birth pups were sacrificed and their brains removed. ^{3}H-5HT specific high affinity uptake (10 nM) was measured in both brainstem and frontal tissue. Nonspecific uptake was defined as that occurring in the presence of 10 uM Fluoxetine.

Both 5MT and FL administration during gestation lead to greater ^{3}H-5HT uptake on both day 1 and 2. However, this effect was more pronounced in the brainstem with 5MT and more pronounced in the frontal section with FL.

In the adult, 5HT has been shown to have an effect on both memory and on general activity levels, we therefore looked at spontaneous alternation, the retention of a passive avoidance response, as well as activity, at 18 and 15 days old respectively. A subgroup of treated offspring were given 1 trial to acquire a passive avoidance response with 0.16 ma. shock to the feet. The 5MT offspring showed significantly less retention when tested the following day, than either the controls or the FL offspring. Furthermore 5MT offspring showed significantly less spontaneous alternation than control offspring. In the general activity test treated offspring from both drug groups were less active than controls.

Preliminary results show a clear effect of both 5MT and FL administration during gestation on both the biochemistry and behaviour of the offspring. Further research is currently underway to explore these phenomena in detail.

177.13 EFFECTS OF MATERNAL TREATMENT WITH PCPA ON THE DEVELOPMENT OF HIGH AFFINITY SEROTONIN RECEPTORS IN RAT BRAIN. P.M. Whitaker-Azmitia and J.M. Lauder. Dept. of Psychiatry and Behavioral Science, SUNY, Stony Brook, NY 11794, and Department of Anatomy, University of North Carolina, Chapel Hill, NC 27514.

Serotonin plays a role in neuronal development prior to assuming its role as a neurotransmitter in the mature brain. We have shown that serotonin receptors occur in fetal rat brain. Furthermore, using a tissue culture model, we have shown that these receptors may regulate the direction and extent of axonal growth (Whitaker-Azmitia and Azmitia, 1984). We now wish to further characterize these fetal receptors by studying their ability to respond to changes in levels of serotonin.

In the mature rat brain, p-chlorophenylalanine (PCPA), a tryptophan hydroxylase inhibitor, has been shown to increase serotonin receptor number (Fleisher et al., 1979). To test the effect of PCPA on developing receptors, pregnant Sprague-Dawley rats were treated as follows: 300 mg/kg PCPA methyl ester given IP on gestational day 8 and 100 mg/kg PCPA methyl ester IP on days 9-17. High affinity serotonin receptors (S_1) were studied in the forebrain and brainstem of pups on day 1, 30 and 60 post-natal. Receptor kinetics were determined from Klotz plots using at least eight different concentrations of ^{3}H-serotonin (0.5 to 20 nM) in triplicate. Five animals were examined at each time point.

Preliminary results indicate a significant increase in the number of S_1 receptors in newborn forebrain (control = 24.5 ± 2.6 fmoles/mg protein: treated = 33.5 ± 3.3 fmoles/mg) and brainstem (control = 47.0 ± fmoles/mg; treated = 72.4 ± 8.3 fmoles/mg) in PCPA-treated rats. However, this effect was not observed at 30 and 60 days postnatally. There were no changes in the apparent K_D of the receptors in either brain region at any time point.

Our results indicate that fetal serotonin receptors may respond to changes in brain serotonin concentrations in the same way as mature serotonin receptors. Furthermore, this finding implies that fetal serotonergic receptors are "functional" and may be capable of playing a role in development.

177.14 EFFECTS OF SEROTONIN AND 5-METHOXYTRYPTAMINE ON GABA AND 5-HT IMMUNOCYTOSTAINED CELLS FROM HIPPOCAMPUS AND MESENCEPHALIC RAPHE GROWN IN TISSUE CULTURE. M. I. Davila-Garcia, P. Alvarez, P. M. Whitaker-Azmitia, A. C. Towle*, and E.C. Azmitia. Dept. of Biology, New York University, New York, NY 10003 and* University of North Carolina, Chapel Hill, NC 27154.

Serotonin has been implicated as a differentiation signal in early neurogenesis (J. M. Lauder and H. Krebs, 1978, Dev. Neuro. Sci. 1:15-30) and as an inhibitor of neurite outgrowth (P. G. Haydon et. al. 1984, Science 226:561-564). Previous studies in our laboratory have shown that 5-methoxytryptamine (5-MT, a specific serotonergic agonist) at low concentrations inhibits growth of serotonergic neurons in vitro (E. C. Azmitia and P. M. Whitaker-Azmitia, 1984, Neurosci. Absts. 10:663).

In this study we examined the morphological characteristics of neurites and growth cones of specific immunocytochemically identified cells from hippocampus (GABA immunoreactive, GABA-IR) and mesencephalic raphe (5-HT immunoreactive, 5-HT-IR). The effects of serotonin (5×10^{-7}M) and 5-MT (5×10^{-7}M) were assessed by light microscopy. The cells were dissociated and plated in 8 well chamber/slides (Lab-Tek). After 18 hours of incubation the cells were immunocytostained for GABA (hipp), 5-HT (raphe), and GABA or 5-HT (co-cultures).

Our results indicate that after 18 hours of plating GABA-IR cells have one or multiple neurites when grown alone or in the presence of raphe cells. The growth cones of these cells are fan-shaped, contain many filopodia, and display a dense immuno reactivity. The 5-HT-IR cells grown alone or in co-cultures are limited to one or two long neurites which sometimes display small varicosities. Bulbous growth cones and small filopodia are common in these cells. When low concentrations of serotonin and 5-MT are added to the cultures they inhibit growth cone elongation of 5-HT-IR cells but have no effect on GABA-IR cells.

Further details on the effects of these chemicals are being investigated by electron microscopy.

177.15 ONTOGENY OF α-BUNGAROTOXIN BINDING IN RAT NEOCORTEX. J.L. Fuchs. Laboratory for Neurobiology GR 4.1, The University of Texas at Dallas, Richardson, TX 75083

The developmental distribution of an acetylcholine binding site was studied using the ligand [^{125}I]α-bungarotoxin (α-Btx). Subjects were 2 or 3 male hooded rats from each of the following age groups: P0, P2, P4, P6, P8, P10, P12, P14, P17, P20, P31 and adult. Coronal sections of unfixed brain tissue were cut on a cryostat. Tritium-sensitive Ultrofilm autoradiographs were prepared from in vitro labeled brain sections. The sections were later stained with cresyl violet.

At ages P0 and P2, high levels of α-Btx binding were present in the subplate (laminae V-VI) and in lamina I. Subsequently (P4-P10), a more complex laminar pattern emerged. Dense label generally appeared in I,IV, V and deep V to upper VI, although regional variation was present. Only the bands in I and in deep V to upper VI remained prominent in adults. The autoradiogaphs also revealed a radial organization which appeared as early as P2 and became more distinct through P10. At least in some cortical areas, the more dense label was in those regions identifiable as "granular", thalamic recipient zones. The radial pattern became progressively less distinct from P10 to adult. The unfolding of laminar and radial α-Btx patterns coincides with or slightly precedes the development of thalamocortical innervation and the segregation of thalamic and callosal afferents into alternating radial zones (Wise & Jones, 1978). These observations suggest a possible role for α-Btx binding sites in forming stable thalamocortical connections during development.

177.16 POSTNATAL DEVELOPMENT OF B_1- AND B_2-ADREDERGIC RECEPTORS IN THE RAT: AN IN VITRO AUTORADIOGRAPHIC STUDY. D. Lorton, and J.N. Davis. Vet. Admin. Med. Ctr. and Depts. of Med. (Neurology) and Pharmacol., Duke Univ., Durham, NC 27705.

Radioligand binding has made it feasible to study a- and B-adrenergic receptors in the brain during postnatal development. We have used in vitro autoradiography to compare the development of B_1- and B_2-adrenergic receptors to our previous studies of a_1-adrenergic receptor development in the rat brain.

Male Sprague-Dawley rats were decapitated on postnatal days 1, 5, 10, 15, 23, 33, and 45. The brains were rapidly removed and frozen. Cryostat cut horizontal and coronal sections of brains from each age group were processed for autoradiography using [^{125}I]-cyanopindolol with either 50 or 100 nM of the B_1 and B_2 antagonists ICI 89,406 and ICI 118,551, respectively. 1 uM (+)-Propranolol was used to determine nonspecific binding.

At birth, levels of B_1- and B_2-receptors were low in all brain regions. With brain development, the levels of B_1- and B_2-receptors in various brain regions developed at different times and rates. In some regions, such as, globus pallidus and substantia nigra, both B_1- and B_2- receptors increased very early in development (between postnatal day (PND) 1 and 5). However, in other regions, such as, cerebral cortex and caudate-putamen B_1- and B_2-receptors levels were low between PND 1 and 10 and then increased rapidly between PND 10 and 15. In the cerebellum, B_2-receptors of the molecular layer increased rapidly between PND 10 and 23 to the high levels normally observed in the adult rat. In contrast, B_1-receptor levels in the cerebellum molecular layer increased gradually from PND 1 to 23.

These studies provide evidence that B_1 and B_2 subtypes may have different developmental patterns and differ from the patterns of a_1-adrenergic receptor development. Since all three receptors respond to norepinephrine, the differing patterns of development suggest that expression of receptors may not be determined by the apperance of neurotransmitter but rather is determined by the development of the cell expressing that receptor. When the cellular localization of noradrenergic receptor subtypes is better understood, it may be that the appearance of receptors can be predicted by the developmental stage of the cell.

177.17 DEVELOPMENT OF DRUG AND NEUROTRANSMITTER BINDING SITES IN FETAL RAT BRAIN: M. Schlumpf, J.M. Palacios+, R. Cortes+*, A. Pazos+*, A. Bruinink* and W. Lichtensteiger. Inst. of Pharmacology, Univ. of Zürich, CH-8006 Zürich, and Sandoz AG+, CH-4002 Basel, Switzerland.

Information on the prenatal ontogeny of receptor sites and their regional distribution pattern in brain is essential for developmental pharmacology. Qualitative and quantitative autoradiographic methods are especially suited to follow the developmental course of individual binding sites that may change rapidly both in density and distribution. For these studies, frozen fetal rat brains were cut on a cryostat; 10 um sections were incubated with tritiated ligand and apposed to tritium sensitive film (Ultrofilm). Microdensitometry of binding sites was based on Amersham tritium standards and standards prepared from fetal brain homogenates.

Binding sites for the muscarinic cholinergic ligand H3-N-methylscopolamine appear at gestational day (GD) 14-15 in spinal cord and lower brainstem. Subsequently, labeling increases in brainstem and spreads to di- and telencephalon, neocortex being labeled in late fetal life. Microdensitometry revealed a predominance of the M2 receptor type in lower brainstem, while the ratio of M1/M2 varies with time and brain region. In contrast, beta-adrenergic (H3-dihydroalprenolol) binding sites are characterized by their early presence in olfactory bulb and neocortex, where the distribution pattern is quite similar to catecholamine fiber innervation. During late fetal stages this distinct neocortical pattern changes into a more uniform dense distribution of binding sites. Specific binding of H3-serotonin, which represents S1 type receptors in adult brain, is found at an early fetal stage (GD 16) restricted to the chorioid plexuses. The same structure is also labeled by the peripheral benzodiazepine ligand H3-methyl-Ro-5-4864. Through further development 5 HT-1 binding sites appear in lower brainstem (GD 18), the septal nuclei, the basal ganglia and in deep layers of the developing neocortex at GD 20, a time when S2 sites are also well documented by biochemical studies (Bruinink et al., J. Neurochem. 40, 1227, 1983). The development of benzodiazepine binding sites corresponds to the caudo-rostral maturation pattern of the fetal CNS (Schlumpf et al., J. Neurosci. 7, 1478, 1983). These distinct differences in the ontogenetic pattern of individual binding sites suggest that drug sensitivity of different brain regions may vary considerably in the course of fetal development.

177.18 PRE- AND POSTNATAL ONTOGENY OF BRAIN NEUROTENSIN RECEPTORS: AN AUTORADIOGRAPHIC STUDY. A. Pazos[1*], J.M. Palacios[1], M. Schlumpf[2] and W. Lichtensteiger[2]. (SPON:R.MAURER) [1]Preclinical Research, Sandoz Ltd., Basle and [2]Inst. of Pharmacology, University of Zürich, Zürich, Switzerland.

In the rat brain neurotensin (NT) has been detected by immunohistochemistry as earlier as day 16 of gestation (GD16) and seen to increase steadily postnatally in several brain regions (Bissette et al., J. Neurochem. 43, 283, 1984). Receptors for NT have been characterized in the mammalian brain membranes by binding assays and visualized by autoradiography (Young and Kuhar, Brain Res. 206, 273, 1981).

Using in vitro receptor autoradiographic techniques we have analyzed the pre- and postnatal development of NT receptors in the rat brain. NT receptors were labeled in mounted tissue sections from animals of ages ranging from GD14 until the postnatal day 21 (PN21) as well as young adult animals. ^{3}H-NT was used as a ligand and unlabeled NT was added to the incubation mixture to produce blanks. ^{3}H-Ultrofilm was used to generate autoradiograms. Autoradiograms were analyzed and quantified using a computer-assisted image analyzer.

Very low densities of NT receptors were visualized on GD's 14 and 15. Between GD16 and GD18 a marked increase in the density of NT receptors was seen in the developing neocortex. Densities in other brain areas, particularly midbrain and brainstem were much lower than cortical densities. The density of NT receptors in the cortex increased throughout the last part of the gestation and the earlier postnatal life with a peak at the end of the first postnatal week. After that, NT receptor binding decreased dramatically to reach the relatively low densities seen in the adult animal towards the end of the third postnatal week. Development of NT receptors in other brain areas followed very different time-patterns. For example, NT receptors associated with dopaminergic cell-bodies in the midbrain were seen first at GD18 and increased slowly with development to reach adult levels at about the second week of postnatal life. NT receptors in the hippocampal formation presented a postnatal development being detected first at PN5 and showing a developmental peak around the second week.

The main finding of these experiments are the clear differential regional ontogenetic patterns for NT receptors. The very high densities present in the cortex even in very early fetal states suggest that NT could play a role as a signal in the growth of the brain. This role has also been suggested for other peptides in other models of cell division and development.

177.19 NEUROPEPTIDE RECEPTORS ARE PRESENT IN FETAL NEOCORTICAL TRANSPLANTS.

T.W. Moody, R.L. Getz, M.M. Shaffer and J.M. Rosenstein. Depts. Biochemistry and Anatomy, The George Washington University School of Medicine, Washington D.C. 20037.

Neural transplantation provides an opportunity to study neuronal development and growth characteristics. Many cell biological parameters may be responsible for extensive growth properties exhibited by transplants of fetal CNS. These might include induction of vascularization or peptide or transmitter elaboration. We have transplanted fetal cerebral cortex from E15-19 donors into the IV ventricle of young adult recipients in order to determine if certain neuropeptide are present. In this atraumatic system, the fetal tissue grows remarkably to fill the ventricular space. Host rats were sacrificed between 1 and 4 months postoperatively. While the anatomical correlates of neocortical transplants have been described, their neurochemical properties remain to be elucidated. Here we report that neuropeptide receptors are present in these transplants in high density.

Specifically, neuropeptide receptors for Vasoactive Intestinal Peptide (VIP) and Bombesin-like peptides (BN) and Substance P (SP) were detected using the in vitro autoradiographic methods described previously (Zarbin et al. J. Neuroscience 5:429, 1985). VIP is a vasodilator in the neocortex and putative neuromodulator. Receptors for VIP which may mediate brain blood flow to the transplant were present in moderate concentrations. The density of VIP receptors in the transplant, however, was lower than some areas of the host brain such as the area postrema or normal cerebral cortex (Shaffer and Moody, Soc. Neurosci Abs. 14:553). In contrast high densities of receptors for BN were present in the transplant in contrast to the normal receptor complement in such areas as nucleus tractus solitarius and cerebral cortex. Only low densities of SP receptors were present in the transplant areas. Since BN peptides function as growth factors in normal and malignant cells, these receptors may facilitate the growth and/or differentiation of the transplant. Thus certain neuropeptides and their receptors such as VIP and BN may play an important role in the continued survival of neocortical transplants as well as possible modulation of blood flow and barrier properties.

MORPHOGENESIS AND PATTERN FORMATION I

178.1 SELF-ORGANIZATION OF EPENDYMA IN REGENERATING TELEOST SPINAL CORD. M.J.Anderson, S.G.Waxman and Chi Choy*. Dept. of Neurology, Stanford University Sch. of Medicine and the VA Medical Center, Palo Alto, CA 94304.

Within spinal cord of the teleost Sternarchus albifrons which is regenerating after amputation of the tail, multiple ependymas, each surrounding a lumen, are sometimes encountered. We have documented two modes of formation of such secondary ependymas. In one mode, secondary ependymas are created by branching from the main (original) ependyma and central canal of the spinal cord. In the second mode, self-organization occurs within a mass of undifferentiated cells given off from the original ependyma. In this second mode, no continuity exists between the original central canal and the lumen of the newly-formed secondary ependyma. In the caudal region of regenerating cord, clusters of cells are frequently seen lateral to the main ependyma, apparently having arisen from it. Within such masses of undifferentiated cells, self-organization of ependymal structure is accompanied by a reduction in electron density of the cytoplasm, the establishment of numerous desmosomes and close junctions between neighboring cells, and the appearance of cilia. Subsequently, some of the central cells in the mass may break down and extracellular space opens up to form a lumen in the center of the new ependyma. The capacity of ependymally-derived cells to spontaneously form the structure of an ependyma correlates with the high degree of developmental potential already documented for Sternarchus ependyma. It has previously been shown that some cells of Sternarchus spinal cord, presumably those of the ependymal layer, remain pluripotent throughout adult life and can generate new neurons and non-neuronal cells both in vivo and in vitro (Anderson and Waxman, Cell Tiss. Res. 219:1, 1981; Anat. Rec. 208:9A, 1984; and Dev. Brain Res., in press, 1985). The present results indicate that not only can adult Sternarchus ependyma generate new neurons and glia, but that cells derived from it can spontaneously self-organize into the complete ependymal structure. Supported by the Veterans Administration and NS 15320.

178.2 DEVELOPMENT OF RETICULOSPINAL NEURONS OF THE ZEBRAFISH. B. Mendelson. Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60201.

The development of identified reticulospinal (RS) neurons of the zebrafish (Brachydanio rerio) was studied in order to learn how neuronal features including size, position and axonal pathway are correlated with the time of cellular development.

The times of origin (birthdays) of the RS neurons were determined by combining ^{3}H-thymidine autoradiography with horseradish peroxidase (HRP) histochemistry. Individual types of RS neurons were born at characteristic developmental times. Dorsally located neurons always had earlier birthdays than more ventral cells located at the same axial level of brain. Often larger and more lateral neurons, located at one axial level, were generated before smaller and more medial ones. There was no overall longitudinal gradient of RS neuronal generation.

The sequence of axonal outgrowth and the early cell body positions of the RS neurons were determined by filling the cells retrogradely with HRP from their growing axons. The lesions were located in the spinal cord and were made at a series of developmental stages. Individual types of RS neurons grew axons into the rostral spinal cord in a similar sequence to that of their birthdays. Some RS neurons grew axons across the midline of the brain while others extended axons directly caudally at nearly the same time and from somata located at similar locations in the hindbrain. All RS somata were initially observed along the ventral surface of the brain and subsequently were found at more dorsal locations. This dorsal displacement could be a passive one, by growth of the ventral hindbrain, which would explain the dorsal to ventral sequence of time of origin. As a population, the RS axonal projections developed in two distinct waves separated by about 10 hours and, where examined, all RS neurons elongated axons at a constant rate of 100 μm/hr through the spinal cord. If the time that an axon reaches the area of its target is important in the determination of specific synaptic contacts, then it is possible that neurons which project axons in the two waves of RS development differ in their synaptic connectivity in the spinal cord. (Supported by NIH grant NS 17963 and GM 07257).

178.3 SEGMENTAL PATTERNS OF DEVELOPMENT IN THE ZEBRAFISH CNS. Bill Trevarrow and Eric Hanneman*. Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

The CNS of developing zebrafish contains individually identifiable neurons that comprise segmentally homologous sets (Kimmel et al., JCN 205 112, 1982; Myers, JCN 237 in press, 1985). Early labeling of cells for acetylcholine esterase (AChE) activity or for the antigen of the zn-1 monoclonal antibody demonstrated that: 1) similar or identical populations of cells were stained by the two different histochemical methods, 2) the cells stained by these techniques were among the earliest appearing neurons, and 3) some of the labeled cells correspond to individually identifiable neurons. These early appearing neurons seemed to follow a common program of cellular differentiation consisting of: 1) cessation of cell division, 2) AChE expression, 3) axogenesis, and 4) zn-1 antigen expression.

AChE staining was observed beginning at 15 and 18 hours postfertilization (h) ventrolaterally in the hindbrain and spinal cord respectively. The first cells stained were bilaterally located single neurons at one neuromere intervals. The length of the hindbrain and spinal cord neuromeres were identical and corresponded to the length of a somite. Later, single cells in the same locations were the first to stain for the zn-1 antigen. In the spinal cord, these cells were identifiable as primary motoneurons, because of their stained motor axons.

As development proceeded, more cells stained for both AChE activity and zn-1. In the spinal cord, clusters of cells were stained where only a single AChE positive cell was found previously. In the hindbrain, single cells staining darkly for the zn-1 antigen, were now present at half-neuromere intervals. By 28 h, in each neuromere, an alternating pair of large and small clusters of cells were found in similar locations, by both staining techniques. Among the cells in these clusters were identifiable reticulospinal cells.

These results support the hypothesis that both the vertebrate hindbrain and spinal cord are segmentally organized and suggest a common developmental basis for segmentation of the hindbrain and spinal cord. (Supported by NIH grants NS17963 & NS21132, and Med. Res. Foundation of Oregon.)

178.4 SEGMENTAL PATTERNING OF MORPHOLOGICAL TYPES OF RETICULOSPINAL NEURONS IN LARVAL ZEBRAFISH. Walter K. Metcalfe, Charles B. Kimmel, and Bruce Mendelson. Institute of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

We have examined the morphology of identified reticulospinal neurons in larval zebrafish by retrogradely labeling them with HRP. We describe the position, axon pathway, and dendritic morphology of twenty-seven different types of reticulospinal neurons found in the hindbrain five days after fertilization. Nineteen of these types are present as single identified neurons on each side of the brain; the others are present as pairs or small groups of cells.

The reticulospinal neurons form a bilaterally symmetric pattern of cells and are arranged in seven clusters spaced at regular intervals along the neuraxis. Each cluster contains 2-5 different types of reticulospinal neurons. We observe that cells with similar morphological features are found within adjacent clusters, although the composition of each cluster is unique. By considering cell position within the cluster and axon pathway, nearly all of the cells can be assigned to one of about seven serially repetitious classes. Independent features of the cells (size, dendritic morphology) support the same classification.

We propose that the neurons of the same class that are present in the different clusters are segmental homologues. Thus these clusters represent the primitive neuromeres from which the vertebrate hindbrain is thought to be derived. Assuming that this series evolved by successive duplications and divergence of primitive neuromeres, we can analyze the changes that occurred during the evolution of a new segment. The results suggest that most cells are conserved, alhtough occasionally some individual features of cells have been modified. For example, changes between ipsilaterally and contralaterally projecting axons may have occurred several times during the evolution of the series. In addition, cells may have been added or deleted. (Supported by NIH grant NS17963, and the Medical Research Foundation of Oregon.)

178.5 DORSAL ROOT AXONS IN THE DEVELOPING TAIL SPINAL CORD OF XENOPUS. D.M.Awwiller* and R.H.Nordlander. (SPON:J.Kriegler). Dept. Oral Biology, Case Western Reserve University, Cleveland, OH 44106.

As in other lower vertebrates, the spinal cord of Xenopus characteristically displays a distinct set of primitive, or primary, neurons that are responsible for the earliest behavior of the animal. Later, a new set of neurons, the secondary neurons, are superimposed upon these and, for the most part, completely replace them in the adult. This study is concerned with development of the central processes of dorsal root ganglion cells and their relationships to primary neurons and to the dendrites of motor neurons within the tail spinal cord.

Dorsal root ganglion cells were filled with horseradish peroxidase (HRP) applied to epidermis and segmental muscle at tail levels of Xenopus embryos and larvae. After dissection and reaction for HRP, spinal cords were mounted whole in glycerine and viewed with the light microscope.

Dorsal root ganglion cells begin to appear in the tail during early larval stages. One to six cells per hemisegment come to sit on each ventral root, and their central afferent processes travel to the spinal cord along the root. From the root entry point, they travel diagonally just beneath the surface of the cord until they reach the dorsolateral fascicle in which they travel rostrally along with ascending processes of primary sensory neurons. During their diagonal traverse, dorsal root axons do not fasciculate but travel independently. In these preparations, the course of an individual central dorsal root process can be followed over its entire length and its relationships with motorneurons labeled from the same region of the periphery ascertained. Growth cones have been observed at the lead of ascending dorsal root processes, as well as the tips of their developing collaterals. A description of these and other growth cones appears elsewhere in these proceedings.

Supported by NIH grant #NS18773.

178.6 QUANTITATIVE ANALYSIS OF THE DEVELOPMENT OF DESCENDING PROJECTIONS IN THE BULLFROG. G.R. Davis and P.B. Farel. Dept. Physiol., Univ. N. Carolina Sch. of Med., Chapel Hill, NC 27514.

In many vertebrate classes, neurons projecting to the spinal cord at early stages of development and in more mature animals are located in similar brainstem regions. However, the number of brainstem neurons projecting to spinal cord increases over development. We are interested in (1) the developmental course of this increase and (2) whether the increase is distributed proportionally among all brainstem regions.

HRP was applied bilaterally to the lumbar enlargement of bullfrog (Rana catesbeiana) tadpoles (st. IV to XX) and juvenile frogs. After survival periods of 3-7 days, the perfused CNS was removed, sectioned at 40-um on a cryostat, and processed with the Hanker-Yates reagent. The locations and numbers of retrogradely labeled cells were determined in every section of brainstem.

Between st. IV (prior to the formation of myotubes in the hindlimb bud) and st. XX (when the forelimbs emerge from the body wall, marking the onset of metamorphic climax), the number of brainstem neurons retrogradely labeled from the lumbar enlargement increased from approximately 1200 to 2000. This developmental span takes 1-2 years in the wild. In contrast to this relatively slow increase, between st. XX and the completion of metamorphosis at st. XXV (requiring about 2-4 weeks) the number of retrogradely labeled brainstem neurons increased to approximately 3300. Thus, the rate of accumulation of descending inputs is not constant with respect to either developmental stage or time.

Retrogradely labeled neurons were located in the same brainstem regions throughout development. However, particular regions showed a disproportionate increase in numbers of projecting neurons: especially the vestibular nucleus (at the level of the facial nucleus) and the inferior reticular formation.

The pronounced increase in the number of retrogradely labeled brainstem neurons between st. XX and the completion of metamorphosis has implications for the interpretation of previous studies (J. Neurosci. 2:654, 1982). Spinal cord transection prior to the onset of metamorphic climax was followed by the restoration of descending pathways only if the operated animals survived until the completion of metamorphosis. These results suggest that the projections restored to the spinal cord from the brainstem may be formed, at least in part, by newly developed axons rather than regeneration of previously transected axons.

Supported by NIH grants NS14899 and NS16030.

178.7 NEUROGENESIS IN THE REPTILE CORTEX: H-3-THYMIDINE AUTORADIOGRAPHIC STUDY. A.M. Goffinet, Ch. Daumerie*, B. Langerwerf*, C. Pieau* (+) Devpt. Neurobiol.,Univ. Louvain Sch. Med. B-1200 Brussels, Belg. (+) Univ. Paris, France.

Histogenesis has been studied in forebrain cortical structures in two widely separated reptilian species, Emys orbicularis and Lacerta trilineata, using tritiated thymidine autoradiography. Four areas were considered for analysis, namely the medial (hippocampal), the dorsal (general) and the lateral (pyriform) cortices, and the dorsal ventricular ridge (DVR).

Following a single injection of the tracer at an early developmental stage, all neurons are labeled, indicating that thymidine remains available at least throughout the period of neurogenesis. With the exception of the medial part of the hippocampus, where it lasts longer, the bulk of neurogenesis in the four cortical areas proceeds within a short period of 8-9 days, between developmental stages 15 and 18 in Emys, and stages 32-34 in Lacerta. Lateral to medial as well as anterior to posterior tangential gradients of histogenesis are present in all cortical fields in both species. Radial neurogenetic gradients are directed from outside to inside, with the exception of the medial, hippocampal cortex of Lacerta, where no radial gradient is seen.

This pattern of timing and of areal, tangential variations in histogenesis of the reptile cortex is comparable to that found in mammals. In contrast to the mammalian cortex, however, which develops according to an inside to outside, "inverted" gradient, radial neurogenesis in reptile cortex follows an outside to inside pattern.

These observations show that the inside-out gradient of neurogenesis has been acquired during cortical evolution from reptiles to mammals. The appearance of the "inverted" gradient of cortical histogenesis might be related to the evolution of radial cortical organization (Goffinet, JCN 215:437-452, 1983).

178.8 DEVELOPMENT OF SPINOCEREBELLAR PROJECTION IN THE CHICK. N. Okado and M. Yoshimoto*. Dept. of Anat. Univ. of Tsukuba, Inst. Basic Med. Sci., Ibaraki 305, Japan.

This study was undertaken to dermine: (1) the termination field of spinocerebellar fibers in the posthatching chick and; (2) the development of spinocerebellar projection in the chick embryo. Mossy fiber terminals were anterogradelly labelled by injections of lectin horseradish peroxidase in the lumbar spinal cord.

In the posthatching chick (two months) the terminals were found to be distributed throughout the entire depth of lobules I-V, whereas in lobules VI and IX they were concentrated in the apical part of the lobules. Labelling in lobules II-IV showed distinct clusters of terminals in the mediolateral dimension, consisting of three sagittal "strips" of aggregations of labelled terminals in the lateral half of cerebellum. The midpoints of the three strips were located 85 µm, 800 µm and 2140 µm lateral to the midline. The width of the medial-most strip was 110 µm, while the intermediate and lateral strips were 690 µm and 860 µm, respectively. The strips were most distinct in lobule II, whereas they were not so clear in the lobule IV. Labelling was found throughout the entire mediolateral extent of lobule I; labelled terminals were most numerous in lobule I compared to other lobules.

Ontogenetic development of the spinocerebellar projection was examined with special reference to the "strip" formation of mossy fibers found in the adult cerebellum. Axons from the lumbar spinal cord projected to the cerebellar plate as early as embryonic day (E)8, a stage when the mossy fiber targets (internal granular layer) had not yet formed. All the labelled axons projecting from the lumbar spinal cord to the cerebellar plate were contained in one distinct bundle, indicating that gross projection errors do not occur during development of spinocerebellar fibers. A dense accumulation of labelled fibers were first found in the granular layer of lobules III-VI on E10; some labelled mossy fibers were also found in the molecular layer. Labelled fibers first began to penetrate into lobules I and II on E12. The initial axon terminals in the granular layer were already distributed in "strips" at this time. Although a few labelled fibers were found in the regions between strips on E12-E14, the basic segregation of terminals into distinct "strips" was basically similar to that found in the posthatching chick.

178.9 DEVELOPMENT OF THE SEROTONERGIC SYSTEM IN THE CHICK EMBRYO, WITH SPECIAL REFERENCE TO SPINAL PROJECTIONS. H. Sako*[1], T. Kojima*[1] and N. Okado[2]. (SPON: Y. Katayama) [1]Dept. of Anat., Nihon Univ. Sch. of Med., Tokyo 173 and [2]Dept. of Anat. Univ. of Tsukuba, Inst. of Basic Med. Sci. Ibaraki 305, Japan.

The ontogenetic development of the central serotonergic system in the embryonic as well as posthatching chick was studied with the PAP method using an antisera to serotonin (5-HT).

On embryonic day (E)4, a distinct cluster of immunoreactive cell bodies were first found in the primitive raphe nuclei of the metencephalon as well as in the upper rhombencephalon, whereas single reactive cells were occasionally observed in the outer boundary of the ventricular zone of the lower rhombencephalon. After a rapid increase in the number of immunoreactive cell bodies around E6, the basic pattern of 5-HT nuclei found in the posthatching chick appeared on E8.

A few 5-HT immunoreactive cell bodies were also found throughout the rostrocaudal extent of the spinal cord. These 5-HT positive spinal cord cells, which first appeared on E8, were also present in adult spinal cord.

5-HT immunoreactive fibers first appeared in the marginal layer of upper cervical spinal cord on E6 and in the marginal layer at lumbar levels on E8. In general, 5-HT fibers were first observed to penetrate into the mantle layer on E10, when they were found in laminae V, VII, VIII and X. 5-HT fibers in lamina IX, which developed slightly later compared to the other laminae in the basal plate, were first observed in the cervical spinal cord on E10. By E16 5-HT positive fibers were found in lamina IX of the lumbar spinal cord as well as in the dorsal horn. A dense accumulation of 5-HT fibers and varicosities were observed around cell bodies in lamina IX of posthatching chicks. Thus 5-HT fibers and "terminals" fully differentiated in the spinal cord during late embryonic (>E16) and early posthatching stages.

The development of the descending 5-HT fiber system in the spinal cord can be divided into three stages: (1) the projection of axons from the brainstem to cervical (E6) and lumbar (E8) regions within the prospective white matter; (2) penetration of fibers into different laminae of the mantle layer of the spinal cord (E8-E16) and; (3) the formation of terminal connections (E16-posthatching).

178.10 CHARACTERIZATION OF SEROTONIN UPTAKE MECHANISMS IN THE REGION OF THE CAUDAL NEUROPORE OF THE EARLY CHICK EMBRYO. J.A. Wallace, S. Lilly* and R.R. Maez*. Dept. of Anatomy, Univ. of New Mexico School of Medicine, Albuquerque, NM 87131.

We previously reported on the occurrence of serotonin (5-HT) uptake mechanisms in the early chick embryo (Am. J. Anat., 165:261, '82). Cells accumulating 5-HT were visualized by formaldehyde-induced fluorescence as well as by anti-5-HT immunocytochemistry, and were localized in the notochord and in the floor plate of the neural tube in the region of the caudal neuropore. Over several stages, there was an apparent movement of these sites that accumulate 5-HT that was correlated spatiotemporally with the caudal advance of neural tube closure. For these reasons, we have undertaken studies to ascertain if 5-HT has a role in closure of the caudal neural tube. As part of these overall investigations, we first examined the characteristics of the embryonic 5-HT uptake mechanisms with respect to their sensitivity to several pharmacologic agents that act as 5-HT uptake inhibitors on adult neurons. Chick embryos between stages 11 and 14 were cultured in vitro for 2 hours with 0.1 uM 5-HT and 10 uM pargyline as controls. Sites of 5-HT accumulation were visualized in paraffin sections by anti-5-HT immunocytochemistry utilizing the peroxidase ABC staining method. Experimental embryos were treated similarly to controls except that they received one of the following compounds at either 10 or 50 uM concentration: amitriptyline, fluoxetine, imipramine or chlorimipramine. Based upon comparisons of staining intensity (scored as either dark, light or no peroxidase staining observed) with controls, all drugs tested at the 50 uM level completely blocked 5-HT accumulation in the caudal notochord and neural tube. At the 10 uM level, all of the compounds either sharply reduced or eliminated 5-HT staining but with a ranked order of efficiency of chlorimipramine>fluoxetine> amitripytline>imipramine. In addition, we tested two 5-HT receptor blockers (cyproheptadine and methysergide) for their affects on embryonic 5-HT uptake mechanisms. At doses 2 to 5 times above those reported to produce 50% inhibition of 2.5 nM 5-HT binding to receptors on adult neurons (Science, 212:827, '81), these drugs did not reduce 5-HT accumulation. From these studies, we now plan to expose chick embryos to these 5-HT uptake inhibitors at the doses shown to inhibit embryonic 5-HT uptake mechanisms in order to determine their potential for producing neural tube closure defects. Supported by NIH grants NLS19712 and RR08139.

178.11 SHAPING OF NEUROEPITHELIAL CELLS DURING BENDING OF THE CHICK NEURAL PLATE. J.L. Smith, D. Folsom* and G.C. Schoenwolf, Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, Ut 84132.

Three selective points of attachment are formed between the neuroepithelium and adjacent tissues. These comprise a median attachment either to the prechordal plate mesoderm at forebrain levels or to the notochord more caudally and paired dorsolateral attachments to the surface ectoderm of the neural folds. These three areas anchor the neuroepithelium and provide hinge-points for bending. Bending involves elevation of the neural folds (associated with the median hinge-point) and convergence of the folds (associated with dorsolateral hinge-points). Neuroepithelial cells change shape from spindle-like to wedge-like within these hinge-points. The present study evaluates two proposed mechanisms for controlling cell shape: constriction of apical bands of microfilaments and alteration of cell cycle length. Neurulating chick embryos were treated in ovo with cytochalasin D for 1-24 hours to disrupt microfilaments and assess their role in cell shape changes. Elevation of the neural folds continued after cytochalasin treatment, and median neuroepithelial cells were predominantly wedge-shaped despite the absence of apical microfilaments. Although elevation occurred, complete convergence and fusion of the folds were blocked consistently, producing dysraphic neural tube defects. In cases where some convergence occurred, dorsolateral hinge-points formed and wedge-shaped cells could be identified in these areas. Frequently, the neural folds seemed to be pulled laterad; this effect may be due to inhibition of surface ectoderm expansion. Collectively, these results suggest that intact microfilaments are not required for maintaining the wedge-shaped configurations of neuroepithelial cells but may act in epithelial expansion, convergence, and fusion. To identify possible regional differences in the lengths of cell cycles, other neurulating chick embryos were treated in ovo with colchicine for 1-3 hours, and percentages of mitotic figures were determined in the median hinge-point and adjacent, non-bending areas. Preliminary results suggest that median cells have a longer cell cycle than more lateral cells. This could be important because interkinetic nuclear migration occurs during the cell cycle and the nucleus is contained within the widest part of the cell. Thus, the shape of the cell changes as the nucleus migrates. Also, previous studies have suggested that the nucleus is positioned basally during most of the length of the cell cycle. Hence, it would be expected that populations of cells with long cycles would contain a greater percentage of wedge-shaped cells than those with shorter cycles. Autoradiographic experiments on embryos treated with tritiated thymidine are under way to explore this possibility further. Supported by grant nos. NS 18112 and HD 18143 from the NIH.

178.12 THE ROLE OF CELL ELONGATION IN NARROWING OF THE CHICK NEURAL PLATE. G.C. Schoenwolf and M.L. Powers*. Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, Ut 84132.

The chick neural plate undergoes striking changes in shape prior to and during its bending into a neural tube. The purpose of this study is to define some of the mechanisms involved in this shaping. During Hamburger-Hamilton stages 4-6, the overall shape of the plate changes from spade shield-like to band-like. This band continues to narrow and elongate during stages 7-11 as bending of the plate occurs. Overall, during stages 4-11, the width of the plate decreases 50%, its length increases 773%, its height increases 28%, and its volume increases 394%. Narrowing of the plate could be due to: increase in the heights of neuroepithelial cells without increase in their volumes, decrease in the volumes of neuroepithelial cells, reduction of the number of cells within the width of the plate, or stretching of the plate. To test the role of cell elongation in narrowing of the plate, microtubules were disrupted by incubating embryos at 4°C for 2 to 24 hours. Neuroepithelial cells in cold-treated embryos remained partially elongated, reducing their heights to those of stage-4 levels. Concomitantly, the width of the plate increased proportionately, providing experimental evidence for a role for cell elongation in narrowing of the neural plate. The effects of cold treatment were readily reversible--within 2 hours of reincubation at 38°C, microtubules had reformed, neuroepithelial cells had re-extended to their former heights, and the width of the plate had decreased to its normal value. The numbers of neuroepithelial cells in cross sections through the future mesencephalon and cranial spinal cord levels of the plate were counted to determine whether cells are lost from the width of the plate during its narrowing. The number of cells within the width of the plate gradually increased during its narrowing and bending, demonstrating that cell loss from the width of the plate is not responsible for these processes. In summary, our results show that over half of the decrease in width of the plate is due to increase in neuroepithelial cell heights without increase in their volumes, and narrowing of the plate is not due to a decrease in the number of cells within its width. Examination of additional mechanisms involved in shaping of the neural plate is in progress. Supported by grant nos. NS 18112 and HD 18143 from the NIH.

178.13 NEUROANATOMICAL, NEUROVASCULAR, AND FUNCTIONAL RELATIONSHIPS OF TRANSPLANTED VASOPRESSIN NEURONS. F.E. Marciano* D.M. Gash and S.J. Wiegand. (SPON: G.J. Thomas) Department of Anatomy, University of Rochester Medical Center, Rochester, N.Y. 14642.

Our laboratory group has shown that fetal vasopressin (VP) neurons can survive and function appropriately in adult Brattleboro rats with congenital diabetes insipidus and neurohypophysectomized (NPOX) rats. The present study was conducted to examine the effect of lesions of the host magnocellular neurosecretory system on transplant growth and survival. One or two weeks prior to the transplantation of fetal anterior hypothalamus to the third ventricle, young adult male Long Evans rats received either an anterior hypothalamic deafferentation (AHD), NPOX, or sham lesions. Approximately 40 days after transplantation the animals were perfused intracardially with Zamboni's fixative followed by 2% gelatin-ink and the brains were processed immunocytochemically for the peptides VP and oxytocin and/or their associated neurophysins.

Following the AHD, the animals exhibit approximately a 50% reduction in urine osmolality, a sensitive indicator of peripheral VP activity, and concurrent increases in water consumption. Bilateral AHD lesions cause almost a complete loss of pituitary projecting magnocellular neurons in the host. This lesion appears to cause a regression or atrophy of the fenestrated capillaries of the median eminence. The grafts in AHD hosts display a vascular density comparable to the neighboring parenchyma of the host hypothalamus. Few magnocellular elements are present within the grafts and are usually located at the graft-ventricular or graft-host brain interface. In grafts that are juxtaposed to the host median eminence, there is an apparent innervation of this structure by the few surviving magnocellular elements. The physiological response of these animals following transplantation was not remarkable. Following NPOX, there is an immediate polydipsia and polyurea as a result of both the loss of pituitary VP and of a portion of pituitary projecting magnocellular elements, an effect that is partially restored. In contrast to AHD animals, NPOX rats present with a proliferation of the fenestrated capillaries in the median eminence. The grafts, when in apposition the underlying median eminence, display an enriched vascular density compared to the parenchyma of the host hypothalamus. Magnocellular neurons, when present, send axonal processes toward this hypertrophied vascular target. Ealier studies have shown that NPOX animals with grafts in juxtaposition to the median eminence respond functionally. Transplants into non-denervated animals display characteristics similar to the AHD animals.

These results suggest that the availability of an appropriate neurovascular target is an important factor for the viabilty, growth and function of transplanted neuroendocrine cells. (Supported by NIH grants NS 19900 and NS 15109)

178.14 DIFFERENTIATED HUMAN NEUROBLASTOMA CELLS GRAFTED INTO THE HIPPOCAMPUS: STUDIES ON RODENTS AND NONHUMAN PRIMATES. D.M. Gash, M.F.D. Notter, J.H. Kordower, A.L. Kraus* and S.H. Okawara*. Dept. of Anatomy, Lab. Animal Medicine and the Neurological Division of Surgery. University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Recently, our research group has begun to examine the potential of using cultured neuroblastoma cells as donor tissue in neural implants into the damaged mammalian brain. In the present study, human neuroblastoma cells were first rendered amitotic by chemical pretreatment. Cultured IMR-32 cells were labelled with H^3-thymidine and then treated with either mitomycin C and 5-Bromodeoxyuridine or prostaglandin E_1 and dibutyryl adenosine 3',5' cyclic phosphate. The differentiated cells were grafted into the hippocampus of medial septum lesioned rats or fornix-lesioned African Green monkeys. Graft survival in the rodent studies was analyzed at 1, 2, and 4 week intervals following implantation while in the five monkey graft recipients were allowed to go for periods ranging from 51 to 270 days. Host animals were perfused with a phosphate buffered 1.0% paraformaldehyde-1.25% gluteraldehyde solution and frozen sections prepared. Alternate series were stained for acetylcholinesterase (AChE) activity, Nissl stained, or processed for light microscopic autoradiography (ARG).

Grafts in the rodent hippocampus could be identified by H^3-thymine ARG and Nissl staining features. The cells were found in the parenchyma of the brain in a radial pattern spreading out for distances of up to 1.5 mm from the transplantation site. The grafted cells tended to cluster around blood vessels and were also prominent in the ependymal layer of the ipsilateral lateral ventricle. Little AChE staining activity was present in the grafted cells, even at 4 weeks following transplantation into the rodent brain.

A similar distribution pattern of grafted IRM-32 cells was seen in two monkeys receiving implants. Numerous grafted cells were present in animals which survived 240 and 270 days, respectively, after implantation. The grafted cells in these two hosts had been pretreated with mitomycin C and 5-Bromodeoxyuridine. Very few implanted cells could be identified in the other three monkeys which received grafted cells pretreated with prostaglandin E_1-cAMP. The major difference seen between grafts into rodents and monkeys was that cells grafted into the primate hippocampus often stained intensely for AChE and processes could followed from the grafted cells into the host brain. No evidence of tumorous growth of grafted cells was found in either the rodent or primate hosts.

Supported by the Brain Fund.

178.15 ORGANIZATION AND EFFERENT PROJECTIONS OF SUPRACHIASMATIC NUCLEI CONTAINED IN INTRAVENTRICULAR TRANSPLANTS OF FETAL ANTERIOR HYPOTHALAMUS. S.J. Wiegand and D.M. Gash. Dept. of Anatomy, University of Rochester, NY 14642.

Anterior hypothalamic anlage obtained from normal Long Evans rat fetuses at 17 days post conception were transplanted to the lateral, third, or fourth ventricles of adult male Brattleboro rats homozygous for diabetes insipidus (DI). Host animals were sacrificed 3 to 6 weeks post-transplantation. Half of the graft recipients received an intravascular (iv) injection of horseradish peroxidase (HRP, 200 mg/kg) 12-24 hrs. prior to perfusion with a mixed aldehyde fixative. The remaining animals were perfused with a gelatin-ink solution and the brains were post-fixed in Zamboni's fixative. Alternate series of frozen sections were processed for immunocytochemical localization of arginine vasopressin (AVP), oxytocin (OT), neurophysins (NP), or vasoactive intestinal polypeptide (VIP). For animals receiving iv HRP, additional series were processed for histochemical localization of HRP and according to a double labeling procedure for simultaneous localization of HRP and AVP- or NP-immunoreactive (ir) neurons.

Fetal hypothalami survive transplantation to all intraventricular sites and usually contain numerous NP-ir and AVP-ir neurons. OT-ir neurons are noted less frequently. The AVP-ir populations of the transplants are heterogeneous and both magnocellular and parvicellular types can be clearly identified. Parvicellular AVP-ir neurons comprise the predominant subtypes in nearly all transplants, and are frequently organized into well defined clusters that exhibit many of the anatomical relations characteristic of the AVP-ir neurons of the suprachiasmatic nucleus (SCN). Like the AVP-ir neurons of the SCN, and unlike vasopressinergic cell populations in the paraventricular and supraoptic nulei, these parvicellular cell clusters exhibit only a moderate capillary density. These cells, but not other AVP-ir neurons within the transplants, are associated with VIP-ir neurons of a similar small size. AVP-ir fibers originating from these cell clusters are of very fine caliber and ramify extensively among the cell bodies of origin and in their immediate vicinity. In addition to innervating other portions of the graft, these AVP-ir fibers also project to areas of the host brain normally innervated by the vasopressinergic component of the SCN, such as the periventricular hypothalamus, paraventricular thalamic nucleus and the host SCN itself. However, these parvicellular VP-ir neurons generally do not project to areas of the brain that normally receive an extensive vasopressinergic innervation from sources other than the SCN (eg. lateral septum, dorsal medulla and neurohypophysis).

These observations demonstrate that the fetal anlage of the SCN not only survive transplantation to the brain of adult host animals, but also retain or develop many of the intrinsic neural and vascular relations characteristic of the SCN in situ, and are capable of innervating appropriate areas of the host brain.

178.16 GRAFTS OF DISSOCIATED FETAL CEREBELLUM DEVELOP TRILAMINAR CORTICAL STRUCTURES BY RECAPITULATING NORMAL ONTOGENETIC EVENTS. Richard Schmidt and R.K. Bhatnagar, Dept. of Pharmacology, Univ of Iowa, Iowa City, IA 52242.

We have reported that grafts prepared by injecting trypsin-dissociated fetal rat cerebellum into the forebrain of adult hosts developed regions of trilaminar cortex (Neurosci. Abst. 9:849, 1983). In this study we used ^{3}H-thymidine autoradiography and immunohistochemical (IHC) staining for glial fibrillary acidic protein (GFAP), 5-HT and cGMP-dependent protein kinase (cGK, a Purkinje cell marker) to further investigate the structure and development of these grafts.

Grafts prepared from 15-17mm CRL fetal cerebella dissociated with trypsin (Schmidt et al., in Seil, Nerve Organ and Tissue Regeneration, 1983) were injected into adult rats with one deposit within the parenchyma of the dorsal hippocampus, and a second deposit in the ambient cistern ventral to the hippocampus. For autoradiography, 5 hosts received 10-20 µCi ^{3}H-thymidine in the cistern, medial to the graft 18 days post-transplantation. 9-day-old rat pups received isotope via the cisterna magnum as positive controls. Tissues were processed 7, 20 and 72 hrs later.

All the intracisternal grafts had areas of trilaminar organization, and in the larger grafts microfoliation was apparent. Grafts within the parenchyma of the hippocampus were disorganized except for small areas of cortical organization which was invariably associated with blood vessels or cystic spaces.

At 18-21 days post-transplantation, a distinct external granule layer labelled heavily with ^{3}H-thymidine. Over time, label began to appear in granule cells in the IGL, especially in cells near the IGL-PC interface. This pattern of labeling corresponded with that seen in the normal 9 day-old cerebellum, indicating a normal pattern of mitosis and migration.

IHC staining for GFAP revealed the presence of radial glial fibers wherever regular laminar organization had developed, both in the 3 week old grafts as well as at later time. Radial fibers were not seen in the disorganized regions of the intraparenchymal grafts, however they were present in those portions which had developed laminar organization around vessels or cysts.

IHC staining for cGK revealed that PC dendrites were present and were oriented toward the molecular layer. Although 5-HT fibers were clearly present within the adjacent hippocampus, they rarely crossed into graft itself.

This study demonstrates remarkable similarities between the dissociated grafts and normal cerebellum with respect to their structure and development. Several factors appear to contribute to the development of cortical organization within the grafts: the preservation of normal granule cell migration, the presence of a surface upon which to organize, and the presence of radial glial fibers. 178.17 AN ANALYSIS OF THE DENDRITIC FORM OF HIPPOCAMPAL NEURONS IN DISSOCIATED-CELL CULTURES GROWN AT DIFFERENT CELL DENSITIES. A.B. Waxman and G A. Banker, Department of Anatomy, Albany Medical College, Albany, New York 12208

Hippocampal neurons in culture develop a class of processes which display many of the features characteristic of dendrites in vivo. In order to assess how cell interactions affect dendritic development, we have analyzed the form of dendrites which develop in cultures prepared at low, intermediate, and high plating densities (1,000, 6,000, and 16,000 cells per cm^{2}, respectively). At higher cell densities the frequency of contacts between developing dendrites and afferent axons is greatly increased. Cells were studied after growth for 24 days in culture, using a monoclonal antibody against Microtubule Associated Protein 2 to selectively stain their dendrites.

The dendrites of cells in high density cultures were significantly longer and more highly branched. Although the number of primary dendrites was fairly constant in the three culture conditions, averaging about 5 per cell, the number of dendritic segments was twice as great in high density cultures. On average the length of individual segments was about 30% less at high cell density, but because of the increased branching the total dendritic length was about 45% greater. Under all conditions, terminal dendritic segments were consistently longer than nonterminal segments, as is true of pyramidal cells in vivo.

These studies establish that cell-cell interactions have an important influence in determining the extent of dendritic arborization in culture. In this regard these findings are consistent with the conclusions drawn from many studies of the role of innervation on dendritic development in situ. Unlike studies in situ, manipulation of cell density in culture involves only a quantitative change in the opportunity for cell interaction. It does not alter the relative numbers of different afferent populations nor does it involve cell degeneration. Nerve cell culture may provide an amenable model for studying the cell biological mechanisms which govern the development of dendritic form.

179.1 ENERGY-DEPENDENT UPTAKE OF IMIPRAMINE IN NEURONS CULTURED FROM RAT CEREBELLUM. A. Novelli, P.G. Lysko* and R.C. Henneberry*. Lab. of Molecular Biology, NINCDS, NIH, Bethesda, MD 20205.

We have characterized the uptake of imipramine in neurons from an 8 day old primary culture of rat cerebellar granule cells.

In our model the uptake of imipramine was time, temperature and pH dependent and was reduced in the presence of inhibitors of cellular energy metabolism such as dicyclohexylcarbodiimide or in the absence of glucose. The maximal cellular capacity for imipramine before the appearance of cytotoxic effect was about 50 nmoles/mg. of protein. The uptake of imipramine was competed by propranolol but not by serotonin. It was also inhibited by chloroquine. Ionophores such as monensin, known to dissipate the proton gradient, greatly reduced the uptake of imipramine. The uptake was sodium independent but required the presence of calcium.

These data show that an energy-dependent uptake of imipramine occurs in neurons in analogy to previous reports on uptake of exogenous basic amines in other cell types.

179.2 CONTINUOUS RELEASE OF INHIBITORY AMINO ACIDS IN RAT HIPPOCAMPUS: GABA AND TAURINE RECOVERY IN PUSH-PULL PERFUSATES. L.P. Hudson* and R.J. Reiffenstein. Department of Pharmacology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Perfusion-dialysis techniques (Lerma et al., Neuropharmacol., 23: 595, 1984) have demonstrated very low extracellular recovery of gamma-amino butyric acid (GABA) in rat hippocampus; such low extracellular levels of this amino acid are thought to reflect a precise regulation of inhibitory neural transmission in this brain region (Ben-Ari et al., Neuroscience, 6: 2445, 1981). In vivo estimation of taurine, however, is substantially higher, and may point to a neuromodulatory role for this compound (Lehmann et al., Neurosci. Lett., 52: 341, 1984).

We have attempted to demonstrate consistent changes in the release of these compounds in response to physiological and neurochemical manipulations, using the local tissue perfusion method described by Bliss et al., (J. Neurosci. Meths., 7: 353, 1983). Male Sprague-Dawley rats (180-220 g) were anesthetized with urethane (1.25-1.5 g/Kg), and a bipolar stimulating electrode was placed within entorhinal cortex. A stainless steel push-pull cannula with attached recording electrode was placed in CA1 or CA3; placement of the tip of the assembly within the pyramidal cell layer was confirmed by reaching the maximum amplitude of the field response evoked by perforant path stimulation (10V, 1 msec, 1/30 sec). Local tissue perfusion was done at 20 µl/min; 10-min samples were stored at -80°C. Amino acid analysis was performed using reverse-phase, fluorometric HPLC with precolumn OPA derivitization.

In the presence of 5 mM nipecotic acid, an antagonist of GABA uptake, we have demonstrated a substantial increase in GABA and taurine recovery. Although perforant path stimulation (10V, 1 msec, 40 Hz) evoked an increased in taurine recovery under these conditions, a corresponding increase in GABA recovery was not observed. Pretreatment of animals with ethanolamine-o-sulfate, an irreversible GABA transaminase antagonist (Fletcher and Fowler, Biochem. Pharmacol., 29: 1451, 1980) produced a significant further elevation in GABA recovery in the presence of nipecotic acid. These findings suggest that control of mechanisms responsible for the removal of GABA may be necessary in order to realistically appraise GABA release in vivo under changing physiological conditions.

179.3 EVIDENCE FOR THE PRESENCE AND CO-RELEASE WITH NORADRENALINE OF MET-ENKEPHALIN FROM ADRENERGIC NERVE TERMINALS. W.De Potter*, E.Coen* and R.De Potter* (SPON:O.H.Viveros).Dept.of Pharmacology, Universitaire Instelling Antwerpen,Universiteitsplein 1, B2610 Wilrijk,Belgium.

The opioid peptides Leu-enkephalin (Leu-Enk.)and Met-enkephalin (Met-Enk.)are present in some neurons of the central and peripheral nervous system and in chromaffin cells of the adrenal medulla.A role in neuromodulation and/or neurotransmission has been suggested and their release from brain nerve terminals and chromaffin cells has been shown.Using the immunogold technique we could visualize Met-enkephalin-like immunoreactivity in the large dense cored vesicles of bovine vas deferens adrenergic nerve terminals,whereas the small dense cored vesicles did not show any Met-Enk.immunoreactivity.By means of differential and density gradient centrifugation we have confirmed a recent report (Neuman,B. et al.,Neurosci.,13:921, 1984)that Met-Enk.is present in large dense cored noradrenaline-containing vesicles.

Release of radiolabelled noradrenaline and Met-enkephalin immunoreactivity was studied using a superfusion technique.The vasa deferentia were preincubated for 1 hr at 37°C in aerated Krebs-Ringer medium containing $3x10^{-7}$ M of (-)-7-^{3}H-noradrenaline,specific activity 14.1 Ci $mmol^{-1}$ (NEN Chemicals).In preparations superfused (1 ml min-1)with control medium,electrical stimulation (rectangular pulses of 200 mA,2ms duration,4 Hz) during 10 min caused an overflow of ^{3}H and Met-Enk.immunoreactivity (S1).After cessation of the stimulus,the release returned to prestimulation levels.A second stimulation period (S2),after 60 min.,evoked an overflow of ^{3}H and Met-Enk.which reached mainly the same level as S1 for both ^{3}H and Met^{5}-Enk.(89.3 ± 11.28% and 89.3 ± 9.90% respectively).Upon adding the adrenergic neuron blocking drug guanethidine (4×10^{-5}M),both the evoked release of total ^{3}H and Met-Enk.was potently inhibited (20.7 ± 6.01% and 27.4 ± 9.63% respectively).Superfusions with Ca^{2+}-free medium nearly abolished the electrically evoked release of ^{3}H and Met-Enk.

The present study,using the bovine vas deferens as a model, gives additional biochemical and morphological evidence for the presence of enkephalins in large dense cored vesicles of peripheral sympathetic neurons.More important,from a physiological point of view,is the demonstration that the neurotransmitter(s) noradrenaline and Met-Enk.are co-released from peripheral sympathetic neurons in a Ca^{2+}-dependent way.

179.4 ION DEPENDENCY PROFILES OF SIX Na^{+}-DEPENDENT TRANSPORT SYSTEMS. R.P. Shank and C.R. Schneider*. Department of Biological Research, McNeil Pharmaceutical, Spring House, PA 19477-0776.

Ion substitution studies have revealed that the synaptosomal uptake (membrane transport or translocation) of many neurotransmitters and other substrates is, in addition to being Na^{+}-dependent, markedly affected by changes in K^{+} and Cl^{-} concentrations. The design of experiments to study specific effects of ions on membrane transport systems is complicated by indirect effects of ions on uptake due to changes in the membrane potential and permeability, and the possibility that the substitute ion (eg., Li^{+} for Na^{+}) exerts a direct effect on the transport system being studied. Consistent with previous observations we have found that uptake as a function of K^{+} concentration is bimodal in that for all systems studied (norepinephrine, NE; dopamine, DA; serotonin, 5-HT, and GABA) the rate of uptake was greatly enhanced as the concentration of K^{+} was increased from 0 to 2 mM, but as the concentration was increased above 5 mM the rate decreased almost linearly as a function of the log of $[K^{+}]$. For NE (other substrates were not studied) changes in K^{+} affected primarily the V_{max}, although high K^{+} concentrations did increase K_{m}. These results are consistent with the concept that effects of K^{+} on transport are due predominantly or exclusively to changes in membrane potential and permeability.

Our Na^{+} substitution studies revealed widely different profiles for uptake as a function of Na^{+} concentration. The uptake of NE, DA and 5-HT was highly sigmoidal as a function of Na^{+} concentration; virtually no Na^{+}-dependent uptake occurred at Na^{+} concentrations below 25 mM. In contrast the uptake of GABA increased linearly (non-saturating) as a function of $[Na^{+}]$ between 0 and 128 mM. For glutamate and ∝-ketoglutarate uptake increased in hyperbolic fashion (saturating) between 0 and 25 mM Na^{+}, but at higher concentrations the uptake increased almost linearly in proportion to the increase in Na^{+}. For NE (other substrates were not studied) changes in $[Na^{+}]$ affected both the K_{m} and V_{max}. Our results are consistent with the view that Na^{+} activates uptake by exerting direct biochemical effects on the transport systems (eg., by increasing substrate affinity) and by increasing the electrochemical potential that drives the uptake process. The relative proportion of these two effects may differ greatly among the various substrates.

Substituting isethionate for Cl^{-} inhibited the uptake of NE, DA, 5-HT and GABA, whereas glutamate uptake was unaffected, and ∝-KG uptake was enhanced. Although Cl^{-} may affect uptake by a direct action on the transport systems, its effect might arise either partly or entirely, from alterations in the membrane potential caused by changes in the Cl^{-} equilibrium potential.

179.5 CHARACTERIZATION OF MgATP-DEPENDENT PROTON PUMP IN GLUTAMATERGIC SYNAPTIC VESICLES FROM BOVINE CEREBRAL CORTEX AND PROPOSAL OF ITS ROLE. J. Shioi* and T. Ueda. Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109.

L-glutamate is now generally accepted as a major excitatory neurotransmitter in the central nervous system. Recently, Naito and Ueda (1983 J.B.C. 258:696) reported MgATP-dependent glutamate uptake into highly purified synaptic vesicles and suggested synaptic vesicular storage and release of this neurotransmitter.

In an effort to show that the uptake is mediated by proton motiveforce (pmf), which consists of chemical potential difference of H^+ (ΔpH) and electrical potential difference ($\Delta\Psi$) across the membrane, we measured ΔpH and $\Delta\Psi$ using fluorescent dye, 9-aminoacridine, and $\Delta\Psi$-sensitive dye, oxanol XI, respectively. Synaptic vesicles were prepared from bovine cerebral cortex. It was further purified by immunoprecipitation using anti-Synapsin I for some experiments. A pre-existing small ΔpH (inside acidic) of synaptic vesicles was detected, but no additional significant contribution by MgATP to ΔpH was observed. In contrast, a substantial magnitude of $\Delta\Psi$ (inside positive) was generated upon addition of MgATP. It was collapsed by KSCN, a $\Delta\Psi$ dissipator, or carbonyl cyanide p-nitrofluoromethoxyphenylhydrazone (FCCP), a pmf dissipator. Correspondingly, there were a small but measurable amount of glutamate uptake in the absence of ATP and a substantially large uptake in the presence of MgATP. The uptake was also sensitive to FCCP. β,γ-Methyleneadenosine 5'-triphosphate, a nonhydrolyzable analog of ATP, did not substitute for ATP in either $\Delta\Psi$ generation or glutamate uptake. Ca^{2+} could not substitute for Mg^{2+}, but Mn^{2+} was more potent than Mg^{2+} in both systems. The results support the hypothesis that a proton pump generates pmf in synaptic vesicles while hydrolyzing MgATP, and the pmf thus formed, whose major component is $\Delta\Psi$, provides a driving force for the vesicular glutamate uptake. The proton pumping activity was further characterized. The $\Delta\Psi$ generation by ATP hydrolysis was resistant to vanadate, ouabain and oligomycin but inhibited by N-ethylmaleimide, quercetin, trimethyltin, 7-chloro-4-nitrobenz-2-oxa-1,3-diazole and 4-acetamido-4'-isothiocyanostilbene-2,2'-disulfonic acid. The results indicate a difference of this proton pump from those in mitochondria, chloroplast and plasma membrane and a similarity to those in chromaffin granule, lysosome and platelet granule.

Supported by NSF Grant BNS 8207999.

179.6 VESICLE CALCIUM PUMP FROM BOVINE BRAIN: SUBSTRATE KINETICS AND PHARMACOLOGY. Steven C. King* and Stanley M. Goldin. Department of Pharmacology, Harvard Medical School, Boston, MA 02115.

Starting with a membrane preparation from lysed synaptosomes (PNAS 76: 3708), our laboratory has reconstituted and purified by transport specific fractionation, a calcium pump from the bovine cerebral cortex. The pump is immunologically distinct from those found in the erythrocyte or sarcoplasmic reticulum (J. Neurosci. 4: 1468). We now report that the purified, reconstituted vesicles (PRV) contain a calcium-translocating ATPase with properties which suggest: i) that it may function to regulate the Ca^{2+} concentration in nerve terminals, and ii) that it is not derived from the plasma membrane.

$^{45}Ca^{2+}$ transport into the PRV depends upon the concentration of ATP in a complex manner, possibly reflecting the presence of two ATP binding sites with different values for $K_{0.5}$ (5 and 500μM). Maximum rates of $^{45}Ca^{2+}$ transport occur with 1mM ATP. Although at lower rates, GTP, carbamylphosphate, and other energy rich phosphate compounds also support calcium transport.

In solutions containing ATP, EDTA, and 2mM free Mg^{2+}, both ATP hydrolysis and $^{45}Ca^{2+}$ transport, measured under initial rate conditions, were activated over the narrow range of Ca^{2+}concentrations (0.1 to 1μM) which are expected to occur in nerve terminals during neurotransmitter release.

The ratio of transported Ca^{2+} to ATP hydrolysed is at least 1:1, indicating that the calcium-translocating ATPase is well coupled and has been purified away from other ATPases present in the starting material. After solubilization in Triton X-100, the ATPase is not inhibited by 500μM ouabain, indicating that the Na/K ATPase does not significantly contaminate the PRV preparation.

$^{45}Ca^{2+}$ transport is inhibited by quercetin, vanadate, and La^{3+} with $K_{0.5}$ values of 1, 10, and 5μM, respectively. Vanadate and La^{3+} also inhibit the ATPase activity at similar concentrations. On the other hand, Sr^{2+}, Ba^{2+}, Cd^{2+}, and Ni^{2+} did not inhibit the ATPase, raising the possibility that some of these ions might be transported by the pump.

In general, calcium pumps derived from the plasma membrane are: i) unable to utilize energy from sources other than ATP to drive calcium transport, and ii) are sensitive to vanadate in the 0.1 to 1μM range (Calcium and Cell Function, Vol. 4, p. 100. Academic Press, 1983). Our observations are not consistent with these generalizations. On the other hand, our results are more consistent with the properties of calcium pumps from intracellular membrane systems. Inasmuch as secretory granules purified from either adrenal chromaffin tissue or the Torpedo electric organ are known to transport Ca^{2+} in an ATP-dependent manner, we are presently investigating the possibility that the PRV calcium pump is derived from synaptic vesicles.

179.7 **UPTAKE AND RELEASE OF [^{3}H]GABA BY CHICK SPINAL CORD AND BRAIN CULTURES.** J. J. Celentano* and D. H. Farb. (SPON: J. Ranck). Department of Anatomy & Cell Biology, SUNY Downstate Med. Ctr., Brooklyn., N.Y. 11203.

It has been suggested that cells which possess high affinity GABA uptake sites also release GABA as a neurotransmitter. We have examined the uptake and release of [^{3}H]GABA, comparing 1 and 3 wk spinal cord and brain cultures. We find a decrease in the number of neurons labeled by autoradiography (ARG) and a decrease in K^+-stimulated [^{3}H]GABA release by spinal cord cells, consistent with a time dependent decrease in the use of GABA as a neurotransmitter in spinal cord cultures. For uptake, cells were exposed to [^{3}H]GABA (60nM, 20 min, 37°C), washed, fixed with glutaraldehyde, rinsed, and processed for ARG (exposure time: 1 wk, 4°C). Labeled spinal cord cells decreased from 18±2% (n=6; 1700 cells counted) to 3.2±0.7% (n=6; 900 cells counted), but labeled brain cells did not change (20±1%, n=4, 1000 cells counted, and 20±4%, n=4; 900 cells counted). At both ages 55% of the GABA taken up was fixed by glutaraldehyde, and there was little change in K_m (6 and 3uM) or V_{max} (18 and 11 pmol/min/cm^2). L-DABA inhibited 30nM [^{3}H]GABA uptake more potently than B-alanine at both ages, suggesting that uptake is mostly neuronal. We have also investigated the release of [^{3}H]GABA. Cells were loaded with [^{3}H]GABA as for ARG, and the rate of release was determined at 21°C. After the last time point cultures were solubilized (0.05% deoxycholate, 1 N NaOH) to determine the cpm remaining. Cumulative [^{3}H]GABA released (as % of [^{3}H]GABA present initially) followed an initial burst and then occurred linearly for up to 1hr. In 1 wk cultures the rate of release was 0.40±0.04%/min (n=3). 100mM K^+ increased release more than 2-fold to 0.96±0.15%/min (n=3). If Ca^{++} was replaced by Mg^{++} the rate decreased to 0.6±0.1%/min (n=3). This implies that K^+-stimulated release is Ca^{++}-dependent. Three wk cultures showed a slightly higher rate of release, 0.7±0.1%/min (n=3), that was not increased significantly by high K^+: 0.7±0.1%/min (n=3). In 1 wk brain cultures, release was 0.22±0.03%/min and 0.6±0.1%/min in the absence and presence of high-K^+, respectively (n=3). In 3 wk brain cultures, the rates were 0.53±0.08%/min and 1.1±0.1 (n=3). These results suggest that in spinal cord cultures, significant changes occur in the uptake and release of GABA during the first 3 weeks in culture, which may prove to be relevent to the factors that regulate the use of GABA as a neurotransmitter during early neuronal development.

179.8 EFFECTS OF MEDIA CONDITIONS ON THE EXPRESSION OF GLUTAMATE UPTAKE IN PURIFIED NEURONAL CULTURES. C.H. Zambrano* and A.G. Hyndman (SPON: A. Feldstein), Rutgers Univ., Department of Biological Sciences, Piscataway, N.J. 08854.

Previous work has shown that media conditions can effect neuronal survival following glutamate exposure (Zambrano and Hyndman, Dev. Brain Res., 1983). Hyndman and Adler (Dev. Brain Res., 1982) have reported that in a purified neuronal culture, cells with glutamate high affinity uptake (GHAU) appear to be resistant to glutamate toxicity. We now examine the effect of different media conditions on the expression of GHAU, and its relationship to glutamate toxicity. Purified neuronal cultures from 8 day embryonic chick retinas were grown in one of the following medium supplements: CI (catalase, insulin), CIT(CI plus transferrin), N1C(CIT plus progesterone, putrescine and seleniun), Ht and OL (N1C plus heart or optic lobe extract from 14 day chick embryos, respectively). At 48h, cultures were treated with 5mM, NaCl(control) or glutamate (glu). At 72h, cultures were exposed to 3H-glutamate (1x10-7M) for 5min, fixed and processed for autoradiography. Cultures were examined for neuronal survival and the presence of GHAU.

	% of cells with GHAU		survival x10^3 cells/dish		
	NaCl	glu	NaCl	glu	% of control
OL	28.9	23.6	26.1	25.3	96.9
Ht	15.7	5.4	45.0	16.5	36.7
N1C	18.9	5.7	41.0	40.2	98.0
CI	8.8	3.0	28.5	13.7	48.1
CIT	8.1	2.0	33.8	28.9	85.5

Our results show that media conditions can effect the expression of neuronal GHAU. A desensitization of GHAU is seen in N1C toxin treated cultures, a condition in which neurons are resistant to glutamate toxicity. However, this desensitization is not noted in the case of cultures grown in OL. Our data suggest that cells which lose their ability to express GHAU, still remain resistant to glutamate toxicity as shown in N1C-cultures. In future studies, we will attempt to return GHAU expression to control levels in cultures that were exposed to glutamate. Also, since different media conditions yield different levels of GHAU expression, we will further identify which media components may serve to enhance the expression of neuronal GHAU.

179.9 **FURTHER STUDIES OF XYLAMINE BINDING TO SYNAPTIC PLASMA MEMBRANE PROTEINS.** S.D. Cushing*, E. Mullieg* and A.K. Cho, Dept of Pharmacol. and Brain Res. Inst., UCLA Sch. of Med., Los Angeles, CA 90024.

We have further characterized the binding of Xylamine [(XYL), N-2-chloroethyl-N-ethyl-2-methyl benzylamine], an irreversible inhibitor of catecholamine uptake, to striatal membrane peptides. Rat striatal synaptosomes (P_2) were incubated with ^{3}H-XYL (0.5μM, S.A. = 19 Ci/mmol) under various conditions. Following ^{3}H-XYL exposure the P_2 was lysed and synaptic plasma membranes (SPMs) were recovered by centrifugation at 45,000g. The SPMs were analyzed by SDS polyacrylamide gel electrophoresis followed by fluorographic detection of radioactivity.

Recently Jacobson and Wilkinson found that 1μM XYL displaced 50% of the ^{3}H-naloxone which was specifically bound to rat hypothalamic tissue [TIPS 6(1):17 (1985)]. We have, therefore looked at naloxone's ability to protect against XYL labeling of striatal synaptosome membrane peptides. With our protocol, no differences were seen in peptide labeling from striatal synaptosomes which had been incubated with ^{3}H-XYL in the absence or presence of 50μM naloxone.

In previous studies we showed that ^{3}H-XYL prominently labeled eleven intrinsic membrane peptides in striatal synaptosomes, and that the labeling of many of the peptides could be blocked by coincubating with various dopamine (DA) uptake inhibitors [Soc. Neurosci. Abstr. 10, part 1: 363 (1984)]. When striatal synaptosomes were exposed to ^{3}H-XYL in the absence of Na^+ or in the presence of gramacidin (a Na^+ ionophore) only two of the eleven peptides were labeled. These peptides correspond to molecular weights of 45K and 31K daltons. Also, ^{3}H-DA uptake was equally inhibited in striatal synaptosomes which were preincubated with 0.5μM XYL in the absence or presence of Na^+. These data imply that either the 45K or 31K peptide or both peptides are functionally involved in the inhibition of DA uptake.

We have recently exposed CHAPS solubilized SPMs to ^{3}H-XYL and found essentially the same labeling pattern as that found for intact synaptosomes. However, binding to the 45K peptide was increased relative to the other peptides. (Supported by USPHS grant MH23839).

179.10 SURFACE AND INTRACELLULAR ALTERATION OF ACETYLCHOLINESTERASE HISTOCHEMISTRY IN CULTURED MYOTUBES AFTER EXPOSURE TO CALCIUM AND IONOPHORE A23187. S. Bursztajn and L.W. Schneider*. Departments of Neurology and Cell Biology, Baylor College of Medicine, Houston, TX 77030.

The enzyme acetylcholinesterase (AChE) becomes localized at the neuromuscular junction during development and is present intracellularly and on the surface of cultured skeletal muscle. We have shown that the organization of the AChR clusters is calcium (Ca^{2+}) concentration dependent in cultured myotubes (Bursztajn et al., J. Cell Biol., 98:507-517, 1984). Since AChRs and AChE are present in high concentrations at the neuromuscular synapse, we have investigated the role of Ca^{2+} concentration on AChE secretion. Cultured chick myotubes were incubated with various concentrations of Ca^{2+} (10^{-2}-10^{-3}M) and the Ca^{2+} ionophore A23187 (10-200 nM). The intracellular AChE activity and the AChE activity secreted into the medium was assayed spectrophotometrically, and the distribution of AChE histochemistry was examined by electron microscopy. Nonspecific cholinesterase was assayed with butyrylthiocholine as a substrate and accounted for less than 5% of the intracellular AChE. Cells incubated with high Ca^{2+} containing medium showed a significant increase in AChE release; and this increase was not observed with equal concentrations of Mg^{2+}, Ba^{2+}, Mn^{2+}, or K^+ ions. Scanning electron microscopy of cells exposed to high Ca^{2+} concentration revealed large amounts of extracellular matrix surrounding each muscle fiber. This matrix was absent in control myotubes. To determine whether this extracellular matrix was associated with AChE histochemistry, cultures were processed for ultrastructural localization of AChE. For this purpose we used thiocyanate as a capturing agent and acetylthiocholine chloride as a substrate which reacts with the cupric ions to form insoluble mercaptides. This procedure produced a small uniform reaction product which was essential for the intracellular localization of AChE. The specificity of the AChE histochemical localization was tested by using inhibitors specific for AChE and others specific for pseudocholinesterase. The AChE histochemistry was found associated with the extracellular matrix in myotubes exposed to high Ca^{2+} concentration and ionophore A23187. In control cells only small amounts of scatter reaction product were observed. Intracellular AChE histochemistry was observed in the perinuclear space, the sarcoplasmic reticulum, the Golgi cisternae, and coated vesicles. Our results indicate that increasing Ca^{2+} concentration and ionophore A23187 induces the secretion of the extracellular matrix, and this extracellular matrix is associated with AChE histochemistry. (Supported by NIH grant NS17876 and a RCDA to S.B.).

179.11 INCREASE IN ACETYLCHOLINESTERASE SECRETION FROM CULTURED CHICK MYOTUBES IS CALCIUM CONCENTRATION DEPENDENT. L.W. Schneider* and S. Bursztajn. (SPON: S.A. Berman). Departments of Neurology and Cell Biology, Baylor College of Medicine, Houston, TX 77030.

Calcium (Ca^{++}) has been shown to have an effect on many important cellular processes. Previous work in this laboratory has shown that Ca^{++} and the Ca^{++} ionophore, A23187, regulates acetylcholine receptor (AChR) cluster formation and increases the number of AChR aggregates in cultured rat muscle cells. Since both the AChR and the enzyme acetylcholinesterase (AChE) are found in high concentration at the synapse we have examined in detail how Ca^{++} may exert its effect on AChE secretion. Chick myotubes were incubated with various Ca^{++} concentrations (5-15mM) and Ca^{++} ionophore A23187 (25-100nM) for periods of 3h - 72 h. The specificity of Ca^{++} concentration on AChE release was determined by substituting other monovalent and divalent ions for Ca^{++}. Intracellular and secreted AChE activities were measured spectrophotometrically using acetylthiocholine iodide as a substrate and radiometrically with ^{3}H-acetylcholine in order to quantitate AChE amounts in fractions obtained from sucrose gradients. To determine the amount of Ca^{++} influx, cells were incubated with ^{45}calcium and intracellular uptake measured by scintillation counting after washing and sonication of the cells. Incubation of cells with high Ca^{++} concentration did not increase AChE secretion during the first 24 h, however after 48 and 72 h a 40 - 50% increase in AChE activity over controls was observed. This 24 h lag time was not observed when cells were incubated with Ca^{++} ionophore A23187. In this case a 40% increase in secreted AChE activity was observed 24 h after addition of the ionophore, and a 70% increase after 48 h of incubation. Treatment of cells with high Ca^{++} concentration and ionophore simultaneously resulted in further increase in secreted AChE activity, but the amount of AChE secreted did not appear to be additive. The intracellular AChE activity did not change significantly under these incubation conditions. $^{45}Ca^{++}$ influx determinations showed that in the presence of high Ca^{++} concentration in the media, myotubes increased their intracellular Ca^{++} content 10 - 100 fold that found in control cells. Other divalent or monovalent ions had no effect on AChE secretion and only Sr^{++} was found to be capable of substituting for Ca^{++}. Sucrose density gradient profiles of secreted AChE forms after 24 hours of treatment with ionophore revealed a minor shift of AChE to a smaller molecular weight (6.5S) than that seen in control cultures. However in both cases AChE activity was distributed as broad peaks. Our results indicate that Ca^{++} and A23187 increase AChE but with different rates of response. (Supported by NIH Grant NS17876 and a RCDA to S.B.)

179.12 UPTAKE OF ASCORBIC ACID BY THE NEUROBLASTOMA X GLIOMA HYBRID CELL LINE NG108-15. E. Bachar* and Z. Vogel. Dept of Neurobiology, Weizmann Institute of Science, Rehovot 76100 Israel.

Ascorbic acid is present at high concentrations in the nervous system where it might play a role as a neuromodulator. For example, it serves as a cofactor for dopamine β hydroxylase (Kaufman, S. and Friedman, S., Pharmacol.Rev.,17:71,1965) and stimulates acetylcholine release from brain synaptic vesicles (Kuo, C.H. and Yoshida, H., Japn.J.Pharmacol. 30:481,1980). Moreover, we have shown that ascorbic acid stimulates collagen deposition and aggregation of acetylcholine receptors on the surface of cultured muscle cells (Kalcheim, C., et al PNAS, 79:3077,1982). In support of the suggestion that ascorbic acid is a neuromodulator we report here that ascorbic acid is actively accumulated by the neuroblastoma x glioma hybrid cell line NG108-15.

Cells were cultured in Dulbecco's modified Eagle's medium containing 10% fetal calf serum. Uptake of [^{14}C]ascorbate was assayed at 37°C in Ringer solution containing 2mM thiourea (to protect ascorbate from oxidation). The uptake exhibited Michaelis-Menten kinetics with K_m of 43μM and Vmax of approximately 100pmol ascorbate/min/mg protein. A similar K_m value (39μM) was obtained for NG108-15 cells that were differentiated by 5 day treatment with 1mM theophylline and 10μM prostaglandine E_1. The uptake of ascorbate was temperature dependent; the rate of uptake at 0°C was 2.5% of that obtained at 37°C. Similar to the observation made with adrenomedullary chromaffin cells (Diliberto, E.J. et al J.Biol.Chem. 258:12886,1983) the uptake into NG108-15 cells was dependent on external Na^+ ions. When Na^+ concentration was reduced to 10mM (Li^+ salts added instead) the rate of uptake was reduced by 8 fold. The uptake was not affected by glucose but was inhibited by several ascorbate related compounds. Dehydroascorbate reduced uptake by 16 and 75% at 1 and 10mM respectively. D-isoascorbate, a sterioisomer of L-ascorbate inhibited uptake by 59 and 92% at these concentrations. HPLC analysis showed that more than 90% of the labeled material which accumulated in the cells following 90 min of uptake coeluted with authentic ascorbate. Allmost all (>95%) of the accumulated ascorbate was found in the cytosolic soluble fraction. The [^{14}C]ascorbate taken up by the cells was spontaneously released with a half life of about 10h.

Supported by the muscular Dystrophy Association and by the US-Israel Binational Foundation.

179.13 **DIFFERENTIAL EFFECTS OF N-ETHYLMALEIMIDE ON NOREPINEPHRINE TRANSPORT, RESERPINE BINDING AND MG ATPASE ACTIVITY OF BOVINE CHROMAFFIN GRANULES** J. D. Deupree and J. J. Hitchcock* Dept. Pharmacology, University of Nebraska Medical Center, Omaha, NE, 68046

Catecholamines are translocated into storage granules by an active transport process requiring a transport molecule and the generation of an electrochemical gradient produced by a Mg ATPase. How this electrochemical gradient is used to drive catecholamines across the storage vesicular membrane is not well understood. We have examined the effects of N-ethylmaleimide (NEM) on the different steps in this transport process using chromaffin granule membranes isolated from bovine adrenal glands. The effects of NEM on the generation of the electrochemical gradient was examined by measuring the effects of NEM on the Mg ATPase activity. The effects of NEM on the transport molecule was studied by looking at the effects of NEM on both ^{3}H-norepinephrine transport into the granules and binding of ^{3}H-reserpine to the chromaffin granule membrane. The IC50 values for NEM inhibition of the Mg ATPase, norepinephrine transport and ^{3}H-reserpine binding was 39 mM, 0.6 μM and 2 μM, respectively. Since there is a 0.5 to 104 fold difference between the IC50 for inhibition of Mg ATPase, norepinephrine transport and reserpine binding, the data suggest that NEM is acting on different sulfhydryl groups when blocking each of these functions. Since norepinephrine and reserpine appear to bind to the same site on the chromaffin granule membranes (J.D. Deupree and J.A. Weaver, J. Biol. Chem. 259:10907-10912, 1984), these results would suggest that the thiol group with a IC50 of 2 μM may be associated with the binding site for reserpine and norepinephrine on the transporter. The thiol group having the highest affinity for NEM may be associated with the transporter but with a site which is more involved with the transport of norepinephrine than with the binding of norepinephrine. (This research was supported by a grant #NS 15187 awarded by NINCDS.)

179.14 STRIATAL DOPAMINE RELEASE: A METHODOLOGICAL STUDY. Jill B. Becker, Department of Psychology and Neuroscience Laboratory Building, The University of Michigan, Ann Arbor, MI 48104.

To study the release of dopamine (DA) from neural tissue, most experimenters have preloaded tissue with either radioactively labelled DA or its precursor tyrosine (TYR). The implicit assumption is made that the efflux of the endogenous neurotransmitter and the efflux of the labelled compound are proportional. Last year I reported that the release of preloaded [^{3}H]DA was not always proportional to the release of endogenous DA. The experiments reported here were conducted to examine whether the release of [^{3}H]DA synthesized from [^{3}H]TYR is proportional to the release of endogenous DA.

Striatal tissue slices were incubated with shaking for 15 min in 5 ml Krebs-Ringer-phosphate at 34° C. Slices were then transferred to beakers containing 3 ml medium with 80 μM [^{3}H]TYR (100 μCi) and the tissue was incubated with shaking for an additional 30 min. The tissue was then washed and transferred to superfusion chambers (Becker et al., J. Neurosci.Meth., 11: 19, 1984). Effluent samples were collected on ice over 5 min intervals. Dihydroxybenzylamine (20 ng in 25 μl 0.05 N $HClO_4$) was added to each tube as an internal standard. Catecholamines were extracted from the effluent by alumina extraction. The amount of [^{3}H]DA in each sample was determined by liquid scintillation counting. The total amount of DA in each sample was determined by high performance liquid chromatography with electrochemical detection. The efflux of [^{3}H]DA and endogenous DA were expressed as a percent of their respective total pools. The effects of various treatments on [^{3}H]DA vs. endogenous DA efflux were examined, including: 1.) temperature dependence; 2.) the role of DA synthesis on in vitro DA release was examined by infusing either [^{3}H]TYR or α-methyl-ρ-tyrosine (MPT) with the superfusion medium; 3.) the influence of MPT on amphetamine (AMPH)-stimulated DA release; and 4.) the influence of timing and duration of AMPH infusion on stimulated DA release.

The results of these experiments indicate that the use of [^{3}H]DA synthesized from [^{3}H]TYR is not always a valid index of endogenous DA release. Under some experimental conditions the release of endogenous and [^{3}H]DA are proportional. However, only minor changes in the experimental procedures can have differential effects on endogenous vs. [^{3}H]DA release. It is suggested that one cannot assume that the release of [^{3}H]DA synthesized from [^{3}H]TYR is proportional to endogenous DA release without first validating the assumption under the specific experimental conditions used.

179.15 METHYLXANTHINE-INDUCED CAUDATE DOPAMINE (DA) RELEASE AS MEASURED BY IN VIVO ELECTROCHEMISTRY IN THE FREELY MOVING RAT. M.E. Morgan and R.E. Vestal*. Clinical Pharmacology Unit, VA Medical Center, Boise, ID 83702 and Dept. of Med., Univ. of Washington, School of Medicine, Seattle, WA.

Methylxanthines (MX) are found in numerous foods and over-the-counter medications. Caffeine (C) is one of the most highly consumed psychoactive drugs. Theophylline (T) is extensively used in the treatment of asthma and chronic obstructive pulmonary disease. MX stimulates the central nervous system. However, the mechanism of stimulation by MX is unknown. Therefore, we now report the time dependent and drug dependent relationship between C, T and caudate DA release using in vivo electrochemistry in freely moving rats. Male Sprague-Dawley rats (250-350 gm) were anesthetized with chloral hydrate (150 mg/kg i.p.) and ketamine (50 mg/kg i.p.). Stearic acid carbon paste electrodes (250μ) were implanted stereotaxically into the left and right caudate. Ag/AgCl reference and auxiliary electrodes were implanted through separate bur holes. The entire apparatus was cemented into place with cranioplastic cement. The animals were allowed a 24 hr recovery period. Electrochemical oxidations were made with a Bioanalytical Systems DCV-5 voltammeter with the electrochemical output processed by semidifferentiation. After achieving a steady basal release, animals were injected with C or T (250 μ moles/kg i.p.). Caudate DA release was monitored for 150 min.

Per Cent Control of Average Baseline Peak Heights (Mean ± SEM)

Drug	0 min	30 min	75 min	150 min
Caffeine†	100±4	69±5*	84±8*	90±8
Theophylline†	100±3	115±5*	125±6*	109±9

† dose: 250 μmoles/kg; * $p < 0.05$ vs 0 min (paired comparison) n = 5-7 experiments per drug

C significantly decreased caudate DA release 30 min after administration with a gradual return to baseline release over 150 min. There was no signifcant difference in C-induced DA release from the left or right caudate. These studies confirm our previous findings in the urethane anesthetized rat (Soc. Neurosci. 9:482, 1983) and indicate that with this paradigm there is no significant anesthetic effect on C-induced DA release. T increased caudate DA release (peak at 75 min) with gradual return to baseline (150 min). At this dose, the data indicate a differential response of MX-induced caudate DA release. Since C is more lipid soluble than T such an effect may be one of MX caudate distribution.

179.16 CHRONIC HALOPERIDOL AND CLOZAPINE ALTER DOPAMINE AND ACETYLCHOLINE RELEASE FROM LIMBIC AND STRIATAL SLICES. David R. Compton and Kenneth M. Johnson. Dept.Pharm.,Univ.Tx.Med. Branch,Galv.,TX,77550.

Chronic treatment of rats with haloperidol (HAL) or clozapine (CZP) has been reported to:1) reduce the number of spontaneously active dopamine (DA) cells, via depolarization block, in the A9 and A10 regions (HAL), or in the A9 region only (CZP); and 2) reduce in vivo DA release in the respective terminal fields. The depolarization block of A9 cells, but not A10 cells, is reversed by transection of the nerve path between the cells and the terminal fields. This report shows that chronic drug treatment also alters some transmitter release mechanisms and/or local neuronal controls of release at the nerve terminal in vitro.

Tissue slices (300 microns) from the striatum (Stri) or nucleus accumbens (NA) were placed into slice superfusion chambers after loading with 3H-DA and C-14 choline. Standard dual label techniques for assessing each isotope were utilized to measure DA and ACh release, respectively. Release was induced by either amphetamine (Amph) or amfonelic acid (AFA) at 1μM (1min), or by electrical field stimulation (60 pulses; 1,5,10 Hz).

ACh release decreased with increasing Hz in both brain areas. DA release decreased slightly in the Stri, but release increased in the NA by 23% from 1Hz to 10Hz ($p<0.05$). The table shows the results from ex vivo experiments (as % of control) using rats injected (s.c.) with HAL on stimulated transmitter release. However, no effect was seen on electrically-stimulated release of DA or ACh in either region after acute or chronic CZP treatment. Also no changes occurred in the ability of Amph or AFA to stimulate DA release in NA after chronic treatment with HAL or CZP. However Amph (but not AFA)-induced DA release in Stri was enhanced to 144% by chronic CZP (but not HAL). CZP could also potentiate Amph-induced DA release in vitro (133% at 10μM, 222% at 30μM, $p<0.05$).

HAL dose x days		0.5mg/kg x 1			0.5mg/kg x 21		
		1Hz	5Hz	10Hz	1Hz	5Hz	10Hz
ACh	Stri	NS	NS	NS	219%	220%	224%
	NA	NS	NS	NS	135%	119%	132%
DA	Stri	NS	NS	NS	NS	NS	NS
	NA	146%	154%	142%	138%	134%	144%

NS=not significant vs control (100%); $p<0.05$ for all values.

These results indicate: 1) basic differences exist in electrically-stimulated DA release between Stri and NA, and the effects of HAL on these regions; 2) chronic HAL enhances ACh release, which may be related to the development of extrapyramidal symptoms; 3) CZP affects the mechanisms of Amph (but not electrically or AFA)-induced DA release in the Stri; and 4) HAL and CZP induced decreases in DA release in vivo are not due to changes in release mechanisms at the nerve terminal. Supported by the Scottish Rite Schizophrenia Research Program, NMJ, USA.

180.1 ANATOMICAL CORRELATES OF LATERALITY AND ENDOCRINE STATE IN A CANARY SONG CONTROL NUCLEUS. R. P. Clower and T. J. DeVoogd, Psychology Department, Cornell University, Ithaca, NY 14853

The hypoglossal nucleus (nXII) is a relay center which is essential for the production of avian song (Nottebohm, et al., 1976). Motoneurons project from it to the tongue and syrinx, the avian vocal organ. All of the syringeal motoneurons appear to accumulate testosterone (Arnold, 1980). The canary nXII is larger on the left than the right (Nottebohm and Arnold, 1976), an anatomical asymmetry associated with the dominance of the left hypoglossal nerve and syrinx in song production. We now report cellular and ultrastructural correlates of lateral asymmetry and hormone induced plasticity.

The brainstems of normal female canaries and female canaries which had received testosterone as adults were sectioned at 100μ, lightly Nissl stained, and photographed. nXII was dissected from the slices and processed for electron microscopy. Cell sizes and distributions were measured on the photographs of the Nissl stained slices. nXII was 8-10% larger on the left than on the right in both T-treated and control females. T-treatment resulted in a 16% increase in the size of the nucleus and a 12% increase in cell size. There was no lateral difference in cell size.

Electron microscopy reveals that more than 90% of nXII synapses occur directly on dendritic shafts, occasionally even wrapping about the shaft. Preliminary results indicate that there are about 15% more synapses per unit area on the left than on the right in both groups of animals. Both Gray type I and II synapses occur in nXII. A striking consequence of T-treatment was seen in the Gray type I: Testosterone results in a sixfold increase in the incidence of axonal processes with very large numbers of round vesicles (200-1000+). In T-treated tissue, vesicles in such synapses sometimes occur in tightly packed paracrystalline arrays.

Thus, these anatomical correlates of functional laterality are not dependent on either androgens or experience with song. In this nucleus as in other song control nuclei, testosterone results in major structural changes. The very high numbers of vesicles seen in nXII synapses after testosterone may give the capacity for the sustained firing needed in producing prolonged bouts of song.

180.2 INDUCED MATERNAL BEHAVIOR AND CONCOMITANT ULTRASTRUCTURAL CHANGES IN THE RAT NEUROHYPOPHYSIS. B.K. Kohn*, A.K. Salm, and G.I. Hatton (SPON: Q. Z. Yang). Neuroscience Prog. and Dept. of Psychology, Michigan State Univ., E. Lansing, MI 48824-1117.

Previous work has shown that the peptide oxytocin promotes the rapid onset of maternal behavior in virgin female rats (Science 216:648, 1982). Oxytocin is produced by some of the magnocellular neurosecretory cells (MNCs) of the paraventricular nucleus and supraoptic nucleus (SON) of the hypothalamus. Many of the axons of these MNCs terminate in the neurohypophysis where under conditions not requiring enhanced hormone release, some are completely surrounded by the cytoplasm of astrocytic glial cells, i.e. pituicytes. Under conditions such as parturition and lactation which involve increased hormone release the number of enclosed axons decreases significantly (Brain Res. Bull. 8:205, 1982). The present study was prompted by recent evidence from our laboratory that ultrastructural changes occurred in SON neurons concomitant with pup-induced maternal behavior in virgin female rats (Salm et. al., this meeting), suggesting that their neurohypophyses might undergo changes also.

Briefly, virgin female rats were exposed to rat pups until exhibiting the behaviors of pup retrieval, anogenital pup licking, crouching in a nursing posture and nesting. On the 3rd day of exhibiting maternal behavior the "maternal behavers" (MBs) were sacrificed by ether anesthesia and prepared for electron microscopy. Controls were similarly housed virgin females, but without direct physical contact with pups. Fourteen neurohypophyses from the rats used in the SON study (7 from the MB group and 7 controls) were sampled.

Without the investigator being aware of treatment group membership, fifteen pituicytes from each neurohypophysis were randomly sampled with an electron microscope (4500X). The total number of axonal processes completely enclosed by the fifteen pituicytes per animal was obtained. The mean number of enclosed axons per animal decreased 43% for the MBs when compared to controls. A t-test showed this difference to be statistically significant ($p<.035$, t-test; 3.2+.56 vs. 5.8+.82 respectively). The group means for number of axons enclosed per pituicyte were .22+.04 for MBs vs .39+.05 for controls, a significant ($p<.035$, t-test) decrease of 43% for the MBs.

These results corroborate the evidence for ultrastructural changes in the SON coincident with induced maternal behavior. Both studies suggest that the hypothalamo-neurohypophysial system may play a role in the induction of maternal behavior in the rat.

180.3 PUP-INDUCED MATERNAL BEHAVIOR IS ACCOMPANIED BY ULTRASTRUCTURAL CHANGES IN THE SUPRAOPTIC NUCLEUS OF RATS. A.K. Salm, B.K. Kohn*and G.I. Hatton. Neuroscience Prog. and Dept. of Psychology, Michigan State Univ., E. Lansing, MI 48824-1117

Evidence exists that the peptide oxytocin is a potent elicitor of maternal behavior (Science 216:648, 1982). The supraoptic nucleus (SON), which contains magnocellular neuroendocrine cells (MNCs) that produce oxytocin, has been shown to exhibit ultrastructural plasticity during conditions which stimulate the release of this peptide (Peptides 5 (Suppl 1):121, 1984). In particular, directly apposed MNC somata (without an intervening glial process), and the occurrence of dendritic bundles (2 or more dendrites in direct membrane apposition) have been reported to increase. In this study, the SON ultrastructure of virgin female rats in which maternal behavior had been induced by exposure to rat pups was examined to determine if like changes occurred.

14 virgin female rats, ages 102-138 days, were divided equally into control and "maternal behaver" (MB) groups. MBs were each exposed to 2 different rat pups each day for 5-16 days prior to exhibiting the 4 behaviors of pup retrieval, anogenital pup licking, crouching in a nursing posture and nesting behavior. On the 3rd day of exhibiting maternal behavior MBs were sacrificed by ether anesthesia and prepared for electron microscopy. The somatic region (6-19 micrographs, $\bar{X}$=13) and the ventral dendritic zone of the bilateral SON in its entirety were sampled from each rat. Electron micrographs (7590X) were then scored for the incidence of somatic apposition and extent of dendritic bundling. Since bundles of 1-4 dendrites had been previously reported to occur in normal rats (Neuroscience 13:769, 1984) bundles were categorized into groups of 1-4, 5-8, or 9-12 dendrites. Differences in the mean number of dendrites per bundle in each category were assessed with a 2-way ANOVA followed by post-hoc comparisons. An overall difference ($p<.025$) between MBs and controls was found for the mean number of dendrites per bundle. Whereas no differences were detected between groups for bundles of 1-4 or 5-8 dendrites, the MBs had more dendrites in bundles of 9-12 (Tukey's, $p<.010$). No differences were found in the total number of dendrites observed in each group. However significantly more micrographs (median test, $p<.0005$) were obtained from the dendritic field of the MB group, suggesting that this area was greater in these rats. At the level of the somata the situation was found to be the reverse, i.e., MNCs of MBs were seen to exhibit fewer (Mann-Whitney U, $p<.04$) direct appositions with other MNCs (19.45% vs 28.88% respectively) relative to controls.

These data point to a differential activation of SON MNC somata and dendrites during maternal behavior and a rapidly emerging picture of a labile SON which may be enlarged to include responses to environmental stimuli as well as possible mediation of a reproductive behavior. The technical assistance of Inge Taubitz is gratefully acknowledged. This work supported by NIH NS09140.

180.4 ADRENAL SEX STEROIDS SPARE MALE SPROUTING RESPONSE FOLLOWING CASTRATION. J.K. Morse, S.T. DeKosky and S.W. Scheff. Depts. of Anatomy and Neurology, Univ. of Kentucky and V.A. Medical Center, Lexington, KY 40536

We have previously reported that sex steroids play a role in a sexually dimorphic sprouting response observed in the hippocampal dentate gyrus. Untreated male and female rats demonstrate equivalent amounts of axon sprouting. Ovarectomized females display significantly decreased sprouting, while castrated males are equivalent to controls. Ovarectomized females with either estrogen (E) or testosterone (T) replacement are found to be equal to female and male controls while castrated males with E or T showed no change in axon sprouting. In the female, gonadal steroids appear to play an important role in CNS reactive outgrowth, while the role of these steroids in males is unclear. Since the adrenal glands also produce testosterone and other androgens, it may be that these adrenal androgens are sufficient to protect the male sprouting response. The present study tested the hypothesis that the adrenal gland sex steroids may be involved in the male sprouting response.

Sprague-Dawley rats 90 days of age of both sexes were randomly assigned to one of two groups: 1) gonadectomy only; and 2) gonadectomy plus adrenalectomy. One week after initial surgery (gonadectomy or gonadectomy + adrenalectomy) the rats were subjected to a unilateral ablation of the entorhinal cortex. Fifteen days after the entorhinal ablation all animals were killed. Changes in axon sprouting were determined by assessing the reactive outgrowth of the hippocampal commissural-associational fiber plexus.

Preliminary results show: a) males in group 2 (N=5) significantly decrease their sprouting response from control levels and in fact match that of ovarectomized females; b) females of group 2 (N=4) show outgrowth equivalent to that of controls. These results indicate a possible role for adrenal sex steroids in the male sprouting mechanism. It appears that estrogen may be sufficent but not essential to the female sprouting response, however, testosterone would seem to be essential for the male response. Adrenal sex steroids may play a role in the sexually dimorphic sprouting response seen in the rat hippocampus following an entorhinal cortex lesion.

180.5 REGENERATION AND RECOVERY OF FUNCTION IN THE LESIONED HYPOTHALAMIC NEUROSECRETORY SYSTEM IS BLOCKED BY ADMINISTRATION OF VASOPRESSIN. J.P. Herman, F.F. Marciano, S.J. Wiegand, M. Matise and D.M. Gash. Department of Anatomy, University of Rochester, Rochester, NY 14642

Rats show considerable capacity for regeneration of the hypothalamic neurosecretory system (HNS) following neurohypophysectomy (NPOX), as evidenced by marked post-surgical recovery of antidiuretic function. Following NPOX, rats exhibit plasma volume depletion and hyperosmolarity and deficiencies in ion regulation, condition believed to signal vasopressin (VP) release and stimulate VP neurons. These physiological stimuli may provide information important for regeneration of the HNS. In this experiment we sought to determine whether elimination of stimulatory physiological information could have deleterious effects on recovery and regeneration of the HNS following NPOX. Fisher 344 rats received NPOX and immediately after surgery were implanted subcutaneously with Alzet miniosmopumps containing 0.9% saline (NPOX-SAL) or 1ug/ul arginine VP (NPOX-VP). The pumps delivered contents at a rate of 0.48ul/h continuously for 2 weeks. The pharmacological dosage of VP insured that plasma entering the renal circulation possessed maximal antidiuretic activity, promoting water retention and therefore putatively eliminating physiological stimulation of VP release. Water consumption and urine osmolality were monitored throughout the experiment. Six weeks following NPOX, rats were perfused with Zamboni's fixative, brains sections at 50um and stained for Nissl substance or VP-specific neurophysin.

Following surgery NPOX-SAL rats showed high normal levels of water consumption and excreted dilute urine. Over the post-operative period water intake remained stable while urine osmolality gradually increased to approximately half of normal levels (1160 mOsm/kg). NPOX-VP rats curtailed water intake and excreted concentrated urine during the period of VP administration. Following cessation of VP delivery NPOX-VP rats were afflicted with a profound diabetes insipidus which lasted for the remainder of the experiment, drinking 133% of their body weight daily and excreting urine with an osmolality of only 170 mOsm/kg. Histological analysis revealed a marked paucity of magnocellular VP-immunoreactive cells in the supraoptic and paraventricular nuclei of NPOX-VP rats relative to NPOX-SAL rats. Marked hypertrophy and increased density of VP staining was evident in the median eminence of NPOX-SAL rats relative to NPOX-VP animals.

The data suggests that administration of VP during the two week period following NPOX blocks the normal regeneration of the neurosecretory system. It is apparent that peripheral stimuli for VP release are necessary for magnocellular VP neurons to survive and sprout following extirpation of the normal target region.

180.6 MORPHOLOGICAL ADAPTABILITY OF HYPOTHALAMIC NEUROSECRETORY ENDINGS AT THE PERIVASCULAR CONTACT ZONE OF THE RAT NEUROHYPOPHYSIS. Charles D. Tweedle and Glenn I. Hatton, Anatomy Dept. and Neuroscience Program, Michigan State Univ., East Lansing, MI 48824.

It was previously reported [Anat. Embryol. (1974) 146:157] that 3 days of water-deprivation increased the size of hypothalamic neurosecretory endings in the rat neurohypophysis and thus led to their greater coverage of the basement membrane of the perivascular contact zone (PCZ) where the hormones oxytocin (OX) and vasopressin (VP) are thought to be released. Would other acute and chronic stimuli leading to OX and/or VP release have a similar effect? Neurohypophyses were prepared for electron microscopy from rats in the following treatment groups (all rats 100-120 days old): untreated female controls [4]; pre-partum (day 21 gestation) [4]; post-partum (2-24 hr after birth) [4]; female rats dehydrated by being given 2% saline for 10 days [4]; female rats similarly dehydrated, then rehydrated by being given tap water again for 14 days [4]. Twelve-fourteen electron micrographs (12,000X) per animal were analyzed for percentage of neuronal (vs. glial) coverage of the PCZ and the average length of individual axonal contacts with the PCZ. Coverage of the PCZ by neurosecretory axons was statistically determined to increase following both birth (vs. pre-partum) and saline treatment (vs. control) ($P < .02$). length of individual neurosecretory axon contacts also was increased by both stimuli ($P < .02$). This measure, but not the total percentage of neuronal coverage of the PCZ went back to normal following rehydration. These data suggest that changes in neuronal coverage at the PCZ of the neurohypophysis can occur rapidly (e.g., at parturition) and may persist for some time following chronic stimuli. One interpretation of the data is also that the number of neurosecretory terminals at the PCZ increases with chronic dehydration. Supported by N.I.H. Grant NS 09140.

180.7 POSSIBLE MECHANISM OF SYNCHRONY AMONG SUPRAOPTIC (SON) NEURONS IN HYPOTHALAMUS OF LACTATING RAT: EVIDENCE FOR ENHANCED DYE COUPLING. Q.Z. Yang, P. Cobbett and G.I. Hatton. Neuroscience Program, Michigan State Univ., E.Lansing MI 48824-1117.

During suckling, the oxytocinergic magnocellular neurons of rat hypothalamus probably fire in relative synchrony to produce the rise in blood oxytocin required for the milk ejection reflex. The mechanism(s) producing this synchrony are not known, but we have hypothesized that electrotonic coupling among these cells may be one of the factors involved. According to this hypothesis, coupling among neurons is labile and for oxytocin-producing cells in particular, would be expected to be more extensive in lactating than in non-lactating rats. As an initial test of this hypothesis we have compared the incidence of dye coupling (as an indicator of at least strong electrotonic coupling) in the SON of virgin female and 8-12 day lactating, actively suckling animals. Slices of hypothalamus were prepared and maintained as in our previously published studies. Magnocellular neurons in the anterior and dorsal (predominantly oxytocinergic) parts of the SON were injected with Lucifer Yellow CH using appropriate precautions to prevent artefactual dye filling and incorrect counts of dye coupling. Fixed, cleared slices were examined microscopically using epifluorescence to determine the number of filled neurons. In each group the Dye Coupling Index (DCI) was calculated as the ratio of the number of dye filled coupled neurons to the total number of dye filled neurons. Tissue containing dye filled neurons is being analyzed immunocytochemically to determine the hormone contents of the coupled neurons, in particular. Results to date are as follows. The DCI for virgin females = 0.231 based upon 45 injections yielding 40 single and 12 coupled neurons. In lactating rats, the DCI = 0.453 based upon 48 injections yielding 35 single and 29 coupled neurons. Comparison of these two groups gave a $\chi^2 = 6.21$, $p < 0.02$. These data indicate that the incidence of dye coupling in the SON is different under the two physiological conditions which immediately preceded the in vitro preparation of the tissue and that this difference persisted. The latter indicates that the enhanced incidence of dye coupling outlasts the suckling stimulus conditions for at least several hours after removal of the suckling stimuli while the brains are maintained in vitro. The physiological importance of these results should become clearer if the immunocytochemical analyses reveal that the majority of coupled neurons are oxytocinergic.

180.8 DYE COUPLING AMONG MAGNOCELLULAR PARAVENTRICULAR (PVN) NEURONS IN SLICES OF RAT HYPOTHALAMUS: EFFECT OF CASTRATION P. Cobbett, Q.Z. Yang and G.I. Hatton. Neuroscience Program, Michigan State Univ., E. Lansing, MI 48824-1117.

Previous in vitro work has shown that some magnocellular PVN neurons are dye coupled and that changes in physiological state induced in vivo may alter the number of dye coupled cells. In males, 2% saline drinking for 8 days has been shown to affect the incidence of dye coupling in PVN and to reduce seminal vesicle weights. These data suggested that testicular hormones influence coupling of magnocellular neurons. To assess such a possibility, we have now determined the incidence of dye coupling among PVN neurons in castrated and sham castrated control rats. Adult male rats were either castrated or sham castrated under methoxyfluorane anesthesia 8 days prior to being used in recording experiments. Slices were prepared and maintained as in our previously published studies. Neurons in the magnocellular region of the PVN were injected with Lucifer Yellow CH using appropriate precautions to prevent artefactual dye filling of neurons and incorrect counts of dye coupling. Fixed, cleared slices were examined microscopically using epifluorescence to determine the number of dye filled neurons. In each group the Dye Coupling Index (DCI) was calculated as the ratio of the number of dye filled coupled neurons to the total number of dye filled neurons.

The DCI for sham castrated rat was 0.327 and was based upon a total of 48 injections producing 39 single and 19 coupled neurons. Since untreated male controls in our previous studies (J. Neurosci. 1984, 4, 3034) yielded a DCI of 0.333, it appears that the sham castration had no detectable effect upon dye coupling. Castration produced a decrease in this index. Based upon 51 injections, 48 single and 6 coupled neurons were found for a DCI of 0.111. Comparison of the sham and castrate groups gave a $\chi^2=7.56$, $p < 0.01$. Interestingly, roughly one half of these data were collected independently by each of two experimenters and each data subset yielded nearly identical DCIs (0.313 vs 0.346 and 0.148 vs 0.074).

We conclude that in the absence of testicular hormones (e.g. testosterone) there is a reduced incidence of dye coupling among magnocellular PVN neurons. This may be a direct effect of reduced testicular hormones which normally support a higher incidence of coupling. Conversely, a suppression of coupling may be caused by other factors (other hormones or transmitters) whose effects become manifest in the absence of testicular hormones.

180.9 BRAIN GRAFTS REDUCE THE OBESITY PRODUCED BY VENTROMEDIAL HYPOTHALAMIC LESIONS. G.A. Mickley, H. Teitelbaum and P.J. Reier. Behavioral Sciences Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145; NIH, Bethesda, MD 20205; Departments of Neurological Surgery and Neuroscience, University of Florida, College of Medicine, Gainesville, FL 32610.

Bilateral lesions of the rat ventromedial hypothalamus (VMH) produce a syndrome which includes hyperphagia and obesity. (Brobeck, J.R. et al., Yale J. of Biol. Med. 15:831, 1943). We attempted to alter these reactions by transplanting embryonic hypothalamic tissue into VMH lesion sites of adult rats.

Bilateral electrolytic lesions completely destroyed the VMH of female Sprague-Dawley rats (200-250g). Immediately following the lesions, some rats were stereotaxically implanted with pieces of hypothalamic tissue dissected from E14-E16 day fetuses. Other similarly-lesioned subjects were implanted with brain tissue from one of a variety of non-hypothalamic regions of the embryonic CNS (including cerebral cortex, spinal cord and hippocampus). Still other VMH-lesioned rats received no brain grafts. In some cases, neurons within donor tissue were labeled with 3H-Thymidine in order to radiographically differentiate graft and host. We recorded both body weight and food consumption for at least 50 days after surgery. Animals were included or excluded from the data analysis after "blind" histological determination of graft viability and lesion locus.

Total VMH destruction produced a reliable hyperphagia and obesity. Over time, surviving hypothalamic brain grafts shortened slightly the duration of the "dynamic phase" of this syndrome and resulted in significantly less total weight gained. Several of these rats lost weight following an initial dramatic gain and plateau. None of the brain grafts produced an immediate reduction of the lesion-induced weight gain. Transplantation of non-hypothalamic brain tissue caused a modest attenuation of the VMH lesion effect.

This experiment suggests that brain grafts can alter the dynamics of weight gain following VMH lesions. The precise neuroanatomical and neurochemical substrates of these findings have not been investigated.

180.10 **A ROLE FOR SEROTONERGIC NEURONS IN THE REGULATION OF SPECIFIC ELECTRICAL SYNAPSES IN HELISOMA.** **A.I. Mercier, P.G. Haydon, and S.B. Kater. Department of Biology, University of Iowa, Iowa City, IA 52242.**

Neurotransmitters have been implicated in playing various roles, ranging from chemical signalling during synaptic transmission to the regulation of neurogenesis. Recently, it has been demonstrated that serotonin can regulate the process of neurite outgrowth and, thereby, determine whether specific neurons will form electrotonic synapses (Haydon et al, Science 226: 561, 1984). Furthermore, experimental manipulation of the serotonin content of Helisoma embryos significantly affects the strength of electrotonic coupling between specific neurons when measured in the adult (Goldberg et al, Soc. Neurosci. Abstr. 1985).

The buccal ganglia of Helisoma receive defined serotonergic inputs from a single pair of neurons whose cell bodies lie in the cerebral ganglia. The present study tests the hypothesis that the presence of such serotonergic inputs can regulate the degree of intercellular communication through mature electrotonic synapses. We injected the serotonin-analogue, 5,7 dihydroxytryptamine, into adult snails at dosages shown previously to functionally remove these serotonergic inputs for up to 30 days (Gadotti et al, Soc. Neurosci. Abstr. 10: 689, 1984). Subsequently, the strength of electrical coupling between selected pairs of neurons was determined from measurements of the electrotonic coupling coefficient. Within the first week following injection, there was no change in the strength of coupling between the left and right buccal neurons 19. By three weeks post-treatment, however, the 19-19 coupling coefficient was 46% higher in serotonin-depleted snails compared to control animals. By contrast, coupling strength between a separate pair of neurons, buccal neurons 4, was unaffected. This indicates that the presence of endogenous serotonin in normal ganglia maintains the strength of a specific electrical synapse (19-19) at a reduced level. As a complement to the serotonin-removal experiments, we determined whether the addition of exogenous serotonin could reduce the strength of the 19-19 synapse. Acutely solated buccal ganglia which were exposed to 5×10^{-5} M serotonin for four hours showed a 53% decrease in 19-19 coupling strength, while the 4-4 electrical synapse was unaffected. Thus, the amount of information flow through a specific electrotonic synapse can be selectively set by the presence of serotonin within the buccal ganglia. In view of our ongoing studies with Helisoma embryos, these results lend support to a general principle that neurotransmitters play a role in determining the degree of intercellular communication among neurons throughout the life of an organism.

180.11 INTRACEREBRAL AUTOGRAFTS OF ADRENAL MEDULLA CHROMAFFIN CELLS IN ADULT CATS WITH UNILATERAL FRONTAL CORTEX ABLATIONS (UFCA): BENEFICIAL EFFECTS ON RECOVERY OF LOCOMOTOR AND TACTILE PLACING (TP) ABILITIES. R.L.Sutton, D.A.Hovda, D.M.Feeney and W.G.Dail. Departments of Psychology, Physiology and Anatomy, University of New Mexico, Albuquerque, NM 87131.

Amphetamine (AMP) treatment produces an enduring acceleration of recovery of beam-walking ability (1) and temporarily (12hr) restores contralateral forelimb TP ability (2) in cats with UFCA. In this study, after 1 week of baseline assessment on beam-walking and TP responses, the right frontal cortex was removed by suction ablation in 6, male or female, adult cats (see 1 and 2 for methodological details). For 3 cats, testing resumed on days 4,8 & 12 postinjury. On day 12 these animals (Group 1) were reanesthetized, a right adrenalectomy (AX) was performed, and chromaffin cell "pellets" were placed adjacent to the striatum and lateral ventricle in the re-exposed cortical wound. In the other 3 cats, testing was conducted on days 4, 8,12,16 & 20 postinjury, with AX and chromaffin cell autografts performed on day 21 postablation in 2 cats (Group 2) while the last cat served as an AX control. Testing (once every 4th day) was resumed on day 33 postablation for all animals.

Behavioral testing is still being conducted, with cats currently 2 1/2 - 4 1/2 months postgrafting or postAX. The Group 1 cats and the AX control animal show slower recovery of beam-walking ability as compared to Group 2 cats who show a postgraft recovery similar to that obtained in UFCA cats given multiple treatments of AMP (1). The Group 1 and AX control cats have shown a complete absence of TP responses since UFCA, while the 2 cats in Group 2 have shown a partial (35-70%), yet "permanent" (now at 128 days postgrafting), restoration of TP responses. These data suggest the later grafts are surviving and acting as "endogenous catecholamine mini-pumps", alleviating a catecholamine depression which occurs after cortical injury and allowing intact neural systems to function such that behavioral recovery occurs. Cats will be sacrificed at 5-6 months posttransplant and brains examined for surviving graft tissue by catecholamine histofluoresence. Supported by a grant from the UNM Research Allocation Committee.

180.12 FINE STRUCTURE AND COMPOSITION OF ADRENAL MEDULLARY GRAFTS IN BRAIN STEM REGIONS INVOLVED IN PAIN MODULATION G.D. Pappas[1], J. Sagen[1], and M.J. Perlow[2] [1]Department of Anatomy and [2]Neurology, University of Illinois College of Medicine, the West Side V.A. Hospital and Augustana Hospital, Chicago, IL 60612.

We are presently studying changes in pain perception in the rat following the transplantion of adult rat adrenal medullary tissue into the periaqueductal gray, nucleus raphe magnus, and the dorsal spinal cord - regions known to be involved in pain modulation. Preliminary findings indicate that these transplants produce significant alterations in pain sensitivity. Electron microscopic studies were undertaken to correlate these behavioral changes with the neural interactions of the host and graft tissues. The transplanted tissue consists of small pieces of adult rat adrenal medulla dissected free from cortical tissue and placed stereotaxically into the parenchyma or adjacent ventricular spaces.

Eight weeks following transplantation, catecholamine-containing chromaffin cells can be identified by fluorescence microscopy. We have also analyzed the catecholamine contents of the grafts using HPLC and found more norepinephrine (NE) than epinephrine (E) as well as low amounts of dopamine. In contrast, the normal, in situ values show much greater E compared to NE and less dopamine. The changes in the concentration ratios of E and NE suggest that the removal of the medullary tissue from the steroid secreting adrenal cortex and placing it into a new intracranial environment alters the relative concentrations of amines. Support for this hypothesis comes from fine structural studies of the chromaffin cells in the grafts which are characterized by granular inclusions morphologically typical to the norepinephrine type (i.e. dense core, often elongate) in contrast to the larger evenly dense appearing epinephrine granules commonly found in the in situ chromaffin cells.

Another striking change found 8 weeks after transplantation is that pronounced myelination has taken place both in the graft and in the host tissue. The new myelin formation in the graft has the typical appearance of PNS myelination and, in the host the appearance of CNS myelination.

By 8 weeks, the graft becomes heavily encapsulated with collagen, while the host CNS tissue shows pronounced gliosis. Chromaffin cells can be found protruding into the host CNS tissue and forming synapses with presumably the host neuronal processes. Occasionally neuronal processes, abutting onto chromaffin cells and containing clusters of clear vesicles suggest presynaptic endings. Other processes have post-synaptic specializations, such as a distinct cytoplasmic density next to the junctional membrane. Thus, chromaffin cells appear to participate as both postsynaptic and presynaptic components of synaptic junctions.

180.13 ALTERATIONS IN PAIN SENSITIVITY FOLLOWING THE TRANSPLANTATION OF ADRENAL MEDULLARY TISSUE INTO THE SPINAL CORD J. Sagen[1], G.D. Pappas[1], and M.J. Perlow[2] [1]Department of Anatomy and [2]Neurology, University of Illinois College of Medicine, West Side V.A. Hospital and Augustana Hospital, Chicago, IL 60612.

Recent studies have demonstrated that adrenal medullary tissue transplanted into the CNS survives and produces alterations in behavior. Adrenal chromaffin cells contain and release pharmacological agents known to alter pain sensitivity in the spinal cord (e.g. met- and leu-enkephalin, norepinephrine, and epinephrine). Furthermore, the release of these substances from chromaffin cells can be induced by nicotine. The purpose of the present study was to determine whether adrenal medullary tissue transplanted to the spinal cord can produce alterations in pain sensitivity when stimulated in vivo by nicotine.

Baseline pain sensitivity and pain sensitivity following nicotine administration was assessed in female rats using the tail flick, hot plate and paw pinch tests. Following laminectomy, 6-8 pieces of dissected adult adrenal medulla were inserted into the subarachnoid space through a slit in the dura. Control animals received an equal amount of either heated killed adrenal medullary tissue or sciatic nerve tissue.

Pain sensitivity was again assessed following an 8 week recovery period. Pain sensitivity was determined at 2, 10, 20, and 30 minutes following a subcutaneous injection of nicotine (0.1 mg/kg).

Without nicotine, the animals with grafts did not exhibit any alteration in pain sensitivity. However, the injection of nicotine induced potent analgesia in animals with adrenal medullary transplants as assessed by all three analgesiometric tests. Tail flick latency was elevated from 4.0 $\pm$ 0.3 sec to 9.2 $\pm$ 0.6 sec, hot plate latency was elevated from 7.9 $\pm$ 0.2 sec to 24.5 $\pm$ 3.3 sec, and paw pinch threshold was elevated from 9.6 $\pm$ 2.0 to 15.4 $\pm$ 1.1. This analgesic response was apparent 2 minutes following the nicotine injection and remained elevated at 10 and 20 minutes, tending toward baseline by 30 minutes. This dose of nicotine had no affect on pain sensitivity in animals with control transplants. Preliminary studies indicate that the observed analgesia induced by nicotine in transplanted animals is reversed by the opiate antagonist naloxone.

Both light and electron microscope studies show that the transplants were attached to the dorsal spinal cord within the subarachnoid space and contained typical chromaffin cells.

Results of this study indicate that it is possible to reduce pain responsiveness in experimental animals following the transplantation of adrenal medullary tissue into the spinal cord.

180.14 PLASTICITY IN CROSSED NIGRO-STRIATAL PROJECTIONS TEN DAYS AFTER HEMI-VIBRISSECTOMY IN THE RAT. J.P. Huston, K. Lange *, S. Morgan *, H. Steiner *. Institute of Psychologie III, University of Düsseldorf, D-4000 Düsseldorf, Fed. Rep. Germany.

There is evidence for plastic changes in the crossed efferents of the substantia nigra (SN) about one week after a unilateral peripheral or central lesion in the CNS. This is manifested by an increase in the number of cells in the SN, labeled by horseradish peroxidase (HRP) injected into the contralateral thalamus or caudate nucleus (CN). These alterations temporally coincided with a decrease in behavioral asymmetries (turning) induced by the lesion. Preventing the animals from turning after a unilateral SN lesion suppressed both the behavioral recovery and the change in the interhemispheric nigro-thalamic projection. These results led to the hypothesis that such apparent changes in crossed efferents from the SN could be part of a morphological correlate of learning to compensate for lesion-induced asymmetries. However, in these previous experiments the possibility that the changes occured in response to large scale central denervation could not be ruled out. Thus, we decided to perform a unilateral intervention with minimal damage to the nervous system. Hence, we examined the effect of unilateral vibrissectomy on the crossed nigro-caudate projection.

Normal male rats had their vibrissae cut unilaterally, and recut on every second day to eliminate regrowth. Ten days after the initial removal, HRP was applied iontophoretically to the CN either ipsilateral or contralateral to the side of vibrissa removal. The SN on both sides of the brain was examined for labeled cells. When the HRP was applied contralateral to the vibrissectomy there were more labeled cells in the SN of the opposite hemisphere than when it was applied ipsilaterally. (Supported by Grant Hu 306/3-2 from the Deutsche Forschungsgemeinschaft).

180.15 INCREASED HOST FIBER PLASTICITY AFTER CORTICAL TRANSPLANTATION IN MICE WHICH RECEIVED BASAL FOREBRAIN LESIONS. C.F. Hohmann, F.F. Ebner and J.T. Coyle. Dept. of Neuroscience, Johns Hopkins Univ. School of Med., Balto., MD. 21205 and Center for Neuroscience, Brown University, Providence, R.I. 02912.

Cerebral cortical plasticity in mammals, the ability of connections to rearrange in response to a modified environment, has been proposed to be regulated by systems diffusely projecting from brainstem and basal forebrain to cortex. Norepinephrine (NE) and Acetylcholine (ACh) have been suggested as possible regulators of plasticity. Studies of the influence of NE on cortical plasticity have yielded contradictory results. The potential role of ACh has not been explored thoroughly. The present experiments investigated the effect of a lesion of basal forebrain cholinergic nuclei on the morphological rearrangement of cortical connections in a transplantation paradigm.

Embryonic neocortex was transplanted into the neocortex of either normal adult mice or mice that had received electrolytic lesions in the ventromedial globus pallidus area prior to transplantation. The lesions decreased cortical ChAT activity by 50-70% and nearly abolished AChE staining. The ability of thalamocortical afferents to invade the transplant tissue was assessed by anterograde tracing methods. Injections (3mm below 0, 1.5mm right of midline, 2.4mm posterior to 0) of 0.25ul (5%) WGA-HRP were made with stereotaxic guidance into the ventrobasal complex of the thalamus. Thalamocortical fibers in host and transplanted cortex were visualized with the TMB enzyme reaction product for HRP. Thalamocortical fiber ingrowth, although variable, could be detected in transplants of all mice with basal forebrain lesions but not the unlesioned mice (N=15). Basal forebrain lesions thus affect the plastic response of adult host thalamocortical fibers to a transplant.

To assess the specificity of the response to cholinergic deficits, the effects of similar electrolytic lesions in basal forebrain on ChAT activity, NE and 5-HT levels and β-adrenergic as well as serotonin type 2 receptor binding were monitored 1 week, 1 month and >2 months after the lesion in a parallel group of mice. ChAT activity always decreased in cortex ipsilateral to the lesion. NE and 5-HT levels decreased in some mice but not in others in cortex ipsilateral to the lesion. Receptor binding changes were not consistent. In conclusion, the most consistent correlate of the basal forebrain lesion on thalamocortical fiber plasticity is a reduction in the levels of presynaptic cholinergic markers. However, it is quite possible that involvement of CA or 5-HT fibers due to the lesion has an impact on the extent of the plastic response. This could account for the variability in the amount of host fiber ingrowth into transplants.

180.16 RELATION BETWEEN FUNCTIONAL RECOVERY AND BRAIN ACETYLCHOLINE CHANGE IN RATS WITH UNILATERAL AND BILATERAL ROSTRAL RETICULAR LESIONS. T. Yamamoto,* Y. Katayama,* S. E. Robinson, C. E. Dixon, B. G. Lyeth, M. L. Giebel,* H. H. Stonnington,* D. P. Becker and R. L. Hayes. Division of Neurosurgery, Department of Pharmacology, and Department of Rehabilitation Medicine, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0001.

Bilateral destruction of the reticular activating system in cats can produce profound, irreversible behavioral suppression resembling coma. When such lesions are made unilaterally in two stages, minimal behavioral disruption results if a sufficient period of time intervenes (Adametz, J. Neurosurg., 16:85-97, 1959). Little is known about changes in neural function associated with this phenomena. Many cholinergic neurons in the reticular formation (RF) comprise a large ascending system with extensive projections to forebrain areas. Thus, we examined relationships between changes in behavioral disruption and levels and turnover of acetylcholine (ACh) in specific brain regions at various times after unilateral and bilateral lesions of the RF employing the rat.

Bilateral electrolytic lesions of the RF including the dorsal tegmental ascending system (10 mA, 5-sec, bipolar coagulation) produced pronounced behavioral suppression in all rats (n=10). Animals displayed no purposeful or spontaneous activity (locomotion, eating, drinking) and did not survive longer than seven days without supplemental feeding. Unilateral lesions produced only transient (<3 days) contralateral motor disturbances. Following unilateral lesions, 40 rats received staged bilateral lesions 1, 5, 15 or 30 days later. Such lesions made at 15 or 30 days did not produce significant behavioral disturbances.

Employing the method of Zsilla et al. (Neuropharmacol., 16:25-30, 1977), ACh levels and turnover were calculated for the diagonal band and medial septum, frontal cortex, thalamus, hypothalamus, amygdala and hippocampus. Initial results indicate that within seven hours following bilateral lesions (n=4) ACh levels and turnover decreased in all areas studied (>50% decrease from unlesioned controls, n=4) with the exception of the hypothalamus.

Within 24 hours, unilateral lesions (n=2) produced a decrease in ACh levels and turnover of >30% in areas ipsilateral to the lesion. A smaller decrease in levels and turnover was seen in contralateral areas. Results of other experiments indicate recovery of ACh levels and turnover in regions ipsilateral to the lesion within 15 days. These results suggest that lesions of the RF which include the dorsal tegmental ascending system change the total amount and turnover rate of ACh in the forebrain and the recovery of cholinergic levels and turnover rate in forebrain regions may be one correlate of the animal's ability to tolerate such lesions. In our model it was shown that 15 days was a sufficient interval to produce tolerance to staged bilateral lesions in the rat. Supported by NIH Grant #NS 12587.

180.17 CORTICAL GRAFTS IMPAIR SPATIAL LEARNING IN ADULT RATS WITH MEDIAL FRONTAL CORTEX LESIONS. Bryan D. Fantie and Bryan E. Kolb. Psychology Department, University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

Previous research has suggested that the recovery of behavioural function in animals with brain lesions can be enhanced by transplanting cortical tissue into the damaged areas. In the present study, we wished to investigate whether cortical grafts would improve the performance of rats with medial frontal cortex lesions on a place navigation task which is especially sensitive to the integrity of this brain site.

Nineteen adult male Long-Evans rats had their medial frontal cortex removed by aspiration under sodium pentobarbital anaesthesia. One group (Lesion+Transplant , n=10) received grafts of cortical tissue taken from one-day old pups 8-25 days later. The other group (Lesion Only, n=9) was re-anaesthetized, had their scalp incision opened and then re-sutured. Approximately 30 days later all of the rats were tested for spatial learning in a water maze with a hidden platform.

Both groups of rats with lesions performed more poorly than did unoperated controls and neither operated group ever achieved a comparable level of task mastery. Significantly, Lesion+Transplant rats were worse at the task than were Lesion Only animals. For example, by the fourth day of testing, 7 of the 9 Lesion Only rats were swimming to the platform within a mean latency of 20 s while only 2 of the 10 Lesion+Transplant rats were performing at a similar level (X^2=6.34, p<.02).

Subsequent Histology revealed that the grafts in the two rats that matched the performance exhibited by the Lesion Only group were not viable. In addition, the lesions in the 2 aberrant Lesion Only rats were much larger than those in the other rats and had, in fact, included damage to the cingulate cortex.

These results, therefore, lead us to conclude that viable cortical grafts do not enhance the behavioural recovery of spatial learning in rats that have medial frontal cortex damage. In fact, these transplants cause further impairment.

180.18 FUNCTIONAL AND ANATOMICAL EFFECTS OF STRIATAL NEURAL GRAFTS TO THE EXCITOTOXICALLY LESIONED STRIATUM. O. Isacson*, S.B. Dunnett[1] and A. Björklund. Dept. of Histology, University of Lund, Sweden, [1]Dept. of Exp. Psychology, University of Cambridge, England.

Striatal neural grafts in rats with extensive unilateral excitotoxic ibotenic acid lesions of the caudate-putamen have previously been shown to increase levels of striatal neural marker enzymes GAD and ChAT levels, normalize local cerebral metabolism (2-deoxyglucose-utilization) and reduce behavioral hyperlocomotor activity (Isacson et al., Nature 311:458, 1984). The present experiment extends these findings by determining histological as well as behavioral effects of fetal striatal cell implantation into the striatum and the globus pallidus following selective bilateral striatal lesions.

Rats received bilateral ibotenic-acid lesions (2 x 10 ug) of the AMC 9 days prior to grafting. Grafts were placed either into the antero-medial caudate-putamen (AMC) or directly into the striatal projection area of the globus pallidus (GP). Behavioral testing involved both conditioned (T-maze) and non-conditioned (locomotor activity) tasks.

The groups with AMC-lesions without grafts showed severe deficits in a T-maze delayed alternation task which involved both memory and left/right choice, and they also had a generally increased spontaneous open-field locomotor activity. The grafted animals showed significantly improved performance in delayed alternation. The grafts placed homotopically into the lesioned AMC were more effective in reducing the lesion-induced deficit than those grafts placed directly into the GP. In the grafted groups the performance in the delayed alternation task was positively correlated with graft-size in the lesioned caudate-putamen (r = 0.8, p<0.01). Histological evaluation revealed surviving grafts with high neuronal densities and expression of acetylcholine-esterase in all of the transplanted animals. Striatal grafts growing in the lesioned area of the AMC were larger in volume than those placed in the intact GP (mean: 7.1 vs 3.8 mm^3) and they significantly reduced the lesion-induced striatal atrophy.

This study provides further evidence that fetal striatal grafts can survive in the excitotoxically lesioned striatum and form a neural substrate that ameliorates functional deficits, both in conditioned and non-conditioned behaviors, produced by striatal lesions.

(Supported by the Swedish and British MRC).

180.19 Reversal of spontaneous locomotor hyperactivity following fetal transplants of the striatum occurs independent of DA mechanisms. A.W. Deckel[1,3], T.H. Moran[1], and R.G. Robinson[1,2], Dept of Psychiatry and Behavioral Sciences, [1]Dept of Neuroscience, [2]Johns Hopkins Univ Sch of Medicine, Baltimore, MD., 21205., Dept of Psychology, [3]Kessler Institute of Rehabilitation, W. Orange, N.J., 07052

Kainic acid (KA) striatal lesions in female Sprague-Dawley rats cause a hyperactivity in spontaneous locomotor activity, and a relative hyperactivity following injection with amphetamine. Previously, we found that fetal striatal (str) implants grafted directly into the KA lesioned str reverse the spontaneous locomotor activity caused by the lesions. This experiment examined the effects of pre and post synaptic DA stimulation on the activity of rats who recovered in their spontaneous locomotor activity following KA lesions and fetal str transplants.

Thirty-three adult female Sprague- Dawley rats were assigned to 1 of 4 groups, including lesion-only (LO; n=7), lesion and transplant (LT; n=9), transplant-only (TO; n=8), and controls (CN; n=9). LO and LT animals received bilateral KA injections (0.8 ug/0.4 ul per 4.5 min per side) in the anterior str; TO and CN received vehicle only. Seven days later, LT and TO received bilateral implants of day 17 fetal rat str. Beginning at 5 months postsurgery, horizontal, vertical, and stereotypical locomotor activity was tested in a computerized activity monitor (Omnitech). Each animal was run for 2 hr periods in the monitor under 3 drug conditions, each condition separated from the next by 1 week. The trials included saline (1.0 ml/kg, i.p.), amphetamine (1.0 mg/kg, i.p.), and apomorphine (0.2 mg/kg, s.c.); drugs were administerd randomly in order to control for drug order effects.

LO animals showed a persistent hyperactivity compared to both CN and LT in their spontaneous (saline) horizontal activity; transplants in the LT normalized behavior (F(1,27)=7.9, p=<.01), with LT appearing nonsignificantly different from controls. Conversely, apo and amp led to a persistent hyperactivity of horizontal and vertical activity in both LT and LO groups compared to CN, with no transplant effect apparent. Transplants did, however, significantly affect LT stereotypical movements compared to LO under the apomorphine condition. Brains were cut at 25um, and tritiated spiperone autoradiography and H+E staining was done. While the transplants survived robustly in both the lesioned and intact brains, few DA receptors were found in them. In summary, fetal str transplants reversed spontaneous locomotor deficits following KA str lesions, but had little effect on locomotion under contions that stimulated DA. We conclude that the transplants do not reinstate the disturbed nigral-striatal circuity, but lead to recovery by other, as yet unknown, mechanims. ACKNOWLEDGEMENTS: This work was supported by a grant from the Huntington's Disease Foundation.

180.20 **Transplants of glial cells after frontal cortex lesion promotes behavioral recovery in rats.** J.P. Kesslak, P.C. Mazur*, M. Nieto-Sampedro and C.W. Cotman, Department of Psychobiology, University of California, Irvine, CA 92717.

Lesions of the frontal cortex in rats produce a deficit on a reinforced alternation task. Transplants of embryonic frontal cortex have been shown to enhance recovery after the lesion[1]. However, the time course for recovery is so rapid that it is unlikely that neural connections with transplants could have been established, suggesting that biochemical actions may be involved. Damage to the CNS elicits production of endogenous neurotrophic and neurite promoting factors[2]. Glial cells proliferate around the wound and in gelfoam in the wound cavity and may be, inpart, responsible for the production of trophic activity[1]. We examined the behavioral effect of transplanting into a frontal cortex lesion cavity; 1) gelfoam that had remained for 5 days in a wound cavity of another animal and, 2) purified astrocytes grown in culture.

Adult male albino Sprague-Dawley rats were used. Five experimental groups were formed: i) Sham-operations; the scalp was retracted with no further damage. ii) Frontal cortex ablations, where the wound cavity was filled with saline-soaked gelfoam. iii) Frontal cortex ablation which received gelfoam transplants from a wound cavity from a previously damaged rat. iv) Frontal cortex ablation which received transplants of gelfoam containing cell-free extracts derived from wound-gelfoam. v) Frontal cortex lesion with transplants of purified astrocytes grown in culture.

Ten days after surgery animals were run on a reinforced alternation task. Results were analyzed using ANOVA. Groups which received wound-gelfoam and glial transplants did not differ from the sham-operated group, and learned significantly faster than the lesion group which received saline-soaked gelfoam. The group receiving wound-fluid extracts did not differ from the saline-gelfoam group. These results indicate that behavioral recovery after frontal cortex lesion is facilitated by transplantation of non-neuronal cells. Replacement of lost neurons is not necessary, although it may be sufficient, for behavioral recovery on this task.

181.1 Mild neonatal stress influences adult analgesia following morphine. H. Schreiber III, B. Zito*, M. Warren*, A. Davis* J. Trambley*, B. Gonzalez*, M. Ortiz*, L. Salazar*, G. Gonzalez*, Div Behav Sci., N.M. Highlands Univ., Las Vegas, N.M. 87701.

A burgeoning literature delineates the complex relationship between stress and analgesia, but most studies involve relatively recent situational stress. We report here that neonatal stress substantially reduces morphine-induced analgesia in adult rats. In Experiment 1, Sprague-Dawley albino litters and dams were left undisturbed or litters received early handling (mild hypothermia produced by removal from nest and dam, 3 min/D, first 10 Ds p partum). At 130 Ds, after 10 Ds of adaptation, rats (split litters) received morphine sulfate (2.5 mg/kg, i p) or saline and daily tail-flick testing (preinj, 30, 60, 90, 120 min p inj) or not for 14 Ds. Then, all rats received morphine and were tested. A significant Time of Testing by Sex by Drug History by Early Treatment interaction was found, $F(4,192)=3.0$, $p<.02$. Early handling reduced analgesia by about 80% in male rats at 30 min p inj, regardless of previous exposure to the apparatus, but not among morphine history rats. In Experiment 2, litters received early handling or not as before, but half of the litters were returned to a dam-absent nest. Dams were returned after 1 hr. This manipulation of the dam can abolish the early handling effect on stereotypy (Schreiber et al, 1978). Nonetheless, at 155 Ds when rats received morphine (2.5 mg/kg) and tail-flick testing (preinj, 30, 90 min p inj.), early handled rats showed little morphine-induced analgesia in comparison with controls, $F(1,16)=9.64$, $p<.01$, regardless of maternal separation. In Experiment 3, Long-Evans hooded litters received early handling or not as before; all dams were removed for 1 hr with half of the dams left undisturbed and half exposed to stressed donor pups. This manipulation of dams is believed to alter maternal behavior in a fashion similar to early handling (Smotherman and Bell, 1980). Control groups for maternal separation and observation were included. At 100 Ds, females received morphine (5 mg/kg, i.p.) and were tested on a hotplate (preinj, 30, 60, 90 min p inj). Analysis of the average latency to paw-lick or footstamp showed a main effect of early handling $F(1,32)=6.44$, $p<.02$ (early handled Ss, less analgesia) and a main effect of dam exposure to donors, $F(1,32)=3.94$, $p=.056$ (offspring of exposed dams, less analgesia). Other experiments involving inhibition of locomotion and catatonia will be discussed. No rat in any experiment was subjected to more than threshold pain. We conclude that stress-related neonatal manipulations are potent influences on the behavioral effects of morphine in adulthood.

181.2 EFFECTS OF DIPRENORPHINE INJECTED INTO THE VTA ON ICS IN THE RAT. M. Washburn* and E.A. Stein. Department of Biology, Marquette University, Milwaukee, WI 53233.

The neurochemical and neuroanatomic substrates of brain stimulation reward (ICS) have been intensively studied using numerous techniques including lesions, pharmacologic manipulations and stimulation site mapping. It now appears that the catecholamines play a significant role in this behavior. Recently, the endogenous opioid peptides have been implicated as modulators of the so-called "standard neurotransmitters" in a number of neuronal systems and behaviors including ICS. However, while agonists such as morphine and the endorphins have reliably been shown to affect both rate and threshold of responding, considerable controversy exists as to the effects of opiate receptor blockers on this behavior. As such, we have undertaken a mapping study of the effects of diprenorphine (Dpr), a μ/δ opiate receptor blocker, on ICS.

Male, Holtzman rats were implanted with monopolar, 250 μ nichrome electrodes aimed at the medial forebrain bundle (flat skull coordinates: -3.3, 1.75, 8.8). In addition, bilateral 26 g stainless steel guide cannulae were implanted 1 mm dorsal to the nucleus accumbens (+1.7, $\pm$1.5, 6.8), medial prefrontal cortex (+2.7, $\pm$0.5, 3.0) and ventral tegmentum (-4.8, $\pm$1.0, 8.45). Following recovery, rats were trained to press for 300 msec trains of 0.5 msec cathodal pulses. When stimulation rates stabilized, eight current levels, representing 10 to 100% responding, were chosen and randomly presented to rats daily until again rates stabilized. A within subjects design was then employed with rats receiving one of three doses of Dpr (1.5, 3 or 5 μg/inj bilaterally in 0.5 μl saline) or saline vehicle once per week. Prior to recording responding at each current during a five min test, subjects are given an additional 30 second interval to acclimate to the new current.

Administration of Dpr into the VTA was not able to alter ICS rate or threshold responding. There were no significant shifts in the current-response curve. These results are discussed in light of a possible modulatory role for opioids in ICS.

Supported by NIDA grant 02234 to EAS.

181.3 IN VIVO ALTERATIONS OF OPIATE RECEPTOR BINDING AFTER AVERSIVE AND REWARDING STIMULATION. M.J. Blake and E.A. Stein. Department of Biology, Marquette University, Milwaukee, WI 53233.

Early studies demonstrated that intracranial brain stimulation (ICS) had analgesic or aversion ameliorative properties in addition to its rewarding qualities. Subsequent work has shown both electrophysiological and pharmacological distinctions between the systems which mediate these effects. Even though the pain-suppressive system from the brain to the spinal cord can be separated from the reward system, activation of the reward system can attenuate the perception of negative environmental stimuli. Observations in our lab have shown that rats actively escaping aversive footshock will attenuate this behavior when presented simultaneously with non-contingent ICS. This provides further evidence that reward systems can override pain perception mechanisms in addition to suggesting that non-contingent ICS has rewarding properties. With regard to numerous studies implicating the endogenous opioid peptides in both pain and reward mechanisms, in vivo autoradiography was employed to determine the changes in opiate receptor occupancy that occur between rats receiving ICS, footshock or both.

Male Holtzman rats were implanted with monopolar stimulating electrodes aimed at the ventral tegmental area. Following a one week recovery, rats were placed in stimulating chambers and primed to press for ICS. Animals showing robust ICS were implanted with chronic jugular catheters and after a three day recovery, the current range supporting ICS was determined for each rat. Animals were then trained to press a lever to escape 300 msec trains of aversive footshock applied to the grid floor every second. One response resulted in turning the footshock off for 5 seconds. Rats were then divided into four groups. The first group received non-contingent ICS, the second group received escapable footshock, the third group received escapable footshock and non-contingent ICS simultaneously, and the fourth group served as a sedentary control. Following their respective treatment, rats were injected with .002 mg/kg H^3-diprenorphine and processed for autoradiography following a previously described technique (Seeger, T.F. et al., Brain Res., 305:303, 1984). After an appropriate exposure, x-ray film (LKB Ultrofilm) was developed and analyzed using an Eyecom II microdensitometer (Spatial Data).

Analysis of results revealed that rats receiving ICS regardless of the presence of footshock had unilateral alterations in opiate receptor binding in several nuclei previously implicated in reward. This suggests that ICS results in a change in opioid release that is unaffected by incoming painful stimuli. The opioid involvement in reward and its relation to central pain mechanisms will be discussed. Supported in part by NIDA 02234 and a fellowship from Marquette University to MJB.

181.4 CHRONIC ADMINISTRATION OF ACTH AND/OR NALTREXONE: EFFECTS ON MORPHINE-INDUCED ANALGESIA. Z.H. Galina and Z. Amit. Center for Studies in Behavioral Neurobiology, Dept. Psych, H-1013, Concordia Univ. Montreal, Quebec, Canada, H3G 1M8.

The substrate for the behavioral effects of ACTH are unknown but it has been suggested that these effects may be mediated by an action at opiate receptors. We thought that a useful way of determining the substrate would be to analyze what effect the chronic administration of ACTH and/or naltrexone would have on morphine analgesia.

Thirty-two male wistar rats which had been part of a previous experiment examining the locomotor effects of ACTH and naltrexone were used. They were given two s.c. injections of either ACTH (20IU/kg), naltrexone (10mg/kg) or saline for 24 consecutive days. The groups were: saline-saline, ACTH-saline, naltrexone-saline, and ACTH-naltrexone. Four days after the final day of drug administration (day28) half the rats in each group received morphine (1mg/kg) or saline five min. before being placed on a hot-plate (54°C). Latency to initial back pawlick and jump/escape were recorded.

Pawlick data indicated (ANOVA) an effect of morphine, and interactions between ACTH x naltrexone, and ACTH x naltrexone x morphine. Post hoc tests revealed that the chronic administration of ACTH or naltrexone alone reduced the latency to pawlick compared to saline controls. The conjoint administration of ACTH and naltrexone prevented this reduction. Morphine given to all groups reduced the latencies independent of group designation.

Jump/escape data indicated an effect of ACTH, and morphine, and interactions between ACTH x naltrexone. Post-hoc analysis revealed that ACTH alone increased the latency to jump but that this could be prevented by simultaneous naltrexone presentation. Morphine increased the latencies to jump in the saline group and this was potentiated in all drug groups.

In summary, we found that the long term administration of ACTH increased latency to jump but decreased latency to pawlick; and potentiated the effects of morphine. Conjoint administration of naltrexone blocked the ACTH effects on both jump and pawlick measures. The effects of morphine were potentiated by chronic administration of either ACTH, naltrexone or ACTH and naltrexone on the jump measure; pawlick was unaffected. Taken together these results suggest that ACTH may operate through opiate receptors to effect analgesia in a complex fashion depending on the measure used.

181.5 DIFFERENTIAL ACTIONS OF INTRACEREBROVENTRICULAR CCK ON AMPHETAMINE-INDUCED LOCOMOTION AND STEREOTYPY IN RATS.
Aaron Ettenberg and Friedbert Weiss Department of Psychology, Univ. of California, Santa Barbara,CA 93106

Cholecystokinin octapeptide sulfate ester (CCK-8) has been reported to have long lasting antipsychotic effects in humans and neuroleptic-like effects in animals. Since CCK has recently been found to coexist, and be co-released, with dopamine (DA) in a subset of mesencephalic (A10 and, to a lesser extent, A9) neurons, it has been suggested that its antipsychotic/neuroleptic effects may stem from a central antagonism of DA neurotransmission. However, in at least one important behavioral assay of DA function (i.e. hyperlocomotion-stereotypy model), we have found that CCK failed to produce effects comparable to those of classical DA-antagonist neuroleptic agents. While both CCK and typical neuroleptics (e.g. haloperidol) attenuate the locomotor increase induced by low doses of amphetamine (AMP), only the neuroleptics antagonize the stereotypies induced by higher doses of AMP. In fact, we report here that CCK produced a marked potentiation in stereotypies while completely reversing the locomotor effects produced by amphetamine administration.

To stimulate hyperlocomotion or stereotypy rats were injected (s.c.) with d-AMP (1 or 3 mg/kg) 15 min before ICV infusion of sulfated CCK-8 (1 or 2 ug/rat). Locomotor activity was measured in cages equipped with automated photocell-activated counters. Stereotyped behaviors were rated by a trained observer who was unaware of the treatment conditions of the animals. Ratings involved an objective assessment of the presence or absence of particular behaviors (e.g. head bobbing, gnawing...) as well as a zero to four point behavioral rating scale similar to those used by others. Ratings were taken at 5 min intervals over a 2 h period immediately following peptide infusion. CCK-8 antagonized AMP-induced (1mg/kg) hyperlocomotion to levels indistinguishable from baseline (at the high dose). The same peptide treatments produced a dose-dependent potentiation in the stereotypy induced by AMP (3mg/kg). These data are comparable to the effects others have observed with the class of "atypical" neuroleptics (e.g. clozapine). We, therefore, hypothesize that a) CCK differentially affects DA function in the mesolimbic and nigrostriatal systems, and b) CCK has a mode of action more comparable to "atypical" rather than classical neuroleptic agents.

181.6 "ATYPICAL" NEUROLEPTIC-LIKE PROPERTIES OF CCK IN A ROTATIONAL-BEHAVIOR MODEL OF DOPAMINE FUNCTION
Friedbert Weiss and Aaron Ettenberg , Department of Psychology, Univ. of California, Santa Barbara CA 93106

A fragment of the gastrointestinal peptide, cholecystokinin (CCK-8), has recently been identified to coexist with the putative transmitter, dopamine (DA), within a subset of mesencephalic DA neurons. Although the functional nature of this CCK-DA coexistence remains uncertain, a growing body of behavioral data suggest that CCK may have antagonist/neuroleptic-like effects on DA neurotransmission. For example, CCK has been reported to have antipsychotic activity in humans and neuroleptic effects in animals (i.e. to delay acquisition, and facilitate extinction of active and passive avoidance behaviors, to suppress exploratory behavior, to reduce responding for rewarding brain stimulation, and to antagonize amphetamine (AMP)-induced hyperlocomotion). However, the neuroleptic-like actions of CCK do not appear to extend to cataleptogenic potency nor to antagonism of AMP-induced stereotypy. In our own work, CCK reversed the hyperlocomotion induced by low doses of AMP but potentiated the stereotypy resulting from higher doses. These results are similar to those observed with the "atypical" neuroleptics (e.g. clozapine) and might suggest that CCK and atypical neuroleptics only weakly influence behaviors mediated by the dorsal striatum (catalepsy, stereotypy), but more strongly inhibit behaviors mediated by the nucleus accumbens (hyperlocomotion). In the present study we compared the DA antagonist actions of CCK, haloperidol (HAL), & clozapine (CLZ) in a rotational model involving unilateral striatal infusions in AMP pretreated rats.

Rats received unilateral intrastriatal infusions of either CCK (2,4,8ug), CLZ (5,20ug), or HAL (5ug) 15 min after s.c. injection of d-AMP (1mg/kg). The animals were then placed into rotational chambers where the number & direction of 360° turns were recorded automatically every 5 min for 1 h. As others have reported, HAL produced strong and almost exclusive ipsilateral circling. In contrast, CLZ & CCK produced relatively weak circling which was highly variable in direction. These data suggest that CLZ & CCK only weakly affect AMP-stimulated DA neurotransmission in the striatum. The reported neuroleptic-like actions of CCK may, therefore, be more comparable to "atypical" rather than typical antipsychotic compounds.

181.7 CHOLECYSTOKININ (CCK) POTENTIATES THE RATE-DECREASING EFFECTS OF MORPHINE ON SCHEDULE-CONTROLLED LICKING IN RATS.
P.J. Winsauer and A.L. Riley, Dept. of Psychology, American Univ., Washington, D.C., 20007.

CCK, a brain-gut peptide, has previously been shown to antagonize the effects of morphine on a variety of measures, such as analgesia (Faris et al., Science, 219:310, 1983) and food intake (Morley, J.E., Life Sci., 30:479, 1982). However, the ability of CCK to antagonize the effects of morphine on schedule-controlled responding has not been demonstrated. The present research examined the interaction of CCK with cumulative doses of morphine on operant licking. As a comparison the prototype opioid antagonist, naltrexone, was also given in combination with morphine. In one component of a two-component multiple schedule, rats (23 hrs. water deprived) were required to respond in the presence of a white stimulus light by licking a dry tube. Responding was reinforced under a fixed-ratio 50 (FR 50) schedule of water presentation, i.e., 2.5 seconds access to water at another tube. In the other component responding had no programmed consequences (timeout). Each session consisted of four 10-min timeout components alternating with four 10-min FR components. Cumulative dose-effect curves for morphine were obtained by giving an injection before each of the four FR components; successive injections increased the cumulative dose in equally spaced logarithmic steps. In general, as the cumulative dose of morphine increased (3.2-18 mg/kg, i.p.), the overall response rate decreased. In two of three subjects CCK alone (10-32 ug/kg, i.p.), produced little or no effect, except small rate-decreasing effects in the first FR component. When CCK was given in combination with morphine, however, the morphine dose-effect curve tended to shift to the left. In contrast, after pretreatment with naltrexone (1 mg/kg, i.p.), these same doses of morphine produced little or no effect on the overall rate of responding. Increasing the cumulative doses of morphine (18-75 mg/kg) indicated that naltrexone shifted the dose-effect curve approximately 3/4 log-unit to the right. Accordingly, these results would indicate that CCK does not interact with morphine in the same way as naltrexone when operant licking is the behavioral measure.

181.8 ATYPICAL NEUROLEPTIC-LIKE EFFECTS OF NEUROTENSIN ON APOMORPHINE INDUCED BEHAVIORS.
F.B. Jolicoeur, M.A. Gagné*, S. St-Pierre* and R. Rivest. (Spon: R. Butterworth) Departments of Psychiatry and Pharmacology, Faculty of Medicine, University of Sherbrooke, Sherbrooke, Quebec, Canada, J1H 5N4.

The examination of the effects of drugs on behaviors induced by both low and high doses of apomorphine constitutes a simple and reliable procedure to detect potential neuroleptics and differentiate between typical and so-called atypical antipsychotics (Protais et al., Eur. Pharm., 94: 271, 1983). Whereas behaviors induced with small doses of the dopamine agonist are antagonized by both typical and atypical neuroleptics, stereotypy produced by high doses of the dopamine agonist is markedly decreased only by typical antipsychotics.

Many behavioral and neuropharmacological effects of neurotensin resemble more those of atypical than typical neuroleptics (Jolicoeur et al., Hdbk. Neurochem. 8:93, 1985). Although neurotensin has been shown to be ineffective in reducing stereotypy produced by dopamine agonists, to our knowledge, the effect of this peptide on behaviors induced by low doses of apomorphine has not been examined. In the present study, the effects of neurotensin on yawning and penile erections induced by 100 µg apomorphine were investigated. The following doses of the peptide were administered intracerebroventricularly 30 min prior to apomorphine injections: 0.9, 1.87, 3.75 and 30 µg. Number of yawns and the presence of erections were monitored for 1 hr following apomorphine administration. Results indicate that apomorphine induced yawning was significantly decreased with 1.87 µg neurotensin and totally abolished with 3.75 and 30 µg of the peptide. Also, no penile erections were observed in animals treated with the two higher doses of the peptide. In a parallel experiment, none of the above doses of neurotensin significantly affected stereotyped sniffing induced by 600 µg of apomorphine, confirming previous similar observation.

Together, these results lend support to the suggestion that the profile of neuropharmacological effects of neurotensin is more akin to that of atypical neuroleptics. Furthermore, since yawning and penile erections induced by low doses of apomorphine are generally attributed to stimulation of dopaminergic autoreceptors, whereas stereotypy is though to be mediated by activation of post-synaptic dopaminergic receptors, the results of the present study constitute behavioral evidence that neurotensin may have a selective inhibitory action on dopamine autoreceptors. Supported by the Medical Research Council of Canada.

181.9 NEUROPEPTIDE Y (NPY)-INDUCED FEEDING: COMPARISON WITH RAT PANCREATIC POLYPEPTIDE (rPP), HUMAN NPY, AND PEPTIDE YY (PYY) IN MALE AND FEMALE RATS. J. T. Clark* and S.P. Kalra (SPON. E. Smith), Dept. OB-Gyn, Univ. Fla. Col. Med., Gainesville, FL 32610

Porcine Neuropeptide Y (pNPY), a 36 amino acid tyrosine rich peptide which has been localized in various hypothalamic and extrahypothalamic sites and co-exists with adrenergic transmitters, is a potent stimulator of feeding activity in satiated, ovariectomized rats (Clark et al, Endocrinol, 115:427, 1984). In the present study, we have compared the feeding response induced by various members of the pancreatic polypeptide family in intact male and female rats. Intraventricular (Ivt) injections of pNPY during the final hours of the light period induced feeding in a dose-related fashion. While the lowest dose tested (0.1 µg) was without effect, higher doses (0.5, 2 and 10 µg) uniformly elicited feeding with a latency of 12-15 min in male rats. With the most effective dose, 2 µg (0.47 nM), the increased food intake was due to an increased local eating rate, and not due to an increased time spent eating. In contrast, the pattern of feeding behavior seen after rPP was quite different and less impressive. During the first hour, only one dose of rPP (2 µg) evoked an increase in food intake due to an increased time spent eating. Further, the effects of pNPY (0.5 and 2 µg) on food intake were significantly greater during the dark phase than during the light phase. Interestingly, increased food intake in nocturnal tests (4 h) was due solely to augmented intake during the first 60 min after pNPY injection, the increased response gradually dissipated to return to control levels between 60 and 240 min. We found pNPY equally effective in intact cycling female rats (2 µg = 2.33 ± 0.28 g/60 min). As in males, the increased food intake was due to increased local eating rate. On the other hand, hNPY or PYY was about half as effective as pNPY in stimulating feeding in female rats and the increased food intake was due to increased time spent eating. These results show that (1) although all members of the pancreatic polypeptide family so far tested stimulate feeding to a varying degree, pNPY was uniformly most effective in male and female rats and (2) either single, as in hNPY (Met^{17} NPY), or multiple amino acid substitutions, as in rPP and PYY, decreased appetetive effects. Thus, these findings are in line with the proposal that NPY, or an NPY-like peptide, discharged in critical areas of the rat brain may normally induce feeding behavior in rats. (Supported by NIH HD 08634 and a postdoctoral fellowship HD 06660).

181.10 VENTRAL TEGMENTAL AREA INJECTION OF DIFFERENT NEUROPEPTIDES : DIFFERENTIAL EFFECTS ON FEEDING AND OPERANT BEHAVIOR. A.E. Kelley*, M. Cador*, L. Stinus* and M. Le Moal. INSERM U-259 Psychobiologie des Comportements Adaptatifs, rue Camille Saint-Saëns, 33077 Bordeaux, France.

The ventral tegmental area (VTA) contains the dopaminergic A10 (DA-A10) neurons which innervate various forebrain limbic regions. The VTA also has a high distribution of the peptides neurotensin (NT), substance P (SP), and enkephalin. Previous studies have shown that these peptides injected into VTA induce a psychomotor stimulation which is dependent on the activation of the DA-A10 neurons. However, little is known about the effects of such peptide injections on consummatory behavior. The present study is divided into two parts; 1) Effects of VTA-peptide injections on feeding behavior, and 2) Effects of VTA-peptide injections on operant responding for food reward.

1) The behavioral consequences of these injections were studied in both food-deprived and non-deprived rats. During a 30-min test, the following parameters were measured : latency to eat, total food intake, food spillage and duration of eating. Similar measures were taken for drinking. In deprived rats SP(0.5, 3.0 µg) increased latency but did not affect other parameters, and had no effect in satiated rats. NT (0.5, 2.5 µg) increased latency and markedly reduced food consumption in deprived rats, and had no effect in non-deprived rats. DALA (0.1, 1.0 µg) enhanced feeding in both deprived and non-deprived animals.

2) The effects of VTA injections of NT (0.0175, 0.175, 0.5 µg) SP (0.1, 1.0, 3.0 µg), neurokinin α (NKA, 0.1, 1.0, 3.0) and DALA (0.01, 0.1, 1.0 µg) were assessed on fixed-interval (FI) responding for food reward. Stable baseline responding and the typical FI scallop were obtained on an FI-40 sec schedule. The index of quarter life was taken as an indication of the temporal pattern of responding. NT induced a dose-dependent reduction in responding without affecting quarter-life, and reduced the number of reinforcements taken. SP and NKA did not affect the level of responding, although responding on the non-reinforced lever was augmented by both peptides. DALA induced a dose-dependent increase in responding which was rate-dependent, and reduced the quarter-life. DALA effects were similar to the classic pattern of responding observed after amphetamine.

These results indicate that although all these peptides elicit behavioral activation and may affect DA neuronal activity, the bahavioral responses can be differentiated with respect to feeding and operant behavior. It is possible that the endogenous peptides modulate the DA systems differentially. The findings are discussed in terms of both motor and motivational mechanisms.

NEUROPEPTIDES AND BEHAVIOR II

182.1 **CHRONIC DESMETHYLIMIPRAMINE BUT NOT LITHIUM MODIFYS LOCOMOTOR RESPONSE TO CORTICOTROPIN RELEASING FACTOR.** **C.L.Ehlers*,R.I. Chaplin, G.F. Koob (SPON:A.J.Mandell) Div. Neuroscience, Res. Inst. Scripps Clinic, La Jolla, CA 92037**

Recent studies have emphasized a role for Corticotropin Releasing Factor (CRF) in the etiology of affective disorder. Increased levels of CRF in the spinal fluid, blunted ACTH response to IV infusion of CRF, and non-suppression of cortisol to dexamethasone administration have all been reported in certain groups of depressed patients. Since these abnormalities in the hypothalamic-pituitary-adrenal system are frequently normalized following successful drug treatment, we sought to investigate whether chronic lithium (LI) or desmethylimipramine (DMI) would modify locomotor response to intracerebroventricular (ICV) administration of CRF in animals.

Thirty-six male Wistar rats were implanted with stainless steel ICV cannula and two weeks later were randomly assigned to one of four treatment groups: LI diet (n=12),Control diet (n=9),daily DMI injections (n=7) (10mg/kg), or daily Water injections (n=8). After 21 days of Lithium or control diet, and eighteen days of DMI or water injections one half of the rats received ICV injections of 0.15 nMols of CRF(ovine) in 5 microliters of saline or saline alone. Five days later the rats who initially received saline got CRF and visa versa. Locomotion was measured following the injections for 3 hours in computer automated cages equipped with two red photocell beams. Repeated measures ANOVA revealed that ICV CRF as opposed to saline injections, produced a significant increase in locomotion over the three hour period in all 4 groups (SAL VS CRF group effect: LI DIET,$p<.001$; C DIET,$p<.001$;DMI,$p<.01$; WATER,$p<.02$).Additionally the pattern of locomotor response to CRF was significantly modified by chronic DMI treatment but not by the control injections (ANOVA group time $p<.05$) with DMI treated rats displaying a more prolonged locomotor response to CRF. However no differences in amplitude or pattern of response to CRF were seen in chronic lithium treated rats as compared to rats on control diet. These studies suggest that the clinical effectiveness of DMI, but not lithium, may be partially enacted through systems responsive to CRF.**(supported by AA06059 and the Mac Arthur foundation)**

182.2 CENTRAL ADMINISTRATION OF CRF DELAYS THE ONSET OF MATERNAL BEHAVIOR AND INCREASES PUP-KILLING IN OVARIAN STEROID-TREATED RATS. A.J. Prange, Jr., J.D. Caldwell*, P.J. Brooks* and C.A. Pedersen. (SPON: D.L. Evans). Department of Psychiatry, Biological Sciences Research Center and the Neurobiology Curriculum, University of North Carolina at Chapel Hill, NC 27514

Corticotropin-releasing factor (CRF) has been reported to inhibit sexual and feeding behavior. Several investigators have observed that maternal behavior (MB) in rats is suppressed by stress. Since CRF has been shown to be released under certain stressful conditions, we have hypothesized that this neuropeptide may play some role in stress-inhibition of MB.

Virgin Sprague Dawley rats (200-250 gm) from Zivic Miller Laboratories were ovariectomized (OVXed). Eight days after OVX a Silastic capsule one cm in length containing 8.8 mg of 17 β-estradiol (E) was implanted SC in each animal. Ten days after OVX one long (90 mm) Silastic capsule containing 120 mg of progesterone (P) was implanted SC in each animal. Twenty days after OVX and 24 hrs before introduction of pups, P implants were removed from each animal. One hr prior to introduction of pups CRF (0.5, 1.0, 2.0, or 4.0 µg in 10 µl of normal saline) or normal saline (NS) vehicle alone were infused ICV. Immediately after ICV infusions, three 1-5 day old rat pups were placed in the cage of each animal. An observer, ignorant of ICV treatment, then looked for and recorded MB over the first six hrs and the 25th hr of pup contact.

Over the first two hours of pup contact, the incidence of full maternal behavior (FMB) was significantly lower in animals receiving 1 µg (4/10), 2 µg (3/10) or 4 µg (2/12) CRF compared to animals receiving NS (27/32); $p < .01$, 1 µg vs NS; $p < .003$, 2 µg vs NS; $p < .0001$, 4 µg vs NS; (Fisher's exact probability test). The incidence of FMB after 0.5 µg CRF (8/14) was not significantly different compared to animals receiving NS. By the end of the sixth hr of pup contact, animals receiving 1, 2 or 4 µg of CRF still had significantly lower cumulative incidences of FMB than animals receiving NS. At the end of the 25th hr of pup contact, there were no differences between CRF and NS recipients in cumulative incidences of FMB. Animals receiving 1, 2 or 4 µg of CRF displayed a significantly greater incidence of killing in the first two hrs of pup contact compared to control animals receiving NS (10/32 vs 1/32, $p < .003$).

We conclude that CRF inhibits the ovarian steroid-induced onset of MB and promotes infanticide. Our results are consistent with the hypothesis that endogenous CRF may contribute to the suppression of MB observed under stressful conditions.

182.3 CORTICOTROPIN-RELEASING FACTOR (CRF) POTENTIATES ACOUSTIC STARTLE REFLEX[1] (ASR) IN RATS:[2] BLOCKADE BY[3] CHLORDIAZEPOXIDE[4]. N.R. Swerdlow*, M.A. Geyer[2], W.W. Vale[3], and G.F. Koob[4]. [1]Dept Neurosci, M.S.T. Program, School of Medicine, U.C.S.D., La Jolla, CA 92093, [2]Dept Psychiatry, U.C.S.D., La Jolla, CA 92093, [3]The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Jolla, CA 92037 and [4]Div Neurosci and Endocrinology, Scripps Clinic and Research Foundation, La Jolla, CA 92037.

CRF is a 41 amino-acid polypeptide distributed throughout the CNS that has been shown to have potent neurotropic properties and to stimulate the release of ACTH and beta-endorphin from the anterior pituitary. Interestingly, CRF acts within the CNS to stimulate numerous behavioral changes in the rat that mimic behaviors normally exhibited during conditions of high stress. The purpose of the present study was to examine the behavioral properties of CRF using a reflex response - the ASR - that is known to be sensitive to states of stress or fear.

The ASR is an easily quantified contraction of skeletal musculature in response to an intense acoustic stimulus. In rats, the ASR has been shown to be sensitive to states of stress or fear, since ASR amplitude is enhanced when the acoustic stimulus is presented during another stimulus (light, for example) that has previously been paired with shock. This 'fear-potentiated' startle is attenuated by drugs, including benzodiazepines, that have anxiolytic properties in humans.

In the first experiment, ASR amplitude was measured in rats (n=32) following icv administration of 0, 0.1, 1.0 or 10.0 ug rCRF. ASR amplitude was significantly potentiated by the 1.0 ug dose. In a second experiment, ASR amplitude was measured in rats (n=36) given 1.0 ug rCRF icv following pretreatment with the anxiolytic chlordiazepoxide (CDP: 0, 2.5, 5.0, 10.0 mg/kg ip). CRF-enhanced ASR was decreased in a dose-dependent manner by CDP; this effect was statistically reliable at the 2.5 mg/kg dose of CDP. In a third experiment, this dose of CDP produced no significant decrease in ASR potentiated by d-amphetamine (2.5 mg/kg sc; n=12) or strychnine (0.75 mg/kg ip; n=12).

Our results indicate that CRF, like stress, potentiates ASR amplitude; this effect of CRF is reversed by the anxiolytic CDP at doses of CDP that do not decrease amphetamine- or strychnine-potentiated ASR. CRF may serve as a critical neural substrate of stress-enhanced acoustic startle.

182.4 EFFECTS OF SYNTHETIC ACTH(4-9)-ANALOGUES ON DIFFERENT LEARNING TASKS IN MICE AND RATS. F.J. Hock, H.J. Kruse* and H.J. Gerhards*. HOECHST AG, D-6230 Frankfurt/M. 80, FRG

Considerable interest has developed over the past several years in the functions of neuropeptides in behavioral processes. There is now a large body of evidence, based largely on the work of deWIED and his colleagues, that ACTH and its related neuropeptides modulate learning behavior. ACTH and several of its analogues have been reported to facilitate one-way active avoidance acquisition and to attenuate ECS-induced amnesia. Hoe 427 and S 82 5972 A are ACTH(4-9) analogues selected from a group of ACTH(4-9) analogues because of their potency in behavioral tests.

(1) Inhibitory (passive) avoidance. Mice were treated 60 min prior to training with Hoe 427, S 82 5972 A, or saline. The animals were trained in a through-shaped straight alley runway with a guillotine door separating a light (L) and dark (D) compartment. Each mouse was placed in the L side facing away from the door. The door was opened and when it stepped through to the D side, a 1 mA, 1 s FS was delivered. Animals were given either electroshock (ECS, 25 mA, 200 ms) immediately after training or they received scopolamine (SCO, 3 mg/kg, i.p.) 5 min prior to training to produce amnesia. The minimal effective dose (MED) for attenuating ECS amnesia was 0.03 µg/kg s.c. for S 82 5972 A and 0.1 µg/kg s.c. for Hoe 427. For SCO amnesia, the MED was 0.3 µg/kg s.c. for S 82 5972 A and 0.03 µg/kg s.c. for Hoe 427.

(2) One-way Shuttle Box. Rats were socially deprived for 5 weeks before training. The animals were trained on 5 consecutive days in an active avoidance paradigm. Each rat was placed on a grid and the onset of shock was signalled by a 10 sec light conditioned stimulus (CS). The rat could escape or avoid the shock by jumping onto the platform. The animals were given 10 trials each day with a 50 sec intertrial interval. No drug was given on the first day; on days 2 - 5, rats were treated with Hoe 427 or saline 60 min prior to training. The number of avoidances was measured for each day. A dose of 10 µg/kg s.c. Hoe 427 was effective in facilitating acquisition of this task.

(3) 8-arm Radial Maze. Rats were trained in an 8-arm radial maze (STÄUBLI et al., Beh. Neur. Biol. 40, 58, 1984) to find a food pellet. After this task was well learned, a delay was introduced between the 4th and 5th choice of the trial. On the 5th day of training with a delay, the animals received Hoe 427 or saline 60 min before the start of the 1st trial. In addition, the animals received an amnestic dose of SCO (0.5 mg/kg, s.c.) 30 min before the delay interval. Two doses of Hoe 427 tested, 3 and 10 µg/kg s.c., antagonized the SCO-induced amnesia: On days 6 - 8 the Hoe 427 treated groups made significantly fewer errors than the control group. By day 8, the performance of the control group had not returned to the pre-SCO treatment level.

182.5 INHIBITORY ACTION OF MSH ON LORDOSIS: POSSIBLE SEROTONERGIC MEDIATION. L.H. Raible* and B.B. Gorzalka*(SPON: J.P.J. Pinel). Dept. Psychol., Univ. British Columbia, Vancouver, B.C., Canada V6T 1W5.

Research in our laboratory has indicated that centrally administered alpha-melanocyte stimulating hormone (MSH) inhibits sexual receptivity in rats (as measured by the lordosis quotient; LQ = lordosis/mount x 100). Work by Leonard et al. (J. Neurosci. Res., 2: 39, 1976) and Root-Bernstein & Westall (Brain Res. Bull., 12: 425, 1984) suggests that MSH and serotonin (5-HT) may interact physiologically. In addition, recent evidence indicates that serotonin type II receptor (5-HT_2) activity facilitates receptivity (Mendelson & Gorzalka, Pharmacol. Biochem. Behav., in press, 1985). The current experiments were designed to determine if the inhibitory action of MSH is due, in part, to an MSH-induced decrease in 5-HT_2 receptor activity.

In Experiment 1, the ability of quipazine (3 mg/kg, ip), a 5-HT_2 agonist, to attenuate the inhibitory action of MSH (200 ng/4 µl, icv) was examined. Ovariectomized estrogen and progesterone primed Sprague-Dawley rats were assigned to one of four groups: saline + saline; saline + quipazine; MSH + saline; MSH + quipazine. Results indicated that mean receptivity in the MSH group was significantly lower than mean receptivity in the remaining three groups, which did not differ from each other. In Experiment 2, subthreshold doses of MSH (20 ng/4 µl, icv) and of pirenperone (10 µg/kg, ip), a 5-HT_2 antagonist, were administered alone or in combination to determine if the two would summate to produce an inhibitory effect. The four groups were as follows: saline + saline; saline + pirenperone; MSH + saline; MSH + pirenperone. Results indicated that the mean LQ for the MSH + pirenperone group was significantly lower than the mean LQs for the remaining three groups, which did not differ from each other. Experiment 3 was designed to determine if the inhibition observed in Experiment 2 could be reversed by quipazine. The four groups were as follows: saline + saline + saline; saline + saline + quipazine; MSH + pirenperone + saline; MSH + pirenperone + quipazine. The doses of MSH and pirenperone used were those employed in Experiment 2 while the dose of quipazine used was that employed in Experiment 1. Results indicated that the mean LQ for the MSH + pirenperone + saline group was significantly lower than the mean LQ for the MSH + pirenperone + quipazine group, which did not differ from the mean LQ for the saline only group.

These results suggest that the inhibitory action of MSH on receptivity is mediated, at least in part, by an MSH-induced decrease in 5-HT_2 activity.

182.6 CENTRALLY ADMINISTERED RAT HYPOTHALAMIC GROWTH HORMONE-RELEASING FACTOR STIMULATES FOOD INTAKE IN FREE-FEEDING RATS F.J. Vaccarino, D. Feifel*, J. Rivier[1], W. Vale[1], and G.F. Koob[2]. Dept. of Psychology, Univ. of Toronto, 100 St. George Street, Toronto, Ont., Canada M5S 1A1; [1]Peptide Bio. Lab., Salk Inst. for Biol. Stud., La Jolla, CA; [2]Scripps Clinic and Res. Fdn., La Jolla, CA.

Recent findings from our laboratory (*Nature*, 314:6007, 1985) suggest that rat hypothalamic growth hormone-releasing factor (rhGRF) can stimulate food intake in hungry rats. We found that intracerebroventricular (icv) microinjections of rhGRF in pmole doses increased food intake in food-deprived rats. Since peripheral injections of rhGRF or growth hormone did not influence food intake, these findings were taken to suggest that rhGRF may be acting centrally to stimulate food intake. While these results demonstrate that central injections of rhGRF can stimulate food intake in food-deprived rats, the extent to which rhGRF stimulates food intake in non-deprived rats is unknown. Thus, the present study examined the effects of central rhGRF microinjections on food intake in rats with food and water made available ad libitum.

The food (Purina Rat Chow) and water of adult male Wistar rats with unilateral cannula implants aimed at the left or right lateral ventricle was measured for a 90 minute period (9:00-10:30 AM) on five consecutive days. On the sixth day rats were tested for food and water intake following icv microinjections of one of the following rhGRF doses: 0.0, 0.4, 4.0 or 40.0 pmoles. RhGRF was administered in a 2 µl volume of 0.01% ascorbic acid vehicle with a 30 gauge injector using gravitational force.

The results demonstrate that icv microinjections of rhGRF produce increases in food intake. The mean percent baseline food intake ± SEM following icv microinjections of 0.0 pmoles (vehicle), 0.4 pmoles, 4.0 pmoles and 40.0 pmoles rhGRF was 86 ± 7, 130 ± 17, 169 ± 37 and 133 ± 16, respectively. No significant effect of rhGRF on water intake was observed. There were no significant differences in baseline food intake across the four groups tested. The present results demonstrate that in addition to stimulating food intake in food-deprived rats, rhGRF can stimulate food intake in free-feeding rats. Based on the finding that neither growth hormone nor rhGRF influence food intake following peripheral administration, the present rhGRF-induced increase in food intake may reflect a direct central action of rhGRF. This further suggests that central and peripheral functions of rhGRF may collectively underly growth processes in an integrated manner. This research was supported by a grant from the Life Sciences Division at the University of Toronto.

182.7 **INTRAHIPPOCAMPAL INJECTION OF CYSTEAMINE DEPLETES SOMATOSTATIN AND PRODUCES COGNITIVE IMPAIRMENTS IN THE RAT.** T. J. Walsh*, D. F. Emerich*, A. Winocur, C. Banki*, G. Bissette and C. B. Nemeroff (SPON: A. L. Riley). Univ. North Carolina School of Medicine, Chapel Hill, NC, 27514, Univ. Pennsylvania Sch. Medicine and Duke University Medical School.

Somatostatin (SRIF) is a tetradecapeptide which is widely distributed in the mammalian CNS. While the role of SRIF in the inhibition of growth hormone release is well established its' potential non-endocrine functions remain uncertain. Recently, several lines of evidence indicate that SRIF modulates learning and memory processes. For example, SRIF attenuates the amnestic effects of ECS (Vecsei et al., Peptides 4, 293, 1983). Furthermore, the concentrations of SRIF are reduced in the hippocampus (HPC), and other brain regions, in neuropsychiatric disorders which are characterized by cognitive impairments (Davies and Terry, Neurobiol. Aging, 2, 9,1983). The studies presented here sought to further examine the functional role of SRIF in the HPC.

Preliminary studies revealed that 30 ug of cysteamine bilaterally injected into the HPC produced a significant decrease of SRIF content (55 %) in this structure 72 hrs following surgery. The content of met-enkephalin in the HPC was not affected by this regimen. The concentrations of SRIF in the olfactory tubercles, striatum, frontal cortex and hypothalamus (HYP) were not affected.

A second series of studies examined the behavioral effects produced by intrahippocampal injections of cysteamine. Male Fischer rats bilaterally injected with cysteamine (30 ug site) 72 hrs prior to training exhibited impaired retention of a passive avoidance response. Initial step-through latencies during the training trial and sensitivity to footshock were not affected by cysteamine. Thus, the retention deficit probably represents an impairment in the acquisition or retention of the task. In contrast, systemic administration of cysteamine (200 mg/kg, i.p.) reduced SRIF content only in the HYP and produced no cognitive deficits. Intrahippocampal cysteamine also produced a persistent decrease in locomotor activity. This finding is in contrast to numerous studies showing that manipulation of the HPC proper, its subfields, and its cholinergic afferents reliably increases motor activity. Another unexpected observation was that intrahippocampal cysteamine produced a significant increase (72 %) in the concentration of TRH in the HPC.

The data presented here suggest that (1) cysteamine produces a regionally specific decrease of SRIF following intracerebral injection, (2) decreases of SRIF in the HPC are associated with cognitive deficits, (3) the decreases of SRIF observed in Alzheimer's Disease probably have clinical significance, (4) there might be important interactions between SRIF and TRH in the HPC, and (5) cysteamine is a useful tool for exploring the neurobiology of SRIF.

182.8 BEHAVIORAL CHANGES FOLLOWING CENTRAL INJECTION OF CYSTEAMINE IN RATS. C. Bakhit and N. R. Swerdlow, Scripps Clinic and Research Foundation, La Jolla, CA 92037.

Recent studies of the peptide somatostatin (SS) in the CNS have documented its presence, calcium-dependent release, high-affinity binding, excitatory or inhibitory effects on cortical and hippocampal neural activity, and behavioral potency when administered intracerebroventricularly (icv). Altered SS activity has been implicated in the pathophysiology of several CNS disorders, including Alzheimer's disease. In the present study, we utilized the SS depleting agent cysteamine (CYS) to examine the effects of CNS SS depletion on locomotor activity and passive avoidance behavior in rats.

Male Wistar rats (n=51) were surgically implanted with icv cannulae. Each rat was injected daily for four days with either 0, 250 or 350 ug CYS icv. One day later, one group of rats was decapitated, and cortex (CX), hippocampus (HC) and hypothalamus (HT) were removed for analysis of tissue SS-14 levels. A second group of rats was tested for their levels of locomotor activity three days following the final CYS injection using automated photocell cages. Beginning one day later, these rats were trained on two consecutive days in a simple runway passive avoidance paradigm; testing took place one day after training. Following completion of testing, these animals were decapitated, and regional SS-14 levels were measured as above.

SS-14 levels in CX, HC and HT showed a significant dose-dependent decrease one day following four daily icv CYS injections. Following completion of behavioral testing, however, SS-14 levels were recovered in CX and HT in animals treated with 250 ug CYS; SS-14 levels in HC were actually elevated in these animals. Levels in CX and HC in animals treated with 350 ug CYS recovered to control levels in CX and HC by this time, but remained depressed in HT.

Photocell activity was significantly elevated in rats treated with 250 ug CYS, but not 350 ug CYS, compared to controls (0 ug). In contrast, passive avoidance performance was significantly impaired in rats treated with 350 ug CYS, but not 250 ug CYS, compared to controls. Our results suggest that changes in CNS SS-14 activity may disrupt central substrates of complicated behaviors such as locomotor activity and passive avoidance. 182.9 SUBSTANCE P ANALOGUE ANTAGONISTS ACT AS SUBSTANCE P AGONISTS IN THE RAT SEPTUM. J.R. Zucker*, H. Lai* and A. Horita* (SPON: R. Haschke). Depts. of Anesthesiology, Pharmacology and Psychiatry, Univ. of Washington, Seattle, WA 98195

Intraseptal microinjection of Substance P (SP) has been shown to reduce the hippocampal turnover rate of acetylcholine (Wood et al, Neuroscience 4:1479, 1979). In the present study, we micro-injected saline, SP, and two analogues of SP ([D-Arg^{1}, D-Pro^{2},D-Trp^{7,9}, Leu^{11}]-SP and [D-Pro^{2}, D-Trp^{7,9},]-SP) into the septum of rats pretreated with pentobarbital and measured the duration of loss of righting reflex and change in choline uptake into hippocampal synaptosomes. Synaptosomal choline uptake from a medium containing 0.3 µM choline chloride and 0.4 µCi of [^{3}H] choline was performed for 4 minutes at 38°C. Nonspecific uptake was from an identical medium containing 2 µM hemicholinium-3 and was approximately 55% of total uptake. Uptake into hippocampal synaptosomes from unanesthetized rats was 31.1 (SEM±1.0) pM choline/4 min/mg protein.

Compared with microinjection of saline, all three drugs potentiated pentobarbital narcosis. Additionally the pentobarbital-induced reduction (27%) of hippocampal synaptosomal choline uptake was potentiated (44-56%) by all three drugs. There was a negative correlation ($r=-0.96$, $p<0.02$) between the durations of loss of righting reflex and hippocampal synaptosomal choline uptake. These data suggest that pentobarbital narcosis may be inversely related to septal-hippocampal cholinergic activity. Significantly, the two analogues of SP that were tested in the septum appear to be acting as SP agonists at that site, in their ability both to reduce septal-hippocampal cholinergic activity and to potentiate pentobarbital narcosis. This is in contrast to their reported action as SP antagonists in various peripheral tissues.

182.10 **PROLACTIN INDUCES YAWNING IN YOUNG ADULT MALE RATS.** N.J.Laping* and V.D.Ramirez (SPON:J.Chan). Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

Previously we reported that prolactin (PRL) infused directly into the caudate nucleus of freely moving rats was capable of activating dopaminergic terminals and in some cases yawning behavior was observed (Chen, J.C. et al., In International Congress on Prolactin, 1984, p. 161). In this report we examined the effect of systemic PRL on yawning behavior. First, we confirmed that in our laboratory and under our conditions, apomorphine (APO) induces yawning in young adult male rats at doses where it is considered to be a dopamine antagonist (binding to dopamine autoreceptors). Also, we have found that these animals yawn more in the afternoon at 16:00h (28 yawns/60 min) than at 10:00h (16/60 min) in response to APO (100 µg/kg body weight).

Herein we report that a subcutaneous injection of low doses of ovine prolactin (oPRL) can induce yawning in young adult male rats (n=8 per group). The most effective doses were 0.25 and 2.5 µg/kg body weight (5 and 4.5 yawns/60 min at 10:00h vs 0.3 in control animals). Doses of 0.025, 0.05, 25 and 250 µg/kg were less effective. The number of yawns per hour were 0.6, 3.0, 2.6 and 0.6 respectively. In addition, grooming behavior was observed with the higher doses of oPRL. Interestingly, yawning in response to oPRL changes over the course of one circadian cycle with the highest number of yawns occurring at 16:00h (11 yawns/80 min). The other times tested, 6:00h, 10:00h and 24:00h showed a mean response of 4, 4.5 and 8 yawns per 80 min respectively. A control group received 0.25 µg/kg boiled oPRL at 16:00h and showed a mean of 2 yawns per 80 min. The average onset of yawning began 37 minutes after the oPRL injection whereas with APO the latency of the response was 12 min at 10:00h. Also, the latency for both oPRL and and APO treatments shift to a shorter time; 23 min and 6 min respectively in the afternoon at 16:00h. This shift was only significant for the oPRL treated animals.

These results indicate that oPRL in addition to other hypophysial peptides such as ACTH and MSH can stimulate yawning. It is proposed that PRL after initial activation of the nigrostriatal dopamine system secondarily induces yawning by inhibiting this system via a negative feedback mechanism using autoreceptors. This may explain the longer latency of ovine prolactin to induce yawning as compared to apomorphine.

182.11 NEUROTENSIN AND 3,3'-DIMETHYLPROLINE-TRH (D-TRH): EFFECTS ON SPONTANEOUS BEHAVIOR AND REINFORCEMENT PROCESSES IN RATS. G. Meisenberg, W.H. Simmons* and Y. Sayeed*. Dep. of Biochem., Ross Univ. Med. Sch., P.O. Box 266, Roseau, Dominica (West Indies) and Dep. of Biochem., Loyola Univ. Med. Sch., Maywood, IL 60153.

After intracerebroventricular (i.c.v.) injection in rats, neurotensin (NT), tested at doses of 0.46, 1.86, 7.5 and 30 μg, significantly reduced locomotor activity (7.5 and 30 μg) and grooming behavior (0.46 and 30 μg) in the open field when determined 10-15 minutes after the injection. D-TRH, tested at doses of 0.063, 0.25, 1.0 and 4.0 μg, reduced locomotion (1.0 μg) and rearing (0.25, 1.0 and 4.0 μg) and induced wet-dog shakes (0.25, 1.0, 4.0 μg). NT (0.46-30 μg) did not significantly change responding for electrical self-stimulation of the lateral hypothalamus (square wave, bidirectional pulse-pairs, 100 Hz, train duration 0.2 seconds) when determined 10-20 minutes after i.c.v. administration. D-TRH significantly suppressed responding at 0.25, 1.0 and 4.0 μg. After administration of NT (1.86 and 7.5 μg) and D-TRH (0.063 and 0.25 μg) in the ipsi- or contralateral nucleus accumbens, self-stimulation was increased after ipsilateral injection of 0.063 μg D-TRH and decreased after ipsilateral injection of 0.25 μg D-TRH. All other treatments were ineffective. In the conditioned place-preference paradigm, both 4.0 μg of D-TRH and 30 μg of NT did not induce significant preference or aversion for the treatment-compartment, suggesting a lack of pronounced rewarding or aversive properties or ambivalent motivational effects at these doses. These data suggest that NT does not specifically attenuate reinforcement processes at the level of the nucleus accumbens while low doses of intra-accumbens D-TRH cause enhancement of self-stimulation and high doses of D-TRH reduce self-stimulation. Both peptides did not show significant aversive properties, suggesting that peptide-induced reductions of motor activity and the induction of wet-dog shakes, respectively, are not secondary to peptide-induced aversion.

182.12 THYROTROPIN RELEASING HORMONE (TRH) REMAINS ELEVATED IN LIMBIC REGIONS FOR 1-2 WEEKS FOLLOWING ELECTROCONVULSIVE SHOCK (ECS). A. Sattin, T.G. Hill*, J.L. Meyerhoff and M.J. Kubek, Depts. of Psychiat. and Anat., Indiana U. Sch. Med. and VAMC, Indianapolis, IN 46223; Dept. Med. Neurosci., Walter Reed Army Inst. Res., Washington, DC 20012.

We have previously reported large increases in TRH content of specific limbic and cortical regions of rat brain 2 days following 3-5 alternate-day ECS (Life Sci. 34, 1149-52, 1984; 36; 315-20, 1985). This phenomenon is not elicited by subconvulsive shock and a single ECS elicits a smaller effect only in pyriform cortex (Pyr). This effect was seen only in Pyr, hippocampus (HC), amygdala (Ay) and posterior cortex (P.Ctx). Several other limbic regions and frontal Ctx were unaffected.

Tonic-clonic seizures were induced in male S-D rats (150-180g) with 35-60 millicoulombs (60 Hz a.c.). Sham ECS rats received identical handling but no current. Sham rats (n=12) and ECS rats (n=8) received either 1 or 3 treatments on alternate days, and were sacrificed 2, 6 and 12 days later. Brains were removed immediately, dissected, weighed and frozen on solid CO_2. TRH was assayed by specific RIA following HAc extraction and results expressed as pg/mg tissue (mean ± SEM). Student t-tests (2-tailed) were performed following log transformation of original data.

Significant increases in TRH were seen two days after 1 ECS in HC (6.03+0.34 vs. 10.51+0.91, $P < .001$) and Pyr (3.83+0.34 vs. 10.30+1.18, $P < .001$) where it remained elevated for 6 days (9.29 +0.64, $P < .001$ and 7.30+0.67, $P < .001$, respectively). Two and 6 days after 3 alternate-day ECS, TRH was increased in HC (16.63 +1.30, $P < .001$; 8.58+0.66, $P < .005$), Pyr (30.09+2.17, $P < .001$; 14.59+1.87, $P < .001$) and Ay (42.77+1.65, $P < .001$; 29.19+1.86, $P < .02$). By 12 days TRH remained significantly elevated only in Pyr (5.60+0.29, $P < .005$). In P.Ctx the ECS effect on TRH lasted only 2 days after 3 seizures (2.36+0.32 vs. 3.14+0.29, $P < .01$) and no significant effects were seen in striatum, anterior Ctx + olfactory tubercle or hypothalamus with either 1 or 3 ECS.

These data confirm our previous results showing a greater increase in TRH after 3 ECS than after 1 ECS. Those differences now appear to be reflected in the greater magnitude and duration of the effect in Pyr than in HC, Ay and Ctx. The results suggest a possible long-term neuromodulatory role for TRH neurons and/or their processes in HC, Ay and Pyr, especially in Pyr where both TRH receptors and TRH metabolism are high. These data also support a role for endogenous TRH as antiepileptic and/or antidepressant, although the mechanism(s) responsible for such changes in TRH in specific CNS regions remain unknown. (VA Res. Serv. and AM 28260).

NEUROPEPTIDES AND BEHAVIOR: VASOPRESSIN

183.1 **MICROINJECTION OF KAINIC ACID INTO THE MEDIAL PREOPTIC AREA OF GOLDEN HAMSTERS INHIBITS VASOPRESSIN-DEPENDENT FLANK-MARKING BEHAVIOR** C.F. Ferris* D. Meenan,* J. Pollock,* H.E. Albers (SPON: P. Grigg). Department of Physiology, University of Massachusetts Medical Center, Worcester MA. 01605.

Scent-marking, a form of olfactory communication, is a complex behavior exhibited by many animals in which urine, feces, sweat or glandular secretion is disseminated in the environment. Golden hamsters scent-mark by rubbing specialized glands, flank glands, against vertical objects. This behavior, called flank-marking, can normally be elicited by odors or aggressive encounters from other hamsters. We have previously reported that microinjection of arginine vasopressin (AVP) into the medial preoptic area (MPOA) of hamsters triggers flank-marking (Ferris et al., Science 224:521, 1984) and that microinjection of a specific AVP antagonist into the same site blocks both the effect of injected AVP as well as flank-marking elicited by odors from other hamsters (Ferris et al., Neurosci. Lett., in press). The present studies investigated whether the neurotoxin, kainic acid, microinjected into the MPOA could inhibit flank-marking behavior. Male hamsters were anesthetized and implanted with guide cannulae stereotaxically aimed at the MPOA. The correct placement of the guide cannulae was tested by microinjecting animals with 0.1 ng of AVP in a volume of 10 nanoliters. Animals responding to AVP were then tested on the following night for flank-marking behavior elicited by placing the hamster into the recently vacated home cage of another hamster. On a subsequent day animals were microinjected with 0.2 μg of kainic acid in a volume of 20 nanoliters or a vehicle control of 1 M NaOH. Four days later animals were again tested for odor-elicited flank-marking behavior. The odor-elicited flank marks observed over a 10 min period prior to these injections was 7.0±.83 and 9.0±1.14 for the kainic acid (n=5) and control (n=5) groups, respectively. Following the microinjections there was a significant ($p<.01$) decrease in the number of flank-marks observed in the kainic acid group (1.8±1.1) while flank-marking remained unchanged in the control group (9.0±2.24). When tested with AVP, animals treated with kainic acid flank-marked significanly fewer times ($p<.01$) than animals treated with the vehicle control (6.0±5.0 and 41.2±13.8, respectively). Microinjection of kainic acid (0.2ug/20nl) into the 3rd ventricle (n=3) and other sites in the hypothalamus (n=4) did not inhibit the odor-elicited flank-marking. These data indicate that the discrete microinjection of kainic acid into the area of the MPOA, responsible for the expression of flank-marking behavior in golden hamsters, can inhibit flank-marking behavior elicited by placing a hamster into the recently vacated home cage of another hamster. (Supported by HD-18022 and GM-34798).

183.2 DIFFERENTIAL PAVLOVIAN CARDIAC CONDITIONING FOLLOWING ANALOGS OF VASOPRESSIN AND ACTH. James D. Valentine* and Linda L. Hernandez. WJB Dorn VA Hospital, and University of S.C., Columbia, SC 29201

Previous work has shown that both des-Gly-Arg^9-vasopressin (DGAVP) and ACTH4-10 enhance bradycardiac orienting responses in rabbits. Furthermore, both ACTH4-10 and Asu-Arg-vasopressin delay disappearance of heart-rate conditioned responses (HR CRs) when administered before extinction of simple conditioning. Since DGAVP and ACTH4-10 have little, if any, peripheral endocrine activity, these effects probably occur via central mechanisms. The present experiment examined the effects of DGAVP and ACTH4-10 on discriminative HR CRs in rabbits, when administered both before initial acquisition and before extinction testing.

Rabbits were subjected to differential Pavlovian conditioning using 2-sec tones as conditional stimuli (CSs) and a 500 msec paraorbital shock as the unconditioned stimulus (US); one tone (CS+) was followed by shock and one tone (CS-) was not. Four consecutive daily sessions were conducted. Session 1 consisted of 60 acquisition (paired CS-US) trials. Sessions 2 and 3 consisted of 30 acquisition, followed by 30 extinction (CS-only) trials. Session 4 included 10 acquisition and then 50 extinction trials. Either saline, DGAVP (5 or 25 μg/kg, s.c.) or ACTH4-10 (50 or 250 μg/kg, s.c.) were administered 1 hour before both sessions 1 and 3.

The results showed that DGAVP had few effects during initial training compared to saline. However, the 5 μg/kg dose decreased bradycardiac HR CR magnitude during sessions 2 and 3, and both doses delayed the rate of deceleration during these sessions. During session 4, following no differential treatment of the groups, 25 μg/kg DGAVP increased the magnitude of the HR deceleration. In contrast, 50 μg/kg ACTH4-10 increased HR CR magnitude throughout initial training. The 250 μg/kg dose had a similar effect, but only early in session 1. Early in session 2, when no differential treatment had occurred, both doses of ACTH decreased the magnitude of the HR CR. In session 3, 50 μg/kg ACTH increased HR CR magnitude during early trials, whereas 250 μg/kg decreased HR CR magnitude throughout this session. Additionally, in sessions 3 and 4, 50 μg/kg ACTH increased the magnitude of the HR deceleration to the CS-.

Thus, DGAVP appears to delay extinction of discriminative HR CRs; this compound had few effects on initial acquisition but altered the topography of the HR CR during subsequent sessions. In contrast, ACTH4-10 enhanced HR CRs during initial training and thus may affect stimulus processing or attention functions. During later sessions the lower dose also appeared to disrupt the discrimination since it enhanced decelerations to the CS-.

Supported by VA institutional research funds.

183.3 VASOPRESSIN REACTIVATES MEMORY AFTER HYPOTHERMIA INDUCED AMNESIA T. P. Tinius*, B. E. Beckwith, K. A. Tinius*, P. Traynor*, and N. Wagner* Psychol. Dept. Univ of North Dakota, Box 7187, Grand Forks, ND 58202.

Studies testing the effect of vasopressin on memory processes have often failed to use an established model of animal memory, such as the contextual cues theory (Spear, The processing of memories: Forgetting and retention, 1978), to explain how vasopressin influences memory. The present experiment was designed to assess whether vasopressin would reactivate memory at a 24 hr. retention interval when an amnestic treatment was administered after the learning trial. Sixty-two Holtzman albino rats were either pretrained or nonpretrained prior to the learning trial of a one trial step through passive avoidance task. Pretrained animals were placed in the dark chamber of the passive avoidance box for 2 minutes immediately followed by 1 trial to enter the dark chamber on day 1, and 2 additional traits to enter the dark chamber prior to the learning trial on day 2. The nonpretrained animals were placed in a clear plexiglass box for 2 min., taken out, and placed in the box for another 10 sec. on day 1, and then placed in the clear plexiglass box for two 10 sec. periods prior to the learning trial given in the passive avoidance chamber on day 2. Immediately after the learning trial all animals were immersed in ice water until their body temperature was reduced to 10 C. Twenty-three and one-half hours after the learning trial half of the pretrained animals and half of the nonpretrained animals were injected with Arginine Vasopressin (1 ug/.1 ml i.p.), while the remaining animals were injected with an equal volume of placebo. One-half hour later, all animals were given a single retention trial.

The results revealed that the pretrained animals treated with vasopressin had a marginally longer initial latency to enter the dark chamber than did the pretrained animals treated with placebo, a significantly longer latency than the nonpretrained animals treated with placebo, but not a significantly longer latency than the nonpretrained animals treated with vasopressin. The pretrained animals treated with vasopressin spent significantly more time on the safe side than all other groups. Thus, vasopressin reactivated memory only when the animals were pretrained to the apparatus.

Pretraining may establish inactive contextual cues which are different from contextual cues established at the learning trial and disrupted by the amnestic treatment. Vasopressin administered prior to the test trial appears to reactivate the cues established during pretraining which in turn reactivates memory at the test trial. The results also suggest that the peptide hormones adrenocorticotropin (ACTH) and vasopressin reactivate memory after an amnestic treatment through different mechanisms of memory retrieval.

183.4 EFFECTS OF VASOPRESSIN ON CRF-INDUCED BEHAVIOR. D.R. Britton, M. Varela*, A. Garcia*, M. Rosenthal*. Dept. of Physiology, Univ. of New Mexico Sch. of Medicine, Albuquerque, N.M. 87131

Arginine vasopressin (AVP) has been known for some time to have common effects with CRF_{1-41}. Both peptides release ACTH from pituitary cells in vitro and in vivo. More recently it has been shown that intracerebral ventricular (icv) administration of AVP decreases the release of endogenous CRF into the hypophyseal portal circulatoin (Plotsky et al., 1985). Both CRF and AVP are most highly concentrated not only in the same brain regions, but are co-localized in some of the same neurons (Roth et al., 1982; Swanson et al., 1984). In addition, both CRF and AVP have been shown to prolong extinction of a conditioned avoidance response. On the other hand, they appear to have some effects which are antagonistic to one another. CRF, when administered to animals in their home cages appears to have arrousing or stress-like properties (Britton et al., 1982, 1984; Sutton et al., 1982). On the other hand, AVP has been reported to have sedative like properties (Krejci et al., 1979).

Given the relationship between these two peptides, we tested animals which had been given a standard behaviorally active dose of 0.5 ug of CRF icv and co-treated with AVP either icv or sc. Animals given CRF alone displayed typical CRF home cage behavior. They showed a decreased food consumption following a 24 hr. fast. They had increased grooming and increased locomotion. Animals treated with AVP alone demonstated a dose related (up to 10 ug/Kg, s.c.) primary effect of sedation. There were no significant changes in amount of grooming. There was a slight decrease in the amount of time spent eating and an increase in the number of observations of inactivity. The combination of CRF and AVP resulted in an increase in the number of inactive periods compared to either CRF alone or AVP alone. Given the previous demonstrations of hypertension produced independently by both of these treatments, it is possible that the observed decrease in activity with combined treatment reflects additive effects on blood pressure.

183.5 INDUCTION OF GROOMING BY NEUROHYPOPHYSEAL NONAPEPTIDES AND ANALOGUES: BLOCKADE WITH PROSTAGLANDIN SYNTHESIS INHIBITORS J.D. Caldwell*, C.A. Pedersen, F. Drago#**, V.J. Hruby+**, and A.J. Prange, Jr. Biological Sciences Research Center and the Neurobiology Curriculum, Department of Psychiatry, University of North Carolina, Chapel Hill, NC; #Institute of Pharmacology, University of Catania, Catania, Italy; +University of Arizona, Department of Biochemistry, Tucson, AR

We have demonstrated that oxytocin (OXY) injected intracerebroventricularly (ICV) increased grooming behavior in both male and female rats. We now report the comparative grooming behavioral efficacy and potency of OXY, arginine vasopressin (AVP), arginine-vasotocin (AVT) and various analogues of OXY after ICV administration. AVP and AVT both demonstrated inverted U dose-response relationships across a dose range of 0.05 - 5 µg while OXY followed a linear dose-response curve. Behavior was measured as the number of 15 second intervals in which body or paw licking or scratching occurred over a 30 min observation period beginning 25 mins after ICV infusion of peptides. Maximum grooming scores following AVP and AVT injections, while not significantly greater than for OXY, were seen at doses of 0.5 and 0.1 µg respectively; whereas maximum grooming resulted after injection of 10 µg OXY. At the 0.1 and 0.5 µg doses AVT and AVP induced significantly ($p < .05$) more grooming than equal doses of OXY (Bonferroni's comparisons). We concluded from these data that the neural substrate mediating grooming is more sensitive to AVT and AVP than OXY. We then compared the grooming effectiveness of 1 µg OXY to equimolar doses of several analogues of OXY with various uterotonic potencies. Deamino-oxytocin, which is almost twice as potent as OXY in inducing uterine contraction, was slightly but not significantly less potent than OXY in inducing grooming. [deamino-4-homoglutamine]-OXY, which has 20% of the uterotonic potency of OXY, displayed 70% of the potency of OXY at this dose. Analogues oxypressin, [9-decarboxyamido]-OXY, [deamino-7-alanine]-OXY, and [3-cyclohexylalanine]-OXY did not significantly enhance grooming. It appears from these data that for some OXY analogues their uterotonic potency does not parallel their grooming-inducing potency. Injections of either of the prostaglandin synthesis inhibitors indomethacin (5 mg/kg) or acetylsalicyclic acid (50 mg/kg) ip thirty minutes before ICV injections significantly ($p < .05$) blocked the excessive grooming resulting from 1 µg OXY (Tukey's comparisons). From these data we suggest that OXY may induce grooming behaviors by increasing prostaglandin activity.

183.6 OSMOTIC STRESS MIMICS EFFECTS OF VASOPRESSIN ON INHIBITORY AVOIDANCE TASK. C.J. Lebrun, T.L. Wall, M. Le Moal* and G.F. Koob. (SPON: B. Will). Div. Preclin. Neurosci. Endocrin., Scripps Clin. and Res. Fdn., La Jolla, CA; *INSERM, Unite 259, Bordeaux, France.

Arginine vasopressin (AVP) or antidiuretic hormone (ADH), has been hypothesized to have a role in the retention of learned responses in addition to its clinical physiological functions of water retention and modulation of blood pressure. However the relationship of the behavioral effects produced by exogenously administered AVP and the behavioral function, if any, of endogenously released AVP have never been evaluated. The purpose of the present study was to determine if a potent peripheral osmotic stimulus, the intraperitoneal injection (IP) of hypertonic saline, at doses known to release AVP both centrally and peripherally produce behavioral effects similar to those produced by exogenously administered AVP. To test this hypothesis, we examined the effects of peripheral injections of AVP and hypertonic saline (NACL) on the retention of an inhibitory avoidance task (Martinez et al., Physiol Behav. 19: 139-149 (1977). On Day 1, the rat was placed in the shock compartment for 2 min, and then given a pretraining trial in which the rat is placed in the start area, and allowed to step through into the shock compartment without receiving shock. On Day 2, two more pretraining trials were given followed by an acquisition trial, during which the rat received a shock. Immediately following the learning trial, the rats were injected either subcutaneously with AVP (2 µg/rat; 4 µg/rat) or intraperitoneally with NACL (0.25M; 0.5M; 1M). A retention test was given 24 hours later. The results showed (see Table) that an interoceptive osmotic stimulus (hypertonic saline) known to release AVP can mimic the effects of exogenous AVP on learned behavior. We also report that the facilitation of retention of the inhibitory task induced by this osmotic stimulus (NACL 1M) is reversed by pretreatment with the AVP pressor antagonist [1 deaminopenicillamine 2- (O-methyl) tyrosine arginine vasopressin] (dPtyr(Me)AVP) suggesting that endogeneously released AVP may also produce behavioral effects. Table mean (± SEM) latency to enter shock compartment 24 hours after training.

183.7 KINDLING IN SPONTANEOUS HYPERTENSIVE RATS AND WISTAR KYOTO NORMAL RATS. R.S. Greenwood, H.C. Sullivan*, and K. Winstead*. Dept. of Neurol. and Neurobiology Prg., UNC Sch. of Med., Chapel Hill, NC 27514.

Recent studies have suggested that vasopressin may have a role in the generation of some types of seizures. Intraventricularly administered vasopressin has been reported to cause seizures that can be blocked by a vasopressin receptor blocker. Amygdala but not pyriform cortex kindling rates are slower in rats deficient in vasopressin, homozygous Brattleboro rats, compared to Long-Evans controls. Amygdala kindling rates in animals with elevated levels of vasopressin have not been studied. The spontaneous hypertensive (SH) rat has higher plasma and urinary excretion of vasopressin than the genetically related Wistar Kyoto normal (WKYN) rat. In vitro hypothalamic slices from SH rats show greater release of vasopressin than slices from WKYN rats. In the present study we compared the kindling rates and characteristics of SH rats and WKYN rats.

Bipolar stimulating electrodes were implanted in the right amygdala of SH and WKYN rats. After one week, daily kindling stimulation (1 sec train, 60 cps, 400 uA) was begun. Kindling was continued until the animal had reached 3 consecutive stage 5 seizures.

Kindled seizures in SH rats and WKYN rats were not behaviorally different at any kindling stage . Afterdischarge (AD) duration was significantly shorter in SH rats at the start of kindling but not when stage 5 seizures had been achieved. SH rats required significantly fewer stimulations and fewer AD than WKYN rats to reach stage 2, stage 3, stage 4, and stage 5 seizures.

The more rapid rate of kindling in SH rats and the shorter duration of AD in SH rats at the start of kindling is consistent with the hypothesis that vasopressin may play an important role in amygdala kindling.

STRUCTURE AND FUNCTION OF IDENTIFIED CELLS II

184.1 APPARENT MEMBRANE PROPERTIES OF THE MAUTHNER CELL'S LATERAL DENDRITE DEPEND STRONGLY UPON ELECTRICALLY COUPLED AXONS: A HYPOTHESIS BASED ON CABLE THEORY. W.D.Crank* (Spon: S.B.Udin), Div. Neurobiology, Dept. Physiology, SUNYAB, Buffalo, NY 14214.

The goldfish Mauthner (M-) cell has a low input resistance (<200 k-ohm) and a fast time constant (T≅0.4msec) when measured at the soma. These properties have been used to estimate membrane specific resistance, R_M=200ohm-cm^2, and specific capacitance, C_M=2.0uF-cm^{-2} (Crank & Faber, Neurosci. Abstr. 1983). On the lateral dendrite (LD), about 250-500um from the soma, numerous eighth nerve axons are electrotonically coupled to the M-cell by gap junctions. Does the coupling of axons to the LD influence its apparent membrane properties? I have used cable theory to investigate this possibility. Axons are treated as membrane cylinders resistively coupled to an R-C representation of LD membrane, which is assumed isopotential.

This cable model shows that subsequent to instantaneous charging of LD membrane, and after rapid redistribution of charge to coupled axons, voltage decay is ultimately governed by an effective membrane time constant (T_E) having a magnitude between the limits set by the membrane time constant of the M-cell (T_M) and that of the axons coupled to it (T_A). Assuming T_M=1.0msec and T_A=0.20msec (R_M=10^{3}ohm-cm^2; C_M=1.0uF-cm^{-2}; and input resistance of a single axon, R_A=10^{7}ohm), the weighting of M-cell and axonal influences on T_E depends on gap junctional resistance, R_J, of a single axon and the density, n, of axons coupled to LD membrane surface. When R_J=10^7 ohm and n=one axon per 667 um^2, computations yield T_E=0.230 msec and effective membrane resistivity, R_E=118ohm-cm^2. Effective specific capacitance is inferred as: C_E=T_E/R_E=1.95uF-cm^{-2}. When the influence of axons is reduced by increasing R_J to 3x10^{7}ohm, results are: T_E=0.261msec, R_E=210 ohm-cm^2, and C_E=1.24uF-cm^{-2}. These examples reveal that while a membrane may have one set of intrinsic properties (e.g. R_M=10^{3}ohm-cm^2, C_M=1.0uF-cm^{-2}), coupling axons to it can lead to quite different apparent properties--decreased specific resistance, increased specific capacitance, and more rapid time constant--which resemble those estimated for the M-cell. Furthermore, the balance of influences depends on strength of electrotonic coupling.

In summary, the apparent electrical properties of LD membrane are predicted to be influenced in a major way by coupled eighth nerve axons. Because the region of eighth nerve innervation of the M-cell is displaced from the soma, axonal coupling may only partially account for properties measured there.

184.2 COMPUTER SIMULATIONS OF CABLE PARAMETERS PREDICT SIMPLE STRUCTURE-FUNCTION RELATIONSHIPS FOR FROG MYELINATED AXONS. P.G. Funch and A. Belanger*, Div. Neurobiology, Dept. Physiology, SUNY at Buffalo and Biomedical Computing Unit, Yale University School of Medicine, New Haven, CT.

Detailed biophysical data have been obtained using voltage clamp techniques on either nodes of Ranvier or internodes of frog peripheral myelinated fibers (Stämpfli, R.F. Adv. Neurol. 31:11, 1981). However, to date little data exist on the cable parameters of these axons (space constant, λ; time constant, T_m; input resistance, R_{in}) which are required for understanding current flow during action potential propagation. Thus, a distributed electrical model of a myelinated axon was analyzed using NEUROS (P. Guthrie, NIH), a modification of the electrical circuit analysis computer program SPICE, which was suggested by Shepherd and Brayton (Brain Res. 175:377, 1979) for application to neural modelling of arbitrary systems of compartments and physiological properties. Each of 8 internodes was divided into 5 identical parallel RC compartments; each node was a single compartment. The two ends of the "axon" were terminated by resistances ($2R_{in}$) and capacitances ($T_m/2R_{in}$) which simulated semi-infinite cable extensions. Using the electrical and morphological parameters for a typical 14 µm diameter fiber (D) (Stämpfli, ibid.), the model yielded R_{in} = 22 Mohm, λ = 0.320 cm, and T_m = 160 µsec.

Cable theory predicts the following size dependencies for unmyelinated axons: $\lambda \propto d^{1/2}$; $R_{in} \propto d^{-3/2}$; and T_m = constant. There are no corresponding theoretical predictions for myelinated axons. Thus, in order to assess them, the 10 µm diameter axon (d) was scaled to 2 and 4 µm using the following observed structural relationships: 1) internodal length (L) $\propto$ d; 2) Nodal length = 1.27 µm (i.e., nodal area = 4d); and 3) Number of myelin lamellae $\propto$ d (i.e., d/D=constant). This scaling procedure maintained constant ratios of: (total internodal)/(nodal) membrane resistance = 2.55; and (total internodal)/(nodal) capacitance = 2.62. With these structural constraints, the model demonstrated that the following simple predictions hold: $\lambda \propto d$; $R_{in} \propto d^{-1}$; and T_m = constant (e.g., for d = 4 µm, R_{in} = 55.2 Mohm, λ = 0.128 cm, and T_m = 160 µsec). Interestingly, these results confirm Tasaki's observation (Amer. J. Physiol. 127:211, 1939) that an action potential (120 mV) can passively decrement across two successive inactivated nodes (by a factor of $e^{-(3L/\lambda)}$ = 0.153), and yet still be sufficiently large (18mV) to bring the third node to threshold. More generally, it appears that the cable properties of some myelinated axons may have simple dependencies on size which, if experimentally verified, should facilitate our understanding of their functioning.

184.3 **ACTIVE AND PASSIVE PROPAGATION IN INHOMOGENEOUS AXONS: THEORETICAL AND SERIAL EM STUDIES OF VARICOSE UNMYELINATED NERVES.** S. A. Ellias*, M.Greenberg*, and J. K. Stevens. Neurology Service, Mass. Gen. Hosp., Boston Mass., 02114, and Playfair Neurosci. Unit, Toronto Western Hospital, Ontario, Canada.

Complete computer assisted serial E.M. reconstructions of over 70 small unmyelinated rat sciatic nerves reveal that most are actually non-uniform and highly varicose, with diameters ranging between 0.2 microns and 2.0 microns within a single axon. This study analyzes the effects of these inhomogeneities on the "average space constant" and the average conduction velocity in varicose axons. The passive properties are obtained by integrating a generalized ricatti differential equation for a "unidirectional local space constant", l(x). The "average space constant" is defined as the reciprocal of the spatial average of the reciprocal of l(x). The average velocity of propagation of action potentials is calculated separately by numerically integrating Hodgkin Huxley equations using a predictor-corrector method. We find that the average velocity is proportional to the average space constant in varicose axons. This linearity is consistent with the finding that local velocity was proportional to a local space constant in axons with a special class of flare or taper (S. S. Goldstein and W. Rall, Biophys. J., 14:731 1974). Thus, the linear relation between velocity and space constant for axon cylinders may be generalized to inhomogeneous structures under certain assumptions. The dependence of this conclusion upon channel density and the average spatial period of the inhomogeneities will be discussed. In simulations using sinusoidal modulation about a mean radius, the average space constant and velocity were found to be 80% of the velocity of the mean cylinder and 12.5% higher than that of the smallest inside cylinder. In simulations using radii obtained directly from reconstructed unmyelinated rat sciatic nerve, the average space constant and velocity were always close to those expected for the smallest neck (not the larger varicosity) for all but the closest spacings of varicosities. This suggests that simple measurement of axonal diameter can not be used as a predictor of conduction velocity. Moreover, we believe that these findings may have important implications to small fiber neuropathies.

184.4 **HIGHLY IRREGULAR SHAPES OF NORMAL TYPE C AXONS: SERIAL EM STUDY**
Michael Greenberg[1], John Stevens[2], and Samuel Ellias*[3], 1&2) Playfair Neuroscience Unit, Toronto Western Hospital, 1) Department of Anatomy, and Division of Neurosurgery, 2) Department of Physiology, University of Toronto, Toronto, Canada, 3) Department of Neurology, Massachusettes General Hospital, Boston

We have performed serial EM reconstruction of 5-micron length segments of 79 mouse sciatic axons and 20 retinal ganglion cell axons to determine if axons follow rules of shape-generation similar to those described in dendrites (Sasaki, et al, J Cell Biol 98:1279, 1984). Morphometry of axonal cross-sections throughout the length of each reconstruction shows that most axons are highly varicose structures. As a first-order index to variability, the ratio of each axon's maximum cross-sectional area to its minimum is provided below (note: max/min=1 describes a cylinder).

(n=99)	Max/Min	Percentage of Axons
	1	10%
greater than or equal to	2	90%
greater than or equal to	4	25%
greater than or equal to	8	10%

This tabulation indicates that the majority of axons are non-uniform cylinders, with a substantial percentage varying in cross-section areas by factors greater than four. Serial EM reconstruction of the contents of the axons revealed that the regions of axonal expansions, or varicosities, contained organelles, especially mitochondria.

We conclude that (1) at least the type C axons are highly varicose, and consequently one cannot be certain of the dimensions of an axon from single-section measurements. (2) Since mitochondria, as well as other organelles, have been observed to be moving (Allen, et al, Science, 218:1127, 1982), axonal varicosities associated with mitochondria move also; this suggests that axons at any given point along their lengths may vary their cross-sectional area in time. (3) Ellias, Greenberg, Stevens (this session) report that varicosities have important functional consequences upon electrical properties of axons. (4) The presence of organelle-associated varicosities could provide mechanisms to explain certain neuropathies.

184.5 A COMPUTER-ASSISTED VIDEO TECHNIQUE FOR PREPARING PICTURES OF INTRACELLULARLY FILLED, WHOLE-MOUNTED NEURONS IN THE CRICKET.
D.G. Tieman* and R.K. Murphey (SPON: S.B. Tieman). Neurobiology Research Center, State University of New York, Albany, NY 12222.

We have developed a computer-assisted video technique for preparing images of cobalt-chloride impregnated, whole-mounted neurons in the cricket. The primary advantages of the technique are its rapidity and accuracy as a method for gathering, storing and depicting anatomical data. The technique employs optical sections of the whole mount and can produce high resolution photographs with essentially infinite depth-of-field. The depth information available in the optical sections makes the creation of stereo pairs relatively simple.

The technique employs a real-time 512 x 512 digitizing frame store (INTELLECT 100), an LSI-11/23 computer, a 32M byte hard disk and software that we have developed. A TV camera is attached to a microscope and successive "optical sections" are stored digitally as the focussing depth is systematically changed. For the cercal ganglion of the cricket, we routinely store an area of about 500um x 500um with 10-20 optical sections sampled at 16um intervals. After storage, each optical section is feature-enhanced to emphasize elements that are sharply focussed. The final two-dimensional image is generated from the "stack" of optical sections. For each of the 256K points in the final image, a pass is made through the corresponding points in the "stack" of optical sections and the blackest value is saved for use in the final image. For the normal image, the stack is traversed perpendicular to the plane of optical section; for the stereo pairs, the stack is traversed twice, once slanting left of perpendicular and once slanting right of perpendicular. Our procedure requires about 30 minutes of experimenter time to store the optical sections and then 2 to 3 hrs of computer time for enhancing and combining the optical sections. Thus, we have developed an easy and reliable method for demonstrating the 3-D organization of individual neurons in whole-mount preparations. The method is of further interest since it can be easily modified for use with sectioned material.

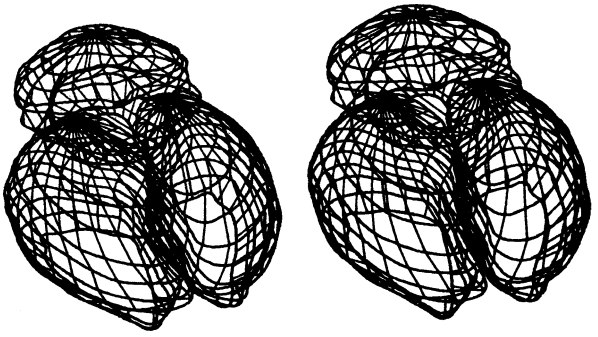
184.6 NEUROANATOMICAL MODELING WITH CADCAM
Mark J. West
Inst. of Anatomy B, Univ. of Aarhus, DENMARK

The increasing availability of programs for computer assisted design and modeling CAD-CAM has prompted an examination of the potential of these programs for making neuroanatomical models. Although originally designed for use with combinations of readily defined geometrical objects or primatives, more advanced versions have facilities for rendering models composed of elements with less regular shapes, such as those associated with biological forms. To demonstrate how programs of this type can be used for neuroanatomical modeling, solid 3-D models of a rat brain, and one of its major components, the hippocampal formation, have been made with the general surface (gsu) feature of Control Data's ICEM solid modeler. In addition to discussing the nature of the data required by the modeling program and describing the process by which this data is obtained from an neuroanatomical specimen, some of the features of the models that promise to be of value in neuroanatomical studies, such as stereo imaging of objects within objects and "slicing" in variable planes, will be illustrated.



184.7 MORPHOLOGICAL AND BIOCHEMICAL EVIDENCE FOR CATECHOLAMINERGIC ACTIVITY IN TISSUE CULTURE OF BRAIN STEM EXPLANTS. B.A. Bennett, M. Morris* and D.K. Sundberg*. Dept. of Physiology and Pharmacology, Bowman Gray Sch. Med., Winston-Salem, NC 27103.

Brain stem ascending and descending catecholaminergic systems are important in controlling endocrine and autonomic function. Areas A1 and A2 of the brain stem were used for tissue culture experiments because of the abundance of noradrenergic (NE) neurons which send input to hypothalamic regions. Both immunocytochemical localization and chromatographic/electrochemical measurement were used to determine the presence of the catecholamines and their synthetic enzymes. Microdissected explants were obtained from neonate rats (3-5 days) and maintained in tissue culture for 1 to 3 wks. For histology, the explants were fixed with acrolein and stained with rabbit anti-tyrosine hydroxylase (TH) or dopamine B hydroxylase (DBH). All tissues were processed using the Vectastain method and the material analyzed by light microscopy. After either 1 or 2 wks in culture, both A1 and A2 regions showed evidence of TH and DBH staining. The TH stain was much more intense with numerous cell bodies with processes present in the explant. The DBH stain was more diffuse, localized mainly in terminals in the explant.

Media and tissues were analyzed for catecholamine content using electrochemical detection after HPLC separation of alumina extracts. The results were similar for the 2 regions. Both media and tissue contained an amine which co-eluted on 2 chromatographic systems with dyhydroxyphenylethyl glycol (DHPG), a monoamine oxidase metabolite. Small amounts of dopamine (DA) were measureable, but NE was not detected. There was also an increase in the DHPG content with tissue culture (a 30 fold change from 1 to 3 wks).

Catecholamine biosynthesis was evaluated by determining the incorporation of ^{3}H-tyrosine (1 hr incubation) into the amines. There was significant incorporation of label into DA.

A model is described for the culture of specific brain stem regions. It is viable on the basis of several criteria: identification of catecholamine synthesizing cells, the presence of catecholamines in both tissue and media, and the ability to incorporate an amino acid precursor into DA. It may prove useful in the investigation of mechanisms controlling autonomic function.

(Supported by NIH HL 30845 and AHA 83227 and 81101)

184.8 GABA AND 5HT IMMUNOREACTIVE NEURONS IN ASCARIS. Antony O.W. Stretton and Carl D. Johnson (SPON: N. Tumosa) Department of Zoology, University of Wisconsin, Madison, WI 53706.

We have previously shown using biochemical assays that acetylcholine synthesis is present in identified branches (commissures) of three classes of excitatory mototneurons (DE1,DE2 and DE3), but not in two classes of inhibitory motorneurons (DI and VI)(J. Neurosci.,in press). ACh is a likely transmitter of the excitatory motorneurons. There have been numerous suggestions that 4-aminobutyric acid (GABA), a compound that hyperpolarizes and relaxes Ascaris muscle cells, may be an inhibitory transmitter at nematode neuromuscular synapses. Consistent with this possibility, we have found that the VI and DI cells are stained with GABA specific antisera. Cell bodies and processes in the ventral nerve cord, commissures and processes in the dorsal nerve cord are all stained. One interesting feature, revealed by staining, is the presence on the inhibitory motorneuron commissures of a short longitudinal branch in the sublateral nerve cord. These branches are prominent in the first three segments, but are not present on VI or DI commissures posterior to the first VI in the fourth segment. Branches off the VI commissure are always in the dorsal sublateral nerve cord, whereas DI commissure branches are in the ventral sublateral nerve cord. Preliminary electrophysiological experiments (by J. Angstadt) suggest that the inhibitory motorneurons recieve excitatory synaptic input from sublateral neurons. In addition to these cord motorneurons, there are at least 10 cells in the ganglia surrounding the nerve ring, one cell in the tail and two cells in the pharynx which stain with the GABA antisera.

There are a bilaterally symmetrical pair of cells in the posterior pharynx which stain intensely with the antisera to serotonin (5HT). Each cell has short posterior branches and two long anterior processes which project forward to the level of the nerve ring where they end in a profusion of small branches. In the female no other cells stain. In males there are, in addition, 5 intensely staining cells in the posterior ventral nerve cord and a number of weakly staining (3 or 4 bilaterally symmetrical pairs) cells in the posterior lateral lines.

Supported by NIH grant AI 20355

184.9 EVOLUTIONARY PROGRESSION IN AN IDENTIFIED SYNAPTIC CONTACT. S.R. Shaw and I.A. Meinertzhagen. Dept. of Psychology, Dalhousie University, Halifax, N.S., Canada B3H 4J1.

In principle, the evolution of a neural network could proceed either by the loss or gain of component neurons inherited from a common ancestor, or by neuronal respecification affecting synaptic connectivity. We have explored the latter possibility in homologous neurons of Diptera (flies), by tracing the connections within the synaptic modules, the cartridges, of the first optic neuropil, the lamina. The compound eye is claimed to have a monophyletic origin (Paulus 1979), suggesting that the lamina cartridges also should be homologous structures; their cellular composition is remarkably constant across different groups, adding further weight to this proposed homology.

The lamina cartridges have been analysed from electron microscopy of short (40-100) series of consecutive sections from 3 representative families of the phylogenetically older Nematocera, and 9 from the more advanced monophyletic suborder Brachycera. In the older families up to the Tabanidae (Brachycera), the photoreceptor terminals form equivalent populations of synaptic contacts, at each of which they are presynaptic to a pair of processes, one each from two axial monopolar cells (homologues of L1 and L2 in Musca). The Mecoptera, which share a common ancestor with Diptera, have the same configuration. The archetype of the synapse is thus dyadic. In the advanced brachyceran families above the Bombyliidae, in Hennig's (1973) taxonomic scheme, however, one extra neuronal process is added at each pole of the postsynaptic pair L1, L2. This tetradic configuration, hitherto the only one described, is thus a later, derived form of the synapse. The two polar elements stem from profiles which resemble, and may thus also be homologous with, α-processes of amacrine cells known in Musca. The transition from dyad to tetrad is not simply a flexibly derived advanced functional trait, for it is no more readily reversed than it was rapidly developed in evolution: flightless, parasitic advanced Brachycera retain the tetradic configuration. Evidence corroborating synaptic evolution comes from fine structure. Both the platform which surmounts the presynaptic ribbon at the tetrad, and the postsynaptic cisternae in L1 and L2 are also derived, advanced structures. Neither is present in lower Diptera, and both are poorly developed in families of intermediate position.

These trends suggest a gradual evolution of some features of this particular synapse, on a time scale which fossil evidence indicates to be about 200 MYr. Within the same period, a single quantum step in postsynaptic configuration has occurred once within the Brachycera, from dyad to tetrad. We believe that this is the first clearly documented case of the evolution of synaptic contacts.

184.10 AXON SIZE DISTRIBUTION: EVOLUTIONARY VARIATION AMONG FLIES. A. J. Benson* and D. G. King (SPON: W. Yau). Dept. of Zoology and Dept. of Anatomy, Southern Illinois University, Carbondale, IL 62901.

Axon diameter is closely related to several functional properties including conduction velocity (or electrotonic decrement in passively conducting axons), synaptic divergence ratio, and current available for electrical transmission. Larger axons should be faster and better able to activate numerous postsynaptic neurons. But smaller axons may be more economical, with lower metabolic costs to support extensive axoplasm. Thus large axons might be expected in pathways where speed, individual reliability, or extensive synaptic output have selective advantage, while small axons might be favored where such factors have less adaptive significance. The most extreme examples of evolutionary specialization affecting individual axonal size are the phylogenetically diverse occurrences of giant fibers in startle-response pathways.

The cervical connective of flies encompasses several thousand axons whose cross-sectional areas can differ by more than three orders of magnitude. A common pattern for axon organization is revealed by the spacial arrangement of identifiable axons and tracts. These display a fair constancy of size and position which is apparent through bilateral symmetry within individuals, close similarity among individuals within a species, and less precise but still recognizable similarities among different species.

Most larger axons are concentrated in a dorsomedial tract, while smaller axons are located ventrally and laterally. The relative size of dorsal-tract axons varies widely among species, so that the proportion of the connective devoted to the 10 largest axons ranges from less than 5% to more than 30%. This proportion appears to be greatest among flies with exceptional flying skill such as asilids, bombyliids and syrphids. One pair of "giant" dorsomedial axons is found in most but not all cyclorrhaphans. One or two pairs of very large axons also occur ventrally in many species; occasionally these large ventral axons assume "giant" proportions. Many flies possess a coherent ventromedial bundle of very small (less than 0.5μm) axons. The number of axons in this bundle is quite variable; no such tract is apparent in several species of diverse taxonomic affinities.

These observations suggest that diversity in the dipteran ventral nervous system may provide an excellent opportunity to explore the genetic and developmental constraints which influence evolutionary differentiation of neuronal form, particularly axon diameter.

184.11 BEHAVIORAL MUTATION *pas* CAUSES CYTOLOGICAL ALTERATIONS IN THE GIANT FIBER PATHWAY AND IN THE GUT OF *DROSOPHILA MELANOGASTER*. D. G. King, Department of Anatomy and Department of Zoology, Southern Illinois University, Carbondale, IL 62901.

The *Drosophila* giant fiber pathway includes cervical giant fibers (CGF), peripherally synapsing interneurons (PSI), and motor axons to the tergotrochanteral muscle (TTM) and the dorsal longitudinal muscle (DLM). In normal flies the CGF synapses with both PSI and TTM axons, while the PSI contacts both TTM and DLM axons. Synaptic transmission from CGF to TTM axon appears to be electrical while CGF transmission via PSI to DLM axons requires one chemical synapse (King & Wyman, *J. Neurocytol.* 9:753, 1980; Tanouye & Wyman, *J. Neurophysiol.* 44:405, 1980). In flies with the mutant genotype *pas*, the CGF is unable to drive action potentials in the DLM, while the latency for CGF activation of the TTM is increased. Motor axons to the TTM and DLM function normally when stimulated directly (Thomas & Wyman, *J. Neurosci.* 4:530, 1984).

Several cytological differences between wild-type and *pas* flies have now been observed. In the nervous system, the PSI can be identified by its chemical synapses onto DLM axons in both *pas* and wild-type flies, although its axon is much less conspicuous in *pas*. Membrane apposition between PSI and CGF and between PSI and TTM is reduced or absent in *pas*, while contact between CGF and TTM is at least as prominent in *pas* as in wild-type, with well-developed chemical synapses. In the cardia (an organ formed around the invagination of the esophagus into the anterior midgut), *pas* flies show enlargement of both short and tall secretory cells (which contribute to formation of the peritrophic membrane) and reduction of the clear zone near the distal limit of the foregut.

These observations confirm that *pas* does alter the connectivity of identifiable neurons. However, they also suggest that the action of this gene is not specific to these neurons, nor even to the nervous system, but involves some general cellular change that effects other organ systems as well. If one assumes that electrical transmission in the giant fiber pathway is mediated by gap junctions interconnecting the CGF, PSI and TTM axons, the neural alterations in *pas* could result from reduction or loss of these gap junctions. Certainly failure of effective short-latency transmission between CGF and DLM is consistent with this hypothesis. Increased latency of CGF to TTM transmission in *pas*, in spite of direct contact between the CGF and TTM axons, suggests that although electrical coupling between these axons might be eliminated in *pas*, the direct CGF-TTM synapse may still allow slower chemical transmission. Extensive gap junctions form a normal feature of gut epithelium in flies; whether alterations in these junctions may also provide a sufficient explanation for the observed modifications of the cardia in *pas* remains unknown.

184.12 SEARCH FOR THE METACEREBRAL GIANT CELL IN DIVERSE GASTROPODS. R.P. Croll. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

A serotonergic, metacerebral giant cell (MCG) has previously been identified in diverse species of two sublasses of gastropods, the opisthobranchs and pulmonates, and it thus represents one of the best existing examples of putative cellular homologies. However, arguments for a common phylogenetic origin for these cells in different species cannot be based solely on similarities between cells in a few extant species. These similarities could be the result of convergent evolution rather than homology. Additional evidence for homology could come from a broader survey of gastropod species. In this way, one can examine whether the MCG is present in all species of opisthobranchs and pulmonates, whether species differences in feeding behaviour (in which the MCG is involved) are correlated with changes in the cell's form and function, and whether a possible phylogenetic origin for the cell can be identified.

In order to address these questions, I have started such a survey. The MCG, in addition to being serotonergic and bilaterally symmetrical, and having a very large soma, is charaterized by its axonal projection out of the cerebral ganglia down the cerebrobuccal connective (CBC). Based upon these characteristics, MCG's in different species can be tentatively identified on the basis of immunohistochemical staining for serotonin and colbalt "backfilling" of the CBC. Once identified, additional information about secondary axonal branching patterns is possible with silver intensification of intracellular cobalt injections. These techniques have now been applied to numerous species of opisthobranchs (including Aplysia californica and Hermissenda crassicornia), pulmonates (including Achatina fulica and Helix aspersa) and prosobranchs (including Littorina litorea and Crepidula fornicata).

Preliminary results confirm earlier studies suggesting that the occurrence of MCG's is generalized throughout the opisthobranchs and pulmonates, despite differences in feeding behaviour. Differences in secondary branching patterns have been noted. Attempts to locate the MCG in the third gastropod subclass, the prosobranchs, which have been hypothesized to represent the evolutionary origin of the opisthobranchs and the pulmonates, have not been successful. It appears that the serotonergic axons in the buccal ganglia and CBC of the prosobranchs arise from one or more clusters of cells in the cerebral ganglia rather than from a single large cell. The evolutionary significance of these findings will be discussed.

184.13 MORPHOLOGICAL AND PHYSIOLOGICAL PROPERTIES OF LAMINA GANGLION CELLS IN CRAYFISH. L.T. Wang-Bennett and R.M. Glantz. Department of Biology, Rice University, Houston, Texas 77005.

Intracellular labeling techniques employing either horseradish peroxidase or lucifer yellow were used to identify lamina ganglion cells physiologically and morphologically. The physiological properties of the penetrated cells: response waveform to light stimuli; receptive field; intensity-response function; and effect of current on light response, etc. were examined. The cell types were revealed following histochemical processing of the eye preparation. This study comprises the first account of the electrophysiological phenomena at the lamina ganglion in Crustacea.

Of the 50 cells studies, we have obtained data on several large to medium field cells (defined by the extent of dendritic spread on the lamina) such as: Tangential$_1$, (Tan$_1$), Tangential$_2$ (Tan$_2$), T-cell, multipolar cell and monopolar type 5 (M5), etc. (see Strausfeld and Nässel 1981 for terminology). Small field monopolar cells (M1-M4) exhibit similar physiological properties; thus, distinguishing among these cells relies upon morphological data.

A major physiological distinction can be made among monopolar cells based on the light response waveforms: nonspiking-hyperpolarization vs. spiking cells. The monopolar cells' hyperpolarizing light response has a transient and a plateau phase (sometimes accompanied by a depolarizing off response). Responses show 30-60% reduction due to lateral inhibition. In some cases the response reversed in polarity when the inhibitory fields were stimulated. The range of intensity-response function is 3.0 log units (s=+ 0.7, n=7). Response onset leads medullary sustaining fiber by 7.9 msec (n=9). Spiking monopolar cells have been recorded from the lamina ganglion. These cells exhibit depolarizing light response with an initial spike rate of 100 Hz.

Light responses of Tan$_1$ and Tan$_2$ are similar in waveform; the hyperpolarizing responses have no separate transient and plateau. Tan$_1$ has dendritic coverage of 151 µm (s=+ 68; n=4) which is accompanied by a 40° receptive field and 5 log units of intensity-response range. The dendrites of Tan$_2$ intersect the entire retinotopic projection; these cells exhibit a diversity of synaptic unitary events. Tan$_1$ and Tan$_2$ show strong spatial summation. This is in contrast to monopolar cells which show no sign of spatial summation. The cell body of Tan$_1$ is located in the medulla. Its axon runs centrifugally into the lamina where its terminals innervate the laminar cells. Tan$_2$ also has a cell body in the medulla and has very broad medullary and lamina lateral branches. The two branches are seen at two different focal planes. Laminar T-cell soma originates in the external chiasma. Spikes are recorded from these cells and its I-R function covers 3 log units.

185.14 IDENTIFICATION OF PEPTIDERGIC NEURONS WITH MONOCLONAL ANTIBODIES RAISED AGAINST HOMOGENATES OF WHOLE CENTRAL NERVOUS SYSTEMS OF THE SNAIL LYMNAEA STAGNALIS. J. van Minnen*, H.H. Boer* and T.A. de Vlieger* (SPON: European Neuroscience Association). Dept. of Biology, Vrije Universiteit, De Boelelaan 1087, 1081 HV Amsterdam, The Netherlands.

Monoclonal antibodies were raised against homogenates of whole central nervous systems (CNS) of the pond snail Lymnaea stagnalis. Selection of antibody producing hybridomas to neural antigens was carried out by staining sections of the CNS with supernatants of the cultures. About seventy percent of the hybridomas produced antibodies against antigens present in the CNS or in the perineurium. Approximately ten percent of the hybridomas were directed against neurons or groups of neurons. Certain antibodies stained selectively known neuroendocrine centres of the snail such as the Caudo-Dorsal Cells (ovulation hormone) and Light Green Cells (growth hormone) and the endocrine Dorsal Bodies, which produce a female gonadotropic hormone. A number of hybridoma cell lines produced antibodies against hitherto unidentified neurons.

It is argued that the antibodies were raised against biologically active peptides and/or their precursors and can be used for the purification of these peptides.

Some of the antibodies also stained neurons in other species (insects and vertebrates).

184.15 MORPHOMETRIC ANALYSIS OF HAMSTER FACIAL AND HYPOGLOSSAL NEURONS FOLLOWING CRUSH INJURY. T.E. Durica and S.K. Jacob. Rush Medical College, Department of Anatomy, Chicago, IL 60612.

Both the short and long term neuronal responses to a crush injury were examined for facial and hypoglossal neurons of the hamster. The right facial and hypoglossal nerves were crushed and the neurons were examined at 5, 30 and 60 days postoperative (dpo). The left side served as control and there were 5 animals for each postoperative time. Point count stereology was used to measure a variety of neuronal cellular components: these included cytoplasmic, nuclear, nucleolar, and total cell area. At 5 dpo, for both the facial and hypoglossal neurons, there was a significant increase in all the measured components which typifies the classical chromatolytic response in motoneurons. At 30 dpo, in both facial and hypoglossal neurons, all measured components were still larger than that for control neurons. However, the size of these components was decreased when compared to those of 5 dpo neurons. Observations on the animals' behavior indicated a functional return for both the facial and hypoglossal musculature at this time. At 60 dpo, for both facial and hypoglossal neurons, all neuronal components were still enlarged being similar in size to that seen at 30 dpo. The only noted difference was in the nucleus of the hypoglossal neurons which was increased in size and was similar to the size of the neuronal nucleus of the 5 dpo hypoglossal neuron. There was no significant loss of neurons at any postoperative time examined in either the facial or hypoglossal motoneuron population. These results show major changes in measured components that may indicate possible alterations in neuronal metabolism during recovery from crush injury. These observations show that crush injury not only produces a significant short term response but also elicits a significant long term response. The long term response suggests that the changes in neuronal architecture may be of a permanent nature even though a functional return has been seen after a relatively short time following crush injury.

184.16 **GENERATION OF ENRICHED POPULATIONS OF CULTURED PHOTORECEPTOR CELLS BY SELECTIVE NEURONAL DESTRUCTION.** L.E. Politi* and R. Adler (SPON: E. Adler-Graschinski). Wynn Center, Wilmer Institute, Johns Hopkins University School of Medicine, Baltimore, MD 21205, and INIBIBB, Bahia Blanca, Argentina.

A monolayer culture system for photoreceptor cells has been recently developed (Adler et al., J. Cell Biol. 99:1173-1178, 1984). Although glial, endothelial, fibroblastic and pigmented epithelial cells are not present in the cultures, biochemical analysis of these photoreceptors is complicated by the presence of other retinal neurons. We have now attempted to eliminate these neurons using kainic acid (KAc) and/or β-bungarotoxin (BBT), which do not affect photoreceptor cells but destroy specific retinal neuronal types (Morgan, Pr. Ret. Res. 2:249, 1982; Hirokawa, Br. Res. 250:309, 1982).

Initially, 8-day chick embryo neural retina cultures were treated for 24 hrs after 6 days in vitro. Both KAc and BBT were capable of destroying many process-bearing neurons in a concentration-dependent manner, and without causing any obvious changes in photoreceptors. Maximal KAc effects (neuronal loss=55-60%) were seen at ca 1.5 mM. BBT destroyed as many as 75% of the neurons at concentrations of 1 nM. This maximal neuronal loss could not be increased by combining KAc+BBT treatments. However, ongoing experiments indicate that combined KAc+BBT treatment results in maximal responses already after 2 hr, when neither KAc nor BBT alone approach the 24 hr level. Neuronal sensitivity to KAc and BBT appeared to be developmentally regulated. Thus, neuronal destruction by KAc was negligible after 2 days in vitro (div), detectable at 4 div, and maximal at 6-8 div.

In summary, then, treatments with KAc and/or BBT offer an important first step for the generation of enriched populations of cultured photoreceptor cells. Their integrity in treated cultures is now being further evaluated by EM, autoradiography and immunocytochemistry. Moreover, procedures are being sought to eliminate a population of small, non process-bearing round cells present in the cultures which are resistent to KAc and BBT.

EFFECTS OF CHRONIC DRUG ADMINISTRATION I

185.1 DETECTION OF DRUG INDUCED NON-STATIONARITIES OF THE ELECTRICAL RHYTHMS OF THE NUCLEUS ACCUMBENS AND AMYGDALA. C.C. Turbes, G.T. Schneider*, R.J. Morgan and T.N. Solie.* Dept. of Anatomy, Creighton University School of Medicine, Omaha, NE 68178.

These are studies of the electrical activity of the extracellular space of the nucleus accumbens and the amygdala. The extracellular microenvironment is a complex medium capable of transmitting information between neurons. The extracellular electrical fields are recorded with microelectrodes. These experiments involve twelve cats. Monopolar and bipolar electrodes with 100 to 200 micron tip exposures are used. Only electrodes with the resistance of 20 megohms or less are used. The electrodes are capable of recording both slow wave potentials and multiple unit spike potentials concurrently. The analog signals are recorded on FM tape and analog to digitally converted and processed with a Varian V-72 minicomputer. In these studies we are interested in electrical activity between 1 Hz to 1 KHz. The d and l isomers of amphetamine are used to enhance the coherence of frequencies from 50 Hz to 1 KHz. To study the interrelationships between these spatially distant neuronal populations, the following signal processing methods are used: coherence, partial coherence and phase spectra. We have utilized certain parametric methods such as autoregressive and cross regressive time stationary spectral filters. The Fast Fourier Transform (FFT) algorithms are used for spectral estimates of continuous analog signals. A large number of epochs of the predrug, during the action of the drug, and postdrug data are used to develop the spectral filter models. The positive values above the average for each frequency are collected and plotted. These methods are used to further characterize the amphetamine induced changes in coherence spectra, autospectra and cross spectra of the nucleus accumbens and certain amygdala nuclei.

There are increases in coherence of certain frequencies above 50 Hz to 1 KHz induced by the amphetamine isomers. Partial coherence estimates showed the interaction of the amygdala and nucleus accumbens. Coherence is influenced by other brain areas synaptically connected. The parametric methods showed synchronous changes at the same frequencies involved in the coherence spectra induced by the amphetamine isomers.

185.2 CHANGES IN SPONTANEOUS FIRING RATE OF NIGRAL NEURONS AFTER CHRONIC HALOPERIDOL. R.F.Gariano*, S.J.Young* and P.M.Groves. Department Psychiatry, School of Medicine, University of California, San Diego, La Jolla, CA 92093.

Chronic treatment with neuroleptic drugs often leads to disabling and sometimes irreversible abnormal movements termed dyskinesias in humans and experimental animals. We are currently investigating the effects of chronic treatment with haloperidol on electrophysiologically identified dopaminergic and non-dopaminergic substantia nigra (SN) neurons in urethane-anaesthetized rats. Animals in the experimental group were administered haloperidol in tap water (0.02mg/ml) ad lib., equivalent to 2mg/kg/day, for four weeks, followed by an 8 day drug free washout period prior to recording. Immunoassay performed at the end of the 8 day drug free period showed that plasma levels of haloperidol were below the limits of detection (1.0ng/ml), corresponding to brain tissue levels of less than 2% of treatment levels (Ohman,R., et al. N.S. Arch. Pharmacol. 299:105, 1977). Approximately 30% of the CHAL rats were cataleptic during the first week of treatment; tolerance developed to this behavioral effect thereafter. A matched control group (CTRL) was maintained on haloperidol-free tap water, available ad lib. All experiments were performed blind with respect to treatment group.

Spontaneous firing rates of pars compacta dopaminergic neurons in the CHAL group were increased 22% over corresponding values for the CTRL group (5.2 vs 4.3 Hz, t=3.03, df=192, $p<.005$). The subset of dopaminergic neurons which were antidromically activated from the striatum showed a similar alteration in firing rate (4.7 vs 3.7 Hz, t=2.10, df=60, $p<.05$). Using the method of terminal excitability testing (Groves,P.M., et al. Brain Res. 221:425, 1981), we are presently investigating the possibility that these effects on firing rate are related to changes in the sensitivity of cell body and/or terminal dopamine autoreceptors. Conversely, spontaneous firing rates of non-dopaminergic pars reticulata neurons in the CHAL group were decreased 35% compared to CTRL pars reticulata neurons (25 vs 38 Hz, t=5.89, df=137, $p<.0001$). These results are of interest in view of the highly stable firing rate of SN dopamine cells across the sleep-waking cycle, the growing recognition of the non-dopaminergic nigral cells in basal ganglia output, an apparent reciprocal relationship between the dopaminergic and non-dopaminergic elements of the SN, and the proposal that GABAergic dysfunction in the basal ganglia may be causally related to the appearance of tardive dyskinesia in humans and primates following long-term neuroleptic therapy (Fibiger,H.C., K.G. Lloyd. TINS 7(12):462, 1984).

Supported by grant DA-02854 and Research Scientist Award DA-00079 to PMG and by NIGMS National Research Service Award 07198 from the UCSD Medical School MSTP to RFG.

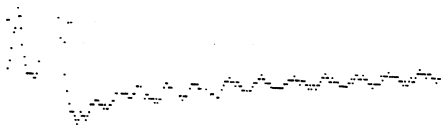
185.3 A COMPUTERIZED TECHNIQUE FOR THE STUDY OF MOUTH MOVEMENTS: EFFECTS OF AGE AND CHRONIC NEUROLEPTICS. Ronald See*, Gaylord Ellison, and Jack Kinney*. Dept. of Psychology and Computer Sciences, UCLA, Los Angeles, CA 90024

Long-term neuroleptic administration has been shown to increase vacuous chewing in rodents, suggesting the possibility of a rodent model of tardive dyskinesia. We have devised a novel method for precisely quantifying oral movements using direct input of video images into a computer. With this technique, subtle alterations in orofacial movements which would be hidden to a human observer can be precisely quantified.

Rats are habituated to a plexiglass tube with an open hole at one end. For testing, 2 small spots of UV-sensitive ink are placed on the upper and lower jaw, and the animal is placed in the tube inside a soundproofed chamber. The only illumination present is from a UV lamp beneath the animal's jaw. The output from a closed-circuit TV camera focused on the animal's mouth region is fed into a specially constructed computer board. This measures the distance (number of TV rasters) between the two spots and places this information into memory 60 times/sec. Oral movements are recorded as the distance between the two dots changes. The resulting data is analyzed for frequency, duration, and train length of oral movements. A very high correlation between oral movements as determined by computer and those reported by the human observer is obtained, particularly for large amplitude oral movements.

In an initial study to establish the validity of this scoring technique, 24 female Sprague-Dawley rats were divided into three equal groups (one control, one low-dose haloperidol, and one high dose haloperidol). Haloperidol was administered using silastic implants containing haloperidol base. These animals were observed once each month for 8 months of continuous haloperidol administration and once each week for 4 weeks following explant. The types of changes in oral movements observed will be discussed.

(Computer record of a typical double open-close oral movement)



(Computer record of an atypical oral movement train following a head movement.)

185.4 HALOPERIDOL TREATMENT OF RATS ALTERS STRIATAL NA,K-ATPASE LEVELS. S.P. Mahadik, P. Aceto*, F. Vilim, A. Korenovsky*, S.E. Karpiak. Div. Neuroscience, NYS Psychiatric Inst., Depts. of Psychiatry, Biochemistry & Molecular Biophysics, Coll. Physicians & Surgeons, Columbia U., 722 W 168th St., NY, NY. 10032.

Neuroleptic treatment of schizophrenic patients often induces extrapyramidal side effects, namely tardive dyskinesia (TD). Since neuroleptics are still a major method of treating schizophrenia, determination of the molecular mechanisms underlying TD may establish methods by which this motor disorder can be eliminated. In the study of such mechanisms, several animal models are available.

One of the neuroleptics, haloperidol, causes an imbalance in dopaminergic-cholinergic transmission, probably due to depolarization blockade of dopaminergic neurons in the nigro-striatal pathway [1]. We are studying the effects of chronic haloperidol treatment on Na,K-ATPase in rat striatum, where the enzyme is present in high concentration in synaptic terminals and plays a role in synaptic transmission, as well as acting as the Na/K pump. Male Sprague-Dawley rats (250gr) were injected daily with haloperidol (2mg/kg i.m.) for various periods of up to 28 weeks. Striatal membranes were prepared from treated rats and saline controls at 1,2,3 days and 2,5,24 & 28 weeks. Na,K-ATPase (determined as total ATPase minus Mg-ATPase with 4mM ouabain, 40mM Tris-HCl, 10mM MgCl2, 150mM NaCl, 40mM KCl, 2mM EDTA, 2mM EGTA, 4mM Tris-ATP, pH 7.5) showed no changes after 1,2 or 3 days of haloperidol treatment. After 2 weeks the level of Na,KATPase increased by 28% and remained elevated (28-40%) for up to 28 weeks. The kinetic properties of Na,K-ATPase as a function of K conc. showed a change in Vmax (3.57 mM vs 2.46 mM for control) but no change in Km (0.45 mM vs 0.46 mM for control) The change in Vmax suggests an increase in the level of Na,K-ATPase. Since we have previously found that chronic haloperidol treatment caused an increase in acetycholinesterase [2], we conclude that chronic haloperidol treatment results in changes of several synaptic membrane enzymes, and these changes may be responsible, or at least contribute, to the dopaminergic-cholinergic imbalance seen in the striatum.

185.5 BEHAVIORAL EFFECTS OF LONG-TERM HALOPERIDOL: INTERACTIONS WITH AMPHETAMINE. A.D. Levy & G. Ellison. Dept. Psychology, UCLA, Los Angeles, CA 90024.

Long-term administration of antipsychotic drugs in humans can produce tardive dyskinesia, as well as other behavioral alterations. In this laboratory we have attempted to model these disorders in rats given continuous long-term administration of haloperidol (HAL), via subcutaneously implanted silicone reservoirs containing 100 mg of HAL. These HAL pillows are designed to release approximately 0.7 mg/kg/day over 8 months of administration. In this experiment we attempted to determine whether amphetamine (AMPH) administration, either concurrent with, or following HAL treatment would alter the syndrome of increased oral movements, or other behavioral effects induced by HAL.

Two groups of 10 rats were implanted with HAL pillows, while two other groups received control pillows. One month later, one HAL and one control group were implanted with slow release AMPH pellets, designed to release approximately 4 mg/kg/day over the 30 days of treatment. During the course of AMPH treatment, locomotor activity and body weights were recorded daily. After 30 days of AMPH administration, animals were monitored monthly for oral movement behavior on a newly developed computerized scoring system. At other times rats were scored for oral movements and activity measurements in a home cage environment. Animals were also observed for limb tremor or changes in gait.

The animals demonstrated some interesting behavioral trends during concurrent AMPH and HAL administration. Animals receiving HAL only showed decreased locomotor activity counts, while rats administered only AMPH showed elevated activity counts for about 5-10 days compared to controls. HAL blocked the increased activity induced by AMPH; rats showed virtually no change from the depressed baseline activity counts. AMPH reduced body weights over the first week of administration, gradually returning to control values. HAL, however did not alter the reduction of body weight observed with continous AMPH administration.

185.6 BEHAVIORAL AND RECEPTOR CHANGES IN NIGROSTRIATAL LESIONED RATS AFTER CHRONIC DOPAMINE AGONISTS. D.R. Liskowsky, A.T. Salvatierra, W.J. Weiner, and L.T. Potter*. Depts. of Pharmacology and Neurology, Univ. of Miami School of Medicine.

Each of five groups of Sprague Dawley rats received unilateral 6-hydroxydopamine lesions of the substantia nigra. Two weeks following lesioning, rats were challenged with apomorphine (2mg/kg) and the resultant rotational behavior quantified. Animals were then given either: bromocriptine (10 mg/kg), ciladopa (20 mg/kg), levodopa/carbidopa (200-20 mg/kg), placebo, or no drug. After 3 weeks of drug administration rotational behavior was again quantified. Twenty-four hours later, D2 receptor binding in the lesioned and intact striata was measured using 1.25 nM ^{3}H-spiroperidol, ± d-butaclamol. The D2 receptor binding of the animals in the no drug group was determined 24 hours after the 'pre'-treatment apomorphine challenge.

Results demonstrated that the placebo group had a significantly higher level of D2 receptors than the no drug group. Analysis of the D2 binding between the lesioned and intact sides indicated increased receptors on the lesioned side in the placebo group (+34%) compared to the no drug group (+19%). The placebo group also demonstrated an increase in apomorphine-induced rotations from 'pre' and 'post' treatment trials. Bromocriptine and ciladopa groups each demonstrated D2 receptor binding levels similar to that seen in the no drug group. 'Pre' to 'post'-drug treatment rotational behavior increased in the bromocriptine group, but not in the ciladopa group. Levodopa/carbidopa produced D2 receptor levels intermediate to those in in the other treatment groups. Differences between lesioned and intact striata (+ 34%) were the same as in the placebo group. No increase in apomorphine-induced rotations were found between 'pre' and 'post' treatment trials.

These results demonstrate the ability of certain agonists to prevent behavioral and receptor changes which usually occur following nigrostriatal lesion. They also demonstrate the differences between direct acting agonists and the dopamine precursor, levodopa. These differences may relate to the varying efficacies of these agents in the treatment of Parkinson's disease.

185.7 [^{3}H]-SULPIRIDE BINDING SITE CHANGES CORRELATED WITH CHRONIC COCAINE ADMINISTRATION IN RATS. S.B. Goehring*, M.J. Kuhar and N.E. Goeders (SPON: A. Goldberg). Department of Neuroscience, Johns Hopkins University School of Medicine and Laboratory of Neuroscience, NIDA Addiction Research Center, Baltimore, MD 21205.

A variety of clinical and animal data suggest that the repeated intermittant administration of cocaine and related psychomotor stimulants may be associated with a behavioral sensitization whereby the same dose of the drug results in increasing behavioral effects. This investigation was initiated to determine the effects of chronic cocaine administration on the binding of sulpiride, a relatively specific ligand for D2 dopaminergic receptors, in the rat brain.

Ten adult male Sprague Dawley rats (230 to 250 g) were divided into two groups. The rats in the first group received single daily intraperitoneal injections of saline while the rats in the second group received daily injections of cocaine (10 mg/kg,i.p.) for 15 days. Twenty minutes following the last injection, each rat was sacrificed by decapitation, the brains removed and the striatum and nucleus accumbens dissected over dry-ice. Saturation studies were carried out with [^{3}H]-sulpiride to characterize changes in dopamine receptors (i.e., K_d and B_{max} values) resulting from the treatment conditions using a previously reported procedure (Zahniser and Dubocovich, J. Pharm. Exp. Ther., 227, 592, 1983). The B_{max} values (mean fmol/mg protein $\pm$ SEM) obtained for sulpiride binding in the striatum and nucleus accumbens of the saline treated rats (441 $\pm$ 34 and 316 $\pm$ 28, respectively) were in agreement with previous reports. Chronic daily injections of cocaine resulted in a significant decrease in the concentration of sulpiride binding sites in the striatum (291 $\pm$ 22; $p < 0.005$) and a significant increase in the concentration of sulpiride binding sites in the nucleus accumbens (407 $\pm$ 27; $p < 0.025$). No significant differences in K_d values were seen in either brain region.

These data suggest that chronic cocaine administration may result in differential effects on D2 receptors in the nigro-striatal and mesolimbic dopaminergic systems. These results are in general agreement with those of K. Akiyama et. al. (Biol. Psyc., 17, 223, 1982) who reported similar changes in [^{3}H]-spiperone binding sites following chronic amphetamine administration. Autoradiographic experiments are currently in progress to further characterize these effects. (Supported by USPHS Grants DA 00266, MH 00053, MH 25951, NS 15080 and MH 09111).

185.8 DISCRIMINATIVE STIMULUS PROPERTIES OF ANORECTIC DRUGS COMPARED TO THE DISCRIMINATIVE STIMULUS PROPERTIES OF COCAINE. D. M. Wood* and M. W. Emmett-Oglesby. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, Texas 76107.

Rats were trained to discriminate the stimulus properties of cocaine using a two-lever choice paradigm in which food reinforcement was delivered for responses on the correct lever: one lever was correct after cocaine (10 mg/kg, i.p.) injection, and the other lever was correct after saline injection. Following training, cocaine (2.5-10 mg/kg) was dose-dependently generalized to the cocaine training stimulus, and methylphenidate (1.25-5.0 mg/kg), phenmetrazine (0.64-10.0 mg/kg), phentermine (0.64-10.0 mg/kg), and diethylpropion (0.32-2.5 mg/kg) substituted for the cocaine stimulus; however, fenfluramine (1.25-5.0) and phenylpropanolamine (5.0-20.0) only partially substituted for the cocaine stimulus. Subsequently, training was halted and cocaine, 20.0 mg/kg, was injected every 8 hours for 7 days. As compared to acute generalization and substitution testing, chronic administration of cocaine shifted the entire generalization curve for cocaine two-fold to the right. Similarly, the substitution curves for methylphenidate, phenmetrazine, and phentermine were also shifted two-fold to the right. However, the substitution curve for diethylpropion was shifted in excess of four-fold to the right, and the substitution curves for fenfluramine and phenylpropanolamine did not change following chronic cocaine administration. All drugs that substituted fully for the cocaine training stimulus and that showed an approximate 2-fold shift of the dose-effect curve during tolerance to cocaine are CNS stimulants with well-established abuse potential. In contrast, diethylpropion is reported to have less dependence liability than these other agents, and it shows a more profound degree of cross-tolerance. In addition, fenfluramine and phenylpropanolamine are also considered to have lesser abuse potential than the preceding agents; acutely, they only poorly substitute for cocaine, and they also show a markedly different cross-tolerance profile than these other drugs. These data suggest that cross tolerance to the discriminative stimulus properties of cocaine may be used as a bioassay in determining dependence liability of anorectic drugs.

185.9 THE DEVELOPMENT OF BEHAVIORAL RESPONSES TO d-AMPHETAMINE IN RATS EXPOSED PRENATALLY TO ETHANOL. J.H. Hannigan and B.A. Blanchard*. Department of Psychology, State University of New York at Albany, Albany, NY 12222.

Rats exposed to ethanol in utero demonstrate a variety of behavioral changes in early postnatal life, including overactivity in an open field. To determine dopaminergic involvement in this overactivity we studied the development of behavioral responses to amphetamine by rats subjected to fetal alcohol exposure (FAE).

Pregnant Long Evans hooded rats were fed liquid diets containing 35% ethanol-derived calories (35%EDC) from gestation day 6 through 19. This dose of ethanol has produced reliable behavioral effects without gross morphological abnormalities. Other animals were either pair-fed the liquid diet with sucrose-substituted calories (0%EDC), or were given water and standard lab chow (LC). At all other times all groups were given water and chow. Pups were weaned on postnatal day 21 and housed in pairs with same-sex littermates. On the day before testing all animals were allowed to explore the open field (38 cm X 38 cm) for 20 min. At 28 or 42 days of age, animals were weighed and injected s.c. with either freshly-prepared d-amphetamine sulfate (1.0 mg/kg) or an equivalent volume of saline/ascorbate vehicle, and placed into the open field for 120 min. Automated monitors recorded horizontal activity and stereotypy.

Rats in the 35%EDC control group showed a small but reliable increase in horizontal activity relative to the 0%EDC and LC groups at both 28 and 42 days. Overall, the 42-day-old animals were more active than the 28-day-old animals. All groups injected with amphetamine had elevated activity relative to vehicle-treated controls. The 28-day-old rats demonstrated a longer latency to onset and a shorter duration of the activating effects of amphetamine than the 42-day-old rats. There were no significant differences between prenatal treatment groups on any of the behavioral effects of the amphetamine treatment.

These results, to date, suggest that amphetamine treatment may eliminate overactivity in rats prenatally exposed to ethanol. However, the absence of FAE-induced overactivity after amphetamine may be due to 'ceiling' effects on activity. Significant increases in stereotypy in all groups at this moderate dose support this possibility. Experiments at other doses of amphetamine are directed currently at the question of FAE-induced differential sensitivity to amphetamine.

185.10 INVOLVEMENT OF BRAIN TRH RECEPTORS IN BEHAVIORAL SUPERSENSITIVITY INDUCED BY CHRONIC METHAMPHETAMINE. M. Sato, S. Kajita*, K. Akiyama*, N. Ogawa† and S. Otsuki*. Depts. of Neuropsychiatry and †Neurochemistry (Institute for Neurobiology), Okayama University Medical School, Okayama 700, JAPAN.

Thyrotropin releasing hormone (TRH), a tripeptide, is distributed throughout central nervous system and involved in a variety of functions some of which can be attributed to dopaminergic mechanism. Chronic administration of methamphetamine (MAP) results in lasting augmentation of behavioral response to dopamine agonists which has been extensively utilized as an experimental model of acute excerbation of paranoid psychotic state (Sato et al, Biol. Psychiatry, 18:429-440. 1983). The present study was aimed at investigating brain TRH mechanism in such behavioral supersensitivity. Male Sprague Dawley rats were treated with either MAP (4 mg/kg/day) or saline for 14 days. After one week of drug free period, a single challenge of either MAP (4 mg/kg) or saline was made, giving rise to 4 treatment groups: chronic saline + saline challenge (S-S), chronic saline + MAP challenge (S-M), chronic MAP + saline challenge (M-S) and chronic MAP + MAP challenge (M-M). The animals were killed 1 hour after the challenge injections, and the brains were dissected out into 7 regions for measurement of TRH-like immunoreactivity (TRH-LI) and specific [3H]TRH binding (at 12 nM). There was no significant difference in TRH-LI in any brain region among the four groups. A challenge of MAP did not affect specific [3H]TRH binding in any brain regions. In the striatum, the specific binding decreased significantly ($P<0.01$) in M-S (11.0$\pm$ 0.7) and M-M (10.5 $\pm$ 0.3) as compared to S-S (18.1 $\pm$ 1.4). In the nucleus accumbens, it decreased significantly ($P<0.05$) in M-M (39.9 $\pm$ 2.2) as compared to S-S (50.6 $\pm$ 3.8), where values are expressed as mean $\pm$ S.E.M. (fmol/mg protein). It did not differ among the treatment groups in other brain regions. The lasting decrease in brain TRH receptors in the rats treated with chronic MAP was shown in this study. Since there is a report by Spindel et al (Brain Res. 216:323-331, 1981) that haloperidol reverses amphetamine-induced decrease in TRH concentrations in the striatum, it might be feasible that such change in brain TRH mechanism occurs secondarily to MAP-induced change in brain dopaminergic system and contributes to a lasting behavioral supersensitivity by chronic methamphetamine.

185.11 THE NEUROTOXIC EFFECT OF MPTP ON THE DOPAMINERGIC CELLS OF THE SUBSTANTIA NIGRA IN MICE IS AGE-RELATED. G.A. Ricaurte*, J.W. Langston, I. Irwin*, L.E. DeLanney* and L.S. Forno*. Depts. of Neurology, Stanford Univ. School of Med., Stanford, CA; Santa Clara Valley Med. Ctr. and the Institute for Medical Research, San Jose, CA 95128.

There are currently conflicting reports as to whether or not MPTP destroys nigrostriatal dopaminergic neurons in mice (Heikkila et al, Science 224: 1451, 1984; Hallman et al, J. Neurochem. 44(1): 117, 1985), as it has been shown to do in monkeys (Langston et al, Br. Res. 292: 390, 1984). Because the validity of using the MPTP-treated mouse as an animal model of Parkinson's disease depends critically on whether dopamine (DA) cell loss occurs in this experimental animal as a result of MPTP administration, this study re-evaluated the effect of MPTP on mouse nigrostriatal dopaminergic neurons using combined chemical and anatomical methods. Male C57BL/6 mice of various ages were used. MPTP was injected intraperitoneally according to either of two dosing regimens: 30 mg/kg/day for 10 days or 20 mg/kg/hour for four hours. After various survival periods, some mice were killed for chemical assay of dopaminergic nerve terminal markers (DA levels, metabolites and uptake); others were used for morphological assessment of dopaminergic neuronal integrity. In young mature (6-8 week old) mice, MPTP destroyed a large fraction of striatal dopaminergic nerve terminals, but left the majority of cell bodies in the pars compacta of the substantia nigra (SN) unaffected. In contrast, in older (8-12 months old) mice, MPTP induced widespread degenerative changes throughout the zona compacta of the SN. This suggests that older mice are more susceptible to the neurotoxic effects of MPTP and indicate that, in older mice, MPTP does indeed destroy nigrostriatal dopaminergic neurons. In this regard, the older MPTP-treated mouse would appear to be a valid animal model of Parkinson's disease. How aging leads to increased sensitivity to the neurotoxic effects of MPTP is not yet clear, but is under investigation. However, it is of interest that the neurotoxic effects of MPTP on the dopaminergic cells of the substanitia nigra should prove to be age-related since this neurotoxin is being used to study Parkinson's disease, which has long been linked to the aging process.

185.12 HEPATIC AND RENAL CHANGES IN MONKEYS TREATED WITH 1-METHYL-4 TETRA-HYDROXYPYRIDINE (MPTP) L.Fagel*, R.J.Schwartzman, P.F.Reyes*, G.Alexander* (Sponsor: John Bertoni, M.D.) Thomas Jefferson University, Department of Neurology, Philadelphia, Pa. 19107.

Although the neurotoxic effects of MPTP on primate and rodent CNS have recently been described, the visceral changes that occur in MPTP treated animals have not been fully investigated. We examined the livers and kidneys of 5 adult Macacca Fascicularis monkeys, 3 of which developed Parkinsonian manifestations after intravenous MPTP administration. Two animals were sacrificied 7 days after the initial injection of MPTP and one, a month later. Two animals were used as controls. All animals were perfused in vivo through the left ventricle with 4% formalin and 1.0% glutaraldehyde solutions. Multiple sections of grossly normal looking livers and kidneys were obtained from each animal and processed for histochemistry and electron microscopy. From these samples, 10 U thick sections were paraffin embedded and stained with hematoxylin-eosin, periodic acid Schiff with and without diastase and sudan black. Renal sections were also stained for urate, phosphate, and calcium crystals. At present, only sections of the liver have been processed for ultrastructural studies. Fatty changes and focal lymphocytic infiltrates in the liver were observed in both the control and treated animals that were sacrificed 7 days after treatment. However, these abnormalities were more severe in the treated group. The distribution and type of fatty change in the treated animals were different from those of the control. Furthermore, hepatic necrosis and eosinophilic infiltrates were noted only in experimental animals. The liver of the animal sacrificed a month after treatment showed focal parenchymal necrosis and chronic inflammatory infiltrates without fatty change. Histopathological examination of the kidney of the same animal revealed massive intratubular deposition of crystalline material, proliferative glomerular changes and chronic inflammatory infiltrates.

We believe the visceral alterations we have observed could result from the direct toxic effects of MPTP and/or its metabolites on the parenchyma, hypersensitivity reaction, fluid and electrolyte imbalance and starvation. Even if these lesions are non-specific, hepatic and renal damage should be considered in assessing the neurotoxic complications of MPTP.

185.13 NEUROTOXIC DAMAGE TO NIGROSTRIATAL SYSTEM FOLLOWING INTRANIGRAL ADMINISTRATION OF THE OXIDATIVE METABOLITES (MPDP AND MPP) OF MPTP. C. J. Sun*, D. J. Richman*, W. Gessner*, A. Brossi*, J. N. Johannessen, S. P. Markey* and C. C. Chiueh, (SPON: J. G. Kenimer), Food and Drug Administration, Rockville, Maryland, 20857, NIADDK and NIMH, Bethesda, Maryland, 20205.

Previous experiments indicated that systemic or intranigral administration of MPTP failed to produce a permanent lesion in the nigrostriatal system of rodents (Chiueh et al., Europ. J. Pharmacol., 100: 189, 1984; Chiueh et al., Fed. Proc., 44: 893, 1985; Hallman et al., J. Neurochem., 44: 117, 1985). Markey et al (Nature, 311: 464, 1984) reported that MPTP is trapped in monkey brain but not in rodent brain after it is oxidized to MPP by MAO-B and/or dehydrogenases. Furthermore, the oxidation process of MPTP appears to be responsible for its neurotoxic effects since pargyline and deprenyl inhibit the formation of MPDP and MPP (Chiba et al., B.B.R.C., 120: 574, 1984; Johannessen et al., Life Sci., 36: 219, 1985) and also prevent the neurotoxic effects of MPTP (Heikkila et al, Nature, 311: 471, 1984; Cohen et al., Europ. J. Pharmacol., 106: 209, 1984).

In C57BL6 mice, MPTP produces a reversible depletion of striatal dopamine but no permanent lesion in the substantia nigra compacta. Its oxidative metabolites cause a decrease in striatal dopamine following intrastriatal administrations (Chiueh et al., Fed. Proc., 44: 893, 1985). In the present study, we synthesized oxidative metabolites of MPTP, i.e. MPDP and MPP, and investigated their neurochemical, behavioral and pathological effects after intranigral administration to rats.

Unilateral intranigral administration (A 3.2, L 2.2, H 2.0) of 1 to 5 ug of MPDP and MPP in 1 ul saline produced a dose dependent depletion of ipsilateral striatal dopamine in rats assayed by HPLC-EC two to three weeks following the treatment. The dopamine levels in the nucleus accumbens were slightly decreased. d-Amphetamine (3 mg/kg s.c.) and apomorphine (1 mg/kg, s.c.) induced a circling locomotion towards the lesioned side in these unilaterally treated animals. The ipsilateral circling scores correlated well with the degree of depletion of striatal dopamine in the individual animal. No receptor supersensitivity was observed. MPP increased the ^{45}Ca influx into cells at the site of injection and produced nonspecific cytotoxic damage seen by histological procedures.

In conclusion, MPDP and MPP, but not MPTP, produced localized cytotoxic damage in nigrostriatal neurons and disrupted their functions following intranigral administration to rodents. The cause of their cytotoxic lesion may be related to the cationic surfactant properties of MPDP and MPP.

185.14 NEUROCHEMICAL EFFECTS OF MPTP IN THE DOG: EFFECTS OF PARGYLINE PRETREATMENT. J.N.Johannessen,C.C.Chiueh,J.P.Bacon*,N.A.Garrick, D.L.Murphy*,R.S.Burns,V.K.Weise*,I.J.Kopin, and S.P.Markey* Lab. Clin. Sci. NIMH and NINCDS, Bethesda, MD 20205

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) produces an irreversible parkinsonism in primates and dogs. Monoamine oxidase (MAO) inhibitors block the toxicity of MPTP in primates and rodents, however effects of this pretreatment on the neurochemical sequelae of MPTP injection in the dog have not been examined.

Beagle dogs were injected with MPTP (2.5 mg/kg i.v.) with or without pargyline pretreatment (5 mg/kg s.c. 16 and 2 hr prior to MPTP). Controls were untreated and a fourth group received pargyline only. Animals were killed at various times after injection and their brains assayed for dopamine (DA), dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), serotonin (5-HT), 5-hydroxyindoleacetic acid (5-HIAA), tyrosine hydroxylase activity (TH), and MAO activity using 5-HT, DA, or phenethylamine (PEA) as substrates.

Pargyline blocked the toxicity of MPTP as defined by three criteria. First, the akinesia and muscular ridgidity seen after MPTP were completely absent. Second, the metabolism of MPTP to MPP+, which has been shown to be critical for MPTP toxicity, was largely prevented. Finally, striatal dopamine, which is depleted following MPTP injection, was normal in dogs pretreated with pargyline. Treatment with pargyline alone had no effect on striatal DA. MPTP also produced marked increases in striatal 5-HT (209% of control), while 5-HIAA was decreased to 76% of control levels. In contrast to dopamine, increases in striatal 5-HT were not blocked by pargyline, but were in fact augmented significantly. This appeared to be an additive effect, since pargyline alone also increased striatal 5-HT.

Curiously, while pargyline pretreatment prevented the loss of DA, it did not prevent the loss of DOPAC or HVA caused by MPTP. This finding cannot be explained by the presence of pargyline because animals treated with pargyline alone exhibited normal striatal DOPAC and HVA levels. The effect was reversible, DOPAC and HVA levels returning to normal by 3 months after injection.

To examine whether the lack of DA metabolites seen in pargyline/MPTP treated animals indicates a role for MPTP as a long lasting MAO inhibitor, MAO activities were measured in cortex and striatum. MPTP alone had no effect on MAO activities in cortex, however MAO B activity in caudate was reduced 25%, suggesting that 25% of MAO B activity in the caudate is contained in DA terminals. TH activity in the caudates of pargyline/MPTP treated dogs was not different from control values, precluding the possibility that damage to DA terminals was responsible for the decreased DA metabolites seen in pargyline/MPTP treated dogs.

185.15 MPTP MODEL OF PARKINSON'S DISEASE. B.R. Ransom and D.M. Kunis*. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

In June of 1982, a group of California drug users suddenly developed symptoms of Parkinson's disease after using a synthetic meperidine-like drug contaminated with 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) (Langston et al., Science 219:979, 1983), and this, ironically has led to the development of a very useful model of Parkinson's disease. MPTP has been shown to selectively destroy dopamine-containing substantia nigra (SN) neurons, probably after being converted by oxidation to 1-methyl-4-phenyl-pyridinium ion (MPP^+), and causes primates to develop parkinsonian symptoms which are benfited by anti-parkinsonian medications such as Sinemet. It has been possible to block both the symptoms and lesions of MPTP treatment with MAO inhibitors. Initial studies suggested that the toxicity of this drug was limited to the brains of men and primates, but recently toxicity has been demonstrated with explant cultures of rat SN (Mytilineou and Cohen, Science 225:529, 1984). Encouraged by this observation we have established dissociated cell cultures of mouse SN and tested this system for MPTP toxicity. The advantages of a culture model of MPTP toxicity would include greatly diminished expense and enhanced experimental control.

Dissociated cell cultures of SN were prepared using 13 day mouse embryos. The mesencephalon was removed, minced and triturated to produce a cell suspension and then plated onto previously prepared monolayers of mouse astrocytes. By two weeks of age these cultures consisted of monolayers of well differentiated neurons whose somal diameters varied between 10 and 20μ. Using the glyoxylic acid method of catecholamine histofluorescence, discreet neuronal staining was observed after preincubation with norepinephrine (10^{-6} M).

MPTP applied to two week old SN cultures at concentrations ranging from 10 to 50 μg/ml produced a dose-dependent destruction of neurons. At 50 μg/ml almost all neurons were destroyed after one week of application. Spinal cord neurons in culture (Ransom et al., J. Neurophys. 40:1132, 1977) were also destroyed by similar applications of MPTP. The MAO inhibitor Pargyline, at a concentration of 100 μM, completely blocked MPTP induced neuronal death in SN cultures. A similar protective effect of Pargyline has been noted in the primate model of drug-induced parkinsonism and is believed to result from the blockade of MPTP oxidation to the charged metabolite MPP^+. Dissociated cell cultures of SN and spinal cord appear highly sensitive to the toxic effects of MPTP and should prove useful in determining its mechanism of action.

Supported by the Institute for Medical Research grant #NSC5-456 and NIH grants NS 00473 and NS 15589.

EFFECTS OF CHRONIC DRUG ADMINISTRATION II

186.1 ACUTE AND CHRONIC EFFECTS OF PYRETHROID INSECTICIDES ON OPERANT RESPONDING FOR FOOD. E.A. Stein, M. Washburn*, C. Wolczak*, and A.S. Bloom†. Dept. of Biology, Marquette University, Milwaukee, WI 53233, and †Dept. of Pharmacology, Medical College of Wisconsin, Milwaukee, WI 53226.

The synthetic pyrethroids are potent insecticides with very high topical lethality on insects and concomitant low oral lethality in mammals. They are becoming important agriculturally and therefore the exposure of non-target species should increase. At high doses, rats receiving these compounds will display marked hyperactivity, tremors, convulsions and finally, death. However, low doses, those more likely to be present in the environment, have not been as well studied. The mechanism and sites of action of these agents in the central nervous system of mammals is not known. It appears that operant responding may be a sensitive method to detect changes in CNS function that may not be evident using other procedures (e.g., neurochemical). As such, male Holtzman rats were trained to respond for 45 mg food pellets on a variable ratio schedule (VR25). Rats were placed on a 23-hr food deprivation schedule with water available ad lib. Testing was performed for 30 min daily between 0900 and 1200 hrs. No water was present during testing. To maintain adequate food and water balance, subjects were given free access to both food and water for an additional 30-min period following daily testing. Responses and reinforcements during each session were recorded. Pyrethroids were administered IP once per week and prepared in a 1:1 vehicle of Emulphor and 95% ethanol and diluted with saline. Chemicals tested were technical permethrin, deltamethrin and fenvalerate. All agents were submitted to a dose-response and time course study. In addition, chronic, low doses of each agent were delivered daily for 3 months to examine possible cumulative effects. A within subjects design was used in all studies, with each rat receiving each treatment; however, only one agent per rat was employed. All agents were effective in reducing operant responding for food in a dose-dependent manner. Effects were seen within the first 15 min post injection with duration of effect lasting approximately 30 min to one hr. Operant responding returned to baseline on subsequent test days. No cumulative effects of these agents were seen, as chronic administration of a dose previously shown effective in reducing responding by approximately 20%, failed to produce any permanent alterations in responding when administered daily for periods up to three months. Results of these studies indicate that the synthetic pyrethroid insecticides can disrupt a well learned behavior response at doses significantly lower than doses producing lethality. However, effects were of short duration and appear not to be cumulative. Supported by NIEHS grant ES03122 to EAS and ASB.

186.2 EFFECT OF PYRETHROID INSECTICIDES ON THE BINDING OF ^{3}H-GLUTAMATE TO RAT BRAIN MEMBRANES. A.S. Bloom, L.A. Sutherland*, C.J. Hillard and E.A. Stein. Department of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226 and Department of Biology, Marquette University, Milwaukee, WI 53233.

The pyrethroids are synthetic derivatives of the natural pyrethrins found in the Chrysanthemum. We have previously shown that this class of insecticides partially blocked kainic acid binding to mouse brain membranes (Toxicol. Appl. Pharmacol. 64: 566, 1982). We have now examined the effects of several pyrethroids on ^{3}H-glutamate binding sites in the rat brain. Both in vitro and in vivo drug treatments were studied. In the in vivo studies, groups of male Sprague-Dawley rats were injected ip with either a pyrethroid or its dimethyl sulfoxide (DMSO) vehicle, daily for seven days. DMSO vehicle was found to have no effect on ^{3}H-glutamate binding, either in vitro or in vivo. Seven days of treatment with the potent cyano-containing pyrethroid, deltamethrin (10 mg/kg), produced a decrease in the binding of ^{3}H-glutamate. This dose produced obvious symptomology such as sinuous writhing which is typical of this type of pyrethroid. The decrease in binding was the result of a 36% decrease in the Bmax parameter. A slight increase in the binding constant (K_d) was also observed after treatment with deltamethrin. Slight (12%), but statistically significant decreases in binding were also produced by the cyano-containing pyrethroid, fenvalerate (20 mg/kg) and by permethrin (100 mg/kg), a pyrethroid without a cyano group. However, symptoms were not usually obvious upon gross observation with the latter two treatments. Higher doses of these compounds need to be examined. In other studies, pyrethroids were added to brain membranes, in vitro, using DMSO as a vehicle. Inhibition of ^{3}H-glutamate binding was produced by permethrin (10 μM), fenvalerate (2 μM) and cypermethrin (2 μM). The decrease after cypermethrin was 30%. The data from these studies offer further support for the hypothesis that an action at receptors for excitatory amino acid neurotransmitters is involved in the neurotoxic effects of the pyrethroid insecticides. (Supported by USPHS Grant No. ES03102).

186.3 TRIETHYL LEAD ATTENUATES FEEDING AND DRINKING, AND INDUCES A CONDITIONED TASTE AVERSION, IN ADULT RATS. P. Faubert* and D.A. Czech. Dept. of Psychology, Marquette Univ, Milwaukee,WI 53233

Our laboratory previously reported that adult rats acutely exposed to tetraethyl lead (TTEL) show a significant reduction in both food and water intake, beginning 2-3 days post-exposure and lasting for about a week. Although substrate affected is not known, it is suspected that the toxic agent is triethyl lead (TEL); TTEL is rapidly metabolized to the triethyl form. To further investigate this issue at the behavioral level, we exposed male adult Sprague-Dawley rats to TEL at the same dosage levels as previously used in TTEL studies. Food and water intake and body weight were monitored daily throughout the experiment. Rats were provided with food and tap water ad lib in the home cage. When intakes were stable, rats were injected SC with 3 doses of TEL (1,4 & 7 mg/kg as lead base) or normal saline vehicle. Intakes and body weight were partitioned into blocks of 3 days, both pre- and post-exposure, and evaluated with analyses of variance (ANOVA) and Dunnett's procedures. Significance levels were set at $p < .05$. Food and water intakes were significantly lower in both 4 & 7 mg/kg groups, or 7 mg/kg group only, depending on post-exposure period. The effect again lasted about a week. Body weights were significantly lower than controls at 7 mg/kg only. Weight reduction lagged food/water shifts, as expected, by 1-2 days, and also recovered in about a week.

In a separate experiment, rats were exposed to the same dosage levels of TEL in a conditioned taste aversion paradigm (CTA). Adult male rats were placed on a 23.5 hour water deprivation schedule with food available ad lib for 16 days prior to TEL exposure. Two bottles, both containing tap water, were attached to the home cage during the drinking period. After water intake was reasonably stable, a single bottle containing a 0.1% sodium saccharin solution was offered to the animal during one drinking period (conditioning trial). Approximately 30 min after the drinking period ended, rats were injected SC with TEL or vehicle, as in the first experiment. On the following two days, tap water (2 bottles) was again available. On the third (test) day, rats were offered a choice between tap water and saccharin. Saccharin preferences (proportion of saccharin relative to total intake) were evaluated with ANOVA and Dunnett's procedures. Again, $p < .05$ was considered significant. Saccharin preferences of lead-exposed groups was significantly lower than the control group at all dosage levels (1,4 & 7 mg/kg), in a dose-related manner. Results are discussed.

186.4 **IMPAIRED ASSOCIATIVE LEARNING AND SPARED RULE-LEARNING IN A SERIAL LEARNING TASK FOLLOWING TRIMETHYLTIN EXPOSURE IN RATS.** **S.B. Fountain*, D.E. Schenk*, and Z. Annau.** Department of Environmental Health Sciences, The Johns Hopkins University, Baltimore, MD 21205.

Trimethyltin (TMT) is a neurotoxic organometal which produces a variety of learning and memory impairments in laboratory animals and humans. We investigated the effects of TMT exposure on serial pattern learning in rats. Rats were intubated once with either 0 or 7.0 mg/kg TMT one week prior to the pattern learning procedure. Rats then learned patterns composed of various quantities of BSR pulses; they received BSR quantitites in a predetermined order for lever presses in a discrete-trial operant task. All rats received two serial patterns (18-10-6-3-1-0 versus 18-1-3-6-10-0 pulses of BSR) that alternated within each daily session of 100 patterns. The 18-10-6-3-1-0 pattern is formally simple because it can be described by a single "less than" rule relating successive BSR quantities. The 18-1-3-6-10-0 pattern is formally more complex because no single rule describes the pattern. These patterns were chosen because rats have previously been shown to be sensitive to the rule-based structure of patterns. In the present study, TMT-exposed rats learned their formally simple 18-10-6-3-1-0 pattern of BSR quantities faster than Controls, but were significantly slower than Controls in learning their formally more complex 18-1-3-6-10-0 pattern. However, TMT exposure did not affect the reinforcing properties of BSR or rats' response to nonreward. In addition, TMT did not affect rats' level of asymptotic performance; TMT-exposed rats responded at least as well to their patterns at asymptote as Control rats. Histology showed that TMT produced thinning of hippocampal CA1, CA3b, and CA3c pyramidal cell fields and virtual destruction of CA4 in the intrahilar region. Hippocampal CA2 and CA3a (the Sommer sector) and dentate were largely spared. Our results support the notion that TMT exposure impaired some aspects of the rote processes involved in serial pattern learning in rats, yet spared the rats' ability to encode some representation of the formal rule-based structure of their simple pattern. Because TMT is a relatively selective limbic system neurotoxicant, these results suggest that the processes involved in learning simple versus complex serial patterns may be mediated by different systems in the brain.

186.5 EFFECT OF SOMAN EXPOSURE ON ACQUISITION OF A TWO LEVER OPERANT ALTERNATION. H.E. Modrow*, N.K. Jaax*, B.L. Harding*, and J.H. McDonough (SPON: B. Hackley). U.S. Army Medical Research Institute of Chemical Defense, APG-EA, MD 21010-5425.

Rats surviving convulsion-producing doses of the toxic organophosphate, soman, exhibit neural damage in a number of limbic sites, including the hippocampus. As experimental hippocampal lesions in rats produce deficits in acquisition of alternation tasks, this study examined whether rats exposed to soman would demonstrate perseveration and deficits in learning a cued alternation task.

Following preliminary training to lever press on a fixed ratio 1 FR1) schedule, 70 rats were divided into 4 groups and injected sc with either saline, 75, 85 or 95 ug/kg soman. After recovery, surviving rats were retrained to lever press on the FR1 schedule. When an animal obtained 100 reinforcements within a 30 min period, alternation training began. Initially, rats were required to simply alternate between the two levers using a FR1 schedule and a 2 sec intertrial interval (ITI) with the correct lever indicated by a cue light. As animals became proficient, the schedule was gradually incremented to the terminal level of FR20 with a 20 sec ITI. Training sessions, 40 min per day, 5 days per week, continued until rats attained criterion ($\leq$ 25% incorrect responses for three consecutive days) or 100 training days had elapsed without criterion performance.

A significant dose-dependent gradation in symptom scores was apparent within one hour after injection ($F(2,67)=23.4, p<.01$). Rats injected with 75 ug/kg had significantly lower symptom scores than rats receiving 85 or 95 ug/kg. There was a significant difference between groups in the number of days required to reach FR 20/20 ITI ($F(3,28)=6.68, p<.01$), with the saline group requiring significantly fewer days than all soman groups. Total days to reach criterion produced similar results ($F(3,28)=6.34, p<.01$). No differences were seen between the three soman groups in the number of sessions to reach criterion. All three groups required nearly twice as long as the saline group. These results confirm previous reports of long-term deficits in learning and performance of soman exposed animals and extend these findings to a cued alternation task. The performance decrements observed in soman exposed animals are best attributed to the irreversible damage to limbic structures such as the hippocampus.

186.6 PYRIDOSTIGMINE-INDUCED FATIGUE IN RAT SKELETAL MUSCLE TWITCH. R. J. Anderson, W.L. Chamberlain*, M. Roesner*, C. Dacko* and D.G. Robertson*. Warner-Lambert/Parke-Davis Pharmaceutical Research and University of Michigan, Ann Arbor, MI.

Pyridostigmine, which does not cross the blood brain barrier, has been suggested as prophylactic treatment for organophosphorus intoxication. Because this cholinesterase inhibitor causes myopathies following chronic administration, the purpose of this study was to determine the relationship between cholinesterase inhibition, changes in responsiveness of skeletal muscle and onset of myopathy. Three dose schedules were used: single daily ip injections (2 mg/kg); constant sc infusion (5 mg/kg/day) and constant sc infusion (25 mg/kg/day). Groups of 5 male rats were withdrawn from the study after 1,4,10 and 20 days of treatment. Under urethane anesthesia (1.5 g/kg) the hindlimb was dissected. Maximal twitch contractions were evoked via sciatic nerve stimulation. Contracture and fatigue were measured during 10 second trains of 20, 50 and 100 Hz stimuli. Drug infusion (25 mg/kg/day) produced significant reductions in muscle contracture during 50 and 100 Hz stimulation. Peak effect was at 4 days and there was partial recovery by 20 days. These animals lost weight during the first 3 days and then gained normally. Throughout the study blood cholinesterase activity was inhibited 40-70%. Drug infusion (5 mg/kg/day) produced a 20% reduction in muscle contracture during 20-100 Hz stimulation, an effect which remained constant during the 20 day study. These rats exhibited decreased blood cholinesterase activity on day 1 and normal enzyme activity thereafter. Weight gain was normal. Daily ip injections (2 mg/kg) produced no significant change in muscle contracture or weight gain. These rats exhibited elevated blood cholinesterase activity on day 4 and normal activity thereafter. These rats showed cholinergic signs immediately after each ip dose but no overt signs 24 hours later, the time of muscle recording. None of the treatments produced significant changes in muscle mass, nor in single twitch contractions. These results show that pyridostigmine produces muscle fatigue at lower doses than those which inhibit enzyme activity, decrease body weight or change muscle mass. The data therefore, indicate that the effects of this drug on muscle tension are not related to cholinesterase inhibition or a result of body weight loss. The data are consistent with the view that fatigue of skeletal muscle is an early sign of the subsequently developing myopathy. (This work supported in part by USAMRDC Contract DAMD-17-C-3187).

186.7 EFFECTS OF ALUMINUM IN VIVO ON NEUROTRANSMITTER-SYNTHESIZING ENZYMES IN RABBITS. I. Vincent*, J.R. Hofstetter*, B. Ghetti, J. Richter, and P. Shea. Departments of Psychiatry, Biochemistry, and Pharmacology, Indiana University Medical Center, Indianapolis, IN 46223.

Aluminum (Al) is neurotoxic in man and other species. Bugiani and Ghetti (Neurobiol. Aging. 3: 209, 1982) have shown that intracisternal administration of a suspension of metallic Al-powder caused neurological signs and the development of neurofibrillary degeneration (NFD) to different extents in different central nervous system regions of the rabbit. In order to investigate the mechanism(s) of the in vivo neurotoxic effects, we administered metallic Al powder (0.15 ml of a 1% suspension in lactated Ringer's solution) into the intracisternal space of New Zealand-White rabbits. The animals were sacrificed when they showed symptoms of neurotoxicity. Control rabbits were injected intracisternally with the vehicle and sacrificed at the same time. The brains were divided midsagittally; one half was fixed for morphological evaluation and the other half was used for biochemical analyses. The following enzyme systems were measured in twelve brain regions: choline acetyltransferase (ChAT), tyrosine hydroxylase (TH), glutamate decarboxylase (GAD), and serine hydroxymethyl transferase (SHMT). The treated rabbits had decreases in ChAT activity in the hippocampus, GAD activity in the cerebellum, and (with somewhat less confidence) TH activity in the striatum. Furthermore, they had increases in TH activity in the cervical spinal cord. Additional rabbits will be treated not only to confirm these effects, but also to determine if the changes in enzyme activity are the result of changes in V_{max} or K_m. These effects may be related to the NFD observed in these regions or in the nuclei which project to these regions. This will be determined by morphological examination of the fixed material. 186.8 LOW DOSES OF DELTA-9-TETRAHYDROCANNABINOL SUPPRESS HIPPOCAMPAL AUDITORY EVOKED POTENTIALS AND PERFORMANCE DURING AUDITORY DISCRIMINATION. T. C. Foster*, K.A. Campbell, R.E. Hampson* and S.A. Deadwyler. Dept. of Physiology & Pharmacology, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

Marijuana's psychoactive ingredient, delta-9-tetrahydrocannabinol (THC), has been consistently reported to alter memory function in human subjects as manifested by impairment of immediate recall and disruption of temporal coding of events (Miller & Branconnier, Psyc. Bull., 1983). Because THC is also known to affect hippocampal synaptic processes (Foy et al, Brain Res. Bull., 1982), we have investigated the effects of THC on auditory evoked potentials (AEPs) recorded from the outer molecular layer (OM) of the dentate gyrus (OM AEPs) of the rat hippocampus during auditory discrimination learning. These potentials have been shown to reflect information processing in the hippocampus, in that a short latency component (N1) of the OM AEP varies systematically in amplitude as a function of the temporal sequence of the preceding CS+/CS- trials (Deadwyler et al., Behav. Neural Biol., 1985).

OM AEPs were recorded from water-deprived rats (n=9) trained to criterion in a 2-tone discrimination task. CS+/CS- tones were presented randomly for 100 trials prior to THC injection, and 100 or 200 trials following injection. I.P. injections were made with THC dispersed in a suspension at doses 0.5, 1.0, 1.5, and 2.0 mg/kg, or with vehicle (pluronic detergent). These doses of THC did not distort the OM AEP waveform, but did produce a significant 50% decrease in the amplitude of the N1 component ($p<.01$) relative to the pre-injection level. This suppression was observed across all 4 dose levels, but the degree of decrease was not dose-dependent. Partial recovery of pre-injection N1 amplitude was observed after 2-4 hrs. There were no systematic effects of THC on the amplitude of the later N2 component, indicating that the decrease in N1 amplitude was not due to nonspecific THC effects.

Performance on the discrimination task decreased in a dose-dependent fashion after THC injection: There was no effect of 0.5 mg/kg THC on behavior, while at 1.0, 1.5, and 2.0 mg/kg respectively, number of responses to the CS+ decreased by 13%, 30% ($p<.01$), and 22%; and latency to respond (on trials in which responses occurred) increased by 28% ($p<.02$), 20% ($p<.05$), and 13%. Behavioral recovery also began in the 2nd 100 trials following THC injection in most animals. Such effects on behavior have previously been reported only with higher doses of THC.

These results indicate that processing of behaviorally-relevant sensory information in the dentate gyrus is selectively altered by low doses of delta-9-THC.

186.9 DEVELOPMENTAL EFFECTS OF PERINATAL TREATMENT WITH VASOPRESSIN, ITS ANTAGONIST AND HETEROLOGUES IN WISTAR AND BRATTLEBORO RAT. G.J. Boer*, F.G.M. Snijdewint*, J. Kruisbrink*, D.F. Swaab* and +M. Manning (SPON: European Neuroscience Association).*Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam ZO, The Netherlands and +Dept. of Biochemistry, Medical College of Ohio, Toledo Ohio 43699, U.S.A.

Based upon the peculiar brain growth anomalies of the vasopressin (VP)-deficient Brattleboro rat and the early ontogenic appearance of this peptide in normal brain, a role for VP in brain development has been postulated. The more so since VP acts as a neurotransmitter and transmitters are likely to be involved as trophic factors at times functional nervous circuitries are established.

At present perinatal treatment with VP, its antagonists and heterologues is applied to explore the possible effects on body and brain development and on body water regulation, both measured at one month of age. A new controlled drug-delivery technique is introduced, allowing continuous treatment of small peptides in both rat newborns and adults. It makes use of microporous Accurel polypropylene tubing (15 mm length, 1.6 mm OD), lumen-loaded with peptide, heat-sealed at the ends and enfilmed with nitrocellulose. Subcutaneously implanted, peptides are released for periods of over one month, with dosage rates of 1-2% of its content each day (Kruisbrink and Boer, J. Pharm. Sc. 73, 1713, 1984). Control preparations contain water medium only.

VP/Accurel devices (15 µg) implanted in Brattleboro neonates failed to restore stunted brain growth, but devices (100 µg) placed during pregnancy in Brattleboro mothers had a slight growth promoting effect for the offspring when LVP was used instead. Daily injections of Pitressin tannate (0.5 U/100 g b.w.) in both cases revealed the same except that after termination of the postnatal injections the already existing polyurea of the offspring had aggreviated. Accurel devices containing VP or the VP-antagonists $d(CH_2)_5[D\text{-}Arg^8]VP$, $d(CH_2)_5[D\text{-}Ile^2,Ala^4]VP$ and $d(CH_2)_5Tyr(Me)VP$ (all 50 µg loads), implanted neonatally, had no effects on body and brain development in Wistar pups. However, repeated injections twice a day for the first 3 weeks of life (2.5 µg/50 µl saline) revealed a temporarily reduced body growth for VP, LVP, VT and OX, not for the antagonists. A total catch-up was seen at one month of age and brain weight was not affected. However, for VP and its heterologues, a persistent polyurea had been introduced.

The results are only consistent with the postulate that VP stimulates growth when a prenatal role of VP in development is assumed. Relatively high doses, moreover given peak-wise by repeated injections, revealed only transient growth disturbances, but alters body water metabolism dramatically. This might point to a role of antidiuretic activity on the maturation of kidney responsiveness.

186.10 CHRONIC ADMINISTRATION OF ANTIDEPRESSANT DRUGS TO RATS REDUCES THE HEAD SHAKE RESPONSE TO L-5-HYDROXYTRYPTOPHAN. I. Lucki, H.R. Ward*, L.S.Y. Tyau* and A. Frazer. Depts. of Psychiatry and Pharmacology, University of Pennsylvania, VA Medical Center, Philadelphia, PA 19104.

The head shake response is produced in rats by the administration of serotonin precursors or the agonist quipazine, and has been associated with the activation of $5\text{-}HT_2$ receptors (J. Pharmacol. Exp. Ther. 228:133, 1984). The repeated administration of many types of antidepressant drugs reduce the number of $5\text{-}HT_2$ receptors measured in the frontal cortex of rats (Science, 210:88, 1980). The present study examined the head shake response produced by the serotonin precursor L-5-hydroxytryptophan (L-5-HTP) in rats treated chronically with antidepressant drugs.

The head shake response was defined for rats as a rapid radial twisting of the head about the rostral-caudal axis. Head shake behavior was induced by the administration of carbidopa (25 mg/kg i.p.) followed 30 min later by the injection of L-5-HTP (150 mg/kg s.c.). Head shakes were counted during 5-min intervals starting at 30, 60, 90, 120, 150, and 180 min after the injection of L-5-HTP. Separate groups of rats were treated with the tricyclic antidepressants desipramine or amitriptyline, or the atypical antidepressant iprindole, at 10 mg/kg twice daily for seven days. Rats were examined for the L-5-HTP-induced head shake response either 24 h or 72 h after the final antidepressant drug injection. Other rats were examined for the L-5-HTP-induced head shake response after a single administration of the antidepressant drugs.

Chronic treatment with each of the antidepressant drugs for seven days produced a significant reduction of the head shake response produced by L-5-HTP when measured 24 h after the final injection. This agrees with the ability of each of these antidepressant drugs to reduce the number of $5\text{-}HT_2$ receptors following their chronic administration. Chronic treatment with these antidepressant drugs was shown previously to attenuate the head shake response in rats produced by the serotonin agonist quipazine (Lucki & Frazer, 1985). At 72 h after cessation of drug treatment, the head shake response was still significantly reduced in rats treated chronically with amitriptyline or iprindole, but not in rats treated chronically with desipramine.

186.11 A NICOTINE WITHDRAWAL SYMPTOM IS INCREASED BY A GABA SYNTHESIS INHIBITOR. H. Lal, C.M. Harris and M.W. Emmett-Oglesby. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107

Withdrawal from drugs of dependence is characterized by both overt signs and subjective symptoms. Until recently, only the physical signs have been studied in laboratory animals. Now, however, a novel approach to investigating subjective events of withdrawal has been developed, utilizing the pentylenetetrazol (PTZ) discrimination paradigm (Lal and Emmett-Oglesby, Neuropharmacology 22:1423, 1983). Food deprived rats are trained in a 2-lever food-reinforced operant task to select one lever after PTZ, 20 mg/kg, ip, and the other lever after saline, 1 ml/kg, ip. Specific treatments are then tested for their ability to substitute for PTZ or to block PTZ-lever selection. This procedure provides a rate-independent measure of an interoceptive stimulus (ie., subjective effect) in that the proportion of rats selecting the PTZ-lever reflects the magnitude of a PTZ-like stimulus. Previously, withdrawal from benzodiazepines (Emmett-Oglesby et al, Eur. J. Pharmacol. 92:127,1983; Lal et al., Fed. Proc. 43:931, 1984), morphine (Emmett-Oglesby et al., Neuropeptides 5:37, 1984), and nicotine (Emmett-Oglesby et al., Soc. Neurosci. Abstr. 10:1210, 1984) have been studied, and in each case, withdrawal substituted for PTZ and the substitution was blocked by diazepam. Thus, 1) there is a subjective effect of withdrawal common to 3 classes of dependence-producing drugs, and 2) the withdrawal stimulus can be blocked by a drug which blocks the PTZ stimulus and blocks anxiety in humans. The present experiment was undertaken to determine the neural basis for the subjective effects associated with nicotine withdrawal. Rats were trained to discriminate PTZ, They were then given a course of subcutaneous nicotine injections, at 8 hour intervals, 0.64 mg/kg/inj on the 1st day and 1.25 mg/kg/inj thereafter, for 15 days. Nicotine treatment was then suspended and on the 5th day after the last dose of nicotine, PTZ-lever selection was increased by isoniazid (200 mg/kg), an inhibitor of the GABA-synthesizing enzyme, glutamic acid decarboxylase. This increase in PTZ-lever selection was reversed by diazepam, 5 mg/kg (% PTZ-lever selection: 35% after saline, 75% after isoniazid, 20% after isoniazid plus diazepam). These results demonstrate that nicotine withdrawal can be modulated by treatments affecting the GABA/benzodiazepine complex, suggesting that this neural system may be involved in mediating subjective aspects of nicotine withdrawal.

Supported by AOA Grant 82-11-045.

186.12 SERUM CHOLINESTERASE ISOZYMES AFTER HALOPERIDOL TREATMENT. A. Korenovsky*, H. Laev* & S.P. Mahadik (Spon: W.C. Clark). Div. Neuroscience, NYS Psychiatric Inst., Depts. of Psychiatry, and Biochemistry & Molecular Biophysics, College of Physicians & Surgeons, Columbia U., 722 W 168th St., NY, NY. 10032.

A variety of pathophysiological conditions alter levels of serum cholinesterase isozymes (ChE). Some changes are due to release of enzymes from muscle and/or neural tissue. Chronic haloperidol treatment, which causes extrapyramidal side-effects in schizophrenic patients, induces cholinergic disturbances. The extrapyramidal effects, collectively described as tardive dyskinesia (TD), can be suppressed by drugs that enhance acetylcholine activity. We have therefore studied the effect of chronic haloperidol treatment of rats on ChE isozymes in serum. Sera were obtained from 19 rats treated with haloperidol (2mg/kg i.m. daily for 28 weeks) and 21 controls injected with saline. Eight ChE isozymes were separated on slab gels (7.5% acrylamide). Although the two classes of ChEs, acetylcholinesterases (AChE) and pseudocholinesterases (ChE) can be distinguished by their ability to hydrolyze acetylthiocholine and naphthylacetate respectively, five isozymes showed considerable activity with both substrates. AChE isozymes are visualized as dark green bands of copper-thio-oxamide and pseudo-ChE as brown bands of naphthol-fast blue-RR. In sera from haloperidol treated rats, isozyme 1 (slowest migration, AChE only) was absent, isozyme 7 (ChE only) was reduced, isozyme 8 (ChE only) was increased, and isozyme 2 (AChE plus ChE) was increased several fold. Isozyme 3 (predominantly AChE) was unchanged. Isozymes 4,5, and 6 (minor components) did not show significant changes. These results clearly show that haloperidol treatment alters the levels of both AChE and ChE isozymes. Since the source of some of these isozymes is muscle and neural tissue, haloperidol may be having a direct effect on the membranes of these tissues. Alternatively, the action of haloperidol may be indirect, since disturbance of cholinergic transmission is known to cause the release of AChE from muscle and neural tissues. Measurement of serum AChE and ChE isozymes may be useful in determining the differential effects of available neuroleptics.

186.13 CHRONIC AND INTERMITTENT NICOTINE-INDUCED CHANGES IN BODY WEIGHT AND FOOD AND WATER CONSUMPTION. E.D.Levin, M.M.Morgan*, C.Galvez* and G.D.Ellison. Department of Psychology, University of California at Los Angeles, Los Angeles, CA 90024.

A previous study in this lab found that in rats chronic nicotine adminstration via a subcutaneously implanted pellet caused a progressive weight loss for the next nine days. Groups given daily injections of nicotine did not show this effect. The weight loss was followed by a progressive weight gain from day nine until day seventeen when the pellets were removed. After explant, the treated rats showed a dramatic weight gain of sixteen grams in two days, which brought them to a level above the control mean. All nicotine-treated groups in this experiment showed hypoactivity in the home cage.

A second experiment was designed to increase the effect of postnicotine weight gain by keeping the rats on the nicotine pellet longer (70 days) and by including a group exposed to nicotine on an intermittent basis (rounds of two weeks exposed and two weeks unexposed). Consumption of food and water was measured to determine the involvement of variation of intake in the nicotine-induced weight changes. The results have replicated the previous findings of a progressive weight loss in the nicotine-exposed groups followed by a weight gain after day nine. Accompanying the weight loss was a decline in food and water consumption. The food and water consumption in the exposed groups increased starting seven days after implantation. Consumption was back to control levels by eleven days postimplantation. After removal of the pellets on day fourteen, the intermittent group increased food and water consumption to levels higher than controls and rapidly gained weight passed the control mean. A more robust post-nicotine weight gain would greatly facilitate subsequent studies of the mechanisms behind the effect.

186.14 ALTERATION OF OVARIAN FUNCTION IN FETAL ETHANOL EXPOSED IMMATURE RATS: POSSIBLE HYPOTHALAMO-HYPOPHYSEAL DEFECT. P.K. Rudeen, J. Hagaman and C.A. Kappel Department of Anatomy, The University of Missouri School of Medicine, Columbia, Missouri 65212.

Exposure to ethanol during pregnancy has been demonstrated to result in decreased body weight, increased mortality, smaller litter size and alteration of central nervous system structure and function. The sexually dimorphic nucleus of the preoptic area, an area involved in the regulation of reproduction in the rat, is altered by fetal ethanol exposure. Little is known about the effects of fetal ethanol exposure on reproductive organ function and regulation. Two experiments were performed to determine the effects of in utero ethanol exposure on ovarian function and its neuroendocrine regulation in the offspring rat. Pregnant female rats were given liquid diets containing either ethanol (5% w/v), a liquid diet containing isocaloric amounts of maltose dextrin, or standard laboratory chow and water throughout pregnancy and continuing until weaning. In the first experiment, 30 day-old female rats from each group were unilaterally ovariectomized. The oviduct was removed from the ovary and the ovary weighed to the nearest 0.1 mg. Ten days later, the animal was autopsied, blood collected and the remaining ovary removed and weighed. In the second experiment, when the female pups reached 30 days of age, each animal received 20 I.U. of Pregnant Mare's Serum Gonadotropin (PMS) alone or PMS followed by 10 I.U. of Human Chorionic Gonadotropin (hCG) to induce ovulation. At autopsy, each oviduct was removed from the ovary, the ova were counted and the ovary and uterus were weighed to the nearest 0.1 mg. Blood was collected and the serum harvested. Serum progesterone levels were measured by radioimmunoassay. In the first experiment, the female rats whose mothers were on a control diet during gestation showed greater relative compensatory ovarian hypertrophy (COH) than did the female offspring from fetal alcohol exposed rats ($p<0.01$). In the second experiment, animals in both the alcohol and control groups which were given PMS/hCG had greater ovarian weights ($p<0.01$) than those animals given PMS alone indicating the LH analog (hCG) enhanced ovarian function. The ethanol exposed animals showed an enhancement of ovarian response due to increased ovarian weights ($p<0.01$), greater number of ova shed, and increased blood progesterone levels when compared with the other control groups given the PMS/hCG treatment. The results indicate the reduction of COH by fetal ethanol exposed rats possibly due to the reduced hypothalamo-hypophyseal response to the loss of steroids following the removal of one ovary. In addition, the intensified response of the ovary to exogenous hormones (PMS/hCG) in the fetal alcohol exposed immature rat may also indicate a loss of the sensitivity of the hypothalamus to steroid feedback. (Supported by NIAAA Grant No. AA05893)

186.15 TOLERANCE DEVELOPS ONLY TO THE RATE DECREASING EFFECTS OF CHLORDIAZEPOXIDE AND ATROPINE UNDER A DIFFERENTIAL REINFORCEMENT OF LOW RATE (DRL) SCHEDULE IN RATS. J. M. Carney*, M. Nakamura*, S. B. McMaster* and H. D. Christensen. Department of Pharmacology, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Male Sprague Dawley rats were trained to respond under a DRL 10 sec schedule of food reward. Six rats were assigned to the chronic atropine group and six rats were assigned to the chronic chlordiazepoxide group. The 80 minute session was divided into 8 components. The session began with a 10 min extinction component, which alternated with a 10 minute DRL 10 sec component during which correct responding resulted in delivery of a 45 mg food pellet. The session ended after completion of the fourth DRL component (4 extinction and 4 DRL components). Control sessions demonstrated a typical pattern of responding for which the total number of DRL responses was 75 ± 6 (SEM) responses/10 minutes. Of these 75 total responses/10 min an average of 43 responses resulted in food reward. The remaining 32 responses resulted in a resetting of the DRL clock and did not result in food delivery. Cumulative doses effect curves for chlordiazepoxide (1.0, 3.2, 10, 32 mg/kg) and atropine (1.0, 3.2, 5.6 and 10 mg/kg) were determined by injecting the appropriate dose at the start of the extinction component. Chlordiazepoxide doses of 3.2 and 10 mg/kg produced increases in the total number of non-reinforced DRL responses. At the 10 mg/kg dose chlordiazepoxide also produced a decrease in the number of reinforced resopnses. Atropine increased non-reinforced DRL responses at relatively low doses 1.0 and 3.2 mg/kg. Higher doses (5.6 and 10 mg/kg) produced decreases in both reinforced and non-reinforced responses. Daily administration of 32 mg/kg chlordiazepoxide (Group I) or 10 mg/kg atropine (Group II) demonstrated the development of tolerance to the rate-decreasing effects of these drugs on reinforced DRL responding. Redetermination of the dose-effect curves failed to demonstrate the development of tolerance to the stimulant effects atropine or chlordiazepoxide on non-reinforced DRL responding. These data demonstrate that the CNS systems involved in controlling reinforced and non-reinforced DRL responding are different.

186.16 BENZODIAZEPINE HYPOTHERMIC TOLERANCE: ANALYSIS OF THE ROLE OF DRUG-PREDICTIVE ENVIRONMENTAL STIMULI AND CROSS-TOLERANCE TO ETHANOL. A.J. Goudie and J.W. Griffiths*. Dept. of Psychology, P.O.Box 147, Liverpool University L69 3BX, England.

Tolerance to the hypothermic effect of midazolam, a short acting benzodiazepine, was assessed in rats with a counterbalanced discrimination conditioning procedure (Cunningham, C.L., et al., Pharmacol. Therap., 23: 365, 1984) in which specific environmental cues were always associated with drug or saline administration. Marked (almost complete) tolerance developed over 16 days of treatment (given every other day) to the acute hypothermic effect (loss of 2.3°C core body temperature) of midazolam (4 mg/kg i.p.). However, the observed tolerance was not environmentally specific since it was present in subsequent tests in the absence of drug-predictive environmental cues. Similar findings were obtained in a subsequent study with a lower dose of midazolam (1.6 mg/kg i.p.) in which the drug was given every fifth day rather than on alternate days. With the lower dose of midazolam tolerance developed more rapidly (over 5 exposures), as expected. However, the observed tolerance was again not environmentally specific, since it was also present in tests in the absence of drug-predictive cues. Since there is some evidence (Baker, T.B., Tiffany, S.T. Psych. Review, In Press) that environmentally specific tolerance is more likely to develop with low drug doses which are given infrequently, such data provide convincing evidence for the absence of environmentally specific tolerance with benzodiazepines. Thus, these data, which were obtained with conditioning procedures designed to maximize the role of environmental cues in tolerance acquisition, indicate that tolerance to benzodiazepine-induced hypothermia differs from that seen with other C.N.S. depressants (ethanol, barbiturates) which have been reliably reported to produce conditioned environmentally specific tolerance (Siegel, S., MacRae, J. Trends Neurosci., 7: 140, 1984).

Cross-tolerance to ethanol-induced hypothermia (1.2 or 1.6 g/kg i.p) was absent in subjects which were tolerant to midazolam-induced hypothermia, regardless of whether or not drug-predictive environmental cues were present in cross-tolerance tests. These findings contrast with the hypothesis of Khanna et al. (Eur. J. Pharmac., 59: 145, 1979), based on studies of drug-induced hypothermia, that tolerance develops to drug effects rather than to drugs themselves, since two drugs (ethanol and midazolam) with apparently common effects did not show cross-tolerance.

186.17 DECREASED SEIZURE RESPONSE TO ELECTROSHOCK AND BICUCULLINE IN RATS AFTER ONE WEEK OF DAILY MAXIMAL ELECTROSHOCK TREATMENT. J. Boschulte* and K. Gale (SPON: J.R. Moffet). Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

To determine whether repeated exposure to maximal electroshock (MES) alters the seizure sensitivity of rats, we treated rats with MES daily and recorded the duration of tonic hindlimb extension (THE). MES was applied via corneal electrodes (60 Hz, 200 msec, 150 mA) using a Wahlquist apparatus. THE duration was significantly lower (as compared to first exposure) after 4 days of repeated MES, and continued to decline thereafter. After one week of daily MES, the duration of THE decreased to approximately 50% of that obtained in response to the first MES exposure.

Twenty-four hours following the last MES treatment, rats were tested for responses to intravenous bicuculline (.36 mg/kg). Controls consisted of rats that had been exposed daily to the electroshock apparatus (in contact with corneal electrodes) but received no shock. In rats with prior history of 7 MES exposures there was a significantly reduced incidence of major clonic or tonic seizures in response to i.v. bicuculline when compared with controls not exposed to MES or exposed to only one MES treatment.

These results indicate that a type of "tolerance" develops in response to repeated daily exposure to electroconvulsive shock and that a "cross-tolerance" develops to bicuculline induced seizures. This suggests that repeated seizures may alter the sensitivity of neural substrates involved in seizure development.

186.18 AVOIDANCE BEHAVIOR FOLLOWING ELECTROLYTIC, AF64A AND KAINIC ACID LESIONS OF THE SEPTUM. D.A. Johnson, B.E. Polenchar, A.L. Beggs, P.R. Sanberg and M.M. Patterson, Department of Psychology and College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

In this study we sought to determine if the effects of electrolytic septal lesions on avoidance behavior are due to damage to the septum per se, or to an interruption of efferent fibers passing through the septum. Sprague-Dawley albino rats were used as subjects. Standard electrolytic lesions were produced which destroyed the entire septum as well as hippocampal efferents in the fornix. Infusion of kainic acid (.3 µg in .3 µl of vehicle) produced small lesions of the septum, involving only about 10% of the structure. These lesions were much smaller than anticipated, however, our previous experience with kainic acid (KA) indicated that dosages larger than this usually resulted in hippocampal and infratemporal cortical damage as well. Infusion of AF64A (1 nm in .5 µl of vehicle) resulted in lesions which more closely approximated the damage produced by electrolytic lesions. AChE staining clearly indicated the decreased presence of the enzyme in smaller lesions, but in most cases there was complete destruction of the septal area. However, in most cases the fornix was spared. Infusion of vehicle only did not produce any noticeable lesion. After a 1 month recovery period, subjects were trained in a two-way avoidance shuttle box for 30 CS-US trials each day. A 10 sec tone CS preceded a .7 mA grid-shock US. Subjects were trained to a criterion of 8 avoidances out of 9 consecutive trials, and then overtrained for an additional 30 trials. Active avoidance acquisition was markedly facilitated (Md=24 trials to criterion, N=8) by electrolytic lesions. The effect of the small KA lesions (Md=85 trials, N=9) was minimal when compared to the vehicle control group (Md=116 trials, N=6). Acquisition was moderately facilitated in the AF64A subjects (Md=55 trials, N=8). Only the electrolytic septal lesion effect was significant. After avoidance overtraining, subjects were trained to the same criterion on a passive avoidance task. The pattern of results was similar but the direction of effects was opposite. Electrolytic septal lesions markedly hindered passive avoidance acquisition (Md=49 trials to criterion vs. Md=8 trials for other groups). While we were not able to compare the effects of KA vs. AF64A in a meaningful way (KA lesions were small, AF64A lesions quite large), it is clear that AF64A destruction of the cells in the septum has a much smaller effect on both active and passive CAR learning than electrolytic septal lesions. These results would indicate that the bulk of the CAR electrolytic septal lesion effects may result from a disruption of fibers passing though the septum.

188 SYMPOSIUM. PEPTIDE-AMINE INTERACTIONS IN THE NEURAL REGULATION OF CELL FUNCTION. A. Negro-Vilar, NIEHS-NIH, and B. McEwen, Rockefeller Univ. (Chairpersons); T.L. O'Donohue, NINCDS-NIH; R.E. Zigmond, Harvard Med. Sch.; H. Viveros, Wellcome Res. Labs.

Neurotransmission includes both excitation and inhibition of electrical activity, as well as involving activation of second messenger systems. However, neurotransmitters also produce effects which are not evident unless another excitatory substance is acting to depolarize or hyperpolarize. Other hormonal or neuroactive agents produce effects which alter, over a longer time course, the functional capacity of neurons to carry on neurotransmission. These latter two categories of action are often referred to under the heading of "neuromodulation" and will be the subject of the present symposium.

These general concepts of neuromodulation will be discussed, focusing particularly in peptide amine interactions as a key example of a modulatory mechanism within the nervous system (McEwen). The concepts of co-localization and co-secretion of peptides, or peptides and amines, will be analyzed using central proopiomelanocortin and dopaminergic neuronal interactions to illustrate regulation of hormone synthesis and secretion (O'Donohue). Several neuroendocrine examples of peptide-amine interactions will be described, including the potentiation of ACTH/β-endorphin secretion under combined stimulation by vasopressin and serotonin; the opiate-amine-LHRH interplay within the preoptic-hypothalamic system that provides a model regulatory system for gonadotropin secretion and gonadal function, and the possible intracellular messenger systems that may underlie these interactions (Negro-Vilar). The increased tyrosine hydroxylase (TH) activity in superior cervical ganglia observed after electrical stimulation is in part mediated by the cholinergic system and in part by a putative peptidergic transmitter related to the glucagon-secreting family. Additional data suggests that the resulting increase in TH activity is mediated via an enhanced production of cAMP, which may then represent the common link between these neuromodulators (Zigmond). Adrenal medulla chromaffin cells co-store large amounts of proenkephalin-derived peptides with catecholamines. Both neural agents are co-released upon neurogenic stimulation, and parallel or reciprocal changes in peptide and amine levels or biosynthesis can be observed under appropriate circumstances. Some of these parameters are also cAMP-dependent (Viveros). The evidence reviewed in this Symposium should provide some key examples of the neuromodulatory role played by peptide-amine interactions, both within the central and peripheral nervous system, and of the resulting modified cellular and hormonal responses observed under those influences.

189 Symposium. NEURAL BASIS OF LATERALIZED BEHAVIOR: FROM LABORATORY TO CLINIC. R. G. Robinson, Johns Hopkins Univ. Sch. Med. (Chairperson); S. Glick, Albany Medical College; V. Denenberg, Univ. of Connecticut; J. Lipsey, Johns Hopkins Univ. Sch. Med.; B. Kolb, Univ. of Lethbridge; A. Galaburda, Beth. Israel Hospital.

This symposium will present mechanisms underlying the behavioral expression of cerebral lateralization. Anatomical, biochemical, and physiological mechanisms involved in an asymmetrical elicitation of behavior or lateralized localization of behavior will be the focus of this symposium. The relationship between laboratory and clinical findings in humans will be emphasized.

Dr. Stanley Glick will present functional and neurochemical asymmetry in the dopaminergic nigrostriatal system. New data concerning mechanisms underlying interindividual differences and the degree and kind of asymmetry will also be presented. Furthermore, the relevance of brain asymmetry to the modes of action of psychoactive drugs will be discussed.

Dr. Victor Denenberg will discuss animals who have had extra stimulation in infancy who have been found to have more lateralized brains than non-stimulated controls. These differences have been found in adulthood using a variety of behavioral tests.

Dr. Robert Robinson will discuss findings in humans of anatomical specificity, including lateralized response, of mood disorders to stroke injury. The relationship between these clinical phenomenon and lateralized behavioral and biochemical response to brain injury in the rat will be presented as a possible basis for understanding the mechanism of mood disorders occurring in brain injured humans.

Dr. John Lipsey will discuss interhemispheric interactions in the lateralized affective and behavioral response to focal cortical brain injury. Data will be presented that support the view that poststroke depression following left anterior hemisphere injury in man and hyperactivity following right anterior hemisphere focal lesions in the rat do not depend on interhemispheric release or interaction.

Dr. Bryan Kolb will examine the effects of cortical lesions on the behavior of human and non-human species, with emphasis upon changes in praxic, spatial, and affective behavior; the relationships between behavioral changes and cortical site and side; and anatomical and neurochemical asymmetries related to the behavioral observations.

Dr. Albert Galaburda will describe his recent studies on the visual cortex of the rat which demonstrates that architectonic asymmetry reflects differences in total cell numbers. Furthermore, experiments aimed at specifying whether these differences result from asymmetrical cell production or asymmetrical cell death will be reviewed.

PAIN MODULATION: STIMULATION STUDIES

190.1 INHIBITION OF RAT SPINAL NEURONAL RESPONSES TO NOXIOUS SKIN HEATING BY STIMULATION IN HYPOTHALAMUS AND OTHER DIENCEPHALIC SITES. E. Carstens. Dept. Animal Physiology, Univ. Calif., Davis, CA 95616.

Electrical stimulation in the hypothalamus was reported to suppress responses of spinal dorsal horn neurons to noxious footpad heating in the cat (J. Neurophysiol. 48:809 and this volume). The present results confirm this in the rat, and provide additional quantitative analyses of hypothalamo-spinal inhibition as well as a map of the distribution of diencephalic sites at which stimulation inhibits or otherwise affects spinal neurons.

The responses of single lumbar dorsal horn units to noxious radiant heating of ipsilateral hindpaw skin were recorded with tungsten microelectrodes in adult male Sprague-Dawley rats deeply anesthetized with sodium pentobarbital. Unit responses to heat stimuli (e.g., 50°C, 10 s) repeated at 2 min intervals were stable; effects of bipolar stimulation (100 ms trains at 100 Hz, 3/s, 0-400 μA) applied during the unit's response to the next heat stimulus were expressed as a percentage of the unit's heat-evoked response in the absence of brain stimulation. To map inhibitory (or other) sites, stimulation was applied through each of 5 electrodes spaced 2 mm apart; the array was lowered in 1 mm steps. In each of 14 such experiments, constant stimulation (usually 200 μA) in the medial hypothalamus (from the level of mammilary bodies to just posterior to the optic chiasm) reliably suppressed heat-evoked responses (to 0-50% of control). Equally strong inhibition was usually generated from midline thalamus and lateral hypothalamus bilaterally and frequently from the ventrobasal thalamic complex bilaterally. Medial amygdalar stimulation frequently produced strong inhibition bilaterally, while more lateral amygdalar sites were less effective.

Responses of each of 30 units were inhibited by medial hypothalamic stimulation. This inhibition generally had a rapid time course, sometimes followed immediately by a post-stimulation rebound in unit firing. Inhibition increased with graded increases in stimulation intensity. The mean current at threshold for inhibition was 71 ± 43 μA for 13 units. Spinal unit responses generally increased linearly with graded increases in the temperature of noxious heat stimuli. The slopes of these linear stimulus-response functions were reduced, with no change in threshold, during medial hypothalamic stimulation in each of 9 units. The inhibition was reduced following systemic administration of the serotonin antagonist methysergide. These results are similar to our previous results in the cat, and indicate that a descending inhibitory system, possibly involved in analgesic mechanisms, can be activated from the medial hypothalamus in vertebrates.

Supported by NIH grants NS 20037 and NS 19330.

190.2 ELECTRICAL STIMULATION OF THE NUCLEUS TRACTUS SOLITARIUS (NTS) CAUSES OPIOID MEDIATED ANALGESIA IN THE RAT. J.W. Lewis, G. Baldrighi*, S.J. Watson, and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Recent evidence suggests that the NTS, a medullary nucleus known to be involved in autonomic control, may be an integral part of an endogenous opioid-mediated pain-inhibitory system. This nucleus is rich in opioid peptides and their receptors, and has anatomical connections with several brain regions involved in the control of pain. We now report that electrical stimulation of the NTS causes opioid mediated analgesia.

Rats were anesthetized with pentobarbital and mounted in a stereotaxic frame. Stimulating electrodes were lowered into the medulla, near the midline at the level of the obex, to reach the NTS. Pain sensitivity was assessed before and after 30 sec of stimulation using the tail-flick test. Tail-flick latencies exhibited by pentobarbital anesthetized rats are very similar to those recorded in awake animals.

Stimulation of the NTS, but not adjacent sites, caused significant elevations in tail-flick latencies. The analgesic response to NTS stimulation was nearly abolished by pretreatment with naloxone (10 mg/kg).

To assess the relationship between NTS stimulation-produced changes in hemodynamics and alterations in pain sensitivity, we measured simultaneously arterial blood pressure and tail-flick latencies. NTS stimulation typically caused hypertension, although some sites elicited hypotension and others had no effect. Overall, elevations in tail-flick latency and changes in blood pressure were not significantly associated. Furthermore, administration of a sympathetic ganglionic blocking drug prevented stimulation-produced hypertension without affecting analgesia, and treatment with naloxone blocked the analgesia without markedly affecting hypertension.

That stimulation of the NTS causes opioid mediated analgesia may alter conceptions of the organization of endogenous pain-inhibitory systems. Although these systems have been characterized as arising in the medial brainstem and descending to the spinal cord, the origin of the neural signals capable of energizing this system is not known. The NTS, a major recipient of somato/visceral sensory information with projections to many classical pain-inhibitory nuclei, is a likely candidate. Finally, since exposure to stress has been shown to cause analgesia and is accompanied by numerous autonomic sequelae, and because the NTS is known to be involved in these autonomic responses and NTS stimulation elicits pain-inhibition, it is reasonable to hypothesize that an important linkage between stressful stimuli and endogenous analgesia systems occurs via the NTS.

190.3 STIMULATION-PRODUCED ANALGESIA FROM VENTROLATERAL PONTINE TEGMENTUM IS NOT MEDIATED THROUGH THE NUCLEUS RAPHE MAGNUS. J. F. Miller & H. K. Proudfit, Dept. of Pharmacology, Univ. of Illinois at the Medical Center, Chicago, IL 60680.

Stimulation of the rat ventrolateral pontine tegmentum (VLPT) produces a potent analgesia on the tailflick test (Miller & Proudfit, Soc. Neurosci. Abstr., Vol. 10, Part 1, p. 201, 1984). The present experiments suggest that the stimulation-produced analgesia (SPA) obtained from VLPT sites is independent of the serotonergic raphespinal projection system arising from the nucleus raphe magnus (NRM).

In the first experiment, adult female Sprague-Dawley rats were implanted with both a unilateral twisted-wire bipolar stimulating electrode in the VLPT and an intrathecal catheter terminating in the lumbar subarachnoid space. Following a 4-5 day recovery period, baseline tailflick latencies (TFLs) were determined and the animals were screened for analgesic VLPT sites (stimulation parameters were: 0.1 msec square wave pulses, 50-200 uA, 60 Hz). Rats in which VLPT stimulation markedly elevated TFLs then received an intrathecal microinjection of either phentolamine (30 ug), methysergide (30 ug), or saline, and the effectiveness of VLPT stimulation in elevating TFLs was again assessed 15, 30, and 60 min after injection. In agreement with our previous report, intrathecal administration of the alpha-adrenergic antagonist phentolamine significantly attenuated VLPT SPA. By contrast, the serotonergic antagonist methysergide was without effect on SPA elicited from VLPT sites.

In the second experiment, adult female rats were implanted with both a unilateral bipolar stimulating electrode into the VLPT and a guide cannula aimed at the NRM. Rats in which electrical stimulation of the VLPT markedly raised TFLs subsequently received a microinjection of the local anesthetic tetracaine (5 ug/ 0.5 ul saline) directly into the NRM. The effectiveness of VLPT stimulation in elevating TFLs was found to be unimpaired by tetracaine microinjections into the NRM.

In summary, these experiments indicate that the SPA obtained from sites in the rat VLPT does not require the involvement of NRM serotonergic projections to the spinal cord, but rather depends on the activation of a descending noradrenergic spinal projection system. (This work was supported by USPHS Grant NS 18636).

190.4 REINVESTIGATION OF INHIBITION OF SPINAL NOCICEPTIVE NEURONS BY HYPOTHALAMIC STIMULATION IN THE CAT. J.M. Horowitz & E. Carstens. Dept. of Animal Physiology, Univ. Calif., Davis, CA 95616.

We previously reported that stimulation throughout the antero-posterior (AP) extent of the hypothalamus (J. Neurophysiol. 48: 808; 981; 50:192) suppressed responses of cat spinal dorsal horn neurons to noxious heating of footpad skin. These experiments were redone with the aim of correcting stimulation intensities which were inadvertently underestimated in the previous studies, and to quantitatively compare inhibition from multiple diencephalic sites.

In cats anesthetized with sodium pentobarbital and 70% N20, tungsten microelectrodes recorded responses of single lumbar dorsal horn units to noxious radiant heat stimuli (e.g., 50°C, 10 s) on glabrous footpad skin. Unit responses to heat during bipolar brain stimulation (100 ms trains at 100 Hz; 3/s; 0-600 μA monitored with a current probe) were expressed as a % of the unit's response without brain stimulation.

Responses of 36/39 units were reliably reduced during diencephalic stimulation. Inhibition (to 0-50% of control) was evoked by 400 or 600 μA stimulation throughout the AP and mediolateral extent of the hypothalamus bilaterally, as previously reported. Inhibition increased with graded increases in brain stimulation intensity. Mean values (± S.D.) for 3 parameters of inhibition are tabulated below according to medial posterior, mid- and preoptic, or lateral, hypothalamic stimulation sites. Recruitment index = slope of current-inhibition plot.

Site (N)	Threshold (μA)	Recruitment Index (%/100 μA)	Current at 50% inhibition (μA)
posterior (16)	109 ± 82	17 ± 6	323 ± 164
mid- (10)	54 ± 36	18 ± 5	291 ± 191
preoptic (10)	124 ± 87	13 ± 7	353 ± 158
all medial (36)	93 ± 74	16 ± 6	321 ± 167
lateral (5)	87 ± 53	28 ± 14	205 ± 117

We believe that these values are more accurate than those in our previous reports, which overestimated inhibition by 1.5-3 fold due to a ground loop in the brain stimulation circuit. Unit responses increased linearly with increasing stimulus temperature, and the slopes of these temperature-response lines were reduced during medial hypothalamic (N=7 units), preoptic-septal (N=4) or lateral hypothalamic (N=4) stimulation with no significant change in threshold, confirming our previous reports. Finally, we have confirmed our report (Soc. Neurosci. Abs. 9:788) that stimulation at more lateral sites including the internal capsule and amygdala produces varying degrees of inhibition of spinal units. Supported by NIH grant NS 19330.

190.5 ELECTRICAL STIMULATION OF THE RAT VENTRAL AND LATERAL MIDBRAIN SUPPRESSES THE TAIL FLICK REFLEX (SOMETIMES). J.M. Rothfeld*, M.J. Guinan*, S. Pretel, E.S. Culhane*, E. Carstens & L.R. Watkins (SPON: P.A. Pappone). Dept. of Animal Physiol., Univ. of Calif., Davis, CA, 95616.

Stimulation of ventral & lateral areas of the midbrain (VMB) strongly inhibit dorsal horn neuronal responses to noxious skin heating in anesthetized rats (Carstens and Watkins, Soc. Neurosci. Abs. 10:674, '84). The present study investigated VMB stimulation effects on the behavioral response of awake rats to noxious heat stimuli. The effects of two different stimulation parameters were compared: (A) the monophasic stimulation parameter (MPS) used in previous electrophysiological studies (monophasic 0.1 ms square waves at 100 Hz given in 100 ms trains 3/s, 50-1100 μA) and (B) a biphasic stimulation parameter (BPS) more commonly used in behavioral studies (20 Hz biphasic pairs of 0.05 ms square waves of opposite polarity & equal amplitude separated by 0.1 ms, 0.25-4.0 mA). The stability of the phenomenon and the effects of naloxone were also examined. Two bipolar electrodes separated mediolaterally by 1-2 mm were chronically implanted in the VMB of each of 130 male Sprague-Dawley rats. Two and 3 weeks after implantation, a system of ascending limits was used to determine the threshold stimulation current (TC), using either BPS or MPS, necessary to increase the tail flick latency (TFL) from control levels (~3 s) to 8 s. The TFL was measured immediately after 20 s of brain stimulation.

Stimulation in various areas in the VMB suppressed the TF reflex, but no area was consistantly effective. BPS was effective (mean TC = 2.1 mA) at 70 of 214 sites while MPS was effective (mean TC = 680 μA) at 72 of 215 sites. Both were effective at 33 of these sites. The effectiveness of a given site could not be correlated with either the intensity of other behaviors exhibited by the animal during the stimulation, or the anatomical location of the electrode. No differences were observed in the effects of naloxone (10 mg/kg i.p.) & saline on TF suppression.

In a second experiment the stability of the TC at 30 sites in 15 animals was examined by repeating the TC determination one week later. For both MPS & BPS, stability was poor; only 69% of the originally effective sites could suppress the TF when retested. Among these remaining effective sites the TC was seen to increase or decrease markedly. Four sites that were initially ineffective became effective in week 2. In these same 15 animals the short term stability was assessed by retesting the animal at the TC 30 min after the original TC determination. Short term stability was also poor; only 65% of the sites remained effective. These results indicate that apparent anti-nociception from the VMB is an extremely labile phenomenon and that great caution must be used in interpreting the results of such brain stimulation studies. Supported by NIH grant NS20037.

190.6 A REINVESTIGATION OF SEROTONIN INVOLVEMENT IN DESCENDING INHIBITION OF SPINAL NOCICEPTIVE TRANSMISSION PRODUCED BY STIMULATION OF MEDIAL FOREBRAIN. M.J. Guinan*, D.A. Van Alstine* and E. Carstens (SPON: L.R. Watkins). Dept. of Animal Physiology, Univ. Calif., Davis, CA 95616.

We previously reported that inhibition of dorsal horn neuron responses to noxious skin heating by medial forebrain stimulation was reduced by (1) the serotonin (5-HT) antagonist methysergide, or (2) pretreatment with the 5-HT synthesis inhibitor p-chlorophenylalanine (PCPA) (J. Neurosci. 3:10, 2112). It was later discovered that the current intensities used were underestimated due to a ground loop in the stimulation circuit. A re-evaluation of currents necessary for spinal inhibition appears in this volume (see Horowitz & Carstens). The present study was undertaken to re-evaluate the role of 5-HT in descending inhibition from the medial diencephalon and forebrain.

In cats anesthetized with sodium pentobarbital and 70% N_2O, we recorded responses of single lumbar dorsal horn neurons to noxious radiant heating (48-52°C, 10 s) of the hind footpad skin. Unit responses to heat during bipolar brain stimulation (100 ms trains, 3/s, of monophasic 0.1 ms pulses at 100 Hz; 100-800 μA) were expressed as a percentage of the response without brain stimulation.

Confirming our previous results, inhibition was greatly reduced or abolished in 6/7 units after methysergide (0.5-1.5 mg/kg, i.v.). For 14 stimulation sites, the average inhibition (21.9%) was significantly reduced (90.9%) after methysergide (paired t-test $p < .005$). Reduction of inhibition was comparable for rostral (medial preoptic) and caudal (periventricular gray) sites. In one unit, inhibition was seen to recover after 90 min. Preliminary results from 14 units in 4 cats pretreated with PCPA (500 mg/kg, 72 h prior to experiment) indicate there is no reduction in inhibition compared to non-pretreated cats.

In addition we have repeated previous experiments (with S. Pretel) describing spinal inhibition from stimulation of the caudate nucleus (Pretel et al., Soc. Neurosci. Abst. 9:788, 1983) and orthodromic activation of raphe-spinal neurons from forebrain stimulation (Guinan et al., Soc. Neurosci. Abst. 9:788, 1983) which were also performed with the flawed stimulation circuit. In 10 cases, contrary to our previous report, no inhibition could be demonstrated from stimulation of the caudate nucleus with bipolar currents of up to 1 mA, while inhibition was generated from more ventromedial sites in the same experiments. We also feel that in some cases the reported forebrain driving of raphe-spinal cells may have been due to current spread and that these latter experiments need to be repeated. Supported by NIH grant NS19330.

190.7 THE EFFECTS OF NEUROTENSIN AND MORPHINE ON BRAIN-STIMULATION ESCAPE. H.S. Wheeling*, T.L. Sullivan*, and A. Pert. (Spon. C.T. Bennett). NIMH, Biological Psychiatry Branch, Bethesda, Maryland, 20205.

Neurotensin, an endogenous tridecapeptide, displays antinocisponsive activity when tested with standard analgesic screening methods. Instrumental escape responding maintained by electrical stimulation delivered to the mesencephalic reticular formation (MRF) has been shown to be responsive to the anti-aversive properties of various opioids administered systemically. Thus, we decided to compare the effects of intracerebroventricularly administered neurotensin and morphine on brain-stimulation escape.

Rats were implanted with bipolar electrode aimed at the MRF and 22 ga. guide cannula aimed 1.5mm dorsal to the lateral ventricle. In a discrete trial paradigm, subjects were trained to press a lever in order to escape from 10s of continuous biphasic electrical stimulation (0.2ms p. width, 0.2ms delay, 0.5ms ISI) delivered to the MRF. Current amplitude was varied according to a modification of the psychophysical method of limits in order to establish an escape threshold. The major dependent variable was the difference between post-treatment and pretreatment escape thresholds.

The administration of morphine (5-15 nmoles, i.v.t.) produced elevations of escape thresholds, as has previously been demonstrated with systemically administered morphine utilizing the same paradigm. In contrast, neurotensin (5-15 nmoles, i.v.t.) not only failed to elevate escape thresholds, but actually lowered thresholds as compared with control injections (0.9% NaCl), suggesting a pronocisponsive effect.

Whether the observed enhancement of aversive brain stimulation by neurotensin is a function of the use of central stimuli or of the measurement of conditioned behavior is unclear. However, our results with this peptide contrast with those obtained by measuring unconditioned responses to peripheral noxious stimuli.

190.8 ELECTRICAL STIMULATION OF THE HABENULA REDUCES TONIC PAIN IN THE FORMALIN TEST. S. R. Cohen and R. Melzack*. Dept. of Psychology, McGill Univ., 1205 Docteur Penfield, Montreal, P.Q., Canada, H3A 1B1.

The habenula connects many limbic forebrain structures with brainstem nuclei known to play an important role in analgesia and is therefore ideally situated to modulate the affective component of pain. We have shown that microinjection of morphine into the area of the habenula/dorsal-posteromedial thalamus produces analgesia in the formalin test, which involves tonic, moderate pain (Pain, Supp. 2, 1984, p. 347). Furthermore, Benabid and Mahieux (Soc. Neurosci. Abst., 1984) report stimulation-produced analgesia from the habenula in the tail-flick test. This analgesia was not present during stimulation, developed slowly, reached a peak 60-80 min post-stimulation, and was reversed by naloxone.

To determine whether habenular stimulation produces analgesia in the formalin test, twisted bipolar electrodes were implanted unilaterally in the habenula of anesthetized rats at least 1 wk prior to testing. Stimulation consisted of monopolar, square-wave pulses of 0.5 msec duration at a frequency of 50 Hz, delivered for 30 sec either once or 10 times over a period of 10 min. Effective current intensities ranged from 50-300 μA.

Electrical stimulation of the habenula reduced pain in the formalin test both during and following stimulation. This effect was not blocked by administration of 5 mg/kg naloxone s.c. The duration and strength of post-stimulation analgesia varied from rat to rat and was also dependent on current intensity. Since testing was stopped 60 min following the formalin injection because baseline pain levels begin to drop after this length of time, it was not possible to determine the maximal duration of the post-stimulation analgesia. However, post-stimulation analgesia was recorded for up to 24 min. While pain was sometimes abolished by habenular stimulation, more frequently the pain was reduced but not eliminated. The unilateral electrode was able to reduce pain in either hindpaw. During the stimulation the rats usually placed the elevated paw on the floor and often became active, walking normally and rearing frequently. Occasionally the rats would urinate during the stimulation. No behavioral effects indicating aversiveness were noted.

These results indicate that habenular stimulation can reduce tonic, moderate pain as well as the phasic, threshold level pain measured in the tail-flick test by Benabid and Mahieux. While the analgesia produced in the formalin test was evident immmediately and was not affected by naloxone, the analgesia reported in the tail-flick test was delayed and completely reversed by naloxone. Whether this difference is due to the different types of pain studied or to different stimulation parameters remains to be determined.

190.9 INHIBITION OF TRIGEMINAL NOCICEPTIVE INPUT BY DORSAL COLUMN STIMULATION (DCst) IN DECEREBELLATE-DECORTICATE CATS. S.F. Atweh, N.E. Saadé*§ and S.J. Jabbur. Fac. of Med., Amer. Univ. of Beirut, Beirut and §Fac. of Sci., Lebanese Univ., Hadath-Beirut, Lebanon.

We have previously shown that DCst in decerebrate and decerebellate cats can modulate pain evoked activities in the spinal cord through a brainstem loop (Brain Res., 310:184, 1984; 335:306, 1985; and in Press 1985). We now demonstrate that ascending activation of the dorsal columns (DC) can also inhibit nociceptive evoked activity in the trigeminal nucleus caudalis (n. caud.) through a brainstem loop. Ten cats were anesthetized (Nembutal or chloralose), immobilized (Flaxedil) and artificially ventilated. They were decerebellated and decorticated through a large craniotomy. The upper cervical cord and lower medulla were exposed through a cervical laminectomy and the C_1-C_4 dorsal roots were sectioned. In two cats, the DCs were dissected as a strand and placed on stimulating electrodes after cutting their caudal ends. In eight cats, the ventral and lateral funiculi were bilaterally lesioned at both C_1 and C_4 levels, leaving the DCs intact; in this preparation (v-cut), the DCs were either stimulated directly through bipolar electrodes placed caudal to the cuts, or indirectly by stimulating the paws. The extracellular activity of 46 neurons in n. caud. were recorded and classified according to their sensory modalities (low threshold mechano-receptive-LTM or wide dynamic range-WDR neurons), their response to tooth pulp (TP) stimulation and their projection (relay or non-relay neurons) to the thalamus. Conditioning electrical stimulation, delivered directly to the DCs or to the paws in v-cut preparations, inhibited 40 (87% of the total) neurons. This inhibition was most marked on the late firing of WDR neurons evoked by nociceptive stimuli to the face or TP, but was also observed on LTM neurons evoked by just-suprathreshold stimuli. Both relay and non-relay neurons were inhibited. In v-cut preparations, stimulation of the forepaws was more effective than the hindpaws and ipsilateral side was more effective than contralateral side.

Thus, our findings show that somatic sensory input triggered by peripheral stimuli and ascending in the DCs can inhibit nociceptive input in trigeminal n. caud. No direct projections have been described between the DCN and the trigeminal nuclei. We have earlier demonstrated, however, DCN inputs into periaqueductal gray and raphe nuclei which have been implicated in stimulus produced analgesia. A DC-brainstem-trigeminal loop can, therefore, account for the findings of this report.

190.10 **INHIBITION OF SPINAL DORSAL HORN RESPONSES TO NOXIOUS SKIN HEATING BY ELECTRICAL STIMULATION IN SUBCORTICAL FOREBRAIN REGIONS OF THE CAT.** J. Siegel[1], C. R. Morton*, J. Sandkühler*, H.-M. Xiao*, and M. Zimmermann. II Physiologisches Institut der Universität Heidelberg, Im Neuenheimer Feld 326, D-6900 Heidelberg, FRG.

Electrical stimulation to regions of the subcortical forebrain produce EEG synchronization, inhibition of motivated behaviors, and inhibition of cellular activity of the rostral brainstem. Electrical stimulation to caudate and septal nuclei and the BFB area produce the above effects as well as analgesia in various species, including man. Antinociceptive effects to stimulation of brain stem structures are due, at least in part, to descending inhibition of spinal dorsal horn neurons. This experiment explored the extent to which descending inhibition also contributes to analgesia from stimulation in forebrain regions.

In 22 cats anesthetized with pentobarbital and N_2O, unit activity was recorded from lumbar dorsal horn cells responding to noxious levels of skin heating. Forebrain sites (A17.0 to 13.5; L0.5 to 6.0; H+8 to -5.0) were mapped for their effectiveness in inhibiting dorsal horn heat-evoked neuronal responses.

The BFB exhibited a rostro-caudal gradient of efficacy; the rostral BFB had fewer inhibitory sites (26% of sites) and weaker effects (inhibition to 80% of control activity) than did sites in the caudal BFB (74% of sites, 50% of control). However, the rostral BFB was more effective in generating EEG synchronization. The dissociation between EEG synchronization and descending effects on spinal neurons was most clear with caudate nucleus stimulation. The caudate was quite effective in generating EEG synchrony but was largely ineffective in inhibiting dorsal horn heat-evoked neuronal activity. Spinal neurons were sometimes inhibited for up to 30 minutes following a single trial of BFB stimulation (50 ms trains of 100 Hz pulses at a rate of 6 Hz for 35 sec).

We conclude that the BFB is the rostral-most extent of a diencephalic-brain stem-spinal nociceptive inhibitory system and that the caudate nucleus achieves its analgesic effects by modulating nociceptive signals at higher supraspinal levels.

190.11 DISTRIBUTION OF NEUROTENSIN-LIKE IMMUNOREACTIVE FIBERS IN THE PERIACQUEDUCTAL GRAY OF THE RAT. M.T. Shipley, J.H. McLean* and M.M. Behbehani. Departments of Anatomy-Cell Biology and Neurosurgery and Department of Physiology and Biophysics, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

It has recently been shown that injection of neurotensin (NT) into the periacqueductal gray (PAG) increases the firing rate of PAG neurons and produces a strong, long-lasting analgesia. Unlike morphine, the NT analgesia is not blocked by naloxone, but like the opiate effect, it is abolished by lesions of the nucleus raphe magnus (NRM) (Behbehani and Pert, Brain Res. 1984). Thus, it is hypothesized that there is a circuit comprised of NT terminals acting upon PAG neurons which in turn activates elements in NMR that project to the spinal cord to particiipate in pain modulation.

In an effort to further elucidate this pathway, we have studied the distribution of NT containing fibers and terminals in PAG using immunocytochemical staining. NT fibers in PAG are extremely fine caliber and in initial experiments we found that neither PAP nor "double" PAP methods provided adequate visualization of these elements. However, improved visualization was obtained when the "ABC" method was combined with osmication of the stained, defatted sections. Additional improvement in the detectability of the NT-like fibers was achieved with an image processing/analysis computer system (Magiscan IIA). Using software developed for this system, distribution maps of NT-like fibers in PAG are being constructed.

NT-like fibers have a markedly heterogeneous distribution in PAG. Although at least some elements are present throughout PAG, the dorsal and dorsolateral parts of the region are only sparsely innervated. The fibers are particularly heavily concentrated in the ventral half of PAG and it appears that the region of highest density corresponds well to the cytoarchitectural boundaries of the dorsal raphe nucleus (DR). The lateral parts of this nucleus have a particularly rich plexus of fibers. A prominent group of fibers courses from the ventral to the dorsal surface around the circumference of the acqueduct, although they fail to reach the most dorsal part of the canal. Fewer, but nonetheless significant, numbers of fibers are present in the mid-lateral parts of PAG. Material sectioned in the horizontal plain shows that the vast majority of NT fibers course longitudinally through PAG.

The regions of highest fiber density coincide with the sites where neurons are sensitive to exogenously applied NT (Behbehani et al., this meeting). Current experiments are aimed at identifying the sources of the NT terminals in PAG. This should provide an anatomical basis for further studies of the neural mechanisms involved in NT mediated central analgesia.

190.12 SITE SPECIFICITY OF THE ACTION OF NEUROTENSIN IN THE PERIACGUEDUCTAL GRAY: AN IN VITRO STUDY. M.M. Behbehani, J.A. Eppley* and M.T. Shipley. Department of Physiology and Biophysics and Department of Anatomy and Cell Biology. University of Cincinnati College of Medicine, Cincinnati, Ohio 45267-0576.

Behavioral and physiological studies have shown that injection of neurotensin (NT) into the periacqueductal gray (PAG) increases firing rate of PAG cells and produces strong analgesia (Behbehani and Pert, Brain Res. 1984). Anatomical studies have shown that distribution of NT terminals and receptors in the PAG is not uniform. In this study, we examined the action of NT on different parts of the PAG area. Rats weighing 40 to 100 grams were used. Each animal was decapitated, its brain was removed and 400 micron sections were cut throughout the pontin region from intraculicular plane to the level of thalamus. The sections were incubated in a buffered physiological saline solution (PSS) that contained in mM: 124 NaCl, 5 KCl, 26 $NaHCO_3$, 1.2 Na_2CO_3, 2.4 $CaCl_2$, 1.3 MSO4, 10 glucose that was continuously oxygenated with 95% O2 and 5% CO2. After one hour of incubation, a single slice was sandwiched between two nylon meshes and placed into a perfusion chamber. The slice was perfused at a rate of 2 ml/min with oxygenated PSS at room temperature (22°C). Under direct visual observation, extracellular recordings were made from different PAG regions and 4 nmole of NT was bath applied in 10 seconds. In some experiments, after making a recording the cell was penetrated and was filled with HRP. Following these injections, the slice was incubated in oxygenated PSS for at least two hours and the DAB method was used to stain HRP filled neurons. In order to examine the presynaptic action of NT after recording from a cell, the tissue was incubated in PSS containing 3 mM $CoCl_2$ and the response of the cell to NT was measured again.

The responses of 46 neurons to NT were recorded. In the majority of these, NT caused an excitation that lasted for at least 4 minutes. In a few cells, the response to NT was short and lasted only 40 to 60 seconds. Eighty eight percent of the neurons in the ventrolateral part of the PAG responded to NT. Neurons adjacent to the aqueduct were mostly excited by NT (12/14). There was no correlation between the duration of response to NT and their location in the PAG. Both long-lasting and short-lasting excitation was observed at all locations in the PAG. When intracellular recordings were made, NT caused a 20 to 35% decrease in the resting potential. Incubation in $CoCl_2$ did not affect the response to NT.

These results indicate that: 1) the majority PAG neurons are excited by NT; 2) the action of NT involves a post-synaptic mechanism, and 3) there are long and short lasting responses to NT which imply that there may be more than one type of neurotensin receptor. This study was supported by grant NS 20643.

190.13 SUPRASPINAL CONTROL OF THE VISCERAL AFFERENT INPUT TO THE THORACIC SPINAL CORD OF THE CAT. F. Cervero*, B.M. Lumb* and J.E.H. Tattersall* (SPON: European Neuroscience Association). Department of Physiology, University of Bristol Medical School, Bristol BS8 1TD, England (U.K.).

Previous reports from this and other laboratories have shown that a large proportion (60-70%) of neurones in the cat's thoracic spinal cord receive convergent somatic and visceral inputs even though only 7% of all primary afferent fibres entering this part of the cord are of visceral origin. We suggested that the widespread actions of these few visceral fibres are mediated by extensive central divergence through polysynaptic pathways. We have now studied further the pathways that mediate the visceral input to some thoracic spinal cord neurones and the possible involvement of descending influences from the Nucleus Raphe Magnus (NRM) and adjacent areas of the Reticular Formation (Ret. F.).

Experiments were performed on choloralose anaesthetized cats. Extracellular single unit recordings were made in the T9-T11 segments of the cord from seventy four neurones driven by somatic inputs and by electrical stimulation of the splanchnic nerve and/or distension of the biliary system. Descending influences on these neurones were tested by reversible spinalisation with cold block at either the T7 or C3 segments and by electrical stimulation of locations within the NRM and Ret. F.

Sixty neurones (81%) showed changes in their responses to splanchnic nerve stimulation when the animals were spinalised. Two groups of neurones were distinguished:

i) twenty nine cells (39%) showed an increased response during spinalisation which suggests that their spinally mediated visceral inputs were under tonic descending inhibition. Sixteen out of seventeen of these neurones were phasically inhibited by electrical stimulation in the NRM and Ret. F. Nearly half of this group of cells (14/29) were recorded in the dorsal horn, particularly in Lamina V.

ii) thirty one neurones (42%) showed a reduction or complete abolition of their visceral response in the spinal state. This indicates that the visceral input to these neurones was partially or wholly mediated by supraspinal loops since the background activity of such cells was not reduced in a similar manner and in some cases was even increased during spinalisation. Most of these neurones (25/31) were located in the ventral horn. Nineteen out of twenty five were phasically excited by electrical stimulation in the NRM and Ret. F.

These results show that the visceral afferent input to the thoracic spinal cord is under considerable central control which involves tonic and phasic descending excitations and inhibitions from supraspinal regions.

190.14 NEUROPATHIC PAIN AND PARESTHESIAE: MICRONEUROGRAPHY OF ECTOPIC IMPULSE GENERATION FROM PRIMARY SENSORY UNITS IN PATIENTS. J. Ochoa, P. Marchettini*, M. Sivak*, and E. Torebjörk*. Dept. of Neurology, University of Wisconsin Medical School, Madison, WI 53792.

In previous reports we have documented anomalous generation of nerve impulses, from non-receptor sites, as the pathophysiological basis for paresthesiae induced by nerve compression-ischemia in healthy volunteers (Torebjörk et al., Acta. Physiol. Scand., 105:518, 1979; Ochoa and Torebjörk, Brain, 103:835, 1980). Hyperexcitability of comparable character has been reported more recently in a variety of neurological patients that exhibited either mechanosensitive or spontaneous paresthesiae (Ochoa et al., Muscle and Nerve, 5:S74, 1982; Nordin et al., Pain, 20:231, 1984). In such patients the abnormal nerve impulse activity was recorded intraneurally from the peripheral branch of primary sensory units and usually originated distal to the recording electrode. Examples of antidromic propagation from proximal sources were also reported, inclusive of mechanosensitive generator sources in the central branch of primary sensory units in dorsal columns (Sign of Lhermitte, Nordin et al., Pain, 20:231, 1984).

Here we report further microneurographic recordings obtained via intrafascicular tungsten semi-microelectrodes from nerves of patients with pain or paresthesiae of primary sensory unit origin. The impulse activity to be reported was abnormal in that it involved spontaneous bursting discharge in the absence of adequate natural stimulus to receptors, or involved discharge in response to mechanical stress applied midway along sensory axons in nerves or nerve roots. In patients with mechanosensitive paresthesiae the ectopic activity correlated optimally in time both with the delivery of the provocative mechanical maneuver (Sign of Tinel, Sign of Spurling) and with the verbalized sensory experience. In patients with spontaneous neuropathic pain it was exceptional to identify the source of ectopic discharge or the kind of nerve fibers involved. Despite a low yield, the microneurographic technique may provide a definitive document on the pathophysiology of positive phenomena of sensory unit origin.

191.1 BRAIN CELLS THAT COMMAND SEX IN THE SNAIL. R. CHASE (SPON: P.D. Evans). Department of Biology, McGill University, Montreal, Quebec, H3A 1B1, Canada.

The mesocerebrum of Helix aspersa is a locus for the integration of sensory information and the issuance of motor commands to the organs of reproduction. There is a substantial asymmetry of structure and function in the mesocerebrum on the right and left sides of the brain, consistent with the location of the reproductive organs on the right side. The population of neurons on the right side numbers 138 + 27 cells (N=7), with mean diameters of 77 + 13 µm (N=140). The left side has 19% fewer cells and they are 19% smaller. Spatial convergence of excitatory sensory inputs, from as many as 7 peripheral nerves, is the dominant feature of synaptic organization for neurons on the right side and, to a lesser extent, for those of the left side . The rapid temporal depression of synaptic responses is also characteristic. All neurons in the right mesocerebrum send an axon into the ipsilateral cerebropedal connective, but the trajectory of axons on the left side is more variable, with many traveling in the contralateral connectives.

Intracellular stimulation of neurons in the right mesocerebrum can produce contractions of the "love dart" sac, the penis sheath, or both (17% of cells tested). In an intact animal, these movements would result in the release of darts and the eversion of the penis. The latencies of the evoked responses are 6-12 secs. In some cells, stimulation for 5 sec causes repeated complex contractions lasting over several minutes. Extracellular stimulation of the right mesocerebrum, but not the left, causes vigorous concurrent contractions of both the dart sac and the penis. All the evoked motor responses are mediated through the right cerebropedal connective and the pedal nerve, NCPD (Schmalz, 1914). Neural activity in NCPD is rhythmically excited for several minutes following a 0.5 sec stimulus to the right mesocerebrum. The motorneurons for the described behaviors are presumed to reside in the right pedal ganglion.

191.2 OPTICAL MEASUREMENTS, USING ABSORPTION, OF ACTIVITY FROM NAVANAX BUCCAL GANGLIA DURING SPONTANEOUS PHARYNGEAL EXPANSION AND DURING FEEDING. D. Zecevic, J.A. London and L.B. Cohen. Dept. of Physiology, Yale Univ. School of Medicine, New Haven, CT 06510, U.S.A.

We are investigating the use of optical methods to simultaneously measure action potential activity from many cells in the nervous system of a minimally dissected opisthobranch mollusc, Navanax inermis. Using a modified whole animal preparation we were able to monitor activity in the buccal ganglion, a ganglion with about 200 neurons. Animals in this preparation exhibited spontaneous and food-induced expansions of the pharynx. A 1 cm slit was made in the ventral body wall and in the pharynx immediately under the buccal ganglion. One end of a light pipe was inserted through a small hole in the dorsal side of the pharynx and dorsal body wall. The preparation was positioned on the stage of a microscope so that the light guide brought the incident light from the microscope condenser to the buccal ganglion. An enlarged image of the ganglion was formed on a 124 element photodiode array. The ganglia were stained with a 0.5 mg/ml solution of the pyrazo-oxonol dye RH155, kindly provided by R. Hildesheim and A. Grinvald. Action potential signals were obtained in experiments where no significant pharmacologic effects or photodynamic damage was observed. We monitored activity in the buccal ganglion during spontaneous expansions and during feeding, and detected activity of between 10 and 30 neurons.

In the best analyzed experiment, 23 different neurons were found to be active during feeding with phases of the neuronal activity clearly correlated with specific feeding movements. Combined morphological evidence and optical monitoring during nerve stimulation suggests that these recordings were at least 70% complete. It appears that more neurons are active during feeding than during spontaneous expansions. In addition, in repeated recordings of the same preparation, it appears that there is a core of neurons consistently active and another population of neurons, putative sensory neurons, which in general is active, but specific neurons in this population may or may not be active. The activity of relatively large neurons was detected on several adjacent photodetectors. In some cases this activity could be associated with identified neurons in the ganglia by superimposing an outline of the array elements with the activity on a photograph of the ganglion.

Supported by NIH Grant NS-08437, a Grass Foundation Fellowship, and Fulbright Grant 83-04765.

191.3 A VOLTAGE CLAMP ANALYSIS OF EGG-LAYING HORMONE AND SEROTONIN EFFECTS ON THE IDENTIFIED MOTONEURON B16 OF APLYSIA. M.D. KIRK, S.H. THOMPSON AND R.H. SCHELLER. Dept. of Biological Sciences, Stanford University, Stanford, CA 94305.

The identified buccal ganglion motoneuron, B16, innervates the accessory radula closer muscle of the buccal mass in Aplysia. Previously, it had been shown that the neuropeptide egg-laying hormone (ELH) excites B16 directly at nanomolar concentrations in a dose-dependent manner. Bath application of ELH causes the B16 membrane potential to slowly depolarize, and the neuron begins to fire tonically with a latency of less than four minutes. The B16 membrane potential usually returns to the control condition within 30 minutes after washing away the ELH. Serotonin (5-HT), at micromolar concentrations, excites B16 in a manner similar to that of ELH, and forskolin mimics both of the transmitters' actions suggesting that these effects may be mediated by cyclic AMP.

We have performed a voltage clamp analysis of the ELH and 5-HT effects on B16. The membrane poential was clamped to various holding voltages (V_H) and ten millivolt hyperpolarizing pulses (2 sec duration) were repetitively applied during bath application of ELH (50-500 nM) or 5-HT (50-100 µM). Little or no response was evident with V_H below -50 mV. However, for V_H between -40 mV and -15 mV, bath application of the transmitters caused a 1-2 nA slow inward shift in holding current. Within this range of V_H, the current responses to the ten millivolt hyperpolarizing pulses changed from inward, in the control condition, to a steady state outward current during the action of ELH or 5-HT. Thus, a negative resistance region was induced within this range of V_H. Steady state I-V curves revealed that a slow inward current (SIC) appeared within the membrane potential range where the maximal effects of ELH and 5-HT were found. Difference I-V curves reflected this increase in inward current, however, above -15 mV the I-V curves did not differ. The SIC was seen with reduced amplitudes before the transmitters were applied. When Na^+ was replaced with equimolar TRIS, the SIC was nearly eliminated, and the response to the transmitters was reduced or eliminated. The response to ELH and 5-HT was not due to effects on I_A or $I_{K'}$ and the response persisted in solutions with 0 mM Ca^{++}, 10 mM Co^{++}.

We have not eliminated the possible contribution of the I_S potassium channels or other voltage-dependent potassium channels in the response of B16 to ELH and 5-HT. Presently, we are testing the reversal potential of the B16 response for its sensitivity to K^+, Cl^- and Na^+.

191.4 CEREBRAL-BUCCAL INTERNEURONS WHICH INITIATE FICTIVE FEEDING IN LIMAX MAXIMUS. K. Delaney* and A. Gelperin, Dept. Biology, Princeton University, Princeton, NJ 08544 and Dept. Molecular Biophysics, AT&T Bell Laboratories, Murray Hill, NJ 07974.

We are characterizing interneurons in the cerebral ganglion (CG) of the land slug Limax maximus which respond to lip chemostimulation and are capable of triggering feeding motor program (FMP) in vitro. We have identified several putative 'trigger interneurons' whose somata are located near the insertion points of the lip nerves which convey afferent taste and mechanoreceptive input.

All the feeding interneurons we have studied belong to a population of about 16 cells in the lateral CG which have a single descending axon in the ipsilateral cerebro-buccal connective. We call these cells cerebral-buccal interneurons (CBIs). These CBIs have extensive branching in ipsilateral lobes of the CG and varicose branches throughout the ipsi- and contralateral buccal ganglia. One CBI, CBI_2, also crosses the midline to branch in the area of the insertion points of the contralateral lip nerves. Using a lip-brain preparation, the activity of CBIs was monitored and controlled by an intracellular electrode while FMP responses were measured by extracellular recordings from multiple buccal nerve roots. CBI_1 and CBI_2 respond with a 15-20mv short latency depolarization to applications of carrot juice to the ipsilateral lip. This depolarization produces a several second burst of action potentials which is interrupted during FMP by a strong hyperpolarization in phase with the protraction burst in buccal roots. The activity of the CBIs declines even while the food extract is still on the lip and while the bite rate is increasing. Depolarizing current injection of .3-.6nA produces rapid firing of CBI_1 and CBI_2 and generates FMP. As with lip stimulation the CBIs receive a strong hyperpolarizing input which interrupts their firing during the phase-locked bursting seen in buccal roots during protraction. The CBIs are not normally active during later parts of the FMP bout but receive cyclical depolarizations and hyperpolarizations in phase with the buccal rhythm. Short bursts of CBI action potentials interpolated between bites can phase advance the bite rhythm while prolonged activation over several cycles first excites, then slows FMP, which speeds up when stimulation ends.

Thus, CBI_1 and CBI_2 are excited by taste stimuli applied to the lips and are capable of initiating FMP in vitro. These cells are most active shortly after chemostimulation of the lips and although they can influence the rate of FMP they are not necessary for the production of bites later in a bout of FMP. The CBIs thus appear to serve an initiating or 'trigger' function. We intend to examine the responses of these cells to applications of a taste paired with an aversive stimulus in vitro to see if they represent a locus for change following associative conditioning. (Supported by NIMH 39160 and an NSERC, Canada, postgraduate scholarship to KD.)

191.5 SIMULTANEOUS OPTICAL RECORDING FROM MANY CELLS FROM APLYSIA ABDOMINAL GANGLIA DURING THE GILL-WITHDRAWAL REFLEX. J.A. London, D. Zecevic and L.B. Cohen, Dept. of Physiology, Yale Univ. School of Medicine, New Haven, CT 06510, U.S.A.

We are studying the possibility of using optical measurements for monitoring membrane potential changes in many neurons from Aplysia abdominal ganglia. We began with fluorescence measurements from ganglia stained with several styryl dyes. In experiments, with RH386 and RH725 (provided by R. Hildesheim and A. Grinvald) the signal-to-noise ratios during individual action potentials were about 10. Measurements of bleaching indicated that illumination of the ganglion for approximately 60 seconds would reduce the signal size by 50%. This period of illumination also led to a reduction in the number of neurons that could be activated by nerve stimulation. In absorption experiments similar signal to noise ratios were measured using the merocyanine dye RGA525 (provided by A.S. Waggoner) or the pyrazoloxonol dye RH155 (Nippon Kankoh-Shikiso Kenkyosho, Co.). With RH155 neither bleaching nor photodynamic damage were detected after 300 seconds of illumination.

An isolated siphon preparation (Kupfermann, Carew and Kandel, J. Neurophysiol.,1974) was modified for use in the optical monitoring system with the intent of observing simultaneous activity from a large number of neurons from the abdominal ganglion during behavior. An isolated siphon, gill and abdominal ganglion were placed in a recording chamber positioned on a microscope stage. The ganglion was stained with a 1 mg/ml solution of RH155 for 30 minutes. In a preliminary experiment, electrical stimulation of the siphon skin was followed by gill contraction. Simultaneous optical measurements from the left side of the abdominal ganglion (dorsal side up) indicated that many neurons were actived by the stimulation. Repeated stimulation of the siphon seemed to reduce this activity. After a short wait, the activity partially recovered. We hope that optical methods can be a useful tool in studying the neuronal interactions involved in the gill-withdrawal reflex.

Supported by NIH Grants NS-08437 and NS-0716901, and a Fulbright Grant 83-04765.

191.6 NEURALLY ACTIVE PEPTIDES ACTIVATE CENTRAL MODULATORS OF THE GILL WITHDRAWAL RESPONSE IN APLYSIA. Ken Lukowiak* and A. Don Murphy (SPON: W.D. Ruwe) I.O.M. Tribhuvan University, Kathmandu, Nepal and Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Neurally active peptides endogenous to Aplysia's CNS affect the amplitude of the gill withdrawal reflex (GWR) evoked by tactile stimulation of the siphon in vitro. The superfusion of arginine vasotocin (AVT) and Met-enkephalin over the abdominal ganglion cause a significant reduction in the amplitude of the evoked GWR, while FMRFamide and SCP_B facilitate the GWR. These substances may, therefore, determine the preparation's level of arousal. The state of the animal just prior to dissection affects non-associative and associative learning of the preparation; it is, therefore, important to understand how these peptides affect the GWR and associated behaviors. Among many possibilities, these peptides may: 1) directly influence the sensory-motor neuron synapse or 2) act on central cells exerting either facilitatory or suppressive control over the PNS of the gill. Evidence for the first hypothesis is available, but possibility 2) has not yet been tested. This series of experiments tests the second hypothesis and shows that the neurons which exert both facilitatory and suppressive control over the PNS are affected by these substances. If the peptides alter the balance of facilitatory and suppressive control the CNS exerts over the PNS, then the ability of a central motor neuron to elicit a gill movement will be affected. Motor neurons L_7, LDG_1, or L_9 were impaled and the amplitude of a gill movement, elicited by a constant number of action potentials evoked by depolarizing current (ISI = 20 min), was measured before, during, and after superfusion of the test peptide over the abdominal ganglion. Two peptides were tested: SCP_B and AVT.

Superfusion of the abdominal ganglion with SCP_B (10^{-6}M) increased the L_7-dependent gill movement to 315% (n=9). Following 1 hr washout, the response was still 147%. Stimulation of LDG_1 in the presence of SCP_B elicited an increase of 312% (n=3) and recovered to 126% following 1 hr washout. L_9's efficacy in eliciting contractions was not affected by SCP_B (n=2). By contrast, superfusion of 10^{-6}M AVT reduced contractions elicited by L_7 to 20% of control (n=3) and by LDG_1 to 29% of control (n=3). One hour washout was sufficient to completely reverse AVT's effect in all cases. Again, L_9 was unaffected by this peptide.

Thus, the superfusion of these peptides affected the ability of a central gill motoneuron to move the gill. Because only central motor neurons were depolarized in these experiments, the most likely explanation for these results is that the central neurons modulating the PNS are affected by these two peptides, independent of the peptides' effects on the central sensory-motor synapse. (Supported by the MRC.)

191.7 THE FORMS OF SPONTANEOUS AND EVOKED GILL MOVEMENTS IN APLYSIA. J.L. Leonard* and K. Lukowiak* (SPON: L.E. Muske). Dept. of Medical Physiology, Univ. of Calgary, Calgary, Alberta T2N 1N4, Canada.

The amplitude of the gill-withdrawal reflex (GWR), the response of the gill of A. californica to a mechanical stimulus to the siphon, is, in in vitro preparations, dependent on the behavior of the animal prior to dissection and can be modulated by a number of endogenous neuropeptides (Lukowiak and Murphy 1985). In order to understand the neural control of the GWR, it is necessary to characterize the form(s) of evoked and spontaneous movements of the gill.

We have identified four types of movement of the whole gill. These are: 1) Roll. The gill rotates along its longitudinal axis, so that the tips of the pinnules describe an arc away from the mantle and toward the midline of the body. The maximum amplitude of Roll is about 90 degrees. 2) Shorten. The base of the gill contracts slightly. 3) Lift. The distal end of gill is brought away from the mantle. 4) Pinnule Contraction. This was described by Kupfermann et al (1974) and consists of a coordinated reduction in length of the pinnules. In addition, we have confirmed the observations of Kupfermann et al. (1974) on the movements of gill halves and pinnules. Any of these movements occurs in a graded fashion and the movements occur in a variety of combinations.

The gill can respond to siphon stimulation in two distinct ways; directly, with a short latency response, or with a long-latency response which closely resembles spontaneous gill movements (SGMs) and which is presumably mediated by the Interneuron II network. The usual short-latency response of the gill to a mechanical stimulus to the siphon involves a Roll, often in combination with Shorten and some degree of Pinnule Contraction. In some cases, particularly in suppressed preparations, Roll may be the only response. The form of response in a particular preparation is the same with or without the abdominal ganglion present. The largest and most common (seen in the greatest number of preparations) spontaneous gill movement involves a tightly coordinated combination of Roll, Shorten, Lift, and Pinnule Contraction. We suggest that the term SGM be reserved for this movement. It is always large but does vary somewhat in amplitude primarily due to a variable degree of Pinnule Contraction. Such movements can occur in response to siphon stimulation. A variety of other movements can occur spontaneously, including Rolls, Lifts, either of the those combined with Shorten, and/or the types of pinnule movements described by Kupfermann et al. (1974).

Supported by the AHFMR and MRC (Canada).

191.8 INTERNEURONS CONTRIBUTING TO THE MEDIATION AND MODULATION OF THE TAIL WITHDRAWAL REFLEX IN APLYSIA. L.J. Cleary and J.H. Byrne Dept. of Physiol. and Cell Biol., Univ. of Texas Med. Sch. Houston, Texas 77225.

Tail withdrawal is one of several defensive behavior in Aplysia that have been utilized to study the synaptic changes underlying behavioral modifications. The sensory and motor neurons which conduct the tail withdrawal reflex have been identified, yet little is known of the contributions made by interneurons.

We have begun to study a population of interneurons in the pleural ganglion which form connections with motor, sensory and other interneurons. Target neurons are located in the pedal, pleural and cerebral ganglia. Recordings were obtained from 288 pleural interneurons. Of these, 78 are excitatory to putative tail motor neurons in the pedal ganglion, and 48 are inhibitory. Seventeen cells produce a mixed response.

Two types of responses in the motor neurons are produced by the excitatory interneurons. The first type is a fast, short latency EPSP evoked by a single spike in the interneuron. The second is a slow, long latency EPSP evoked by a brief burst of spikes. On average, this response peaks at 2.3 sec, lasts for 42 sec and is associated with a decreased input conductance. The slow EPSP can modulate the effect of sensory input to the motor neurons. Weak nerve shocks which normally generate subthreshold EPSPs can trigger spikes during the slow EPSP. In some cases, the slow EPSP itself produces a prolonged discharge of spikes in the motor neuron.

Excitatory interneurons share several characteristics. First, they receive excitatory input from sensory neurons. Second, they inhibit sensory neurons. Third, they excite neurons in the cerebral B cluster. Fourth, after HRP injection, three major branches are observed: one to the motor neuron region of the pedal ganglion, a second to the cerebral ganglion, and a third to the pleural-abdominal connective. There is also a small dendritic arborization within the pleural ganglion itself.

The excitatory interneurons may act via a feed-forward pathway to amplify the withdrawal response to noxious stimulation of the tail. In addition, they may provide a means by which a brief afferent volley is transformed into the prolonged motor neuron discharge and consequent tail withdrawal that is typically observed in response to brief tail stimulation. The connections between excitatory interneurons and motor neurons may also be an additional site for the synaptic plasticity underlying behavioral sensitization and associative learning. Finally, excitatory interneurons may be responsible for the integration of tail withdrawal with other defensive responses triggered by stimulation of the tail such as locomotion, inking and gill and siphon withdrawal.

191.9 CHANGES IN CELLULAR EXCITABILITY IN A NEW CLASS OF SIPHON MOTOR NEURONS DURING SENSITIZATION IN APLYSIA. W. N. Frost , G. A. Clark, and E. R. Kandel. H. Hughes Medical Institute and Ctr. for Neurobiol. & Behav., Columbia Univ., P & S, and NYS Psychiatric Instit., New York, NY 10032.

Sensitization and classical conditioning of the gill and siphon-withdrawal responses in Aplysia involve a cAMP-dependent decrease in a specific K^+ channel in siphon sensory cells. Closure of the K^+ channel can broaden each action potential and thereby enhance transmitter release at the terminals (Hochner et al., 1985; Belardetti et al., 1985). In addition, K^+ channel closure can result in an increase in the probability and frequency of action potential discharge (Klein and Kandel, 1978; Hochner et al., 1985).

If similar mechanisms were to occur in postsynaptic cells, one might expect such cells to exhibit an increase in tonic firing rate and increased discharge to a given synaptic input. Previous studies of the several known classes of gill and siphon motor neurons did not reveal changes in excitability. We have recently discovered in the abdominal ganglion a new group of siphon motor neurons (the LF_s cells) whose interneuronal connections differ from other previously identified motor neurons. At rest, these cells are tonically active at rates below threshold for eliciting siphon contraction. Sensitizing stimuli to the tail or connective stimulation produce, in most of these cells, an increase in tonic firing lasting several minutes as well as an apparent increase in input resistance (Clark & Kandel, 1984). The increase in tonic firing rate can amplify siphon contractions produced by constant spike trains in the LF_s cells, perhaps due to the facilitating effect of tonic firing rate on release from the motor neuron terminals (Jacklett & Rine, 1977).

To compare the mechanisms of the excitability change in the LF_s siphon motor neurons to those of the sensory neurons, we applied either 8-benzylthio cAMP (a membrane-permeable cAMP analog) or IBMX (a membrane-permeable phosphodiesterase inhibitor) extracellularly. We also injected cAMP intracellularly. All of these treatments produced a depolarization and increase in tonic firing rate in the LF_s cells, thereby simulating sensitizing stimuli. We are now exploring whether this depolarization is due to a decreased K^+ conductance, as occurs in siphon sensory cells.

Although the evidence for cAMP mediation is not complete, these preliminary data suggest that the mechanisms underlying plasticity in the sensory cells may contribute to changes in excitability of a subgroup of siphon motor neurons. Therefore, sensitization of this reflex may involve the coordinated regulation of cellular excitability at several different circuit elements -- facilitation of sensory neurons, disinhibition of excitatory and facilitatory interneurons (Frost and Kandel, 1984), and increased excitablity of LF_s motor neurons -- perhaps using a common molecular mechanism: cAMP-dependent protein phosphorylation of ion channels.

191.10 **DEVELOPMENT OF LEARNING AND MEMORY IN *APLYSIA*: I. FUNCTIONAL ASSEMBLY OF THE GILL AND SIPHON WITHDRAWAL REFLEX.** T. J. Carew, C. H. Rankin* and M. Stopfer* Dept. of Psychology, Yale University, New Haven, CT 06520

Learning and development are two areas of major importance in Neurobiology. We have combined these two areas in an analysis of the development of learning and memory in *Aplysia californica*. We have focussed on the defensive withdrawal reflex of the gill and siphon, for it displays associative and nonassociative learning, both of which can exist in short and long-term forms.

In adults the gill and siphon show two kinds of contractions: (1) endogenous and (2) elicited. To permit developmental comparisons we first characterized the quantitative relationship between gill and siphon withdrawal in the adult. Animals were restrained and both spontaneous and elicited contractions were videotaped and digitized for subsequent computer analysis. During elicited and spontaneous contractions the siphon and gill always contracted together and the responses were highly correlated both in amplitude and duration.

We next examined the assembly of the siphon and gill withdrawal components in 3 early juvenile developmental stages: 9, 10, and 11 (Kriegstein, 1974). The siphon first appears in Stage 9, the gill in Stage 10. Animals of these stages (.05 - 4 mm in length) were restrained with suction electrodes and videotaped under a stereomicroscope. As soon as the siphon develops in Stage 9, it exhibits both elicited contractions to brief tactile stimuli and spontaneous contractions.

The gill emerges in Stage 10 and immediately exhibits spontaneous contractions. In early Stage 11 two types of gill contractions are evident: (1) high frequency twitches (40/min); and (2) lower frequency spontaneous contractions (2 - 4/min). The twitches appear to be the passive result of blood-flow since they are correlated 1:1 with heart beat and are abolished by surgically disconnecting the heart. Interestingly, although spontaneous contractions of both gill and siphon are present at this stage, they appear to be relatively independent, occurring synchronously only 20% of the time. In contrast, in late Stage 11 animals spontaneous contractions resemble the adult form (*ie* siphon and gill co-contract). These data suggest that early in development there are independent oscillators for the siphon and gill (perhaps sub-components of INT. II), which become coupled in late Stage 11. Elicited gill contractions to siphon stimulation also progressively develop during this stage.

In conclusion, both spontaneous and elicited siphon and gill components of the withdrawal reflex are functionally assembled in Stages 9-11 of development. In the two companion abstracts behavioral and neuronal studies of the development of learning and memory in this reflex system are described.

191.11 **DEVELOPMENT OF LEARNING AND MEMORY IN *APLYSIA*: II. HABITUATION, SENSITIZATION AND SHORT TERM MEMORY** C. H. Rankin* and T. J. Carew (Spon: M.Constantine-Paton) Dept. of Psychology, Yale University, New Haven, CT. 06520

The developing gill and siphon withdrawal reflex of *Aplysia* provides an excellent system in which to analyze the development of a variety of forms of learning and memory. In our initial studies of this system we have examined the development of two forms of nonassociative learning, habituation and sensitization, in the siphon component of the reflex in early juvenile *Aplysia* (Stages 9-11; Kreigstein, 1974; Carew *et al*, this vol.).

Animals (0.5-4 mm in length) were restrained under a stereomicroscope with suction electrodes and the siphon was stimulated with a brief quantifiable water-jet. A suction electrode was attached to the tail to deliver a sensitizing stimulus. The behavior was measured by videotaping and digitizing the response for subsequent computer analysis. In these studies we examined whether different forms of learning (habituation and sensitization) and different forms of memory emerge at different stages of development. To examine short-term memory we used three different inter-stimulus intervals (ISIs: 10, 5 and 1 sec) during habituation.

Stage 11 animals exhibited clear habituation at all 3 ISIs, with progressively greater decrement with shorter intervals. As in adults, sensitization was evident at this stage. Stage 10 animals showed little habituation at a 10 sec ISI, but clear and progressively greater decrement with 5 and 1 sec ISIs. Sensitization was also evident at this stage. Finally, Stage 9 animals showed no habituation at either 10 or 5 sec ISIs; only a 1 sec ISI produced decrement. Moreover, in contrast to Stages 10 and 11, sensitization was completely absent at Stage 9.

Thus our results show that different forms of learning emerge at different stages of development: habituation is present in the youngest animals we tested (Stage 9), while sensitization emerges at a distinct and later stage (Stage 10). Memory also appears to develop systematically: greater habituation occurs at progressively longer intervals during development, suggesting that at successive stages short-term memory is progressively more mature.

In addition to nonassociative learning, *Aplysia* has been shown capable of classical and, quite recently, operant conditioning (Cook and Carew, this vol.). Therefore it will now be possible to determine the developmental timetable of associative learning in this system, as well as the emergence of long-term memory for these various forms of learning. Thus development in *Aplysia* can serve as a valuable tool for analyzing the nature of different components of learning and memory as they emerge and are assembled into their adult form.

191.12 **DEVELOPMENT OF LEARNING AND MEMORY IN *APLYSIA*: III. CENTRAL NEURONAL CORRELATES.** T.G. Nolen, E. Marcus*, T.J. Carew. Dept. of Psychology, Yale University, New Haven, CT 06520.

The defensive gill and siphon withdrawal reflex of *Aplysia* has been useful for gaining insights into the neural mechanisms of different forms of learning and memory. Since it is now possible to study the development of learning and memory in this reflex (Rankin and Carew, this vol.), we have begun to explore neural correlates of learning at different stages of development. As a first step in this analysis, we examined the central control of the reflex in two preparations: (1) semi-intact, and (2) isolated central nervous system (CNS).

Semi-intact: the gill of Stage 11 animals (2-4 mm in length) was removed leaving it attached to the abdominal ganglion by the branchial nerve. The afferent siphon nerve was electrically stimulated (with a single 5 ms pulse) by a suction electrode and the amplitude of the evoked gill contraction was measured by videotaping and digitizing the response for subsequent computer analysis. A 2.5 sec train of facilitating stimuli was delivered by a suction electrode to one of the pleuroabdominal connectives. Stimulating the siphon nerve reliably evoked a contraction of the gill which completely decremented within 15 successive stimuli (ISI=30 sec). Stimulating the connective facilitated the evoked gill response. Behavioral experiments in intact Stage 11 animals show that habituation is more profound with shorter ISIs (Rankin and Carew, this vol.). Similarly, the evoked gill response decremented more rapidly with a shorter ISI (10 sec). These results show that both centrally-projecting siphon afferents and facilitatory inputs make functional connections with gill motor neurons in Stage 11 animals.

Isolated CNS: we have identified neural correlates of habituation and sensitization in the isolated abdominal ganglion by recording the efferent output (spike number and PST histogram) of the branchial nerve in response to siphon nerve stimulation. Using the same parameters as in the semi-intact preparation, the evoked branchial nerve response decremented with repeated stimuli and was facilitated following stimulation of the connective. As in the behavior and the semi-intact preparation, decrement was greater with a 10 sec than with a 30 sec ISI.

In summary, our data show that in Stage 11 *Aplysia* a component of the withdrawal reflex, as well as its habituation and sensitization, is centrally mediated. Similar studies are being carried out in Stages 9 and 10. These studies, coupled with an intracellular analysis in the CNS of juvenile *Aplysia* at different stages, will permit us to investigate the developmental changes which underlie the emergence of different forms of learning and memory in an identified neural circuit.

192.1 A SET OF PROTEINS ENRICHED IN SMALL SYNAPTIC VESICLES FROM MAMMALIAN BRAIN. E. Floor, S.F. Schaeffer*, and S.E. Leeman. Dept. of Physiology, Univ. Massachusetts Med. Sch., Worcester, MA 01605.

Small synaptic vesicles were substantially purified in modest quantities (3-4mg) from mammalian brain. Rat or cow brain (~75g) was homogenized in a 0.3M sucrose buffer, the homogenate osmotically shocked by 1:1 dilution with water, and the solution returned to isotonicity with KCl after 1min. Debris was removed by centrifugation at 7,500xg and particles in the resulting supernate pelleted at 50,000xg. The particulate material was resuspended in a 0.15M KCl buffer and sedimented to equilibrium on an isoosmotic 10-30% linear Nycodenz/KCl gradient. Material just denser than the bulk membrane bands was collected and fractionated by size on a calibrated, 400ml column of CPG-3000 controlled-pore glass beads.

Particles ~50nm in diameter based on the size calibration contained a distinctive set of about a half dozen major proteins of molecular weights about 33, 38, 41, 57, 62, and 76kd by SDS gel electrophoresis. These proteins were present in similar relative abundances in ~50nm vesicles from rat or cow brain or from rat brain synaptosomes but were not present in rat liver membranes purified by the same protocol. By electron microscopy >50% of the particles in column fractions richest in these proteins were spherical vesicles about 50nm in diameter. These vesicles were bounded by a trilamellar unit membrane and were electron lucent. A synaptic vesicle-specific monoclonal antibody (antibody 48) isolated by W. D. Matthew et al. (J. Cell Biol. 91, 257) selectively immunoprecipitated vesicles with this set of proteins in a procedure utilizing second antibody-coated beads. When large membranes from the void volume of the CPG column were added to the small vesicle preparation, they were not immunoprecipitated by antibody 48. In summary, the ~50nm vesicles studied here were identified as synaptic vesicles by their size, tissue specificity, presence in nerve endings, and synaptic vesicle-specific surface antigen.

At present the identities of the small synaptic vesicle proteins are not known. By molecular weight or immunoblotting these proteins are not actin, synexin, or the synaptic phosphoproteins synapsin Ia or Ib, or protein IIIa or IIIb. The possible identities of the 62kd protein with the antigen recognized by antibody 48 or of the 57kd protein with tubulin have not yet been tested. The 41 and 62kd synaptic vesicle proteins appear to be integral membrane proteins as indicated by partitioning into the detergent-rich phase of Triton X-114 solutions. The 33, 38, 57 and 76kd proteins distributed between the two detergent phases.

192.2 ARE PRESYNAPTIC CALCIUM STORES PRESENT IN CENTRAL NERVOUS SYSTEM SYNAPSES? S.B.Andrews*, R.D.Leapman*, D.M.D.Landis and T.S.Reese (SPON: J.Fex). NINCDS and DRS, NIH, Bethesda, MD 20205 and The Marine Biological Laboratory, Woods Hole, MA 02543.

We have used quantitative elemental imaging and microanalysis of freeze-dried cryosections of selected, rapidly-frozen, synaptic preparations to address the question of the presence, identity, and activity of putative calcium storage organelles in nerve terminals. This approach permits an exhaustive, unbiased sampling of the calcium distribution in synaptic structures without the complicating influences of chemical fixation or organelle isolation.

In vitro preparations of two diverse central nervous system synapses were studied, namely, the synapses of parallel fibers with Purkinje cell spines within excised hemispheres of the molecular layer of mouse cerebellar cortex, and the predominantly cholinergic presynaptic synaptosomes from the optic lobe of the squid. Following incubation under control (normal Ringer) or stimulating (50 mM K^+) conditions, samples were rapidly frozen against a liquid helium-cooled copper block. The outer layer of well-frozen material was then prepared for imaging and analysis by ultracryomicrotomy at -135°C followed by controlled freeze-drying, or for structural analysis by freeze-substitution or by freeze-fracture. Analytical electron microscopy was carried out by means of a recently developed, computer-controlled instrument that is capable of simultaneously acquiring digital scanning transmission (STEM) and quantitative elemental (x-ray) images.

Imaging and microanalysis of unstimulated cerebellar slices revealed no pre- or postsynaptic organelles larger than 40 nm in diameter that contained calcium at a concentration greater than 5 mmol/kg wet weight; this conclusion extends to morphologically identified parallel fiber synapses. However, following a brief (less than two min) stimulation of resting cerebellar slices with a depolarizing, high-potassium solution, numerous sites of focal calcium accumulation (typically less than 200 nm diameter and containing ca. 30 mmol/kg wet weight Ca) were evident. Thus, calcium is detectable under these preparative conditions and a calcium-sequestering system is present which is loaded by neuron activity. Similar results were obtained with squid synaptosomes; synaptosomes that had enough internal potassium to qualify as functional models of presynaptic endings had calcium concentrations less than 5 mmol/kg in synaptic vesicles and in other organelles larger than 40 nm diameter. Thus, the concentration and the distribution of calcium do not support the notion that synaptic vesicles function as a primary calcium storage site. However, the results are consistent with the presence of a calcium sequestration system as an integral part of synaptic transmission.

192.3 SYNAPSIN-I-LIKE IMMUNOREACTIVITY IN THE NERVOUS SYSTEM OF APLYSIA CALIFORNICA. M.E. Bongiðvi, R.T. Ambron, A.-J. Silverman, M. Flaster and P. Greengard. Dept. of Anatomy and Cell Biology, Columbia Univ., NY, NY 10032 and Dept. of Molecular and Cellular Neuroscience, Rockefeller Univ., NY, NY 10021.

Synapsin-I, a phosphoprotein associated with synaptic vesicles in the mammalian nervous system is postulated to play a role in synaptic vesicle fusion and neurotransmitter release (De Camilli, et al., JCB, 1983). We have investigated the distribution and biochemical nature of synapsin-I-like antigens (SILA) in the nervous system of the marine invertebrate Aplysia californica. Polyclonal antibodies directed against bovine brain synapsin-I combined with light microscopic peroxidase cytochemistry was used to localize SILA in vibratome sections of the abdominal ganglion and body wall. SILA are present in neuronal cell bodies and axons and at presumptive terminals in the neuropil. Immunoreactive neurons displayed various staining patterns. In some cells the entire cytoplasm of the soma and axon hillock contained reaction product, while in others, discrete perinuclear staining was observed. Still other neurons exhibited punctate staining on the periphery of their soma, a pattern expected of axo-somatic synaptic contacts. In the neuropil, the major site of synaptic transmission in invertebrates, punctate staining was present. In order to determine the subcellular localization of SILA, EM immunoperoxidase studies were initiated. Preliminary results indicate that SILA are associated with vesicles, both in axons and in varicosities in the neuropil.

To associate SILA with identified cells, we first examined the body wall which contains gland cells innervated by the giant neuron, R2 of the abdominal ganglion (Rayport, et al., J. Neurophysiol., 1983). Patches of staining are present on some glands. Others were enveloped completely by immmunoreactive axons. Differences in staining intensity and pattern may represent underlying differences in the patterns of innervation of the glands by R2. The pair of serotonergic giant neurons of the cerebral ganglion (GCN) were also found to be immunoreactive.

The molecular weights of the immunoreactive species were determined by immunoprecipitation of ^{32}P- or ^{35}S-methionine labelled Aplysia nervous tissue with the anti-synapsin-I antibodies. Proteins of 57kD and 67kD were found by SDS-PAGE analysis to be precipitated selectively. These are in the M_r range reported for synapsin-I-like molecules by Goelz and colleagues (J. Neurochem., in press) in a survey of various vertebrate and invertebrate species. Our biochemical and immunocytochemical studies suggest, therefore that a synapsin-I homologue is present in Aplysia neurons.

192.4 ASSOCIATION OF SYNAPSIN I WITH NEURONAL CYTOSKELETAL PREPARATIONS. J. R. Goldenring, Lasher, R. S., Vallano, M. L., Ueda, T., and DeLorenzo, R. J. Dept of Neurology, Yale Med. School; Dept. of Anatomy, U. Colorado Med. School; Dept. of Psychiatry, U. Michigan

Calcium and calmodulin are important regulators of cytoskeletal dynamics. A calmodulin-dependent kinase purified from rat brain cytosol (CaM Kinase II) phosphorylates several cytosketal proteins including MAP-2, synapsin I and tubulin. CaM Kinase II is associated with both microtuble preparations (Larson, et al., J. Neurochem, In Press) and neurofilament preparations prepared from in vitro polymerized microtubules (Vallano, et al., PNAS, In Press). CaM Kinase II in these preparations phosphorylates endogenous MAP-2, tubulin and an 80,000 dalton phosphoprotein doublet. We now report that this 80,000 dalton phosphoprotein doublet is identical to synapsin I.

The 80,000 dalton phosphopeptide (pp80) demonstrated identical migration in SDS-PAGE gels with authentic synapsin I. Phosphorylation of pp80 by both cAMP-dependent and calmodulin-dependent kinases yielded identical phosphopeptide maps to those seen with synapsin I. pp80 failed to focus on equilibrium isofocusing gels but ran as a rapidly migrating basic doublet in non-equilibrium pH gradient electrophoresis (NEPHGE). pp80 comigrated with authentic synapsin in NEPHGE. Like synapsin I, pp80 was highly susceptible to digestion with collagenase. Affinity-purified anti-synapsin I antibodies specifically labelled an 80,000 dalton doublet co-migrating with pp80. Anti-synapsin I antibodies also labelled neurofilaments when examined under electron microscopy.

These results suggested that synapsin I was tightly associated with neurofilaments. The distribution of synapsin I in tissue sections under both light and electron microscopy was also studied with affinity purified anti-synapsin I antibodies. We found that the results were dependent on the presence of Triton X-100 in the incubation solutions. When Triton was absent, strong cytoplasmic staining was evident with labelling of neurofilaments, microtubules, the presynaptic grid, post-synaptic densities as well as dense labelling of synaptic vesicles. In the presence of Triton, staining of microtubules and neurofilaments was markedly reduced.

These results indicate that synapsin I is associated with the cytoskeleton and may be an important link between cytoskeletal elements as well as between the cytoskeleton and membrane.

192.5 IMMUNOCYTOCHEMICAL EVIDENCE FOR THE ASSOCIATION OF CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE II WITH THE CYTOSKELETON. R. S. Lasher, J. R. Goldenring, M. L. Vallano* and R. J. DeLorenzo. Dept. of Anatomy, Univ. Colorado Med. Sch., Denver, CO 80262, and Dept. Neurology, Yale Univ. Sch. Med., New Haven, CT 06510.

Recent studies have demonstrated that calcium/calmodulin-dependent protein kinase II (CaM kinase II) activity co-purifies with in vitro preparations of neurofilaments and microtubules (Larson et al., 1985. J. Neurochem., in press; Vallano et al., 1985, PNAS 82, in press). This association of CaM kinase II with cytoskeletal elements has now been studied by immunocytochemical methods employing a monoclonal antibody (MAb) 39-29:x which reacts with the α/ρ subunit of CaM kinase II and with highly purified major postsynaptic density protein (Lasher et al., 1985, Anat. Rec. 211:105A). Light and electron microscopic evaluation of vibratome sections of rat brain fixed in 5% paraformaldehyde and processed by indirect immunoperoxidase methods indicates that the MAb binds to both synaptic and cytoplasmic structures in axons and dendrites, including intense labeling of neurofilaments and microtubules as well as of amorphous material bridging these structures. This cytoplasmic labeling is especially apparent in Purkinje cells and pyramidal cells, but is also present in other neurons and in Bergmann glial cells. In some sections, antigen appears to be associated with microtubules in the form of 25nM diameter spheres having a center-to-center spacing of 35nM. Fixation of the brain tissue in 5% paraformaldehyde + 0.2% glutaraldehyde and use of 0.3% Triton X-100 in the incubations with antibody resulted in the loss of most of the antigen associated with the cytoskeleton, but the labeling of postsynaptic densities and presynaptic dense projections appeared to be enhanced.

In order to confirm observations made using tissue sections, we examined isolated cytoskeletal preparations by electron microscopy coupled with indirect immunogold methods. MAb 39-29:x was found to specifically decorate neurofilaments isolated from multiply-cycled microtubule preparations. The microtubules were also specifically decorated by the MAb. The degree of MAb binding to neurofilaments and microtubules appeared to correspond to the amount of endogenous kinase II activity present.

The presence of CaM kinase II on cytoskeletal elements may provide a mechanism for rapid modulation of the interaction of these structures by autophosphorylation or phosphorylation of associated proteins.

192.6 INHIBITION OF PURIFIED CALMODULIN KINASE II BY AUTOPHOSPHORYLATION. J.M.Bronstein*, C.G.Wasterlain*,and D.B.Farber. UCLA School of Medicine, Depts. of Neuroscience, Neurol., and Opthal., Los Angeles, CA.

Calmodulin kinase II (Calm-K II) is a calcium/calmodulin dependent protein kinase which is highly concentrated at synaptic junctions. It is ideally located to mediate some of calcium's postsynaptic actions and may have a presynaptic role in transmitter biosynthesis and release. Calm-K II is composed of 50 and 60 Kilodaltón subunits which undergo autophosphorylation. We examined the effect of autophosphorylation on purified Calm-K II activity and its role in determining substrate specificity. Phosphorylation of Calm-K II was found to dramatically inhibit kinase activity and the degree of inhibition was closely correlated with the degree of autophosphorylation. Maximal inhibition resulted in a 12.6 fold decrease of ^{32}P incorporation into glycogen synthase, 7.1 fold decrease into lysine rich histone, and 3.4 fold decrease into synapsin I. Inhibition of Calm-K II by autophosphorylation was observed over calmodulin concentrations ranging from 50-1000nM. Synapsin I and glycogen synthase were found to be excellent substrates for Calm-K II possibly because they are rapidly phosphorylated prior to autophosphorylation of the enzyme which greatly reduces kinase activity. Lysine rich histone was a poorer substrate possibly because autophosphorylation of Calm-K II preceeds phosphorylation of this protein. These data suggest that autophosphorylation of Calm-K II maybe a rapid means of terminating some of calcium's actions in synaptic events.

Supported by the Epilepsy Foundation of America (JMB), by the Research Service of the VA, and by research grants NS13515 (CGW) and EY02651 (DBF).

192.7 **REGULATION OF TYPE II CaM KINASE ACTIVITY BY AUTOPHOSPHORYLATION.** S.G. Miller* and M.B. Kennedy. Div. of Biology, 216-76, Caltech, Pasadena, CA 91125.

Type II CaM kinase is an oligomer of ~ 12 homologous 50 and 60 kDal catalytic subunits. In the presence of Ca^{2+} and calmodulin (CaM), it is rapidly autophosphorylated at several sites on both subunits. We have investigated the effects of this autophosphorylation.

Kinase was first autophosphorylated with cold ATP in the presence of Ca^{2+} and CaM, then diluted 500-fold and assayed for ability to phosphorylate synapsin I in the absence and presence of Ca^{2+}. Autophosphorylation had two effects. The initial rate of phosphorylation of synapsin I was reduced to 20-30% of controls. However, most of the reduced activity no longer depended on the presence of Ca^{2+} and CaM. Thus, authophosphorylation produced a significant Ca^{2+}-independent kinase activity. Addition of phosphate to 3 or more subunits per oligomer apparently produced an allosteric change in the conformation of all the subunits since it was sufficient to cause the complete reduction of initial rate. The reduced rate resulted from a decreased V_{max} rather than decreased affinity for synapsin I. In vivo, this mechanism could produce Ca^{2+}-dependent bursts of high kinase activity followed by low levels of Ca^{2+}-independent activity outlasting the initial Ca^{2+} transient.

Rapid autophosphorylation of an entire oligomer was initiated by autophosphorylation of only a few of its subunits. The initial "trigger" autophosphorylation depended on Ca^{2+} and CaM, while autophosphorylation of the rest of the subunits continued at the same rate after removal of Ca^{2+} by addition of EGTA. The final number of phosphates incorporated per mole of kinase was higher in the presence of Ca^{2+} suggesting that a portion of the autophosphorylation sites are strictly Ca^{2+}-dependent. Multiple site phosphorylation of the kinase may prolong its Ca^{2+}-independent state by prolonging the time required for removal of phosphate by phosphatases.

The rate of Ca^{2+}-dependent autophosphorylation of native kinase was unchanged over an 80-fold range of kinase concentration, indicating that this reaction is primarily intramolecular. To test whether the Ca^{2+}-independent phospho-kinase is capable of activating native kinase by intermolecular phosphorylation, maximally phosphorylated kinase was incubated with native kinase at various ratios in the presence of ATP. Under these conditions, intermolecular autophosphorylation occurred at < 5% of the intramolecular rate. No increase in Ca^{2+}-independent activity of the native kinase was observed. It is therefore unlikely that, in vivo, phospho-kinase is able to transmit its activated state by triggering Ca^{2+}-independent activity of native kinase.

192.8 CHARACTERIZATION OF A SYNAPTIC MEMBRANE-ASSOCIATED PROTEIN PHOSPHATASE. L.A. Dokas, L. Jeziorowski* and D. Ondrejka*, Depts. of Neurosciences and Biochemistry, Medical College of Ohio, Toledo, OH 43699.

Rat brain synaptic plasma membranes (SPM) enriched in presynaptic elements, contain an endogenous protein phosphatase that will dephosphorylate ^{32}P-labeled B50. The latter protein is a substrate for protein kinase C and its phosphorylated state correlates with the activity of membrane-bound diphosphoinositide kinase. Moreover, this protein phosphatase can be inhibited by a somatostatin analog ([D-Trp^8]-somatostatin) which has a high affinity for brain membrane binding sites. Determination of the activity of this protein phosphatase, therefore, could be one means by which presynaptic functions are regulated. Based on these functional considerations, we have begun to characterize this SPM-associated protein phosphatase. Crude rat brain membranes were treated with 0.5% Triton X-100 - 75 mM KCl and the extract was chromatographed on a DEAE-cellulose column with a 0-400 mM NaCl gradient. Using ^{32}P-labeled B50 as a substrate, the major portion of protein phosphatase activity elutes at 260 mM NaCl and can be further enriched by fractionation between 0 and 55% ammonium sulfate. A heat-stable protein inhibitor does not alter the activity of the protein phosphatase. Addition of 20 mM EDTA to the dephosphorylation assay medium (containing 10 mM Mg^{2+} and 1 mM Ca^{2+}) inhibits the column-purified protein phosphatase, as well as the endogenous activity found in SPM. A similar concentration of EGTA has relatively little effect on this enzyme. Protein staining of the ammonium sulfate fraction demonstrates a number of protein bands, with one major species migrating at about 43,000 daltons. In the classification of Ingebritsen and Cohen (Science 221:331, 1983), protein phosphatase 2C is insensitive to the heat-stable inhibitor, dependent upon Mg^{2+}, but not Ca^{2+} and composed of a single protein subunit with a molecular weight of 43,000 daltons. The correspondence between the characteristics of protein phosphatase 2C and the SPM-associated protein phosphatase suggest a common identity between the two forms. Supported by Grants AG04190 from the National Institute on Aging and 84-1472 from the Alzheimer's Disease and Related Disorders Association.

192.9 EFFECTS OF CALCIUM ON THE BINDING OF CALMODULIN (CM) TO POSTSYNAPTIC DENSITY (PSD) PROTEINS AND ITS ACTIVATION OF A PROTEIN KINASE. L. Sachs*, R. Carlin*, and P. Siekevitz, Lab. of Cell Biology, Rockefeller University, N. Y., N. Y. 10021

We have examined the concentration dependence of Ca^{2+} to promote the binding of CM to specific proteins in cortical PSDs. Two techniques were used. The first employed the binding of 10 μg of ^{125}I-CM to 200 ug of EGTA treated PSDs in the presence of 40 mM HEPES/KOH, pH 6.8, 2 mM EGTA/KOH, pH 6.8, and varying $[Ca^{2+}]$ for 2 hours at 25° C, with subsequent centrifugation and washing to remove unbound ^{125}I-CM. The second was the gel overlay method (Carlin, R., et al., J. Cell. Biol., 89, 449, (1981)), where ^{125}I-CM was bound in the presence of increasing Ca^{2+} to proteins on SDS gels and examined by autoradiography. The first method revealed that 50% binding of CM to PSD proteins occurred at a free Ca^{2+} conc. of 0.6 μM. The second method indicated that CM became bound abruptly to all known CM binding proteins of the PSD at a Ca^{2+} conc. of 0.5 μM, with the 51 kD protein, the major PSD protein and presumably the Ca^{2+}/CM-dependent protein kinase, being the major CM binding protein.

Next examined was the effect of phosphorylation conditions on the Ca^{2+} conc. necessary for binding and phosphorylation. Using slightly different conditions (40 mM PIPES/KOH, pH 6.8, 2 mM EGTA/KOH, pH 6.8, 1 mM $MgCl_2$, and 1 mM DTT), it was found that the addition of CM stimulated phosphorylation but the stimulation was independent of Ca^{2+} above 0.08 μM. In addition, we used binding conditions as immediately above but without DTT, and with the addition of the bifunctional and photoactivatable crosslinking agent (cysteamine-^{35}S)N-succinimidyl-3-((2-nitro-4-azidophenyl)-2-aminoethyldithio)proprionate to identify CM binding proteins of the PSD. Again, binding was independent of Ca^{2+} above 0.08 μM, becoming abruptly bound to the known CM binding proteins of the PSD (Carlin, et al., as above).

The most significant difference between the phosphorylation and non-phosphorylation experiments is the presence of high Mg^{2+} conc. in the former, a concentration where Mg^{2+} is known to bind to the 4 Ca^{2+} binding sites of CM (Haiech, J., et al., Biochem., 20, 3890, (1981)). This might explain the difference in Ca^{2+} conc. necessary for CM binding between the two conditions. It is known that the free intracellular Mg^{2+} conc. in brain is 0.6 to 1.0 mM (Veloso, D., et al., J. Biol. Chem., 248, 4811, (1973)). This suggests that Mg^{2+} might be involved in modulation of interaction between Ca^{2+}, CM, and CM binding proteins. Further experiments will be done to determine how Mg^{2+} quantitatively and qualitatively modifies the interaction of Ca^{2+} and CM in binding to appropriate proteins of the postsynaptic density.

192.10 EXISTENCE OF A VOLTAGE-DEPENDENT Ca^{2+} CHANNEL PROTEIN IN SYNAPTIC MEMBRANE (SM) AND POSTSYNAPTIC DENSITY (PSD) FRACTIONS ISOLATED FROM CEREBRAL CORTEX (CTX) AND CEREBELLUM (CL) OF CANINE BRAIN, AS DETERMINED BY NITRENDIPINE BINDING. P. Siekevitz, R. Carlin* and K. Wu* (Spon: D.R. Griffin). Lab. Cell Biology, The Rockefeller University, 1230 York Ave., New York, NY 10021.

We have used (^3H)-nitrendipine, a specific blocker of voltage-dependent Ca^{2+} channel, to study its binding to SM and PSD fractions of canine brain. After incubation under dim red light (in 20 mM Tris, 50 mM choline-Cl^-, 1.5 mM $CaCl_2$, pH 7.4) at 0-4°C for 90 min., the reaction mixtures were immediately filtered through Whatman GF/B filters, washed with 3 x 5 ml. of ice cold wash buffer (20 mM Tris, 0.2 M choline-Cl^-, 1.5 mM $CaCl_2$, pH 7.4) and the bound radioactivity on the filters determined. Specific binding was defined as the difference in binding between the absence and presence of 1 μM nifedipine. The specific binding constants thus obtained were: CTX-SM, KD=110 pM (Bmax=126 fmol/mg protein); CTX-PSD, KD=207 pM (Bmax=196 fmol/mg); CL-SM, KD=100 pM (Bmax=65 fmol/mg); CL-PSD, KD=189 pM (Bmax=80 fmol/mg). No significant difference was found between fresh and frozen samples. All fractions showed one single class of nitrendipine binding sites. The values of 110 pM and 126 fmol/mg for canine CTX-SM were similar to those obtained with a rat SM fraction (98±25 pM and 160±9 fmol/mg) (H. Schoemaker et. al., in Nitrendipine, 1984, p.133). Calmodulin may be important in the interaction between nitrendipine and its receptor since the calmodulin inhibitor R24571 (calmidazolium) at 5 μM was found to inhibit by about 80% of the binding of nitrendipine to CTX-SM or CTX-PSD fractions; similar results were reported on binding of nitrendipine to a rat brain membrane fraction. (S.A. Thayer and A. S. Fairhurst, Mol. Pharmac., 24(1983)6). Treatment of CTX-PSD with 0.5% deoxycholate, 1% N-lauroyl sarcosinate, 4 M guanidine-HCl, pH 7.0 and 1.0 M KCl resulted in removal of the receptors from the PSD by 42%, 51% 51% and 16%, respectively. However, the two detergents solubilized about 90% of the receptor from CTX-SM, indicating the presence of the Ca^{2+} channel also in non-synaptic membranes and in accord with its presence in erythrocyte membranes (H. Glossmann et. al., T I P S, 3(1982)431). The data suggests that at the synapse there is about a 3-fold concentration of the Ca^{2+} channel protein in the CTX-PSD fraction. The findings also indicate that the nitrendipine binding protein, which spans the postsynaptic membrane, is an intrinsic PSD component. The presence of the voltage-dependent calcium channel, of a Ca^{2+}-dependent K^+ channel (K. Wu et. al., Brain Res., in press) and of various neurotransmitter receptors (by ourselves and by others) in the isolated PSD fraction suggest that the PSD may play an important role in the mediation of neurotransmission.

192.11 COMPARISON OF BINDING OF L-GLUTAMATE TO SYNAPTIC MEMBRANE (SM) AND POSTSYNAPTIC DENSITY (PSD) FRACTIONS ISOLATED FROM CEREBRAL CORTEX (CTX) AND CEREBELLUM (CL) OF CANINE BRAIN. K. Wu*, R. Carlin* and P. Siekevitz (Spon: N.E. Miller). Lab. of Cell Biology, The Rockefeller University, 1230 York Avenue, New York, N.Y. 10021

The Na^+-independent binding of the excitatory neurotransmitter, L-glutamate, to SM and PSD fractions of canine brain was studied using L-(^3H)-glutamate. With 10 mM HEPES/KOH, pH 7.4 as the assay buffer, the specific binding constants were (A) fresh fractions (fresh tissue):CTX-SM, KD_1=20.1 nM ($Bmax_1$=0.8 pmol/mg protein) and KD_2=792.8 nM ($Bmax_2$=22.0 pmol/mg);CTX-PSD, KD=400.0 nM (Bmax=35.6 pmol/mg);CL-SM, KD=869.0 nM (Bmax=56.4 pmol/mg);(B) frozen fractions (fresh tissue):CTX-SM, KD_1=18.9 nM ($Bmax_1$=0.8 pmol/mg) and KD_2=874.1 nM ($Bmax_2$=23.6 pmol/mg);CTX-PSD, KD=456.0 nM (Bmax=32.1 pmol/mg);CL-SM, KD=704.0 nM (Bmax=52.8 pmol/mg);(C) frozen fractions (frozen tissue):CTX-PSD, KD=417.7 nM (Bmax=28.9 pmol/mg);CL-PSD, KD=500.3 nM (Bmax=92.0 pmol/mg). Under these conditions, there was a concentration of glutamate binding sites in CTX-PSD and CL-PSD over the respective membrane fractions. When the binding was assayed with 10 mM HEPES/KOH, pH 7.4, containing 1 mM Ca^{2+} and 40 mM Cl^-, fresh CTX-SM (fresh tissue) had KD_1=10.8 nM ($Bmax_1$=1.2 pmol/mg) and KD_2=709.9 nM ($Bmax_2$=55.6 pmol/mg), whereas fresh CL-SM (fresh tissue) had a KD=789.4 nM (Bmax=139.1 pmol/mg). The results, together with those of others, suggest that the thin CL-PSD are probably derived from the excitatory synapses in the molecular layer. The ion dependency of glutamate binding to CTX-SM was similar to that to rat brain SM (A. Foster and G. Fagg, Brain Res. Rev. 7(1984)103):(a) Cl^- increased number of glutamate binding sites, and the effect was enhanced by Ca^{2+}; Ca^{2+} alone had no significant effect;(b) both amino-phosphono-butyrate (APB) and freezing abolished Cl^-/Ca^{2+}-dependent glutamate binding;(c) low concentrations of Na^+ (< 5 mM) specifically depressed Cl^-/Ca^{2+}-dependent glutamate binding. Na^+-dependent glutamate binding to CTX-SM was inhibited by K^+ and was reduced by 50 % upon freezing and thawing. CL-SM showed similar ion dependency except for the absence of Na^+-dependent glutamate binding sites. CTX-PSD had neither Na^+-dependent nor APB-sensitive binding sites and its glutamate binding was unaffected by freezing and thawing, in agreement with the findings using rat PSD (G. Fagg and A. Matus, PNAS, 81(1984)6876). Glutamate binding to CTX-SM or CTX-PSD was not affected by pretreatment with 10 mM L-glutamate, nor by simultaneous incubations with calmodulin. Also, phosphorylation of the CTX-SM or CTX-PSD proteins had no effect on glutamate binding. Treatment of CTX-PSD with 0.5 % deoxycholate, 1 % N-lauroyl sarcosinate, 4 M guanidine-HCl pH 7.0 and 1.0 M KCl removed the receptor from the PSD by 25 %, 44 %, 40 % and 11 %, respectively. The respective percentages of protein solubilized by these reagents were similar, indicating no preferential dissociation of the receptors, and suggesting that the glutamate receptor is an intrinsic PSD protein.

192.12 TRANSCELLULAR FILAMENTS AT SYNAPSES: A STRUCTURAL CONTINUUM LINKING SYNAPTIC MEMBRANES AND CYTOSKELETONS. Mark H. Ellisman, R.D. Fields, Karen L. Anderson*, Thomas J. Deerinck*. Lab. for Neurocytology, Dept. Neurosci., UCSD, La Jolla, CA 92093.

We recently reported observations on an extensively distributed but previously undescribed pattern of filamentous structures within cells of tissues. These structures form a structural continuum between cells linking together cytoskeletons and extracellular matrices. We have referred to this network as a transcellular filament system (TCFS). Some constituents of the TCFS have been identified by immunoelectron microscopy as intermediate filaments (Ellisman, JCB 99:195a, 1984). We have now examined several different types of synaptic complexes and observed filamentous structures crossing synapses, interconnecting the cytoskeletons of pre- and post-synaptic cells. These structures have been observed by several methods including 3-D imaging by high voltage EM of thick sections, contrast enhancement by computer aided image analysis, platinum shadowing of resinless sections and freeze-etching. Trans-synaptic fibers have been observed in all synaptic specializations examined in detail thus far. These have included synapses at sensory receptors, motor nerve terminals and between neurons within the CNS. At ribbon synapses of the ampulla of Lorenzini (an electrosensory receptor of sharks, skates and rays) filaments course across the synaptic cleft connecting the presynaptic ribbon with filaments of the postsynaptic cytoskeleton. At electromotor synapses on eel (Electrophorus electricus) electric organ, stain resistant fibers within the nerve terminal are structurally continuous with cytoskeletal elements within the electrocytes. In the rat CNS, trans-synaptic filaments are observed linking pre- and post-synaptic structures. Clusters of ribosomes characteristic of some synaptic specializations appear to associate with the stain resistant fibers. We consider the trans-synaptic complex of fibers linking pre- and post-synaptic structures across the synaptic cleft to represent focal differentiations of the TCFS.

Immunolabeling studies to identify constituents of the TCFS indicate that this network, although forming a structural continuum, may be composed of many different macromolecules. These macromolecules probably include a group of cytoskeletal proteins, membrane proteins and extracellular matrix components that can co-polymerize or otherwise link together. A primary characteristic shared by components of the TCFS is resistant to staining with most procedures used for electron microscopy. Description of this type of structure has become possible in part due to new developments in electron microscopic imaging technology. The distribution and likely molecular constituents of this system indicate possible roles in cell-cell recognition, differentiation, ion regulation, and the regulation of cell form.

193.1 A cDNA PROBE TO STUDY CELLULAR INTERACTIONS DURING CNS DEVELOPMENT. D. Goldowitz, M. Vijh* and J. Rossant*. Daniel Baugh Institute of Anatomy, Thomas Jefferson University, Philadelphia, PA 19107; and Dept. Biol. Sci., Brock Univ., St. Catharine, Ontario, Canada.

A cell marking system is described that can be used to monitor the interactions of differentially-derived cells in transplant studies, experimental mouse chimeras and cell culture work. The marking system is based upon a sequence of satellite DNA that is highly abundant in Mus musculus cells but not in the cells of another mouse species, Mus caroli (Siracusa et al., 1983, J. Embryol. exp. Morphol. 73:163). Thus, hybridization of the cloned cDNA (pMR 196) to cell or tissue mixtures can detect cells of M. musculus origin vs. M. caroli origin. For several important reasons this is an ideal marker for the numerous cell interactions involved in CNS development.

The cDNA is labeled with either ^{3}H-nucleotides or biotinylated-d-UTP with an in vivo nick translation system. The labeled cDNA probe is applied to fixed tissue or cells. Several fixatives were examined with the aim of optimizing tissue DNA preservation and subsequent hybridization to the cDNA probe. Perfusion fixation with acetic acid:95% ethanol (1:3) or 2% glutaraldehyde in 0.1 M phosphate buffer (pH 7.3) was found to give the best results for both large and small neurons. Other fixatives such as Bouin's, 4% paraformaldehyde, Carnoy's and periodate polylysine paraformaldehyde (PLP) gave inferior results. Tissue pieces were routinely embedded in paraffin. Sections of tissue mounted on poly-L-lysine coated slides or cells on coverslips were treated for 10 minutes at 80° C in 2 x SSC to denature DNA in preparation for in situ hybridization. Throughout denaturation and hybridization formamide was found to be unnecessary as long as temperature parameters were properly adjusted. The hybridization solution of 10% dextran sulfate, 2.5 x SSC, 250 ug/ml sonicated salmon sperm DNA worked at least as well as more complex hybridization formulations. Hybridization was at 60°C for 12-16 hr. After thorough rinsing in successively lower concentrations of SSC and lower temperatures, tissue or cells were either coated with NTB-2 emulsion for autoradiography or processed for ABC (Vectastain)-diaminobenzidine (DAB) reaction. Detection could easily be amplified by longer exposure for autoradiograms or heavy metal intensification of the DAB reaction product. Studies of CNS development using this marking system will be discussed.

193.2 NEURONAL DEGENERATION MUTATIONS THAT SPARE PRIMARY NEURONS IN THE ZEBRAFISH. C.B. Kimmel, D.J. Grunwald*, C. Walker*, M. Westerfield and G. Streisinger[1]. Institute of Molecular Biology, Univ. of Oregon, Eugene, OR 97403.

To learn how genes control the development of functional neuronal circuits in a vertebrate we are inducing mutations in lethal-free clonal lines of zebrafish and systematically screening for mutations that perturb the nervous system of the embryo. We describe a set of independent zygotic recessive lethal mutations (2 induced by γ-rays, 1 by UV, and 1 by ethylnitrosourea) that specifically produce massive cell death in the CNS shortly after its formation. However, the mutations appear to spare large cells we call "primary" neurons. These neurons are generated during the first half-day after fertilization, and are subsequently assembled into a functional network that mediates the first motile behaviors of the embryo.

We have characterized one γ-ray induced mutation, let(b39), in some detail. It segregates as a single Mendelian gene. Mutant embryos appear unaffected during most of the first day of development. Spontaneous motile behaviors at 24 hr, and responses to tactile stimulation at 32 hr, are normal. Degenerating single cells and clusters of cells become evident in the CNS during the second day, and by the third day cell death is widespread; only a few viable cells remain in some CNS regions such as central retina and dorsal brain. By this stage embryonic behaviors are grossly abnormal, and within the next 2-3 days the larvae die. Primary neurons, including Rohon-Beard neurons, identified reticulospinal interneurons and primary motoneurons were identified by HRP labeling, acetylcholinesterase histochemistry, staining with a monoclonal antibody, and inspection with Normarski optics of living embryos. These neurons appear unaffected by the mutation. Furthermore, the connections between primary motoneurons and muscle cells appear physiologically normal.

The existence of genes that appear not to be required for the development and maintenance of primary neurons but that are essential for survival of neurons that develop later could mean separate genetic control of these two classes of cells.

193.3 RETINAL CHIMERAE OF XENOPUS: ANALYSIS OF NEURAL GRAFT INTEGRATION AND GROWTH USING A CELL AUTONOMOUS GENETIC MARKER. S. O'Gorman*, J. Kilty*, and R.K. Hunt* (SPON: W.M. Cowan). The Salk Institute, La Jolla, CA 92037.

Compound eyes, formed by surgical fusion of half eye rudiments of Xenopus embryos, have long been used to study the formation of retinotectal projections without an independent means of assessing the retinal areas occupied by graft- and host-derived neurons. In quinacrine-stained paraffin sections of compound retinae formed by fusion of X. laevis (Xl) and X. borealis (Xb) half eyes, graft- and host-derived neurons can be reliably distinguished because of striking differences in the patterns of nuclear chromatin staining in the two subspecies. Compound eyes were constructed by replacing the excised right temporal half eyes of albino Xl hosts with stage-matched, pigmented Xb half eyes. Orthotopic compound eyes were formed by replacement with right temporal half eyes, heterotopic compound eyes were formed by replacement with either left temporal, left nasal or right dorsal half eyes. The grafts included recently postmitotic neurons and pigment epithelial cells from the back of the eye (BOE) and mitotically active cells from the germinal zone at the front of the eye (FOE) that generate neurons and pigment epithelial cell during continued growth of the eye. Donor pigment epithelium could be seen in the intact embryo, and cases showing robust growth of graft-derived pigment epithelium were processed for histologiccal analysis of the neural retina at St 50-57.

In both orthotopic (N=15) and heterotopic (N=18) compound eyes, grafted neurons and neurons derived from grafted germinal zone occupied large contiguous sectors whose angular positions were conserved from the BOE to the FOE. In most cases Xb neurons comprised 40% to 50% of the retina; in no case did they comprise less than 25%. In chimerae sacrificed at St 50-52, the graft-host borders of all three retinal nuclear layers were in close register with one another and there was little evidence of cell mixing across borders. In chimerae sacrificed at later stages, the registration of graft-host borders was less precise. Additionally, individual neurons along the inner surface of the inner nuclear layer and in the ganglion cell layer were often seen on the "wrong" side of the graft-host borders, separated from other members of their genetic cohort by many cell diameters. Anomalies of initial graft integration, including laminar faulting, hypoplasia, and tubular rosettes, were present at the BOE of many cases and were propagated during initial postoperative growth in some of these. These were resolved during further growth of the eye so that in sections closer to the FOE the angular positions of these malformations were occupied by normally laminated, well integrated retina derived from the grafted Xb germinal zone. Host-derived tissue did not extend into angular territories initially occupied by graft-derived tissues. Supported by NSF Grant PCM83-11082 and by the Keck Foundation.

193.4 MITOTIC WITHDRAWAL AND GERMINAL CELL FATE IN DEVELOPING NEURAL RETINA: GENETIC CHIMERAE IN XENOPUS. R.K. Hunt* and S. O'Gorman* (SPON: D.D.M. O'Leary). The Salk Institute, La Jolla, CA 92037.

The back of the eye (BOE) becomes mitotically quiescent at embryonic St 28-38 (2.5-4 days) in Xenopus, and cell division is confined thereafter to a bilayered germinal ring on the front of the eye (FOE). This germinal ring has an outer pigmented layer, which adds post-mitotic melanocytes to the margin of the pigment epithelium (PRE), and an inner neuroepithelial layer, which adds annuli of neurons to all layers of the neural retina (NR). We have analyzed the fate of small patches of embryonic eye cells transplanted from St 36-38 donor embryos (pigmented X. borealis and X. borealis/X. laevis hybrids) into St 32-36 albino X. laevis host eyes. Orthotopic FOE transplants successfully healed into the host germinal ring in about 70% of cases and adopted a germinal cell fate. New 'arcs' of black PRE cells were added to the rim of the PRE to yield an elongating black sector visible in the living albino eye; and cases fixed at St 50-57 (2-7 mo. after surgery) and stained with quinacrine to demonstrate X. borealis (Xb) chromatin, showed a grossly corresponding sector of Xb neurons in all layers of NR. By contrast, although orthotopic BOE grafts healed into the mitotically quiescent region of the host eye, thereafter they remained as a tiny black spot on the back of the host eye; and sectioned material at St 50-57 revealed a tiny cluster of Xb neurons in the back of the host retina (N=4). Following heterotopic transplantation (FOE-into-BOE or BOE-into-FOE), the pigmented cells of the graft adapted quickly to their new environment; and sectioned material at St 50-57 revealed a similar modulation of neural cell fates. In 11 FOE-into-BOE cases, where germinal cells had been introduced into the mitotically quiescent BOE, Xb neurons were confined to a small cluster at the back of the host retina. The exact size (and precision of integration) of these clusters varied from case to case and may reflect varying residua of mitotic activity in the first days after the surgery. The 13 BOE-into-FOE cases, in which mitotically quiescent PRE and NR cells had been transposed into the host germinal ring, gave mixed results. Four showed little or no growth of either PRE or NR cells; the grafted cells were quickly displaced from the host germinal ring, leaving a small spot of black PRE and a small cluster of Xb neurons at the back of the St 50-57 eye. One graft grew out a black sector of PRE, but the final NR (and, by inference, the original graft) contained no Xb neurons. In the remaining 8 cases, both PRE and NR showed a robust sector of graft-derived cells; and, in 5 of these, marked neuroepithelial cells persisted on the germinal ring and continued to support new growth up to the stage of sacrifice. We infer that local positional cues modulate the fate of neurogenic cells to withdraw from cell division or to become germinal cells that support the larval growth of the retina. Supported by NSF grant PCM83-11082 and by the Keck Foundation.

193.5 *SEVENLESS*, A CELL-SPECIFIC HOMEOTIC MUTATION THE *DROSOPHILA* RETINA. A. Tomlinson* and D. F. Ready (SPON: C. Sahley) Dept. of Biology, Princeton University, Princeton, N.J. 08544

During development cells select pathways of specialization which lead to the differentiation of specific cell types. Lesions in the genetic elements mediating these selections can cause cells to follow inappropriate pathways, resulting in homeotic transformations. For example, in *Drosophila*, the homeotic mutant *bithorax* causes mesothoracic structures to produce their methoracic counterparts (Lewis,E.B., Nature 276:565,1978). The developing compound eye of *Drosophila* offers several advantages for studying pathway selection at the single cell level. Each eye is a several hundred-fold reiteratior of a stereotyped cellular pattern, the ommatidium. Within each ommatidium, four lens-secreting cone cells overlie a core of eight photoreceptors. Ommatidia assemble in a choreographed sequence of cell movements. The photoreceptor core is assembled apically in the prospective retinal epithelium, and then sinks basally. Concomitant with this basal shift, four surrounding non-photoreceptor cells rise along the flanks of the cluster to meet over the cluster apically. Later in development this quartet of cells secretes a refractile extracellular lens, the cone, above the photoreceptors.

In *sevenless*, cell clustering proceeds normally and early clusters contain the full complement of eight cells. As the mutant photoreceptor cluster sinks, the cell in the R7 position is left behind, remaining apically. Subsequently, it is joined by three cells which rise along the flanks of the descending cluster to produce a typical cone cell quartet. *sevenless* is thus a cell-specific homoeotic mutation, causing a cell to adopt a path of differentiation inappropriate for its postion.

Mosaic analyses indicate that the developmental pathways taken by retinal cells are directed by their environment, rather than their ancestry (Ready, D.F., Hanson, T.E. and Benzer, S., Dev. Biol., 53:217,1976). Separate experiments also indicate that *sevenless* is cell-autonomous (Harris, W.A., Stark, W.S. and Walker, J.A., J.Physiol. (Lond.) 256:415, 1976; Campos-Ortetga, J.A., Jurgens,G. and Hofbauer, A., Wilhelm Roux Archiv. 186:27,1979). Together with the present results, these observations suggest that *sevenless* cells "misread" the R7 position. Whether the mutation specifically redirects prospective R7 cells into a cone cell pathway, or represents a "default" pathway for a defective R7 remains to be discovered.

193.6 NEURAL PLATE MORPHOGENESIS AND CELL LINEAGES DURING NEURULATION IN THE ASCIDIAN EMBRYO. D. Nicol and I.A. Meinertzhagen. Dept. of Biology, Dalhousie Univ., Halifax, N.S., Canada B3H 4J1.

The determinate cleavage and mosaic development of the ascidian embryo combine with its chordate ancestry and the apparent eutely of its larval nervous system to offer a favourable model of vertebrate neurogenesis. Embryos of Ciona intestinalis have been reconstructed at 12-min intervals from 7.9 - 11.7 hr (16°C), using serial semithin sections to analyse the morphogenetic events which produce a neural tube from a superficial plate of neurectoderm. We have previously confirmed the cell lineage originally described by Conklin (J. Acad. Nat. Sci. Phila., 13:1-119, 1905) by which, at the end of gastrulation (7.0 hr: 16°C), the neural plate comprises 40 cells. The cells are arrayed over the dorsal surface of the embryo in regular rows, 2 posterior rows each of 8 cells and 4 anterior ones each of 6.

Between 7.9 and 9.5 hr, neurulation follows a postero-anterior wave of transversely-directed cleavages which advances the lineage from these 40 to at least 74 cells arranged in their 10th generation into 12 rows. The morphogenesis of cells of the posterior rows occurs in three consecutive steps which resemble the amphibian pattern of neurulation but are analysed here at single-cell level. Each cell: 1. decreases its apical surface area and changes from columnar- to wedge-shaped; 2. elongates, the neural plate lengthening from 50µm at 7.0 hr to 120µm at 11.7 hr, along with the rearrangement and elongation of the underlying presumptive notochord cells; 3. undergoes shearing movements with respect to its neighbours, so as to disrupt their orderly rows. In each row, the pair of midline cells shears, each to straddle the ventral midline of the neural tube, with one (either left or right) in front of the other; two pairs of medio-lateral cells shear to form the walls of the tube, while the pair of lateral cells meets and intermingles at the dorsal midline. This gives the characteristic arrangement of presumptive ependymal cells in cross section. Anteriorly, the cell rows merge into each other increasing the number of cells in any cross section, with each cell remaining columnar and surrounding a large central lumen. Between this region, which becomes the brain, and the ependymal region is a transitional zone.

The cell lineage has been followed through the 11th generation, the first cells to enter which (at 10.5 hr) are ventral ependymal cells, originally the midline cells in the most anterior of the posterior rows of 8. These divide symmetrically, other ependymal cells following suit non-synchronously till the end of neurulation (11.7 hr). In the brain, synchronous cleavages occur between 11.3 and 11.7 hr to produce a total of 134 cells for the entire nervous system at the end of neurulation. Divisions occur later in the transition zone between ependyma and brain.

193.7 CENTRIFUGATION AFFECTS CELL FATE IN THE LEECH EMBRYO S.Astrow* and D.A. Weisblat, Dept. Zoology, Univ. of Calif., Berkeley, CA 94720

One mechanism thought to be important in the specification of distinct cell lines during development is the localization of cytoplasmic factors that restrict or direct developmental potential. In the leech, domains of yolk-deficient cytoplasm, called teloplasm, become segregated into one cell, D, of the 8-cell embryo. Cell D is unique; it generates the five bilateral pairs of stem cells (teloblasts) that give rise to all segmental tissues of the leech. We have tested the hypothesis that D owes its unique character to factors associated with the teloplasm, by centrifuging embryos to effect changes in teloplasm distribution and in cell fate.

At the 2-cell stage, the teloplasm is localized in two caps at the dorsal and ventral poles of cell CD. Mild centrifugation just prior to the second cleavage partially stratifies the cellular contents so that the yolk-free cytoplasm is displaced centripetally. Most spun embryos cleave on schedule, generating 4-cell embryos. Normal 4-cell embryos undergo a round of asymmetric divisions (micromere production), then cell D cleaves equatorially, producing teloblast precursors DM and DNOPQ while A,B, and C produce another round of micromeres. While most spun embryos (75%) cleave normally, in approximately 20% of spun embryos cells C and D cleave simultaneously and equatorially. These abnormal progeny of C appear mirror-symmetric to DM and DNOPQ and are called CM and CNOPQ.

Evidence that redistribution of teloplasm may be responsible for the fate change is that the fates of spun embryos correlate with the distribution of yolk-deficient cytoplasm between C and D at the second cleavage. Embryos in which D inherits most of the teloplasm usually cleave normally (95%). But embryos in which cells C and D receive roughly equal portions of teloplasm cleave symmetrically. Rarely, the prospective C cell receives a larger portion of teloplasm than D. In these cases, C cleaved equatorially.

Observation of symmetrically cleaving embryos, stained at stage 8 with Hoechst 33258 to label nuclei, suggests that supernumerary germinal bandlets are generated. This possibility has been investigated using microinjected lineage tracers to label descendents of early blastomeres. We find that cells CM and CNOPQ are capable of giving rise to teloblasts and germinal bandlets which may contribute to the germinal bands. Cells DM and DNOPQ in spun embryos follow the same fate as in controls.

These initial results are consistent with two alternate hypotheses: 1)the difference in fate between cells C and D depends on some component of the cytoplasm normally being segregated exclusively to cell D; 2)the fate of cells C and D is governed by a disproportionate distribution of teloplasm between the two cells.

193.8 Protein Differences Between Sister Cells of Different Fates in Leech Embryos. B. Holton and D. Weisblat. Dept. of Zoology, Univ. of Ca. Berkeley, Berkeley, CA 94720.

Embryonic cells of different fates must exhibit qualitative or quantitative biochemical differences either as a cause or as an effect of individual fate determination. We have begun to study such differences in embryos of the leech, Helobdella triserialis, where cell fates can be observed and manipulated. Cell CD divides into cells C and D which normally follow different fates. C forms transient larval epithelium and some nonsegmental cells of the adult, including neurons of the supraesophageal ganglion. D cell gives rise to all of the segmental ectodermal and mesodermal derivatives. Cells C and D are visibly different. D contains a region of yolk-deficient cytoplasm (teloplasm) and C does not; D produces one micromere then divides equally to form cells DM and DNOPQ, whereas cell C produces two micromeres. Cells C and D are large (250µm diam.) and can be dissected apart in quantities sufficient to make biochemical comparisons feasible.

We used SDS polyacrylamide gel electrophoresis (PAGE) coupled with a sensitive silver stain for proteins to compare cells C and D. Before comparing these cells we sought to distinguish between yolk-associated proteins and those associated with yolk deficient cytoplasm. To do this we centrifuged 4-cell embryos to stratify their intracellular components (see preceding abstract). Each embryo was cut into two pieces: the light part contained predominantly yolk-deficient cytoplasm and the heavy part contained the yolk-rich cytoplasm. Equal amounts of protein from each fraction were compared by 1-dimensional PAGE. The yolky fraction yielded only about a dozen prominent protein bands whereas the yolk-deficient fraction separated into over one hundred bands. When the C and D cells were compared, cell C proved to be greatly enriched in yolk associated proteins. Cell D contained relatively more of the non-yolk proteins which we expect are primarily associated with the teloplasm. In particular, two protein bands (50 kdaltons and 80 kdaltons molecular weight) appeared in much higher (greater than ten fold) amounts in D than in C cells. S. Astrow (see preceding abstract) is able to redistribute cytoplasmic components in the 2-cell embryo so that cell C later undergoes D cell-like cleavages. The protein pattern from such modified C cells was indistinguishable from that of D cells, including the presence of the two D cell-enriched proteins. We are now using 2-dimensional PAGE to further examine differences between the C and D cells.

193.9 UNEQUAL CELL DIVISION IN LEECH DEVELOPMENT. S. A. Settle* and D. A. Weisblat. (Spon: M. Law). Dept. of Zoology, Univ. of CA Berkeley, CA 94720

Cell divisions which produce daughters of unequal size are observed at various stages of development in leeches and other animals. To determine how the asymmetry of unequal cell divisions arises we have observed the position of nuclear DNA in embryonic cells of the glossiphoniid leech Helobdella triserialis. Leech embryos were fixed with formaldehyde, stained with the DNA stain bisbenzimide (Hoechst 33258), and viewed by fluorescence microscopy. A novel approach was used for observing the nuclei in the large cleavage blastomeres. Daughter blastomeres were separated along their cleavage plane and mounted with the flat face of the cleavage plane facing the microscope objective. This provided a rapid method for viewing nuclei located near the center of the spherical embryo. We have observed that large cleavage blastomeres (200um in diameter) and small ectodermal blast cells (25um in diameter) differ in their mechanisms of unequal cell division. In large cleavage blastomeres the prophase nucleus moves toward the cortex of the cell, and metaphase occurs in a an eccentric location. This premitotic nuclear movement accounts for most but not all of the asymmetry in the division of a blastomere into a micromere and a macromere. Further inequality in blastomere cell division arises from an asymmetrical anaphase which projects the future micromere nucleus into a small cytoplasmic bud protruding from the surface of the blastomere. Unequal divisions of small n_f, o, q_f, and q_s ectodermal blast cells may be mechanistically less complex than those of the large blastomeres. In the unequal divisions of ectodermal blast cells the metaphase DNA is located centrally within the cell. An asymmetrical anaphase ensues, as in the budding process of the blastomere division. One daughter nucleus moves into a cortical region of the blast cell and the blast cell cortex deforms into a bud which becomes the smaller daughter of the unequal division. The combined process of asymmetrical anaphase and cytoplasmic budding account for all of the asymmetry in the unequal blast cell divisions. These findings indicate that both movement of the premitotic nucleus and an asymmetrical anaphase contribute to the asymmetry of the unequal division of the large yolk-filled blastomeres. In contrast, asymmetrical anaphase is the predominant mechanism of unequal divisions of the small ectodermal blast cells.

193.10 DEVELOPMENTAL COMMITMENT OF ONLY ONE OF THE TWO DAUGHTER CELLS DURING SERIAL BLAST CELL DIVISIONS IN THE LEECH. M. Shankland. Dept. of Molecular Biology, U. of California, Berkeley, CA 94720.

The o and p bandlets of the leech embryo are parallel columns of ectodermal blast cells which arise from the egg via equivalent cell lineages. The blast cells in these two bandlets are born with comparable developmental potential, but undergo an interaction which brings about subsequent divergence in their fates. The O and P fates have been distinguished both by the set of identified pattern elements which comprise the blast cell's descendant clone, and by the sequence of blast cell divisions in the lineage leading to that clone.

Previous work has shown that the o blast cells, although initially capable of following either the O or P pathway, become committed to the O pathway 20-35 hr after their birth. This commitment is not a single event, but rather a sequence of at least three separate events which determine the fates of different pattern elements within the clone. These three commitment events occur around the time when the o blast cell experiences its first few cell divisions, and I propose that each partial commitment is (i) associated with a different division in the o blast cell's descendant lineage, and (ii) determines the fate of only one of the two daughters of that division.

If this model is correct, then those O pattern elements whose fates are determined in unison at a particular commitment event should arise from a single o blast cell daughter, and should be more closely related to one another than to elements whose fates are determined at other events. This prediction has been tested by injecting different progeny of the o blast cell with rhodamine-conjugated dextran, and then scoring the cellular composition of the labeled descendant clone at later times in development.

The normal o blast cell clone contains 7 unambiguously identifiable O pattern elements. The fate of 2 of these elements is determined at the first commitment event, and injections reveal that these 2 elements arise from cell o.aa, a granddaughter of the primary o blast cell, while the other 5 elements arise from the sister cell o.ap. Within the latter group of 5 pattern elements there are 4 whose fates are determined at the second commitment event--and which arise from the anterior daughter of cell o.ap--and 1 whose fate is determined at the third commitment event and which arises from the posterior daughter of cell o.ap. Thus, there appear to be at least two sequential divisions in the o blast cell lineage where one of the two daughter cells becomes committed to the O pathway, while the other daughter remains uncommitted.

193.11 EVIDENCE FOR TWO ALTERNATING CLASSES OF N BLAST CELLS IN THE LEECH EMBRYO. S.T.Bissen* and D.A.Weisblat (Spon: G.S.Stent). Dept. of Zoology, Univ. of California, Berkeley, CA 94720.

In the embryo of the leech Helobdella triserialis there are five bilateral pairs of teloblasts (M, N, O/P, O/P, Q) that generate bandlets of blast cells; blast cells in turn proliferate to form the segmental tissues. Each half segment contains cells derived from two n blast cells. Alternate blast cells (designated n_f and n_s) can be distinguished early in development by the timing and geometry of their first mitosis. Eventually one n blast cell gives rise to cells in the anterior portion of the ganglion and the other gives rise to cells in the posterior portion of the ganglion, plus a few peripheral cells.

As a preliminary to testing the hypothesis that these two alternating classes of n blast cells are formed with a single developmental potential, we first determined the correspondence between the two classes of early n blast cells and the two classes of N progeny. Fluorescein dextran (FDX) and HRP were injected into N teloblasts that had already begun making blast cells. The embryos were later separated into two groups on the basis of the first labeled blast cell, which was identified as either n_f or n_s using a combination of bright field and fluorescence optics. After further development, the embryos were fixed and stained for HRP. It was found that the n_s blast cell gives rise to the anterior portion of the ganglion and the n_f blast cell gives rise to the posterior portion of the ganglion and the peripheral cells.

To determine whether the n blast cells are developmentally equivalent, several FDX-labeled n blast cells in the germinal band were ablated by laser microbeam irradiation before their first division, and the fate of the first surviving blast cell posterior to the lesion was examined. If the n_f and n_s blast cells form an equivalence group at this stage, one fate should be dominant. It was found, however, that the first cell posterior to the lesion gives rise to either the n_f or n_s progeny. These results suggest that, unlike the o/p blast cells, the alternating n blast cells are determined to be different well before their first mitosis, and that they may, in fact, be intrinsically different at birth.

193.12 MICROMERE DERIVATIVES IN THE EARLY LEECH EMBRYO. R.K. Ho* and D.A. Weisblat (Spon. J. Weeks) Dept. of Zoology. Univ. of California, Berkeley, CA 94720

Previous studies have revealed that segmentally iterated cells in the leech Helobdella triserialis arise by the proliferation of longitudinally arrayed columns of blast cells produced by the five teloblast pairs. But the contributions of a set of much smaller cells, the micromeres, have remained obscure. Because of their size, these cells have been difficult to inject with lineage tracers, or even to see in the intact embryo. The present study was undertaken to determine the normal fate of these cells as the first step in determining their role in various morphogenetic and determinative events in which they are thought to participate.

It was previously shown that the progeny of the first quartet of micromeres a, b, c and d, derived from cells A, B, C and D, respectively of the four cell embryo, give rise to non-metameric prostomial structures including the supraesophageal ganglion and body wall tissues. They also contribute cells to the epithelium of the provisional integument, a transient tissue that arises between the germinal bands during stages 5-8 and covers the surface of the embryo during stages 5-10. In this study, the existence of other micromeres has been confirmed and their fates followed by lineage tracer injection. The following micromeres have been examined: a", b" and c", produced in the second micromere division by cells A, B and C; dm' and dnopq' produced by proteloblasts DM and DNOPQ; left and right nopq', produced by the left and right NOPQ cells; and left and right n' and opq', produced from the left and right N and OPQ cells. These cells complete the set of micromeres described on other leech species and we have found no other micromeres in Helobdella.

We have found that progeny from identifiable micromeres give rise to reproducible, stereotypic and lineage specific patterns of epithelial cells within the micromere cap of the stage 8 embryo. The mitoses of the micromeres are highly sensitive to -amanitin treatment. Moreover, we are able to inject micromeres with photo-sensitizing tracers and specifically ablate labeled micromere progeny to ask what roles these cells play in the early morphogenisis and organization of the leech embryo.

194.1 THE CHOLINERGIC SYSTEM IN THE RAT VISUAL CORTEX: INTRINSIC NEURONS AND AFFERENT PROJECTIONS. J.G. Parnavelas* and F. Eckenstein* (SPON: J.K. McDonald). Dept. of Anatomy and Embryology, University College London, London WC1E 6BT, U.K. and Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The morphology and distribution of cholinergic neurons and the distribution and synaptic organization of cholinergic axons were examined in the rat visual cortex by immunocytochemical visualization of choline acetyltransferase (ChAT). The preparation and characterization of the monoclonal antibody to ChAT have been described previously (Eckenstein and Thoenen, EMBO J., 1: 363, 1982). ChAT-labelled perikarya were observed in Tayers II through VI with the majority situated in layers II and III. They were all nonpyramidal neurons displaying chiefly bipolar morphology. Their ultrastructural features were consistent irrespective of layer or dendritic geometry: they showed relatively large nuclei and a thin rim of perinuclear cytoplasm containing clusters of ribosomes, abundant mitochondria and sparse granular endoplasmic reticulum. ChAT-labelled fibers, most arising in the nucleus basalis, formed an elaborate network throghout all cortical layers. Although the preponderance of fibers appeared to have no definite orientation, many in layers I and VI and in the subcortical white matter showed a horizontal preference. Examination of this dense fibre system with the electron microscope revealed that in a given section only a small proportion of axons and axon-terminals formed synapses (Gray type II) with dendrites and somata of pyramidal and nonpyramidal neurons.

194.2 VISUAL CORTICAL AFFERENTS AND EFFERENTS WITH POSSIBLE EXCITATORY NEUROTRANSMITTERS IN THE RAT: IPSILATERAL PATHWAYS. G. A. Looney and A. J. Elberger, Dept. of Anatomy, Div. of Neuroscience, Univ. of Tennessee Ctr. for Health Sci., Memphis, TN 38163

Evidence from several species suggests that excitatory amino acids are used as neurotransmitters by many efferent and afferent neocortical pathways. Studies in the cat show selective uptake and transport of excitatory amino acids by corticogeniculate and thalamocortical pathways (Baughman and Gilbert, 1981; Hicks et al, 1981). Similarly, studies in the rat show that excitatory amino acids are transported by corticotectal, corticogeniculate, corticostriatal and claustrocortical pathways (Divak et al, 1977; Fischer et al, 1982; Kvale and Fonnum, 1983). The present study attempted to confirm these findings, and elaborate on them further by defining afferents and efferents of visual cortex in the albino rat that selectively transport [3H] D-Aspartate (Asp).

Male rats weighing 175-200 gr were given 0.1-0.3 ul injections of 0.7-3.6 mM Asp in buffered saline along the medial, lateral and posterior borders of Area 17. With 24 hr survival the rats were perfused with a mixed aldehyde fixative; brains were frozen sectioned at 30um and coated with Kodak NTB-2 emulsion. After exposure times ranging from 3-6 months the sections were developed and Nissl stained. Sections were examined for the presence of retrogradely labeled cell bodies, and regions of distinctly increased grain concentrations indicating anterograde transport.

Four separate ipsilateral regions had labeled cell bodies: dorsal lateral geniculate nucleus (dLGN), superior colliculus (SC), lateral posterior nucleus of the thalamus (LP), and claustrum (Cl). In the dLGN and Cl these cells were uniformly distributed throughout the nucleus; in the SC and LP they were found in segregated areas. These four regions have been shown to reciprocally connect with the cortical areas injected in the present study (Carey and Neal, 1985; Hughes, 1977; Lund, 1978). In addition, dense concentrations of grains were noted throughout the dLGN, SC, and Cl, more so in the dLGN and Cl than in the SC. The results indicate: 1)Both afferent and efferent visual cortical pathways selectively take up and transport Asp, suggesting that they utilize excitatory amino acids as a neurotransmitter. 2)The present study's results confirm the more infrequently demonstrated phenomenon of anterograde transport of Asp (Baughman and Gilbert, 1981; Cuenod et al, 1981). 3)Specific uptake and transport of Asp is demonstrated by the absence of retrograde or anterograde transport to other regions of the brain connected with the cortical regions injected in this study (Rieck and Carey, 1984).

In conclusion, we have demonstrated the specific transport of Asp by reciprocal pathways between the rat visual cortex and the dLGN, SC and CL, and by visual cortical afferents from LP.

194.3 VISUAL CORTICAL PATHWAYS VIA THE CORPUS CALLOSUM WITH POSSIBLE EXCITATORY NEUROTRANSMITTERS IN THE RAT. A. J. Elberger and G. A. Looney, Dept. of Anatomy, Div. of Neuroscience, Univ. of Tennessee Ctr. for Health Sci., Memphis, TN 38163

Several cortical regions in the rat are connected by the corpus callosum with contralateral cortex. Studies using retrograde and anterograde tracers show that the borders of Area 17 have abundant callosal connections with contralateral visual cortex (Cusick and Lund, 1981; Miller and Vogt, 1984; Olavarria and Montero, 1984). Callosally connected cortical regions have been examined for specific uptake of putative neurotransmitters. Homotopic and heterotopic callosal pathways of sensorimotor and frontal cortex in the normal rat, and heterotopic pathways of visual cortex in neonatally lesioned rats had selective uptake of [3H] L-Glutamate (Glu) or [3H] D-Aspartate (Asp) (Cuenod et al, 1981; Divak et al, 1977; Fischer et al, 1982; Kvale and Fonnum, 1983). Physiological evidence indicated that excitatory amino acids mediate callosal transmission between contralateral visual cortices in the cat (Hicks and Guedes, 1981). The present study attempted to correlate the callosal connections at the borders of area 17 with selective uptake of an excitatory amino acid in the normal rat.

Adult male albino rats were given 0.1-0.3 ul injections of 0.7-3.6 mM Asp along the medial, lateral and posterior borders of Area 17 and perfused 24 hr later. Brains were frozen sectioned at 30um and coated with Kodak NTB-2 emulsion, exposed for 3-6 months and then developed and counterstained. The contralateral cortex was examined for evidence of retrograde or anterograde transport.

Retrogradely labeled cell bodies were found; there was no clear evidence of anterograde transport. Asp labeled cell bodies were found in seven subregions of contralateral cortex. They are: Area 29, Area 29/18b border, Area 18b, Area 18b/17 border, Area 17/18a border, Area 18a, Area 18a lateral margin. (Area 18b has also been referred to as 18, medial to Area 17.) In these seven subregions many more labeled cell bodies were seen in the supragranular than in the infragranular layers, although the difference was less in Area 29. The number of labeled cells was far less than that of HRP labeled callosal cell bodies (Miller and Vogt, 1984) showing that the Asp labeled a specific segment of the callosal population.

The Asp labeled cells are found in visual Areas 18b, 17 and 18a which have abundant reciprocal callosal connections (Cusick and Lund, 1981; Miller and Vogt, 1984; Olavarria and Montero, 1984). The labeled cells in Area 29 of cingulate cortex also are located in regions with reciprocal callosal connections (Cusick and Lund, 1981; Miller and Vogt, 1984). Thus, the results of the present study suggest that in all regions giving rise to callosal cells, some of these cells use aspartate/glutamate as a neurotransmitter. This parallels other reports of glutamatergic or aspartatergic callosal pathways. Supported by Grant NS20597 awarded to A.J.E.

194.4 RESPONSE VARIABILITY OF NEURONS RECORDED FROM THE VISUAL CORTEX OF MONKEY AND CAT. D.B. Hamilton,* E.T. Vu* and D.G. Albrecht. Department of Psychology, University of Texas, Austin, Texas 78712.

Any systematic interpretation of the signaling properties of visual cortical neurons must take into account the variability associated with responses; such variation clearly sets the limits of reliable information transmission. To quantitatively assess the response variability of neurons recorded from the cat and monkey striate cortex, we examined the relationship between the standard deviation and the amplitude of the response for 617 neurons as function of spatial contrast, spatial frequency and temporal frequency.

We found that when the standard deviation is plotted as a function of response on double logarithmic axes, giving a response-standard deviation (R-SD) function, the data points were best fitted by a straight line (i.e. a power function) with a slope of 0.67 (s.e. 0.01) and an intercept of 2.19 (s.e. 1.02). The R-SD function for simple cells was significantly different from that of complex cells, with the former showing less variability than the latter. Further, a multiple regression analysis showed that response variability was not actually determined by the contrast level per se, but rather the amplitude of the response. Finally, an analysis of the R-SD function measured at optimal vs nonoptimal spatial frequencies revealed no significant differences for the simple cell group, but a very interesting difference for the complex cell group. Specifically, for complex cells, as the spatial frequency is shifted away from the optimal value, the slope of the R-SD function increases monotonically.

194.5 RESPONSES OF SIMPLE AND COMPLEX CELLS IN THE CAT VISUAL CORTEX TO VISUAL DOT STIMULI. Bernt C. Skottun*, David Grosof* and Russell L. De Valois* (SPON: Theodore E. Cohn). Department of Psychology, University of California, Berkeley, CA 94720.

It has previously been claimed that random dots are potent stimuli for complex cells but fail to activate simple cells. This would imply, among other things, that simple cells cannot provide input to complex cells as was originally proposed by Hubel and Wiesel. We have quantitatively compared the responses of simple and complex cells to drifting dot patterns.

Extra-cellular recordings were made from neurons in Area 17 and in the 17/18 border region in anaesthetized and paralysed adult cats. Stimuli were presented on a high resolution video monitor and consisted of either drifting sinusoidal luminance gratings or drifting patterns of random, bright dots (9 min diam) on a dark background. Responses to both sine gratings and dot patterns were determined for drift directions at 15 deg intervals around the clock. Units that responded to gratings with a modulated discharge were classified as simple cells and those that responded with a uniformly elevated firing were classified as complex cells.

Some simple as well as some complex cells were found to respond to random dot patterns; others from each class did not. Typically, those simple and complex cells that showed directional selectivity to sine gratings also showed directional selectivity to dot patterns. In order to make sure that a response was not due just to some local feature in a particular dot pattern, we frequently repeated the experiment using different patterns with identical statistics. Responses from both simple and complex cells were fairly reproducible and have been examined over a wide range of dot densities and drift velocities. To patterns of dots covering 0.5 % of the screen and drifting at 3 deg/sec, complex cells responded on average with a 3-4 times higher firing rate than simple cells. However, complex cells also fire more to conventional stimuli. In our sample, sine gratings of optimal orientation and spatial frequency were found to elicit firing rates from complex cells that are on average more than double those of simple cells. We calculated the relative response to dots vs. gratings for each cell: (response to dots)/(response to gratings). We find that simple cells have relative dot responses that averages 2/3 of those of complex cells. Therefore, one may attribute much, but not all of the complex vs. simple cell differences in dot response to differences in general responsiveness. The finding that many simple cells respond well to dot stimuli contrasts with previous claims that all simple cells are unresponsive to such stimuli. We are currently investigating possible sources for this discrepancy. Supported by NSF grant BNS 78061 & NIH grant EY 00014.

194.6 SEPARABILITY ASSUMPTIONS IN SIMPLE RECEPTIVE FIELDS R. Szulborski*, R. Stepnoski*, J. Jones* and L. Palmer. Dept. of Anatomy, Univ. of Penn. Sch. of Med., Phila., Pa. 19104

Conventional experimental methods, such as generation of length and width tuning curves or orientation (OR) and spatial frequency (SF) tuning curves, implicitly assume that the receptive fields (RFs) of simple cells are Cartesian separable in the two dimensional (2D) space domain and polar separable in the 2D SF domain. For Cartesian separablilty, the response function is given by: $r(x,y) = l(x)w(y)$, where l and w are independent 1D length and width response functions, respectively. Similarly, for polar separability, the response is given by: $R'(OR,SF) = G(OR)H(SF)$, where G and H are independent 1D OR and SF response functions, respectively. If simple cells sum spatially distributed inputs linearly, a well supported notion, these assumptions are mutually inconsistent since the Fourier transform of a Cartesian separable function is Cartesian separable but not polar separable.

In an attempt to resolve this inconsistency, we examined simple RFs using methods which make no assumptions about separability. In the space domain, the responsive region was enclosed by a 16x16 grid which defined 256 unique stimulus locations. In the spatial frequency domain, a 16x16 grid defined 256 unique SF/OR pairs, each pair determining the parameters of a drifting sinosoidal grating. These stimuli were randomly presented, the response amplitudes plotted as surfaces, and the surfaces analyzed for separability. Cartesian separability in the space domain was demonstrated when sections through the surface parallel to the width (length) axis differed only by scale factors. Analogously, polar separability in the SF domain was established when iso-OR (iso-SF) sections differed only by scaling.

We found that more than half of the RFs studied were Cartesian separable in the 2D space domain. As expected, their RFs were also Cartesian separable in the 2D SF domain. Since they are not polar separable, they are poorly characterized by single SF/OR tuning curves. The remaining RFs were not Cartesian separable due to oblique staggering of individual subregions in space (ARVO Abs. 26:265). In the SF domain, the RFs were neither Cartesian nor polar separable and thus are inadequately characterized by length/width or SF/OR tuning curves.

These results are consistent with our recent demonstration that simple cells are well described by Gabor functions (Neurosci. Abs. 11:800). These functions can be, but are not required to be, Cartesian separable in the space domain. However, they can never be polar separable in the SF domain. Clearly, determination of separate tuning curves for length and width in the space domain and SF and OR in the SF domain constitute an incomplete description of simple cell behavior. Methods making no assumptions about separability better characterize simple RFs.

194.7 A GENERAL METHOD FOR MODELING RECEPTIVE FIELDS COMPOSED OF GAUSSIAN SUBUNITS, AND ITS APPLICATION TO ORIENTATION TUNING IN LGN AND CORTICAL NEURONS. R. E. Soodak* and R. M. Shapley* (SPON: J. Gordon). The Rockefeller University, New York, NY 10021.

When modeling receptive fields in the visual system, it is natural to assume that at any given level of integration, the receptive fields are composed of subunits from previous levels. Since the introduction by Rodieck of the difference of gaussians model for retinal ganglion cell receptive fields, it has become standard practice to explain the response properties of LGN and cortical neurons in terms of convergence of multiple gaussian inputs. Such models have proven extremely useful in explaining major qualitative aspects of neuronal responses, such as spatial filtering properties and the existence of orientation and directional tuning.

We will present a method for quantitative prediction of the behavior of model neurons made up of any arbitrary number of linearly summing gaussian subunits. These subunits can assume any position in the X,Y plane with individually specified amplitudes and widths. In addition, the temporal phase of the response of each subunit can have any value between 0 and 360 deg., allowing the construction of receptive fields which are not spatio-temporally separable. With the parameters thus specified, the model will predict the response to drifting gratings at any spatial frequency and at any orientation. Both response amplitude and response phase are given.

In brief, the method is based on the fact that the response amplitude of an individual subunit depends on its height and width, and the spatial frequency of the grating, but is independent of its position and the grating orientation. The response phase of a single subunit, on the other hand, depends on its position, and both the spatial frequency and orientation of the grating, but does not depend on its height or width. After calculation of the individual amplitudes and phases, the subunit responses are summed vectorially.

With this approach we have successfully modeled the unusual, "four-leaf clover" orientation tuning curves seen in the cat LGN by Soodak, Shapley and Kaplan (Invest Ophthalmol Vis Sci 26(suppl):264, 1985). We will also compare and contrast the predictions of various models of simple cortical cell orientation tuning. Copies of a PASCAL source will be made available.

194.8 VELOCITY-TUNING MECHANISMS OF DIRECTION-SELECTIVE NEURONS IN STRIATE CORTEX OF THE CAT. Curtis L. Baker, Jr., Department of Psychology, Dalhousie University, Halifax, Nova Scotia B3H 4J1, Canada.

Flashed and continuously moving bar-shaped stimuli were used to study direction-selective neurons in striate cortex of the N_2O/barbituate-anaesthetized cat. Velocity-tuning was measured with stimuli moving continuously through the receptive field at velocities ranging from 1 to 200 deg/sec, both in preferred and null directions. The difference in peak spike frequency for preferred vs null directions always showed a characteristic optimal velocity, V_{opt}. Measured values of V_{opt} ranged from 2 to 150 deg/sec.

Stimuli flashed sequentially at two adjacent points in the receptive field produced direction-selective behaviour comparable to that observed with continuously moving stimuli. Independent variation of the positions of the 2 flashes allowed determination of the optimal displacement, D_{opt}, to produce direction-selectivity. Measured values of D_{opt} ranged from .2 to 2.0 deg for receptive field sizes of .5 to 10 deg.

The optimal velocity, V_{opt}, for a given neuron was systematically related to the optimal displacement, D_{opt}, for 2-flash motion: $V_{opt} = D_{opt}/T_c$. The temporal proportionality coefficient, T_c, represents the time lag for a stimulus moving at a velocity, V_{opt}, to move a distance, D_{opt}. Consequently, T_c can be interpreted as the time delay in a Reichardt-type correlation model of motion detection, for detectors spaced at a distance of D_{opt}.

The histogram of T_c values measured on all sampled neurons showed a peak at 40-80 msec, comparing well with previous estimates of optimal temporal delay for human motion perception.

This temporal delay, T_c, was found to vary inversely with D_{opt}, typically over a range of 20-160 msec. This co-variation of temporal and spatial factors allows a 2-3 octave range of variation of spatial properties (i.e., D_{opt}) to provide a 6-7 octave range of optimal velocities. Thus, striate visual cortex neurons achieve higher values of optimal velocity by making correlations over larger spatial distances as well as over smaller time lags.

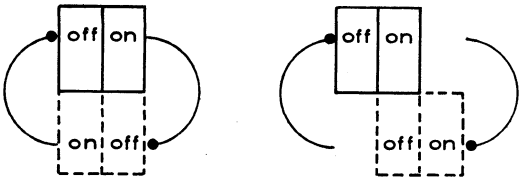
Also, since previous findings imply that D_{opt} is inversely proportional to the optimal spatial frequency for a given neuron, these results suggest a direct relationship between velocity-tuning and spatial frequency-tuning.

(Supported by MRC Centennial Fellowship).

194.9 DIRECTION SELECTIVITY OF VISUAL CORTICAL NEURONS EXAMINED WITH A STROBOSCOPICALLY ILLUMINATED LIGHT BAR. J. Duysens, G.A. Orban and H. Maes*. Laboratorium voor Neuro- en Psychofysiologie, K.U.L., Campus Gasthuisberg, B-3000 Leuven (Belgium).

Despite numerous studies it is still unclear whether the interactions underlying direction selectivity of S cells occur within subregions (e.g. in-field inhibition) or between subregions (i.e. facilitation through superposition in the preferred direction; lateral inhibition in the non-preferred direction). To distinguish between these alternatives one needs to know the spatial and temporal spread of the direction selective mechanisms. We investigated direction selective S (or A) cells, having receptive fields with a wide range of eccentricities, in areas 17 and 18 of anesthetized and paralyzed cats, using a light bar which was moved at speeds between 0.5 and 900°/sec and illuminated stroboscopically (90 μsec) at frequencies between 2 and 50 Hz.

At 2 Hz the responses were never direction selective and thus could be used as a reference to evaluate suppression or facilitation of responses obtained at higher flash frequencies. The maximum interflash distance over which direction selective responses were obtained equalled on average the subregion width and varied little with interflash time interval. The largest effective distances were encountered in cells which were more direction selective at high speeds than at low speeds. The increase in direction selectivity at high speeds in the latter cells was due to an increase both in facilitation in the preferred direction and in suppression in the null direction. Most commonly these cells lost their direction selectivity at interflash intervals of more than 65 msec. In contrast, cells with strong direction selectivity at low but not at high speeds, often tolerated interflash intervals as large as 250 msec. It is concluded that facilitatory and inhibitory interactions between subregions underly direction selectivity in S cells. A model is proposed in which direction selectivity depends on the mutual inhibition of pairs of S cells with receptive fields which are either partly or completely overlapping with subregions of opposite polarity.



194.10 INFLUENCE OF A MOVING NOISE BACKGROUND ON THE AREA 17 CELL RESPONSES TO A MOVING LIGHT BAR. G.A. Orban, B. Gulyás* and J. Duysens. Laboratorium voor Neuro- en Psychofysiologie, K.U.L., Campus Gasthuisberg, B-3000 Leuven (Belgium).

Modulation of responses to a narrow (0.3°) moving light bar by motion of a random noise background (grain size 0.04°; mean luminance 2.75 or 0.35 cd/m^2) was investigated in area 17 cells recorded in paralyzed and anesthetized cats.Preliminary to the testing of the interactions, the optimal velocity for slit motion was determined with a velocity-response curve (Orban et al., J. Neurophysiol., 45:1043, 1981). Also the slit contrast producing 50% of the maximum response when the slit moved over the background held stationary was determined. The interaction series was run with a fixed slit velocity (usually the optimal one) and 7 background motion conditions : in- and antiphase motions at 3 speeds (same speed as slit, 2 octaves slower and 2 octaves faster) and no motion. Fifty-one cells were successfully tested : 95% of them had receptive fields within 10° from the fixation point. Four patterns of direction selectivity were observed under relative motion conditions : (1) cells were direction selective for all background motion conditions (n=7); (2) cells preferred a fixed slit direction, but direction selectivity was clearcut only for antiphase background motion (n=9); (3) cells were direction selective only for 2 or 3 background velocities close to zero (n=16) and (4) cells preferred the direction of slit motion opposite to background motion (n=4) The latter cells which exhibited a relative direction selectivity, switched their preferred velocity when the direction of background motion was reversed. They were all 4 endstopped layer VI cells and were not direction selective when tested with a slit alone. With respect to the influence of background velocity on the slit response, many cells (n=14) were inhibited for background motion faster than 1 or 2°/sec, resulting in a narrow tuning for near zero background velocities, 7 cells were tuned to zero background velocity, 4 cells to a low inphase background velocity and 3 cells to a low antiphase background velocity. These tunings were not invariant with slit velocity showing that these were tunings for background velocity as such and not for the relative velocity between slit and background. These tunings indicate that these cells will be inhibited by any background movement above 1 or 2°/sec and thus will operate only during fixation. The sharpness of the tuning suggests that these cells may encode depth relationships specified by the optical flow. These cells would not directly encode the distance between the slit and the background surface, but rather specify the position of the background surface with respect to the plane of slit motion and the fixation plane (the cells cannot distinguish whether the slit moves behind or in front of the background). Depending on the value of the background velocity yielding optimal slit response, the cell signals that the background is located at the fixation point (when zero background velocity is optimal), between the slit and the fixation point (when a low inphase background velocity is optimal), or just at the other side of the fixation plane (when a low antiphase background velocity is optimal).

194.11 CAT CORTICOTECTAL CELLS: STANDARD COMPLEX AND SPECIAL COMPLEX CELLS HAVE ORTHOGONAL ORIENTATION ANISOTROPIES. T.G. Weyand, J.G. Malpeli and C. Lee. Dept. Psychology, University of Illinois, Champaign, IL 61820.

We have determined the optimal stimulus orientation and length response characteristics of 68 antidromically identified corticotectal (CT) cells in area 17 of the cat. Following Gilbert (J. Physiol., 268: 391-421), those cells whose response increased with increased stimulus length were classified as standard complex (n=41), while those that responded best to short stimuli were classified as special complex (n=27). Virtually all of our sample is from cells whose receptive field centers were within 6 degrees of the horizontal meridian, and the distributions of receptive field positions for both standard and special complex cells are similar. The distribution of orientation preferences for the special complex cells is skewed toward horizontal and vertical orientations, whereas standard complex cells have a strong preference for stimuli with oblique orientations. Vertical orientation preferences are particularly uncommon among standard complex cells. For the oblique 45 degree sectors the ratio of standard to special complex cells is 2.9, while for the horizontal and vertical sectors this ratio is 0.8.

We conclude that in layer 5 of area 17, the orientation hypercolumn is internally heterogeneous. The relative contributions of standard complex and special complex CT cells vary cyclically and orthogonally within the hypercolumn. We have previously shown that standard complex CT cells are dependent upon layer A of the lateral geniculate nucleus, whereas special complex CT cells do not depend upon any single geniculate subdivision (Weyand et al., Neurosci. Absts., 10: 727, 1984). Thus, within an orientation hypercolumn, those orientation columns tuned to vertical and horizontal edges differ from those tuned to oblique orientations both in receptive field properties and in controlling thalamic inputs. Since the receptive field locations of our sample were predominately from the horizontal meridian, we cannot as of yet determine if the orientation anisotropies are actually related to absolute orientation or to orientation relative to polar angle of receptive field position. (This research was supported by NIH grants RO1 EY32114, T32 EY07005, K04 EY00229, and grants from the University of Illinois Research Board).

194.12 A NEW STEREO ILLUSION INDUCED BY BINOCULARLY PRESENTED GRATINGS: EFFECTS OF DISTANCE, AND FIELD SIZE. J.V. Odom and G.M. Chao*. Department of Ophthalmology, West Virginia University, Morgantown, WV 26506.

We have previously reported the parameters under which a new stereo illusion may be observed. If a single grating is viewed with both eyes, the grating appears to have several levels of depth. The sensation of several levels of depth disappeared if one 1) viewed the patterns monocularly, 2) oriented the pattern horizontally, or 3) changed the spatial frequency from an optimum of 3-4 cpd. The effects of distance and field size on the number of levels of depth seen were determined in two experiments with the authors as subjects. Photographic prints of vertical square wave gratings were viewed binocularly. The prints had a mean luminance of 150 cd/m^2 and a contrast of 75%. The subjects task was to state the number of levels of depth seen. The percept was classified as a single level even if the surface was wavy, had individual bars which tilted, or was visible through an indistinct layer without a clear boundary separating levels. To be classified as having two or more levels, a percept of several levels had to be simultaneously visible and have clear, distinct boundaries between the levels. In experiment 1 the effects of field size were studied. At a standard distance of 35 cm field size varied from 5° to 40° for spatial frequencies of 1.5-5.7 cpd. The stereo illusion was not present if field size was 10° or less. As field size increased more levels of depth were seen. In experiment 2 distance was varied from 20 to 140 cm as three levels of spatial frequency (3.2-5.7 cpd) and three field sizes (14°-26°) were held constant. As the viewing distance increased the number of levels decreased. The distance at which only one level was seen increased as field size increased and spatial frequency decreased. Although the illusion is observed when a single grating is viewed binocularly, we believe that it can be accounted for, in part, by the same mechanisms which cause stereo illusions when two gratings of differing spatial frequencies are presented dichoptically (e.g., Blakemore, Vis. Res., 10, 1181-1199). A discussion on these mechanisms and a demonstration of the illusion will be prsented. (Supported by NIH Grant EY 04806 and an unrestricted departmental grant from Research to Prevent Blindness).

194.13 BINOCULAR SPATIO-TEMPORAL INTERACTIONS IN CAT VISUAL CORTEX: A NEUROPHYSIOLOGICAL CORRELATE OF THE PULFRICH EFFECT. T.Carney*, M.A.Paradiso and R.D.Freeman. Neurobiology group, Minor Hall, University of California, Berkeley, CA 94720.

A pendulum moving in the frontoparallel plane of an observer is perceived to follow an elliptical path in depth when a light attenuating filter is placed in front of one eye. In 1922, Pulfrich described the effect and suggested that the filter delays neural processing such that the signal from the filtered eye refers to an earlier moment in time than the signal of the other eye. For objects in motion, this temporal delay is equivalent to adding an interocular spatial disparity to the object's retinal images, hence the perceived shift in depth. In fact, when moving stimuli are presented dichoptically, the shift in depth can be canceled by introducing an appropriate spatial shift to the stimulus being presented to the filtered eye.

It is often assumed that stereopsis involves binocular neurons, of the type observed in the cat visual cortex, which are selective for interocular spatial disparity. We examined the effect monocular light attenuation has on the disparity sensitivity of cat striate cortex neurons. The responses of single units were recorded during dichoptic presentation of drifting sinusoidal luminance gratings at various interocular spatial phases, with and without filters in front of one eye. As previously reported, most cells were selective for interocular spatial phase. When we introduced the filters however, the optimal phase (disparity) shifted. The magnitude of this phase shift was correlated with the degree of filter - induced light attenuation.

The response of disparity selective simple cells has been modeled as a simple linear summation of the temporally varying signals from the two eyes. At some particular spatial disparity (depth) the temporal signals from the two eyes will be in phase and maximally excite the cell. If the filter introduces a delay in one signal the response after binocular summation should decrease. To again elicit a maximal response one must compensate for the spatial shift that the temporal delay mimics by making the stimulus enter the neuron's receptive field in the filtered eye earlier. We accomplished this by changing the spatial disparity (phase) of the stimulus in the two eyes. Therefore, the optimal interocular spatial disparity changed as a function of the temporal delay introduced by the neutral density filter and the velocity of the stimulus.

Although we don't actually know if cats can perceive the Pulfrich Effect, it is a reasonable supposition if the observed change in optimal spatial disparity with filter density is essentially the physiological substrate for this perceptual illusion in man. (EY01175 & EY05636)

CHARACTERIZATION OF CHOLINERGIC RECEPTORS IV

195.1 MOLECULAR STRUCTURE OF THE GLYCINE RECEPTOR Heinrich Betz, Bertram Schmitt*, P. Knauss*, and K. Beyreuther* (SPON: ENA). Institute for Neurobiology, ZMBH, University of Heidelberg, D-6900 Heidelberg, FRG, and Institute for Genetics, University of Cologne, 5000 Köln 41, FRG

The glycine receptor of mammalian spinal cord is an oligomeric membrane glycoprotein which, after affinity purification, contains three polypeptides of 48K, 58K, and 93K. The strychnine binding site of the glycine receptor is located on the 48K subunit and partially overlaps to the 58K polypeptide. The function of the 93K polypeptide is unknown; immunological and peptide mapping experiments have provided evidence of homologies between all three glycine receptor polypeptides.

Two conditions were found which separate the 93K polypeptide from the two smaller glycine receptor subunits: i) purification of cholate-solubilized receptor in the absence of the putative protease inhibiting agent, iodoacetamide, gave receptor preparations containing only the 48K and 58K polypeptides; ii) upon prolonged centrifugation in sucrose gradients, the 93K polypeptide migrated more rapidly than the other glycine receptor subunits. Also, the biochemical properties of the 93K polypeptide differ from those of the smaller ones (concanavalin A binding, microheterogeneity etc.). Immunocytochemistry indicates that all three receptor polypeptides are co-located at spinal cord synapses, the main immunogenic region of the 93K polypeptide being exposed at the cytoplasmic face of the membrane (Triller et al., submitted). These data assign a special role to the 93K polypeptide; it may serve in the ionophore function or postsynaptic anchoring of the glycine receptor.

In order to obtain primary structural information, the N-terminal region and a V8 protease-derived peptide of the 48K-polypeptide were subjected to gas phase microsequencing. The N-terminal information was used for the synthesis of a decapeptide which then served for the production of antibodies. The resulting antiserum bound exclusively to the 48K polypeptide in immunoblots of purified rat glycine receptor. Also, it precipitated [^{3}H]-strychnine binding sites from detergent extracts of rat spinal cord membranes. The N-terminal portion of the 48K polypeptide thus is accessible to antibody binding in the receptor's native conformation.

195.2 LOW AFFINITY ACETYLCHOLINE BINDING TO TORPEDO POST-SYNAPTIC MEMBRANES? Nina P. Strnad & Jonathan B. Cohen. Dept. of Anatomy & Neurobiology, Washington Univ. Med. Sch., St. Louis, MO 63110.

Interactions of acetylcholine (AcCh) with the membrane-bound AcCh receptor from Torpedo electric tissue have previously been characterized in terms of ligand binding parameters and the AcCh-induced permeability response. [3H]-AcCh binds at equilibrium with high affinity (Keq=10nM) to a binding site associated with the α-subunit of the receptor, and there are two such sites per receptor monomer. Two observations raise the possibility that additional low affinity binding sites might exist that have not been detected by radioligand binding assays. First, the AcCh concentration producing half-maximal permeability response (Kap~70μM) is considerably higher than the transient low affinity binding (K~1μM) observed in studies of [3H]-AcCh binding kinetics. Second, extensive sequence homologies exist between each of the four distinct receptor subunits. An equilibrium binding assay has been developed to evaluate whether additional low affinity sites for [3H]-AcCh exist in Torpedo membranes.

Equilibrium binding of [3H]-AcCh at concentrations up to 300μM was examined at 23°C by ultracentrifugation of receptor-enriched membranes in physiological saline. The binding of [3H]-AcCh was determined from [3H]-AcCh retained in the pellet, and the water content in each pellet was determined by a dual label procedure. Apparent non-specific binding of [3H]-AcCh was accounted for by the pellet aqueous volume. For membranes from T. californica and T. nobiliana, all of the observed specific binding was of high affinity, characterized by a Keq=10nM.

To ascertain the limits of the assay, various sulfhydryl reduction and alkylation conditions were used to modify the equilibrium binding properties of the high affinity sites. For example, reduction by 1mM DTT followed by alkylation with 10mM [14C]-iodoacetamide (IAA) at pH 8 results in alkylation of 80 to 100% of the α-subunit cysteine residues. Following such alkylation by IAA, [3H]-AcCh equilibrium binding was characterized by Keq=15μM and a Hill coefficient of 1. Alkylation of reduced receptors by 5mM N-ethylmaleimide produces similar results.

With the sensitivity of this assay it is possible to conclude that any additional low affinity sites present at the same concentration as the observed high affinity sites must be characterized by Keq > 1mM. This establishes that the AcCh receptor does not contain sites binding AcCh at equilibrium with an affinity similar to the Kap for channel activation and that any additional sites on other subunits must bind AcCh 10^5 -fold more weakly than sites on the α-subunit.

195.3 PURIFICATION AND GENERATION OF MONOCLONAL ANTIBODIES AGAINST THE NEMATODE LEVAMISOLE RECEPTOR. J.A. Lewis, S. McLafferty*, J. Skimming*, J. Prenger*, and T. Hodgkiss. Dept. of Biological Sciences, Univ. of Missouri, Columbia, MO 65211.

Mutants of an apparent juvenile acetylcholine receptor in the nematode Caenorhabditis elegans can be isolated by selection for resistance to the nicotine-like compound levamisole. We have previously shown that mutants of 7 genes associated with extreme resistance to levamisole all have abnormal receptor activity as defined by (^{3}H)meta-aminolevamisole binding and thereby define a set of genes needed for the proper expression of the nematode receptor. To better define the role of these genes in receptor expression than possible by binding assay alone, we have devised a method of highly purifying the receptor to generate monoclonal antibodies as specific probes of receptor structure. A several fold receptor-enriched starting material was obtained by using dauer larvae of the receptor mutant lev-1(x61). Receptor was purified by extraction into 1% Triton X-100 solution, by chromatography on an affinity column derivatized with trimethyl-aminocaprylic acid (a choline analog) attached to a long spacer arm, and finally by chromatography on Concanavalin A-agarose. The final preparation was purified to a specific activity 30,000 to 60,000 times that of receptor found in crude extracts of wild type worms but the material was still estimated to be less than 10% pure. Triton X-100 was removed with Amberlite XAD-4. Monoclonal screening was done by first adsorbing any monoclonal to goat anti-mouse IgG-derivatized Sepharose beads and then assaying the ability of the monoclonal-coated beads to remove detergent-solubilized receptor from solution. Three anti-native receptor monoclonals were found from 392 hybridoma wells screened. One monoclonal identifies a receptor peptide of 43,000 daltons M.W. on Western blots. A second monoclonal antibody when coated on beads removes both the 43,000 dalton peptide and additionally another peptide of 38,000 daltons M.W. from highly purified receptor preparations, implicating both peptides as receptor peptides. Our purification method may provide a generally useful paradigm for the purification of cholinergic binding proteins.

195.4 THE EFFECTS OF INTRACELLULARLY INJECTED ACETYLCHOLINE ON CULTURED MESENCEPHALIC NEURONS. K.L. Futamachi* and J.H. Peacock (SPON: C. Wakefield). Division of Neurology, University of Nevada School of Medicine, Reno, NV 89557.

In view of recent findings that acetylcholine (ACh) exists in the cytoplasm as well as in the vesicles of presynaptic terminals of the Torpedo, we decided to investigate the consequences of ACh in the cytoplasm of cultured mesencephalic neurons.

ACh was injected intracellularly into presumed substantia nigra (SN) cells obtained from Swiss Webster mouse fetuses of 18-19 days gestational age and cultured for 24-70 days. Recordings were obtained in Dulbecco's Modified Growth Medium containing 5% fetal bovine serum, 5% horse serum and 6.8mM $CaCl_2$ at 37°C and pH 7.2-7.6. The 300MOhm ACh filled electrodes, with which the intracellular recordings were obtained, contained 2M ACh and were pretested on myotube cultures to determine the negative holding current levels which prevented ACh leakage. After a stable intracellular recording was obtained, the holding current was turned off and the ACh was either pulsed or allowed to diffuse into the cells.

The time required for ACh to diffuse into a cell varied from 10 minutes to over 3 hrs. However, in each case EPSP amplitudes were enhanced from 5 to 10mV to values up to 50mV, often leading to increased action potential frequencies. Action potential durations increased from a normal 1-2 msec to 20-30 msec and developed waveforms similar to those of Ca^{++} spikes. Cobalt blocked both the EPSP and the broad spike activity. Preliminary results suggest that the agonist carbamyl choline chloride also has similar effects when injected into these cells.

These results are consistent with the notion that potassium conductance, gK, is decreased by ACh. Present experiments are designed to elucidate whether this K-current is muscarinic (I_M), delayed rectifier (I_K), Ca^{++} activated (I_C) or transient outward (I_A).

Supported by Medical Research Service, Veterans Administration and the Robert Z. Hawkins Foundation.

195.5 ACETYLCHOLINE RESPONSES IN SYNAPTICALLY ACTIVE NEURONS IN MOUSE SUBSTANTIA NIGRA CULTURES. J.H. Peacock and K.J. Futamachi*. Division of Neurology, University of Nevada School of Medicine, Reno, NV 89557.

A definitive cholinergic function for substantia nigra (SN) has not been established, despite intense staining of SN neurons for acetylcholinesterase, because of low levels of choline acetyltransferase in SN and lack of an identified, cholinergic, afferent pathway. We have addressed the issue of putative cholinergic function using electrophysiologic techniques in dissociated cell cultures from ventral mesencephalon; many neurons in these cultures have dopamine histofluorescence and are probably from SN.

Acetylcholine (ACh) was applied iontophoretically to neurons in 24-50 day old cultures prepared from Swiss Webster mouse fetuses of 18-19 days gestational age. Cells were studied in Dulbecco's Modified Growth Medium containing 5% fetal calf serum, 5% horse serum, 6.8mM $CaCl_2$ at 37.5°C and pH 7.2-7.6. ACh micropipettes containing 1-2M ACh were each pretested on myotube cultures to determine negative holding current levels which prevented ACh leakage. Responses were recorded from intracellular micropipettes containing KCl (3M) or KOAc (4M, pH 7.0).

Data are reported here for 60 neurons of which 29 had intracellular recordings and the other 31 were synaptically coupled to them. ACh caused either a slow depolarization which returned slowly to baseline after ACh application (9/29) or altered the synaptic input to the recorded neuron (20/29). Some neurons (19/29) demonstrated both response types. Membrane conductance increased little if any during the slow depolarization. Synaptic alteration included activation of postsynaptic potentials (PSPs) either excitatory (30/60), inhibitory (10/60), or both (2/60), as well as inhibition of spontaneously occurring excitatory PSPs (4/60) and inhibitory PSPs (5/60). Responses were predominantly muscarinic and blocked by atropine (1-2 μM), although a nicotinic action has not been entirely excluded.

Our findings are consistent with separate pre- and postsynaptic effects of ACh. Experiments are in progress to determine the mechanism of each.

Supported by Medical Research Service, Veterans Administration and the Robert Z. Hawkins Foundation.

195.6 DISTRIBUTION OF CEREBRAL METABOLIC EFFECTS OF NICOTINE IN THE RAT. E.D. London, R.J. Connolly*, M. Szikszay*, J.K. Wamsley and M. Dam*. Neuropharmacology Lab., NIDA Addiction Res. Ctr., Baltimore, MD 21224, Dept. of Psychiatry, Univ. of Utah Med. Ctr., Salt Lake City, UT 84132.

Autoradiographic studies have demonstrated specific D,L-[^{3}H]nicotine binding sites in the rat brain (Clarke, P.B.S. et al., Brain Res., 323:390, 1984; London, E.D. et al., Neurosci. Lett., 53:179, 1985). To test the functionality of these sites, we used the 2-deoxy-D[1-^{14}C]glucose ([^{14}C]DG) method to measure the in vivo effects of nicotine on local cerebral glucose utilization (LCGU), an index of cerebral functional activity (Sokoloff, L. et al., J. Neurochem., 28: 897, 1977).

Male Fischer-344 rats were prepared with indwelling femoral arterial and venous catheters. After recovery from halothane anesthesia and at various times (2-60 min) before the injection of [^{14}C]DG (125 μCi/kg, intravenously), they were injected (1 ml/kg, subcutaneously) with 0.9% NaCl or an equal volume of D,L-nicotine bitartrate (0.05-1.75 mg/kg free base) in 0.9% NaCl. In some rats, mecamylamine HCl (2.5 mg/kg free base) was injected subcutaneously 10 or 20 min before nicotine.

Nicotine produced time- and dose-dependent, heterogeneous increases in LCGU, reflecting varied sensitivities to nicotine among different functional systems. Marked increases were noted in the medial habenula, anteroventral thalamic nucleus, interpeduncular nucleus and superior colliculus. Moderate increases were seen in the retrosplenial cortex (layer I, but not deeper layers), caudate-putamen, interanteromedial thalamic nucleus, and lateral geniculate body. No significant effects were observed in the frontoparietal cortex, lateral habenula or central grey matter. LCGU responses were antagonized by mecamylamine, indicating the specificity of nicotine's effects.

These LCGU findings correlate well with the reported distributions of [^{3}H]nicotine binding sites. In general, those areas which showed dense labelling with [^{3}H]nicotine (i.e. thalamic nuclei, interpeduncular nucleus, medial habenula, superior colliculus) also manifested moderate to marked LCGU increases which persisted for up to 2 hr. Areas with less binding (i.e. lateral geniculate body, caudate-putamen) showed lesser LCGU responses to nicotine. The central grey matter, which lacked specific [^{3}H]nicotine binding, demonstrated no LCGU response.

These results indicate that the [^{3}H]nicotine binding sites visualized autoradiographically are functional nicotine receptors, and may direct further anatomical investigations to elucidate the behavioral and physiological effects of nicotine.

195.7 Mr 72,000 AND Mr 86,000 FORMS OF MUSCARINIC ACh RECEPTORS IN AVIAN CNS: SHIFT IN PREDOMINANT FORM DURING DEVELOPMENT. T.H. Large, J.J. Rauh, N.J. Cho‡ A.F. Skorupa‡ and W.L. Klein. Department of Neurobiology and Physiology, Northwestern University, Evanston, Illinois 60201.

Two forms of muscarinic acetylcholine receptors from the avian central nervous system have recently been reported (Large, et al., Proc. Natl. Acad. Sci. in press). Receptors from embryonic chick retina, cerebrum, optic tectum and cerebellum, covalently labeled with (3H)PrBCM and subject to SDS/urea/PAGE, showed two electrophoretic forms with apparent molecular weights of 86,200 ± 400 and 72,200 ± 300. Each form was present, although decreased in mass by 6,000 daltons, after treatment with deglycosylating enzymes, consistent with molecular differences occurring in the protein portions, rather than carbohydrate portions, of the molecules. Pulse-chase labeling of receptors on cultured retina cells demonstrated that both forms were present on the cell surface; the labeled Mr 86,000 population had a half-life of 5 hours while the Mr 72,000 population had a half-life of 19 hours. Incubation of retina membranes with proteolytic enzymes indicated that Mr 72,000 receptors were more resistant to degradation than Mr 86,000 receptors. The two molecular weight forms appear to be unrelated to M1 and M2 pirenzepine subtypes since pirenzepine binding in the retina is exclusively low affinity (M2)(Large, et al. J. Biol. Chems. in press).

The relative proportions of the Mr 86,000 and Mr 72,000 receptors in retina showed a striking inversion during development. Before synaptogenesis, receptors were mainly of Mr 86,000, while after synaptogenesis receptors were mainly of Mr 72,000. The increase in Mr 86,000 receptors was not due simply to elevated proteolytic activity. The apparent molecular weight and relative proportion of receptor forms from embryonic membranes were unchanged by incubation with crude homogenate from hatched chick retina. Development of a predominantly low molecular weight receptor population also occurred in aggregate, but not monolayer, retina cell culture suggesting a possible role for cell-cell interactions in triggering the change. Two molecular weight forms of muscarinic receptors may represent products of differentially-regulated gene transcription, products of a single RNA transcript subject to differential processing, or post-translational conversion of the Mr 86,000 form to the Mr 72,000 form. The novel change in size of muscarinic acetylcholine receptors supports the hypothesis that molecular modification of neurotransmitter receptors plays a role in the development and regulation of synapses. (This work was supported in part by NIH grants NS18490 and DA02950 to WLK, NIMH post-doctoral grant MH08904 to JJR and NIMH pre-doctoral grant MH09228 to THL)

195.8 HYDROXYEICOSATETRAENOIC ACIDS (HETES): BLOCKADE OF MUSCARINIC RECEPTOR-MEDIATED CYCLIC GMP FORMATION AND ESTERIFICATION INTO PHOSPHOLIPIDS IN MURINE NEUROBLASTOMA CELLS (CLONE N1E-115). Michael McKinney. Dept. Pharmacology, Mayo Foundation, Rochester, MN 55905.

Muscarinic receptors in N1E-115 cells mediate increased cGMP formation and decreased hormone-induced cAMP formation. A biochemical and pharmacologic study of the relationship between arachidonate metabolism and muscarinic responses in N1E-115 cells was initiated. The cGMP response, but not the cAMP response, was blocked by lipoxygenase but not cycloxygenase inhibitors. Certain perturbants of the cellular oxidation state (e.g., methylene blue) also inhibited the cGMP response. The cyclic GMP response was blocked by arachidonate itself (IC_{50}=45 μM), while agents like stearate and lysophosphatidylinositol did not inhibit this response at concentrations up to 100 μM. The potency of arachidonate was increased 10-fold by the air-oxidation of the fatty acid. These findings are consistent with the idea that the oxidative metabolism of arachidonate is involved in the cyclic GMP response. In support of this, enzymatically-synthesized 15-HETE and 12-HETE were found to block the cyclic GMP response (IC_{50}'s 8 μM and 18 μM, respectively). [^{3}H]Arachidonate was metabolized by N1E-115 cells, primarily by rapid esterification into phospholipids and neutral lipids, but small amounts of prostaglandins and other unidentified products were also formed. ETYA and 15-HETE elevated free arachidonate levels in N1E-115 cells, consistent with the blockade of metabolic routes for the fatty acid. ETYA and 15-HETE both reduced the labeling of phospholipids by [^{3}H]arachidonate. However, 15-HETE was more selective than ETYA in decreasing the label in phosphatidylinositol (PI), suggesting the 15-HETE was an inhibitor of the acyl CoA-PI transferase or was a substrate for this enzyme. Further, [^{3}H]15-HETE itself was shown to be esterified into N1E-115 phospholipids; 65% of the esterification was into PI and 24% into the neutral lipids, with much lower amounts appearing in other lipids. [^{3}H]15-HETE also labeled the polyphosphatidylinositides. [^{3}H]5-HETE and [^{3}H]12-HETE were also esterified into N1E-115 lipids, but with profiles different from that of [^{3}H]15-HETE or [^{3}H]arachidonate. 15-HETE was shown to decrease the esterification of [^{3}H]arachidonate into PI with an IC_{50} of 7 μM, a value similar to the IC_{50} of 15-HETE for blockade of cyclic GMP formation. Thus the possibility exists that 15-HETE and other lipoxygenase inhibitors could block the muscarinic receptor-mediated cyclic GMP response by a mechanism involving the redistribution of arachidonate or the substitution of the inhibitor for the fatty acid in the cellular phospholipids. This may occur in addition to or exclusive of the inhibition of a putative lipoxygenase. (Supported by NIH grant NS21319 and the Mayo Foundation)

195.9 PURIFICATION OF MUSCARINIC RECEPTORS FROM RAT BRAIN. J. Baumgold. Clinical Neurogenetics Branch, DIRP, NIMH, Bethesda, Md. 20205

Since muscarinic receptors represent less than 0.01% of rat brain membrane protein, the purification of this and other receptor proteins from brain is impractical using conventional biochemical techniques. Successful purifications of this magnitude require use of specific affinity chromatography steps. I have taken advantage of a specific affinity chromatography gel first developed by Haga and Haga (J. Biol. Chem. 258 13575, 1983) which, when used in conjuction with conventional purification steps, was able to purify the muscarinic receptor to near homogeneity in substantial yield. This approach is similar to that recently taken by Peterson et al (PNAS 81 4993 1984) for purification of atrial muscarinic receptors.

Muscarinic receptors were solubilized at a 25-35% yield using the detergent digitonin. The solubilized receptor was first purified 4-6 fold by ion-exchange chromatography on DEAE-TRISACRYL gel. A further 4-6 fold purification was obtained on a hydroxylapetite column. The final 300-500 fold purification was obtained using the following affinity chromatography steps: 1) the receptor protein bound specifically to an aminobenzhydrol tropine (ABT) sepharose affinity gel and could be specifically eluted with either carbachol or scopolamine; 2) a wheat germ agglutinin sepharose affinity gel was used to concentrate the receptor and separate it from the cholinergic ligands used to elute it from the ABT affinity gel. This entire procedure resulted in the purification of a 75,000 dalton protein which bound 3H-QNB and could be affinity labeled with 3H-propylylbenzyl choline mustard. This protein was purified 5000-10,000 fold at an overall yield of 10-20% with respect to solubilized material. Work is currently underway in our laboratory to characterize the purified receptor.

195.10 CHOLINERGIC REM SLEEP INDUCTION: EFFECTS OF ARECOLINE IN MAN AND IN RAT BRAIN. J.I. Nurnberger, Jr., W.H. Berrettini*, W. Mendelson*, T.I. Soncrant*, D. Sack* and E.S. Gershon*. Clinical Neurogenetics Branch and Clinical Psychobiology Branch, DIRP, NIMH and Laboratory of Neuroscience, NIA, Bethesda, MD 20205

Various brainstem areas may be involved in the generation of REM (rapid eye movement) sleep, including the dorsal and lateral pontine tegmentum, the pontine and midbrain reticular formation, the locus coeruleus and the parabrachial area. Neurochemical control is also complex, probably involving NE, 5-HT, and Ach at various sites.

Pharmacologic manipulation of muscarinic receptors has been reported to affect the timing of REM sleep in animals and man. We have confirmed this in 22 persons given an injection of 0.5 mg intravenous arecoline (after peripheral blockade with 0.15 mg glycopyrrolate) timed to end at 25 minutes after the end of the first REM period. Arecoline was followed by wakening or the onset of the second REM period within 20 minutes in 9/22 subjects as compared with 1/14 subjects given no infusion or placebo ($p < 0.03$ by Fisher's exact test). At present 6/10 euthymic drug-free bipolar subjects demonstrate awakening or REM induction within 20 minutes, as opposed to 3/12 controls; increased sensitivity to cholinergic REM induction in bipolar subjects has been previously reported[1].

Arecoline effects in rat brain have been examined using the quantitative (^{14}C) 2-deoxy-D glucose method 3 minutes after intraperitoneal administration of 0.05 to 50 mg/kg arecoline. Rats were pretreated with methylatropine 4 mg/kg subcutaneously. Nine areas thought to be involved in REM generation were examined. After 0.05 mg/kg of arecoline, increases ($p < 0.05$) in cerebral glucose utilization were seen in the dorsal and median raphe nuclei and in the pons. After 0.5 mg/kg, increases were also seen in the mesencephalic and anterior pontine reticular formation and in the dorsal tegmental nucleus. Only after higher doses were significant effects seen in the locus coeruleus, the posterior pontine reticular formation and the lateral pontine tegmentum. Doses of 5 mg/kg and above cause an activation in most brainstem regions[2].

Cholinergic REM induction may be an effective tool for examining muscarinic receptor sensitivity in experimental animals and clinical studies. In another experimental paradigm, a correlation between the concentration of muscarinic receptors in the striatum of rats and their sensitivity to behavioral effects of arecoline has been demonstrated[3]

196.1 EFFECT OF EXTRACELLULAR IONIZED CALCIUM ON THE BIPHASIC GROWTH HORMONE RESPONSE TO RAT GROWTH HORMONE-RELEASING FACTOR. G.A. Ortolano and L.C. Terry. (SPON: K.L. Casey) Depts. of Neurol. & Physiol., Univ. of Michigan Med. School and Veterans Admin. Med. Center, Ann Arbor, MI 48105.

Thyrotropin-releasing hormone-induced growth hormone secretion by GH_4C_1 cells is biphasic (Aizawa, T. and Hinkle, P.M.: Endocrinol., 116:73,1985), as is glucose-induced insulin secretion (Curry, D.L. and Bennett, L.L.: Proc. Nat'l. Acad. Sci. 73:248,1976); however, similar effects in normal rat pituitary cells in response to rat growth hormone-releasing factor (rGRF) have not been reported. It is well established that Ca is required for the secretion of GH, but the sensitivity of pituicytes to small changes in extracellular ionized Ca, viewed as the physiologically important form of Ca, has not been determined. Using pituitary cell culture techniques (Brazeau, P. et al.,: Proc. Nat'l. Acad. Sci. 79:7909,1982) and a NOVA 2 Ionized Calcium Analyzer (Courtesy of NOVA Biomedical, Newton, MA), the GH secretory response to rGRF (100 pM) was shown to be temporally biphasic in the presence of 1.1 mM ionized Ca. The first phase reached a plateau within 1 hour and the second was evident at 3 hrs. Because most studies using Ca or Ca channel blockers utilized prolonged (> 2 hrs) incubation times, the 60 min incubation period was selected to study Ca-dependence associated with the first phase of the observed secretory response. A rGRF dose-response design was employed at 3 levels of ionized Ca (0.8, 1.1 and 1.4 mM). The EC(50) for rGRF (approx 4 pM) remained unchanged at all concentrations of extracellular ionized Ca, whereas, the maximal secretory responses were significantly different and positively correlated with ionized calcium (7, 8.5 and 12.5 ugm GH/0.5 X 10^6 cells for 0.8, 1.1 and 1.4 mM ionized Ca, respectively). Using a similar experimental design, a verapamil dose-response experiment was conducted in the presence of varying concentrations of extracellular ionized calcium and a fixed concentration of rGRF (100 pM). Increasing ionized calcium caused a shift to the right in the dose-response curve, and 100 uM verapamil inhibited only 60% of the GH secretory response to rGRF. From these data it is concluded that (a) temporally biphasic GH secretion from normal pituicytes occurs in response to rGRF at physiologic levels of extracellular ionized Ca, and (b) the GH secretory response to rGRF is only partially dependent upon extracellular ionized Ca because the maximal secretory response to rGRF increased with increasing Ca while verapamil was unable to totally inhibit the secretory response. One or both phases may be partially dependent upon extracellular ionized Ca.

196.2 SUBPOPULATIONS OF SOMATOTROPES REVEALED BY REVERSE HEMOLYTIC PLAQUE ASSAY ARE DIFFERENTIALLY INHIBITED BY SOMATOSTATIN. GY Nagy* and JD Neill* (Spon: J. Brown). Department of Physiology and Biophysics, University of Alabama at Birmingham, Birmingham, Alabama 35294

Two functionally distinct sub-populations of somatotropes are reported to exist in the rat pituitary gland. Using a reverse hemolytic plaque assay for measurement of GH release from individual cells, Frawley and Neill (Neuroendocrinology 39:484, 1984) obtained evidence for sub-populations of somatotropes, one of which is preferentially responsive to GHRH. The aim of this study was to determine the effect of somatostatin on the responses of sub-populations of GHRH treated somatotropes. Pituitary cells from proestrus rats were dispersed with trypsin and cultured for 24 h before the plaque assay for GH secretion was performed. Pituitary cells (plated at 6.5 x 10^4 cells/ml) were incubated for 2 h in the presence of anti-growth hormone antiserum (1:100) and guinea pig complement (1:50). We constructed dose response curves using GHRH or somatostatin at concentrations of 10^{-8} M- 10^{-11}M. We then used the dose of GHRH (10^{-8}M) which resulted in maximal plaque size (maximum GH secreted), for use in combination with different doses of somatostatin (from 10^{-8} to 10^{-11}M). All of the doses of somatostatin decreased the mean plaque size (mean amount of GH secreted per cell) but only the highest doses (10^{-8}M, 10^{-9}M) decreased the fraction of plaque forming cells (% secretory somatotropes). Frequency distributions of GH plaque areas in normal and somatostatin treated pituitary cells were unimmodal. A bimodal frequency distribution of plaque areas was observed when GHRH was applied. One mode of plaque areas was equal to the control group and a second larger mode appeared. The size of this mode was dose related. 10^{-8}M and 10^{-9}M GHRH increased both the mean plaque size and the % of plaque forming cells. When pituitary cells were treated with a combination of GHRH and different doses of somatostatin, the fraction of somatotropes forming large plaques after GHRH treatment was reduced in a dose dependent fashion with a corresponding increase in the number of smaller plaques; however the proportion of plaque forming cells did not decrease. These results confirm the previous findings that GHRH produces a bimodal frequency distribution suggestive of a preferentially responsive population of somatotropes. Furthermore, they suggest that somatostatin preferentially inhibits the population of cells forming large plaques which are preferentially stimulated by GHRH. (Supported by NIH Grant # HD18130 to J.D. Neill).

196.3 SOMATOTROPE AND LACTOTROPE RESPONSES TO cAMP: POPULATION ANALYSIS BY REVERSE HEMOLYTIC PLAQUE ASSAY. J.J. Mulchahey*, G. Nagy*, E. Luque* and J.D. Neill* (Spon: M. Friedlander). Dept. of Physiology and Biophysics, University of Alabama at Birmingham, Birmingham, AL 35294.

The demonstration of heterogeneous responses of somatotropes to growth hormone releasing hormone (GHRH) and lactotropes to thyrotropin releasing hormone (TRH) suggests that the variability in cell response to these secretagogues may lie in differentially responsive subpopulations of cell types. We have applied the reverse hemolytic plaque assay to detect growth hormone (GH) and prolactin (PRL) secretion from individual somatotropes and lactotropes, respectively, to determine whether these secretagogue-responsive subpopulations remain during 8Br-cAMP stimulated hormone secretion. Monodispersed anterior pituitary cells were obtained by tryptic dispersion of anterior pitutiary tissue from estrus rats. Recently dispersed pituitary cells were incubated with Protein A-coated oRBC and anti-growth hormone antiserum (1:100) with medium, GHRH or 8Br-cAMP or anti-prolactin antiserum (1:40) with medium, TRH or 8Br-cAMP for 2h after which guinea pig complement (1:50 and 1:100, respectively) was added for 30min. Pituitary cells secreting hormone are visible in zones of hemolysis (plaques) proportional in size to the amount of hormone secreted. TRH consistently increased PRL secretion to 156±8.0 percent of control (mean±SEM; n=4) with a maximally effective dose of 10^{-7}M in this assay system. Frequency distribution analyses of plaque areas revealed unimodal, log-normal distributions in controls which were uniformly increased by TRH. 8Br-cAMP increased PRL secretion to 223±21 percent of control with a maximally effective dose of 10^{-3}M and slightly augmented frequency distributions as compared to TRH. GHRH increased GH secretion 18.6±5.0-fold compared to control (mean±SEM; n=5) with a maximally effective dose of 10^{-7}M Frequency distributions were unimodal, log-normal in control cells but bimodal in GHRH-treated cells. 8Br-cAMP increased GH secretion 11.9±3.4-fold compared to control with a maximally effective dose of $5x10^{-2}$M while the frequency distributions were similar to the GHRH treatment. Both GH increases were greater than those reported previously for cultured cells. Because the heterogeneity of cellular response to secretagogue persists when somatotropes or lactotropes are stimulated with 8Br-cAMP, an agent mimicking the intracellular messenger cAMP these data suggest that this heterogeneity in hormone secretion exists as an intrinsic, post-receptor occupancy, post-adenylate cyclase heterogeneity in cellular metabolism. (Supported by NIH grant HD-19314 to JDN).

196.4 EFFECT OF IN VIVO PRETREATMENT WITH ESTROGEN ON GROWTH-HORMONE AND PROLACTIN SECRETION IN A SUPERFUSED RAT PITUITARY CELL SYSTEM. J.Horvath*, M.Mason-Garcia*, E.Winsor*, L.Debeljuk* and A.V.Schally* (SPON:W.Macklin), Tulane Univ. Sch.of Med. and VA Med.Ctr., New Orleans, LA 70146.

Prolactin and growth-hormone (GH) secretion was investigated in a superfused rat pituitary cell system. The pituitaries were obtained from rats pretreated with estradiol (Progynon, 500 µg/kg, twice a week for three weeks prior to the experiment) and from rats in estrus. The basal prolactin secretion from pituitary cells of estrogen treated rats could be inhibited with infusion of somatostatin. Different concentrations of somatostatin ($2.5x10^{-9}$M - 10^{-7}M, for 15 min) produced the same inhibition during the infusion; however, larger doses resulted in a more prolonged inhibition. Pituitary cells of rats in estrus showed no response to somatostatin. Elevation of prolactin secretion above the baseline during 3 or 15 minute superfusion with TRH ($2.5 x 10^{-8}$M) was greater in estradiol pretreated cells. When the same concentration of TRH was infused together with somatostatin (10^{-9}M- $2.5x10^{-8}$M) prolactin secretion was more markedly inhibited in the pituitary cells from rats pretreated with estrogen, due to their increased sensitivity to somatostatin. Dopamine inhibited the TRH-induced prolactin secretion equally in both systems; however, on a molar basis somatostatin appeared to be a more potent inhibitor of TRH-induced prolactin secretion than dopamine. Estrogen pretreatment reduced $hpGH\text{-}RH_{44}$ (10^{-9}M, 3 or 15 min pulses) stimulated GH-release. When somatostatin (10^{-9}M- $2.5x10^{-8}$M) and $hpGH\text{-}RH_{44}$ (10^{-9}M) were infused simultaneously for 15 min, somatostatin completely prevented the release of GH during the infusion. However, after the infusion was ended, a marked release of GH could be observed which was much larger than the rebound in GH which occurs after the superfusion of pituitary cells with the same doses of somatostatin. TRH consistently induced some stimulation of GH-release in both cell types, but this release was much smaller than that observed with $hpGH\text{-}RH_{44}$. In conclusion, in vivo pretreatment with estradiol increases the sensitivity of lactotroph cells to somatostatin and TRH in a superfused pituitary cell system. The sensitivity of somatotroph cells from estradiol pretreated rats to $hpGH\text{-}RH_{44}$ is reduced. In the doses used in this study, somatostatin delays the effect of $hpGH\text{-}RH_{44}$ but does not prevent it.

196.5 RAPID DESENSITIZATION TO THE ACUTE STIMULATORY EFFECTS OF NICOTINE ON RAT PLASMA ADRENOCORTICOTROPIN AND PROLACTIN. B. Sharp* and S. Beyer* (SPON:S. Nicol). Dept. of Medicine, Hennepin Cty. Med. Ctr. and Univ. of Minnesota, Mpls., MN 55415.

Nicotine rapidly elevates plasma adrenocorticotropin (ACTH) and prolactin (Prl). Since tolerance to some of the acute depressant effects of nicotine has been shown after both acute and chronic dosing, we tested for acute desensitization to its stimulatory effects on ACTH and Prl.In each experiment, 200 g male Holtzmann rats received 2 ip injections (I) containing nicotine (N in mg free base/kg BW) and/or saline (S); decapitation was 7.5 min after the second I. Values for plasma Prl and ACTH measured by radioimmunoassay are mean ± SE. The interval (min) separating the 2 I is shown.

I_1	Min	I_2	ACTH(pg/ml)	Prl(ng/ml)
S	+60	S	54.6±7.4	3.2±0.9
S	+60	$N_{0.1}$	181.8±52.6	2.6±0.5
S	+60	$N_{0.25}$	807.2±86.5**	30.4±3.4*
S	+60	$N_{0.5}$	960.9±136.9**	21.4±4.6*
S	+60	$N_{1.0}$	1180.9±167.9**	31.8±3.3*
S	+60	$N_{2.0}$	953.5±66.0**	24.0±4.5*
$N_{0.5}$	+60	S	71.4±8.6	1.9±0.4
$N_{0.5}$	+60	$N_{0.25}$	146.8±32.7	1.8±0.4
$N_{0.5}$	+60	$N_{0.5}$	286.1±133.0	1.9±0.4
$N_{0.5}$	+60	$N_{1.0}$	526.3±113.8*	12.2±3.6

Comparisons by ANOVA are between S/S vs S/N or N/S vs N/N. *p<.025; **p<.01; ***p<.001. Since this experiment demonstrated significant desensitization following a single dose of $N_{0.5}$, a time course with increasing intervals between the 2 injections was done.

S	+60	$N_{0.25}$	538.6±70.0	29.7±3.3
$N_{0.5}$	+60	$N_{0.25}$	72.4±20.2***	5.9±1.2***
S	+120	$N_{0.25}$	588.9±23.0	23.2±3.9
$N_{0.5}$	+120	$N_{0.25}$	61.9±11.5***	3.9±0.7**
S	+240	$N_{0.25}$	858.8±111.0	21.8±3.7
$N_{0.5}$	+240	$N_{0.25}$	173.0±39.3***	6.1±0.5**
S	+360	$N_{0.25}$	842.0±121.7	22.5±5.0
$N_{0.5}$	+360	$N_{0.25}$	287.3±105.0**	10.5±2.9*

Asterisks are for unpaired t-tests between groups at the same time interval. ANOVA failed to show a significant difference in ACTH and Prl values between any of the groups that received the initial dose of $N_{0.5}$. The role of negative feedback by corticosterone in this desensitization was evaluated. All rats were bilaterally adrenalectomized 24H prior to receiving 2 injections separated by 2H. A partial ACTH response to the second N dosing was observed (S/S:284.5±31.9; $S/N_{0.25}$: 923.6±107.9; $N_{0.5}/N_{0.25}$:458.7±26.6; ANOVA showed S/S<N/N<S/N p<.01). Desensitization of the Prl response was unaffected.

In nicotine naive rats, a single dose of N elevated ACTH and Prl levels within 7.5 min. These responses desensitized to a second dose for at least 6H. Adrenalectomy did not affect the Prl desensitization; it minimally affected ACTH. (Supported by DA03977)

196.6 LITHIUM STIMULATES ADRENOCORTICOTROPIN (ACTH) RELEASE FROM CULTURED ANTERIOR PITUITARY CELLS. M. Zatz and T. Reisine. Lab. of Cell Biology, National Institute of Mental Health, Bethesda, MD 20205

Lithium (Li) is useful for investigating the role of phosphatidylinositol (PI) turnover in signal transduction because it inhibits the phosphatase that catalyzes the conversion of inositol phosphates (IPs) to inositol. In the presence of Li, the products of inositol lipid breakdown are not reutilized and hormones that increase PI turnover elevate the levels of IPs. To determine the role of PI turnover in the secretion of ACTH, Li was applied to a tumor cell line (AtT-20/D16-16) derived from mouse anterior pituitary, that consists of a homogenous population of corticotrophs. Cells were pretreated for 24 hours with ^{3}H-inositol and the effects of a number of agents on inositide metabolism and ACTH release were examined. Most ACTH secretagogues (CRF, isoproterenol, VIP, forskolin, 8-bromo-cAMP, K^+ and phorbol ester) did not change IPs levels either in the presence or absence of Li. Lithium itself did increase the levels of ^{3}H-inositol monophosphate (IP_1). Furthermore, Li itself stimulated ACTH release in a time and concentration dependent manner, which correlated with its effects on IP_1 levels. This effect was not unique to the tumor cell line; primary cultures of rat anterior pituitary cells also released ACTH in response to lithium. Pretreatment of AtT-20 cells with Li reduced the subsequent response to Li. Such pretreatment did not affect the response to CRF, isoproterenol, forskolin or K^+. Another class of drugs which stimulates ACTH release from these cells are the phorbol esters (PE). Active PE are thought to specifically stimulate protein kinase C. Pretreatment with Li did reduce ACTH release in response to subsequent treatment with PE, suggesting a link between lithium's effects and protein kinase C. Diacyl glycerol (DAG), another product of PI breakdown, is the putative intracellular regulator of protein kinase C. DAG itself did not stimulate ACTH release. However, pretreatment with DAG reduced lithium's effects on ACTH release and ^{3}H-IP_1 levels. DAG and IPs are formed from PI through the actions of phospholipase C. An activator of phospholipase C is calcium. Elevated extracellular calcium levels stimulated ACTH release and, in the presence of Li, markedly raise IP_1 levels. Pretreatment of AtT-20 cells with DAG also attenuates the cells' response to high extracellular calcium; both ACTH release and the increase in ^{3}H-IP_1 are blocked. The data suggests that Li and calcium stimulate ACTH release through mechanisms distinct from the other known ACTH secretagogues. These mechanisms may involve stimulation of phospholipases, PI turnover, and protein kinase C.

196.7 EFFECT OF AGENTS WHICH ALTER INTRACELLULAR SODIUM AND CALCIUM ON LUTEINIZING HORMONE RELEASE FROM CALF PITUICYTES. J.P. Kile, S. McConnell* and M.S. Amoss, Jr. Dept. Veterinary Physiology, Texas A&M University, College Station, TX 77843-4466.

While it is known that calcium (Ca^{++}) is required for release of hormones from both rat and bovine pituitary cells, little work has been done to study the role of calcium flux or intracellular mobilization in the release of luteinizing hormone (LH) from bovine gonadotrophs. Therefore, a study was done to compare the effects of agents which alter sodium (Na^+) and Ca^{++} entry into cells on LH release from calf pituicytes.

Calf pituitary cells from calves 4-10 months of age were dispersed using 0.2% collagenase for 1 hr; then plated at 3 x 10^5 cells/multiwell well for 5 days. On day 5, cells were washed and treated with 10 µl of ion agent alone or 10 µl ion agents plus 10 µl gonadotropin releasing hormone (GnRH, 10 µg/ml) in 1 ml of Hank's Balanced Salt Solution (HBSS). Cells were then incubated 6 hr at 37°C, the medium removed and stored at -20°C prior to LH determination by radioimmunoassay. Each treatment was repeated 2-3 times, n=3 or n=6 depending on the trial.

In cells pre-treated with the Ca^{++} channel blockers nifedipine or verapamil at concentrations ranging from 10^{-8} to 10^{-5} M, only nifedipine between 10^{-7} and 10^{-5} M produced a significant inhibition ($p<0.05$) of GnRH stimulated LH release with LH values falling from 7.6 ± 0.9 ng/ml to 4.6 ± 0.4 ng/ml respectively. These values compare to 5.6 ± 1.0 ng/ml for HBSS control and 28.1 ± 5.5 ng/ml for GnRH 100 ng/ml. In contrast, only verapamil reduced baseline LH values from 30-60% ($p<0.01$) at the concentrations tested. Mg^{++} (2-10 mM) produced no significant effects on either basal or stimulated LH release. The Ca^{++} ionophore A23187 over the range of 1-10 µM induced a linear increase in LH secretion, with significant release at 2.5 µM (23.2 ± 5.3 ng/ml) through 10 µM (79.7 ± 2.5 ng/ml). In comparison, the Na^+-K^+ ATPase inactivator, ouabain, at 10^{-5}-10^{-3} M also produced increases in basal LH ranging from 2.5 fold ($p<0.05$) up to 12 fold ($p<0.01$) respectively. Further challenge by GnRH produced no additional LH release over that by A23187 or ouabain alone. Finally, the Na^+ channel blocker tetrodotoxin (TTX) produced a dose-dependent, significant decrease in GnRH-induced LH release at concentrations between 10^{-9} and 10^{-7} M, while basal release was unaffected (9.4 ± 1.4 ng/ml at 10^{-9} M compared to GnRH (18.1 ± 2.7) and HBSS (9.2 ± 1.3 ng/ml) controls). The results of this study suggest that calcium influx and mobilization (whether or not subsequent to Na^+ fluxes) may play an important role in basal and GnRH-stimulated LH release from calf gonadotrophs. The findings are also consistent with the belief that nifedipine and verapamil have different sites of action.

196.8 1,2-DIDECANOLYGLYCEROL AND PHORBOL 12,13-DIBUTYRATE ENHANCE ANTERIOR PITUITARY HORMONE SECRETION IN VITRO. A. Negro-Vilar and E. G. Lapetina (SPON: P. Cuatrecasas). Reprod. Neuroendocrinology Sec., Lab. Reprod. Dev. Tox., NIEHS, NIH, Res. Tri. Pk., NC 27709, and Department of Molecular Biology, The Wellcome Research Labs.

Experiments were designed to evaluate the role of well-known activators of protein kinase C, such as 1,2-diacylglycerol and phorbol esters, on the release of all the anterior pituitary hormones in vitro. Dispersed rat anterior pituitary cells were incubated in the presence of 1,2-didecanoylglycerol (DiC_{10}), a synthetic diacylglycerol, or phorbol 12,13-dibutyrate (PDBu), a tumor-promoting phorbol ester, at different concentrations and for varying periods of time.

ACTH and β-endorphin (β-END) secretion were enhanced by DiC_{10} in a concentration-dependent manner, with a minimal effective concentration of 5 µM. PDBu at 5 nM produced a significant release of both ACTH and β-END. The effect of DiC_{10} and PDBu was time dependent, with maximal responses occurring at 15-30 min for DiC_{10} and 30-60 min for PDBu. Release of growth hormone (GH) was also enhanced significantly by DiC_{10} and PDBu, with minimal effective concentrations of 1 µM and 1 nM, respectively. Maximal release of GH was already attained within 15 min with DiC_{10} or 60 min with PDBu. In additional experiments, the effects of DiC_{10} and PDBu on secretion of LH, FSH, PRL and TSH were evaluated. The results indicate that 5-25 µM DiC_{10} produced a concentration-dependent release of each of those hormones, and that 5 µM was the minimal effective concentration in every case. Nearly maximal stimulation was achieved within 15 min for each hormone. PDBu (50 nM) significantly enhanced LH, FSH, PRL and TSH release within 30 min. Although qualitatively all hormones were similarly stimulated, both with respect to time and concentration, some quantitative differences were observed. ACTH and β-END release were enhanced 100% by DiC_{10} and 300% by PDBu, while the increase in other hormones was of a lesser magnitude.

The present study indicates that two specific stimulators of protein kinase C, diacylglycerol and phorbol ester, can enhance secretion of all anterior pituitary hormones in a concentration- and time-dependent manner. This suggests that formation of endogenous 1,2-diacylglycerol may represent a physiological intracellular messenger in the events leading to anterior pituitary peptide hormone release.

196.9 DEMONSTRATION OF DOPAMINERGIC BINDING SITES IN THE ANTERIOR PITUITARY OF THE MALE SYRIAN HAMSTER. D.M. Burns*, C.A. Leadem* and B. Benson (SPON:D.E. Blask). Dept. of Anatomy, Univ. of Arizona, Arizona Health Sciences Center, Tucson, AZ 85724.

The characterization of dopaminergic binding in the anterior pituitary has implications in the study of neuroendocrine regulatory mechanisms, particularly with regard to prolactin (PRL) secretion. Changes in the responsiveness of PRL cells to the inhibitory action of dopamine may play an important role in PRL physiology. Specific dopaminergic binding sites have been previously described in anterior pituitaries of several mammalian species. However, it has recently been reported (Steger et al., Biol. Reprod. 29:872) that dopamine is ineffective in inhibiting PRL secretion in long photoperiod exposed male hamsters. We therefore wished to investigate whether there are specific dopamine binding sites in the hamster anterior pituitary. We utilized the dopamine antagonist ^{3}H-spiroperidol to label binding sites in membrane preparations of adult male hamster (14:10 light:dark cycle) anterior pituitaries. Non-specific binding was determined in the presence of 10 µM (+)-butaclamol. The specific interaction of ^{3}H-spiroperidol with these membranes reached a steady-state level within 10 minutes at 37° C, and specific binding was directly proportional to the membrane concentration between 0.07 and 0.3 mg protein. Saturation curves were analyzed by an iterative least-squares nonlinear regression method (LIGAND). F-test comparison of goodness-of-fit shows that these curves fit a two-site model significantly better than a one-site model ($p<.001$). Dissociation constant (Kd) and total binding site concentration (Bmax) for the high affinity site were estimated to be 60 pM and 49 fmol/mg protein, respectively. Corresponding estimates for an apparent low affinity binding site were 6.6 nM and 105 fmol/mg protein. Additional investigations are currently under way to further define this low affinity binding. These data suggest that there are specific binding sites for dopamine in the anterior pituitary of the male hamster with physical parameters (Kd and Bmax) similar to those reported for other mammals. Therefore, the reported lack of effect of dopamine on PRL secretion in these animals is not due to an absence of specific dopaminergic binding sites.

196.10 LITHIUM TREATMENT ENHANCES THE ACTIVITY OF TUBEROINFUNDIBULAR AND TUBEROHYPOPHYSEAL DOPAMINERGIC NEURONS. T. Koyama,* J.I. Koenig, H.Y. Meltzer and G.A. Gudelsky. Dept. of Psychiatry, Hokkaido Univ., Sapporo, Japan, Dept. of Psychiatry, Univ. of Chicago and Ill. State Psychiatric Institute, Chicago, IL.

Lithium has been shown to alter the dynamics of catecholaminergic and serotonergic neurotransmission within the CNS. Lithium also has been shown to alter the plasma concentrations of several hormones (e.g., PRL, corticosterone and beta-endorphin), as well as the serotonergic control of the secretion of these hormones. In the present study we have investigated the influence of chronic treatment of rats with lithium on the dopaminergic control of PRL secretion. The synthesis rates of dopamine within the terminal regions of tuberoinfundibular and tuberohypophyseal neurons (i.e., median eminence (ME) and neurointermediate lobe (NIL), respectively) were estimated from the in vivo accumulation of dihydroxyphenylalanine (DOPA) after the inhibition of the activity of amino acid decarboxylase with m-hydroxybenzylhydrazine (NSD 1015, 100 mg/kg). The accumulation of 5-hydroxytryptophan (5-HTP) also was measured as an index of 5-HT synthesis. Rats were killed 30 min after the administration of NSD 1015. DOPA was measured in acidic extracts of ME and NIL by HPLC with electrochemical detection. Dopamine concentrations also were measured in anterior pituitary gland tissue of rats not given NSD 1015. Maintenance of rats on a diet containing lithium carbonate (0.23%) for 3 or 21 days resulted in a 60-70% reduction of plasma PRL concentrations. There also was a significant increase in the accumulation of DOPA in the ME and NIL of animals given lithium for 3, 7 or 21 days when compared to control animals. The accumulation of 5-HTP in the ME and NIL was unaltered by lithium treatment. Dopamine concentrations in anterior pituitary glands of lithium-treated animals were more than twice those in tissues from control rats. The inclusion of lithium in the diet for 7 or 21 days also altered the secretion of PRL from anterior pituitary tissue in vitro and the effect of dopamine to inhibit PRL secretion. The secretion of PRL in 1 hr from pituitary tissue of control animals was 55 ± 9 ng/mg tissue, whereas that from tissue of rats treated with lithium for 21 days was only 22 ± 2 ng/mg tissue. Moreover, dopamine (10^{-6}M) effected a 70% inhibition of the release of PRL from pituitary tissue of control animals, whereas only a 45% dopamine-induced inhibition of PRL secretion was observed in tissue from lithium-treated rats. These results are suggestive that lithium treatment enhances the activity of tuberoinfundibular and tuberohypophyseal dopamine neurons. An increased secretion of dopamine from these hypothalamic neurons may account for the lithium-induced reduction of plasma PRL concentrations and the suppressed secretion of PRL in vitro from anterior lobe tissue.

196.11 THE EFFECT OF NEONATAL PROLACTIN DEFICIENCY ON ADULT TUBEROINFUNDIBULAR AND TUBEROHYPOPHYSIAL DOPAMINERGIC NEURONAL ACTIVITY. S.W. Shyr*, W.R. Crowley, and C.E. Grosvenor. Dept. of Physiol. & Biophys., Univ. Tenn. Ctr. Hlth. Sci., Memphis, TN 38163.

In the adult, non-lactating rat, prolactin (PRL) regulates its own activity via stimulation of tuberoinfundibular dopaminergic neuronal activity (TIDA). We have shown previously that PRL from maternal milk crosses the gut into the circulation of the rat pup (J. Endocrinol. 79:191). In this study we investigated the effect of reducing the amount of PRL available to the pups during days 1-5 of lactation on the turnover of dopamine in median eminence (ME) and neurointermedial lobe (NIL) of the pituitary. Lactating Holtzman rats received daily sc injections of either saline or bromocriptine (0.5 mg/rat) for days 2-5 postpartum. Some rats were anesthetized on postpartum days 2, 3, or 5, at which time milk was collected and analyzed for PRL content by RIA. The remaining rats were kept with their litters until pups were weaned (day 21). The pups thereafter were fed and housed under standard conditions. When 33-35 days of age, the rats were injected sc with either saline or α-methyl-p-tyrosine(250 mg free base /kg); they were decapitated under light ether anesthesia 30 or 60 min later. ME and NIL were rapidly removed and analyzed for dopamine content, using radioenzymatic assay.

	Milk PRL (ng/ml)			Turnover rate of dopamine (pg/µg protein/hr)	
days	2	3	5	TIDA(ME)	THDA†(NIL)
saline	275.5 ±34.9	483.2 ±49.0	442.6 ±29.3	84.9 ±10.6	6.9 ±1.1
CB-154		137.1 ±24.0*	13.7 ±7.5*	29.0 ±6.6*	8.8 ±1.9

*$p < 0.05$ vs. saline control group.
†THDA: tuberohypophysial dopamine

Treatment of mothers with bromocriptine markedly reduced the PRL content of the maternal milk and decreased pup weight gain. However, by day 33-35, the pups' weight gain was comparable to the saline control group. In addition, such treatment resulted in a significantly decreased turnover of dopamine in the median eminence in the 33-35 day old offspring. Dopamine turnover in the NIL was unaffected in these animals. These results indicate that a deficiency in PRL delivered by maternal milk consequently decreased activity in TIDA neurons in the offspring. The data suggest that the normal PRL-TIDA feedback regulation may be impaired by such treatment. (Supported by HD 04358 to CEG and HD13703 and HD 00366 to WRC.)

196.12 QUANTITY OF TYROSINE HYDROXYLASE IN THE MEDIAN EMINENCE: EFFECT OF AGE, SEX, AND REPRODUCTIVE STATUS. John C. Porter. Cecil H. and Ida Green Center for Reproductive Biology Sciences, Departments of Obstetrics and Gynecology and Physiology, Southwestern Medical School, Dallas, TX 75235

In rats, secretion of dopamine from tuberoinfundibular dopaminergic neurons into hypophysial portal blood varies throughout the estrous cycle, is greater in females than in males, and is greater in young animals than in old. Since secretion of dopamine by tuberoinfundibular dopaminergic neurons is dependent on the rate of synthesis of L-dihydroxyphenylalanine from L-tyrosine, we investigated the relationship of these physiological states to the amount of tyrosine hydroxylase (TH) in the median eminence (ME), the site of release of dopamine into portal blood.

The ME (≅40 µg wet wt) was homogenized in Laemli buffer, heated 3 min in a boiling water bath, and subjected to acrylamide gel electrophoresis. Highly purified rat TH was used as the standard. After electrophoresis, protein on the gel was transferred to nitrocellulose paper. The paper was incubated overnight with rabbit antiserum (1:500 dilution) to rat TH, and then immersed in the color development solution. The developed nitrocellulose paper was dried, and the TH-containing band was analyzed by reflectance spectrometry. Between 0 and 100 ng of TH, the area enclosed by the reflectance envelope was a linear function of the quantity of TH.

In cycling female rats (12-16 wks old), the quantity of TH in the ME was as follows: estrus, 42 ± 2.9 ng (mean ± S.E.); diestrus 1, 61 ± 2.8 ng; diestrus 2, 75 ± 4.2 ng; and proestrus, 84 ± 3.3 ng. In ovariectomized rats (15-16 wks old), the ME contained 24 ± 1.6 ng TH. In pre-pubertal rats (5-5.5 wks old), the ME of females contained 25 ± 2.0 ng TH, and that of males 24 ± 2.1 ng. The amount of TH in the ME of mature males (15-16 wks old) was 34 ± 3.3 ng, whereas that of old males (17-20 mos old) was 37 ± 1.6 ng TH. In aged female rats (22-24 mos old), the ME of diestrus animals contained 75 ± 4.2 ng TH, and the ME of estrus animals contained 71 ± 2.8 ng TH.

In summary, TH in the ME (1) increases with sexual maturity, (2) is greater in mature females than in mature males, (3) and is greatest in cycling females when circulating estrogen levels are greatest (Butcher et al. ENDOCRINOLOGY 94:1704, 1974). The amount of TH in the ME of old female rats is much greater than that of old male rats. Prior to puberty, the amounts of TH in the ME of male rats is the same as that in female rats. Castration of mature female rats results in a reduction of TH in the ME to the level seen in pre-pubertal animals. It is suggested that estrogen causes an increase in the amount of TH in the ME. In the ME of aged rats, the existence of TH levels comparable to those in young, mature animals is inconsistent with the reduced secretion of dopamine seen in aged rats.

197.1 NERVE GROWTH FACTOR (NGF) REGULATES THE ACTION POTENTIAL DURATION OF MOUSE DORSAL ROOT GANGLION (DRG) NEURONS DURING MAINTENANCE IN LONG-TERM ORGANOTYPIC CULTURES. S.M.Crain, A.Chalazonitis and E.R.Peterson*. Dept. of Neuroscience, Albert Einstein College of Medicine, Yeshiva University, Bronx, N.Y. 10461.

NGF has been shown to regulate the levels of Substance P and somatostatin in mature mouse DRG neurons long after the developmental period when these cells require NGF for survival (Kessler & Black, PNAS '80,'81; Otten etal, Nature,'80). The present study investigates whether NGF may also regulate some of the bioelectric properties of DRG neurons. Intracellular recordings were made of the somatic action potentials (APs) of DRG neurons in cultures of fetal mouse spinal cord with attached DRGs (Chalazonitis & Crain, Soc. Neurosci.Abstr.'83).

Initial studies were carried out on DRG-cord explants exposed to the antimitotic alkaloid, taxol, for the first few days and then maintained for many weeks in high NGF (3ug/ml) media (see abstract by Peterson & Crain, this volume). Recordings from these DRG neurons (tested in 5mM Ca^{++}/5mM Ba^{++} BSS) revealed APs with Ca^{++} components that were about 3x shorter in duration than those from control cultures where NGF was routinely withdrawn after 1 wk in vitro. Proof that the shorter AP-Ca component was due not to prior taxol exposure, but to prolonged maintenance in NGF, was obtained by tests on drug-free cultures. The duration of the AP-Ca component (in 5mM Ca^{++}) was significantly shorter ($p<0.025$) for DRG neurons grown with NGF for 6 wks: 1.6±0.2 msec (n=31) vs 2.1±0.1 msec (n=52) in controls. This difference was demonstrated more sharply in tests made in Ca^{++}/Ba^{++} BSS: 5.4±0.7msec (n=24) in neurons on NGF for 6 wks vs 14.6±1.3 msec (n=62) in controls ($p<0.001$). Even after only 2 wks of exposure to NGF the AP-Ca component was much shorter than controls: 6.4±0.7 msec (n=17). Furthermore, when DRG-cord explants grown for weeks in high NGF were returned to control media (for 1-4 wks) the AP-Ca components again showed long durations: 12.8±0.7 msec (n=37). Neurons in isolated DRG explants maintained in high NGF for 6-8 wks also showed much shorter AP-Ca components: 6.9±0.8 msec (n=8) vs 18.5±1.5 msec (n=46) in controls, indicating that this NGF effect can occur in the absence of spinal cord tissue.

These data provide the first demonstration that NGF regulates a specific bioelectric property of DRG neurons--the duration of the Ca component of the somatic AP--at stages when the cells no longer require NGF for survival. Furthermore, these alterations in the AP duration occur within 1 wk after introduction or withdrawal of NGF. Further analyses are required to determine if NGF-regulation of the AP duration of DRG neurons is mediated by alterations in Ca^{++} and/or K^{+} channel functions. (Supported by research grants DA-01031 and BNS-821847 to S.M.C.)

197.2 DETECTION OF NERVE GROWTH FACTOR-BINDING PROTEINS SECRETED BY L-929 CELLS. K. Siminoski* and R.A. Murphy. (SPON:T.E. Phillips) Dept. of Anatomy and Cellular Biology, Harvard Medical School, Boston, MA 02115.

L-929 cells secrete a high molecular weight nerve growth factor (NGF) complex that differs from mouse salivary gland 7S NGF. The complex is known to have a molecular weight greater than 7S NGF by gel filtration and although it contains β NGF, it does not contain the α or γ NGF subunits (Biochem. 22:4264; C.R.Acad.Sc. Paris, Series III, 297:523). The other components of the complex have not been identified. In this study, we have detected proteins with NGF-binding activity in L-cell conditioned medium.

^{125}I 2.5S NGF was added to L-cell conditioned medium, the pH was briefly lowered (pH 2-3), then raised to neutrality. On Sephadex G-200, radiolabelled NGF eluted near the void volume, in a position indistinguishable from that of native immunoreactive NGF in L-cell conditioned medium. When the pH shift was carried out in the presence of excess unlabelled NGF, radioactivity near the void volume was diminished by >70%. Without a pH shift, radiolabel eluted with free NGF. Radioactivity also appeared near the void volume when L-cell conditioned medium was dissociated with 8 M urea, 6M guanidine HCl, 40 uM octyl glucoside or 2% SDS.

NGF-containing complexes were also examined by gel electrophoresis. ^{125}I NGF bound to L-cell proteins was cross-linked using dissucinimidyl suberate (50 uM), reduced with 2-mercaptoethanol, and electrophoresed on 7.5% SDS gels. Radioactivity migrated in 2 principle bands (160 KD and 60 KD) and in 7-8 fainter bands, all of which were competed by unlabelled NGF, and were not present in the absence of a pH shift. In unreduced samples labelling diminished in intensity and increased competible activity appeared near the top of the gel.

Efforts are now underway to characterize and isolate these NGF binding proteins.

197.3 LOW- AND HIGH-AFFINITY NGF RECEPTORS POSSESS NGF BINDING MOIETIES IDENTICAL IN MOLECULAR WEIGHT ON SDS-PAGE. S.H. Green and L.A. Greene*. Department of Pharmacology, New York University School of Medicine., 550 First Ave., New York, NY 10016.

We have reported the isolation of four mutant PC12 cell lines which neither respond to nor internalize NGF but are otherwise very similar to PC12 cells (Green et al., 1984, Soc. Neurosci. Abstr. 10, 367). Scatchard-type analysis of ^{125}I-NGF binding to these mutant $PC12^{nnr}$ lines reveals that they have low-, but not high-affinity NGF binding sites as opposed to PC12 cells which possess both forms. We have used EDC, a water-soluble cross-linking reagent, to affinity-label the NGF receptor with ^{125}I-NGF. Proteins were then separated and sized by SDS-PAGE. Crosslinking was done following conditions in which (1) only rapidly-dissociating ^{125}I-NGF should be washed off or (2) neither slowly nor rapidly dissociating ^{125}I-NGF should be washed off. Under the first type of condition, a 100 kD protein was labeled in PC12 cells and binding of ^{125}I-NGF to it was competed with by unlabeled NGF with an ID_{50}~0.2 nM. The labeled protein was not solubilized by 0.1 percent Triton X-100. No labeling under these conditions was seen in $PC12^{nnr5}$ cells. These experiments establish the high-affinity binding moiety as a 100 kD protein (including the covalently attached NGF). Under conditions in which both types of receptors should be labeled, a single 100 kD protein was observed and binding of ^{125}I-NGF to it was competed with by unlabeled NGF over a concentration range of 0.2-6 nM. In $PC12^{nnr5}$ cells, a labeled 100 kD protein was observed under these conditions and binding of ^{125}I-NGF to it was competed with by unlabeled NGF with an ID_{50} of 2-6 nM. Therefore the binding moieties of low- and high-affinity receptors have similar or identical molec. wts. and may be the same molecule. This is consistent with the reported interconvertability of low- and high-affinity forms (Block and Bothwell, J. Neurochem. 210, 1654). We are currently testing this by peptide-mapping. We have observed the 158 kD protein reported by Hosang and Shooter (JBC 260, 655, 1984) only if we use HSAB, a hydrophobic crosslinker, which, unlike EDC, can rapidly enter the cell. Therefore the 158 kD band may result from an association between the NGF binding moiety and a 58 kD protein not exposed on the cell surface. We are investigating the identity of this 58 kD protein and its possible role in regulating NGF receptor affinity or signal transduction. We have found one other difference between PC12 and $PC12^{nnr}$ cells: ^{32}P labeling reveals phosphorylation of 66 kD and 58 kD proteins in all $PC12^{nnr}$ lines, but not in PC12 cells, particularly after dibutyryl cAMP treatment. Possible relationships between these phosphorylation events and the NGF receptor are being investigated. Support was from NIH grant NS16036 to L.A.G. and from ACS Institutional grant IN-14-7 and a grant from Dysautonomia Foundation Inc. to S.H.G.

197.4 CELL FREE DETECTION OF AN NGF-ACTIVATED KINASE ACTIVITY IN PC12 CELLS. E.A.Rowland*,T.H.Müller*, M.Goldstein, L.A. Greene*, Depts. of Pharmacol. and Psychiat., NYU Med. Ctr., New York, NY, 10016.

Exposure of target cells to NGF causes a number of biochemical and morphological changes. Among these changes are differences in the phosphorylation of several proteins (Yu, Tolson and Guroff, J.Biol.Chem., 1980, 225, 10481; Halegoua and Patrick, Cell, 1980, 22, 571). To better understand the role of these phosphorylations in the mechanism of NGF action, we have begun to purify and characterize an NGF-activated protein kinase in PC12 cells. When the latter are exposed to NGF, they take on many of the properties of sympathetic-like neurons (Greene and Tischler, P.N.A.S. USA, 1976, 73, 2424). Tyrosine hydroxylase(TOH) has been shown to increase in phosphorylation and activity when PC12 cells are exposed to NGF. We therefore chose this enzyme as a substrate for measuring NGF-stimulated phosphorylating activity in a cell-free assay. In this assay, exogenous semi-purified TOH is incubated with [32P] ATP, EGTA and an extract of control or NGF-treated PC12 cells. TOH exposed to extracts of NGF-treated cells show a 2-3 fold faster rate of phosphorylation than controls. Characterization of the kinase has shown that: (1) activation does not occur in broken cell extracts, but only in intact cells; (2) maximal activation is at 4nM NGF and half maximal at 0.5 nM NGF; (3) activation occurs after 1-3 minutes of NGF treatment and is maximal by 10 minutes; (4) the kinase is more active in the presence of Mn^{++} than of Mg^{++}, does not require Ca^{++} and is not affected by the presence of cAMP; (5) the activity is found only in the soluble fraction of the cell; (6) material removed from extracts by gel filtration over G-10 Sephadex is not required for the activity; (7) DTT does not reduce the activity. In addition, inhibitors of Ca^{++}/calmodulin-dependant protein kinase, protein kinase C and casein kinase II do not inhibit the NGF-activated kinase. Peptide mapping by HPLC of TOH after phosphorylation by the NGF-activated kinase, shows a greatly enhanced radiolabeled peak relative to controls. This peak is distinct from that obtained when cAMP is added to the assay. Furthermore, the NGF-dependant site of phosphorylation appears resistant to mild alkali treatment. In a search for other substrates of the kinase, protamine, bovine serum albumin, casein, an amino acid polymer substrate for tyr phosphokinases [(Glu Na, Tyr) 4:1] and histones HV-S, HII-A, HI gave negative results. However, initial experiments indicate that the histone HIII may be a substrate. When EGF and FGF were tested under the same assay conditions, there was no increase in phosphorylation found with extracts from either the membrane or soluble portions of the cell. Additional experiments are in progress to further characterize and purify the NGF-activated kinase. Supported by NIH grant NS16036, NIH training grant GM07238 and NIMH grant 02717.

197.5 STRUCTURE AND PROCESSING OF THE NERVE GROWTH FACTOR PROHORMONE. D.O. Clegg and L.F. Reichardt. Division of Neurobiology, Dept. of Physiology, University of California, San Francisco, Ca. 94143.

The sequence of the beta - Nerve Growth Factor (NGF) cDNA clone from male mouse submaxillary gland predicts that the NGF peptide is synthesized as part of a larger precursor which is then processed in the submaxillary gland by cleavages at di- and tetrabasic amino acid residues to produce mature beta-NGF and several other peptides. However, the forms of NGF made in sites relevant to neuronal development, such as targets of sensory and sympathetic innervation, are not known. The structure of the gene makes it possible that the prohormone, alternately processed peptides containing the beta-NGF sequence, and other peptides from the prohormone are secreted and important for the developmental program.

The gene sequence suggests two possible initiation sites for translation. To determine the preferred initiation site, a synthetic mRNA, generated from the NGF cDNA fused to the SP-6 promoter, was translated in vitro. A protein of Mr 34,000 was the major product, and its N-terminal amino acid sequence indicates that the first possible initiator codon is utilized to make the larger of the two possible precursors (cf. Scott, J. et al.(1983), Nature, 303, 538-540. and Ullrich, A. et al. (1983), Nature, 303,821-825.)

To facilitate analysis of the prohormone and its derivative products, a synthetic peptide predicted to be a part of the precursor has been employed to raise antibodies specific for the prohormone. These antibodies precipitate the Mr 34,000 translation product made in vitro, and bind in sections to the same cells in the submaxillary gland that make beta-NGF in vivo. Furthermore, a cross-reacting antigen can be detected in saliva, which may correspond to the prohormone or a smaller product derived by proteolytic processing. The major antigen has been substantially purified. NGF gene products made in vivo and in vitro are both being used to examine processing in vitro. The antibodies are being used to examine processing of the NGF prohormone in sympathetic effector organs.

Supported by NIH grant #NS21824 and a Jane Coffin Childs Memorial Fund for Medical Research Fellowship to D.O.C.

197.6 DEVELOPMENTAL, REGIONAL AND POST-LESION EXPRESSION OF NERVE GROWTH FACTOR (NGF) AND NGF mRNA IN RAT BRAIN. S.R. Whittemore[1], T. Ebendal[2]*, L. Lärkfors[2]*, L. Olson[3]*, Å. Seiger[3]*, I. Strömberg[3]* and H. Persson[1]*. Departments of Medical Genetics [1] and Zoology[2], Uppsala University, Uppsala, Sweden and Department of Histology[3], Karolinska Institute, Stockholm, Sweden.

β-nerve growth factor (NGF) plays a major role in maintaining peripheral sympathetic and sensory ganglionic neurons. However, the existence, distribution and possible function in the central nervous system (CNS) remains elusive.

To assess the expression of NGF mRNA in the CNS, a cDNA probe complementary to mouse submaxillary gland NGF mRNA (Scott et al., Nature 302:538) was used both to probe poly A+ RNA from the rat brain and to isolate a rat genomic NGF clone from a Charon 4A phage library. This genomic clone was sub-cloned in phage M13 and used as a probe in S1 endonuclease analysis of NGF mRNA. Levels of endogenous NGF were determined using a two site enzyme immunoassay.

Northern blot and endonuclease S1 analyses showed wide variation in the levels of NGF mRNA in different regions of the adult rat brain. Maximal levels were observed in the cortex (CTX) and hippocampus (HC), at levels 500 fold less than those seen in the male mouse submaxillary gland. The olfactory tubercle, striatum, pons/medulla and thalamus were intermediate in NGF mRNA expression, while in the cerebellum, septum and hypothalamus NGF mRNA could not be detected. Control hybridization with a cDNA for actin showed little regional heterogeneity. Endogenous NGF levels were consistent with the distribution of NGF mRNA, with the CTX and HC having about 2.0 ng NGF/g tissue. In addition, NGF was found in the septum, a finding consistent with the reported retrograde transport of NGF from the HC to the septum (Schwab et al., Brain Res. 168:473).

NGF mRNA was first detectable in the later stages of embryonic development (E18) reaching adult levels by 3 weeks postnatal. At 1 week, NGF mRNA levels in the HC and CTX are 50% of those seen in the adult structures. Endogenous NGF was also detected prenatally.

Bilateral fimbria transections were made in 1 week old rat pups by a knife cut which also transected the overlying CTX. 3 days post-lesion, the levels of NGF mRNA in the lesioned HC had decreased 50%, while the NGF mRNA in the lesioned CTX had increased two-fold. Endogenous NGF levels were consistent with the alterations in NGF mRNA seen in the lesioned regions. Results of NGF and NGF mRNA expression in the HC following entorhinal lesions will also be discussed. Immunohistochemical studies are presently being undertaken to examine the cellular localization of the altered NGF expression.

197.7 NERVE GROWTH FACTOR (NGF) PROMOTES SURVIVAL OF SEPTAL CHOLINERGIC NEURONS AFTER INJURY. F. Hefti. Dept. of Neurology, University of Miami Medical School, Miami, FL 33101.

Several findings obtained in recent years suggest that NGF acts as specific neurotrophic factor for the group of ascending cholinergic neurons of the mammalian forebrain. NGF and the mRNA coding for NGF are present in target areas of these neurons, and forebrain cholinergic neurons have been shown to react to NGF with an increase in choline acetyltransferase (CAT) activity. I now present further support for a role of NGF in the function of forebrain cholinergic neurons by showing that NGF is able to promote survival of these cells after axonal injury in vivo and in vitro.

In vivo, NGF was given intraventricularly to adult rats with lesions of the cholinergic septo-hippocampal pathway. The pathway was cut unilaterally by transsecting the fimbria, and a cannula was chronically inserted into the lateral ventricle after lesioning. During 4 weeks, lesioned animals received intraventricular injections of mouse salivary gland 2.5S NGF (10μg twice weekly) or of equal amounts of a control protein. The animals were then taken for histochemical visualization of cholinergic cell bodies using acetylcholinesterase (AChE) histochemistry (after pretreatment with DFP). In control animals, the fimbrial transsections resulted in a pronounced reduction of the number of cholinergic cells in the medial septal nucleus and the vertical limb of the diagonal band of Broca on the side ipsilateral to the lesion. NGF-treament significantly attenuated this lesion-induced degeneration. In lesioned control animals, the total number of AChE-positive cells contained in medial septal nucleus and the vertical limb of the diagonal band on the lesioned side was reduced by 50% as compared to the number on the contralateral side. In lesioned animals treated with NGF, the number of cholinergic cells on the lesioned side was reduced by 12%.

To establish the dose-response relationship and the specificity of NGF's effect on survival of forebrain cholinergic neurons, further experiments were carried out in vitro. The septal area was dissected from brains of rats of postnatal day P2. At this developmental stage, cholinergic neurons had already started to invade hippocampal tissue and therefore lost their processes during the dissociation procedure. Dissociated cells were grown for 10 days in a modified L15 medium and were then taken for visualization of cholinergic neurons using CAT immunocytochemistry and AChE cytochemistry. NGF significantly elevated the number of cholinergic cells surviving in the cultures. The ED_{50} of NGF's effect was approximately 10ng/ml, and it was blocked by antibodies to NGF.

The findings of the present study indicate that NGF is able to rescue rat forebrain cholinergic neurons from degeneration after transsection of their processes in vivo and in vitro. Since forebrain cholinergic neurons degenerate selectively in human Alzheimer's disease, these findings might help to understand the cause and find an effective treatment for this disease.

197.8 NGF SPECIFICALLY ENCHANCES DEVELOPMENT OF BRAIN CHOLINERGIC NEURONS IN CULTURE. H.J. Martínez*, C.F. Dreyfus, G.M. Jonakait and I.B. Black. Cornell Univ. Med. Coll. New York, NY 10021.

Recent evidence suggests that the trophic protein nerve growth factor (NGF) affects brain cholinergic neurons. In the present study, we examined the effect of NGF on organotypic cultures of fetal rat neostriatum (NS) and basal forebrain (BF). The NS or BF from E19-20 (gestational day) rat fetuses were grown on collagen-coated coverslips and maintained in Maximov chambers as lying drop preparations. Treatment of NS or BF cultures with NGF for 10-12 days resulted in a 5- to 12-fold increase in the specific activity of the cholinergic enzyme, choline acetyltransferase (CAT), in a dose-dependent fashion. This effect was not elicited by insulin, ferritin or cytochrome C, proteins structurally or physicochemically similar to NGF, indicating specificity of the response to the trophic protein. Conversely, the effect of NGF was blocked by anti-NGF antiserum, a further indication of specificity. Immunocytochemical studies of the treated cultures, using a monoclonal antibody against CAT, identified the cholinergic population revealing a network of positively stained neurons, exhibiting long dendritic and axonal processes. NGF did not alter total protein content of NS or BF cultures, indicating selectivity of the effect. Moreover, levels of substance P, a peptide localized to non-cholinergic neurons in the NS, were not altered by NGF, while CAT activity increased 12-fold in sister cultures. Although the mechanisms of action of NGF on NS and BF cholinergic neurons remain to be determined, the marked, specific response of CAT suggests that this defined trophic protein plays a critical role in normal brain development. It may now be possible to determine whether NGF, its processing or its reception is defective in degenerative disorders that involve these brain cholinergic neurons. 197.9 NERVE GROWTH FACTOR EFFECTS ON DEVELOPING CENTRAL CHOLINERGIC NEURONS: TEMPORAL RESPONSE CHARACTERISTICS IN SEPTUM, HIPPOCAMPUS AND STRIATUM. M.V. Johnston, K. Buchanan*, J.L. Rutkowski and W.C. Mobley. Depts. of Ped. and Neurol., Univ. of Michigan, Ann Arbor, MI 48104; Div. N.P., Walter Reed Institute of Research, Washington, DC 20307; Dept. of Neurol., Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

Nerve growth factor (NGF), injected intracerebroventricularly (ICV), stimulates choline acetyltransferase (ChAT) activity in regions of immature rat brain enriched in cholinergic perikarya (septum, nucleus basalis, striatum) and nerve terminals (neocortex, hippocampus). Previous work demonstrated a response on postnatal day (PD) 12 following injection of 4 doses of purified NGF (PD's 2, 4,6,8; Mobley et al, Neurosci. Abstr. 10,367,1984). Now we report results of experiments using simplified dose schedules to dissect regional and temporal features of the response. Single or multiple ICV injections (30 ugm) of mouse NGF were used (Biochem. 15,5543).

Three doses (PD's 2,4,6) elevated ChAT in the septum by 94% compared with littermate controls on PD12, and this effect could be duplicated by a single injection on PD8 (+90%). However, both protocols elicited less response than the complete 4 dose schedule, which raised ChAT by 290%. Injection on PD2 or PD2&4 produced no measurable increase on PD12. The results suggested that the neonatal doses (PD2&4) may have enhanced the response to NGF on PD6&8, but it was unclear if they stimulated ChAT independently.

To examine effects of a single early dose, groups of 5 neonatal rats were given single injections on PD2 and assayed along with littermate controls at intervals up to PD12. At 6, 12 and 24 hrs post-treatment, ChAT remained unchanged in septum, hippocampus and striatum, but at 48 hrs activity rose by 75% in septum and 152% in striatum. In contrast, hippocampal ChAT remained low for another 48 hrs (PD6) when it increased by 90%. By this time, septal and striatal ChAT activity had peaked (217% and 337% of control, respectively). At 8 days after injection (PD10), ChAT in septum and striatum returned to control levels but hippocampal activity remained high (+85%), falling to age appropriate levels 48 hrs later (PD12).

Immature cholinergic neurons respond strongly to a single dose of NGF on PD2, providing additional evidence that it is a potent signal for them during development. The initial delay in ChAT elevation and sequential responses in septum followed by hippocampus suggest that NGF may stimulate synthesis of new enzyme molecules which are transported outward from perikarya to nerve terminals. The temporal relationship between peaks of activity in septum and hippocampus is consistent with a transport velocity similar to slow axoplasmic flow. NGF may provide an important probe for studying the molecular events required for expression of ChAT enzyme activity in developing central cholinergic systems.

197.10 EFFECTS OF ANTIBODIES AGAINST NERVE GROWTH FACTOR ON DEVELOPING CHOLINERGIC FOREBRAIN NEURONS IN RAT. U.Otten, G. Weskamp*, M.Schlumpf, W.Lichtensteiger and W.C.Mobley. Dept. of Pharmacology, Biocenter of the University, Basel, Dept. of Pharmacology, University of Zürich, Switzerland and Div. N.P. Walter Reed Institute of Res.,Washington DC 20307.

A number of observations suggest that nerve growth factor (NGF) plays a physiological role for basal forebrain cholinergic neurons: messengerRNA encoding NGF as well as NGF immunoreactive material have been found in brain. Morphological studies showed that NGF is selectively transported retrogradely to cholinergic neurons of the basal forebrain. In addition, NGF increases the activity of choline acetyltransferase(ChAT) in rat forebrain cholinergic neurons both in vivo and in vitro. However, so far no effects of NGF-antibodies on central cholinergic neurons could be found.

In the present study, we have injected anti-NGF antibodies into rat fetuses in utero. Using this approach we have previously shown that NGF is necessary for the normal development of a significant population of prenatal rat dorsal root ganglion cells. We report that a single administration of anti-NGF antibodies to 15.5-day-old rat fetuses produced a significant reduction in ChAT-activity in the nucleus basalis region,septum and hippocampus (52%, 35% and 15% respectively, $P < 0,01$) in animals examined 7 weeks later.Concomitantly, reduction in binding of ^{3}[H]-N-methylscopolamine was observed in neocortex and hippocampus. In contrast, no changes in ChAT and muscarinic cholinergic receptor levels were observed in the striatum. Quantitative histological studies are in progress to determine whether these biochemical changes are a reflection of neuron destruction.

These results, however, indicate that endogenous NGF is a trophic agent for rat forebrain cholinergic neurons.

197.11 NEURITE-PROMOTING FACTORS FOR SPINAL NEURONS. INHIBITORY SUBSTANCES IN MUSCLE OF PATIENTS WITH SPINAL MUSCULAR ATROPHY. C.E.Henderson*[1] T.Taguchi*[1], J.P.Changeux[1], S.L.Hauser*[2], P.A.Cazenave*[2], F. Hentati*[3] and M.Fardeau*[3]. Neurobiologie Moléculaire[1] and Immunochimie Analytique[2], Institut Pasteur, 25 rue du Dr.Roux, 75015 PARIS; INSERM U153[3], 17 rue du Fer-à-Moulin, 75005 PARIS, France.

Various lines of in vivo and in vitro evidence suggest that at different stages of their development, spinal motoneurons depend on muscle-derived factors for survival, axon outgrowth and acetylcholine synthesis. We have used serum-free cultures of embryonic (4.5 d in ovo) chicken spinal neurons to detect and study factors affecting neurite outgrowth. Early embryonic spinal cord was used with the aim of enriching motoneurons in the cultures, but the responsive cells have not been directly identified.

Neurite-promoting activity from two principal sources was studied: medium conditioned by embryonic myotubes in vitro ("embryonic" activity) and extracts of 4-day post-hatch leg muscle ("neonatal" activity). Levels of the latter were developmentally regulated.

In the course of the spinal muscular atrophies, there is a selective loss of motoneurons in the ventral horn. It has been hypothesised that this is due to a lack of muscle-derived trophic support. We tested the capacity of extracts of muscle from patients with spinal muscular atrophies (SMA) to inhibit the action in vitro of the neurite-promoting activities described above. In a series of soluble extracts prepared from fresh muscle biopsies, all SMA extracts tested (5/5) inhibited the "neonatal" activity, by up to 100%. Total muscle protein concentrations necessary for inhibition were <1 ug/ml; no cytotoxicity was observed. No extract (0/7) from neurological or morphologically normal control muscles inhibited to the same extent. In the same test using "embryonic" chick activity, there was no difference between SMA and control groups.A second series of biopsies conserved at -80° was tested in the same way. In this case, some SMA extracts (6/17) did not inhibit the "neonatal" activity, whereas one control (1/14) did. The difference between the groups was still highly significant ($p<.001$ by a χ^2 test). The nature of the inhibitory substances is under investigation.

Levels of neurite-promoting activity in chick muscle extracts were increased 15-fold three days after denervation. These muscle extracts were used as starting point for purification of the active factor(s). In the most highly purified fractions obtained to date (still containing several protein species), the specific activity was estimated to be 5×10^6 biological units/mg protein, which represents a 10^4-fold enrichment. The active species migrated with an apparent mol. wt. of 50 K upon gel filtration in non-denaturing conditions.

197.12 EFFECTS OF INSULIN AND INSULINLIKE GROWTH FACTOR-II ON TUBULIN mRNA LEVELS AND NEURITE FORMATION IN CULTURED HUMAN NEUROBLASTOMA CELLS. J.F. Mill*, M.V. Chao* and D.N. Ishii. Pharmacol. Dept., Columbia Univ., New York, NY 10032; and Dept. of Cell Biol. and Anat., Cornell Univ. Med. Sch., New York, NY 10021.

Tubulin is one of the major protein constituents of axons and dendrites. We have previously shown that insulin and insulinlike growth factor-II (IGF-II) can increase neurite formation in sensory, sympathetic and human neuroblastoma SH-SY5Y cells. Here, we demonstrate that insulin and IGF-II can increase both alpha- and beta-tubulin mRNA levels in SH-SY5Y cells, in a manner which correlates with their capacity to enhance neurite formation. SH-SY5Y cells can survive for longer than one week in serum-free media (SFM) without a loss in the number of cells. The quiescent cells resume growth on the reintroduction of serum. SH-SY5Y cells, grown for two days in SFM, were treated with and without 0.1 μM insulin for 24 hours, RNA was extracted, and equal quantities of RNA were analyzed by Northern blot with cDNA probes containing the coding regions for the alpha- and beta-tubulins. Densitometric scans of the resulting autoradiograms showed a 3-4 fold increase in both alpha- and beta-tubulin mRNAs relative to the controls. A similar result was seen on treatment with IGF-II. Cytoplasmic dot blot analysis showed that the observed increases were even greater on a per cell basis. There was a transient peak between 12 and 24 hours of exposure to insulin, followed by a decrease. Neurite outgrowth attains a maximum in about 1 day, but, in contrast, is sustained. These results show that elevated levels of tubulin mRNAs are associated with the extension of neurites, but may no longer be required once neurites have formed. The effects of 1 pM to 1 μM insulin were studied. Tubulin mRNA levels were increased half-maximally at 3 nM insulin. The dose-response curve for the increase in tubulin mRNA levels closely approximated that for the increase in neurite outgrowth in response to insulin. The broad dose-response curves for these functions may be explained by the cross occupancy of insulin and IGF-II receptors. Nerve growth factor (NGF) can induce neurite outgrowth in SH-SY5Y cells in either serum-containing media or in SFM containing low concentrations of insulin. In contrast to insulin and IGF-II, NGF did not appreciably increase tubulin message levels under either of these conditions. Because neurite outgrowth can be synergistically potentiated by the combination of insulin and NGF, we suggest these factors may cooperate to form neurites by two distinct mechanisms. Insulin and its homologs may act primarily to increase tubulin mRNA levels, whereas NGF may act largely to increase the fraction of the tubulin pool in the polymerized, microtubule state. (Supported in part by NIADDKD grant RO1 AM32841 to DNI, and NIH grant BRSG RR05396 to MVC.)

198.1 EVIDENCE FOR GABAERGIC INNERVATION OF MOUSE THYMUS AND SPLEEN. K. Bulloch, S.A. Cohen*, S.A. Robinson* and J.-Y. Wu (1), Dept. of Neurology, S.U.N.Y. Stony Brook, N.Y. 11794 and (1) Dept. of Physiol., Penn. State Univ. 17033

The thymus and the spleen are two major organs of the immune system. Both organs are innervated by fibers of the ANS. The thymus receives a rich cholinergic (AChE-positive) innervation from the vagus nerve which is distributed to the corticomedullary boundaries and from the phrenic and recurrent laryngeal nerves which is localized to the thymic subcapsular region. Catecholaminergic (CA) innervation derived from the superior cervical ganglia, stellate ganglia and other small ganglia of the sympathetic chain is primarily vascular in nature with dense plexuses evident at the corticomedullary boundaries. A more delicate distribution of nonvascular-associated CA fibers is evident in the subcapsular and cortical regions of the thymus. The spleen predominantly receives a rich CA innervation from fibers arising in the celiac ganglion. Most of these fibers are evident along the periarterial sheath and within the marginal zone of the lymphoid nodules. Anatomical studies coupled with pharmacological studies now show that these two neurotransmitters have a profound effect on the migration, differentiation and function of immune cells within these organs (Bulloch, K. Raven Press 111, 1985). In this study we have sought to determine the distribution of another neurotransmitter, gamma-aminobutyric acid (GABA), within the thymus and spleen of young adult C57BL/6J mice by means of standard immunocytochemical fluorescence techniques. We used as our GABA markers specific antibodies against GABA-T AND GABA. Our results show that the thymus contains a plexus of GABAergic-like nerve terminals which are densely distributed throughout the cortex. There is a close and rich association of these GABAergic-like nerves with the cortical autofluorescent cells. A less dense GABAergic innervation is evident within the spleen. These fibers are very fine and are distributed along the periarterial sheath and within the marginal zone of the lymphoid nodules. The density of GABAergic nerves within these two tissues correlates well with the biochemical analysis (J.G. Gerber and T.A. Hare, Diabetes 28:1073, 1979) which showed high levels of GABA within the thymus and low levels within the spleen. The presence of GABAergic-like nerves within the thymus and the T-cell zones of the spleen offers an exciting new probe into the multidimensional roles of neuroimmune interactions. Supported by NIH grant #18401

198.2 TRANSMITTER MODULATION OF IMMUNE CELLS. V.P. Calabrese and J. Yoshino*. Departments of Neurology and Biochemistry, Medical College of Virginia, Richmond, Virginia 23298-0001.

It is becoming increasingly evident that there is a functional relationship between the nervous system and the immune system. There are neurotransmitter receptor sites on the surface of lymphocytes which may have a functional role in the immune response.

In our study we have looked at the effect of neurotransmitters on the turnover rate of human mononuclear cells in culture as well as the immunoglobulin production. Epinepherine, at a concentration of 10^{-3}M and 10^{-5}M, had a suppressive effect on mononuclear cell DNA as measured by ^{3}H thymidine uptake. A similar suppression was seen with 5-HT at 10^{-4}M and 10^{-5}M. Epinepherine inhibited most of the stimulatory effect of pokeweed mitogen but had no effect on Concanavalin A stimulation. This would indicate a different effect of the neurotransmitters on various cell types.

The effects of neurotransmitters on mononuclear cells after the cells were stimulated by brain and viral antigens was also evaluated. The different effects on monocytes/macrophages (cells adherent to plastic) and lymphocytes (nonadherent cells) was also studied. Results of these studies will be presented.

198.3 NORADRENERGIC INNERVATION OF THE SPLEEN IN ADULT AND AGING FISCHER 344 RATS. L.L. Wheeler*, D.L. Bellinger, S.Y. Felten, P.D. Coleman, T.J. Collier, and D.L. Felten (SPON: J. Olschowka), Dept. of Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Noradrenergic (NE) innervation of the spleen was examined with fluorescence histochemistry in Fischer 344 rats of 8 months and 27 months of age. The 27 month old rats were divided into 2 groups, based upon behavioral testing for gustatory neophobia (enhanced fearfulness of novel stimuli), a condition previously associated with lesions of locus coeruleus in young rats and with noradrenergic diminution in aging rats (Collier et al., 1985). Spleens of 8 month old rats were innervated abundantly. Large plexuses of NE varicosities entered with the splenic artery, followed branches into the spleen, and formed a subcapsular plexus that continued alongside the trabeculae. These arterial and trabecular plexuses continued into the white pulp, associated mainly with the central artery and its branches. Only scattered varicosities were present in the red pulp, associated with vessels. Areas of white pulp were large and well defined. Linear chains and tortuous profiles of NE varicosities diverged from the vascular plexuses, extended into the parenchyma of the white pulp, and ended among lymphocytes in the periarterial sheath. In all of the 27 month old rats, NE innervation was decreased markedly. Capsular plexuses and parenchymal fibers, both linear and punctate in appearance, were reduced markedly. The varicosities associated with blood vessels, especially the central artery of the white pulp and its branches, were present but were diminished in density as well as in overall fluorescent intensity. The white pulp was diminished in size and was difficult to separate clearly from red pulp. In the neophobic 27 month old rats, the white pulp was reduced even further, and NE varicosities were even less abundant. The reduced innervation of the spleen in aging Fischer 344 rats may be related to the decline in immune function seen in the aging process. Since neophobia may be related to decreased central NE, the reduced NE innervation of the spleen may reflect a generalized reduction of NE in these rats. Supported by Grant N00014-84-K-0488 from the Office of Naval Research and by NIH Training Grant AG T32 107.

198.4 NORADRENERGIC INNERVATION OF MESENTERIC AND POPLITEAL LYMPH NODES IN YOUNG AND AGING MICE WITH AUTOIMMUNE DISORDERS. P. Yeh*, D.L. Bellinger, S. Livnat*, R. Ader*, S.Y. Felten, and D.L. Felten. Depts. of Anatomy, Psychiatry, and Microbiology (Immunol.), Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Noradrenergic (NE) innervation of mesenteric and popliteal lymph nodes was examined with fluorescence histochemistry in several strains of New Zealand mice. NZW mice served as controls, and were examined at 4-6 weeks of age, 8 months, and 18-19 months. NZB mice, a strain that develops autoimmune hemolytic anemia, were examined at 4-6 weeks of age, and at 6 months of age, shortly before the lethal onset of the hemolytic anemia. NZB x NZW mice, a hybrid that demonstrates a lupus-like syndrome, were examined at 4-6 weeks of age, 8 months, and 18-19 months. All mice at 4-6 weeks of age showed similar distribution of NE fibers. Large plexuses of varicosities entered the nodes in the hilar region and continued with vessels through the medullary cords. Some fibers traveled just beneath the capsule in a subcapsular plexus; these varicosities also followed septa into the parenchyma. The fluorescent fibers from the medullary cords continued into the parenchyma and ended among lymphocytes in paracortical regions, while some fibers from the subcapsular plexus branched into the parenchyma to end among lymphocytes in cortical regions. No fibers were found in nodular regions. Mesenteric lymph nodes were innervated more densely than popliteal lymph nodes, particularly in the large plexuses. At 8 months of age, both the NZW and the NZB x NZW strains demonstrated a pattern of NE innervation whose density and distribution were similar to their young counterparts. In 6 month old NZB mice, there was a marked decrease in innervation of lymph nodes, and an infiltration of these nodes with metachromatic cells that resembled mast cells and possibly with macrophages. It is possible that this altered innervation may contribute to the autoimmune disorder in these mice, although it also may be secondary to other changes. In 18-19 month old mice, the innervation diminished in both extent and intensity of fluorescence, including the distribution in the paracortical and cortical regions in which T lymphocytes reside. However, this reduced innervation was more severe in NZB x NZW mice, again raising the possibility of an association of diminished NE innervation of lymph nodes with an autoimmune disorder. These findings suggest that the NE innervation of lymph nodes differed regionally (mesenteric more densely innervated than popliteal), diminished normally with age, and diminished further in certain strains of mice with autoimmune disorders. Supported by Grant N00014-84-K-0488 from the Office of Naval Research.

198.5 NORADRENERGIC INNERVATION AND ACETYLCHOLINESTERASE ACTIVITY OF LYMPH NODES IN YOUNG ADULT AND AGING MICE. D.L. Bellinger, S.Y. Felten, P.D. Coleman, P. Yeh and D.L. Felten. Dept. of Anat., Univ. of Rochester, Sch. of Med., Rochester, NY.

Popliteal and mesenteric lymph nodes in C57BL/6 mice of 7, 12, 21, 30 and 36 months of age, were examined with fluorescence histochemistry for catecholamines and with acetylcholinesterase (AChE) staining. In young adult mice, noradrenergic (NE) fibers entered the lymph node in the hilar region in a dense varicose plexus associated with the vasculature. These fibers continued with the vasculature into the medullary region, or formed a subcapsular plexus that extended around the lymph node and followed the septa between the nodules. Fine delicate strands of fibers exited the perivascular and subcapsular plexuses into the paracortical and cortical regions surrounding germinal centers, where they closely apposed, and ended among, lymphocytes. The paracortical and cortical regions also contained intensely yellow autofluorescent cells. No fibers entered the germinal centers. In lymph nodes of aging mice, there was a decrease in the number of intensely yellow autofluorescent cells, and the capsule appeared thicker. NE fibers in lymph nodes of aging mice were distributed similar to NE fibers seen in young mice; however, the density of fibers in the subcapsular and perivascular plexuses decreased. In addition, there was a loss of fluorescence intensity in the fibers. Neurochemical measurements currently are under way to confirm these findings.

A modified thiocholine method (El-Badawi and Schenk, 1967), specific for AChE, revealed positive-staining fibers that entered the lymph nodes in association with blood vessels in the hilar region. These fibers continued into the lymph node along with the vasculature. From these plexuses, AChE-positive fibers coursed into the paracortical and cortical regions surrounding the germinal centers, where they branched extensively among lymphocytes. Terminals of the AChE-positive fibers formed claw-shaped endings that surrounded individual lymphocytes. In popliteal lymph nodes, a large number of mast cells were present in clusters beneath the capsule, and to a lesser extent, near blood vessels. AChE-staining profiles also traveled in close proximity to these aggregates of mast cells. In aging mice, no differences in the distribution and appearance of AChE-positive fibers was noted. However, mast cells were more abundant in aging popliteal lymph nodes than in their younger counterparts. Since the distribution of NE fibers and AChE-positive fibers closely overlaps, it is possible that they coexist. It also is possible that lymph nodes are innervated by both NE and cholinergic fibers. Additional methods are being used to explore these possibilities. Supported by Grant N00014-84-K-0488 from the Office of Naval Research and NIH training grant AG T32 107.

198.6 IMMUNIZATION SELECTIVELY DECREASES NOREPINEPHRINE IN THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS AT THE TIME OF THE PEAK SPLENIC PLAQUE-FORMING CELL RESPONSE IN ADULT C3H MICE. S.L. Carlson, S.Y. Felten, S. Livnat* and D.L. Felten, Departments of Anatomy, Microbiology (Immunology) and Psychiatry, Univ. of Rochester Sch. of Medicine, Rochester, NY 14642.

Evidence from several lines of investigation reveals the existence of reciprocal communication between the nervous and immune systems, although the identification of specific sites of interaction in the CNS remains elusive. In this regard the hypothalamus has been examined as a potential major regulatory center for modulating immune responses. Hypothalamic norepinephrine (NE) was reported to decrease during the peak of a primary immune response in rats (Besedovsky, et al, 1983). The present study was undertaken to search for possible sites in the hypothalamus where specific alterations in NE may occur following immunization.

Adult male C3H mice were immunized intraperitoneally with the antigen sheep red blood cells or with vehicle (controls). The mice were sacrificed on days 2, 4 and 8 following immunization, corresponding to time points before, during, and after the peak immune response respectively, as measured by the splenic plaque-forming cell (PFC) response. Specific hypothalamic nuclei and brain stem regions were microdissected for subsequent measurement of monoamines using LCEC. The density, distribution, and appearance of catecholamine varicosities was examined with SPG histofluorescence. We report here our observations in paraventricular nucleus (PVN), supraoptic nucleus (SON), anterior hypothalamus (AH), and the A1 catecholamine cell group in the medulla.

NE was decreased in the PVN on day 4 only, but not in the SON, AH, or the A1 region at any time. In addition, no changes in dopamine were found in any of these nuclei at any time point. Serotonin was decreased only on day 4 in both PVN and SON, with no changes in the AH or A1 region. These results indicate that immunization results in a selective decrease in NE in the PVN during the peak PFC response. The lack of change in NE content in the A1 region, which contains NE cell bodies that project to PVN and SON, suggests that modulation of the NE system is likely to occur at the terminal fields in the PVN and not at the cell bodies. This may be important for the increased output in the CRF-ACTH-glucocorticoid axis reported to occur at the peak of an immune response, particularly in view of selective localization of CRF neurons in PVN but not SON, and the selective decrease in NE in PVN but not SON reported here. Direct projections from the PVN to preganglionic autonomic neurons may also be involved in the regulation of autonomic neurons that innervate lymphoid tissue. Therefore, PVN may be a specific anatomical link in the reciprocal communication between the nervous and immune systems. Supported by Grant N00014-84-K-0488 from the Office of Naval Research.

198.7 NEURAL MODULATION OF THE IMMUNE RESPONSE BY PHOTOPERIOD: SPLENIC CELL COUNTS AND IMMUNE RESPONSIVENESS. F.D. Lublin*, R.L. Knobler, P. L. Podolin*, G.C. Brainard . Department of Neurology, Jefferson Medical College, Philadelphia, Pa. 19107

To establish the effect of prolonged differences in photoperiod on the immune system, we studied Syrian hamsters which were exposed to either a long photoperiod (14 hours daylight/day) or a short photoperiod (10 hours daylight/day). After 12 weeks in either long or short photoperiod, half of each group (N=12) was immunized with an immunogenic random sequence amino acid polymer of glutamic acid, lysine, alanine and tyrosine (GLAT) The animals were bled by cardiac puncture and sacrificed after 14 weeks. Various organs were removed and weighed and immunologic assays performed. Splenic lymphocytes and macrophages were counted morphometrically by light microscope. Animals in a long photoperiod had means of 37×10^6 lymphocytes (nonimmunized group) or 64×10^6 lymphocytes (immunized group). In contrast, animals in short photoperiod had means of 100×10^6 lymphocytes (immunized group) or 165×10^6 lymphocytes (immunized) group). Data were analyzed by ANOVA and significance levels determined by a Neuman-Keuls test. Among the immunized animals, the short photoperiod animals had significantly more lymphocytes ($P<0.01$). Between the nonimmunized groups, the short photoperiod animals also had significantly higher lymphocyte counts ($P<0.05$). Similar analysis demonstrated that between immunized animals, the short photoperiod group had significantly more macrophages than the long photoperiod group ($P<0.01$). Among nonimmunized animals, the short photoperiod group had more than twice the number of splenic macrophages as long photoperiod animals, but this difference was not statistically significant. Preliminary data from cell proliferation assays demonstrate a trend towards increased splenic lymphocyte responsiveness to mitogens concanavalin-A and lipopolysaccharide in long photoperiod animals versus short photoperiod animals. Studies are underway to determine whether there are photoperiod induced differences in antibody production to GLAT. These data indicate an effect of photoperiod on certain components of immune tissue, and raise the possibility of specific light mediated neuroendocrine regulation of immune responsiveness. Supported by USPHS #RR-05414 and the Pfeiffer Research Foundation.

198.8 NEURAL MODULATION OF THE IMMUNE SYSTEM BY PHOTOPERIOD: IMMUNE ORGAN WEIGHTS AND CELL COUNTS. G.C. Brainard, F.D. Lublin,* R. L. Knobler, and P.L. Podolin*. Department of Neurology, Jefferson Medical College, Philadelphia, Pa. 19107

The neuroendocrine-reproductive axis of the Syrian hamter is physiologically regulated by the photoperiod in which animals are housed. The purpose of the following study was to examine the capacity of the environmental photoperiod to influence the immune organs and cells of adult male hamsters (Mesocricatus auratus) . Twenty-four age matched hamsters were divided randomly into two groups and housed under a daily light:dark cycle (LD) of either 14:10 or 10:14 (lights on in both groups 07:00 hours) for 14 weeks. After twelve weeks, 6 animals in each photoperiod were immunized with an immunogenic random sequence amino acid polymer of glutamic acid, lysine, alanine and tyrosine (GLAT). At 14 weeks, blood samples were collected by cardiac puncture, and testes, accessory sex organs, spleens, thymuses, Harderian glands, adrenal glands and brown fat pads were weighed. Data were analyzed by ANOVA and significance levels determined by a Newman-Keuls test. Animals in LD 14:10 had significantly higher reproductive organ weights than animals in LD 10:14 ($P<0.001$). Immunization did not significantly alter the effect of photoperiod on testicular weights; however, immunized animals in LD 10:14 had lower accessory sex organ weights than nonimmunized animals in the same photoperiod ($P<0.05$). Neither photoperiod nor immunization had any influence on thymus weight. In contrast, spleen weights were significantly reduced by long photoperiods compared to short photoperiods ($P<0.01$). Furthermore, immunized animals had significantly higher spleen weights than nonimmunized animals in short photoperiods ($P<0.05$). The spleen weight differences observed between groups were paralleled by differences in spleen lymphocyte and macrophage cell counts. Specifically, higher spleen weights were matched by increased numbers of lymphocytes and macrophages while lower weight spleens had fewer lymphocytes and macrophages. Thus, photoperiod induced changes in total spleen weight as well as in the immunologically functional cells of the spleen. These data demonstrate that the immune system is responsive to ambient photoperiod and may be regulated by neuroendocrine control systems. Supported by USPHS #RR-05414 and the Pfeiffer Research Foundation.

198.9 CHRONIC ADMINISTRATION OF PROPANOLOL DELAYS DEVELOPMENT OF A MURINE PLASMACYTOMA TUMOR. C.G. Frondoza*, R. Grzanna, G.L. Hung*, and A. Sastre. The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Tumor incidence and growth rates have been suspected to be influenced by the activity of the sympathetic nervous system. We have previously shown that LPC-1 plasmacytoma tumors develop significantly slower in sympathectomized mice than in untreated animals. This study was conducted to determine the effect of prolonged adrenergic receptor blockade on the development and growth of subcutaneous LPC-1 plasmacytoma tumors.

Mice were implanted with Alzet osmotic mini-pumps for continuous delivery over a 15 day period of either D,L-propranolol, D-propranolol, L-propranolol, or saline. Tumor development was monitored by electrophoretic quantitation of the tumor specific protein IgG2a$^{\kappa}$ in plasma and by caliper measurements of the tumor. Administration of D,L-propranolol at concentrations of 0.6, 6 and 60 mg/kg/day produced a dose-dependent, highly significant delay in the appearance of LPC-1 tumors. The propranolol effect was stereospecific in that the L-isomer produced the same effect as the racemic mixture while the D-isomer had no effect. The tumor growth curves in mice injected with $1 \cdot 10^6$ LPC-1 tumor cells and treated with 60 mg/kg/day were similar to those seen in untreated mice after an inoculum of $1 \cdot 10^5$ LPC-1 cells suggesting an apparent 10-fold reduction in the initial tumor load.

The findings extend our earlier observation of a significantly delayed appearance of LPC-1 tumors in sympathectomized mice and provide the first direct evidence for an involvement of β-adrenergic receptors in the regulation of tumor development by the sympathetic nervous system. (Support: NS 16654 and CA 31499)

198.10 DEPRESSION AND IMMUNITY: ROLE OF AGE, SEX, AND SEVERITY. S.J.Schleifer*,S.E.Keller*,J.Cohen*,M.Stein, Mount Sinai School of Medicine, CUNY, New York,N.Y. 10029.

We have previously reported that mitogen induced lymphocyte stimulation and the number of peripheral blood lymphocytes (PBLs) were lower in 18 apparently healthy, drug-free hospitalized patients with major depressive disorder (MDD) compared with matched controls. In contrast, 15 ambulatory patients with MDD had decreased PBLs but did not differ from their controls in mitogen responses. The sample was expanded to include an additional 20 inpatients and 22 outpatients to investigate the role of severity of depression, inpatient vs ambulatory status, age, and sex. All patients met Research Diagnostic Criteria for unipolar MDD. Severity of depression was assessed using the Hamilton Depression Scale. Subjects were free of medical disorders, were not taking medications known to affect immunity, and had not received antidepressant treatment for at least 3 months prior to study. Patient-control pairs were age and sex matched and were each studied on the same day during the morning hours.

Heirarchical regressions (forced stepwise) on responses to the mitogens PHA, ConA, and PWM, on PBLs, and on numbers of T and of B cells were performed on the total sample of 75 patient-control pairs for age, sex, severity, hospitalization status, first vs second patient series, and interactions among the independent variables. Differences between patients and controls for each of the mitogens were found to be related to the subject's age and to severity but not to sex. Older and more severely depressed patients had significantly lower mitogen responses than matched controls, while responses of younger patients were similar or higher than those of their controls. Neither hospitalization status nor first vs second patient series was related to the findings when age and severity of depression were statistically controlled. Lymphopenia in the depressed patients was related to increased age but was not associated with severity suggesting that different mechanisms may be involved in the quantitative and functional lymphocyte changes found in depression.

The findings demonstrate a complex relationship between MDD and immunity. Specific patterns of neuroendocrine dysregulation in older and more severely depressed patients may account for the role of age and severity in the altered immunity found in MDD.

198.11 STRESS-INDUCED CHROMOSOMAL ALTERATIONS: SISTER CHROMATID EXCHANGES AND UNSCHEDULED DNA SYNTHESIS. Dennis D. Kelly (1), Ronald W. Pero* (2) and Harlow K. Fischman* (1). (1) New York State Psychiatric Institute & Dept. of Psychiatry, Columbia University, New York, NY 10032 and (2) University of Lund, Sweden, & Preventive Medicine Institute/Strang Clinic, New York, NY 10016.

We have established that exposure of an intact organism to a variety of behavioral stressors can trigger within 24 hrs an increase in exchanges between sister chromatids (SCEs) in dividing bone marrow cells. Within 2 hrs of exposure to stress there is also an increase in DNA repair in circulating leukocytes. Genotoxicity is a property shared by a diverse range of physical and psychogenic stressors and appears to be graded with respect to the severity of the stressor.

Exp 1: 24 rats were exposed to a forced 3.5-min swim in either cold or warm water, or to no stress. Two hrs later a bromodeoxyuridine pellet was implanted subcutaneously. Sacrifice occurred 25 hrs post-stress and bone marrow analyzed for SCEs. Both warm and cold swims significantly elevated SCEs and lengthened the cell cycle.

Exp 2: The generality of the phenomenon was tested in 20 rats exposed to one of 5 conditions: cold swim, intense white noise, intermittent inescapable footshock (IFS), continuous IFS or no stress. All four experimental stressors increased SCEs, although to differing degrees. Hence, neither exercise nor physical pain appears to be a prerequisite for SCE induction.

Exp 3: 16 rats were exposed either to intermittent IFS or to no stress. Trunk blood was collected 2 hrs later and unscheduled DNA synthesis (UDS) measured in leukocytes. This method utilizes 3H-thymidine to measure the incorporation of DNA precursor in non-dividing cells as evidence of DNA damage and repair. The level of UDS in stressed rats was twice that of the controls.

Exp 4: 20 rats received either 480, 240 or 120 shocks during 20 mins, or were placed in the same chamber where other rats had been shocked, or were left in their homecages. SCEs were related in a graded manner to the severity of IFS. Rats exposed only to the physical environment in which conspecifics had been stressed showed significant intermediate elevations. UDS measurements produced similar, graded results.

A hypothesis supported by these results is that stress may trigger pathology by directly altering the molecular instructions that guide cellular behavior. [PHS Grants R03 MH39420 (HKF) and R01 NS 18822 (DDK)]

198.12 MORPHINE-INDUCED SUPPRESSION OF NATURAL KILLER (NK) CELLS: EVIDENCE FOR CENTRAL MEDIATION VIA OPIOID RECEPTORS. Y. Shavit, A. Depaulis, G.W. Terman, F.C. Martin, C.J. Zane*, R.P. Gale* and J.C. Liebeskind. Departments of Psychology and Medicine, University of California, Los Angeles, CA 90024.

Much evidence suggests that the immune system is partially regulated by neural and hormonal influences. Studying the role of opioids in modulating NK cell activity, we have recently found that both systemic morphine and stress-released opioid peptides suppress NK cell cytotoxicity in rats. A single systemic injection of relatively high doses of morphine (>20 mg/kg, s.c.) induced transient NK suppression evident 3 h after the injection and returning to normal by 24 h. This suppression is blocked by the opiate antagonist, naltrexone, and develops tolerance with repeated morphine injections. Furthermore, systemic administration of a quaternary analogue of morphine (N-methyl morphine) that does not cross the blood brain barrier, had no effect on NK activity, indicating central mediation of the morphine effect. In the present study, we examined the effect on NK activity of morphine adiministered intracerebroventricularly (ICV).

Male Fischer 344 rats were implanted with cannulae in the right lateral ventricle. Two weeks after surgery, groups of rats were given ICV injections of 10, 20 or 40 µg of morphine or vehicle. Other rats were treated with naltrexone (10 mg/kg, s.c.) 10 min before ICV morphine. Three hours after injections, spleens were removed and dissociated into single cell suspensions. Spleen cells were co-cultured with chromium labeled YAC-1 target cells, and NK cytotoxicity was determined in a 4 hr chromium release assay.

ICV morphine at doses of 20 and 40 µg significantly suppressed NK activity to a similar degree as 20 or 40 mk/kg of morphine given systemically. ICV morphine at a dose of 10 µg did not affect NK activity. The NK suppression when induced by ICV morphine (40 µg) was blocked by systemic naltrexone (at a dose as low as 4 µg/kg, s.c.), and when induced by systemic morphine (30 mg/kg) was blocked by ICV naltrexone (two injections of a dose as low as 0.5 µg, 1.5 h apart). These low doses of naltrexone did not antagonize morphine's cataleptic effect. These results indicate that morphine-induced NK suppression is mediated by central opioid receptors. These results also complement other reports showing the involvement of the central nervous system in mediating NK activity. (Supported by NIH grant NS-07628, Fondation Fyssen, and a gift from the Brotman Foundation).

199.1 COMPARATIVE DISTRIBUTION OF [^{3}H]PIRENZEPINE AND [^{3}H]HEMICHOLINIUM-3 BINDING SITES IN RAT BRAIN. C. Pilapil and R. Quirion. Douglas Hospital Research Centre and Dept. of Psychiatry, McGill Univ., Verdun, Quebec H4H 1R3 Canada.

Recent data have suggested that [^{3}H]pirenzepine labels the muscarinic$_1$ (M_1) cholinergic receptor sub-type in brain. Moreover, it appears that most of the M_1 receptors are post-synaptically located at the level of the cholinergic terminals (Potter et al, TIPS, Jan. 1984, p.22). As putative presynaptic markers, hemicholinium-3 appears to be one of the best candidates. Here, we report on the comparative autoradiographic distribution of [^{3}H] hemicholinium-3 and [^{3}H]pirenzepine binding sites in rat brain using them as marker of pre- and post-synaptic cholinergic nerve terminals, respectively. Rat brain sections were prepared as described before. For [^{3}H]hemicholinium-3, sections were incubated for 60 min at 4°C in 50 mM Tris.HCl, pH 7.4 plus 300 mM NaCl and 20 nM [^{3}H]hemicholinium-3 in presence or absence of 10 µM hemicholinium-3 to determine the amount of specifically bound ligand. For [^{3}H]pirenzepine, sections were preincubated for 15 min in Krebs buffer followed by a 60 min incubation at 22°C in Krebs buffer with 10 nM [^{3}H]pirenzepine in presence or absence of 1 µM atropine to determine the amount of specifically bound ligand. At the end of the incubation period, slides were washed for six min ([^{3}H]hemicholinium-3) or 12 min ([^{3}H]pirenzepine) in cold incubation buffer. Slides were then juxtaposed against tritium-sensitive film for appropriate exposure. In many brain regions, [^{3}H]pirenzepine and [^{3}H]hemicholinium-3 binding sites are similarly distributed. High densities of sites are present in areas such as the striatum, nucleus accumbens, olfactory tubercule and superficial layers of the cortex. Low to moderate densities of sites are seen in the thalamus, hypothalamus and reticular portion of the brainstem. However, important differences are also observed. For example, high densities of [^{3}H]hemicholinium-3 binding sites are found in the habenula, superior colliculus and cerebellum, three regions devoid of [^{3}H]pirenzepine binding sites. In the hippocampus, the laminar distribution of [^{3}H]hemicholinium-3 binding sites correlates well with the localization of cholinergic terminals. [^{3}H]pirenzepine binding sites are not as discretely distributed in the hippocampus. These data demonstrate that [^{3}H]hemicholinium-3 and [^{3}H]pirenzepine could be used as respective pre- and post-synaptic markers of cholinergic nerve terminals in various brain regions but not in others.

199.2 EFFECT OF CONCANAVALIN A ON ACETYLCHOLINE RECEPTOR REDISTRIBUTION DURING NEUROMUSCULAR JUNCTION FORMATION IN CULTURE. Y.Kidokoro, B.Brass*, and H.Kuromi*
Jerry Lewis Neuromuscular Res. Ctr., UCLA School of Medicine, Los Angeles, CA. 90024

During neuromuscular junction formation acetylcholine receptors(AChR) accumulate at the nerve contact region. It has been shown that this is, at least partly,due to lateral migration of existing receptors in the membrane (Anderson,Cohen and Zorychta,1977). Randomly diffusing AChR molecules in the membrane may be trapped at the nerve-contact region to form a high receptor density area. If this were the major mechanism, cross-linking AChRs by tetravalent concanavalin A (Con A) should immobilize receptors and prevent nerve-induced receptor accumulation.

We examined the effect of Con A on nerve-induced accumulation and on the mobility of AChRs in cultured Xenopus muscle cells. ACh receptors were stained with rhodamine conjugated α-bungarotoxin. The cells were then briefly treated with Con A and neural tube cells were added to these cultures. The mobility of AChRs was measured by the fluorescence photobleaching recovery method. The Con A treatment prevented rapid diffusion of AChRs as well as nerve-induced receptor accumulation.In contrast, divalent succinyl Con A did not affect the mobility of AChRs nor prevented nerve-induced AChR accumulation. When the Con A concentration was varied the blocking effect on the nerve-induced receptor accumulation was inversely related with the mobile fraction of receptors. Newly inserted AChRs after the Con A treatment were found mobile and to accumulate to the nerve-contact region.In these cultures at some spots along the nerve contact, new receptors were accumulated surrounding old, immobilized ones. This observation suggests that new receptors were inserted elsewhere and migrated to the nerve-contact region surrounding immobilized old ones.

In addition to accumulation of receptors,the nerve disperses pre-existing receptor clusters prior to induction of high density regions along the contact area and at this early stage denervation disperses nerve-induced receptor clusters in Xenopus cultures. When cultures were treated with Con A both of these events did not occur, suggesting that these are also diffusion mediated.

Anderson,Cohen and Zorychta (1977) J.Physiol.268,731.

199.3 ATYPICAL ANTIPSYCHOTICS PROFILED BY DOPAMINE RELEASE SHOW PREFERENTIAL S_2 AND MESOLIMBIC D_2 POTENCIES WITH [3H]SPIPERONE AUTORADIOGRAPHY. C. A. Altar, P. L. Wood and A. M. Wasley*. Neurosci. Res., Pharm. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

We determined effects of atypical and typical antipsychotics on neostriatal dopamine (DA) release inferred from 3-methoxytyramine (3-MT) levels and turnover (DOPAC and HVA levels) and on the binding of [3H]spiroperidol to serotonin (S_2) and dopamine (D_2) sites throughout the cortex and basal ganglia.

Mice were injected with the ID_{50} dose for apomorphine-induced climbing (S. Gerhardt and J. Liebman, Pharmacologist, 25:129, 1983) and killed 80 min later. DA, DOPAC, HVA and 3-MT were determined by GC/MF with single ion monitoring (P. L. Wood, Biomed. Mass Spec. 9:302, 1982). N=6-9/group, * $p < 0.05$, ** $p < 0.01$:

	CAUDATE-PUTAMEN CONC. (% control)			
Neuroleptic (Climbing ID_{50})	3-MT	DOPAC	HVA	DA
Clozapine (8)	94	143	142	105
Thioridazine (5)	115	280*	174*	92
Chlorpromazine (2)	128*	180*	170*	85
Metoclopramide (2)	144**	373**	218**	94
Haloperidol (.12)	137*	368**	245**	55**

The atypical antipsychotics clozapine and thioridazine promoted the smallest, and haloperidol and metoclopramide (typicals), the largest increases in DA release (3-MT) or turnover (DOPAC, HVA). The potencies of these antipsychotics at S_2 sites in claustrum or layer V of motor cortex or D_2 sites in the caudate-putamen, nucleus accumbens, or olfactory tubercle were determined (C. A. Altar et al, J. Pharm. Exp. Ther. 233:1985).

The atypical antipsychotics were 2- or 3-fold more potent at D_2 sites in nucleus accumbens or olfactory tubercle than in caudate-putamen whereas the typicals were equipotent in these regions. The typicals were equal or more potent at D_2 than S_2 sites whereas the atypicals were 4- to 30-fold more potent at S_2 sites.

These data indicate that at behaviorally effective doses, atypical antipsychotics increase DA release and turnover less than typical antipsychotics. The considerable preference of clozapine and thioridazine for cortical S_2 sites and their small potency advantage at mesolimbic versus mesostriatal D_2 sites indicates that their atypical behavioral and neurochemical profiles may result from interactions with S_2 binding sites.

199.4 AUTORADIOGRAPHIC LOCALIZATION OF ^{3}H-METHYLPHENDIATE BINDING SITES IN THE RAT BRAIN. A.S. Unis, T.M. Dawson, D.R. Gehlert* and J.K. Wamsley. Depts. of Psych. and Pharm., University of Utah Medical Center, Salt Lake City, UT 84132.

Methylphenidate (MPH), a mild central nervous system stimulant used primarily in the treatment of attention deficit disorder (ADD), appears to exert its therapeutic effect by blocking the reuptake of dopamine by the presynaptic neuron. As such ^{3}H-MPH could be a marker for dopaminergic nerve terminals. Using the techniques of in vitro receptor autoradiography we have localized specific ^{3}H-MPH binding sites within the rat brain.

Ten micron-thick brain sections were incubated for 40 min. at 4°C in 25 nM ^{3}H-MPH (spec. act.=87Ci/mmol). Alternate sections were incubated in medium to which unlabeled MPH was added to a final concentration of 25µM. Autoradiograms were generated by apposing the slide-mounted tissue sections to tritium-sensitive film along with tritium-containing standards in X-ray cassettes and these were analyzed using computer-assisted microdensitometry.

Autoradiographic grains, representing specifically bound ^{3}H-MPH, were localized to several discrete brain areas. The highest specific binding was observed in the caudate-putamen, the olfactory tubercle, the median eminence, the bed nucleus stria terminalis and the nucleus accumbens. Low density, diffuse specific binding was also demonstrated in the frontal cortex and the dentate gyrus. The biochemical parameters of ^{3}H-MPH binding were similar to those obtained using tissue homogenates. Optimal specific binding occurred at 40 minutes and half of the specifically bound ^{3}H-MPH dissociated after 10 seconds. ^{3}H-MPH was not only displaced by unlabeled MPH but also by 25µM nomifensine which has also been shown to be a dopamine-reuptake blocker.

^{3}H-MPH appears to bind to areas in which there are high concentrations of dopamine nerve terminals and our results suggest that MPH is interacting primarily with dopaminergic pathways. Autoradiography can be used to characterize the ligand-binding site interactions and thus improve our understanding of the mechanisms of action of the psychostimulants.

199.5 **β_2-Adrenergic Receptors Are Specifically Associated with the "Whisker Barrels" in the Somatosensory Cortex of the Rat.** P. Vos*[1], D. Kaufman[2], E. Mansfield*[3] B.B. Wolfe[1] P.J. Hand[3], U. of Penn., Sch. of Med., [1]Dept. Pharmacol., [2]Inst. Neurol. Sci., [3] Sch. of Vet. Med., Dept. Animal Bio.

The primary neocortical representation of the mystacial vibrissae of the rat is located in the posteromedial barrel subfield of the somatosensory cortex (PMBSF). In lamina IV of the PMBSF this representation shows a one-to-one correspondence with the pattern of "whisker barrels" as seen in succinate dehydrogenase (SDH) stained tangential cortical sections. We now report that this same "whisker barrel" pattern is also observed for β_2-adrenergic receptors using the quantitative autoradiographic techniques developed by Rainbow et al. (PNAS, 1984)

Serial tangential sections (32 μ) were cut from the frozen brains of adult rats. Sections were thaw-mounted and prepared for autoradiography or SDH staining. The "whisker barrels" were located by staining every fifth section for SDH activity. Intervening sections were labelled for either: Total β- adrenergic receptor binding, β_1-adrenergic receptor binding, β_2-adrenergic receptor binding, or nonspecific binding.

Tangential cortical sections labelled for total β-adrenergic receptor binding revealed a diffuse pattern of binding with regions of slightly increased labelling in the PMBSF which seemed to correlate with SDH stained "whisker barrels" seen in adjacent sections. Cortical sections labelled for β_1-adrenergic receptor binding also revealed a diffuse pattern of receptor distribution. However, this pattern did not appear to correspond to the pattern of "whisker barrels" seen in SDH stained adjacent sections. Alternatively, cortical sections labelled for β_2-adrenergic receptors showed a discrete distribution of receptors in the PMBSF which closely correlated with the SDH stained "whisker barrels" seen in adjacent sections.

Deafferentation experiments were done to determine if the β_2-adrenergic receptor distribution was developmentally modifiable. In order to deafferent the "whisker barrels" unilaterally all mystacial vibrissae and underlying follicles were surgically removed from neonatal rats before postnatal day three. No significant changes were seen in the distribution of β_1-adrenergic receptors. A dramatic change, however, was observed in the distribution of β_2-adrenergic receptors in the PMBSF. Specifically, the altered SDH staining patterns of the "whisker barrels" observed after peripheral neonatal lesions corresponded to similarly deranged patterns of β_2-adrenergic receptors from adjacent sections. For example, total unilateral mystacial vibrissae follicle removal produced a five banded pattern in SDH stained sections. The same banded pattern was observed in adjacent sections labelled for β_2-adrenergic receptors. No discrete SDH stained or β_2-adrenergic receptor labelled "whisker barrels" were observed.

We conclude that a specific receptor subtype, the β_2-adrenergic receptor, is specifically associated with the vibrissae follicle representation in the PMBSF of the rat. It is suggested that the β_2-adrenergic receptors may be involved in the development of this cortical representation. Studies are currently under way to test this hypothesis.

199.6 IS KETANSERIN A SELECTIVE 5-HT_2 LIGAND? E.D. Mitchell*, D.R. Gehlert, J.K. Wamsley and T.M. Dawson (Spon: W. Stevens). Depts. of Psychiatry and Pharmacology, University of Utah School of Medicine, Salt Lake City, Utah 84132.

[^{3}H]-ketanserin is believed to be a ligand which is highly selective for the serotonin type 2 (5-HT_2) receptor. Recent homogenate binding studies have shown that 28% of [^{3}H]-ketanserin binding to the striatum, as defined with 10^{-6}M methysergide, is due to binding to the 5-HT_2 receptor, 10% of the binding is due to adrenergic alpha-1 receptors, and a negligible amount to histaminergic H-1 receptors (Leysen et al., Mol. Pharmacol. 21:301, 1982). Therefore, approximately 60% of the total binding cannot be accounted for by an interaction with 5-HT_2, alpha-1 or H-1 receptors.

[^{3}H]-Ketanserin was evaluated for its selectivity as a 5-HT_2 ligand in several discrete rat brain structures by combining the technique of quantitative autoradiography with classic saturation and competition experiments. Serial tissue sections from areas corresponding to the prefrontal cortex, substantia nigra, dorsal raphe and striatum were incubated with 2 nM [^{3}H]-ketanserin with varying concentrations of several 5-HT antagonists and uptake blockers, SCH 23390, prazosin and verapamil. In addition, several major classes of compounds were added at a 10^{-6}M concentration to the incubation media. Autoradiograms were produced by apposition of the labeled sections along with tritium standards to LKB Ultrofilm. Binding was quantified by using computer-assisted microdensitometry.

The binding of [^{3}H]-ketanserin to several brain regions was saturable and of high affinity. In the areas with the highest amount of [^{3}H]-ketanserin binding sites, such as the striatum, substantia nigra compacta and dorsal raphe, approximately 20% to 30% of the binding was due to an interaction with 5-HT_2 receptors. However, a majority of the binding was only displaceable by unlabeled ketanserin and demonstrated the presence of a "ketanserin recognition site." Imipramine, fluoxetine, SCH 23390, verapamil, and prazosin had K_i's in the micromolar range. Of the other compounds studied, an insignificant displacement was observed.

Selective lesioning of the catecholamine and serotonin containing neuronal systems using 6-hydroxydopamine (6-OHDA) and 5,7-dihydroxytryptamine (5,7-DHT) indicates that the "ketanserin recognition site" in several brain structures is presynaptic on catecholamine neurons (Dawson et al., in preparation). This observation coupled with the data presented here suggest that a majority of [^{3}H]-ketanserin binding is not interacting with the 5-HT system. Therefore, both in vivo and in vitro studies utilizing ketanserin as a selective 5-HT_2 ligand must be interpreted with caution, especially in experimental designs utilizing striatal preparations.

199.7 QUANTITATIVE AUTORADIOGRAPHY OF GUANINE NUCLEOTIDE BINDING SITES: COMPARISON WITH THE DISTRIBUTION OF ^{3}H-FORSKOLIN BINDING SITES. D.R. Gehlert, T.M. Dawson, H.I. Yamamura and J.K. Wamsley (Spon: B.I. Grosser). Depts. Psychiatry and Pharmacology, Univ. Utah Sch. Med., Salt Lake City, UT 84132 and Dept. Pharmacology, Univ. Arizona, Tucson, AZ 85724.

Second mesenger generation is an important component of central neurotransmission. Adenylate cyclase has often been implicated as a principal second mesenger for a number of neurotransmitter systems. The activity of adenylate cyclase is modulated by both neurotransmitters acting via specific receptors and guanine nucleotides acting via a nucleotide binding protein (N). Recently, we reported the distribution of high affinity binding sites for ^{3}H-forskolin, a potent stimulator of adenylate cyclase activity. This compound is believed to interact with a site on the catalytic subunit of adenylate cyclase. In order to determine the distribution of the N protein, we have labeled slide-mounted tissue sections with a radiolabeled guanine nucleotide analog to detect the presence of the N protein by quantitative autoradiography.

Ten micron tissue sections were labeled with 400nM ^{3}H-Gpp(NH)p. Nonspecific binding was assessed by adding a 100 micromolar concentration of unlabeled GTP to the incubation media. Labeling with ^{3}H-forskolin was accomplished according to a previously described protocol (Gehlert et al., Eur. J. Pharmacol. 106:223, 1984: Brain Res., in press). Dry, labeled tissue sections along with tritium standards were apposed to LKB Ultrofilm (Rockville, MD). Binding was quantitated using a DADS-560 (Stahl Res., Rochester, N.Y.) microdensitometry system.

Initial biochemical studies indicated that ^{3}H-Gpp(NH)p binding rapidly reached equilibrium at 25°C and slowly dissociated at 4°C. By optimizing these binding conditions we were able to obtain 99% specific binding to slide-mounted tissue sections. As previously reported, high affinity ^{3}H-forskolin binding sites were found primarily in structures in the basal gangila such as the caudate-putamen, nucleus accumbens, olfactory tubercle and substantia nigra. Binding was also detected in discrete regions of the hippocampal formation and in the molecular layer of the cerebellum. In contrast, ^{3}H-Gpp(NH)p bound to a variety of brain structures not only in the basal gangila, but also in brain regions such as the cerebral cortex, thalamus, hypothalamus, brainstem and olfactory bulb; regions where ^{3}H-forskolin binding was relatively low. Therefore, high densities of ^{3}H-forskolin binding sites were present in only a few of the areas which contain the N protein. These results indicate that the N protein is present in brain regions which do not contain high densities of "forskolin-identified" adenylate cyclase.

200.1 NEUROTRANSMITTER PLASTICITY IN CHOLINERGIC NEURONS: ACCUMULATION OF CATECHOLAMINES BY TRANSPLANTED CILIARY NEURONS. J.N. Coulombe and M. Bronner-Fraser, Depts. of Devel. and Cell Biology, and Physiology and Biophysics, Univ. of California, Irvine, CA. 92717

Under appropriate conditions, post-mitotic sympathetic neurons can acquire cholinergic traits. Here, we examine whether the reciprocal transition can occur; i.e. can cholinergic neurons acquire adrenergic properties? We have developed techniques for selectively labeling cholinergic ciliary neurons, using retrogradely transported fluorescent latex microspheres. These cells are then microinjected into regions of the avian embryo where neural crest cells normally give to rise to sympathetic ganglia and adrenomedullary cells.

Fluorescent latex microspheres (0.05 to 0.2 microns) were injected into the iris and ciliary body of eyes from 6½ day quail embryos. The microspheres were retrogradely transported from these target sites to a subpopulation of cholinergic neurons (approximately 20%) in the ciliary ganglion. Only ganglion cells with large cell bodies (characteristic of neurons) were labeled by the latex microspheres. Those cells containing latex microspheres also stained with antisera recognizing neurofilament proteins, indicating that the labeled cells are, in fact, neurons. The important advantage of this technique is that only differentiated neurons which have sent axons toward their target tissues are labeled with the retrograde marker.

Microsphere labeled ganglia were dissociated into a suspension of single cells and microinjected into the trunk region of 2½ day chicken embryos. Embryos were allowed to develop for an additional 4 days during which neural crest cells had coalesced and differentiated into adrenergic derivatives. They were then freeze-dried, processed for catecholamine histofluorescence, and serially sectioned. Those neurons labeled with latex microspheres were easily recognizable by their intense, punctate, reddish-yellow fluorescence.

In these embryos, cholinergic ciliary neurons survived and translocated to neural crest-derived structures. Heavily labeled cells were primarily found in the region surrounding the dorsal aorta, where sympathetic ganglia, adrenal gland, and aortic plexuses form. As a control, embryos were injected with unlabeled ciliary ganglion cells together with cell debris containing latex microspheres. No cells labeled with multiple microspheres were found in these controls. Thus, the the microsphere label is not acquired by previously unlabeled cells during either transplantation or incubation in the host.

To date, 13 cells in 5 different embryos have been identified that contain both fluorescent latex microspheres and catecholamine histofluorescence. Thus, the previously cholinergic ciliary neurons have acquired catecholamine stores. Our results suggest that some cholinergic neurons are able to acquire adrenergic neurotransmitters in the proper embryonic environment. (NIH HD15527-04 and Basic Research Grant 1-896 from the March of Dimes)

200.2 DEVELOPMENT OF TYROSINE HYDROXYLASE IMMUNOREACTIVITY IN NEURONS OF THE PARASYMPATHETIC SPHENOPALATINE GANGLION IN THE RAT G.G. Leblanc* and S.C. Landis (SPON: J. Dodd). Dept. of Neurobiol., Harvard Medical School, Boston, MA 02115.

Some populations of parasympathetic neurons express one or more adrenergic traits. For instance, tyrosine hydroxylase immunoreactivity (TH-IR) is expressed in subpopulations of neurons in the ciliary ganglia of adult rats (Landis et al., Soc. Abs. 9, 937) and embryonic chicks (Teitelman et al., J. Neurosci. 5, 29). Most of the neurons in the submandibular ganglion of adult rats exhibit dopamine-beta-hydroxylase-IR (Grznna and Coyle, Brain Res. 151, 206).

As a first step toward understanding the factors which cause the expression of adrenergic traits in parasympathetic neurons, we examined the time of onset of these traits in the rat sphenopalatine ganglion (SPG). The SPG is a cranial parasympathetic ganglion which innervates the nasal mucosa, lacrimal glands, and palate. The SPG seemed particularly well suited to developmental studies because, unlike most rat parasympathetic ganglia, it is large and relatively discrete.

TH immunoreactivity is present in a small proportion (less than 5%) of principal neurons in the adult SPG. The TH-IR neurons resemble other SPG neurons in size and morphology, and are clearly distinct from SIF cells, which are also present in the SPG. In order to determine when TH-IR first appears in SPG neurons, the ganglion was located in sections of embryonic rat heads using either acetylcholinesterase (AChE) staining or an antiserum which recognizes neurofilament protein. No TH-IR neurons were seen in the SPG of E16.5 embryos, although ganglionic condensation appeared nearly complete at this stage, and AChE staining revealed bundles of processes issuing from the ganglion. By E18.5, a few TH-IR neurons were present near the rostral pole of the ganglion. The number of TH-IR neurons in the SPG reached a peak around postnatal day 1. In fact, preliminary cell counts suggest that the proportion of TH-IR neurons in the newborn SPG is at least twice that observed in the adult. SIF cells, on the other hand, were far less numerous in the newborn than the adult SPG.

The expression of adrenergic traits in sympathetic neurons is thought to depend on signals received by the precursors of these neurons during their migration from the neural crest. Thus, sympathoblasts express TH-IR as soon as they begin to condense into ganglia. In contrast, TH-IR does not appear in parasympathetic SPG neurons until several days after ganglionic condensation has begun, and at least two days after the initiation of process formation. Interestingly, TH-IR neurons are not evenly distributed in the neonatal SPG, but rather appear to be concentrated in the ventral half of the ganglion. We are therefore examining the possibility that the TH-IR neurons share a common target structure.

200.3 THE EXPRESSION OF CATECHOLAMINE ENZYMES BY NEOCORTICAL NEURONS. L.M. SMITH, T.H. JOH, AND F.F. EBNER. Center for Neural Science, Brown University, Providence, R.I. and Department of Neurology, Cornell University Medical College, New York, N.Y.

Tyrosine hydroxylase (TH) is the initial and rate limiting enzyme in catecholamine synthesis and is first expressed on embryonic day 12 (E12) in the developing rat brain. A few cell processes are labeled transiently with TH immunocytochemistry in the ventricular zone of the telencephalic vesicle from E12 to E16. In addition, a few cell bodies become TH-positive near the olfactory bulb for 1 or 2 days around E18. However, with this exception neocortex never contains TH-positive neurons either in the developing or in the adult brain.

In contrast to normal development, we have found that when neocortex is removed from the anlage of mouse sensory-motor cortex and placed in a comparable area of adult mouse neocortex, it develops cells that express TH for months and presumably for the lifetime of the adult host. Over half of the implanted cells develop TH-immunoreactivity if the embryos are very young (E12-13). Embryos that are older at the time of surgery give rise to progressively fewer labeled cells, until by the age of E19 no cells are induced to express TH. The TH-positive neocortical cells never show catecholamine fluorescence. Embryonic hippocampal cells do not express TH under these conditions.

We have now examined other catecholamine enzymes to determine why the TH-positive cells do not show catecholamine fluorescence. Only a small number of transplanted cells ever develop immunoreactivity to aromatic-L-amino acid decarboxylase, and none has been immunocytochemically labeled at any donor age with antisera to dopamine-B-hydroxylase or phenethanolamine-N-methyltransferase.

This is the first demonstration of a set of conditions that induces the expression of TH in CNS cells which normally never synthesize this enzyme. Inducing TH enzyme synthesis depends upon the state of differentiation of the embryonic neocortical cells when they are placed in the adult neocortex. TH is the only one of four main catecholamine enzymes that is induced under these conditions. The enzyme induction initiated by embryonic cells growing in adult neocortex appears to be specific for neocortical cells, since hippocampal cells are not similarly affected when they are required to differentiate in adult neocortex. (supported by grant #NS-13031)

200.4 EMBRYONIC RAT CEREBRAL CORTICAL CELLS EXPRESS TYROSINE HYDROXYLASE IN TISSUE CULTURE. L. Iacovitti, J. Lee*, T.H. Joh and D.J. Reis. Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

The neurotransmitter phenotype expressed by peripheral autonomic neurons remains labile during development in vivo and in vitro. In the present study, we sought to determine whether neurotransmitter phenotypic plasticity is also characteristic of neurons of the central nervous system. Although intrinsic catecholaminergic (CA) cells have not been observed in rat cerebral cortex in vivo (Specht et al., J. Comp. Neurol. 199:255-276, 1981), cultures of chick cortex develop activity for the CA enzyme, tyrosine hydroxylase (TH) (Arnold and Vernadakis, Dev. Neurosci. 2:46-50, 1979; Pettmann et al., Nature 2:46-50, 1979) and transplants of rat cortex contain numerous TH-immunoreactive cells (Ebner et al., submitted for publication, 1985). We further examined whether the central neurons of the cerebral cortex could be influenced by environmental factors in culture to express other CA phenotypic traits.

Whole brains removed from embryonic day (E) 14, 16 or 18 rat were fixed, sectioned and processed for the immunocytochemical localization to TH according to the PAP method. In agreement with previous reports, sections of cortex did not contain intrinsic TH-immunoreactive cells at any of the times examined. However, when cortices from E14 rat were dissociated into single cells, plated on collagen-coated dishes at a density of 2 cortices/dish and maintained on feed supplemented with 10% fetal calf serum, we found that a population of approximately 500 cells/dish were TH immunoreactive after only 3 days in vitro. These cells had a darkly stained rim of cytoplasm surrounding a large nucleus and, in many cases, extended long varicose stained processes. Cultures of rat cortex isolated from older embryos (E16 or E18) contained only an occasional TH immunoreactive cell. To test whether contact with older brain or substances released by it prevent the expression of TH in cortical cells, co-cultures were established consisting of both E14 and E18 cerebral cortex. After 5 days in vitro, co-cultures contained the same number (500/dish) of TH immunoreactive cells as was seen in cultures comprised of E14 cortex only.

In contrast to rat, cultures established from E8 chick cortex did not contain any TH immunoreactive cells even at 7 and 14 days in vitro, suggesting that either by E8 chick cortex is developmentally too advanced or that chick cortical cells are incapable of TH expression.

The results of these studies indicate that a) a subpopulation of early embryonic rat cortical cells can express a trait which is characteristic of a CA phenotype but that this ability is lost in older embryos and b) neither contact with older cortex nor substances released by it inhibit the expression of TH in young cortical cells in culture. Since TH immunoreactivity is not observed in the rat cortex in vivo, our findings further suggest that certain classes of central cells, like peripheral cells, can respond to environmental cues in culture and express traits fo a novel neurotransmitter phenotype. (Supported by NSF Grant PCM-8303019.)

200.5 TARGET INFLUENCES ON TRANSMITTER CHOICE BY SYMPATHETIC NEURONS DEVELOPING IN OCULO. L.M. Stevens* and S.C. Landis. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

The sympathetic fibers which innervate rat sweat glands (SGs) are initially noradrenergic and undergo a transition in which they acquire cholinergic properties as their noradrenergic traits become diminished. Experiments on cultured sympathetic neurons have shown that a similar switch in transmitter status can be induced by factors secreted by non-neuronal cells. To examine the possibility that the SGs promote the development of cholinergic properties in those neurons which innervate them, we caused the glands to become innervated by sympathetic neurons which would normally develop noradrenergically. SGs and superior cervical ganglia (SCG) from one day-old rat pups were grown in the anterior eye chamber of 6 week-old host rats using the transplantation technique devised by Olson and Malmfors (Acta physiol. scand. Suppl. 348, 1970).

Glands developed in footpad tissue which was transplanted without an accompanying ganglion, but they did not become innervated by the nerve supply of the host iris. Ten to 12 days after ganglia and footpads were co-transplanted, the developing glands had become innervated by fibers which exhibited both acetylcholinesterase (AChE) activity and catecholamine (CA) fluorescence, a dual phenotype also seen during the normal development of the gland innervation in situ. By 28 days after co-transplantation, the AChE-positive fiber plexus surrounding the glands no longer demonstrated CA fluorescence. The development of AChE activity and the loss of CA fluorescence in the transplanted glands parallels the development of the innervation in situ. Biochemical and immunocytochemical studies are in progress to characterize further the transmitter status of the transplant innervation. The small percentage of transplanted neurons surviving at 28 days exhibited strong AChE activity and did not contain endogenous CAs. We believe that these neurons are the source of the gland innervation; to verify this we are currently sympathetically and parasympathetically denervating the host iris prior to assay.

To determine whether this change in phenotype is specific to the SGs, we are growing SCG in the anterior chamber with targets which receive only noradrenergic sympathetic innervation. In preliminary experiments in which SCG were grown with pineal gland for 28 days, both the gland innervation and the neurons exhibited prominent CA fluorescence. These results suggest that the change in phenotype seen in the innervation of the transplanted SGs is due to a specific influence of the glands and is not a result of growth in the anterior chamber. This raises the possibility that during the normal development of the SGs, the noradrenergic neurons which innervate the glands are induced by the target to differentiate cholinergically.

200.6 PURIFICATION OF A GLYCOPROTEIN WHICH CONTROLS TRANSMITTER CHOICE. Keiko Fukada. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Individual neurons can be plastic with respect to transmitter phenotype (Patterson, P.H., Ann. Rev. Neurosci. 1:1, 1978). The existence of a diffusible factor which controls the choice of transmitter in developing sympathetic neurons, without affecting neuronal survival or growth, has been demonstrated in culture studies. Moreover, in vivo studies have shown that the transition from the noradrenergic to the cholinergic phenotype demonstrated in culture actually occurs in vivo as part of the normal development of sympathetic cholinergic neurons (Landis, S., Fed. Proc. 49:1633, 1983). In order to understand the molecular mechanism of such plasticity and the role of the cholinergic factor in development, it is essential to purify the molecule.

The cholinergic factor is obtained from conditioned medium (CM) prepared by incubation of serum-free, hormone-supplemented medium on cultures of rat heart cells (Fukada, K., Nature 287:555, 1980). Using column chromatography and SDS-PAGE, $>10^5$-fold purification in specific activity has been achieved with a reasonable recovery. The most purified fraction is active at <10 ng/ml and retains the ability to both inhibit the development of noradrenergic characteristics as well as to induce cholinergic differentiation. The activity has the same apparent molecular weight of 45 Kd under denaturing and native conditions, suggesting that the factor is a single subunit. The 45 Kd area where activity resides on the SDS gel is only faintly stained by silver methods, and it is not labeled by the Chloramine T, Iodogen or lactoperoxidase methods. However, the Bolton-Hunter (B-H) reagent does label this area. That the labeled 45 Kd protein is the cholinergic factor is strongly suggested by the following recent results. (i) The activity and the iodinated 45 Kd protein are both sensitive to trypsin but not to chymotrypsin and the 45 Kd protein is only labeled by B-H iodination which labels lysine residues. (ii) When the iodinated Sephadex fraction is analyzed by 2-D gel electrophoresis, five discrete labeled spots of different charge are seen in the 45 Kd region. Each of these ^{125}I-labeled spots precisely lines up with the five activity peaks in the second dimension. (iii) Cleavage of the labeled 45 Kd protein with endoglycosidase F (Endo F) gives six discrete bands of different MWs on 1-D gels. When Endo F is allowed to exhaustively digest the labeled 45 Kd protein, only the lowest MW band of the six is found, and the cholinergic activity comigrates with this 22 Kd protein. Thus, the cholinergic factor is a slightly basic molecule whose core protein is composed of a single polypeptide of 22 Kd, and the biological activity resides in the protein moiety. (Supported by grants to P.H. Patterson from the NINCDS and the McKnight Foundation)

200.7 DIFFERENTIAL REGULATION OF CHOLINERGIC AND PEPTIDERGIC DEVELOPMENT IN THE RAT STRIATUM IN CULTURE. J.A.Kessler. Lab. of Developmental Neurobiology, Albert Einstein College of Medicine, Bronx, New York 10461.

The development of substance P, somatostatin, and choline acetyltransferase activity was examined in embryonic rat striatum in vivo and in culture. Choline acetyltransferase was present in striatum before gestational day 13.5 (E13.5), and enzyme levels increased continually between E13.5 and birth. By contrast, substance P and somatostatin did not develop in vivo until E15, and peptide levels fluctuated between E15 and birth. However cultured striatal neurons from E13.5 embryos expressed substance P and somatostatin de novo after several days in culture, and peptide levels and choline acetyltransferase activity increased significantly in vitro. Insulin was required for substance P expression in culture but not for development of somatostatin or choline acetyltransferase activity. Treatment with potassium (35mEq) to depolarize neuronal membranes significantly increased choline acetyltransferase activity, but significantly decreased levels of substance P and somatostatin. Co-culture of striatal neurons with ventral mesencephalon (substantia nigra) significantly increased choline acetyltransferase activity and substance P levels but had no significant effect on levels of somatostatin. Co-culture of striatum and substantia nigra also stimulated development of tyrosine hydroxylase in nigral neurons. Finally, medium conditioned by exposure to one of a variety of cell types had widely differing effects on development of substance P, somatostatin, and choline acetyltransferase in cultured striatal neurons. Moreover, treatment with a purified factor found in human, bovine, and rat tissues elevated choline acetyltransferase activity and substance P but not somatostatin in cultured striatum. Our observations suggest that different populations of neurons in the striatum are regulated by different mechanisms, so that alterations in the environment may produce strikingly different responses in the develoment of different phenotypic traits within the same structure.

200.8 PEPTIDE REGULATION OF CATECHOLAMINERGIC TRANSMITTER METABOLISM IN PRIMARY SENSORY NEURONS IN VITRO. D.M. Katz, J.E. Adler, and I.B. Black. Cornell Med. Coll. New York, NY 10021.

Catecholaminergic (CA) phenotypic expression in the mature peripheral nervous system is now known to extend beyond the sympathoadrenal axis. As we have previously shown, primary sensory neurons in the nodose and petrosal (NP) cranial nerve ganglia also express functional CA traits, including catalytically active tyrosine hydroxylase (TH), formaldehyde induced CA fluorescence, and sensitivity of CA levels to monoamine oxidase inhibition (Katz, et al., PNAS, '83). It is not known, however, whether sensory and sympathetic CA neurons, differing markedly in function, morphology and presumptive embryonic origin, express similar mechanisms of CA phenotypic regulation.

In sympathetic neurons, TH activity is regulated by specific trans-synaptic stimuli, including cholinergic and peptidergic depolarizing agents (Kessler, et al., '83; Ip, et al., '83). To define the potential role of depolarizing stimuli in sensory CA regulation, initial experiments examined TH activity in NP explant cultures grown in the presence or absence of depolarizing concentrations of potassium (K+). After one week in 40mM K+, TH activity was increased 2-3 fold over controls. Total protein was unchanged, indicating that enzyme specific activity rose, and suggesting that the increase was not due to increased cell survival. Thus, these data suggest that depolarizing stimuli may normally play a role in sensory CA regulation.

To determine whether agents known to activate NP neurons in vivo also increase sensory TH activity, we examined the effects of the stable Substance P (SP) agonist, Sar-SP. The peptide dramatically increases impulse activity in petrosal afferents in vivo (Prabhakar, et al, '84), and is immunocytochemically detectable in glomus cells, presynaptic to NP neurons (present study). Exposure to 10^{-6}M Sar-SP for one week increased TH activity in NP cultures, mimicking the effect of high extracellular K+. These data suggest that peptide ligands regulate sensory, as well as sympathetic, CA metabolism. Consequently, catecholaminergic sensory neurons may be subject to orthograde trans-synaptic regulation by peptides of peripheral target origin. (Supported by American Heart Assoc. and Dysautonomia Fndtn., Inc.).

200.9 ENVIRONMENTAL REGULATION OF NEUROTRANSMITTER GENE TRANSCRIPTION. K. Spiegel and J.A. Kessler (SPON: G.S.F.Ling). Laboratory of Developmental Neurobiology, Albert Einstein College of Medicine, Bronx, New York 10461.

The role of the environment in regulating gene transcription of neurotransmitter traits was examined in pure neuronal cultures of the neonatal rat sympathetic superior cervical ganglion (SCG). Previous studies have shown that the expression of tranmitter phenotype is influenced both qualitatively and quantitatively by the environment of the neuron. However, it is not known whether this phenotypic plasticity reflects transcriptional, translational, or post-translational events. To define the mechanisms regulating transmitter expression, somatostatin (SS) and tyrosine hydroxylase (TH) levels and levels of their messenger RNA's (mRNA's) were examined in SCG neurons cultured in different environments.

Sympathetic neurons cultured for two weeks in control medium ($F_{12}FCS_{10}$) developed substantial levels of both somatostatin (2.9 fg per neuron) and tyrosine hydroxylase activity (2.7 fmole product per neuron minute). However, cultures in the presence of elevated potassium (35 meq) to depolarize neuronal membranes reduced somatostatin to negligible levels (0.1) but increased TH activity (4.4). Northern blot analysis of mRNA levels demonstrated that potassium treatment greatly reduced levels of SS mRNA, in parallel with the decrease in neuronal SS levels. Conversely, the potassium-induced increase in TH activity was accompanied by an increase in TH mRNA, suggesting that membrane depolarization regulated gene transcription of both SS and TH.

In contrast to the stimulatory effects of potassium treatment on noradrenergic traits, exposure of sympathetic neurons to medium conditioned by non-neuronal cells decreased noradrenergic development while enhancing cholinergic expression. To determine whether conditioned medium also altered neurotransmitter gene transciption, TH mRNA levels were examined in sympathetic neurons cultured in medium conditioned by human fibroblasts (FCM). Exposure to FCM increased cholinergic expression (choline acetyltransferase activity) but decreased TH activity by 45%. Northern blot analysis demonstrated a corresponding decrease in TH mRNA in cultures exposed to conditioned medium. Our results suggest that the environment of a neuron may influence neurotransmitter phenotypic expression by regulating gene transcription.

200.10 DEPOLARIZATION REGULATES THE LEVEL OF PREPROTACHYKININ MESSENGER RNA IN THE CULTURED SUPERIOR CERVICAL GANGLION. A.H. Roach*, J.E. Adler, J. Krause and I.B. Black (SPON: E. DiCicco-Bloom). Cornell Med. Coll., New York, NY 10021, and Dept. of Anatomy and Neurobiology, Washington Univ., St. Louis, MO 63110.

Multiple neurotransmitters have been demonstrated within single neurons of many classes. These findings raise questions concerning the patterns and mechanisms of regulation of the individual transmitter types both during development and in maturity. The rat superior cervical ganglion (SCG) is a simple model system in which single neurons produce both substance P (SP) and norepinephrine (NE). Decentralization in vivo, or explantation to culture (with consequent denervation) elicit an increase of up to 40-fold in ganglion SP levels. In contrast, tyrosine hydroxylase, the rate-limiting enzyme in NE biosynthesis, does not increase. The recent cloning of cDNA copies of the messenger RNAs (mRNAs) for the preprotachykinins, the precursors of SP (Krause, this volume), now allows study of underlying mRNA synthetic and processing mechanisms.

Previous work has shown that explanted ganglia exhibit small increases in SP content after 12 hours in culture, but achieve a 40-fold rise by the fourth day. In the present studies, we report that PPT mRNA increased significantly by RNA blot analysis after only six hours in culture, well before an increase in SP was detectable. PPT mRNA levels reached a maximum after 24 hours and declined thereafter to lower steady-state values. Camptothecin and actinomycin D, inhibitors of RNA synthesis previously shown to prevent SP elevation, also prevented the increase of PPT mRNA in the present experiments. Moreover, veratridine, which depolarizes neurons in culture by increasing sodium channel conductance, prevented the rise in SP, and also prevented the increase in PPT mRNA in the current studies. Finally, tetrodotoxin, which blocks the same sodium channels, simultaneously prevented the effects of veratridine on both peptide and mRNA levels.

The sequential increases in PPT mRNA and SP, in conjunction with the effects of RNA synthesis inhibitors, suggest that the elevation of SP reflects altered expression of the PPT gene. Our observations further suggest that depolarization changes the pattern of PPT gene expression in sympathetic neurons. We are presently exploring underlying mechanisms. BEHAVIORAL PHARMACOLOGY: AMINERGIC SYSTEMS

201.1 QUANTITATIVE AND QUALITATIVE DIFFERENCES BETWEEN THE DOPAMINE SYSTEMS INVOLVED IN YAWNING AND FORWARD LOCOMOTION IN THE RAT. J.M. van Rooyen and J. Offermeier. Dept. of Pharmacology and MRC Research Unit for the Design of Catecholaminergic Drugs, Potchefstroom University, Potchefstroom 2520, South Africa

Piribedil and apomorphine dose-dependently increase yawning and forward locomotion in rats. The maximal increases of yawning occur at intraperitoneal (ip) doses of 5mg/Kg piribedil and 0,5mg/Kg apomorphine respectively while the maximal increases for locomotion occur at ip doses of 50mg/Kg piribedil and 5mg/Kg apomorphine. The maximal increases of yawning and of locomotion produced by piribedil is greater than the maximal increases produced by apomorphine.

Metoclopramide (1,6 - 3,2mg/Kg) antagonizes piribedil- and apomorphine-induced yawning. Metoclopramide (1,6mg/Kg) potentiates apomorphine- but not piribedil-induced locomotion. Metoclopramide (16mg/Kg) antagonizes both piribedil- and apomorphine-induced locomotion.

Reserpine pretreatment attenuates piribedil-induced yawning, apomorphine-induced yawning and piribedil-induced locomotion but potentiates apomorphine-induced locomotion.

Atropine pretreatment (0,625 - 10mg/Kg) dose-dependently antagonizes piribedil- and apomorphine-induced yawning. Atropine pretreatment (10mg/Kg) does not alter apomorphine-induced locomotion but potentiates piribedil-induced locomotion.

These data suggest a partial agonistic action of apomorphine on the dopamine receptors involved in yawning and in locomotion. The dopamine system involved in piribedil-induced locomotion appears to differ from the system responsible for apomorphine-induced locomotion.

201.2 QUANTITATIVE BEHAVIORAL ANALYSIS OF DOPAMINERGIC SUPER- AND SUB-SENSITIVITY: METHODOLOGY AND COMPUTER SIMULATION FOR CONTINUOUS AND CATEGORICAL RESPONSE VARIABLES. P.K. Randall, Dept. of Physiology and Biophysics, USC Sch. of Med. and Andrus Gerontology Ctr. U.S.C., Los Angeles, CA 90089

Quantitative analyses of a DA agonist- and antagonist-induced behavior in a number of preparations involving alterations in DA receptor number are presented. In general the degree to which variation in receptor number leads to predictable consequences in behavioral response is highly dependent upon the model system used. Changes in apomorphine-induced stereotypic behavior in the mouse resulting from chronic haloperidol treatment for example, are highly consistent with the moderate increases in DA receptor number usually reported (a 1.5 -fold shift in a family of logistic dose response curves representing individual components of the response). Selective depletion of striatal DA, in the striatal output lesion model has similar consequences. However, chronic agonist treatment, strain differences in receptor number, and selective striatal depletion produce very different alterations in agonist dose-response curves for stereotypic behavior which are difficult at present to resolve with measurements of DA receptor number.

Computer simulations of both continuous and categorical response variables based on receptor binding equations and classical "null" pharmacological methodology suggest that experimental design and data analysis procedures must be highly optimized to discriminate between different models and to test quantitative predictions made from them. Analysis of variance techniques, for example, are much less powerful than weighted least-squares, non-linear curve-fitting in detecting the behavioral consequences of moderate alterations in receptor number when a full agonist is used as a test substance. Multivariate extensions of "null" methods for agonist affinity, and competitive and functional antagonists are suggested as the appropriate models for experiments of this type.

201.3 SPECIFIC [^{3}H] MAZINDOL AND [^{3}H] P-CHLOROAMPHETAMINE BINDING SITES IN THE HYPOTHALAMUS: CORRELATION WITH ANORECTIC PROPERTIES OF PHENYLETHYLAMINES I. Angel*, M.D. Luu*, R. Hauger*, B. Giblin*, P. Skolnick, and S.M. Paul* (SPON: M. Goldman). Sections on Molecular Pharmacology and Preclinical Studies, Clinical Neuroscience Branch, National Institute of Mental Health, Bldg. 10, Room 4N214, 9000 Rockville Pike, Bethesda, Maryland 20205 USA

Specific and saturable binding sites for the anorectic drug mazindol were demonstrated in crude synaptosomal membranes from rat hypothalamus. The kinetic analysis of specific [^{3}H] mazindol binding revealed a single class of binding sites with an apparent affinity constant (Kd) of 9.3 ± 1.4 μM and maximum number of binding sites (B_{max}) of 433 ± 88 pmol/mg protein (n = 12). The association and dissociation of [^{3}H] mazindol to synaptosomal membranes were very rapid. Specific binding reached equilibrium in approximately 15 min. and dissociation was complete by approximately 2 min. Specific binding was temperature sensitive, labile to preincubation with proteolytic enzymes, and inhibited by physiological concentrations of NaCl. Subcellular fractionation of crude brain homogenates revealed that specific binding was highly enriched in the synaptosomal fraction with very low levels of binding detected in nuclei or mitochrondria. Specific [^{3}H] mazindol binding is also unevenly distributed in brain with the highest binding observed in the hypothalamus and brain stem. In most peripheral organs, such as the liver and kidney, only low levels of binding were detected whereas the adrenal gland had relatively high levels of specific binding. The characteristics of [^{3}H] mazindol binding were very similar to the previously described [^{3}H] amphetamine binding site and the relative potencies of a series of drugs in inhibiting both ligands were highly correlated. Moreover, structure activity studies revealed a good correlation ($r = .84$, $p < 0.01$) between the potencies of a series (n = 15) of phenylethylamine-like drugs in inhibiting specific [^{3}H] mazindol binding and reducing food intake (anorectic potencies) but not with their motor stimulatory effects nor their potencies in inhibiting drinking behavior. In related experiments saturable and low affinity (Kd 4μM) binding sites for [^{3}H] p-chloroamphetamine were also demonstrated in rat hypothalamic membranes. These binding sites had virtually identical structure-activity characteristics as the [^{3}H] mazindol binding sites and a good correlation existed between the inhibitory potencies of a series of compounds at displacing both ligands. Our results suggest the presence of novel recognition sites for mazindol and p chloroamphetamine in brain that appear to mediate the anorectic actions of mazindol and various phenylethylamine derivatives. Preliminary data suggests that these low affinity (high capacity) binding sites are associated with a membrane-bound enzyme.

201.4 EFFECTS OF CLONIDINE ON THE MOTOR SYNDROME OF THE GENETICALLY DYSTONIC RAT. J. Lutes, J. F. Lorden, and G. A. Oltmans, Dept. Psych., Univ. Alabama at Birmingham, AL 35294; and Dept. Pharmacol., Chicago Med. Sch., No. Chicago, IL 60064.

The dystonic (dt) rat displays an inherited neurological disorder characterized by sustained twisting movements, frequent falls to the side, hyperflexion of the trunk, poor limb placement during locomotion, and self-clasping the hindlimbs and forelimbs. Steady state levels of norepinephrine (NE) are elevated in the cerebellum of the dt rat around the time that clinical signs begin to appear. Forebrain terminal fields of the locus coeruleus are unaffected; however, recent studies on this mutant suggest that NE levels are also increased in the spinal cord. Therefore, we have attempted to modify the motor syndrome of the dystonic rat with adrenergic drugs.

Sixteen to 20 day old dystonic rats were observed in a open field for three 3-min periods: prior to injection and 20 and 40 min postinjection. During each period, the number of axial twisting movements, falls, and paw clasps was counted. Three doses (.05, .1, and .3 mg/kg, i.p.) of the alpha 2 adrenergic agonist clonidine were administered to separate groups of rats (N = 8/group). Clonidine decreased the characteristic movements and postures of the mutant rats. At the two highest doses, all dystonic movements were affected. However, the tendency of the dystonic rats to fall to the side and hold their limbs rigidly extended was significantly reduced even at the lowest dose. Two additional groups of mutants were tested in an open field for 3 min prior to drug injection. Immediately after, they were given 2 or 4 mg/kg, i.p., of rauwolscine, the alpha 2 receptor antagonist. Twenty min later, the rats were again examined in the open field and injected with .05 mg/kg of clonidine. The final observation period took place 20 min later. Rauwolscine alone had no effect on the movements of the mutant rats, but blocked the clonidine effect.

The effect of clonidine on gross locomotor activity was also quantified. After a 30 min habituation period to the photocell chambers, normal and dystonic rats were given injections of saline or clonidine. Although the .3 mg/kg dose produced a general suppression of activity in the 40 min following the injection, the lowest dose increased activity. Thus, the effects of clonidine on the falls and hindlimb extension of the dystonic rats cannot be attributed simply to a general suppression of movement. The effects on clonidine in conjunction with the alterations in NE levels in the cerebellum and spinal cord of the dt rat suggest that central NE mechanisms may be involved in the motor syndrome of the mutant. This is interesting in light of reports of altered NE metabolism in humans with inherited dystonia. (Supported by NS 18062 and the Alabama Consumer Research Fund.)

201.5 CHLORPROMAZINE: EFFECTS ON THE DETECTION OF NON-REWARDING BRAIN STIMULATION. J.E.G. Williams and C. Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118

Previous experiments in our laboratory demonstrated that chlorpromazine (CPZ) raises the threshold for rewarding brain stimulation to the medial forebrain bundle-lateral hypothalamic (MFB-LH) (Esposito, R.U. et al, Pharmacol. Biochem. Behav. 15(6):903-905, 1981). In order to determine whether or not these threshold changes are due to actions on a motivational system rather than alterations in attentional or perceptual processes the effects of CPZ on the detection of stimulation to this same brain site were determined. In addition to thresholds, intertrial responding and latency of response as a measure of the psychomotor effects of CPZ were recorded. The threshold level of stimulation for detection as employed in this procedure is by itself neither positively nor negatively reinforcing, however, this level of stimulation can be used as a discriminative stimulus in a simple instrumental task.

Bipolar stainless steel electrodes were stereotaxically implanted in male albino rats (CDF-Charles River Laboratories). Electrodes were aimed bilaterally at the MFB-LH. Following surgery, the animals were trained in a rate-independent procedure to make an instrumental response to a non-reinforcing 0.5 sec MFB-LH stimulation cue (S1). Responding to the cue within 5 sec was maintained by the delivery of a positively reinforcing stimulus (S2) to the contralateral MFB-LH area. Absolute detection thresholds were determined by varying the current intensity of the brain stimulation cue (S1) according to a modification of the psychophysical method of constant stimuli. The reinforcing stimulus (S2) remained at a fixed highly rewarding intensity level. Preliminary results indicate that chlorpromazine caused a raising of the threshold for detection of stimulation at doses that had no effect on the threshold for rewarding stimulation. These results suggest that the threshold raising effect of CPZ on rewarding brain stimulation is, at least in part, due to an alteration in attentional or perceptual processes. Also, since these doses of CPZ did not alter latency of response or intertrial responding it is unlikely that the observed changes in the detection threshold are due to a drug effect on motor behavior. (Supported in part by NIDA grant DA 02326 and NIDA Research Scientist Award (CK) KO5 DA 00099).

201.6 MAGNESIUM ALTERS CATECHOLAMINE FUNCTION: IMPLICATIONS FOR ABUSE POTENTIAL OF DRUGS. K.M. Kantak and L.K. Adlerstein*. Laboratory of Behavioral Neuroscience, Dept. Psychology, Boston Univ., Boston, MA 02215.

Previous research from my laboratory has demonstrated that limiting dietary magnesium (Mg^{2+}) to 15% or 25% of the daily requirement leads to reductions in offensive threat and attack behaviors in male mice. These reductions began 3 weeks after initiation of these diets and continued through 8 weeks. We have also examined the effect of Mg^{2+} excesses on offensive behavior. At doses of 15 mg/kg and 30 mg/kg $MgCl_2$, threat and attack behaviors on mice were significantly elevated. At higher doses, 125 mg/kg and 250 mg/kg, these behaviors were significantly reduced. These data on excesses and deficiencies suggest an inverted U-shape function to magnesium's influence on behavior. This is highly suggestive that Mg^{2+} is influencing catecholamine function in vivo, because catecholamine stimulation typically displays this type of relationship to behavior, including aggression. Consequently, apomorphine-induced sniffing, which is an index of dopamine function, is reduced by Mg^{2+} deficiency as is l-amphetamine-induced locomotion which is an index of norepinephrine activity. In the present experiments, we determined if aggression altering doses of $MgCl_2$ were capable of increasing catecholamine function as assessed by these drug-induced behaviors in male mice.

Pretreatments consisted of either 0.9% NaCl, 30 mg/kg $MgCl_2$ or 125 mg/kg $MgCl_2$ and groups of mice were injected with 1 of 5 doses of apomorphine or l-amphetamine. $MgCl_2$ caused a dose-dependent shift to the left for the dose response to apomorphine-induced sniffing and l-amphetamine-induced locomotion. The ED_{50} values for half maximal stimulation of sniffing were 0.34, 0.19 and 0.14 mg/kg for increasing doses of $MgCl_2$. The ED_{50} values for half maximal inhibition of locomotion were 3.0, 0.12 and 0.0 mg/kg for increasing doses of $MgCl_2$. This indicates an enhancement of apomorphine action and dopamine function as well as an enhancement of l-amphetamine action and norepinephrine function with increasing doses of $MgCl_2$. These data indicate that behaviorally active doses of $MgCl_2$ can increase the efficacy of drugs that stimulate catecholamine systems. This may have bearing on the abuse potential of drugs such as cocaine and amphetamine, in that Mg^{2+} status can either contribute to or prevent tolerance and physical dependence to these agents or alter their effectiveness.

201.7 A NEW ANIMAL MODEL OF DEPRESSION THAT PRODUCES LONG-LASTING EFFECTS. L. A. Hoffman* and J. M. Weiss, Rockefeller University, New York, NY, 10021.

A rodent model of depression in which the depressive syndrome endures for long periods of time has yet to be developed. Whereas certain procedures generate a sufficient number of symptoms to approach reproducing an adequate animal model of depression, most of these symptoms are short-lived. We report here a procedure which, following treatment, generates depression of active behavior that endures for at least two months. Also, this behavioral depression, once produced, can be reversed by the chronic, but not acute, treatment with the tricyclic antidepressant desipramine.

In these experiments, depression of active behavior was measured by placing animals in a tank of water and measuring the time that animals struggled vigorously and also floated. Time spent floating is subtracted from time spent struggling to obtain an Activity Score (AS). This index has proved to be particularly convenient because untreated animals normally show approximately the same amount of struggling and floating in the 15-min swim test, thus achieving an AS of zero. A negative AS thereby indicates depression of active behavior. This test has been previously shown to reflect depression of active behavior produced by exposure to stressful conditions (e.g., Weiss, Goodman, Losito, Corrigan, Charry, and Bailey, Brain Res. Rev., [1981] 167-205).

Behavioral depression was produced by administering clonidine (CLON) to animals for 14 days and then withdrawing the drug. In the first study, drug was administered in two ways: (1) by daily injection (0.1 mg/kg) together with drug in the animal's drinking water (3 ug/ml) (CLON Group A), and (2) drug in drinking water only (CLON Group B). After 14 days, drug was withdrawn. When tested in the swim test 10 days after CLON withdrawal, CLON-withdrawn animals showed significant behavioral depression (mean AS for CLON A = -273.7 ± 136.9; for CLON B = -258.7 ± 71.1; for no-drug controls = -16.7 ± 43.2). When tested repeatedly up to 65 days after drug withdrawal, CLON-withdrawn animals continued to show behavioral depression in the swim test.

In two subsequent experiments, it was shown that this behavioral depression following CLON withdrawal could be reversed by chronic treatment with desipramine (DMI). Following 14 days of CLON treatment (Procedure of CLON A), CLON was withdrawn, which resulted, as expected, in behavioral depression in the swim test 7 days later. CLON-withdrawn (i.e., behaviorally depressed) animals were then divided into two groups, one treated daily with DMI (4mg/kg) and one treated with vehicle. After 8 days of DMI, CLON-withdrawn animals showed significant attenuation of behavioral depression, the Activity Scores for this group averaging only 53.5 ± 51.1 lower than the mean AS of no-drug controls, whereas CLON-withdrawn animals not given DMI showed Activity Scores averaging 171.1 ± 65.0 lower than mean of the control group. By the 36th day of DMI treatment, CLON-treated animals were virtually the same as non-treated animals (AS averaged 12.9 ± 37.4 lower than mean AS of control group) whereas the CLON-treated animals not given DMI remained depressed (AS averaged 233.7 ± 86.7 lower than mean AS of control). A third experiment replicated these findings with testing on the 8th day of DMI treatment but also showed that DMI had no significant beneficial effect on the first day of its administration.

In summary, when clonidine was administered for 14 days and then withdrawn, a long-lasting depression of active behavior in a swim test was seen. This procedure therefore generated persisting behavioral depression in the absence of any further or ongoing behavioral or pharmacological treatment. Behavioral depression produced in this manner was reversible by the tricyclic antidepressant desipramine. Whether the procedure described above produces other symptoms of depression in addition to reduction of motor activity remains to be determined.

201.8 OBLIGATORY D1-D2 RECEPTOR COACTIVATION AND THE GENERATION OF DOPAMINERGIC BEHAVIORS. A.R. Braun* and T.N. Chase. (SPON: T. Lanthorn) Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205.

Dopamine agonists produce a variety of behaviors in laboratory animals. We have sought to distinguish between further characterize these behaviors on a pharmacologic basis, utilizing agents which are selective for the D1 and D2 subclasses of dopamine receptors.

Two hundred thirty male Sprague-Dawley rats were utilized. Behaviors were observed for 3 to 10 hours, and were scored using a behavioral check list which allowed independent quantification of locomotion, endogenous behaviors, movements of the head, mouth and limbs. Responses to a novel object, a noxious stimulus and behavior in an open field were also quantified.

The D1 agonist SK&F 38393, administered in 6 doses from 2 to 32 mg/kg i.p., produced a dose dependent increase in grooming behavior. No stereotypic behavior was observed. The D2 agonist LY 171555 was administered in 8 doses from .05 to 24 mg/kg s.c. The lowest dose produced cataleptoid hypomotility; the higher doses produced dose dependant increases in locomotor activity, grooming, nonstereotypic sniffing and responsiveness to environmental stimuli. Stereotypies characteristic of high doses of mixed agonists such as apomorphine or amphetamine were not seen.

A dose response matrix was constructed utilizing 12 combinations of the D1 and D2 agonists. As levels of both agonists were increased, locomotor activity, other endogenous behaviors, and general sensory responsiveness decreased and all classes of well recognized stereotypies appeared. These ranged from licking, biting or gnawing syndromes seen with mid-range doses of both drugs, to more complex head and limb stereotypies and self-mutilatory behavior seen at higher abolute doses and higher ratios of D1 to D2 stimulation.

Animals in whom endogenous catecholamines had been depleted by acute pretreatment with reserpine and AMPT displayed no recognizable agonist-induced behaviors when challenged with either agonist alone. The full range of behaviors, from locomotion to complex stereotypy, could be restored in these animals, however, by concurrent administration of D1 and D2 agonists in the same doses and ratios which elicited these behaviors in intact animals. Finally, in the intact animal, all behaviors elicited by either agonist alone or in any combination were completely inhibited by either the specific D1 antagonist SCH 23390 or the specific D2 antagonist RO 22-1319.

These results suggest that all well-recognized dopamine induced behaviors depend upon concurrent activation of D1 and D2 receptors. The particular category of behavior expressed - from goal directed exploratory behaviors to fragmented stereotypies - depends upon the absolute levels of D1 and D2 activity and the ratio between these levels. D1 receptor stimulation appears to be critical in the transition from locomotion to stereotypy.

201.9 CONTINUOUS AMPHETAMINE INFUSION PRODUCES A BIPHASIC LOMOTOR AND EXPLORATION RESPONSE IN THE RAT. P.F. Gately*, D.S. Segal, and M.A. Geyer, Department of Psychiatry, School of Medicine, University of California, San Diego, La Jolla, CA 92093.

Alzet minipumps were implanted subcutaneously into male rats under ether anesthesia, enabling the delivery of either saline or amphetamine sulfate at a rate of 0.65 mg/kg/hr. Commencing 24 hours post-implantation, and continuing on a daily basis for nine days, rats were tested in 40-minute sessions in a behavioral pattern monitor, which provided computer-generated graphic representation of the spatio-temporal patterns of locomotion, rearings, and holepokes. Animals were also systematically observed and rated for the occurrence of stereotyped behaviors. For the first four days of infusion, amphetamine-treated rats displayed highly focussed stereotypy, weight loss, and normal levels of locomotor and exploratory activity. By day six, and extending through the end of the experiement, fewer and less intense episodes of stereotypy were seen; the anorexogenic effect was lost, and progressively higher levels of locomotor and exploratory activity were evident. The biphasic locomotor and exploratory responses have previously not been reported and may be manifestations of the "end stage" behaviors associated with chronic exposures to amphetamine.

201.10 DIALYSIS PERFUSION STUDIES OF THE EFFECTS OF AMPHETAMINE ON THE STRIATUM. R.W. Keller, C.L. Hucke*, M.J. Zigmond and E.M. Stricker. Dept. of Biological Sciences and Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260

Many effects of amphetamine (AMPH) have been proposed to result from its ability to release catecholamines from terminals and block their reuptake into neurons. The use of in vivo voltammetry to monitor dopaminergic activity in the rat striatum has led to confusion regarding the amount of dopamine (DA), versus other electroactive species, that actually is released after AMPH treatment. Some electrochemical studies indicate that a significant amount of DA is released, whereas other studies indicate that virtually no DA is released and the signal observed is almost solely due to ascorbic acid (AA). We have studied the source of the rise in the electrochemical signal after AMPH by examining the extracellular fluid using a hollow fiber dialysis perfusion system.

After AMPH (5 mg/kg, ip) treatment there was a 20-fold increase in extracellular DA, from 0.015 uM to 0.30 uM; however, even this elevated value was a fraction of the extracellular concentration of AA (13 uM), dihydroxyphenylacetic acid (DOPAC, 2.8 uM), homovanillic acid (HVA, 2.6 uM) and 5-hydroxyindoleacetic acid (5HIAA, 1.6 uM). Large amounts of AA (peak value of 23 uM) were released by AMPH and probably accounted for most of the electrochemical signal at carbon electrodes. The concentration of the DA metabolites, DOPAC and HVA, in the extracellular fluid decreased after AMPH administration and hence it cannot have played a role in the observed increase in electrochemical signal. Similarly, the dose of AMPH used in these studies did not produce significant changes in extracellular serotonin or its major metabolite, 5HIAA.

In contrast to the effects of systemic AMPH, the administration of AMPH via the perfusion medium produced no significant increase in AA; however, it did result in a marked increase in DA release in the striatum, whereas extracellular concentrations of DOPAC and HVA were reduced significantly. This finding indicates that AMPH can cause the release of DA without AA, and therefore suggests that AA and DA may be released from different populations of neurons when AMPH is administered systemically.

201.11 EFFECTS OF d-AMPHETAMINE ON THE DETECTION THRESHOLD FOR BRAIN SELF-STIMULATION AND ON LOCOMOTOR ACTIVITY. Gerald J. Schaefer and Richard P. Michael. Dept. of Psychiatry, Emory Univ., School of Medicine and the Ga. Mental Health Inst., Atlanta, GA 30306

Rats were implanted with stimulating electrodes aimed at the medial forebrain bundle-lateral hypothalamus (MFB-LH), and trained in a discrete trial procedure to make a differential response (right or left lever press) in the presence or absence of brain stimulation (ICSS). For each trial, the animal was required first to press an "initiating" lever which gave either suprathreshold ICSS or no ICSS in a random sequence. When the first press of the initiating lever produced stimulation, half of the animals were required to press the right choice lever for further stimulation; when the first press did not produce stimulation, these animals were required to press the left choice lever for stimulation. The opposite conditions were in effect for the remaining animals. A wrong choice terminated the trial without brain stimulation reward. When animals reached 95% accuracy in this discrimination, testing with d-amphetamine (0.03, 0.1, 0.3, 1.0 mg/kg) and saline began. During test sessions, the initiating lever produced current intensities of from 0 to 100% of the training current. The intermediate intensities were presented in random order. During test sessions, but not in training sessions, a response on either choice lever produced the reinforcing stimulus and terminated the trial. We measured the number of trials completed on the stimulation-appropriate choice lever as a function of the current intensity on the initiating lever; 20 trials occurred at each intensity. For saline and each dose of drug, the current intensity was plotted against the number of trials completed on the stimulation appropriate lever. In addition, the time to complete the test session and the number of lever presses between trials were recorded. Three animals lowered the detection threshold as evidenced by a shift to the left in the current intensity necessary to produce 50% responding on the stimulation-appropriate lever; the two remaining animals produced opposite effects, resulting in higher detection thresholds. The overall result was not significant. However, a significant increase in both time to complete the test session ($P < 0.025$) and in inter-trial presses on the initiating lever ($P < 0.025$) occurred. These animals were also tested with d-amphetamine and saline in an Omnitech Digiscan^{R} activity monitor. A reliable increase occurred in both total horizontal ($P < 0.001$) and in locomotor activity ($P < 0.005$) scores. These data aid in differentiating the effects of d-amphetamine on motor performance from the discriminative stimulus properties of ICSS.

BLOOD-BRAIN BARRIER I

202.1 AVENUES FOR ENTRY OF EXOGENOUS PROTEIN TO THE CNS. B.J. Balin* and R.D. Broadwell (SPON: M. Salcman). U of MD, Balt., MD 21201.

Pathways for the extracellular diffusion into the brain of peripherally administered protein tracers were investigated by light and electron microscopy in adult mice. Native horseradish peroxidase (HRP) was injected intravenously, into the cerebral ventricles, or intranasally; wheat germ agglutinin (WGA)-HRP, which binds to the cell surface, was delivered intraventricularly or intranasally. All animals were fixed by vascular perfusion 5 mins-24 hrs post-injection. Blood-borne HRP entered the brain through fenestrated capillaries in circumventricular organs. When the circulating titer of blood-borne HRP was high (5 mins), peroxidase reaction product was associated with the ventricular and pial surfaces, the Virchow-Robin space of large vessels, and with pericytes and deep microvasculature. Reaction product was seen frequently on the luminal surface and less so on the abluminal surface of cerebral capillaries. Numerous endocytic vesicles and tubules derived from the endothelial luminal surface were labeled with blood-borne HRP and directed to endosomes/dense bodies. Extravasations of HRP around arterioles/venules, but not capillaries, were scattered throughout the brain; tight junctions between the cells of these leaky vessels were open and filled with HRP reaction product, perhaps the result of the perfusion-fixation process. Similar extravasations were not evident when the titer of blood-borne peroxidase was low (30 mins-2 hrs). Intraventricular administration of HRP and WGA-HRP revealed that the endocytic activity of the abluminal surface of the cerebral endothelium was virtually non-existent. This observation indicates that: a polarity exists regarding the internalization of the endothelial plasmalemma from the luminal vs. abluminal side; bidirectional vesicular transport across the cell does not occur; and HRP is not toxic to and does not stimulate endocytosis in the endothelium. When HRP and WGA-HRP were delivered intranasally, only native HRP diffused extracellularly to the pial surface of the olfactory bulbs (45 mins). The results suggest that pathways for the extracellular diffusion of large molecular weight substances into the brain exist from the blood and nose. Blood-borne HRP enters the cerebral ventricles through circumventricular organs, distributes in the CSF over the pial surface of the brain, and enters the perivascular clefts of large penetrating vessels for diffusion to pericytes and deep microvasculature. HRP delivered intranasally diffuses into the brain, presumably between nasal epithelial cells. Patent avenues through the circumventricular organs and the nasal epithelium offer potential routes for the introduction of blood-borne and air-borne toxic, carcinogenic and infectious agents to the CNS.

202.2 VASCULARIZATION OF BRAIN TRANSPLANTED INTO THE THIRD CEREBRAL VENTRICLE. R.D. Broadwell, H.M. Charlton*, and W.F. Ganong. Univ. MD, Balto., MD 21201, Univ. Oxford, Oxford, England, Univ. CA, San Fran., CA 94143.

The potential for fenestrated capillaries of the median eminence in the hypothalamus to invade grafts containing neurosecretory cells from areas in the CNS devoid of such vessels was investigated by light/electron microscopy. Grafts of the medial preoptic area harboring neurons that secrete gonadotrophic hormone releasing hormone (GnRH) and of the arcuate nucleus from late fetal/early neonatal AKR mice were transplanted into the third cerebral ventricle of adult female, hypogonadal(HPG) mice incapable of synthesizing GnRH. The grafts were allowed to develop within the host brains for 1 day - 3 mos. Vasculature of the host and grafted brain parenchyma was analyzed with diaminobenzidine cytochemistry in two ways: (1) areas possessing "leaky" vessels were identified with HRP injected intravenously 2-5 mins prior to perfusion-fixation; (2) the pattern of vascularization was outlined in sections of brains fixed by immersion with incubation of the sections for endogenous HRP activity in red blood cells retained in the vessels. Fenestrated capillaries within the median eminence of HPG mice not receiving grafts were restricted largely to the outer plexiform layer with loops extending into the subependymal zone. Grafts delivered into the brains of HPG mice frequently filled the third ventricle. The graft parenchyma and ependymal layer of the host median eminence at one month were well-demarcated and organized; however, at 3 mos. the ependymal layer appeared in disarray with neuronal processes and glial cells from the graft invading the median eminence proper. Vasculature linking the host brain and graft was identified at the dorsal, lateral, and ventral margins of the graft. Occasionally, a vessel linking the graft and median eminence was continuous with that in the host arcuate nucleus. Blood-borne HRP leaked from fenestrated vessels in the host median eminence and diffused into the graft; no leak of HRP was discerned from vasculature supplying the graft. Fenestrated endothelial cells, readily identified within the median eminence, were not observed in the graft. Contiguous endothelial cells within the graft exhibited tight junctions typical of those that contribute to the formation of a blood-brain barrier (BBB); the host median eminence contained similar endothelial cells, perhaps derived from the graft. The results suggest that fetal/neonatal CNS tissue destined to develop and possess a BBB does so when grafted into the third ventricle and placed in contact with the median eminence. If fenestrated capillaries of the host median eminence contribute to the vascularization of grafted tissue, this contribution may be minimal.
NINCDS Grant #NS18030.

202.3 NORADRENERGIC INNERVATION OF BRAIN MICROVESSELS FROM THE NUCLEUS LOCUS CERULEUS MODULATES THE TRANSPORT OF SODIUM AND POTASSIUM ACROSS THE BLOOD-BRAIN BARRIER. S.I. Harik. Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

The functions of the putative noradrenergic innervation of brain microvessels from the nucleus locus ceruleus (LC) remain controversial. We recently presented evidence that the LC is important for preserving the integrity of the blood-brain barrier (BBB) to macromolecules during hypertension and seizures (Harik & McGunigal, Ann. Neurol., 15:568, 1984). We now present further evidence suggesting that this noradrenergic innervation regulates Na^+ and K^+ transport across the BBB. Since brain microvessels possess specific ouabain binding sites (Harik et al., J. Cereb. Blood Flow Metabol., 5:156, 1985) that probably represent molecules of Na^+,K^+-ATPase, a major transport system of the BBB, we measured specific ouabain binding to microvessels isolated from the cerebral cortex, ipsilateral and contralateral to unilateral LC lesion.

Male Wistar rats (200-250 g) had unilateral LC lesion by the stereotaxic injection of 6-hydroxydopamine or sham operation. Two weeks later, the rats were decapitated and the cerebral mantles dissected and used to obtain cerebral microvessels. Samples from each cerebral cortex were taken for norepinephrine (NE) assay, to assess the efficacy of LC lesion, and for ouabain binding assays to membranes of the whole cerebral cortex. Microvessels from 4-10 ipsilateral or contralateral cerebral cortices were pooled. Particulate fractions of brain microvessels and of cerebral cortex were assayed for specific [^{3}H]ouabain binding as described by Harik et al. (J. Cereb. Blood Flow Metabol. 5:156, 1985).

LC lesion depleted NE by about 90% in the ipsilateral cortex without affecting the contralateral cortex. Specific ouabain binding to membranes of cerebral cortex and cerebral microvessels was saturable. Maximal binding was reduced by about 40% in microvessels of the ipsilateral, NE-depleted, cortex (8.9 $\pm$ 1.1 and 5.5 $\pm$ 0.9 pmol/mg protein in contralateral and ipsilateral microvessels, $p < 0.01$, paired Student t-test, 2-tailed). Ouabain binding to preparations of the whole cerebral cortex was not affected by LC lesion. Also, LC lesion did not affect the dissociation constants of ouabain binding in any of the preparations.

These results indicate that LC lesion decreases the density of ouabain binding sites in brain microvessels although it has no effect on the density of ouabain binding sites in the NE-depleted cortex. This suggests that intrinsic NE innervation of cerebral microvessels modulates their density of Na^+,K^+-ATPase and, consequently, the transport of Na^+ and K^+ across the BBB. The data provide further evidence for the functional importance of the neural control of the cerebral circulation.

202.4 ADENOSINE TRANSPORT IN CEREBRAL MICROVESSELS AND CHOROID PLEXUS. Rajesh N. Kalaria and Sami I. Harik. Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106

Evidence derived from in vivo and in vitro experiments shows that adenosine and other nucleosides are transported across the blood-brain barrier (BBB) via a saturable carrier-mediated mechanism. Adenosine also appears to modulate neural and cerebrovascular functions by interacting with specific receptors. This action of adenosine may be terminated by a rapid uptake or transport process in cell membranes. Nitrobenzylthioinosine (NBI) has been used as a probe to investigate the adenosine transporter of erythrocytes and neural tissue. In this study, we used [^{3}H]NBI as a ligand to investigate the adenosine transporter of isolated cerebral microvessels and the choroid plexus of the rat and pig.

Rat and pig cerebral microvessels were obtained by bulk isolation as described previously (Harik et al., J. Cereb. Blood Flow Metabol. 5:156, 1985). Microvessels, choroid plexus and cerebral cortical samples were homogenized using a polytron and their particulate fractions washed and resuspended in 50 mM Tris buffer, pH 7.4. Total [^{3}H]NBI binding was performed by incubation at 22^{o}C for 30 min. Nonspecific binding was determined in the presence of 10 uM of nitrobenzylthioguanosine (NBG). Specific binding was estimated by substracting nonspecific binding from total binding.

Our results indicate that specific [^{3}H]NBI binding to the various preparations was saturable. Scatchard analysis showed a single class of binding sites (Kd about 0.5 nM). Maximal binding density (Bmax) was up to 6-fold higher in microvessels and choroid plexus than in particulate fractions of the cerebral cortex. The results suggest that adenosine transporters of the BBB are important for the supply of adenosine, not only to the endothelial cells of cerebral capillaries but to the larger mass of surrounding brain. There were no diffrences in [^{3}H]NBI binding between brain microvessels obtained from perfused and unperfused rats, thus ruling out the possibility that erythrocytes trapped within microvessels contribute to the [^{3}H]NBI binding. In further experiments, we studied the ability of unlabeled adenosine, other nucleosides and adenosine analogues, to displace specific [^{3}H]NBI binding to microvessels. NBI, NBG and dipyridamole were most effective in displacing [^{3}H]NBI from specific binding sites (IC_{50} about 1 nM). In contrast, adenosine, uridine, inosine, papaverine and cyclohexyladenosine were 4 to 5 orders of magnitude less active in displacing [^{3}H]NBI from its specific binding sites. Our results indicate the existence of a high density of adenosine transporters in brain microvessels and choroid plexus.

202.5 BLOOD-BRAIN BARRIER PROTEIN PHOSPHORYLATION AND DEPHOSPHORYLATION. W.M. Pardridge, J. Yang*, and J. Eisenberg*. Department of Medicine, UCLA School of Medicine, Los Angeles, CA 90024.

Capillaries in vertebrate brain have unique permeability properties which make up the blood-brain barrier (BBB). Although it is known that capillaries are innervated by both aminergic and peptidergic nerve endings of intracerebral origin and that brain capillary function is likely acutely regulated by neuronal inputs, the possible mechanisms of neuronal regulation of capillary function are at present unknown. One possible mode of regulation is via the phosphorylation of brain capillary proteins. The present studies characterize, for the first time, the major phosphoproteins in the bovine brain capillary using both intact bovine cortical brain capillaries and plasma membrane fractions from bovine brain capillaries. Phosphorylation studies using ^{32}P-γ-ATP labeling of intact capillaries is possible since brain microvessels obtained with a mechanical homogenization technique are permeable to small molecules. The patterns of endogenous phosphorylation of capillary proteins are compared to similar patterns obtained with synaptosomal (P_2) fractions from bovine brain cortex. Based on measurements of γ-glutamyl transpeptidase activity, a BBB-specific enzyme, the contamination of P_2 proteins by BBB proteins was only 2.4%. The major findings of this study are: (a) the activity of protein phosphorylation in brain capillaries is localized almost exclusively to the capillary plasma membrane, and is nearly comparable to the activity of protein phosphorylation in synaptosomal membranes; (b) a major phosphoprotein doublet in the capillary fraction comigrates on an SDS gel with a major phosphoprotein doublet of approximate molecular weight of 80K in the synaptomal fraction, and the latter is presumed to be synapsin I; in dephosphorylation assays the synaptosomal 80K phosphoprotein doublet is not subject to measurable dephosphorylation whereas the capillary 80K doublet is subject to rapid dephosphorylation, and is essentially completely dephosphorylated within 5 seconds at 0^{o}C; (c) a prominent triplet of phosphoproteins with molecular weight of 50K-55K is present in the capillary fraction, and is not present in the synaptosomal fraction; thus, this 50K-55K triplet of phosphoproteins appears specific for brain capillaries. In summary, these studies provide the basis for future investigations of a protein phosphorylation paradigm in regard to the rapid control of brain capillary function by brain.

202.6 ISCHEMIC BRAIN EDEMA AND ALTERED BLOOD-BRAIN BARRIER FOLLOWING PHOTOCHEMICALLY INDUCED CORTICAL INFARCTION . R. Busto*, W. D. Dietrich, M. D. Ginsberg and B. D. Watson* (Spon: M. Rosenthal). Cerebral Vascular Disease Research Center, Dept. of Neurology, Univ. Miami School of Medicine, Miami, FL 33101

Brain edema is known to play an important role in the pathophysiology of stroke. In this study, we monitored the early development of ischemic brain edema following photochemically induce cortical infarction in the rat. This stroke model results in small vessel occlusion initiated by severe platelet aggregation. Alterations in brain water content were correlated with blood-brain barrier alterations to serum proteins as assessed with Evans blue . Cortical infarction was induced by irradiating the intact skull for 20 minutes with green light following the systemic injection of Rose Bengal.

As early as 30 minutes following irradiation, water content in the irradiated zone increased from control levels of 79.6% to 80.4%. By 8 hours, water content was significantly elevated within the irradiated zone (88.5%), and in ipsilateral cortical regions not destined to undergo irreversible cell damage (81.0%). Significant increases in water content were not demonstrated within the contralateral hemisphere. Widespread cortical permeation of Evans blue with prominent pial-surface staining was observed at 30 minutes and 8 hours when Evans blue was given immediately post-irradiation. In contrast, when Evans blue was infused 30 minutes prior to sacrifice, peri-infarct permeation was slight at 8 hours. These findings suggest early vasogenic edema in this experimental model of cortical infarction. Cerebral blood flow studies in this model have indicated that the central ischemic zone continues to increase in size after the period of irradiation has ceased. It is therefore hypothesized that this increase is due to progressive microvascular compression secondary to brain edema. Ultrastructural investigations are needed to answer this question.

202.7 DIETHYLDITHIOCARBAMIC ACID FACILITATES ENTRY OF CADMIUM INTO BRAIN BUT PREVENTS CADMIUM-INDUCED NEUROTOXICITY. J.P. O'Callaghan and D.B. Miller. Neurotoxicology Division, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711 and Northrop Services, Inc., Research Triangle Park, NC 27709.

Although cadmium is toxic to the central nervous system (CNS) of the developing rat, the adult CNS is not affected, presumably because cadmium does not cross the blood-brain barrier. Substituted dithiocarbamates have metal-binding properties that have proven effective in the treatment of cadmium intoxication. These compounds form a lipophilic complex with cadmium that readily penetrates the blood-brain barrier, resulting in elevated cadmium concentration in the brain, which might be expected to increase the potential for neurotoxicity. To investigate this possibility we assessed the effects of diethyldithiocarbamic acid (DDC) on cadmium-induced neurotoxicity in the developing and adult rat. Indices of neurotoxicity included: brain weight and histology, and radioimmunoassays of the neuron-specific phosphoprotein, synapsin I and the astrocyte-specific protein, glial fibrillary acidic protein (GFAP). Distribution of cadmium to brain, liver, kidney and teste also was determined.

Cadmium (2.75-3.75 mg/kg,s.c.) alone or in combination with DDC (100 mg/kg,i.p.) was administered to Long-Evans rats on postnatal day (PND) 5. All measurements were obtained on PND 22. Deposition of cadmium was reduced in liver and elevated in brain and kidney as a result of co-administration of DDC. Cadmium administration alone caused large dose-related decreases in brain weight. DDC did not affect brain weight and attenuated the cadmium-induced decreases in brain weight. Histological examination of the brain revealed necrosis of the neostriatum and overlying cortex following exposure to 3.0-3.75 mg/kg cadmium; these effects were blocked by co-administration of DDC. Synapsin I was decreased 39% and GFAP was increased 29% in neostriata obtained from rats that received 2.75 mg/kg of cadmium, a dosage that did not result in overt cytopathology. When expressed as per mg neostriatal protein, synapsin I was decreased by 19% and GFAP was increased by 80%. These effects, which are indicative of cadmium-induced loss of neurons and reactive gliosis, were blocked by concommitant administration of DDC.

Cadmium (1.0 mg/kg/day, i.p. x 4 days) alone or in combination with DDC (500 mg/kg/day, s.c. x 4 days) also was administered to adult Long-Evans rats. Co-administration of DDC caused a significant accumulation of cadmium in brain which persisted for at least 2 weeks. Measurements of brain weight and regional amounts of synapsin I and GFAP did not show any significant changes as result of any of the treatments. Collectively, these data suggest that the increased brain concentration of cadmium resulting from co-administration of DDC does not increase the potential for cadmium-induced neurotoxicity.

202.8 PHARMACOLOGICAL CHARACTERIZATION OF ADRENERGIC INFLUENCE ON BRAIN EXTRACELLULAR SPACE. T.A. Kent*, A. Oke, B. Moghaddam and R.N. Adams. Dept. of Neurology, Univ. of Texas Medical Branch, Galveston, TX and Dept. of Chemistry, Univ. of Kansas, Lawrence, KS.

Local brain neuronal activity alters the extracellular space (ECS) volume in the brain, an effect thought to be due to changes in membrane ion permeability and resultant osmotic shifts. We have been interested in remote neuronal influences on ECS. Our studies have focused on the possible role of the central noradrenergic system, because of reports that this biogenic amine innervates the cerebral microvasculature. We have previously found that increases in inspired CO_2--a stimulus to the firing rate of the main noradrenergic cell body, the locus coeruleus--increase ECS volume in the rat thalamus as measured by ion-selective microelectrodees sensitive to the ECS marker, alpha-naphthalene sulfonate (ANS). This effect of CO_2 was potentiated by the amine reuptake inhibitor, amitriptyline, and reversibly attenuated by injection of lidocaine into the region of the locus coeruleus (Kent et al. Brain Res., in press).

In this study, we investigated whether adrenergic receptors mediate this effect. Rodents were anesthetized (chloral hydrate, 400 mg/kg i.p.), intubated, and passively ventilated with N_2 (55-70%), O_2 (30%) and CO_2 (0-15%). A double-barrel micropipette was implanted into the thalamus. One side was filled with 0.9% NaCl and used to follow field potential changes. The pipette used to follow ANS concentration changes was filled with a PVC-based ion exchanger mixture containing Aliquat (Aldrich)/Na-ANS as active material. Previous studies have demonstrated that the electrode is not sensitive to changes in chloride, glutamate, ascorbate, or pH. A pipette filled with 0.01 M ANS was placed 1-3 mm away and ANS was injected via a nanoliter pump. We confirmed that CO_2 produced a decrease in ANS concentration, indicating a 15-20% increase in ECS volume. Prazosin, an alpha-1 adrenergic antagonist (0.05-1 mg/kg i.v.) reduced the effect of CO_2 by 60-70%. Propranolol, a beta-adrenergic antagonist, had no effect in doses from 0.005 mg/kg i.v. to 6 mg/kg i.p. Yohimbine, an alpha-2 adrenergic antagonist with some alpha-1 effects, only minimally reduced (20%) the effect of CO_2 in doses from 1-2 mg/kg i.v.

These results indicate that the effect of CO_2 on increasing ECS volume is mediated primarily by alpha-1 adrenergic receptors. These receptors may be located on cerebral vessels, or other structures, such as glia, which may influence the local concentration of compounds in the brain.

202.9 STRUCTURAL ENDOTHELIAL CHANGES THAT UNDERLIE THE MATURATION OF THE BLOOD-BRAIN BARRIER. P.A. Stewart, E.M. Hayakawa* and K. Hayakawa* Dept. of Anatomy, Univ. of Toronto, Toronto, Ontario, Canada, M5S 1A8.

The blood-brain barrier (bbb) is a selectively permeable interface between blood and brain that embodies both structural and functional specializations. The formation of a structurally "tight" layer of endothelium, that is essential for maintaining concentration gradients across the bbb, develops in tandem with the functional specializations. In highly permeable (non-barrier) vessels, blood-borne molecules cross the capillary wall via 3 routes: a) between adjacent endothelial cells, b) through tubulovesicular channels, or chains of vesicles in the endothelial cytoplasm, and c) through fenestrae, when these are present. In mature bbb vessels continuous bands of tight junctions seal the paracellular route, few vesicles exist and there is a virtual absence of fenestrae.

The non-specific permeability of brain capillaries is high in embryonic life, but drops towards adult levels around the time of birth in most species. We have investigated the structural basis of this developmental "tightening" in the mouse by quantitating the density of endothelial vesicular structures, and the number of gaps within the junctional areas. Recent evidence indicates that gaps, or spaces, seen between successive tight junctional strands are profiles of anastomosing channels through the junctional regions.

Cerebral hemisphere and cerebellum taken from perfusion-fixed mice were processed for routine electron microscopy. We examined vessels in brain at various ages from fetal stages to two weeks after birth. Vessels sectioned transversely were photographed and the negatives projected onto a digitized bit pad for computer-assisted image analysis.

We found that fenestrae are absent in fetal as well as mature bbb vessels. Vesicular density dropped only slightly during development. The incidence of enlarged junctional clefts, a frequent finding in fetal endothelium decreased dramatically by two weeks after birth. Changes in the cerebellum occurred slightly later than those in the cerebrum. These results indicate that a major factor in the developmental "tightening" of the bbb is a change in the ultrastructure of the junctional areas.

202.10 **NEOSYNEPHRINE INDUCED CHANGES IN CEREBRAL BLOOD FLOW IN FREEZE LESIONED RATS.** W.D.Johnson*, D.Dow-Edwards, T.H.Milhorat, (SPON: M.Friedlander). Laboratory of Cerebral Metabolism, Department of Neurosurgery, SUNY Downstate Medical Center, Brooklyn, NY 11203.

The freeze lesion is a time-honored model of vasogenic cerebral edema first introduced by Klatzo who demonstrated the qualitative relationship between hypertension and the extent of edema spread (Klatzo et al., Brain Edema, p. 554, 1967). Blasberg et al. reported a profound depression in local cerebral blood flow (LCBF) acutely in freeze lesioned areas (Adv. Neurol., Vol. 28:255, 1980). In order to determine the effects of increased systemic blood pressure on LCBF in the traumatized brain, we applied the ^{14}C-antipyrine method (Sakurada et al., Am. J. Physiology 234(1):H59-H66, 1978) to four groups of animals: 1) normotensive control, 2) hypertensive control, 3) normotensive freeze lesion, 4) hypertensive freeze lesion.

Sprague-Dawley rats (150-225g) of either sex were anesthetized with halothane/O_2/N_2O mixture and subjected to either freeze lesion by application of a metal rod at -75°C to the exposed cranium midway between the coronal and lambdoid sutures, just to the right of midline for one minute, or to a sham operation. A solution of 2% Evans Blue (1.0cc/kg) was injected intravenously as a marker of blood-brain barrier breakdown. Thirty minutes following operation, either 0.1% Neosynephrine or normal saline was infused for sixty minutes; the Neosynephrine was titrated to maintain a mean blood pressure 20-30% above baseline. LCBF was determined during the last minute of drug or saline infusion.

The current study demonstrates that moderate hypertension increases both the amount of vasogenic cerebral edema and its rate of spread which was significantly reduced in the Neosynephrine treated animals compared to controls. The decrease in LCBF appeared to be congruent with the field of edema.

202.11 PERFORATION OF CNS BASAL LAMINA AND MARGINAL GLIA BY EMBRYONIC LEPTOMENINGEAL CAPILLARIES: EM STUDY. M. Marin-Padilla. Department Pathology, Dartmouth Medical School, Hanover, N.H. 03755.

At first, the embryonic CNS is deprived of its own vasculature. It is surrounded by a prominent perineural vascular plexus, from which its vasculature will progressively evolve. Leptomeningeal capillaries start to perforate the CNS basal lamina and marginal glia of the cerebral cortex, around the 9th - 10th day gestation in the hamster. The mechanism of the vascular perforation of the CNS by leptomeningeal capillaries remain poorly understood. Transmission electron microscopic preparations of the developing cerebral cortex of 9,10 and 11 day hamster embryos were made. Each preparation represents a perpendicular section including the leptomeninx primitiva and the upper portion of the cerebral cortex. Perforating leptomeningeal capillaries showing different degrees of penetration were identified in semi-thin sections and ultra-thin sections of them were subsequently prepared. Four distinct phases were identified in the vascular perforation of the CNS. First. The leptomeningeal capillary aproaches and establishes direct contact with the CNS surface. Its endothelium becomes aligned parallel to the marginal glia and contacts between the vascular and the CNS basal laminae are established. Second. Endothelial cell filopodia from this glia-touching capillary perforate both the vascular and the CNS basal laminae and penetrate into the neural tissue through an opening formed between two contiguous marginal glial endfeet. The glial endfeet facing the perforating filopodium undergo hydropic changes and focal disintegration. Third. The original opening enlarges thus allowing the entire endothelial cell (or cells) to penetrate into the neural tissue. The glial endfeet in front of the penetrating endothelium undergo disintegration and fragmentation. Fourth. Proliferation of the penetrating endothelial cells and their subsequent canalization result in the in situ formation of a new cortical capillary bed. New glial processes, which seem to replace degenerating ones, start to surround the newly formed cortical capillary establishing a new vascular-glial barrier around it. Also, a shallow pial-funnel can be recognized at this time around the entrance of the capillary. This represents an early embryonic stage in the formation of the Virchow-Robin space. Each phase of the active vascular perforation of the embryonic mammalian cerebral cortex will be illustrated and discussed.

202.12 REGIONAL CEREBRAL GLUCOSE UTILIZATION DURING INSULIN INDUCED HYPOGLYCEMIA IN UNANESTHETIZED RATS. R M Bryan, K A Keefer*, and C MacNeill* Depts. of Surgery (Neurosurgery) and Physiology, M S Hershey Medical Center, Hershey, PA 17033.

Regional cerebral glucose utilization (rCMRgl) was measured during insulin induced hypoglycemia in unanesthetized rats in order to answer the following questions: (1) Can some brain regions extract glucose from the blood more effectively than other brain regions and thus tolerate more severe hypoglycemia without compromising glucose utilization? (2) Can the existing models for glucose transport from blood to brain predict when the supply of glucose becomes limiting during progressive hypoglycemia causing rCMRgl to decrease? Rats were anesthetized with halothane (1.5%) and nitrous oxide (70%) in a balance of O_2 and surgically prepared with catheters in the left femoral artery and vein. A plaster restraining girdle was fitted around the lower quarter of each rat and anesthesia was discontinued. Each rat was allowed 5 hours to recover from the anesthesia before rCMRgl was measured. The rats were divided into 3 groups consisting of: (1) a normoglycemic group which received only saline, (2) hypoglycemia A which was given 15 units of insulin IV per kg body weight 30 min before rCMRgl was measured, and (3) hypoglycemia B which was given 15 units of insulin IV per kg body weight 2 hours before rCMRgl was measured and 5 additional units per kg body weight 1 hour before rCMRgl was measured. rCMRgl was measured using [6-^{14}C]glucose. Mean arterial blood pressure and PaO_2 were not different in the three groups, while $PaCO_2$ and pHa decreased in the hypoglycemic group B. Plasma glucose was 7.03 um/ml in the normoglycemic group, 1.96 um/ml in the hypoglycemic group A, and 1.40 um/ml in the hypoglycemic group B. rCMRgl in the hypoglycemic group A decreased 8-12% in seventeen brain regions measured of which 9 were statistically significant. rCMRgl in the hypoglycemic group B decreased significantly in all of the brain regions measured. The decrease ranged from a 15 % decrease in the pyramidal tract to 36% in the motor and auditory cortices. rCMRgl in every brain region began to decrease when plasma glucose fell below 1.5-2.5 um/ml demonstrating all brain regions were affected by glucose limitation at about the same plasma glucose concentration. Thus no brain region was more effective than other brain regions in maintaining rCMRgl in the face of decreasing plasma glucose. Theoretical models of glucose influx (Hawkins et al., J. Neurochem. 40:1013, 1983; LaManna and Harik Br. Res. 326:299, 1985) accurately predicted the plasma glucose concentration below which rCMRgl was limited by the supply of glucose and the degree that rCMRgl decreased for a given plasma glucose. (AHA Grant-in-Aid with funds contributed from the Palm Beach County Chapter, FL and PHS Grant NS19341)

STRUCTURE AND FUNCTION: CORTICAL AND SUBCORTICAL ORGANIZATION III

203.1 "COUNTER-CURRENT FLOW" OF CORTICO-CORTICAL INFORMATION PROCESSING THROUGH THE LAMINAR SEGREGATION OF RECIPROCAL CONNECTIONS. T. W. Deacon. Biological Anthropology, Harvard University, Cambridge MA 02138. (SPON: W. B. Forbes)

A variety of hydrodynamic exchange systems found in organisms (e.g. gills) and man-made devices (e.g. heat-exchangers) employ a pattern of "counter-current flow" to maintain an optimal exchange gradient between two fluid media. It is argued that an analogous principle may be employed for information processing in both sensory and motor cortico-cortical circuits.

HRP-WGA tracer experiments were employed to investigate laminar patterns of cortico-cortical connections in macaque brains. Reciprocal connections between neocortical areas in all regions of cortex analysed exhibited similar, distinctly asymmetric laminar patterns of origins and terminations, previously described by other investigators for different cortical regions. The two major patterns can be described as "upstream" and "downstream" projections respectively, where "downstream" characterizes the pattern exhibited by major sensory input and motor output directions. "Downstream" projections are typified by connections originating from pyramidal cells in deep supragranular layers (especially IIIc) and terminating in granular (IV) and deep supragranular layers (IIIc; sensory-prefrontal projections also include a projection to layer II). The reciprocal projections constituting the "upstream" flow are typified by connections which originate from cells predominantly in infragranular layers as well as some in middle supragranular layers (more prominant in eulaminate areas) and terminate predominantly in superficial layer I and infragranular layers, but not in granular layers. In general, posterior limbic cortex is downstream from eulaminate sensory cortex, is downstream from koniocortex; motor cortex is downstream from prefrontal cortex, is downstream from anterior limbic cortex; and finally prefrontal-motor areas are downstream from sensory areas. Upstream projections follow the reverse pattern.

Although the simple analogy must be modified to incorporate variations in quantities of connections, lamination, cross-modal relations, as well as noncortical connections at each stage, these do not obscure the prominence of these two major countervailing directions of information flow which are superimposed in neocortex. The countercurrent analogy suggests that each cortical area embodies a particular intermediate "gradient" of information transfer at an interface between neural pathways carrying information in opposite directions, from opposite origins: endogenous limbic activity at one extreme and extrinsically patterned and constrained sensory or motor information at the other. Increasing the number of intermediate stages decreases the "gradient" of difference at each stage.

203.2 THE ORGANIZATION OF INTRACORTICAL NEURONS WITHIN THE PRE- AND POSTSUBICULUM. J.M. Wyss, B. Sripanidkulchai and K. Sripanidkulchai. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, AL 35294.

In past studies, the organization of diencephalic and entorhinal projections from the subiculum cortex have been examined. To extend these findings, the present study investigated the laminar organization of neuronal cell bodies within the pre-and postsubicular cortices in relation to their cortical and/or thalamic projections. In each of 38 rats, a single 10-50nl injection of 4% fast blue (FB) was placed into a small region (~ 0.5mm^3) of the retrosplenial cortex, or the anterior thalamic nuclei. Following appropriate survival time the animals were perfused, and the brains were removed, sectioned and inspected using a Leitz A filter system.

The results demonstrate that the pre- and postsubicular neurons projecting to the posterior cingulate cortex, have cell bodies which reside in the deep portion of layers V and VI. The layer VIb neurons are continuous with the associational projecting neurons located in layer VIb of posterior cingulate cortex, and the cell bodies of layer VIb neurons in both regions are morphologically similar. The layer Vb cell bodies which have associational projections lie in a thin, AChE rich strip of cortex which has the same position and staining pattern as deep layer V of the posterior cingulate cortex. Again these neurons are morphologically similar to those in layer Vb of the posterior cingulate cortex; however, both the layer V and VI associational cell bodies are smaller than their entorhinal counterparts. Further experiments demonstrated that the neurons which divide layer Vb from VIb, project to the anterior thalamic nuclei. A few layer VIb, pre- and postsubicular neurons were labeled by thalamic injections, but double labeling studies demonstrate no collateralization between the thalamic and cortically projecting populations.

Injections of the pre-and postsubicular cortices demonstrate that the homotopic projections arise from neuronal cell bodies in layer II, III, V and VIb of the ipsilateral cortex. The homotypic projections arise in the contralateral layer III and to a lesser extent in layer II and V neurons.

Thus, the cell bodies of the pre- and postsubicular cortices are laminated in a fashion quite similar to that seen in the posterior cingulate cortex.

203.3 LAYER VI OF CINGULATE CORTEX: ASSOCIATIONAL PROJECTIONS. K. Sripanidkulchai and J.M. Wyss. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, AL 35294.

Layer VI of the cortical mantle has usually been considered to be populated by neuronal cell bodies with axons that project to the thalamic nuclei. Catsman-Berrevoets and Kuypers (Brain Res 154:359-365 [1978]) suggested that these cells could be classified as superficial neurons that project to the corresponding principal thalamic nuclei and deeper neurons that project to non specific thalamic nuclei. In the present study, we have examined both the thalamic and cortical projections of the layer VI neurons of the rat cingulate cortex using the fluorescence dye, retrograde labeling technique. Each of thirty albino rats received an injection of 10-50nl of 2-4% fast blue (FB) via a 500nl Hamilton syringe placed into a restricted region (approximately 0.5mm effective injection site) of the posterior cingulate cortex. In 15 of these rats 2-5 days after the FB injection, a 10-50nl injection of 2-4% nuclear yellow (NY) was placed either into a second region of the ipsilateral or contralateral posterior cingulate cortex, or into the anterior thalamic nuclei. All rats were sacrified 4-7 days after the FB injection; the fixed brains were sectioned at 30μ, and these sections were inspected under fluorescent illumination (Leitz A cube). Alternate sections were stained with methylene blue (1 in 3 series) and thiocholine (1 in 3 series for ACHE).

Injections into the retrosplenial cortex resulted in the labeling of a large number of neuronal cell bodies in layers II, III, V and VIb of the ipsilateral homotopic cortex near (within 2mm) the injection site. In regions of the posterior cingulate cortex more distant from the injection site, a considerable number of neuronal cell bodies in deep layers V and VI were labeled, but few cell bodies were labeled in layers II, III and superficial V. Within the anterior cingulate cortex deep layer V and VI neurons were labeled continuously to the rostral pole of the cortex. Very seldom was a layer II, III or superficial layer V or VI neuron labeled in the anterior cingulate cortex following a posterior cingulate cortex injection. The double labeling studies demonstrate that very few of the deep layer V and VI neurons innervate the contralateral, homotopic cortex. Further, the thalamic injections indicate that the posterior cingulate cortico-thalamic neurons are located primarily in the superficial part of layer VI. The few thalamic projecting cell bodies that are located in deep layer VI do not appear to have associational projections to the homotopic cortex.

203.4 TEMPOROPOLAR CORTEX OF THE MACAQUE: M.A. Moran,* E.J. Mufson, M-M. Mesulam, Harvard Med. Sch., Boston, MA.

The temporopolar cortex (TP) is one of the major paralimbic (mesocortical) components of the primate brain. The agranular-periallocortical sector of TP is directly contiguous with the temporal limb of prepiriform olfactory cortex (POC). This periallocortical core of TP is surrounded by a dysgranular zone which is, in turn, flanked by granular cortex. Dorsally, the cortical transition in TP proceeds from the POC towards the auditory association cortex of the anterior superior temporal gyrus. Ventrally, a similar transition proceeds towards the granular cortex of inferotemporal visual association areas. The two lines of differentiation converge within the multimodal association cortex of the superior temporal sulcus. The present study was undertaken to determine some cortico-cortical connections of TP cortex in the rhesus monkey.

Injections of HRP in subsectors of TP resulted in neuronal labeling within the amygdala, the uncal hippocampus, POC, anterior cingular cortex (including the parolfactory region FL), the caudal orbitofrontal and anterior insular regions, prorhinal cortex, entorhinal cortex, parahippocampal areas TF-TH, the granular isocortex of rostral orbitofrontal cortex (areas 10, 14, 12 and 13), the banks of the superior temporal sulcus, the auditory association area TA and the visual association area TE. It is important to note that TP is one of the very few cortical areas to have direct connectivity with the hippocampus, with area FL and with the entorhinal region.

Individual sectors of TP showed differences in their connectivity. For example, the nonisocortical parts of TP (the agranular and dysgranular sectors) received the majority of their inputs from limbic areas and from the nonisocortical sectors of paralimbic regions. In contrast, the granular part of TP received much less input from entorhinal cortex, the amygdala, POC and the hippocampus. The dorsal part of TP receives most of its modality-specific input from auditory association cortex whereas an analogous visual input dominates the modality-specific afferents of the ventral TP. Most of the inputs into TP from nonisocortical areas tended to come from infragranular layers whereas those from isocortical cortex tended to originate mostly within supragranular layers.

These observations, together with those previously obtained in the insula, show that the connectivity of subsectors within paralimbic zones is organized along cytoarchitectonic lines of demarcation. Furthermore, area TP, together with other components of the paralimbic brain, provides a major site for spatially organized sensory limbic interactions. For example, olfactory-visual and olfactory-auditory interactions occur in medial TP. Furthermore, dorsal TP provides a site for auditory-limbic intractions whereas analogous visuo-limbic interactions occur in ventral TP. Supported in part by NS 20285, NS 09211, AG 05134, the ADRDA, the McKnight Foundation, IPB 8402034 and Fogarty Fellowship FO5 TW03624.

203.5 CORTICO-CORTICO AND LIMBIC-CORTICO PROJECTIONS TO RODENT PREFRONTAL CORTEX. B.L. Wilhite* and T.J. Teyler, Northeastern Ohio Universities College of Medicine, Neurobiology Dept., Rootstown, Ohio 44272.

The afferent projections to the rodent prefrontal cortex were examined using the horseradish proxidase (Sigma VI) localization technique in an attempt to elucidate possible cortico-hippocampal pathways. Injection sites were localized to the Prc_m (prefrontal) and/or adjacent Prc^I (premotor) areas of Zilles et al. (Anat. Embryol. 159:335, 1980). Neither the pipette nor the reaction product involved the medially adjacent cingulate cortex, or the underlying white matter (corpus callosum). The tissue was processed by the TMB procedure.

Analysis of the tissues revealed two previously uncharacterized projections to prefrontal cortex. A sparce projection from the hippocampus was discovered and although these cells were primarily ipsilateral to the injection sites, a few contralateral cells were filled as well. Label was principally limited to non-pyramidal cells, although in some instances pyramidal cells of CA1 were filled. The cells appeared most generally in the stratum oriens and were found throughout the septo-temporal extent of the hippocampus.

The other, and much more predominant projection, was from the somatosensory cortex (Sm 1 of Zilles). The labelled cortical cells which projected to prefrontal cortex were found primarily in the middle layers of the neocortex and appear to be layer III pyramidal cells. The pattern of labeled cells exibited a columnar organization, and in three-dimensional perspective, appear as linear bands within the confines of the somatosensory cortex. A small number of cells were also indentified in temporal and entorhinal corticies but appeared to be few and random in their arrangement. Previously documented projections to prefrontal cortex from medial dorsal thalamus and perirhinal cortex were also reconfirmed.

203.6 INTERHEMISPHERIC CONNECTIONS OF THE NEOCORTEX OF THE BAT, ANTROZOUS PALLIDUS. G.O. Ivy, L. Beasley*, M. Leon and G. Lynch. CNLM and Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

The insectivorous Microchiroptera are generally considered to have poorly developed parietal, temporal and occipital neocortical areas and to lack entirely a frontal region (Henson, 1970). These views are based on a combination of cytoarchitectonic and physiological data; to date, studies demonstrating neocortical connectivity have not been carried out. Since patterns of interhemispheric connections are thought to reflect the relative development of a cortical region, we decided to examine these patterns in the bat.

Four bats were anesthetized, and the skull covering one hemisphere surgically removed. Multiple injections of HRP were placed at regular intervals throughout the neocortex. The following day the animals were perfused and the brains were processed using TMB and BDHC histochemical procedures on alternate sections.

Retrogradely labeled neurons were found continuously throughout the tangential extent of neocortex contralateral to the injection site. In addition labeled neurons were found in every lamina of the cortex. However, the laminar distribution of labeled cells was found to vary substantially among cortical regions. In particular, laminae V and VI were densely labeled throughout the cortex. This includes the cells of lamina Vb which in rodents and higher mammals project subcortically but not, in general, transcallosally. Regional variations in the pattern of labeling in laminae V and VI reflected cytoarchitectonic differences among cortical areas. In contrast, the variable pattern of labeling in more superficial laminae reflected regional differences in the degree of interhemispheric connectivity. Regions of dense labeling in superficial layers alternated in a complex fashion with regions of little or no labeling. In densely labeled areas, HRP filled neurons above laminae V and VI resided predominantly in lamina III, with fewer in lamina IV and very few in lamina II. Small areas within motor, parietal, temporal and occipital cortices (Rose, 1912) contained few or no HRP filled cells in the superficial layers. By analogy with patterns of callosal connections in other mammals, these regions correspond to primary motor, somatosensory, auditory, and visual cortices, respectively.

In conclusion, the complex patterns of neocortical interhemispheric connections in the pallid bat indicate that, as in other placental mammals, regional variations in these connections probably reflect specializations for sensory and motor processing. It is interesting to note that the continuous pattern of labeling in laminae V and VI of Microchiroptera resembles that seen in neonatal rodents. This pattern suggests a neotonized state for the deeper cortical layers in the pallid bat. Further, the relative lack of a dense callosal projection from superficial laminae suggests that cells in these layers preferentially mediate ipsilateral cortico-cortical information processing. Supported by NIH NS21484 (to ML).

203.7 PROJECTIONS FROM THE BASAL FOREBRAIN TO THE CORTEX DEMONSTRATED BY ANTEROGRADE TRANSPORT OF PHASEOLUS VULGARIS LEUCOAGGLUTININ (PHA-L). N. J. Woolf, M. C. Hernit*, and L. L. Butcher. Dept. of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

In order to trace the trajectories and to study the terminal endings of basal forebrain projections to the cortex, the plant lectin PHA-L was iontophoretically injected (Gerfen & Sawchenko, Brain Res., 290:219, 1984) into various regions of the basal forebrain containing cholinergic somata. PHA-L was demonstrated by an immunofluorescent protocol employing a fluorescein isothiocyanate second antibody. In order to compare the total number of neurons taking up PHA-L to cholinergic somata accumulating the anterogradely transported label, tissue sections were additionally reacted with monoclonal antibodies directed against choline acetyltransferase (ChAT), which was visualized with a rhodamine-conjugated secondary antibody.

Following injections of PHA-L into the magnocellular preoptic area many fibers could be traced to the olfactory bulb, amygdala, and the pyriform cortex. A large bundle of fibers entered the olfactory tract and continued to the bulb. In the anterior olfactory nucleus a few fibers could be traced leaving the bundle. Scattered fibers emanating from the magnocellular preoptic area coursed laterally to innervate the amygdala and pyriform cortex. Most of the magnocellular preoptic cells that took up the lectin did not contain ChAT, and only a few PHA-L cells were also immunoreactive for ChAT. It is likely, therefore that many fibers observed in the olfactory bulb, amygdala, and pyriform cortex were not cholinergic. A few fibers probably were cholinergic, however, since cholinergic as well as non-cholinergic cells of the magnocellular preoptic area are known to project to the olfactory bulb, amygdala, and pyriform cortex.

Injections of PHA-L into medial portions of the substantia innominata resulted in the labeling of numerous fibers coursing through the medial septal nucleus and diagonal band area. A few of these fibers continued dorsally to innervate the anterior cingulate cortex. Some coursed caudally in the cingulate to innervate medial and posterior cingulate, as well as the visual cortex. Many cells labeled with lectin were also co-labeled for ChAT. Thus, it is likely that these cortical fibers demonstrating PHA-L were cholinergic.

PHA-L injected into the nucleus basalis resulted in the labeling of fibers in the frontal cortex. These fibers did not appear to have any regular orientation. Several bifurcations in these fibers were noted. PHA-L was co-localized with ChAT in some basalis cells suggesting that the frontal cortex fibers were cholinergic.

203.8 THE CONNECTIVITY OF TWO SUBREGIONS OF THE INFERIOR PARIETAL LOBULE WITH THE PULVINAR COMPLEX OF THE THALAMUS IN THE RHESUS MONKEY. L.J. Lobeck*, J.C. Lynch and S.G.P. Hardy. Dept. of Anatomy, U. Miss. Med. Center, Jackson, MS 39216.

The cortex of the inferior parietal lobule (IPL) and the pulvinar complex of the thalamus share many functional properties. Neurons in both regions fire during active reach, hand manipulation, saccadic eye movements, interested fixation of gaze, and combinations of the above. Neural activity in both regions is strongly affected by the animal's level of attention. The inferior parietal lobule sends dense projections to the pulvinar and receives reciprocal projections from it. The projection to the pulvinar has been reported to end in multiple dense patches separated by terminal-free regions, but the interpretation of this observation has been complicated by the use of multiple injections. We have studied the pattern of corticothalamic terminations in the pulvinar and relationship of the thalamocortical cell bodies to these terminal zones using large single placements of tracers. We have also compared the corticothalamic connectivity of the convexity of the IPL (area PGc) with that of the IPL cortex buried within the inferior bank of the intraparietal sulcus (area POa). These two cortical areas differ cytoarchitecturally as well as in their afferent and efferent connectivity with other regions of the cortex and with the superior colliculus.

Eight hemispheres of six monkeys were studied using anterograde transport of tritiated amino acids and anterograde and retrograde transport of horseradish peroxidase (HRP). Injections of tritiated amino acids were made in five hemispheres and placements of HRP gel were made in three hemispheres. Large single placements of either tracer in PGc resulted in multiple patches of labeled axons within the lateral, medial, and oral nuclei of the pulvinar. These terminal zones were characterized by dense horizontal bands of labeled axons and terminals separated by less heavily labeled or unlabeled zones. Large single placements in POa resulted in single, generally smaller, zones of label extending across the lateral and medial pulvinar nuclei. Only faint labeling was observed in pulvinar oralis following POa placements. Retrogradely labeled thalamocortical cell bodies were found predominantly in clusters that were almost totally restricted to the regions of labeled corticothalamic axons. These findings suggest that the two subregions of the inferior parietal lobule that we have studied have different patterns of connectivity with the pulvinar complex. There is a close relationship between the corticothalamic terminal regions and the thalamocortical cell bodies that connect pulvinar and IPL. Furthermore, the heterogeneous distribution of areas of connectivity with the IPL within each pulvinar nucleus suggests that each of these three nuclei are composed of functionally specialized subregions. [Supported by grants from NIH (EY-04159) and the Vaughan Stroke Research Trust]

203.9 DISJUNCTIVE DISTRIBUTION OF MEDIODORSAL THALAMIC AFFERENTS IN THE PREFRONTAL CORTEX OF RHESUS MONKEYS. M. Giguere and P. Goldman-Rakic. Yale University School of Medicine, Section of Neuroanatomy, 333 Cedar Street, New Haven, CT 06510

Although the reciprocal connections between the mediodorsal (MD) nucleus and prefrontal association cortex in primates are well established and their basic topographic organization worked out, the details of laminar and tangential distribution of MD afferents in primate prefrontal cortex are not known. In the present study, we employed injections of WGA-HRP in different subdivisions of MD in rhesus monkey in order to determine: i) the layer(s) in which MD afferents terminate; ii) the location of the cells of origin of the reciprocal cortico-thalamic pathway; and, iii) whether the terminal fields of this pathway - like that of the cortico-cortical afferents - is organized in bands of a specific width.

(i) With injections confined to the medial (MDmc) and lateral (MDpc) portions of MD labeled terminal were present in layer IV and deep layer III in the ventral and dorsolateral regions of the prefrontal cortex, respectively. No terminal label was found in layers I, superficial III, V or VI in any part of the prefrontal cortex following these injections.

(ii) Analysis of retrograde transport reveals labeled cortico-thalamic neurons mainly in layer VI with some labeled cells situated also in the superficial part of layer V. The distribution of retrogradely labeled cells corresponds to the location of anterogradely labeled terminal fields, and, in addition, fluctuations in the density of labeled cells parallel changes in terminal field density. In contrast, in the anterior cingulate and supplementary motor cortex, which lay outside the traditional borders of prefrontal cortex, reciprocity was totally absent. These areas also contain high concentrations of retrogradely labeled neurons but received only sparse reciprocal projections from MD.

(iii) The projection from MD to the cortex formed a disjunctive pattern of bands ranging in width from 0.3 to 1.3 mm. These bands were evident only when injections were circumscribed; when the injection involved more than a single moiety of MD or extended into a larger area of the thalamus, such as the adjacent VA-VL complex, the pattern of the terminal labeling was more diffuse and tangentially extensive throughout layers III and IV. These data suggest that the thalamic inputs from the nuclear subdivisions of the intrinsic association nuclei and/or from the motor relay nuclei of the thalamus may interdigitate in the prefrontal cortex.

In conclusion, MD has reciprocal connections with the prefrontal cortex that exhibit precise laminar specificity. In addition, the disjunctive patterning of thalamocortical terminals supports the concept of a modular prefrontal architecture.

203.10 SOMATOSENSORY REPRESENTATION IN PRIMATE PREFRONTAL CORTEX: CONNECTIONS OF THE PRINCIPAL SULCUS WITH S-I, S-II, AND ADJACENT AREAS OF THE FRONTOPARIETAL OPERCULUM. T.M. Preuss and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

Although it is commonly believed that primate prefrontal association cortex does not receive direct projections from primary sensory cortex, several studies have demonstrated connections between prefrontal cortex and the frontoparietal operculum, a region containing the intraoral representation of S-I (Robinson & Burton, J. Comp. Neurol., 192: 43, 1980). We have examined prefrontal-opercular connections in macaques using frontal lobe injections of HRP or tritiated amino acids, making particular reference to cytoarchitectonic and physiological maps of the opercular region. In four cases with injections that included the ventral rim of the principal sulcus (Walker's area 46), dense anterograde and retrograde labeling occurred over the rostrocaudal extent of the frontoparietal operculum, including the deep gustatory area, the intraoral representation of S-I, and S-II. The heaviest labeling in S-II occurred in its rostral and superficial portions, corresponding to the orofacial representation (Robinson & Burton, 1980). Within the S-I complex, labeling occurred mostly in areas 1-2. Anterograde and retrograde labeling in the operculum took the form of rostrocaudally oriented stripes or columns. Cells projecting to prefrontal cortex were found mostly in layers III and V; terminal labeling was heaviest in layer I, followed by layer III.

Labeling was also found in several areas adjacent to the operculum, including the anterior and middle insular cortex, which receives input from the principal gustatory thalamic nucleus (VPMpc); the ventral precentral cortex (Von Bonin & Bailey's area FCBm), which contains the representation of the laryngeal muscles (Hast et al., Brain Res., 73: 229, 1974); and areas 2 and 7b of the rostral inferior parietal lobule, where cells have trigeminal receptive fields (Robinson & Burton, J. Comp. Neurol., 192: 69, 1980).

This study demonstrates that primate prefrontal cortex has strong reciprocal connections with primary somatosensory cortex as well as with other areas (S-II, insula, deep gustatory cortex) which receive input from principal somatosensory or gustatory thalamic relay nuclei. Further, the finding that the ventral rim of the principal sulcus is connected with cortical subdivisions representing intra- and perioral regions, the laryngeal muscles, and taste, suggests that an area of frontal association cortex in monkeys contains an orofacial representation. The functions of this region may include the voluntary control of facial movements in feeding and/or communication.

203.11 GEOMETRY AND QUANTITATIVE CHARACTERISTICS OF DENDRITIC ARBORS OF THALAMOCORTICAL PROJECTION NEURONS IN THE CAT VA AND VM. S. Al-Hussain and K. Kultas-Ilinsky. Dept. of Anatomy, Univ. of Iowa College of Med., Iowa City, IA 52242

Dendritic geometry and branching patterns are important in understanding the conduction properties of the nerve cells. Very little is known, however, about these parameters in regard to neurons in the motor thalamic nuclei. In the present study various quantitative and qualitative parameters of the dendritic arbors of thalamocortical projection neurons in Golgi impregnated preparations were compared in the ventral anterior (VA) and ventral medial (VM) thalamic nuclei. The parameters measured were those descrbed by Hillman (The Neurosci. 4th Study Progr. MIT Press, 1979, p. 477) and included: the number, width (W), and length (L) of consecutive order dendritic branches, correlation between the soma size and the sum of dendrite diameters, type of branching, ratio between cross sectional diameters of daughter branches (R), branch power (n) and the segment taper (a).

The results indicate that in both nuclei the diameters of consecutive order dendritic branches vary and wide overlap occurs between W of primary (1D) secondary (2D), and tertiary (3D) dendrites. Positive correlation was found between the surface area of somata and the sum of dendrite diameters of cells in the VA whereas in the VM it was less pronounced. The mean number of 1D per cell in VM was 7 ranging from 5 to 10. In the VA the number was slightly higher. Branching pattern of different order dendrites on the same cell was also quite variable. Most of the dendrites divided dichotomically whereas about 1/3 of dendrites in each TCPN studied gave rise to tufts of 3-5 daughter branches. Both in the VA and VM for about 25% of primary dendrites R = 1 whereas in the rest it ranged from 1.2 to 2.3. Almost all dendrites of the VM neurons regardless of type of branching had $n < 2$. In the VA, however, n for about 60% of dichotomically branching segments was < 2, for the rest $n \geq 2$. The values were reversed for the tufted type dendrites: 66% had $n > 2$, and the rest < 2. The length of dendritic segments was also very variable. The L of 1D in VM ranged from 5-30 μm, 2D length varied from 5-20 μm and the 3D L from 5-90 μm. In VA wider range of variations (5-100 μm) in L of all segments was observed. No tapering of dendritic segments was found in either VA or VM neurons.

These findings demonstrate that the dendritic arbors of TCPN in the motor thalamus display great diversity. The fact that diverse branching patterns are found in dendritic trees of individual cells suggests that conductance properties of different dendrites of the same cell may not be same. The comparison of the morphological parameters of TCPN in the nuclei indicates that in the VA individual neurons display more variability in different parts of their dendritic arbors as compared to the VM. Supported by NIH NSR0119280.

203.12 DESCENDING PROJECTIONS ORIGINATING WITHIN THE NUCLEUS BASALIS IN THE RAT. Elizabeth L. Weiss and Richard W. Rieck. Dept. of Anatomy, Tulane Medical School, New Orleans, Louisiana 70112.

The nucleus basalis, Ch4, (Mesulam, et al., Neurosci., 10: 1185, 1983) is known to provide an extensive cholinergic projection to all areas of the neocortex. In addition, neuronal loss within the nucleus basalis may be the basis of many of the severe deficits observed in patients with senile dementia of the Alzheimer's type (Whitehouse, et al., Ann. Neurol., 10:122, 1981). Furthermore, recent evidence suggests that another cholinergic component of the basal forebrain, i.e., the diagonal band of Broca, may also contribute a descending projection into the thalamus. Thus, the presence of a descending projection from the nucleus basalis to the dorsal thalamus was investigated in the present study. Injections of retrograde tracers, i.e., 1.7% wheat germ agglutinin-horseradish peroxidase (WGA-HRP) or 30% HRP, were placed electrophoretically within the dorsal thalamus. Retrogradely labeled neurons are located within the rostral portions of Ch4 following placement of injections within the stria medullaris and the mediodorsal nucleus. In contrast, labeled neurons are located within intermediate levels of Ch4 following placement of injections within the centromedian-parafascicular complex. These thalamic projecting neurons are either located within the ansa pedundularis or are immediately ventral to the globus pallidus. Thalamic projections, however, apparently do not originate within the Ch4 component that is interdigitated between the putamen and the globus pallidus. The retrogradely labeled neurons within Ch4 have a perikaryal morphology that is consistent with that of acetylcholinesterase and choline acetyltransferase positive neurons within the same region, i.e., large multipolar isodendritic cell types. Furthermore, the same cellular type within the nucleus basalis is known to project to the neocortex. These data suggest that the nucleus basalis, as other basal forebrain cholinergic systems, may also contribute a subcortical projection to specific targets within the thalamus. Thus, the specific subcortical projections of the nucleus basalis may contribute to the symptomatology associated with certain degenerative disease states. Supported by BRSG 532802 (R.W.R.).

203.13 TOPOGRAPHY OF DORSAL RAPHE PROJECTIONS TO NEOSTRIATUM. J.W.Boja* and H.K.Kulmala (SPON: J.Reinglass), Pharmacology Program, NorthEastern Ohio Universities College of Medicine, Rootstown, OH 44272.

The neostriatum receives a large, mainly serotonergic projection from the dorsal raphe nucleus (DRN). Whereas most serotonergic projections to the forebrain are topographically organized, no such topography has been reported in DRN projections to neostriatum. Indeed, the same DRN cells have been shown to project to medial and lateral striatum. However, the density of serotonergic innervation of neostriatum is organized in a rostro-caudal gradient, with the highest concentration in the tail of this nucleus. We have determined whether a rostro-caudal topography is evident in this projection.

Male Sprague-Dawley rats were anesthetized with sodium pentobarbital (50 mg/kg i.p.) and placed in a Kopf stereotaxic instrument. Injections of 0.2-0.5 ul of a 25-35% horseradish peroxidase (HRP) solution were made via a 1 ul Hamilton microsyringe at one of three rostrocaudal levels of the neostriatum. Following 48-72 hrs, animals were killed under deep anesthesia by transcardial perfusion of saline followed by 1.5% glutaraldehyde - 1% paraformaldehyde and ice cold 10% sucrose. Forty, 50 um thick sections were cut on a CO_2-freezing microtome and reacted with tetra-methyl benzidine - hydrogen peroxide to localize the HRP.

Labeled neurons were evident in the rostral 2/3rds of the DRN after striatal HRP injections. Very few median raphe neurons contained HRP. These few probably were labeled by the small amount of HRP evident along the needle tract in the cortex overlying the striatum. Rostral injections labeled cells more medially in the DRN. Caudal injections led to label in DRN cells in the dorsal cluster and lateral wings of the DRN. More cells were labeled after caudal injections than after rostral striatal injections.

It is concluded that a rostro-caudal topography is evident in the projection from the DRN to the neostriatum.

204.1 AN ELECTRONIC MORPHOMETRY AND MAPPING ANALYSIS MICROSCOPY SYSTEM (EMMA) FOR THE QUANTITATIVE AND COMPARATIVE STUDY OF NEURAL STRUCTURES. Warren G. Young, John H. Morrison, and Floyd E. Bloom, Div. Preclinical Neuroscience and Endocrinology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

As methods for the selective demonstration of neurons and neural circuitry have expanded, the morphologically oriented neuroscientist requires methods to measure and map structures and compare them with existing anatomic data. Existing commercially-developed systems are expensive and lack analytic flexibility. Therefore, we have developed a general analytic system to acquire accurate morphological date quickly, compare them with previously acquired data, and an enlargeable text data base of neuronal microscopic circuitry, transmitters, and other functional properties. EMMA uses the Digital Equipment Corp. LSI 11/73 super microcomputer combined with a Zeiss Inverted ICM 405 microscope through highly accurate optical position sensors on the X,Y and Z axes, and through a high resolution video interface. EMMA can accurately measure and record structural elements from 1 micron to 50 mm. The live video images from the microscope are displayed on a monitor, with overlaid menus of program commands and computer-generated tracings of desired structures. A separate color monitor displays cumulated computer graphic data. With this configuration we can reconstruct the arborization of most neuronal structures, determine their macro-regional distribution, and compare these cells for 2- or 3-dimensional morphological and positional properties with previously analyzed fields. The image may also be digitized for storage or mathematically processed to enhance or subtract images, or to assign colors to gray levels. In a typical application, EMMA can render a 2-dimensional distribution of cytochemically-defined soma versus fibers in a single field, contingent only on the resolving power of the cytochemical method. If the density or size distribution of the reactive structures is discriminable, EMMA can automatically estimate the density and frequency of the two defined structural components. EMMA users can also consult several online anatomic databases while analyzing specimens. Frontal and sagittal atlas sections of brain structures can be overlaid onto the televised microscopic specimen to assist in identifying neuronal structures, and to provide templates onto which cell body or neuropil data may be mapped, stored and compared. A text-oriented data base of known anatomic structures, indicating afferent projections, efferent projections, as well as transmitters and functional properties are tied to selected anatomic regions. (Supported by grants from MacArthur Foundation and the Sam and Rose Stein Charitable Trust).

204.2 THE IMMUNOHISTOCHEMICAL DISTRIBUTION OF SOMATOSTATIN 28 (SS28) AND SOMATOSTATIN 28(1-12)(SS28(1-12)) IN MONKEY PREFRONTAL (PFC) AND TEMPORAL (TC) CORTICAL REGIONS. M.J. Campbell, D.A. Lewis*, J.H. Morrison. Div of Preclin. Neurosci. & Endocrinol, Scripps Clinic and Res. Fdn., La Jolla, CA 92037.

We have used antisera that selectively recognize the prosomatostatin-derived peptide fragments SS28 and SS28(1-12) to characterize their immunohistochemical distribution in the PFC (including Area 24) and TC of the cynomolgus and squirrel monkey. These antisera demonstrates that SS28 is largely restricted to cell bodies, whereas SS28(1-12) is preferentially localized in neuronal processes and terminals. Although it was not invariant there was a characteristic laminar pattern of fiber staining. The densest terminal arborization was in layers I, II and superficial III. Deep III and IV were traversed by radial fibers with little arborization. V and VI contained both radial fibers and a moderately dense terminal plexus. There were fewer labelled fibers in the white matter. These fibers tended to run parallel to the pial surface until they swept into layer VI and assumed a radial orientation. This radial orientation was most striking in the TC where it was often possible to follow fibers from the white matter or infragranular layers to superficial layer III. Somatostatin-positive cells were found throughout all cortical layers and the white matter. The largest number were located in layers II and superficial III and deep V and VI. This bimodal distribution was more pronounced in TC than in PFC. There were regional differences in cell body density which were paralleled by differences in fiber density. For example, in PFC, area 24 had the greatest cell and fiber density, area 46 the lowest and area 9 had an intermediate density of both. However all regions of the PFC and TC had far greater density of cells and terminals than primary visual cortex. These regional patterns imply that intrinsic cortical systems can exhibit substantial regional variation. Many stained cells had a Golgi-like quality displaying both dendritic processes and a presumed axonal process. These neurons represented a diverse morphological group that included examples of established cell types such as Martinotti and basket cells. As in the rat (Morrison et al., Brain Research 262, 1983) and the human (Morrison et al., Nature 314, 1985) the antisera to SS28 and to SS28(1-12) allowed for a much more extensive characterization of the distribution and morphology of both cell bodies and processes than antisera to SS-14. The complexity and the density of this heterogeneous group of SS-containing neurons suggest that they are likely to play an important role in several aspects of intrinsic circuitry of the neocortex. Supported by AG0513, MacArthur Foundation, Sam and Rose Stein Charitable Trust, K1-00519, AA07456-01, and AA06420.

204.3 AN EXPERIMENTAL ANALYSIS OF THE INTRACORTICAL SOMATOSTATIN-CONTAINING NEURONS. J.H. Morrison, S. Scherr, M.J. Campbell, and D.A. Lewis. Scripps Clinic and Research Foundation, La Jolla, CA 92037

Prosomatostatin derived peptide fragments somatostatin-28(SS28) and somatostatin 28(1-12) (SS28 (1-12) have been shown to have a preferential intracellular distribution in the rat neocortex. SS28 is located primarily in cell bodies whereas SS28(1-12) is located in fibers and terminal processes. In the rat neocortex both the cell bodies and terminal plexuses have their highest density in a supragranular band and infragranular band. There are long radial fibers that traverse deep III, IV and superficial V. Also, there are labelled cells and fibers present in the sub-cortical white matter. In order to further characterize the branching patterns of specific axons and sources of the axonal plexuses, we initiated an experimental analysis of the somatostatin system. Three techniques were used in combination with somatostatin immunohistochemistry: 1) small iontophoretic injections of phaseolus vulgaris-leucoagglutinin (PHA-L), which fills cells locally and is transported anterogradely, and 2) true blue injections (transported retrogradely), and 3) carefully placed undercut lesions. The PHA-L was localized with an anti-PHA-L made in guinea pig, followed by FITC-conjugated anti-guinea pig IgG, allowing for double-labelling with peptide antisera made in rabbit (Gerfen and Sawchenko, Brain Research, 1985). The iontophoretically applied PHA-L formed an injection site 100-300 um in diameter, and labeled cells within a 1 mm radius that had a dendritic process extending into the injection site. When the PHA-L loaded cells were visualized simultaneously with anti-SS12 fine radial SS12-positive processes were seen in association with pyramidal cell apical dendrities. The true blue double-labelling studies demonstrated that there were multiple sources for both the infra- and supragranular terminal fields. Following superficial application of true blue, three major somatostatin-containing cell classes were double-labelled; 1) cells with elongated, horizontally disposed dendrites at the VI-white matter border, 2) small multi-polar cells throughout VI directly below the injection site, and 3) multi-polar cells within layers II and III 300-1200 um from the injection site. Following the layer VI undercut experiments, the supra- and infragranular terminal plexuses were not decreased in density, implying that most of the somatostatin-containing terminals are intrinsic in origin. We conclude that horizontally and radially projecting somatostatin containing cells are present in neocortex, and layer III pyramidal cell apical dendrites may be one of the primary targets of radially projecting, multi-polar somatostatin cells. Supported by AG0513, MacArthur Foundation, K1-00519, AA07456, and AA06420.

204.4 DETERMINATION OF BIOLOGICALLY RELEVANT QUANTITIES OF NEUROTENSIN AND ITS FRAGMENTS USING ISOCRATIC OR GRADIENT ELUTION HIGH PERFORMANCE LIQUID CHROMATOGRAPHY WITH ELECTROCHEMICAL DETECTION. R. Rivest, A. Drumheller*, S. St-Pierre* and F. Jolicoeur. Departments of Psychiatry and Pharmacology, Faculty of Medicine, University of Sherbrooke, Sherbrooke, Quebec, Canada, J1H 5N4.

High Performance Liquid Chromatography coupled with electrochemical detection (HPLC-ECD) has become the method of choice for the determination of many electroactive substances in biological samples. The sensitivity of this method often surpasses that achieved with either UV or fluorometric detection. Recently it has been shown that peptides containing tyrosine and/or tryptophan residues are electroactive and can be detected amperometrically (Bennett et al., Life Sci, 29:1001, 1981). In this study we investigated the potential of using HPLC-ECD for the separation and quantification of neurotensin, a 13 amino acid peptide containing two tyrosine residues at positions 3 and 11. Results indicate that under isocratic conditions less than 300 pg of neurotensin can be separated and detected within 10 min. The sensitivity of this assay greatly surpasses that of HPLC-UV detection and approaches that achieved with radioimmunoassay techniques.

In a parallel study the use of a modest gradient to separate and quantify biologically relevant fragments of neurotensin including NT1-8, NT1-10 and NT9-13 was examined. Several mobile phase compositions and gradient profiles were tested and compared in terms of resolving power and sensitivity. Results indicate that less than 50 ng of neurotensin and fragments can be separated and detected within 25 min using 0.05 M ammonium acetate (pH 4.2) /acetonitrile (90/10 v:v) as equilibrating buffer and increasing the concentration of acetonitrile stepwise until neurotensin eluted (23% acetronitrile). Although the gradient method outlined here is 100 to 200 x more sensitive than HPLC-UV detection, extraneous noise and baseline drift generated by the gradient increased the detection threshold approximately 100 fold as compared to that found using isocratic elution.

Finally, in preliminary experiments we have examined the ability of this procedure to detect neurotensin and selected fragments in rat brain. In whole brain homogenates peaks having the same retention time as synthetic neurotensin, NT 1-8 and NT 1-10 were observed. We are presently examining the regional distribution of neurotensin-like electroactivity to see if it resembles that of the immunoreactivity of the peptide.

Supported by the Medical Research Council of Canada.

204.5 RE-EVALUATION OF THE DISTRIBUTION OF ANGIOTENSIN IN RAT BRAIN BY PAP IMMUNOCYTOCHEMISTRY USING NICKEL INTENSIFICATION: COMPARISON TO THE DISTRIBUTION OF RENIN SUBSTRATE. M.S.Brownfield* and B. Poff*. (SPON: S. Lorens). Department of Physiology, University of California, San Francisco, CA 94143 and Department of Structural and Functional Sciences, University of Wisconsin, Madison, WI, 53706.

Biochemical studies have shown that a renin substrate (RS) from which angiotensin (ANG) can be liberated in vitro is present in the brain and cerebrospinal fluid of rats. It has been suggested that this material could be the precursor of brain ANG. A map of the distribution of brain ANG has been evolving as a result of several immunocytochemical (ICC) studies. However, ICC studies of brain RS are lacking and so a knowledge of its cellular origins and how they may relate to those of ANG is unknown. In this study, we have (1) evaluated the distribution of brain ANG using the peroxidase-antiperoxidase method in combination with nickel intensification (PAP-Ni) of the final reaction product, and (2) compared the distribution of ANG to that of RS. Cryostat sections were processed using two specific ANG (DE, courtesy D. Ganten and UW-MB- #R29) and one RS (gift of J. Bouhnik) antibodies at dilutions of 1:750 to 1:1500 and 1:8,000 to 1:20,000, respectively.

The PAP-Ni method stained immunoreactive ANG much more intensely and with a much greater distribution than has been reported previously using peroxidase methods. Colchicine treated rats (100 ug ivt) revealed the presence of a large number of neuronal perikarya in hypothalamic parvocellular and magnocellular nuclei and lateral hypothalamus. The latter appeared to give rise to an intense fiber system (as shown in untreated rats) projecting through the lateral hypothalamus to numerous areas including (but not limited to) periventricular structures, the amygdalaoid complex, preoptic area, nucleus of the solitary tract, spinal cord and cerebellum. Lesser numbers of immunopositive cells are also found in several of these apparent terminal fields.

The distribution of RS in areas also occupied by ANG was overwhelmingly glial, in contrast to the neuronal localization for ANG. Moreover, most brain areas contained reactive glial cells, but were devoid of ANG. Substantial background staining was encountered which under the electron microscope was shown to be intercellular.

These results demonstrate that the source of RS is glial and that it is morely widely distributed than ANG. Glial to neuronal contacts might supply RS to many neurons directly, or they could take it up from the interstitium. Whether they produce ANG would depend on whether they contain renin. Alternatively, RS might have a more general role in the brain that might not be related to ANG production. (Supported by the UWGS and NIH HL 29714).

204.6 QUANTITATIVE AUTORADIOGRAPHIC DETERMINATION OF ANGIOTENSIN-CONVERTING ENZYME DISTRIBUTION IN RAT BRAIN WITH ^{125}I-MK351A, A SPECIFIC INHIBITOR. F.M.A. Correa, L.M. Plunkett* and J.M. Saavedra. Section on Clinical Psychopharmacology, NIMH, Washington, DC 20205-1000

Quantitative determination of angiotensin converting enzyme (ACE, kininase II) can be accomplished by dissecting brain nuclei with the "punch" technique and incubating the homogenates with the ACE substrate hippuryl-His-Leu [glycine-1-^{14}C] (Brain Res.309: 389-392, 1984). Recently ACE has been localized in the brain by incubating brain sections with the ACE inhibitor [^{3}H]-Captopril (PNAS, 81:1599-1603, 1984). Although [^{3}H]-labelled compounds have the advantage of improved neuroanatomical localization, enzyme quantitation cannot be determined in individual brain structures.

We report a quantitative autoradiographic method for the kinetic analysis of ACE in discrete brain areas using a ^{125}I-ligand. ACE was localized, levels were quantitated and enzyme kinetics determined by incubation of tissue sections with ^{125}I-MK351A (Merck, Sharp, Dohme). Compound 351A is a p-hydroxybenzamidine derivative of MK521, which is the Lys-Pro analog of MK422, the active di-acid form of the specific ACE inhibitor enalapril (MK421). Compound MK521 was used as a displacer.

^{125}I-MK351A binding sites were observed throughout the CNS with a very localized distribution. The density of ACE sites was found to be higher in the choroid plexus and the subfornical organ (320±22 and 166±38 fmol/mg protein). A good correlation was observed between ACE-site density and areas rich in AII receptors. High densities of ^{125}I-MK351A sites were observed in the supraoptic and paraventricular nuclei, the median eminence, the area postrema and the nucleus tractus solitarius (48±8, 35± 12, 43±8, 58±4, 39±2 fmol/mg protein), areas which are involved in important physiological processes such as cardiovascular regulation. In addition, a large part of ACE binding is present in areas not involving the angiotensin system, such as the nigrastriatal system. ACE distribution was found to be relatively homogenous throughout the caudate-putamen (average value of 104± 21 fmol/mg protein), the globus pallidus (50±6 fmol/mg protein) and the substantia nigra pars reticularis (177±33 fmol/mg protein). Scatchard analysis indicates the existence of two slightly different groups of binding sites with significantly different dissociation constants. Structures such as choroid plexus and subfornical organ display a Kd of around 0.8nM whereas areas such as caudate-putamen and globus pallidus have a Kd of around 2.0mM.

The use of ^{125}I-MK351A autoradiography allows the quantitation of ACE-sites in tissue, since it interacts on a one to one molecular basis with the enzyme. Our results point to a possible heterogeneity among dipeptidyl carboxipeptidases in the brain.

204.7 **THYROTROPIN-RELEASING HORMONE (TRH) PROJECTION TO THE HIPPOCAMPAL FORMATION VIA THE FORNIX.** W.C. Low, T.G. Hill*, and M.J. Kubek. Depts. of Physiology and Biophysics, Anatomy, and Psychiatry, Indiana Univ. School of Medicine, Indianapolis, IN 46223.

Thyrotropin-releasing hormone (TRH) and TRH receptors have previously been localized throughout the limbic system and other areas of brain. Recent studies in our laboratory have demonstrated sustained elevations of TRH within the hippocampal formation (HF), amygdala (AY), and cortex (CTX) as a result of electroconvulsive shock (Life Sci., 36:315-320, 1985; and this meeting). TRH within these areas of brain may be intrinsic and/or originate from TRH-containing nerve cells within the hypothalamus and/or brainstem. The fornix is a possible pathway by which TRH or its synthesizing enzyme(s) can reach the HF. To test this hypothesis unilateral lesions of the right fornix and overlying neocortex were made by aspiration in male Sprague-Dawley rats (200-350 gm). Control animals received aspirated unilateral lesions of the neocortex overlying the right fornix sparing its fibers. Two weeks after the lesion, animals were decapitated and brains were removed, dissected, weighed and frozen on dry ice. Tissues were extracted with acetic acid and TRH was quantified by a specific radioimmunoassay. TRH content was expressed as pg/mg wet weight (mean +/- SEM). Lesions of the fornix resulted in a highly siginificant decrease in HF TRH in comparison to sham operated controls (6.2 +/- 0.39 vs. 2.06 +/- 0.21; $p < 0.001$). In contrast, a significant increase in cortical TRH was observed following the fornix lesion (1.27 +/- 0.20 vs. 2.75 +/- 0.18, $p < 0.005$). No significant changes were found in the anterior, medial or posterior hypothalamus, amygdala or septum. These results support the hypothesis of an extrinsic source of hippocampal TRH via the fornix. The amount of TRH remaining in the HF after fornix lesions may reflect levels intrinsic to the hippocampus or a second TRH fiber projection. The increase in cortical TRH was unexpected and may be due to a sprouting of the severed TRH fibers. This phenomenon remains to be determined along with the source of HF TRH innervation. Supported by the Veterans Administration Research Service (M.J.K.), and PHS grants AM-28260 (M.J.K), RR-5371F (W.C.L.), and AG-5575 (W.C.L.).

204.8 THE AMYGDALA IS A SOURCE OF CHOLECYSTEKININ OCTAPEPTIDE FOUND IN THE PONTINE PARABRACHIAL NUCLEUS OF THE CAT. T.H. Burke, B.G. Kirol*, B.E. Maley, and W.M. Panneton Depts. of Anatomy, Univ. of Kentucky, Lexington, Ky. 40536 and St. Louis University, St.Louis, Mo. 63104.

Cholecystekinin Octapeptide (CCK-8), a peptide found in both gut and the central nervous system, has been implicated in the regulation of vasomotor tone. Both the amygdala and the parabrachial nucleus have been shown to contain CCK-8, and also are components of central cardiovascular control. Since large numbers of CCK-8 containing neurons are found in the amygdala, while none are found in the parabrachial nucleus it was therefore hypothesized that the CCK-8 immunoreactivity found in the parabrachial nucleus originates in the amygdala.

In this study, CCK-8 immunoreactivity was identified by means of the peroxidase, antiperoxidase (PAP) method. Adult cats were injected with 0.01 μl of horseradish peroxidase (HRP) in the parabrachial nucleus. After four days, 240 μl of colchicine were injected intracisternally, and the animals were allowed to survive for two additional days. They were then perfused transcardially with 4% paraformaldehyde in Sorenson's phosphate buffer pH 7.2. 50 μm frozen sections were collected, pretreated with cobalt chloride to enhance the HRP staining, and then reacted with 3,3' diaminobenzidine containing 0.3% hydrogen peroxide prior to employing the free floating PAP procedure of Sternberger.

Following injections into the parabrachial nucleus, the amygdala was examined for labelled neurons. The amygdala contained neurons which exhibited either black HRP granules or the brown reaction product of CCK-8 immunoreactivity. In addition, several cells also contained both the black HRP reaction product and the brown immunostaining of CCK-8 immunoreactivity.

These results indicate that at least some of the CCK-8 immunoreactivity in the parabrachial nucleus arises from neurons in the amygdala. The central regulation of cardiovascular control contains several loops of which the amygdala-parabrachial loop is a part. The presence of CCK-8 in this loop suggests its use as the neuropeptide involved in cardiovascular regulation of the amygdala and parabrachial nucleus.

204.9 PEPTIDERGIC EFFERENTS FROM THE INTERCALATED NUCLEI OF THE AMYGDALA TO THE PARABRACHIAL NUCLEUS IN RAT. T.S. Gray and M.M. Moga*. Dept. Anat., Loyola Stritch Sch. Med., Maywood, IL 60153

The peptide content of the intercalated nuclei (ICN) of the amygdala and their projection to the parabrachial nucleus was studied using the combined retrograde transport-immunofluorescence method. Stereotaxically-guided injections of 50nl of fast blue retrograde tracer were made into the parabrachial nuclei of 150-300gm male rats. Bilateral injections of colchicine were administered to all animals 36-48hr prior to sacrifice. Post-fast blue injections survival periods were 9-12 days. Animals were overdosed with sodium pentobarbital, and then fixed via transcardial perfusion with 4.0% phosphate buffered paraformaldehyde. Brains were cut into 20um coronal sections. Alternate sections were processed using antibodies to neurotensin (NT), somatostatin (SS), corticotropin releasing factor (CRF) or enkephalin (ENK). Immunoreactivity was visualized using rhodamine conjugated antirabbit immunogammaglobulin. One set of sections was counterstained with cresyl violet.

In animals with fast blue injections centered within the lateral parabrachial nucleus, retrograde labeling was observed within a distinct cluster of cells in the rostral amygdala. This cluster corresponded in shape and location to an anterior group of intercalated cells first described in the rat by Guardjian ('28). Most rostrally, the retrograde labeling appeared as a plate of cells just ventral to and aligned with the posterior limb of the anterior commisssure. In more caudal sections, the retrograde labeling appeared as a tightly-packed sphere and was located adjacent to the external capsule. Distinct clusters of NT-immunoreactive cells were seen in corresponding positions to the retrogradely labeled cells. Many NT-immunoreactive cells were double-labeled with fast blue. SS-, CRF- and ENK-immunoreactive cells were diffusely distributed within the ICN. Only a few CRF- and SS- cells were retrogradely labeled. Retrogradely labeled ENK-immunoreactive neurons were never observed. Both SS and ENK terminal immunoreactivity densely filled the ICN. NT- and CRF-immunoreactive fibers were sparsely distributed within the ICN.

Results of this study suggest that NT, and to a lesser degree, CRF and SS, are contained with ICN neurons which innervate the parabrachial nucleus. ENK and SS terminals surround parabrachial efferent cells within the ICN. To our knowledge, the present study is the first to identify an efferent pathway originating from the intercalated nuclei of the amygdala. Our results indicate a functional link between the ICN and the lateral subdivision of the central nucleus of the amygdala based on their similar peptidergic projections to the parabrachial nucleus. (Supported by NIH grant NS 20041)

204.10 HYPOTHALAMIC PEPTIDERGIC EFFERENTS TO THE PARABRACHIAL NUCLEUS IN THE RAT. M.M. Moga* and T.S. Gray. Dept. Anat., Loyola Stritch Sch. Med., Maywood, IL 60153

Previously, we found that the parabrachial nucleus receives substantial corticotropin releasing factor, neurotensin, and somatostatin projections from both the central nucleus of the amygdala (CNA) and the bed nucleus of the stria terminalis (BNST). In this study, we examine the contribution and content of hypothalamic peptidergic efferents to the parabrachial nucleus using the combined retrograde transport-immunofluorescence technique.

Fifty nanoliters of the retrograde tracer fast blue was injected into the parabrachial nucleus of 150-300g male rats. Animals were treated with bilateral injections of colchicine 36-48 hours prior to sacrifice. Post-fast blue survival periods were 9-12 days. Animals were overdosed with sodium pentobarbital, and then perfused transcardially with 4.0% phosphate buffered paraformaldehyde. The brains were cut into 20um coronal sections. Four series of sections, each with a different primary antibody, were processed for each animal. A number of primary antibodies were tested including: neurotensin (NT), corticotropin releasing factor (CRF), somatostatin (SS), met-enkephalin (ENK), vasoactive intestinal peptide, substance P, cholecystokinin, oxytocin (OXY), and vasopressin. Immunoreactivity was visualized with rhodamine conjugated antirabbit immunogammaglobulin.

Retrogradely labeled neurons were found in the lateral hypothalamus, medial and lateral preoptic areas, arcuate nucleus, paraventricular nucleus, dorsal hypothalamus, and periventricular nucleus. Neurons labeled with both fast blue and rhodamine immunofluorescence were located predominantly in the lateral hypothalamus. Preliminary cell counts indicate that approximately 12% of the NT-, 9% of the CRF-, and 8% of the SS-immunoreactive neurons found in the lateral hypothalamus project to the PBN. Less than 1% of the NT-, CRF-, SS-, OXY- and ENK-immunoreactive neurons in the PVN were retrogradely labeled with fast blue. A few cells in the medial preoptic area were double-labeled with fast blue and either ENK or NT. Still fewer were double-labeled for CRF or NT in the lateral preoptic area.

In summary, the lateral hypothalamus is the major hypothalamic source of CRF, NT, and SS terminals to the PBN. The PVN peptidergic contribution to the PBN is minor. In the CNA and BNST, a high percentage of CRF-(57% and 28%, respectively), NT-(50% and 23%), and SS-(42% and 22%) immunoreactive neurons project to the PBN. In conclusion, the results from all three of our studies (i.e., CNA, BNST and hypothalamus) indicate that the CNA and BNST are the major forebrain sources of CRF, NT and SS terminals to the PBN. (Supported by NIH grant NS 20041)

204.11 THE MEDIAL PREOPTIC AREA RECEIVES A MAJOR SUBSTANCE P PROJECTION FROM THE REGION OF THE VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS IN THE RAT. Charles W. Malsbury, Dept. Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada, A1B 3X9

Autoradiographic tracing studies have revealed long-axon projections from the ventromedial nucleus (VMN) to a number of forebrain and midbrain sites. The VMN contains numerous substance P-immunoreactive cell bodies (Ljungdahl et al., Neuroscience, 1978, 3, 861) and some of the VMN projection sites have a substantial substance P (SP) innervation. The origins of the SP innervation of most of these areas are not known.

Immunocytochemistry (ICC) was used here to explore the possibility that VMN projection neurons contribute to the SP innervation of these areas. Adult female rats received large unilateral radiofrequency lesions of the VMN region and were killed 6 days later. The brains were processed for ICC using the PAP method. Known VMN projection sites including septal area, bed nuc. of the stria terminalis, medial preoptic area (MPOA), medial amygdala, peripeduncular nucleus, and midbrain and pontine central gray were examined for a reduction of SP staining on the side of the brain ipsilateral to the lesion. The only site where an obvious reduction of staining was observed was the MPOA, including the periventricular POA. Takatsuki et al. (Exp. Brain Res., 1983, 53, 183) reported that lesions rostral to the VMN, in the ventral part of the medial anterior hypothalamus, reduced SP staining in the MPOA. Given the present results, it is possible that their lesions interrupted ascending axons from VMN to MPOA. Further studies combining retrograde tracing of MPOA afferents with SP ICC will be necessary to precisely identify the cells of origin of this innervation.

The functional significance of this SP projection is not known, but it is possible that it is involved in the control of mating-induced prolactin release, as lesions of either VMN or MPOA, or knife cuts between these areas, disrupt this response (Gunnet & Freeman, End. Rev., 1983, 4, 44).

204.12 THE DEVELOPMENT OF NEUROPEPTIDE Y-LIKE IMMUNOREACTIVITY IN THE HYPOTHALAMUS OF THE GOLDEN HAMSTER. JOAN M. MURNANE, FRANK D. SABATINO*, ROGER A. HOFFMAN*†, JOHN K. MCDONALD. Departments of Anatomy, Emory Univ. Sch. of Med., Atlanta, GA 30322, and †Biology, Colgate Univ., Hamilton, NY 13346.

High concentrations of Neuropeptide Y (NPY) have been found in the hypothalamus of several species. Previous studies in the rat have demonstrated that neurons in the intergeniculate leaflet (IGL) project NPY labeled axons to the suprachiasmatic nucleus (SCN) (Moore et al., Cell Tiss. Res., 1984). Injections of NPY into the SCN of the Golden hamster (Mesocricetus auratus) phase shift circadian activity rhythms (Albers & Ferris, Nsci. Lett., 1984). In addition, injections of NPY into the third cerebral ventricle of ovariectomized rats decreased plasma levels of luteinizing hormone (LH) and growth hormone (GH), while directly stimulating LH and GH release from pituitary cells in vitro (McDonald et al., PNAS, 1985).

In view of these reports, we have investigated the distribution of NPY-like immunoreactivity in the hypothalamus of adult and developing Golden hamsters. Adult and neonatal animals of both sexes at 2, 3, 6, 8 and 11 days after birth were anesthetized and perfused through the aorta with fixative containing 4% paraformaldehyde, 0.1 M DL-lysine and 0.01 M sodium periodate in 0.05 M phosphate buffer. The brains were sectioned at 40 µm with a freezing microtome and alternate sections were stained with cresyl violet to identify nuclear landmarks. Conventional immunohistochemical methods were used with our own rabbit anti-porcine NPY serum at a dilution of 1:1500. Incubation of the antiserum with 10^{-6} M synthetic porcine NPY prevented staining.

In the adult, labeled perikarya were observed in the arcuate nucleus, and in the ventral lateral geniculate nucleus and IGL of the thalamus. High concentrations of NPY immunoreactive fibers were seen in the SCN, and also in the preoptic (medial and median), paraventricular, periventricular, dorsomedial and lateral hypothalamic nuclei. With the notable exception of the SCN, a network of labeled fibers was present in these nuclei on postnatal day 2 which gradually attained the adult pattern of staining by day 11. The SCN displayed 1 or 2 fibers on the second postnatal day and a striking increase in the number of labeled fibers between days 3 and 11, at which time the adult pattern was observed. These results provide a description of NPY-like immunoreactivity in the hypothalamus of the adult and developing Golden hamster. The functions of NPY in these hypothalamic nuclei remain to be determined. However, the gradual increase in NPY labeled fibers in the SCN during the first eleven days of postnatal life may have important implications for the development of circadian rhythms. Supported by NIH HD 19731, Emory Univ. Research Fund and †Faculty Development Council, Colgate Univ.

204.13 NPY LOCALIZATION IN MONKEY HYPOTHALAMUS. C.L. Shen and R.Y. Moore. Dept. of Anatomy, Col. of Medicine, Natl. Cheng Kung University, Taiwan, Rep. of China and Departments of Neurology and Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, New York, 11794.

Neuropeptide Y (NPY) is a 36 amino acid peptide originally isolated from porcine brain by Tatemoto ('82). It has a wide distribution in rat brain with highest concentrations occuring in hypothalamus (Emson and Quilt, '83). Although no detailed analysis of NPY distribution in hypothalamus has been published, it is likely that a prior study demonstrating avian pancreatic polypeptide (APP) like immunoreactivity in the rat hypothalamus (Card et al., '83) actually showed NPY since the APP antibody actually demonstrates NPY (Moore et al., '84). In the present study, the distribution of immunoreactive structures was identical with the two antibodies and cross blocking studies have shown that they both demonstrate NPY.

Hypothalami were provided by Dr. Anita Hendrickson, University of Washington Regional Primate Center. The animals were perfused with periodate-lysine-paraformaldehyde and 30 um coronal sections through the hypothalamus were processed using the peroxidase-anti-peroxidase procedure of Sternberger ('79).

Immunoreactive axons and terminals were present throughout the hypothalamus, however, with the exception of the ventral division of the bed nucleus of the stria terminalis and the arcuate nucleus , no immunoreactive cells were evident. This contrasts with previous findings in the rat (Card et al., '83) and probably reflects differences in methodology since immunoreactive cells were most effectively demonstrated in rats pretreated with colchicine. Axons containing NPY are densest in the periventricular zone extending from the preoptic area to the caudal tuberal area. A dense plexus of immunoreactive axons is present in the medial preoptic nucleus, ventral tuberal area, arcuate nucleus and in the lateral hypothalamus, particularly in the zone surrounding the fornix. Other areas of hypothalamus are more lightly innervated. In general, the pattern of innervation is quite similar to that of noradrenergic afferents arising from lateral tegmental cell groups. Since many of the lateral tegmental noradrenergic neurons also contain NPY (Everitt et al., '84), these data suggest that a significant portion of the NPY system that we have identified in the hypothalamus may arise from brainstem cell groups which colocalize noradrenaline and NPY. Hypothalamic axons which do not arise from brainstem noradrenergic neurons but exhibit NPY immunoreactivity are also apparent in our material. This is illustrated by thin varicose immunoreactive axons in the suprachiasmatic nucleus that presumably arise from the lateral geniculate nucleus (Card and Moore, '82). Supported by NIH grant NS-16304.

204.14 ULTRASTRUCTURAL FEATURES OF THE HYPOTHALAMIC CORTICOTROPIN RELEASING FACTOR (CRF)-IMMUNOREACTIVE NEURONAL SYSTEM OF LONG TERM ADRENALECTOMIZED RATS. W.K. PAULL and Zs. LIPOSITS (SPON: J.D. Dexter). Department of Anatomy, University of Missouri-Columbia, School of Medicine, Columbia, MO 65212.

Recent light microscopic immunocytochemical studies (Merchenthaler et. al., Reg. Peptides 5:295-305,1983; Paull and Gibbs, Histochemistry 78:303-313,1983) indicated that following long term adrenalectomy (ADX) the paraventriculo-infundibular CRF-system is characterized by an increased hormone content. The present study deals with the ultrastructural aspects of adrenalectomy induced alterations of the hypothalamic CRF-system. The peroxidase-antiperoxidase-complex (PAP)-immunocytochemical method was used in a preembedding manner for the detection of CRF immunoreactivity in both long term (2-3 weeks) adrenalectomized and adrenalectomized-dexamethasone treated (100 µg/100 g.b.w., 24 hours before sacrifice) administered male rats.

CRF-positive neurons located in the medial and dorsal parvocellular subnuclei of paraventricular nucleus (PVN) were completely filled with hypertrophied rough endoplasmic reticulum (rER). The rER demonstrated considerable dilatation of the cisternae. Neurosecretory granules (NSG), in the vicinity of active Golgi complexes, measured 80-120 nm diameter. The CRF-neurons also contained an increased number of multivesicular bodies. CRF dendrites possessed labeled smooth endoplasmic reticulum (sER) and microtubules. Within the PVN, CRF-positive neurons received both axo-somatic and axo-dendritic synapses. In addition, ephaptic contacts were observed to occur between CRF-immunopositive and other CRF-immunopositive, as well as CRF-immunonegative parvocellular cells. The area of apposition was increased due to the retraction of glial processes and the cell membranes were coupled by puncta adherentia.

Axons within the median eminence contained CRF positive NSG's, small vesicles and hypertrophied sER. The preterminal portions of the axons were characterized by a dominance of NSG's, while the greatly enlarged terminals possessed few NSG's. Within the palisade layer the axon terminals made frequent contact directly on the abluminal basal lamina in that ependymal processes were retracted. Occasionally, CRF positive terminals were observed within the pericapillary space of portal vessels.

The short-term glucocorticoid administration further increased the hormone content of paraventricular CRF neurons in adrenalectomized animals.

These data suggest, that: 1) CRF-production is adrenal steroid dependent. 2) Removal of adrenal glands results in hypertrophy of organelles associated with protein synthesis and transport in CRF neurons. 3) Glial and ependymal elements possibly take part in the regulation of the paraventriculo-infundibular CRF-system. 4) In adrenalectomized rats the effect of short term glucocorticoid treatment is opposite to that of the long term administration of the hormone. Supported by NIH grant NS 19266 to WKP.

204.15 INFLUENCE OF THE CENTRAL NUCLEUS OF THE AMYGDALA ON THE CONTENT OF CORTICOTROPIN-RELEASING FACTOR IN THE MEDIAN EMINENCE. L. Dêsy*, S. Beaulieu, M.-C. Tonon*, H. Vaudry*, G. Pelletier and N. Barden (Spon: M. Beaulieu). MRC Group in Molecular Endocrinology, CHUL, Quebec, G1V 4G2, CANADA and Groupe de Recherche en Endocrinologie moléculaire, Faculté des Sciences de Rouen, Mont-Saint-Aignan, FRANCE.

High concentrations of corticotropin-releasing factor (CRF) in the amygdaloid central nucleus (ACE) of different species have been reported by various groups. We have also accumulated evidence that the ACE exerts a stimulatory action on ACTH secretion in response to stress (S. Beaulieu and al., this meeting). The present study was designed in order to investigate whether or not this stimulatory action of the ACE was mediated via modification of the CRF concentration in the median eminence.

Ovariectomized Sprague-Dawley rats (250-300g) were either left intact or submitted to bilateral electrocoagulation lesions of the ACE one or two weeks before perfusion with Bouin's fixative under ketamine anesthesia. Some of the intact and lesioned animals received an intraventricular injection of colchicine (30 µg in 15 µl of isotonic saline) 48 hrs before perfusion. Brains were removed, post-fixed for 18 hrs in the same fixative and embedded in paraffin. Slices (7 um thickness) were mounted on slides and incubated with a specific anti-rat CRF antibody or an anti-rat neurophysin antibody according to the standard peroxidase-anti-peroxidase procedure.

The CRF-like immunoreactivity was markedly decreased in the median eminence of rats bearing bilateral lesions of the ACE performed either one or two weeks before perfusion. Lesion of the ACE did not alter the neurophysin-like immunoreactivity in the median eminence, indicating the integrity of the efferent neurophysin-containing fibers of the supraoptic and paraventricular hypothalamic nuclei. Moreover, in comparison with intact colchicine-treated animals, the number of cells containing CRF-like immunoreactive material in the hypothalamic paraventricular nucleus was higher in colchicine-treated rats bearing two weeks old lesions of the ACE.

These results substantiate the hypothesis that the ACE can influence the content of CRF-like material in the median eminence. Finally, they also indicate that long-term (2 weeks) bilateral lesions of the ACE may trigger an enhancement of the synthesis of CRF in the paraventricular nucleus of the hypothalamus in order to compensate for the decreased CRF content in the median eminence. (Supported by the MRC)

204.16 DISTRIBUTION OF CORTICOTROPIN-RELEASING FACTOR-LIKE IMMUNOREACTIVITY (CRF-LI) IN MICRODISSECTED AREAS OF THE RAT BRAIN. P. B. Chappell*, M. A. Smith, C. M. Anderson*, G. Bissette, C. D. Kilts, and C. B. Nemeroff. (Spon: G. R. Marsh) Dept. of Psychiatry, Duke Univ. Med. Ctr., Durham, N. C. 27710

CRF-LI was measured in thirty-six rat brain regions by modification of a radioimmunoassay described in detail elsewhere (Meth. Enzymol. 103:565, 1983) using an antiserum raised in rabbits against synthetic ovine CRF which is directed toward the C-terminal region of the peptide (amino acids 31-41) and a tracer of ^{125}I-Tyr-CRF, purified by HPLC, with the lowest detectable level of CRF-LI being 2.5 pg/tube. Subjects were ten adult male Sprague-Dawley rats in which care had been taken to minimize stress by two weeks of daily handling prior to decapitation. Brains were rapidly removed and frozen on dry ice. Thirty-six brain nuclei were then micropunched from 300 µm coronal brain slices using the microdissection technique of Palkovits. Brain samples were sonicated in 1N HCl and centrifuged; duplicate aliquots of supernatant were lyophilized and assayed for CRF-LI. Protein was determined by the method of Lowry.

Concentrations of CRF-LI, expressed as picograms CRF/mg protein, were detected in all brain nuclei sampled. The highest concentrations were found within the hypothalamus in the median eminence/arcuate nucleus (5054 ± 674), the paraventricular nucleus (498 ± 44), and the periventricular nucleus (316 ± 15). The next highest levels of CRF-LI were found in the dorsal (238 ± 28) and the median (241 ± 17) raphe nuclei and the dorsal motor nucleus of the vagus (193 ± 15). The locus ceruleus which is rich in norepinephrine cell bodies contained 148 ± 9 pg/mg. CRF-LI was well represented in the central (192 ± 17), cortical (148 ± 21), and medial (110 ± 10) amygdaloid nuclei and in the bed nucleus of the stria terminalis (136 ± 14). In the dorsal and ventral hippocampus and in all cerebrocortical regions examined, relatively low levels (12 to 28 pg/mg protein) of CRF-LI were detected. In the midbrain/brainstem, the ventral tegmental area (134 ± 11), the periaqueductal grey (144 ± 18), and the substantia nigra, zona compacta (190 ± 13) were found to contain appreciable concentrations of CRF-LI.

These RIA findings are generally concordant with previous RIA studies of CRF-LI distribution in rat brain as well as with the results of immunocytochemical studies. CRF-LI was found to be widely distributed in the rat CNS as well as in the hypothalamus, and appreciable concentrations were detected in major serotonergic and adrenergic nuclei suggesting that CRF may be involved in the central integration of endocrine, behavioral, and autonomic responses to stress. (Supported by NIMH MH-39415)

204.17 RELATIONSHIP OF CRF-IMMUNOSTAINED CELLS AND MAGNOCELLULAR NEURONS IN THE PARAVENTRICULAR NUCLEUS OF THE RAT HYPOTHALAMUS.
D.T. Piekut and S.A. Joseph. The Neuroendocrine Unit, University of Rochester School of Medicine, Rochester, NY 14642.

Following the isolation and synthesis of corticotropin releasing hormone (CRF), immunocytochemical studies have elucidated the anatomical identification and localization of this peptide in rat brain. In the paraventricular nucleus (PVN) of hypothalamus, a dense accumulation of immunostained neurons containing CRF has been demonstrated in the parvocellular component of this nucleus. A potential modulating role of neurohypophyseal hormones (vasopressin, oxytocin) in the pituitary-adrenal axis has been speculated. In our studies of the PVN, a new immunocytochemical technique in which the glucose oxidase-antiglucoseoxidase complex (GAG) is combined with the PAP or ABC complex is employed to visualize two antigens with contrasting colors in the same tissue section. This dual antigen immunocytochemical staining protocol is utilized to study a potential relationship of perikarya containing oxytocin, vasopressin and CRF. Brains from (a) normal untreated, (b) colchicine treated and (c) adrenalectomized animals are utilized. Results indicate that within the confines of the nucleus separate and distinct populations of cells containing the immunoreactive (ir) elements are seen within the magnocellular and parvocellular divisions in PVN of rat hypothalamus. Examination of dual stained vibratome sections is extended to the one micron level and in both thin and thick sections, results are consistent in the normal untreated, colchicine treated and adrenalectomized rat. CRF-ir cells are for the most part concentrated in the medial parvocellular component of PVN. Immunostained CRF neurons are present in the ventral medial portion of the posterior magnocellular (pm) division in which oxytocinergic neurons predominate; juxtaposed CRF-ir and oxytocin-ir perikarya are identified in the colchicine treated and adrenalectomized animals. Few CRF immunostained cells are seen in the dorsal lateral portion of the pm division in which vasopressin-containing cells are localized. However, an intimate anatomical proximity between CRF-ir and VP-ir perikarya is evident in brains of adrenalectomized animals. The latter is localized in the medial parvocellular division of PVN, an area normally VP-ir poor except in the adrenalectomized rats. This extension of VP-ir cells into this CRF-rich region and the very close approximation between the two cells bodies suggests potential cell to cell communication following pertubation of the brain-pituitary-adrenal axis.

204.18 CRF-IMMUNOREACTIVE NEURONS WITHIN THE INFERIOR OLIVE PROJECT TO THE FLOCCULUS AND DORSAL AND VENTRAL PARAFLOCCULI. S. Cummings, R. Wade and B. Sharp*. Depts. of Anatomy and Medicine, University of Minnesota, Minneapolis, Minnesota 55455

Corticotropin releasing factor (CRF) has been demonstrated by RIA and immunohistochemistry to be widely distributed throughout the central nervous system, in extrahypothalamic regions as well as within the hypothalamic-hypophyseal axis. One rather unexpected observation was the presence of CRF-immunoreactive (CRF-IR) fibers within the cerebellum, an area in which few peptides have been localized. In the present study have examined CRF-IR fibers within the flocculus and dorsal and ventral paraflocculi of cat and monkey cerebellum. In these regions the CRF-IR fibers appear to be intimately associated with the cell bodies and dendrites of Purkinje cells.

There are several nuclei within the brainstem which provide input to the cerebellum and also contain CRF-IR cell bodies. Therefore, we initiated a tract tracing study combining the retrograde transport of the fluorescent dye Fast Blue with the peroxidase-anti-peroxidase method of immunohistochemical detection of CRF in order to explore the possible projections of CRF-containing fibers from these regions. Fast Blue (1%) was injected into the right flocculus and paraflocculi of randomly bred cats (1.5-2.0 kg). After 5 days, colchicine (500 ug) was injected intracisternally. The animals were perfused transcardially with buffered paraformaldehyde 48 hr later. Sections were observed under UV illumination and Fast Blue-labeled cells were photographed. Subsequently, the sections were processed for immunoperoxidase staining using a primary antiserum directed against rat CRF, and then re-photographed. We were able to demonstrate populations of both Fast Blue-labeled cell bodies and CRF-IR neurons within the medial vestibular nucleus, n. prepositus hypoglossi, n. raphe dorsalis, locus ceruleus, and the inferior olivary nucleus. However, comparisons of negatives and photographs revealed co-localization of CRF immunoreactivity and Fast Blue only within neurons of the inferior olive.

These results demonstrate that CRF-IR fibers arising from cell bodies within the inferior olive project to the flocculus and dorsal and ventral paraflocular lobules of the cerebellum. Because the inferior olive is known to be the region from which climbing fibers project to these ventral cerebellar lobules, we suggest that the CRF-IR fibers may represent a subpopulation of such climbing fibers. A study to determine the ultrastructural identity of these CRF-IR fibers is in progress. Demonstration that ovine CRF binding sites are likewise present in the cerebellum, (Wynn et al. Peptides 5:1077, De Souza et al. J. Neurosci. in press) suggests a possible role here for CRF as a neurotransmitter. Supported by DA02148.

204.19 IMMUNOLOCALIZATION OF PEPTIDES CONTAINED WITHIN PROGLUCAGON IN RAT CENTRAL NERVOUS SYSTEM. C. Jin*, A.C. Towle*, V.K.M. Han*, M. Hynes, J.G. Simmons*, J.M. Lauder and P.K. Lund*, School of Medicine, University of North Carolina, Chapel Hill, N.C. 27514.

A Rat pancreatic cDNA was previously shown to encode a large molecular weight proglucagon containing a glicentin related polypeptide (GRPP), glucagon, intervening peptide I (IP-I), glucagon-like-peptide I (GLP-I), intervening peptide II (IP-II) and glucagon-like peptide II (GLP-II) (Heinrich et al. Endocrinol. 115, 2176,1984). GRPP, glucagon and GLP-I are co-localized in the rat pancreatic A cells which is consistent with the structure of proglucagon predicted from the cDNA. In rat brain the predominant glucagon-like immunoreactant (GLI) was shown to correspond to glicentin (Tager et al, PNAS 77, 6229, 1980) which contains GRPP, glucagon and IP-I. In the present study we investigated the distribution of peptides present in proglucagon in rat central nervous system. Rats were perfused with Bouins fixative and 10μ paraffin sections prepared. Coronal brain sections were stained with antisera to GRPP (R64), glucagon (R32) and GLP-I (R1). Immunostaining was detected by the Avidin-biotinylated-peroxidase complex (ABC) method. GRPP and glucagon antisera stained many fibers in medial hypothalamus and mediodorsal thalamus but stained few or no fibers in cortex, striatum and brain stem. In contrast, GLP-I antisera stained only a few fibers in medial hypothalamus. The similarity of staining pattern of thalamic and hypothalamic fibers with GRPP and glucagon antisera is indicative of cosynthesis of these peptides in a brain proglucagon, and axonal transport of both peptides. The low abundance of hypothalamic fibers containing GLP-I immunoreactivity, compared with GRPP and glucagon, raises several possibilities about proglucagon synthesis and processing. Brain and pancreas may synthesize the same glucagon precursor but post-translational processing of proglucagon in brain may result in (a) segregation of GLP-I from GRPP and glucagon so that few neurons transport GLP-I to axonal projections, or (b) transport of GRPP, glucagon and GLP-I to axonal projections but different rates of release and/or metabolism of GLP-I or (c) transport of GRPP, glucagon and GLP-I to axonal projections but lack of recognition of the axonal molecular form of GLP-I in most fibers, by the GLP-I antiserum. Alternatively,hypothalamic neurons or neuronal subpopulations could synthesize a different glucagon mRNA and precursor than pancreas resulting in fewer fibers containing GLP-I immunoreactants compared with GRPP and glucagon. Consistent with this hypothesis, we have detected a 1300 base glucagon-related mRNA in rat brain compared with the characterized 1100 base pancreatic glucagon mRNA. Further investigation of brain glucagon mRNAs, and of the distribution of GRPP, glucagon and GLP-I immunoreactants in neuron cell bodies of colchicine treated rats, should provide further information about proglucagon synthesis and processing in central nervous system.

205.1 CHANGES IN SPONTANEOUS SINGLE UNIT ACTIVITY IN THE PUTAMEN FOLLOWING AREA 4 and 6 ABLATION IN PRIMATES. J.W. Aldridge, S. Gilman & G.W. Dauth, Dept. of Neurology, Univ. of Mich., Neuroscience Lab Bldg., 1103 E. Huron, Ann Arbor, MI., 48104.

The purpose of this study is to examine the changes in spontaneous single unit activity in the Putamen (PUT) after ablation of the motor cortex. The PUT receives a large component of its afferents from ipsilateral motor cortical areas 4 & 6 of Brodmann. The projection is believed to use glutamate as its transmitter. Intracellular studies show that this projection produces EPSP-IPSP sequences that dominate other inputs.

Two M. fascicularis primates were used. Under general anesthesia one control animal and one experimental animal were prepared for chronic single unit recording. In the experimental animal area 4 and 6 were ablated by sub-pial aspiration. Recording chambers were fixed stereotaxically to the skulls of the animals to allow daily recording sessions using tungsten electrodes. Daily recording with the animals sitting quietly in the awake state began 1 week after implantation. After accessible areas of PUT were explored, small lesions were made to mark electrode tracks, the animals were sacrificed and the brains were fixed and sectioned for histological reconstruction of tracks. Only units recorded within PUT were included.

Data were collected for 127 units in the control animal. The data from the experimental animal consist of 82 units collected in the period 8 to 31 days after the cerebral cortical ablation. During this period there was no recovery in the ability of the animal to use the affected limbs. The PUT units in the control animal fired with a mean interspike interval of 571 ms and a modal interspike interval of 16 ms, which indicates a highly skewed distribution. These values reflect the low firing rate and bursting nature of unit activity normally found in the PUT. Units in the animal with the cortical ablation had a mean interspike interval of 302 ms and a modal interval of 111 ms. Thus, there is a decrease in interspike interval (increased firing rate) of 41% and an increase in the modal interval of 594%. These changes demonstrate a new pattern of activity after ablation of areas 4 and 6 in which the units fire in more regular spike trains with fewer and less intense bursts. Loss of an important cortical influence has left the neurons to fire in a pattern that may now be determined by other afferents and the intrinsic properties of the neurons. The greater firing rate indicates that the net change may be decreased suppression due to loss of the potent collateral inhibition induced in putamenal neurons by cortical excitation.

205.2 ELECTROPHYSIOLOGICAL DEMONSTRATION OF AN INHIBITORY PALLIDOSUBTHALAMIC PATHWAY IN PRIMATES. R.D. HUFFMAN AND L.P. FELPEL. Div. of Neuropharmacology, Dept. Pharmacology, Univ. Texas Health Science Center, San Antonio, TX 78284.

Anatomical studies have demonstrated that the pallidal input to the subthalamic nucleus originates exclusively from the lateral pallidal segment of globus pallidus. Stimulation of globus pallidus in rat and cat has been shown to suppress neuronal activity in subthalamic nucleus (Brain Res. 35:67, 1971; 264:255, 1983); however, excitation of subthalamic and zona incerta neurons following globus pallidus stimulation has also been reported (Brain Res. 35: 67, 1971; Br. J. Pharmac. 65:511, 1979). Stimulation of the medial pallidal segment in monkey has also been reported to depress spontaneous discharge of subthalamic neurons (Brain Res. 111:241, 1976). In the present study, we have employed extracellular microelectrode recording techniques to assess the effects of pallidal stimulation on the activity of subthalamic and zona incerta neurons in primates. Adult Macaca mulatta (2) or Macaca fascicularis (2) monkeys anesthetized with either pentobarbital or chloralose-urethane were employed. Bipolar concentric stainless steel electrodes (6) were employed to stimulate the two pallidal segments. Extracellular recordings were obtained from the 4M NaCl-filled barrel of 2 or 5 barrel glass micropipettes. Glutamate or acetylcholine were ejected microiontophoretically onto subthalamic and zona incerta neurons to provide a steady level of neuronal activity. The effect of pallidal stimulation was assessed on the activity of 12 subthalamic and 21 zona incerta neurons. Two types of inhibition of subthalamic neuronal discharge were characteristically observed following stimulation of the lateral pallidal segment. The most common response consisted of a prolonged depression of neuronal discharge (437 ± 51 msec, n=5). The second type of response consisted of an inhibition-excitation-inhibition sequence. The initial inhibitory period (69.5 ± 16.2 msec, n=3) terminated abruptly in a rebound excitation which was then followed by a second period of inhibition of variable latency and duration. The average latency to inhibition as indicated by suppression of neuronal discharge following pallidal stimulation was 4.8 ± 0.4 msec; the discharge of several subthalamic neurons was suppressed without any evidence of post-stimulus neuronal discharge. Stimulation of the caudal half of the lateral pallidal segment resulted in suppression of activity in the lateral part of the caudal half of the subthalamic nucleus. Stimulation of the medial pallidal segment also evoked inhibition of activity in subthalamic nucleus, but putaminal stimulation occasionally resulted in excitation followed by inhibition. No zona incerta neurons were found that responded either with excitation or inhibition in response to stimulation of either pallidal segment. (Supported in part by NIH Grant NS 14091).

205.3 BEHAVIORALLY CONTINGENT ACTIVITY OF PUTAMEN NEURONS DURING LEARNED MOVEMENT IN THE MONKEY (Macaca fuscata). M. KIMURA
Dept. of Physiology, Jichi Medical School, Minamikawachi, Tochigiken, 329-04 Japan.

There are two categories of neurons in the primate putamen; type I with tonic discharges (3-7 Hz) and type II with low spontaneous discharges (< 2 Hz). The type I cells respond to sensory cue for a movement only when the animal initiates the movement by the sensory cue and type II cells exhibit phasic time-locked discharges to the body movement (Kimura et. al., Proc. Nat. Acad. Sci., 81:4998,1984). The present study aimed to examine the activities of these two types of neurons during repetitive arm and orofacial movements triggered by sensory stimulus, especially whether the type II cells have behaviorally contingent responses or not.

Neuronal activity was recorded in the left putamen and somatotopic organization was identified by microstimulation (300 Hz, 10 pulses, < 200 μA) which evoked discrete movement of body musculatures. Two movement tasks were used; (1) 3 repetitive flexion-extension of right elbow across the target for juice reward triggered by the visual command (AM), and (2) repetitive licking movements to consume juice reward triggered by a solenoid click (FR). Type I cells (n=77) showed either excitation followed by inhibition or inhibition in response to the solenoid click (latency 70 msec, 56 cells) which accompanied juice reward in AM and/or FR and to the visual command (90 msec, 38 cells) triggering arm movements in AM. These responses to the sensory cue were evoked only when the monkey initiated learned orofacial or arm movements by the cue. Type II cells (n=67) showed phasic discharges locked to the somatotopically related body movement. However, most type II cells in orofacial area exhibited phasic discharges at only initial period of repetitive licking movements triggered by the solenoid click and 60 % of type II cells in arm area discharged at only first extension or flexion phase of 3 repetitive flexion-extension movements of elbow triggered by the visual cue. All these type II cells showed almost no response at spontaneous movement without the sensory cue. The rest (40 %) of type II cells in arm area exhibited phasic time-locked activities to every 3 repetitive arm movements in AM. The onset of activities of 55 % of all the type II cells in arm area preceded (mean, 46 msec) the EMG activities in m. biceps and triceps brachii. These behaviorally contingent nature of both type I and type II putamen cell activities suggested a role of the putamen in linking sensory stimuli to behavioral responses.

205.4 CAUDATE UNIT ACTIVITY DURING JAW MOVEMENTS. C. Manetto*, J.S. Schneider, T.I. Lidsky, College of Vet. Med., VPI, Blacksburg, VA 24061.

Neuronal activity was recorded extracellularly in the caudate nucleus (CN) of partially restrained, awake cats. Jaw position and electromyographic (EMG) activity from masticatory muscles were monitored. Rhythmic jaw and tongue movements were elicited by periodically delivering a small quantity of milk to the cat via a tube resting against its upper lip. 60% of CN units changed firing rate during some phase of ingestion. The majority of ingestion-related CN units showed activity changes that were associated with the situational and stimulus events controlling ingestion rather than jaw movements per se. The firing of 49% of these cells was temporally associated with the milk contacting the perioral tissue rather than the subsequent tongue and jaw movements. All of these cells were sensitive to tactile stimulation and had perioral receptive fields. It seems plausible that the ingestion-related activity of this population reflects stimulation of the somatosensory receptive fields by the milk. An additional 16% of cells with ingestion responses had activity that was temporally-related to milk delivery but had no perioral tactile sensitivity. Conceivably these rate changes were conditioned responses.

The activity of 14% of ingestion-related units was temporally associated with jaw muscle activation. Firing rates changed at or after the onset of EMG activity increases. During ingestion, jaw muscle EMG shows rhythmic phasic bursts that are time-locked to the cyclic opening and closing of the jaw. CN units showed no relation to these individual EMG bursts: rather, unit activity changes were tonic. In addition, there was no association between the patterns of CN unit responses and the latency or magnitude of oropharyngeal movements. Moreover, the activity of these neurons typically returned to baseline rates well before the cessation of ingestional movements. Only 22% of these cells had perioral receptive fields.

The remaining 21% of responsive units had activity related to both sensory and motor aspects of ingestion. All had perioral sensitivity but showed responses that were time-locked to EMG activation. However, unit responses were only associated with milk-triggered jaw movements rather than all jaw movements. Thus, these cells showed sensory-related movement responses.

These data underscore the importance of the CN to sensory aspects of motor control. In this connection it should be noted that perioral receptive fields were seen in 70% of the cells with ingestion-related activity. The manner in which the various cell types described here interact as well as the way in which CN processing ultimately influences movement remains to be determined.

205.5 GLOBUS PALLIDUS NEURONS RELATED TO PARAMETERS AND MODES OF MOVEMENT. J.W. Mink and W.T. Thach. Depts. of Anatomy & Neurobiology, Neurology & Neurosurgery, and The McDonnell Center for Higher Brain Function, Washington U. Sch. Med., St. Louis, MO, 63110.

The discharge of single neurons in the globus pallidus was recorded in a rhesus monkey trained to perform 5 wrist movement tasks designed to dissociate several movement modes and parameters. All tasks were performed by flexing and extending the wrist with opposing or assisting torque loads (0.2 Nm). The 5 tasks included (1) a visually cued step tracking task, (2) a visually guided hold-ramp-hold tracking task, (3) a self-paced hold-ramp-hold task with delayed alternation, trained velocity, and no visual feedback of wrist position, (4) a visually guided rapid sinusoidal tracking task, and (5) a self-paced rapid sinusoidal movement without visual feedback of wrist position. Wrist position and velocity were monitored during all recordings and wrist, arm, shoulder and back EMG was monitored periodically. Neurons were recorded from both segments of the globus pallidus, but were similar in the present analysis and are considered together.

The 46 task-related globus pallidus neurons recorded to date showed activity patterns that were highly task dependent. The discharge of 41 neurons (89%) changed during visually guided step tracking movements, 21 neurons (46%) changed during visually guided ramp tracking movements, 20 neurons (44%) changed during the visually guided sinusoidal movement, 4 neurons (9%) changed during the self-paced ramp movement, and 7 neurons (15%) changed during the self-paced rapid alternating movement. 19 neurons (41%) were related to 1 task only and 5 cells (11%) were related to all tasks. For the remaining 22 neurons (48%), the relation of the discharge of a given neuron to one task did not predict its relation to other tasks. The task-dependent differences in the discharge of pallidal neurons was not due to differences of wrist velocity or position or to task-dependent differences of muscle activity.

These results address controversies concerning basal ganglia function. First, we saw no systematic relation to position or velocity, per se; second, more neurons were related to visually guided than to self-paced movements; and third, many pallidal neurons (46%) were related to step tracking ("open-loop") movements and not to ramp tracking ("closed-loop") movements. (Supported by NIH grants RO1 NS12777, T32 GM07200, NS15070, and The McDonnell Center.)

205.6 DIRECTIONAL AND BIDIRECTIONAL SIGNALS FOR MOVEMENT CONTROL IN PALLIDAL AND CEREBELLAR NEURONS. W.T. Thach, J.W. Mink, and S.A. Kane. Depts. Anatomy & Neurobiology, Neurology & Neurosurgery, and The McDonnell Center for Higher Brain Function, Washington University Medical School, St. Louis, MO, 63110.

Do signals relating to movement direction exist in the basal ganglia and cerebellum? Two rhesus monkeys were trained to perform hold-ramp-hold and hold-step-hold visually guided movements by flexing and extending the wrist with and against uniform torque loads (0.2 Nm). In one monkey recordings were made in the globus pallidus internal segment (GPi), external segment (GPe), and deep cerebellar nuclei during ramp tracking and step tracking. In a second monkey neurons were recorded in cerebellar cortex and deep nuclei during ramp tracking only. Wrist position, velocity, force and EMG were recorded simultaneously.

Task related neurons were classified as directional if the discharge rate was reciprocal for opposite movements or increased or decreased during movement in one direction only, bidirectional if the discharge rate increased or decreased during movement in both directions, and mixed if it was directional under one load and bidirectional under the other.

During step tracking, 10 GPi, 31 GPe, and 15 cerebellar nuclear neurons were related to the task. Of the GPi cells, 8 were directional, 1 bidirectional, and 1 mixed. Of the GPe neurons, 10 were directional, 18 bidirectional, and 3 mixed. Of the cerebellar nuclear cells, 1 was directional, 10 bidirectional, and 4 mixed.

During ramp tracking, 4 GPi, 17 GPe, 28 cerebellar nuclear, and 17 cerebellar Purkinje cells were related to the task. In GPi 3 neurons were directional, 1 bidirectional, and 0 mixed. In GPe 5 neurons were classified as directional, 8 bidirectional, and 4 mixed. In cerebellar nuclei, 6 neurons were directional, 14 bidirectional, and 8 mixed. In cerebellar cortex, 1 Purkinje cell was directional, 12 bidirectional, and 4 mixed.

These data suggest that a majority of GPi cells carry information related to direction of movement, independent of which muscles are used to make that movement. These data also confirm previous observations from this laboratory that in steps and ramp tracking most cerebellar neurons have a bidirectional signal. The GPe appears to carry both a bidirectional and a directional signal. We have suggested previously that the bidirectionality of cerebellar neurons is related the activity of spindles afferents, (Schieber and Thach, 1980) but whether the bidirectional GPe cells are also related to spindle afferents is not known. None of the neurons we recorded in globus pallidus and cerebellum had discharge patterns that were obviously related to the EMG of wrist, arm, or back muscles. 205.7 DISTINCTIVE AND TOPOGRAPHICALLY ORGANIZED MOTOR FUNCTIONS OF THE RAT'S LATERAL STRIATUM. M. Pisa. Depts. of Neurosciences and Psychiatry, McMaster Univ., Hamilton, Ontario, Canada, L8N 3Z5.

The aim of this study was to examine the hypothesis of regional heterogeneity of motor functions in the rat's striatum. After being trained in tasks of food-reinforced tongue protrusion and forelimb reaching, male Wistar rats were anesthetized with Equithesin (3.5 cc/kg, i.p.) and assigned to groups (N=6) for bilateral stereotaxic injections of either the axon-sparing somatodendrotoxin ibotenic acid (7.5 ug in .5 ul of PBS vehicle solution) or an equal volume of vehicle solution into either of these regions of the rostral striatum: dorsomedial (DMS), dorsolateral (DLS), ventrolateral (VLS), dorsomedial and ventromedial (DMS + VMS), dorsolateral and ventrolateral (DLS + VLS). Tongue extension and forelimb extension performance in the food-reaching tasks, and times spent on 'normal' (extended) and 'abnormal' (stooped) postures of the neck and trunk during manipulation and eating of 5 g pellets were examined on postoperative Days 2, 15 and 30. The lesion sites were verified histologically after behavioral testing. The behavioral results were as follows: 1) compared with the control rats, the rats with VLS lesions showed a chronic impairment of both tongue and forelimb extension, with no reliable alteration of head and trunk posture during food manipulation; 2) the rats with DLS lesions showed chronic alterations of both forelimb extension and neck-trunk posture, with no reliable impairment of tongue extension; 3) the rats with DLS + VLS lesions showed chronic impairments of tongue extension, forelimb extension, and neck-trunk posture, and these impairments were more severe than those shown by the rats with DLS lesions or VLS lesions; 4) the rats with either DMS lesions or DMS + VMS lesions showed no reliable chronic alterations in any of the measured motor parameters.

These findings are interpreted as follows: 1) in the rat, the lateral, but not the medial, rostral striatum facilitates extension movements of the tongue and the forelimbs, and extension posture of the neck and trunk; 2) the lateral striatum displays a topographically organized gradient of segmental motor control, with the tongue being represented ventrally, the neck and trunk dorsally, and the forelimb in both ventral and dorsal regions; 3) within the lateral striatum, the motor impairments caused by large lesions are more severe than those caused by more localized lesions (regional, mass action effect). The present findings are consistent with anatomical data (Wise and Jones, JCN, 175: 129, 1977) indicating that, in the rat, the striopetal projections of the sensorimotor cortex mainly terminate in lateral regions of the striatum (supported by the MRC of Canada. M.P. is an OMHF Scholar).

205.8 EFFECTS OF ELECTROLYTIC LESIONS IN THE SUPERIOR COLLICULUS, VENTROMEDIAL THALAMUS, OR MIDBRAIN RETICULAR FORMATION ON BEHAVIORAL RESPONSES TO INTRANIGRAL MUSCIMOL. A.A. Baumeister and G.D. Frye, Department of Medical Pharmacology and Toxicology, Texas A&M University, College Station, TX 77843.

Bilateral injection of muscimol into the substantia nigra produces stereotyped behavior, self-injurious behavior (SIB), and analgesia in rats (Pharmacol Biochem Behav, 21(1984), 89; Soc Neurosci Abstr, 10(1984), 414). Among the nigral efferent pathways that may mediate these effects are projections to the superior colliculus (SC), the mesencephalic reticular formation (MRF), and the ventromedial thalamus (VMT) (Brain Res, 175(1979), 191). In the present studies the role of these structures in the behavioral effects of intranigral muscimol was evaluated. Male Sprague Dawley Rats (180-220g) were anesthetized with sodium pentobarbital, and a stainless steel electrode (0.2mm diameter) insulated except at the tip (1mm) was stereotaxically placed in the SC (A 1.75, L^{+} 1.5, V 5), MRF (A 1.0, L^{+} 1.5, V 6.5) or VMT (A 5.5, L^{+} 1.25, V 7.25). A 2mA anodal current was then passed through the electrode for 5 seconds. After two weeks, the animals received bilateral intranigral injections of muscimol and behavior was recorded as previously described (Pharmacol Biochem Behav, 21(1984), 89). In unoperated controls intranigral microinjection of 30ng or 60ng of muscimol produced SIB in 5/10 and 12/17 animals, respectively. Lesions of the SC or MRF completely blocked muscimol-induced SIB. Muscimol produced SIB in 9/11 animals with VMT lesions, and in 6/9, 14/21, and 7/10 animals with sham electrode placement in the SC, MRF, or VMT, respectively. Lesions of MRF increased muscimol-induced stereotyped rearing, sniffing, head nodding, and locomotion. Lesions of the SC increased muscimol-induced rearing and locomotion but blocked stereotyped gnawing. On the hot water tail-flick test, the analgetic effect of muscimol was suppressed by lesions of the MRF. In animals with lesions of the SC the muscimol-induced analgesia was increased at 90 minutes but decreased at 180 minutes from the intranigral injection, suggesting little change in the overall analgetic effect. VMT lesions had no effect on stereotyped behavior, but potentiated muscimol-induced analgesia. These results suggest that analgesia and stereotyped gnawing play an important role in SIB induced by intranigral muscimol. The MRF appears to be important in the expression of muscimol-induced analgesia, while the SC appears to be important in the expression of stereotyped biting and gnawing. The VMT does not appear to play a role in the stereotyped behavior or SIB produced by intranigral muscimol, but may be involved in muscimol-induced analgesia. (Supported by HD-18668 & AA-06223.)

205.9 RAPHE NUCLEI LESIONS BLOCK LATERAL HABENULA INDUCED TURNING BEHAVIOR

H.Lara* and M. Garcia-Munoz (SPON: H. Brust-Carmona).
Centro de Investigaciones en Fisiología Celular, U.N.A.M., P.O.Box 70-600, 04510 Mexico D.F.

Anatomical evidence indicates that the lateral habenula (LH) projects to the dorsal (DR) and medial (MR) raphe nuclei (Herkenham, M. and Nauta, W.J., J. Comp. Neurol.,187:19, 1979; Stern, W.C. et al,Neuropharmacol.,20:979, 1981). It has been reported that an electrolytic lesion of LH produces turning behavior induced by apomorphine systemic administration (Ahlenius, S., et al, Exp.Brain Res.,47:270, 1982). The aim of the present experiment was to investigate:a) if turning to apomorphine persists after a more specific lesion using kainic acid into LH and b) to find out if the raphe nuclei are involved in the expression of the motor behavior induced by LH stimulation.

Male Wistar rats (150-175 g) were anesthetized with Halothane (0.8-2.0% in 95% O_2- 5% CO_2) and fixed to a stereotaxic apparatus. Kainic acid was used to lesion the LH (50 ng/0.1 µl) or the DR or MR (0.1 µg/0.1 µl). Apomorphine (2.0 mg/kg i.p.) was administered a week after the lesion. Haloperidol (1.0 mg/kg) 30 min prior apomorphine was also administered to a group of lesioned rats. Kainate (1.0 µg/ 0.3 µl) was acutely administered into LH as an stimulating agent. In this case, as soon as the animal recovered from anesthesia the behavior was quantified. The total time for surgical procedure,from exposure to anesthesia to waking up did not exceed 15 min.

As previously reported, apomorphine induced turning behavior in animals with a lesion in LH (60 ± 5,C), DR (61 ± 11, I) or MR (113 ± 29, C), (X ± SD, C= contra, I= ipsilateral, turns/ 30 min). This behavior was blocked by haloperidol. Acute injections of kainate into LH,induced turning (378 ± 34, I) which was abolished after either a lesion in DR (4.4.± 3, I) or MR (0.2 ± 0.4, C).

It can be concluded that the raphe nuclei are necessary for the motor expression induced by LH stimulation. Since it has been suggested that LH may exert some control on raphe neurons innervating the basal ganglia (Soubrie, P. et al, Brain Res., 47: 270, 1982), it remains to be explored if the basal ganglia provides another link for the motor output of LH-induced turning behavior.

This experiment was partially supported by a grant from CONACYT, PNCCBNA 001888.

205.10 DEMONSTRATION OF BEHAVIORAL DA-SUPERSENSITIVITY AFTER CHRONIC HALOPERIDOL TREATMENT USING THE ROTATIONAL MODEL

R.J. Mandel and P.K. Randall. Depts. Psychology and Physiology and Biopyhsics, U.S.C. Andrus Gerontology Ctr., Los Angeles, CA 90089-0191.

To date, behavioral supersensitivity, attributable to striatal DA activity, after chronic antipsychotics has been studied exclusively by quantifying agonist-induced stereotypies with rating scales. The developement of a striatal efferent lesion that blocks the expression of striatally mediated behaviors by Marshall and Ungerstedt (Eur. J. Pharm. 41 361-367, 1977), enables the use of the rotational paradigm to measure neuroleptic-induced DA supersensitivity. This is the first demonstration of increased apomorphine (APO) induced rotational behavior after chronic haloperidol (HAL) in the striatal output lesion model.

Thirty-two C57BL/6J mice were administered an electrolytic lesion in the internal capsule at 6 weeks of age. One week after surgery animals were screened for rotational behavior with 2 mg/kg amphetamine (IP). The mice were separated into 2 groups with approximately equal levels of rotational behavior. One group received 2.5 mg/kg HAL for 30 days, while the other group received vehicle, both in drinking water. The mice were then tested in a 4X4 Latin Square (LS) design, each treatment 1 week apart with doses 0.117, 0.46875, 1.875, and 7.5 mg/kg APO (IP). Mice were maintained on HAL throughout the testing phase of the experiment and 10 days after withdrawal of HAL animals were tested in the same LS design to study the decline of the hypersensitivity. Surgical procedures, behavioral testing, and curve fitting procedures have been described elsewhere (Br. Res. 330 358-363, 1985).

The estimated ED_{50}'s obtained from best fitting logistic curves for control and treatment group in response to APO were 7.3 and 0.99 mg/kg respectively, indicating approximately 7 fold increase in sensitivity. Ten days after HAL withdrawal, animals' response had already diminished and by 17 days post-withdrawal appeared to have reached control levels of response.

Potentially the most interesting finding is the rapid loss of the supersensitivity after withdrawal. This does not agree well with previous reports of longer lasting supersensitivity after chronic HAL and also indicates that increased rotational behavior is evident despite continued HAL administration.

205.11 THE EFFECTS OF SELECTIVE DOPAMINE RECEPTOR SUBTYPE MANIPULATION ON STEREOTYPIC BEHAVIOR.

D.M. Yurek and P.K. Randall, Dept. of Physiology and Biophysics, USC Sch. of Med., Andrus Gerontology Ctr., Los Angeles, CA 90089.

Behavioral responses associated with selective dopamine receptor subtype manipulation were studied by treating mice with systemic or intraventricular administrations of selective dopamine agonists and antagonists. The behavioral response to a systemic injection of either 1.0, 5.0, or 10.0 mg/kg of LY 171555, a selective D-2 agonist, was characterized and compared to stereotypic behavior produced by pretreating mice with 1.0 mg/kg of SCH 23390, a selective D-1 antagonist, and a subsequent injection of either 1.0, 5.0, or 10.0 mg/kg of apomorphine (APO), an agonist at D-1 and D-2. SCH 23390 blocked the expression of the oral behavior associated with the higher doses of APO. However, other components of stereotypic behavior, e.g. stereotypic sniffing and an unusual splayed posturing, were still present. Mice injected with any one of the three doses of LY 171555 exhibited similar stereotypic sniffing and posturing. The consistency between the stereotypic behavioral ratings for these two treatments indicate that selective D-2 stimulation produces a reliable behavioral response.

Behavioral responses associated with D-1 receptor stimulation were also studied in mice pretreated with an intraventricular administration of sulpiride (SULP) or spiperone (SPIP), both selective D-2 antagonists, and a subsequent injection of APO. It was recently shown that intraventricular injections of low doses of SULP or SPIP enhance APO-induced stereotypic behavior, characterized by intense licking and biting, and simultaneously produce catalepsy. Though scopolamine reduces and pilocarpine increases catalepsy in these mice, neither treatment blocks the enhanced APO-induced stereotypic behavior or the unusual oral component. These data are consistent with Christensen et al. (Life Sci., 34 1529-1540, 1984) who report that D-1 receptor activity is relatively insensitive to cholinergic manipulation. In a related study we pretreated mice with systemic injections of SPIP in a dose range between 0.0001 - 1.0 mg/kg to examine the effects on APO-induced stereotypic behavior. Doses between 0.005 - 0.01 mg/kg of SPIP enhance APO-induced stereotypic behavior and doses between 0.005 - 0.075 mg/kg produce intense, vacuous licking and biting while also exhibiting an increase in locomotor activity. Doses at or greater than 0.1 mg/kg blocked expression of stereotypic behavior while locomotor activity was substantially attenuated at doses greater than 1.0 mg/kg.

These data suggest that both D-1 and D-2 receptor stimulation mediate the expression of stereotypic behavior and that dopaminergic antagonism at one DA receptor subtype influences the effects produced by stimulation of other DA receptor subtypes.

205.12 STRIATO-NIGRAL ROTATIONAL MODEL IN THE RAT: INTERACTION OF NUCLEUS ACCUMBENS AND STRIATUM.

S.L. Hartgraves*, R.J. Mandel, J.A. Severson, J.J. Woodward, R.E. Wilcox, and P.K. Randall (Spon. J.S. Randall).Dept. Physiol. and Dept. Psychiatry, USC Sch. Med., Dept. Psych. and Andrus Gerontol. Ctr., U.S.C., Los Angeles, CA 90089, and College of Pharmacy, U. Texas, Austin, Texas 78712

Apomorphine-induced Rotational behavior in rodents bearing lesions of striatal efferents (predominantly striato-nigral pathway) provides a control measurement for rotation in response to stimulation of "normosensitive" dopamine (DA) receptors. Subsequent lesion of the contralateral nigro-striatal pathway leads to a 10-40 fold increase in sensitivity to apomorphine. Most such experiments utilize 6-OHDA placements which destroy DA afferents to the nucleus accumbens as well as the striatum. In order to determine whether depletion of accumbens DA contributes to the high estimates of supersensitivity we examined apomorphine-induced rotational behavior after 6OHDA placements which have differing effects on accumbens DA.

Sprague-Dawley rats received electrolytic lesions (2mA,20 sec) directed at the striato-nigral pathway at the tip of the internal capsule. All animals were subsequently screened for rotational behavior with both amphetamine and apomorphine to confirm that the lesion effectively interrupted the striatal output. A dose-respone curve for rotational behavior to apomorphine was then obtained (9-doses at equal log-intervals from .0156 to 8 mg/kg). Subjects then received micro-infusions of 6-OHDA (8ug/2ul) into the MFB, the tail of the caudate nucleus, or bilaterally into the nucleus accumbens. The MFB placement destroys both the accumbens and striatal DA input, while the placement at the tail of the caudate spares the nuclues accumbens DA. Two weeks later, a second dose-response curve was obtained using the same dose-range as above with the exception of the highest dose.

Rats with depletion of both striatal and accumbens DA showed a marked increase in rotation relative to that after the striato-nigral lesion alone (12-20 fold shift in the ED50 depending upon method of calculation). Striatal depletion alone also increased rotational behavior, but only by a factor of 2-4 fold. Bilateral accumbens DA depletion surprisingly led to a reduction, rather than enhancement of rotation, suggesting that either the interaction of accumbens DA activity with that in striatum occurs via striatal efferents other than those lesioned in this study or that nucleus accumbens contributes a directional and activational component to rotational behavior. Regardless, these data show that quantitative estimates of supersensitization are highly sensitive to accumbens depletion. The 2-4 fold shift following selective striatal denervation is much more consistent with the typical 20-40% increase in DA receptor number.

205.13 LACK OF BROMOCRIPTINE-INDUCED ROTATIONAL BEHAVIOR AFTER UNILATERAL STRIATAL EFFERENT LESION R.K. Easley, R.J. Mandel, and P.K. Randall (Spon. D.F. Lindsley). Depts. Psychology and Physiology and Biopyhsics, U.S.C. Andrus Gerontology Ctr., Los Angeles, CA 90089-0191.

Bromocriptine (BROMO) was first regarded as a direct acting dopamine (DA) agonist because its injection resulted in contralateral rotation in a unilaterally 6-OHDA lesioned rat. However, BROMO induced rotation is inhibited by pretreatment with the tyrosine-hydroxylase inhibitor, a-methyl-p-tyrosine (AMPT). This experiment was designed to examine whether BROMO-induced rotation exhibits the same characteristics when the rotation is mediated by normosensitive DA receptors (DAr).

Eight, 6-week-old, male, C57BL/6J mice were lesioned in the striatum with 6-OHDA. This group was included to demonstrate that mice respond to BROMO in a similar manner as do rats. Electrolytic lesions of striatal efferent pathways were administered to 16 mice and the behavioral effectiveness was confirmed with both amphetamine (AMPHET) and apomorphine (APO) screening tests. All lesion and behavioral testing procedures have been described previously (Mandel and Randall, Br. Res., 330 358-363, 1985). The 6-OHDA lesioned group received 5.0 and 10.0 mg/kg of BROMO (SC) while the "output" lesioned group received vehicle, 5.0, 10.0, and 30.0 mg/kg BROMO (SC). Both groups were tested in a crossover design for each dose with 100.0 mg/kg (IP) AMPT 2 Hr. and 1/2 Hr. before BROMO.

As expected, animals with unilateral 6-OHDA lesions responded to BROMO by rotating contralaterally after a 90-120 minute onset delay. This effect was inhibited by AMPT pretreatment. Mice with unilateral striatal output lesions, however, did not show an asymmetry in response to BROMO at any dose as compared to vehicle injection but did show behavioral hyperactivity at similar onset latency as the 6-OHDA group. The hyperactivity was also completely attenuated by AMPT pretreatment.

These data indicate that BROMO is behaviorally active as a DA agonist but its action is clearly different from AMPHET or APO in preparations with either normo- or supersensitive DAr. The peculiar characteristics of BROMO-induced behavior may be related to its apparent selectivity for the D-2 DAr (Gershanik et al., Br. Res., 261 358-360, 1983). Such selectivity may predispose BROMO to affect particular striatal efferents (Herrera-Marschitz and Ungerstedt, Br. Res., 323 269-278, 1984) in different preparations or, equally plausible, BROMO may preferentially stimulate DAr in the n. accumbens in the output model.

205.14 ROTATION IN RATS AFTER UNILATERAL INFUSION OF HEMICHOLINIUM-3 INTO THE CAUDATE NUCLEUS. L.L. Wing, K.E. Asin and D. Wirtshafter. Dept. of Psychology, Univ. of Illinois at Chicago, P.O. Box 4348, Chicago, IL 60680.

Considerable evidence supports the existence of an interaction between central cholinergic and dopaminergic systems. For example, anticholinergics both attenuate the catalepsy induced by dopamine (DA) receptor blockers in experimental animals and reduce some of the symptoms of Parkinson's disease in man. Although data from a number of other behavioral situations are also compatible with the notion of a cholinergic/dopaminergic blance, little is known as to the anatomical locus of this interaction. It is possible that cholinergic mechanisms within the striatum itself may modulate the effects of dopaminergic activity or it is possible that the interaction might take place elsewhere.

In an effort to further investigate the role of cholinergic striatal functioning in behavior, we made unilateral infusions of the reversible choline uptake blocker hemicholinium-3 (HC-3) into the caudate nucleus of rats and observed spontaneous and amphetamine-induced rotation in these animals. Unilateral infusions of one microliter of distilled water containing various doses of HC-3 (10, 5, 2.5, 1.25, 0.6, 0.3, 0.15, 0.075, 0.03, 0.015, 0.003, 0.0015 and 0.00075 ug) or the vehicle alone were made into the caudate nucleus of rats which were operated on under ether anesthesia. Biochemical studies have demonstrated that intracranial injections of HC-3 produce a depletion of brain acetylcholine (ACh) which is maximal between 3 and 4 hours following injection.

Spontaneous rotation was observed for a ten minute period 3.5 hours post-operatively. Animals were then given an intraperitoneal injection of 4 mg/kg amphetamine, and tested 15 minutes later for 10 minutes. Net rotation scores were calculated by subtracting the number of ipsilateral turns from the number of contralateral turns. No net spontaneous rotation was observed in vehicle-treated controls or in HC-treated animals. When tested after an injection of amphetamine, however, animals treated with doses of HC-3 greater than or equal to 0.003 ug displayed significant net contralateral rotation (e.g., 0.3 ug HC-3: mean net rotation=20.8), while animals treated with lower doses of HC-3 or with vehicle showed no such effect.

Another group of rats treated with 0.3 ug HC-3 or the vehicle alone and tested 24 hours post-operatively did not demonstrate either spontaneous or amphetamine-induced rotation, thus demonstrating the transient nature of the effect of HC-3.

These results support the notion of DA/ACh interactions in the striatum.

Data from apomorphine-induced rotation studies will also be presented.

205.15 SHORT-TERM EFFECTS OF DOPAMINE-DEPLETING BRAIN LESIONS ON SPONTANEOUS ACTIVITY OF TYPE II STRIATAL NEURONS: RELATION TO LOCAL STRIATAL DOPAMINE LEVELS AND BEHAVIOR. W.B. Orr, T.W. Gardiner, E.M. Stricker, M.J. Zigmond, and T.W. Berger. Departments of Psychology and Psychiatry, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Striatal dopamine (DA) depletion in animals results in profound deficits in sensorimotor and consumatory behaviors, but only if the loss of DA is greater than 90% (Zigmond and Stricker, Life Sci. 35: 5-18, 1984). Electrophysiological studies show that the spontaneous activity of striatal neurons increases after treatments that deplete striatal DA. If striatal neuronal activity is related to the behaviors disrupted by DA-depleting lesions, changes in spontaneous activity of striatal neurons should occur only when DA depletions exceed 90%.

Spontaneous activity of single striatal neurons (n=687) was recorded 5 to 9 days after rats were given intraventricular (ivt) injections of 100 ug (n=5), 180 ug (n=9) or 250 ug (n=12) 6-hydroxydopamine (6-HDA), or intranigral injection of 16 ug (n=12) of 6-HDA, to induce different levels of DA depletion. Vehicle-injected (ivt, n=12) and nontreated (n=15) control groups also were prepared and used for recording. All except nontreated animals also received pretreatments of pargyline (40 mg/kg, ip) and desipramine (25 mg/kg, ip). Behavioral testing included a latency measure of front paw akinesia and daily consumption of water and food. Because this laboratory has shown that 6-HDA administered ivt results in a medio-lateral gradient of DA depletion (Onn et al., Soc. Neurosci. Abstr. 8: 743, 1982), cells within both medial and lateral regions of striatum were recorded from all groups. Type II striatal neurons were located by their orthodromic activation in response to neocortical stimulation. Striatal tissue punches were removed from medial and lateral regions for subsequent determination of DA concentration.

Type II neuron activity was significantly increased in medial and lateral regions of striatum only when local DA depletions exceeded 90%. Additionally, severe disruption of sensorimotor and consumatory behaviors always was associated with medial striatal depletions of greater than 90%. For example, animals given 180 ug 6-HDA showed behavioral dysfunctions even though no change was observed in the spontaneous activity of Type II neurons in lateral striatum and DA depletions in that region were 89.9% of vehicle-injected controls. Thus, spontaneous activity in medial, but not lateral, Type II striatal neurons appears to be related to the behaviors disrupted by DA-depleting brain lesions. Supported by NIH (NS19608).

205.16 A STRATEGY FOR SEPARATING BEHAVIORALLY-RELATED VS. DRUG-RELATED CHANGES IN UNIT ACTIVITY IN FREELY MOVING RATS. M.O. West, A.J. Michael, J.K. Chapin and D.J. Woodward. Univ. of TX Health Science Center, Dallas, TX.

We have previously shown that the activity of units in the rat neostriatum during locomotion increases following injection (i.p.) of d-Amphetamine (d-A) (Michael et al., Neurosci. Abstr. 1984, 10:350). This effect was presumably mediated by direct actions of d-A in the nigrostriatal system, i.e., to augment dopaminergic activity. However, even though locomotor behavior following d-A injection appeared similar to control locomotion (following saline injection), drug-induced changes in movements during locomotion could alternatively have been responsible for a portion of the increased striatal unit activity. Our current aim is to develop a strategy for separating behaviorally-related vs drug-related changes in observed unit activity.

An essential feature of the strategy is to minimize behaviorally-related differences by generating behaviors before drug injection which were similar to those exhibited by the animal after drug injection. This was accomplished by utilizing a simple treadmill locomotion paradigm in conjunction with doses of d-A known to increase locomotor behavior in rats (0.5-1.0 mg/kg). However, since these doses produce behaviors in addition to locomotion (e.g., rearing, or increased sniffing and exploring), a further tactic is to examine correlations between these discrete behaviors and unit activity. The magnitude and direction of such correlations indicate the extent to which changes in unit activity are a direct result of behavior. Alternatively, the absence of such correlations indicates that changes in unit activity may be due to a more direct action of the drug on the neural circuit under investigation.

In initial applications of this procedure, we have focused on rearing behavior (the animal's shifting to a vertical posture supported on its hindlimbs), which consistently increases in frequency following d-A administration. Peri-event histograms of caudate unit activity were constructed around the onset of rearing. Neither the magnitude nor the direction of changes in unit activity related to rearing could have accounted for the increased firing rates following d-A administration. This evidence, in addition to the fact that locomotor movements were similar before and after drug injection, suggests that the increased caudate unit activity was not related to observable changes in behavior. Rather, the increased firing rates may have been due to drug-induced changes in the animal's internal behavioral state or to more direct changes in central catecholaminergic activity. We anticipate that this approach will prove useful in a continuing analysis of synaptic activity in the basal ganglia. Supported by DA02338, NIAAA 3901, and the Biological Humanics Foundation.

205.17 ANATOMICAL, PHARMACOLOGICAL AND PHENOMENOLOGICAL CHARACTERISTICS OF MUSCIMOL-INDUCED CIRCLING ELICITED FROM THE VENTRAL MESENCEPHALON: COMPARISONS WITH MORPHINE-INDUCED CIRCLING. Larry J. Holmes* and Roy A. Wise. (SPON: Michael Bozarth) Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Quebec.

In a previous study we reported that unilateral ventral mesencephalic morphine injections induces naloxone-sensitive, dopamine-dependent contralateral circling. The best site was localized in the ventral tegmental area. The behaviour involved forward locomotion and resembled exploration with a bias in the direction of turning. The present study investigated the anatomical, pharmacological and phenemonological characteristics of muscimol-induced circling elicited from the same brain regions. Muscimol (25,50 or 100 ng) was applied unilaterally to the ventral mesencephalon in rats; it caused contralateral or ipsilateral picrotoxin-sensitive circling, depending on the site of injection. Muscimol induced strong contralateral circling when applied to the rostral or caudal substantia nigra pars reticulata (SNR) and weak ipsilateral circling when applied to the zona compacta of the substantia nigra (SNC); only the ipsilateral circling was blocked by pimozide pretreatment. There was very little circling noted when injection sites were located outside of the medial substantia nigra; when circling was recorded from extra-nigral sites, it was only with the highest dose of muscimol. The phenomenological characteristics of muscimol-induced contralateral circling differed from morphine-induced contralateral circling in several ways: 1) in contrast to morphine-induced circling, muscimol-induced circling was accompanied by a strong postural asymmetry (even when the dose was adjusted to produce the same rate of circling) 2) muscimol-induced circlers reared less often than morphine-induced circlers but engaged in more stereotypic mouth movements 3) whereas the direction of morphine-induced circling could be reversed by environmental contingencies, muscimol-induced circling could not. These studies suggest that three types of circling can be elicited from the ventral mesencephalon. Morphine-induced contralateral circling is throught to activate dopaminergic cells, muscimol-induced ipsilateral circling is thought to inhibit dopaminergic cells and muscimol-induced contralateral circling is thought to result from activation of striato-nigral GABAergic systems which seem to serve as output pathways mediating dopamine-induced circling.

CEREBELLUM: ANATOMY, PHARMACOLOGY AND CELLULAR PHYSIOLOGY

206.1 FUNCTIONAL TOPOGRAPHY OF THE HUMAN CEREBELLUM, DEMONSTRATED WITH POSITRON EMISSION TOMOGRAPHY. Peter T. Fox* and Marcus E. Raichle, (Departments of Neurology and Radiology), (Washington University School of Medicine, St. Louis, MO 63110)

Physiological activation within the human cerebellum during motor tasks and sensory stimulation was observed in 15 normal volunteers using positron emission tomographic (PET) measurements of regional brain blood flow (rBF). 15-O-labeled water administered by intravenous bolus was used as a blood flow tracer (J Nucl Med 24:782). Each subject underwent a series of 8 sequential, 40-sec, BF emission scans with an inter-scan delay of 8-10 min (for isotope decay). No stimulus was given during the initial or final scans in a series. Activation paradigms were performed during the intervening 6 scans, with task onset preceeding scan initiation by 40-60 sec. A finger movement task (FM; n = 15) consisted of bilateral, 2 Hz, alternating flexion-extension of the fingers (opening & closing the hands). An eye movement task (EM; n = 7) consisted of alternating (left-right), 2 Hz, large amplitude (90 degrees) saccadic eye movements. A finger stimulation task (FS; n = 8) consisted of passively-received vibration (2 mm amplitude; 130 Hz) of the pads of all fingers on one or both hands. All responses were computed as the % change in rBF from the resting-state value (J Neurophysiol 51:1109). Anatomical localization within PET images was determined stereotactically (J Comput Assist Tomogr 9:141).

Focal increases in cerebellar BF occurred during each of the three tasks. Digital-task (FM, FS) responses lay in anterior, superior cerebellum, probably in anterior-lobe cortex. In both instances, the responsive loci were parasagittal (mean = 13 mm from midline), with no significant difference in location of FM and FS responses. Response magnitudes did differ, with FM responses (mean = 20%) exceeding FS responses (mean = 8%), although cerebral responses to the two tasks were equal (mean = 29%). Unilateral task performances (FS) produced solely-ipsilateral cerebellar rBF responses, and solely-contralateral responses in cerebral sensorimotor cortex. The oculomotor task (EM) induced a single, midsagittal response in the posterior vermis (mean = 13%). Thus, a consistent topography was observed, with digital activation lying lateral and anterior to oculomotor activation.

To our knowledge, this is the first demonstration of physiological activation of the human cerebellum by any technique. A technique allowing rapid, non-invasive mapping of human cerebellar responses to voluntary movement and sensory stimulation now exists.

206.2 AN ANALYSIS OF THE RECURRENT COLLATERALS OF PURKINJE CELLS IN ZONE B OF THE CAT'S VERMIS. G.A. Bishop, D.L. O'Donoghue and J.S. King. Department of Anatomy and Neuroscience Research Laboratory, The Ohio State University, Columbus, Ohio 43210.

Purkinje cells in Zone B of the cat's vermis were physiologically characterized on the basis of their receptive fields and intracellularly injected with horseradish peroxidase. The distribution pattern of the collaterals of these cells was reconstructed from serial sections and illustrated in camera lucida drawings. Typically, one or two primary collaterals arise from the Purkinje cell axon as it courses through the granule cell layer. Primary collaterals recur toward the Purkinje cell-granule cell border and arborize into four to six secondary branches which form a varicose plexus along the bases and apices of adjacent Purkinje cells. In addition, some beaded branches distribute to: 1) the superficial and deep granule cell layer; and 2) the lower molecular layer. Two distinct patterns of distribution are observed with respect to the sagittal and transverse distribution of the collaterals. In one pattern, the collaterals are confined to the immediate area of the cell of origin, extending approximately 400 um in the sagittal plane and 200 um in the transverse plane. The second pattern is more complex. The major portion of the collateral arborizes within the immediate vicinity of the parent cell in both planes of section. However, one or two branches course up to 480 um medial or lateral to the cell of origin. Often, these latter branches terminate in the same transverse plane as the major portion of the collateral. However, in other cases, beaded branches arborize in spatially remote areas in both the sagittal and transverse planes relative to the cell of origin. In general, the sagittal distribution pattern for both classes of collaterals does not form a continuous band as there are regions which are devoid of varicosities interspersed between varicosity rich areas. Data derived from physiological studies (Oscarsson, TINS, '79) have suggested that Zone B of the cat's vermis can be subdivided into 5 microzones. The present anatomical account suggests that the collaterals of Purkinje cells could subserve different functions in processing information in Zone B. One population may process information within a single microzone. Purkinje cells with the second, more extensive pattern of distribution may not only participate in intrazonal circuitry, but also have the potential of participating in the local circuitry of adjacent microzones and possibly of adjacent zones. The presence of varicosities in all three cortical lamina and their discontinuous pattern of distribution suggest that the collaterals have multiple discrete foci of influence on diverse populations of cortical neurons. (This work was supported by NS 18028 and 08798).

206.3 INDUCED RESPONSES OF TRANSMEMBRANE POTENTIAL TO EXTERNALLY APPLIED ELECTRIC FIELDS IN TURTLE PURKINJE CELLS. C. Y. Chan, J. Hounsgaard* and G. Nicholson. Panum Inst. Neurophysiol., Copenhagen Univ. (Denmark); Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Externally applied low-frequency electric fields modulate the firing rate of turtle cerebellar neurons (Chan & Nicholson, 1985, J. Physiol. in press). Since Purkinje cells have nonhomogeneously distributed membrane properties, the modulation mechanism was investigated. We studied the effect of 0.1 Hz sinusoidal electric fields on the transmembrane potential (TMP) and electrophysiological responses in Purkinje cells.

Constant fields (5 mV/mm–250 mV/mm) were induced in the pia-ventricle axis of an isolated turtle cerebellum bathed in Ringer solution. TMP was determined at various depths by subtracting extra- from intracellular potential recorded at matched depths. TMP recorded from deeper levels (>210 μm deep) showed depolarization when the field was ventricle-directed (V-phase) and hyperpolarization when the field was pia-directed (P-phase). The opposite occurred for upper levels. The degree of polarization was greater at distal or proximal than at mid levels of the Purkinje cell. TMP was generally field strength-dependent, but distal TMP showed a flattening or reversal of the depolarization at P-phase when presumed Ca^{2+} spikes appeared; deep TMP showed similar flattening of depolarization at V-phase when presumed Na^{+} spikes occurred at high rate, or during inactivation. The minimum field eliciting Na^{+} spikes was 2-4 times lower than that for Ca^{2+} spikes. Outward currents injected through the intracellular electrode also induced flattening of otherwise sinusoidal TMP. Injected currents had synergistic or compensatory interaction with the field, consistent with simple polarization of membrane by the field. At all levels, responses from climbing fiber (CF) stimulation were diminished in the V and increased in the P phase, suggesting the response to be an EPSP generated proximally, but near the peak of the P-phase, the response usually failed, suggesting CF conduction block. Responses to surface parallel fiber stimulation were small but larger at the V than P phase and showed no failures. Mossy fiber responses were much smaller than CF responses and were largest at the P phase, sometimes showing an IPSP after the EPSP.

These results show that applied fields can directly modulate the behavior of neurons through interaction with nonhomogeneous membrane properties. Additionally, the use of such extrinsic fields provides a potent tool for the study of localized membrane excitability. [Supported by grant NS-18287 from NINCDS].

206.4 BURST FIRING PROPERTIES OF DEEP CEREBELLAR NUCLEI CELLS STUDIED IN THE ISOLATED GUINEA-PIG BRAINSTEM CEREBELLUM, IN VITRO. M. Mühlethaler* and R. Llinas (SPON: L. Kaufman). Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Electrophysiological properties of the deep cerebellar nuclei (CN) were investigated by intracellular recordings from the in vitro guinea pig brainstem cerebellar preparation (Llinás et al., Fed. Proc. 40:2240, 1981). These neurons are known to receive a GABA-mediated monosynaptic IPSP from Purkinje cells (Ito et al., Exp. Brain Res. 10:64, 1970). To evoke such IPSPs, an array of concentric bipolar stimulating electrodes was introduced in white matter overlaying the nuclei. Stimulation at these sites generated IPSPs in CN cells which were occasionally preceded by an antidromic invasion and/or a small EPSP. The EPSPs probably resulted from the activation of climbing or mossy fiber collaterals to the nuclei. The IPSP displayed a powerful summation at frequencies in the 300-500 Hz range and could be reversed by injection of hyperpolarizing current. In the presence of harmaline, which induces oscillations in the olive, the occurrence of spontaneous oscillatory IPSPs in CN neurons indicated the preservation of the entire olivo-cerebellar circuitry (Mühlethaler & Llinás: Soc. Neurosci. Abst., 1984). These spontaneous IPSPs could also be reversed by hyperpolarizing current. More interesting, however, was the fact that these IPSPs were followed by a rebound excitation in the form of a burst of action potentials. This rebound which is voltage- and time-dependent could be mimicked by injection of hyperpolarizing pulses through the recording microelectrode. Depolarizing current pulses delivered at different levels of membrane hyperpolarization revealed a low threshold calcium spike (LTS) similar to that originally described in the olive by Llinás & Yarom (J. Physiol. 315:549, 1981). However, the amount of hyperpolarization needed to reach threshold for de-inactivation was 10-20 mV negative to rest potential, resembling the rebound described in Substantia nigra (SN) where it appears to be of dendritic origin (Llinás et al.: Brain Res. 294:127, 1984). LTS in CN are probably calcium-mediated; they are TTX-resistant but completely abolished by cobalt, as are the LTS in the olive, thalamus and SN. From the above, we propose that the CN, as the thalamus (Jahnsen & Llinás, J. Physiol. 349:205, 1984), have two modes of signalling, (1) as a relay nucleus for mossy and climbing fiber collateral inputs modulated by Purkinje cell inhibition, and (2) as an oscillator when olivary neurons fire in synchrony. Indeed the resultant spike bursts produce powerful IPSPs in the nuclear cells due to Purkinje cell activity. This serves to activate the LTS, resulting in a rebound excitation which may serve as a resonant throughput, most probably involved in phasic motor organization. [Supported by USPHS grant NS13742 from NINCDS]

206.5 SOME PROPERTIES OF AN ORGANOTYPIC CULTURE MODEL OF THE CEREBELLUM R. Kapoor*, C. B. Jaeger and R. Llinás (SPON: S. M. Simon). Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

We have maintained rat cerebellar slices in organotypic cultures using the roller tube technique (Gähwiler: J. Neurosci. Methods 4:329, 1981). Modifications were used in an effort to duplicate some of the morphological and physiological observations made in the mature in vivo cerebellum and in acute cerebellar slices. Thus, 450 μm parasagittal slices were taken from rats aged P9-12. Our studies were performed following 5-10 days culture in vitro, when the slices were less than 100 μm thick, but the overall foliar architecture was preserved.

The intradendritic and intrasomatic recordings obtained from neurons in the cultures were in every way similar to those described for somatic and dendritic impalements of Purkinje cells in acute cerebellar slices (Llinás & Sugimori: J. Physiol. 305: 171 & 197, 1980). The mean resting potential was 62.1 mV for an n of 11 ± 7.19. The input impedances were somewhat higher than previously reported, with a mean of 57 MΩ (n = 8 ± 11.2). Selective channel blockers showed that both Na- and Ca-dependent action potentials were present. Indeed, dendritic spikes were characterized by two types of electroresponsive properties. All-or-nothing fast spikes of low amplitude which were blocked by tetrodotoxin (TTX) and were previously demonstrated to be generated at somatic level and electrotonically conducted to the dendrite. The second type of spike was larger in amplitude and in duration, was not TTX-sensitive but was blocked by 0.5 mM Co or Cd added to the bath. This dendritic Ca electroresponsiveness is also quite similar to that originally described in the mature cerebellar slice. At somatic levels the large action potentials were Na-dependent and Ca spikes were electrotonically conducted from dendrites. The neurons also showed anomalous rectification and a high level of spontaneous excitatory and inhibitory unitary postsynaptic potentials. These potentials could be reversed by outward and inward transmembrane current injection, respectively. Moreover, IPSPs evoked by local stimuli showed a similar time course as those in vivo.

Intracellularly labelled Purkinje cells had oriented dendritic trees and characteristic dendritic spine structures. Their morphology resembled that of age P10 Purkinje cells in vivo. Other neuronal and non-neuronal cell types were revealed in the slice cultures by silver stains and specific localization of astroglia.

Short-term slice culture, as performed in this study, may be employed advantageously in the preservation of physiological response patterns and of morphological structure in this cortex. [Research supported by USPHS grant NS14732 from NINCDS]

206.6 DIRECT DEMONSTRATION OF DENDRITIC INHIBITION IN CEREBELLAR PURKINJE CELLS IN VITRO. M. Sugimori and R. Llinás. Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., New York NY 10016.

Intrasomatic and intradendritic recordings were obtained in guinea pig cerebellar slices (Llinás & Sugimori: J. Physiol. 305, 1980). In addition to voltage recording, glutamic acid and GABA-filled microelectrodes were simultaneously utilized for iontophoresis in order to test the interactions between a putative excitatory and inhibitory transmitter on neuronal integration. As reported previously (Sugimori & Llinás: Soc. Neurosci. Abst., 1983), iontophoresis at dendritic level can generate tetrodotoxin-resistant calcium-dependent spikes. These responses are characterized by either a gradual plateau-like potential and/or by the generation of clear all-or-none spikes which can be shown to be generated at different sites in the dendrite. Here we report that iontophoresis of GABA from a second electrode in the immediate vicinity of the first was shown to block very specifically the calcium-electroresponsiveness (both the plateau and the dendritic spike components). This powerful inhibition could not be totally accounted for on the basis of increased conductance to chloride. This suggests that GABA may have, in addition to an inhibitory effect via chloride conductance, a direct effect on voltage-dependent calcium channels. In order to test this possibility, experiments were done such that the conductance change produced by GABA inhibition could be measured either at somatic or dendritic level. Following the application of picrotoxin, which blocks the GABA-dependent chloride channels (Takeuchi & Takeuchi: J. Physiol. 205, 1969) a marked reduction of the chloride conductance change was observed; however, a sizeable inhibition of calcium spikes could still be seen. Finally, in situations where the g_{Na} was not blocked, glutamic acid injection at the dendritic level was accompanied, at somatic level, by both sodium- and calcium-dependent spikes. Upon iontophoresis of GABA and the dendrites, there was a marked decline in calcium electroresponsiveness without obvious modification of the sodium spike properties observed at the soma. It is suggested, therefore, that dendritic inhibition of Purkinje cells by GABA can regulate chloride conductance as well as have a certain degree of direct action on the voltage-dependent calcium channels. [Supported by USPHS grant NS13742 from NINCDS]

206.7 DIVERSITY AMONG PURKINJE CELLS IN THE MONKEY AND RAT CEREBELLUM. J.M. Gossels*, C.L. Chatot*, B. Blanchard Owens*, M.P. Ogren* and V.M. Ingram. Dept. of Biology, Massachusetts Institute of Technology, Cambridge, MA 02139, USA, and Dept. of Ophthalmology, Children's Hospital, Boston, MA 02115.

A monoclonal antibody (B1) produced as an antibody against rat embryonic forebrain membranes shows specific and striking immunohistochemical staining of Purkinje cells in the monkey cerebellum in a pattern of broad parasagittal alternating bands of B1 positive and B1 negative cells. In addition, some neurons of the deep cerebellar nuclei, the motor cortex and the spinal cord stain positively.

The adult rat cerebellum also shows B1 staining of neurons of the deep cerebellar nuclei and selective staining of Purkinje cells. The rat Purkinje cell dendrites, unlike those of the monkey, do not stain. In neonatal rats the cerebellar neurons are not yet reactive.

The parasagittal banding pattern of B1 positive Purkinje cells in the monkey is quite different from the patterns for other antigens - neurotransmitters, neuropeptides, etc. - previously reported by others in the rat. For example, in the vermis of the adult monkey B1 positive Purkinje cells cluster at the edges of the lobes, whereas the center is occupied almost exclusively by B1 negative cells. Our findings in the adult rat resemble our findings in the adult monkey and are also different from those reported in the literature for other antigens.

206.8 **CEREBELLAR TRANSMITTER RECEPTORS: AUTORADIOGRAPHIC LOCALIZATION IN NEUROLOGICALLY MUTANT MICE.** A. Rotter and A. Frostholm. Department of Pharmacology, California College of Medicine, University of California, Irvine, CA 92717.

An important problem in chemical neuroanatomy concerns the identification of transmitter receptor phenotypes of specific neuronal populations, and the cellular factors influencing their expression. To address these questions we have chosen the cerebellum as a model system. The cerebellum is particularly suitable since it contains several types of transmitter receptors, and it has a limited number of neuronal cell types whose connections are known. Neurological mouse mutants with specific defects in cerebellar structure are available, which make it feasible to correlate the absence of a specific cell group with the loss of a particular population of receptors. In addition, the consequences of disrupted cerebellar circuitry on the expression of receptor phenotypes can be studied.

We have studied the distribution of transmitter receptors in the cerebellae of "weaver", "staggerer", "Purkinje cell degeneration (pcd)" and "reeler" mutants. Autoradiography of receptor bound ligands was used to visualize receptors for muscarinic acetylcholine (^{3}H-quinuclidinyl benzilate), adenosine (^{3}H-cyclohexyladenosine), benzodiazepine (^{3}H-flunitrazepam), gamma-aminobutyric acid (^{3}H-muscimol), histamine (^{3}H-mepyramine) and noradrenaline (^{3}H-dihydroalprenolol) following procedures described by Young and Kuhar (Brain Res. 175,255, 1979). In all cases, cerebellar sections from mutant mice were mounted side by side with sections from normal background strain mice to assure identical processing for the two groups.

In the "weaver" cerebellum, in which granule cells have degenerated, a reduction in the density of muscarinic acetylcholine, adenosine and GABA receptors, no change in beta-adrenergic receptors and a slight increase in the density of benzodiazepine and histamine receptors were observed. In the "pcd" cerebellum, benzodiazepine, beta-adrenergic and histamine receptors were reduced in density, while muscarinic acetylcholine, adenosine and GABA receptor levels were unaffected. In the "staggerer" cerebellum, granule cells fail to form synapses with Purkinje cells, this is probably due to a defect in the latter. Receptor densities are normal in this mutant with the exception of benzodiazepine and GABA receptor levels which were decreased. In the "reeler" cerebellum, there is extensive neuronal malpositioning; however, the majority of synaptic connections maintain their specificity. Receptors in "reeler" display normal densities, despite a disruption in their laminar distribution. Our studies describe the cellular localization of transmitter receptors in the rodent cerebellum, and demonstrate that receptor densities are influenced by intercellular connections. Supported by USPHS grant NS 18089.

206.9 AN ANALYSIS OF MONOCLONAL GLUTAMATE IMMUNOREACTIVE NEURONS IN THE DEEP CEREBELLAR NUCLEI AND THEIR PROJECTIONS TO THE RED NUCLEUS AND THE THALAMUS. P.L. Monaghan*, A.J. Beitz, J.E. Madl*, A.A. Larson (SPON: R.E. Phillips). University of Minnesota, St. Paul, MN 55108.

The deep cerebellar nuclei (DCN) provide the major output of the cerebellum. The excitatory neurotransmitters responsible for this output have yet to be identified. Using a monoclonal antibody to carbodiimide-fixed glutamate in conjunction with polyclonal antisera to glutaminase (GLNase) and aspartate aminotransferase (ATTase), we have examined whether glutamatergic neurons are present in the DCN. Three Sprague-Dawley male rats were perfused intracardially with 4% paraformaldehyde and glutaraldehyde (0.1%-0.2%) and sections were subsequently reacted with either the GLNase or AATase antibody. Three additional rats were perfused with a solution of 5% carbodiimide - 0.5% glutaraldehyde in phosphate buffer followed by 5% glutaraldehyde. The sections were post-fixed in 5% glutaraldehyde, washed and then reacted with the monoclonal glumate antibody. Sections incubated with either the polyclonal or monoclonal antibody were subsequently incubated with the avidin biotinylated peroxidase procedure and reacted with diaminobenzidine to visualize the immunoreactive cells. Glutamate-like, GLNase-like and AATase-like immunoreactive profiles were found in the medial, interpositus and lateral nuclei. A combined retrograde transport immunohistochemical technique was used to determine if glutamatergic neurons of the DCN project to the red nucleus or the thalamus. Horseradish peroxidase (HRP) was injected into the ventroposterior nucleus of the thalamus or the red nucleus and a retrograde transport-immunohistochemical procedure was performed as previously described (Beitz, A.J., Neurosci. 7:2753, 1982). Following injections of tracer into these two areas, HRP labeled neurons were found in all three deep cerebellar nuclei. Retrogradely labeled neurons and neurons containing both retrogradely transported HRP and glutamate or glutaminase immunoreactivity were most prominent in the interpositus and lateral nuclei. These results suggest that glutamatergic neurons project to the thalamus and the red nucleus. Further studies attempting to localize putative neurotransmitters in the DCN are currently in progress using a monoclonal antibody against carbodiimide-fixed aspartate. We thank Dr. R. Altschuler for providing the antisera against glutaminase and aspartate aminotransferase. This work was supported by NIH grants NS19208 to A.J.B. and NS17407 to A.A.L.

206.10 ELECTROPHYSIOLOGICAL EFFECTS OF 3-(3-HYDROXYPHENYL)-N-(1-PROPYL) PIPERIDINE (3-PPP) ON SPONTANEOUSLY ACTIVE CEREBELLAR PURKINJE NEURONS. [1]M. Lee, [2]A. L. Gundlach, [1]J. C. Strahlendorf.

[1]Dept. of Physiology, Texas Tech Univ. Health Sciences Center, Lubbock, Texas 79430, [2]Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Although 3-PPP has been reported as a selective dopamine autoreceptor agonist in the central nervous system, recent autoradiographic studies revealed that localization of specific 3-PPP binding sites did not parallel that of dopamine neurons (Gundlach, A. L., et al., Neurosci. Abstr., 1984; Largent, B. L., et al., Proc. Natl. Acad. Sci. 81:4983-4987, 1984). Moreover, localizations of (+)-[^{3}H]3-PPP binding sites were identical to those of σ receptors, which mediate psychotomimetic effects of some opiates. Specific (+)-[^{3}H]3-PPP binding sites were labelled in many brain areas, including limbic, midbrain, brainstem, and cerebellar regions. In the cerebellar cortex, high receptor labeling was found in the Purkinje cell layer.

On the basis of these anatomical studies, this study was designed to evaluate the effects of iontophoretically applied (+)-3-PPP and (-)-3-PPP on extracellularly recorded Purkinje cells in urethane-anesthetized rats.

In the majority of Purkinje cells tested (31 of 39 cells), (+)-3-PPP (0.05M) elicited inhibition. It had no effect on 3 of the remaining cells, but elicited a biphasic effect (slight inhibition followed by excitation) or excitation in the other 5. Iontophoretic applications of (-)-3-PPP elicited inhibitions in 13 of 19 Purkinje cells. It had no effect on 6 cells. In the majority of cases, (-)-3-PPP induced less inhibition of Purkinje cells than did (+)-3-PPP with the same currents. Continuous applications of haloperidol blocked or attenuated the inhibitory effects of (+)-3-PPP consistently in 8 of 8 cells tested. Spiperone attenuated the inhibitory effects of (+)-3-PPP to a lesser degree than did haloperidol.

Currently, we are examining whether the observed effects of (+)-3-PPP and (-)-3-PPP on Purkinje cells are direct or occur indirectly through other neurotransmitter systems in the cerebellum. Preliminary results from studies using the cationic inhibitors of synaptic transmission manganese and cobalt suggest that presynaptic sites may not be the main sites of the observed effects of 3-PPP in the present study. (Supported by NIH grant RO1-NS 19296 to J.C.S.)

206.11 ENHANCEMENT OF CEREBELLAR PURKINJE CELL (PC) COMPLEX DISCHARGE (CD) ACTIVITY BY MICROIONTOPHORETIC SEROTONIN. J. C. Strahlendorf, H. K. Strahlendorf, and M. Lee. Dept. of Physiol. and Med. and Surg. Neurol., Texas Tech Univ. Health Sci. Ctr., Lubbock, TX 79430.

We have reported previously that serotonin (5-HT) applied iontophoretically to cerebellar PCs elicited one of three effects: inhibition (62%), biphasic (27%), and excitation (11%), effects that appeared to be correlated with the initial firing rates of the cells. Specifically, PCs that responded to 5-HT with increases in firing rate had significantly slower predrug firing frequencies than those that were suppressed by 5-HT. These previous studies have addressed the actions of serotonin on simple spike (SS) activity. The present study was designed to monitor the effects of iontophoretic 5-HT on the absolute number of CDs and mean post-complex-discharge interval (MPCI) and to correlate these effects with predrug spontaneous activity in urethane-anesthetized rats. The major finding of the present study is that iontophoretically applied 5-HT increased the number of CDs markedly (average 94.0%, n=132) in the majority (75%) of PCs tested. The remaining 25% of the cells showed an average 23% decrease in the number of complex discharges. A correlation was apparent between the actions of serotonin on CD activity ($r=0.799$, $p<0.05$) and the initial SS firing rate of the PC. Specifically, a greater percentage of the faster firing cells, which are as a class characterized by fewer initial CDs, responded to 5-HT with an increase in complex activity, and increases were progressively greater in magnitude. The other component of the CD pattern analyzed in this study was the MPCI phase. It became evident that in the control state, slower firing cells exhibit higher MPCI values, whereas faster firing cells have characteristically lower MPCI values ($r=0.987$). PCs evidencing lower MPCI values were those in which 5-HT increased the MPCI value preferentially, whereas those cells in which 5-HT depressed MPCI values exhibited the higher predrug MPCI values. Furthermore, it was apparent that with increasing MPCI values, the proportion of cells displaying a shortening in the MPCI increased ($r=0.939$), and the reverse situation was evident, also. The 5-HT antagonists methysergide and metergoline antagonized 5-HT-induced enhancements of the numbers of CDs, whereas ketanserin failed to alter the response, suggesting a degree of receptor specificity. It would appear that the effect of 5-HT arises from an enhanced efficacy of junctional events at the climbing fiber-PC synapse such that in the presence of 5-HT, normally subliminal climbing-fiber volleys become adequate to produce a complex spike in the Purkinje cell. (Supported by NIH grant RO1-NS19296 to J.C.S.)

206.12 INCREASED RESPONSIVENESS OF CEREBELLAR PURKINJE CELLS TO THE FACILITATORY EFFECT OF IONTOPHORETICALLY APPLIED SEROTONIN ON COMPLEX SPIKE ACTIVITY IN THIAMINE DEFICIENT RATS. H.K. STRAHLENDORF, J.C. STRAHLENDORF AND M. LEE. Medical and Surgical Neurology and Physiology, Texas Tech University Health Sciences Center, Lubbock, Texas 79430

Thiamine deficiency (TD) is believed to be an important etiologic factor in Wernicke's encephalopathy. TD decreases the high affinity uptake for serotonin (5-HT) in rat cerebellar synaptosomes and alters cerebellar 5-HT metabolism (Plaitakis et al, Ann. N. Y. Acad. Sci., 378, 1982). We have previously demonstrated that Purkinje cells (PC) from TD rats show qualitative and quantitative changes to iontophoretically applied 5-HT. These actions were manifest as a shift from mixed simple spike responses of excitation and inhibition in normal rats to solely inhibitory actions that were elicited by significantly lower amounts of 5-HT in TD rats (Lee et al, Brain Res. 327, 1985). As part of a larger, continuing study on the effects of 5-HT on cerebellar PC in normal rats, we have recently found that iontophoretically applied 5-HT increases the number of spontaneously occurring complex spikes (CS) (Strahlendorf et al, this Volume). The present experiments extend these studies to TD rats. Male rats were fed a thiamine-free diet and received daily subcutaneous injections of pyrithiamine 0.5 mg/kg. Controls were either pair-fed the identical diet with thiamine replenishment or were fed standard rat chow. After 15 days the TD group displayed severe neurological impairment. All animals were anesthetized with urethane and prepared for extracellular single neuron recording and microiontophoretic application of 5-HT. Numbers of CS spontaneously occurring in 120 second epochs were compiled by interspike interval histogram software before, during and after 5-HT ejection. Currents were adjusted to produce minimal effects on simple spike firing (5-30nA). TD markedly reduced the number of CS which could be recorded from PC: Control = 56 $\pm$ 4 per 120 sec or 0.47 Hz, n=176; TD = 9 $\pm$ 2 per 120 sec or 0.08 Hz, n=52. The post CS pause did not differ in the two groups: Control = 47.9 $\pm$ 2.5 msec; TD = 42.0 $\pm$ 6.0 msec. 5-HT enhanced the number of CS in both groups, however the increase in the TD rats was markedly greater: Control = 94 $\pm$ 9% increase; TD = 325 $\pm$ 70% increase. These data provide additional support for our previous findings of enhanced sensitivity of PC to 5-HT in TD. (Supported in part by NIH RO1 NS 19296)

206.13 RETROGRADE TRACING STUDIES REVEAL THE ORIGIN OF ASCENDING PROJECTIONS TO THE BASILAR PONTINE GRAY IN THE RAT. R.J. Kosinski, S.A. Azizi, B. Border and G.A. Mihailoff, Dept. of Cell Biology, Univ. Texas Health Science Ctr., Dallas, Texas 75235.

Previous orthograde tracing studies have described the topographic distribution of spinal (Sp), dorsal column nuclear (DCN) and spinal trigeminal nuclear (Vsp) projections to the basilar pontine gray (BPG) in rats. The present study examined the origin of these ascending brainstem projections to the BPG as well as the origin of other novel pontine afferent projections. Under halothane anesthesia and through a ventral surgical approach, the BPG was unilaterally injected with a 2% solution of WGA/HRP (0.02 ul-0.08 ul). Following a survival period which ranged from twelve to thirty hours, animals were sacrificed, perfused and the tissue processed according to routine HRP histochemical methodologies.

Retrogradely labeled Sp, DCN and Vsp neurons were usually distributed contralateral to the injection sites except for a few cells observed within the ipsilateral Vsp. Although Sp labeling was relatively sparse, large round and fusiform shaped cells were localized to the T_{12}-L_3 segments of Clarke's column. While labeled neurons were seen throughout all levels of the DCN, particularly for the cuneate nucleus, the location of most labeled cells corresponded to levels at and caudal to the obex. Labeled neurons within the DCN included round to oval dorsally located neurons as well as more ventrally positioned small oval, fusiform and triangular shaped cells. Labeled Vsp neurons were confined to the interpolaris subdivision and included a variety of round to multipolar shaped cells that were primarily localized to the dorsal half of this nucleus. Additional labeled neurons were observed near the central canal at caudal medullary levels and within caudal and medial portions of the contralateral external cuneate nucleus. Other labeled somata were seen within various regions of the reticular formation including some scattered cells within the medullary and pontine raphe nuclei. Reticular formation labeling included contralaterally located cells just medial to the labeled cuneate and Vsp neurons, ipsilaterally located cells dorsolateral to the inferior olivary complex (IOC) and bilaterally distributed cells dorsal and lateral to the pyramids at levels rostral to the IOC.

Results thus confirm the topography of Sp, DCN and Vsp projections to the BPG in the rat as well as provide evidence for additional novel pontine afferent sources. Furthermore, the existence of contralaterally labeled neurons within the DCN and the Vsp as well as the column of Clarke and the external cuneate nucleus might provide the substrate for certain peripheral somatosensory inputs described on the basis of related electrophysiological studies. Supported by NS-12644 and BNS 80-0453.

206.14 THE ORIGIN OF DESCENDING PROJECTIONS TO THE BASILAR PONTINE NUCLEI AS REVEALED BY RETROGRADE TRACING STUDIES IN THE RAT. G. A. Mihailoff, S. A. Azizi, R. J. Kosinski, B. Border and D. J. Woodward, Dept of Cell Biology, Univ. TX Hlth Sci Ctr, Dallas TX 75235.

This study was undertaken to determine the origin of descending afferent projections to the basilar pontine gray of the rat from the cerebral cortex, diencephalon, mesencephalon and the deep cerebellar nuclei. The pontine gray was exposed under halothane anesthesia by a ventral surgical approach. Various areas of the basilar pons of 10 rats received small or large hydraulic injections of WGA-HRP (2% solution in H20). Brain sections were processed using the TMB procedure. Computer assisted serial reconstruction was employed to accurately visualize the totality of projections. Only cases in which HRP did not spread to the overlying crus cerebri, medial lemniscus or reticular formation were used in this analysis.

The basic trend of projections noted was as follows. Within the cerebral cortex groups of neurons were localized from caudal to rostral in the secondary visual (areas 18 and 19) and auditory cortices, the somatosensory cortices and bilaterally within the motor cortex. In addition, clusters of labeled cells were observed in the cingulate and entorhinal cortices. The labeled cortical neurons were almost exclusively of the pyramidal type and were restricted to layer V of the cortex. Within the diencephalon a number of cells were observed in the zona incerta as well as the mammillary, lateral and anterior hypothalamic nuclei. The mesencephalic projections to the pontine nuclei include HRP-labeled neurons in the substantia nigra, pretectal complex, and ventral lateral geniculate. Several regions within the periaqueductal gray contained labeled somata as well as the dorsal tegmental and dorsal raphe nuclei. Also, intensely labeled neurons were found in the perirubral area and retrorubral fields. The midbrain reticular formation including nucleus cuneiformis as well as the region medial to the mdial geniculate nucleus also exhibited labeled somata as did the superior and inferior colliculi. Lastly, labeled neurons were observed in the deep cerebellar nuclei, particularly the dentate and interposed nuclei. Although many of these connections have been established in earlier studies, several new basilar pontine afferent projections are demonstrated in the present study and these include the substantia nigra, periaqueductal gray, perirubral areas, and the reticular formation. These observations emphasize the diversity of afferent systems projecting to the pontine nuclei and point out the complex integrative function that must be served by pontine neurons in the transfer of information to the cerebellum. (Supported in part by grants DA-2338, NS-12644 and the Biological HumanicsFoundation)

206.15 RESPONSES OF CAUDAL PONTINE GRAY TO CORTICAL AND PERIPHERAL SOMATOSENSORY STIMULI: CONVERGENT INPUTS TO THE BASILAR PONS S. Ausim Azizi, R. J. Kosinski, D. J. Woodward and G. A. Mihailoff. The University of Texas Hlth Sci. Ctr, Dallas, TX 75235

In this series of experiments we have carried out an electrophysiological investigation of somatosensory afferents to neurons of the basilar pontine gray (BPG). Bipolar concentric stimulating electrodes were implanted ipsilaterally into the primary motor face (MF), motor forelimb (MFL), sensory face (SF) and sensory forelimb(SFL) cortical areas as determined later by histological verification of the electrode tracts. Other electrodes were implanted bilaterally into each vibrissal pad (Vb), both forelimbs (FL) and contralateral hindlimb (HL). The basilar pons was exposed by a ventral surgical approach under halothane anesthesia. Conventional electrophysiological recording and stimulation apparatus including a computer for building on-line histograms was used. In 175 BPG neurons (17 rats), evoked responses to electrical stimuli (doule pulses .2 ms duration, 1.5 ms interpulse interval, 40-250 μA) of different regions of the cerebral cortex and/or the periphery were recorded. At threshold currents, responses were elicited (single or multiple spikes) following cortical stimulation with latencies of 6 - 8 ms. BPG neuronal responses to peripheral electrical stimulation often consisted of two components occuring at latencies of 5 and 12 ms respectively. Of the 175 BPG neurons, many responded to stimulation of either a single cortical area: MFL (28), SFL (15), SF (13) or to a single peripheral locus: Vb (7), FL (10) and HL (7), whereas a substantial number of cells (81/175) responded to electrical stimulation of two or more locations. Such locations involved either different cortical zones or a combination of cortical and peripheral areas. Within the later category several cells (23) responded to stimulation of corresponding cortical and peripheral areas. In the three most recent cases, natural stimuli were applied to body zones responsive to electrical stimlulation. A total of nineteen cells responded to natural stimuli and exhibited either discrete cutaneous (light brushing) or deep receptive fields (squeezing and limb manipulation). BPG neurons reponsive to cutaneous stimuli tended to respond to electrical stimulation of the corresponding sensory cortical area, whereas neurons responsive to deep stimuli tended to be responsive to motor cortical stimulation.

These data indicate that neurons in the caudal BPG receive discrete as well as diffuse assortments of descending and ascending sensory and motor inputs. Although, these inputs correspond to previous anatomical tracing studies, the convergence of these affents suggests that BPG neurons may be involved in more complicated sensorimotor integrative functions than previously thought. (Supported in part by DA-2338, NS-12644 and the Biological Humanics foundation)

206.16 CERTAIN BASILAR PONTINE AFFERENT SYSTEMS ARE GABA-ERGIC, B. Border*, R. Kosinski, S.A. Azizi, and G. Mihailoff, (SPON: T. Cope), Cell Biology, Univ. Texas Hlth Sci Ctr., Dallas, 75235

Previous light and electron microscopic immunocytochemiocal studies performed in this lab have demonstrated the presence of glutamic acid decarboxylase (GAD), a key enzyme in the synthesis of gamma-aminobutyric acid (GABA), in neuronal somata, axons, and axon terminals within the basilar pontine nuclei (BPN) of the rat. Although these findings suggest that some labeled terminals might arise intrinsically from the population of GABA-ergic pontine neurons, the distribution of the labeled terminals suggests that some might take origin from a source extrinsic to the BPN. In order to identify the extrinsic source of GAD-positive terminals, a double-label strategy was employed that involved both retrograde transport of HRP and immunocytochemical visualization of GAD. In this procedure, WGA/HRP was injected into the BPN from a ventral approach to demonstrate retrograde axonal transport without damaging afferent axons coursing through the pontine tegmentum. After a 12-30 hour survival period, animals were perfused with fixative, and the brain removed and sectioned (30μm) on a Vibratome. Tissue was first reacted with TMB in order to visualize the HRP reaction product which was subsequently stabilized with cobalt chloride and nickel ammonium sulfate. Overnight incubation of tissue sections in sheep GAD antiserum was then carried out and the unlabeled antibody enzyme (PAP) method of Sternberger utilized to visualize neuronal cell bodies containing GAD. Sections were examined for cells exhibiting both the black reaction product of WGA/HRP labeling and the reddish-brown product of the immunocytochemical procedure.

Our principal findings in these studies are the following. 1) Neurons in the zona incerta were seen to contain both WGA/HRP reaction product and GAD-positive labeling. These small to medium-size somata were located predominantly ipsilateral to the pontine injection site and were observed in medial and lateral portions of the zona incerta. 2) Double-labeled neurons were also observed bilaterally in the brainstem reticular formation (ipsilateral predominance) at levels rostral and caudal to the pontine nuclei. Such neurons were diffusely distributed with some located dorsomedially and others positioned ventrolaterally. 3) The anterior pretectal nucleus at the level of the posterior commissure also contained double-labeled neurons located predominantly ipsilateral to the pontine injection site.

The present observations suggest that the origin of at least some of the GAD-positive axon terminals in the BPN of the rat arise from extrinsic sources. The function of this GABA-ergic input to the BPN is not fully understood; however, further studies will attempt to determine which pontocerebellar circuits are being affected by GABA-ergic neurotransmission. (Supported by NS-12644).

206.17 THREE-DIMENSIONAL RECONSTRUCTIONS OF THE OPOSSUM CEREBELLAR NUCLEI. P.S. Klinkhachorn* and P. Klinkhachorn.* (SPON: W. Flory). Department of Veterinary Anatomy, School of Veterinary Medicine and Department of Electrical Engineering, College of Engineering, Louisiana State University, Baton Rouge, LA 70803.

The purpose of this project is to use computer graphics to reconstruct a three-dimensional model of the opossum cerebellar nuclei. Serial sections through the cerebellum of normal adult opossums were used in this study. They were cut in the coronal plane, 40 micrometers thick, and stained with cresyl violet acetate. The outlines of four cerebellar nuclei in each section were traced from caudal to rostral directions with a microprojector. Each section was digitized as the contour line. The digitized file created only X and Y coordinates. Since the thickness of each section was known, a simple program was written to add the Z coordinate for each point. The cerebellar nuclei of the opossum, although incompletely separated from each other, can be divided into four individual nuclear masses located on each side of the midline. The most medial nucleus is large and is located adjacent to the midline. The posterior interposed nucleus is located at a more ventromedial position of the interposed complex and is closer to the medial nucleus than the anterior one, which is situated in a more dorsolateral position. Both nuclei have a somewhat rostral to caudal relationship to each other in contrast to the medial to lateral relationship as seen in primates. The most laterally located nucleus is a rounded mass of cells without any appearance of hilus or denticulations, which are present in higher mammals. It is established that each region of every nucleus appears to receive and project the nerve fibers from and to different areas of brain. The computer graphic technique will help to reconstruct these nuclei and represent them in a three-dimensional model. It is believed to be more accurate and less time-consuming than the regular histological method, in which only one plane of section can be investigated at a time.

206.18 ORGANIZATION OF CORTICONUCLEAR AND OLIVOCEREBELLAR CONNECTIONS IN THE PIGEON. J.J.A. ARENDS*.(SPON: H.P.Zeigler). West Laboratory, American Museum of Natural History, NY 10024, and Biopsychology Program, Hunter College, CUNY, NY 10021.

In order to clarify the organization of the avian cerebellar nuclei and the inferior olive, anterogradely labeled corticonuclear fibers and retrogradely labeled olivary cells were traced following small iontophoretic or pressure injections of WGA-HRP throughout the cerebellar cortex, both longitudinally and mediolaterally.

Vermal injections in lobules I through X produced a topographically organized ipsilateral projection covering 3 of the 4 purportedly separate cerebellar nuclei, i.e. the medial, intermediate and intercalate nuclei: apparently these 3 nuclei together constitute the medial cerebellar nuclear complex (CbM). Posterior lobe vermal cortex injections, particularly those in the vestibulocerebellum, also labeled peripheral parts of the superior vestibular nucleus, e.g. the lateral cerebellovestibular process (PCV). Lateral injections produced topographically organized labeling in the (ipsi-)lateral cerebellar nucleus (CbL). Termination was also present throughout the vestibular complex, excluding the tangential nucleus and the dorsolateral vestibular nucleus of Sanders (VDL). Injections in the auricular area (flocculus and paraflocculus) and lateral unfoliated cortex produced labeling in CbL and in the vestibular complex, including the tangential nucleus and VDL.

Using a subtractive approach, complementary injections in the cerebellar and subjacent vestibular nuclei showed that the cortex, excluding the vestibulocerebellum, contains at least 4 mediolateral efferent zones. Purkinje cells in the medial 2/3 of the ipsilateral cortex (zone A) were labeled after injections in CbM. The lateral 1/3 (comprising zones B, D1 and D2) was labeled after injections in CbL. Labeling was limited to zones B and D2 after injections in the dorsal part of the lateral vestibular nucleus, whereas the lateralmost D2 zone was the only cortical area labeled after injections in the medial and/or descending vestibular nuclei.

Retrograde labeling in the contralateral inferior olive (OI) after the injections in the cerebellar cortex also showed a topographical organization. After medial cortex injections narrow, elongated clusters of labeled cells were observed in the lateral part of the large dorsal lamella of OI, shifting from lateral to medial with injections ranging from lobule I through IXa. Lateral cortex injections produced a similar picture in the smaller ventral lamella of OI. These injections were never seen to label the area of OI medial to the exiting rostral cervical nerve roots, except when the lateral unfoliated cortex and the vestibulocerebellum (cortical lobules IXb and X), including the auricle, were involved as well.

These data suggest the absence of an avian homologue of the mammalian nucleus interpositus, its associated cortical C zones, and the C-zone afferent parts of the inferior olive.
Supported by NSF Grant BNS-8216604.

206.19 THE CONNECTIVITY OF A CEREBELLAR STRUCTURE, (EMINENTIA GRANULARIS PARS POSTERIOR) IN THE TELEOST APTERONOTUS LEPTORHYNCHUS. E. Sas* and L. Maler(SPON:W. Hendelman). Dept. of Anatomy, Univ. of Ottawa, Ottawa K1H 8M5 Canada

The cerebellum in teleost fish consists of the corpus cerebelli, valvula cerebelli and eminentia granularis pars anterior and pars posterior (lobus caudalis of older nomenclature). The lateral granule cell mass of the eminentia granularis pars posterior (EGp) is the most caudal region of the cerebellum; it comprises an outer granule cell layer, a Purkinje cell layer, an inner molecular layer, and a particular cell type, the eurydendroid cells, which give origin to cerebellar efferents, and probably represent the deep cerebellar nuclei of other species.

I) Injections of HRP into different locations (rostral, caudal, dorsal, ventral) and depths of this cerebellar region, resulted in labeled fibers in the following locations: a) around eurydendroid cells and molecular layer of ipsilateral eminentia granularis pars posterior; b) in the dorsal molecular layer of ipsilateral and contralateral electrosensory lateral line lobe, in a stratified lamellar fashion; c) n. praeeminentialis dorsalis, pars principalis and pars lateralis; d) contralateral torus semicircularis layer 8b.

II) Cells projecting to the lateral granule cell mass of EGp were labeled in: a) lateral line ganglion; b) lateral portion of contralateral inferior olive; c) lateral reticular nuclei, bilaterally; d) n. raphe posterioris, bilaterally; e) n. prepositus, bilaterally; f) n. raphe dorsalis, bilaterally; g) n. praeeminentialis pars principalis and pars lateralis; h) a cell group within the ventral efferent bundle of contralateral n. praeeminentialis; i) acousticolateral area, bilaterally.

The connections of the lateral cell mass of the eminentia granularis pars posterior are highly topographical and due to the laminar segregation of its afferents, specific structures appear labeled according to the depth of the HRP injection. The medial cell mass of the eminentia granularis pars posterior, receives somewhat similar inputs to those of the lateral granular cell mass; in addition these granule cells receive a unique input from certain subnuclei of the pretectal region. Particularities in the connectivity of the lateral and medial granular cell masses of EGp will be discussed with special reference to the possibility of corollary discharge in this system.

VESTIBULAR SYSTEM II

207.1 EFFECTS OF CEREBELLAR STIMULATION ON VELOCITY STORAGE IN THE MONKEY D. Solomon*, T. Raphan and B. Cohen (SPON: J. Goldfarb). Depts. of Neurology and Physiology, Mt. Sinai Sch. of Med., NY 10029 and Computer & Information Science, Brooklyn College, CUNY, Brooklyn., NY 11210

Tilting the head during post-rotatory nystagmus or optokinetic after-nystagmus (OKAN) causes a reduction in slow phase velocity (SPV) that does not recover when animals are brought back to the upright position. This indicates that this maneuver had caused a rapid discharge or "dump" of central vestibular system activity that produces slow phases of nystagmus. The same occurs during visual suppression. The origin of activity responsible for the dumping process has been localized to the nodulus and uvula (Waespe et al. Science 1985). This suggests that it may be possible to suppress nystagmus and reduce stored central activity by nodular and uvular stimulation. To study this the region of the posterior vermis was electrically stimulated in alert rhesus monkeys with constant currents of 60-100 microamps at frequencies of 150-400 Hz for periods up to ten seconds. Trains of pulses caused a rapid loss in SPV during per- or post-rotatory nystagmus and OKAN, shortening the duration of the response. SPV did not recover at the end of stimulation, suggesting that central activity responsible for the nystagmus had been lost. The loss of SPV was directionally specific, occurring when slow phases were to the stimulated side. The latency of the decline in velocity was about one second, similar to the response to tilt. The time constant of decline in SPV varied as a function of stimulus duration. This was consistent with the decline after visual suppression, and was significantly faster than the decline in SPV in darkness without suppression. Contralateral SPVs were generally enhanced by stimulation, leading to a longer response than in the absence of stimulation. With the animal in darkness and the eyes stationary, stimulation caused eye movements to either side, depending on electrode location. This was followed by contralateral SPVs that had the characteristic time course of post-rotatory nystagmus or OKAN. Vertical eye velocities were also induced. The discharge of stored activity could not be accounted for by a simple summation of the ongoing SPV with that induced by stimulation. Stimulation during the initial step in eye and head velocity had little effect on the response.

These data show that stimulation of the posterior vermal area that includes the nodulus and uvula can evoke nystagmus "dumping" similar to that elcited by visual suppression or tilt suppression. Presumably the ipsilateral output projections of the nodular and/or uvular Purkinje cells inhibit cells in the vestibular nuclei that are responsible for producing velocity storage without affecting portions of the VOR that are responsible for generating rapid changes in velocity during compensatory eye movements.

207.2 POSTURAL COACTIVATION AND THE HABITUATION OF SWAY STABILIZING RESPONSES. E.A. Keshner, J.H.J. Allum and C.R. Pfaltz. Dept. of ORL, Univ. Hosp., 4031 Basel, Switz.

Coactivation of pitch sway stabilizing responses and their habituation to a series of 10, 36 deg/s dorsiflexion support surface rotations was investigated in the ankle and neck muscle responses of normals and patients with bilateral peripheral vestibular deficit (BILATS). Areas under the EMG curves were calculated for the avg. of the first 3 and next 7 trials of each muscle at latencies determined from individual responses. Short latency (SL) responses appeared in soleus (SOL) at 60 ms and tibialis anterior (TA) at 84 ms. Medium latency (ML) responses of SOL (125 ms) and TA (122 ms) were measured for a 75 ms window and long latency (LL) responses for the following 75 ms. The same procedure was used for ML trapezius beginning at 116 ms, and longus capitus at 128 ms. Average head angular acceleration amplitudes, recorded from an angular accelerometer mounted on a helmet, and incremental torque exerted on the platform were measured. Habituation was assessed through t-tests for paired comparisons. Correlations were calculated between the muscles, and bivariate regressions performed to assess the actions of TA and SOL on foot torque, and the neck muscles on head acceleration.

Significant decreases occurred across trials in the muscles of normals and BILATS in all but the SL responses. ML and LL responses of the BILATS were significantly smaller than those of normals. Muscle response decrements were reflected in decrements of torque and head acceleration. Strong correlations existed between the ankle muscles at both ML (r = 0.81) and LL (r = 0.88) with eyes open and closed. TA and SOL actions were highly correlated with foot torque for normals and BILATS at SL (r = 0.85), ML (r = 0.88), and LL (r = 0.61). ML neck muscle correlations were strong in normals (r = 0.83). Correlations between neck muscles and head acceleration in normals (r = 0.61) increased when initially tested with eyes closed (r = 0.83).

Our results demonstrate that habituation is not dependent on an intact vestibular system. It is essential to account for coactivation of antagonistic muscles acting across a joint to adequately describe sway stabilization. Separate pathways appear to control the stabilizing responses at the ankle and neck.

207.3 DOES VISION AFFECT OCULAR COUNTERROLLING? S.G. Diamond and C.H. Markham. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Ocular counterrolling (OCR) is the reflex rotation of the eyes opposite to head rotation, governed by the vestibular otoliths. Most OCR studies are conducted in ambient light, and any contribution of vision to this response is assumed to be negligible. This study was an attempt to systematically evaluate what effect light and vision might have on this otolith reflex response.

Six normal subjects, two men and four women, aged 24 to 65, were each studied in three protocols in counterbalanced order.

1) Standard condition in which subjects were rotated in ambient room light at constant velocity of 3°/s about their naso-occipital axis, twice to 90° right and left. Central vision was occupied by the camera which rotated with the chair. Peripheral vision of the room was unobscured.

2) White mode. Peripheral vision was obscured by draping the entire tilting chair in a white tent. Light entered freely but subjects had no visual reference to verticality. Rotation was performed as in the standard condition.

3) Dark mode. Both central and peripheral vision were eliminated by conducting the trials in complete darkness.

Results of the latter two conditions were compared to those obtained in the standard procedure, using the same parameters found useful in earlier studies.

Consistency, the extent to which the second trial resembles the first. One subject showed greater consistency in the white and dark modes than in the standard; two showed less in the dark mode.

Smoothness, the absence of abrupt changes of direction of OCR. One subject had less smooth OCR in white mode. Five subjects had less smooth OCR in the dark.

Symmetry, equal amplitude of response to right and left tilt. Three patients showed less symmetry in white mode. One of these three had less symmetry in the dark also, and one had more.

Conjugateness, the tendency of the two eyes to move together. In the white mode, one subject showed less and one showed more disconjugate movement. In the dark, four subjects showed more disconjugate movement, three of these dramatically so.

Amplitude, the magnitude of the response. Four subjects showed slightly diminished response in white and three of these persons had somewhat increased amplitude in the dark.

In summary, the changes observed in OCR when peripheral or all vision was interrupted were either none or mild in no systematic way, with two exceptions. In the dark condition, the occurrence of disconjugate eye movement and less smoothness may be due to a lack of cortical fusion. These findings are not sufficient to propose that OCR studies by conducted in other than the usual ambient light conditions.

207.4 BACLOFEN AND THE VESTIBULO-OCULAR REFLEX (VOR). D. Helwig*, B. Cohen and T. Raphan. Departments of Neurology and Physiology, Mount Sinai School of Medicine, New York, NY 10029, and Computer & Information Science, Brooklyn College of CUNY, Brooklyn, NY 11210.

The dominant time constant of OKAN and of vestibular nystagmus is a measure of the dynamic properties of a mechanism in the vestibular system that stores activity related to slow phase eye velocity. This time constant was reduced in monkeys after administration of baclofen. Effects began within 15 minutes of injection and lasted for more than 12 hours, paralleling increases in blood levels of baclofen that have been reported after a similar injection (Brogden et al. Drugs 8: 1, 1974). The decrease in VOR time constant was dose-dependent between 2-8 mg/kg, the range that was tested. Generalized skeletal muscle weakness occurred at higher dosages. Analysis of the response to steps of velocity as well as to sinusoids showed that the time constant of the VOR that was originally 15-20 seconds was reduced to 6-8 seconds at higher dose levels. There was a concomitant reduction in the falling time constant of OKAN. Peak velocities during continuous nystagmus elicited by off vertical axis rotation or by pitch while rotating, which also depend on the velocity storage mechanism, were also attenuated by baclofen. In contrast, the gain of the VOR in response to steps of constant angular velocity was unchanged at all dose levels. The rapid rise in OKN was equally unaffected.

These results suggest that baclofen specifically alters the dynamics of the velocity storage mechanism without affecting the pathways that mediate the direct visual or vestibular responses. This type of decrease in the VOR time constant is brought about by repeated testing and/or by repeated exposure to conflict stimuli. The ability to habituate nystagmus disappears after the nodulus and uvula are ablated (Waespe et al. Science 228: 199, 1985). Since baclofen is a GABA-agonist believed to act primarily on GABAb synapses, GABAb synapses may be utilized by the vestibulo-cerebellum in differentially controlling cells in the vestibular nuclei specifically involved in realizing velocity storage.

207.5 **POSITION-DEPENDENT ASYMMETRIES IN HORIZONTAL NYSTAGMUS IN THE SQUIRREL MONKEY.** **L.B. MINOR* AND J.M. GOLDBERG.** Dept. Pharm. Physiol. Sci., University of Chicago, Chicago, IL 60637.

Caloric nystagmus has a position-dependent asymmetry which cannot be explained on the basis of thermal convection (Coats, A.C., and Smith S.Y., Acta Otolaryng., 63:515, 1967). The maximum slow phase eye velocity (SPEV) of the caloric response is greater in nose up (NU) than in nose down (ND) positions. There are at least two explanations for the asymmetry: a direct thermal effect on hair cells and/or afferent nerve fibers; or a position-dependent, possibly otolith-related modulation of horizontal nystagmus. If the latter effect is involved then similar position dependent asymmetries should be seen with rotational stimuli.

Eye movements were recorded by a search coil technique from four squirrel monkeys. The SPEV in response to warm or cold air calorics was about 5x greater in the supine than in the prone position. Long-duration accelerations about the earth-vertical axis (3°/sec^2 acceleration, 60 sec) were presented in darkness after the animal had been pitched 45° NU or 45° ND. NU responses were 52% greater than ND responses. The results indicate that a position-dependent modulation of horizontal nystagmus can account for a portion, but perhaps not all, of the caloric asymmetry.

In contrast to long-duration head accelerations, sinusoidal rotations about the earth-vertical axis (0.1 Hz, 40°/sec maximum velocity) with the animal pitched to 30, 60, and 90° showed no consistent asymmetries between NU and ND positions. The presence of a positional asymmetry confined to low frequency (<0.1 Hz) rotational responses suggests that velocity-storage mechanisms may be affected by static head position. To study this possibility, velocity steps to 60°/sec in darkness were given with the animal in 45° NU or 45° ND positions. Following the decay of the vestibular nystagmus, the room was illuminated and the animal continued to rotate at 60°/sec for 30 sec, at which time the lights were again extinguished and the decay of optokinetic after-nystagmus (OKAN) was evaluated. Time constants for decay of vestibular nystagmus and OKAN were greater for 45° NU than 45° ND for all animals with the average values (in sec) being $T(VOR)_{NU}$ = 21.7, $T(VOR)_{ND}$ = 13.0, $T(OKAN)_{NU}$ = 23.6, and $T(OKAN)_{ND}$ = 15.9. When the NU and ND time constants for each animal were compared, the average ratio of 45° NU to 45° ND was 1.8 for T(VOR) and 1.5 for T(OKAN). These findings support the hypothesis that static pitches can influence velocity storage for the horizontal VOR. The differences in time constants are appropriate in magnitude to explain the asymmetry in responses to long-duration head acceleration.

207.6 Vestibular neurons in cerebral cortex: Two populations with different locations and different activation by optokinetic stimulation. U. Schreiter*, Dept. of Neurology, Univ. of Düsseldorf, 4 Düsseldorf, W. Germany, U. Büttner, Dept. of Neurology, Univ. of Munich, 8 München, W. Germany.

Single unit recordings were performed in the cortex of awake Java monkeys during natural vestibular and optokinetic stimulation. Eye position was recorded with chronically implanted ECG-electrodes. Two populations of vestibular neurons at different locations could be identified: group A-neurons in the upper bank of the lateral sulcus (parietal operculum), group B-neurons in the intraparietal sulcus (area 7b). Both groups were activated similarly by natural vestibular stimulation (sinusoidal rotation about a vertical axis in the dark at 0.05 - 2.0 Hz and 20 - 60 deg/s max. velocity). In both groups type I (activation with rotation to ipsilateral side) and II (to contralateral side) neurons were found. Neurons showed no modulation with individual eye movements. All neurons were activated by optokinetic stimulation. Stimulation was applied in the horizontal plane either sinusoidally (0.01 - 5.0 Hz, 10 - 60 des/s max. velocity) or at constant velocity (10 - 100 deg/s). In order to elicit an activation the optokinetic and vestibular stimulus had to move in opposite directions.

The two groups showed considerable differences in their response to optokinetic stimulation. Group A-neurons responded only at low frequencies of optokinetic stimulation (below 0.2 Hz) and displayed only gradual activity changes after onset of constant velocity stimulation. Activation continued throughout optokinetic after-nystagmus (OKAN). In contrast group B-neurons responded even at high frequencies (up to 3 - 5 Hz) and showed immediate activity changes with constant velocity stimulation. There was no modulation during OKAN.

It is concluded that group A-neurons display an activity pattern similar to that found in the vestibular nuclei. For group B-neurons the visual-vestibular response properties have to derive from different, yet unknown, sources. In particular, the lack of response during OKAN indicates that group-B cortical vestibular neurons are not involved in 'velocity storage' mechanisms, which are found in vestibular nuclei neurons.

207.7 ANATOMOPHYSIOLOGICAL CORRELATES IN THE AFFERENT ANTERIOR SEMICIRCULAR CANAL FIBERS OF THE BULLFROG. V. Honrubia, A. Kuruvilla* and S. Sitko*. Div. of Head and Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024.

Approximately 1200 neurons ranging in diameter from 1 to 17 μm innervate the anterior semicircular canal of the bullfrog. The number of fibers (Nd) for each diameter (d) is given by the equation Nd = 446 exp (-d/2.26). The larger neurons (d > 7 μm) innervate the central region of the crista where they represent 37% of the fibers in the two central bundles. The smaller neurons predominate in the bundles at the periphery (93%). Thirty-seven neurons were intracellularly impaled with microelectrodes to measure their spontaneous activity and to inject them with horseradish peroxidase. The axon diameters, soma volumes and internodal distances of the fibers are linearly related to the coefficient of variation (CV) of the spontaneous activity. It is estimated that 92% of the neurons with fiber diameters of < 7 μm have a CV of < 0.5. All neurons innervate the same areas of the various vestibular nuclei except for the more irregular ones (CV > 0.5) which do not innervate the medial nucleus. The distribution of terminals and the length of dendritic branches along the nuclei are different for regular and irregular fibers. The response to rotational stimuli (0.0125-0.5 Hz) and the spontaneous activity of another group of 73 neurons were also obtained. The frequency response characteristics (Bode plots), middle frequency dominant time constant and sensitivity coefficient were determined. More regular fibers show a negative correlation between their CV and time constant (range 10.4 to 0.9 sec) but a positive correlation between their CV and sensitivity (range 1.2 to 5.3 [spikes/sec][deg/sec^2]). More irregular fibers have a time constant and sensitivity coefficient which are uncorrelated with the CV; there is, however, a positive correlation between the time constant (range 0.05 to 5.5 sec) and sensitivity coefficient (range 0.5 to 12 [spikes/sec][deg/sec^2]).

207.8 GAIN REGULATION OF THE VESTIBULOSPINAL REFLEX BY THE NORADRENERGIC LOCUS COERULEUS SYSTEM. O.Pompeiano, P.d'Ascanio*, E.Horn* and G. Stampacchia*. Ist.di Fisiologia Um.,Univ.di Pisa,56100 Pisa,Italy.

The increased activity of the extensor triceps brachii during side-down tilt of the animal depends on both an increased discharge of excitatory vestibulospinal (VS) neurons and a reduced discharge of medullary inhibitory reticulospinal neurons (mRS).Since these mRS neurons are tonically excited by the dorsal pontine reticular formation (pRF), whose activity is in turn inhibited by noradrenergic locus coeruleus (LC) neurons,experiments were performed to find out whether pontine microinjections of adrenergic agonists or antagonists may modify the characteristics of the VS reflex.

In precollicular decerebrate cats,iniection of an α 2-agonist(0.25 μl of a solution of 0.012-0.15 μg/μl of clonidine) into the LC of one side at P3,L2.5 or 2.8,H-2 decreased the extensor rigidity in the ipsilateral limbs,but greatly increased the gain (imp./sec/deg) of the first harmonic component of the multiunit EMG response of the triceps brachii to roll tilt of the animal (at 0.15 Hz,±10°);however,the phase angle of the response was not modified.Similar results were also obtained after unilateral injection of an α 1-antagonist (0.25 μl of a solution of 0.1-1.0 μg/μl of prazosin) into the dorsal pRF at P2 or P3,L2.8,H-3.5 or -4.5.In both instances,the increased gain of the VS reflex did not depend on the decreased postural activity following injections,since it was still observed when an increased static stretch of the extensor muscle compensated for the reduced EMG activity.

In conclusion,the tonic inhibitory influence exerted by the noradrenergic LC neurons on the dorsal pRF was greatly depressed,either i) by microinjections into the LC of the α 2-agonist clonidine,which acts on the somatodendritic α 2-adrenoceptors by enhancing collateral inhibition of the corresponding neurons,or ii) by injection into the dorsal pRF of the α 1-antagonist prazosin,which blocks the inhibitory influence that the LC neurons exert on this pontine region,probably by activating inhibitory interneurons via α 1-adrenoceptors.In both instances, the increased discharge of the pRF neurons and the related mRS neurons decreased the postural activity in the ipsilateral limbs;moreover, the higher the resting discharge of these mRS neurons,the greater the disinhibition which affected the limb extensor motoneurons during side-down animal tilt.These motoneurons would then respond more efficiently to the same excitatory VS volleys elicited during side-down tilt, thus leading to an increased gain of the EMG response of limb extensors to labyrinth stimulation.The LC may thus exert a permissive role in the gain regulation of the VS reflex.

207.9 EFFECTS OF BEHAVIORAL ACTIVATION OF THE EFFERENT VESTIBULAR SYSTEM ON THE RESPONSE DYNAMICS OF THE HORIZONTAL SEMICIRCULAR CANAL AFFERENTS IN THE TOADFISH, OPSANUS TAU. R. Boyle* and S. M. Highstein (SPON:A.Steinacker). Marine Biological Laboratory, Woods Hole MA. 02543 and Dept. of Otolaryngology, Washington University, St. Louis, MO. 63110.

A paradigm was previously described (J. Neurophysiol. in press) for behavioral activation of the efferent vestibular system in spinalized fish. A light touch of the snout activates vestibular efferents which excite vestibular primary afferents presumably via axo-axonic synapses within the labyrinth (Sans and Highstein, Brain Res. 308: 191,1984). We have now characterized the response dynamics of horizontal semicircular canal primary afferents (HSCA) and the change in these dynamics with efferent activation. Adult toadfish were clamped in an experimental tank, perfused through the mouth with running sea water and oscillated horizontally. Dorsal craniotomy exposed the labyrinth and HSCA were penetrated with glass microelectrodes; eye retraction served as a behavioral marker of efferent activation. Resting discharge of 400 fibers ranged from 0 impulses/sec (ips) to low rates (<10ips) with irregular interspike intervals, to higher rates (>80ips) with more regular interspike intervals as reported for other vertebrate labyrinths. Sinusoidal rotation, (0.008-8.0 Hz) at various amplitudes (±0.5° to ±45°; 2-30°/s; 0.2-600°/s^2) was used to determine the sensitivity and phase of response. We compared control-response cycles to ones with efferent activation and constructed cumulative histograms of HSCA discharge. Phase and sensitivity were calculated using a sinusoidal fit by a least-squares process. Background discharge (BD) was calculated as the average ips during each cycle of rotation. Major efferent effects were on irregular HSCA; regular afferents usually did not respond to behavioral activation. To date, 12 HSCA have been analyzed in detail. In 3 HSCA with BD 2-8ips, efferent activation raised the BD 200-700% relative to control, increased the sensitivity from 1.5-2.5x and either advanced the phase re:velocity (n=1, from +47° to +78°) or retarded it (e.g. from +30° to +5°). In 4 HSCA with BD 11-43ips efferent activation raised the BD 115-145%, decreased the sensitivity 0.6-0.9x and shifted the phase re:velocity (e.g. from +40° to +25°). In 1 HSCA BD decreased from 74 to 61ips, phase shifted from +65° to +53°, sensitivity decreased 0.6x, but inhibitory cutoff was prevented. In the other HSCA with higher BD the only noticeable effect of efferent activation was brief excitatory bursts of APs. Thus behavioral activation of efferents is able to selectively modify the response dynamics of vestibular primary afferents during physiological stimulation.
(Supported by NIH NS 21055)

207.10 OCULOMOTOR AND SUBJECTIVE RESPONSES DURING CORIOLIS STIMULATION DEPEND ON GRAVITOINERTIAL FORCE BACKGROUND. J. R. Lackner, P. DiZio* and J. N. Evanoff. Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254

Lackner and Graybiel (AGARD Monograph CP-372, 1984) reported that susceptibility to motion sickness during Coriolis/cross-coupling stimulation (CCS) decreases in the free fall phase of parabolic flight and increases in the high force phase relative to ground based tests. We expected parallel oculomotor and perceptual responses to be evoked. Thus, we examined the intensity of reflexive eye movements and perceived self-motion during constant levels of CCS produced by voluntary head movements (HMs) during whole-body rotation in the alternating 20 sec periods of low (0 G) and high (1.8 G) gravitoinertial force generated in parabolic flight maneuvers.

The experiment was conducted aboard NASA's KC-135 aircraft. The seated, blindfolded subject was continuously rotated about his z-body axis at 80°/s in a chair equipped with a device that restrained HMs to the pitch plane. For at least 60 s before every HM, the subject's head was positioned 20° forward in pitch. At the next available period of constant force, the subject moved his head backwards 40° within 1 s after being instructed. Horizontal eye movements were recorded using conventional DC electro-oculography for the next 10 seconds. The subjects made pitch-up HMs alternately in 0 G and 1.8 G, rating the relative magnitude of apparent body tilt and rotation after each pair. Seven subjects participated each making between 3 and 11 pairs of HMs.

Recordings indicated no differences in chair velocity or the HM kinematics (duration, amplitude and peak velocity) between 0 G and 1.8 G, thus constant levels of CCS were acheived. All 7 subjects judged the magnitude of illusory body tilt and rotation to be less in 0 G than in 1.8 G. Both average slow phase velocity and beat frequency for the 10 s periods of nystagmus were significantly lower in 0 G than in 1.8 G. ($p < .05$).

Average Characteristics of Nystagmus

	0 G	1.8 G
Slow phase velocity (deg/s)	4.6 (s.e.=1.23)	6.8 (s.e.=.63)
Beat frequency (beats/s)	1.47 (s.e.=.22)	1.69 (s.e.=.21)

We conclude that oculomotor and subjective responses to constant levels of CCS are greater in 1.8 G than in 0 G. These differences appear to be related to both the relative provocativeness of CCS and the ability to adapt to it. The difference in the subjective responses between 0 G and 1.8 G was large while the difference in oculomotor responses was relatively small, suggesting that sensory and motor factors in addition to reinterpretation of canalicular activity are involved in responses to CCS.

207.11 DYNAMIC RESPONSES OF CENTRAL VESTIBULAR NEURONS TO OFF-VERTICAL AXIS ROTATIONS IN CATS: EFFECTS OF VELOCITY AND AMPLITUDE OF HEAD TILT. Y.S. Chan, Y.M. Cheung* and J.C. Hwang. Department of Physiology, Faculty of Medicine, University of Hong Kong, Sassoon Road, Hong Kong.

The dynamic responses of static-tilt sensitive central vestibular neurons during off-vertical axis rotations were analyzed in decerebrate cats. It has earlier been shown that each unit showed modulation of firing rate, with a position dependent maximum and minimum during 360° rotation (Chan Y.S. et al., Brain Res., 1985, in press).

The effect of velocity (ranging from 1.7 to 15°/s) on the neuronal responses during constant speed 10° off-vertical axis rotations was studied. Positional responses were still observed within this range of velocity of rotation. Both the amplitude of the peak-to-peak discharge modulation and the locations of the discharge maxima were apparently insensitive to velocity in the range studied.

The relation between unitary discharge and the degree of off-vertical axis (5° - 15°) rotation was also studied over any one velocity within the specified range. There was a linear relationship between the gain of the unitary discharge modulation and the degree of off-vertical tilt, but no change in the locations of the discharge maxima was observed.

The response patterns of such central vestibular neurons during off-vertical axis rotations may well convey the information from the otolith for continuous nystagmus (Cohen B. et al., Brain Res., 276: 159, 1983) in otolith-ocular reflexes.

207.12 ANATOMICAL CHARACTERISTICS OF THE VESTIBULAR NERVE IN THE SQUIRREL MONKEY. A. Kuruvilla* and V. Honrubia (SPON: D. S. Maxwell). Div. of Head and Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024.

A study was made of the dimensions and number of nerve fibers innervating each of the three semicircular canals, the utricle, the superior vestibular nerve and the whole vestibular nerve root in the squirrel monkey in order to determine whether these fibers segregate according to their diameter as they do in amphibians (Honrubia, V. et al., Laryngoscope, 94, 464, 1984). Fiber counts and dimensions were analyzed by photographing 1-µm-thick cross sections of the nerve and digitizing the outlines of the nerve fibers with the aid of a laboratory computer at more than 1000 X magnification.

The superior vestibular nerve has an average of 8850 fibers: 2850 fibers to the anterior semicircular canal, 3100 fibers to the horizontal semicircular canal, and 2900 fibers to the utricle. The posterior ampullary nerve (branch from the inferior vestibular nerve) has 3250 fibers. Individual fibers to the various cristae range in diameter from 0.5 µm to 8 µm with 80% of fibers being $\leq$ 2 µm and only 5% > 4 µm. Utricular fibers range in size between 0.5 µm and 6 µm. Here again, 80% of fibers are $\leq$ 2 µm in diameter and only 5% are > 4 µm. A pattern of segregation of fibers according to their diameters is found, both in the peripheral cristae and in the superior vestibular root. In the cristae, small-diameter fibers ($\leq$ 2 µm) segregate into bundles at the periphery. At the center, larger-diameter fibers predominate. Large-diameter fibers predominate in the anterior portion of the superior vestibular nerve, while smaller-diameter fibers predominate in the posterior part. In the anterior part, the fibers range in size from 0.5 µm to 12 µm, with 65% of fibers being $\geq$ 4 µm in diameter. In the posterior part, on the other hand, 75% of fibers have diameters $\leq$ 4 µm. In the vestibular nerve root the above pattern of segregation of fibers according to their diameter is not clearly discernible. This is because the primary vestibular fibers divide into smaller secondary branches within the nerve root itself so that there is an intermixture of large- and small-caliber fibers. We counted an average of 17,000 fibers at this level.

Supported by grants from NIH (NS08335, NS09823) and the Pauley Foundation.

207.13 PROBABLE LOCALIZATION OF GABA AND ACETYLCHOLINE SYNTHESIS IN THE VESTIBULE OF STREPTOMYCIN-TREATED GUINEA PIGS. A.G. Iturbe* and G. Meza (SPON: A.M.López-Colomé) Dept. Neurociencias CIFC, UNAM, Apdo. Postal 70-600 04510 México D.F.

The presence of glutamate decarboxylase (GAD) and choline acetyltransferase (ChAT) the GABA and acetylcholine (Ach) synthesizing enzymes, respectively, in the anfibian and avian vestibule is evidence of their participation as neurotransmitters in these systems. However, in mammalian vestibule this has not investigated, although GABA and Ach have been assumed to be mediators there.

In support to this assumption we measured GAD and ChAT using the vestibule of pigmented guinea pigs as a model.

When both enzymes were measured in homogenates of the whole vestibule as already reported (1), (2) we found GAD activity to be 0.250 μ mol /hr/mg prot. and activity of ChAT 0.550 nmol/min/mg prot.

The precise localization can not be assessed by these experiments, thus in order to localize the cells of origin of these enzymes we used streptomycin sulfate (300 mg/kg daily for 20 days, intramuscular) treated animals, knowing in advance that this treatment causes severe damage in vestibule sensory cells, starting with degeneration, and finally disappearance of the sensory hairs cells, the nerve fibers and nerve endings being however, not affected (3).

After treatment, the animals showed vestibular damage, according to the observation of lossing of the rightening reflex and disappearance of the nystagmus response with caloric stimulation.

When GAD and ChAT were measured in the vestibule of treated animals GAD was found to have decreased about 50% of the vestibular enzyme of control animals injected with normal saline solution. ChAT was not modified in either group.

Although morphological controls are needed to support this assumption, based on the streptomycin effects reported (3) and our results, we can suggest that GAD is localized in at least 50% of the hair cells whereas ChAT is probably in efferent endings, being the GABA and Ach their respective neurotransmitters. (supported in part by Grant PCCBBNA 020897 of CONACyT México)

207.14 POSSIBLE EFFERENT NEUROTRANSMISSION IN THE INNER EAR OF THE FROG G.Meza,I.López*and A.Feria-Velasco.Dept.Neurociencias,CIFC UNAM Apdo.Postal 70-600 04510 México,D.F.(GM and IL),Div.Developmental Biology.Unidad de Investigación Biomed.Occidente,I.M.S.S.Guadalajara,Jal.MEXICO(AFV)

Neurotransmission in the sensory periphery of the vestibular system is chemical in nature; the efferent neurotransmitter is apparently acetylcholine(Ach). In earlier studies we demonstrated choline acetyltransferase(ChAT) activity in homogenates of frog vestibule and choline transport in the whole vestibule of this anfibian(1); however with this type of experiments, the cell of origin of these biochemical parameters can not be assessed. With the purpose of localization of the Ach-utilizing cell by elimination of certain population of terminals, we used Hillman model(2) in which the VIII craneal nerve of the frog was excised and degeneration of efferent nervous fibers was observed. We utilized adults frogs(Rana pipiens) in which denervation of the right VIII craneal nerve was performed leaving the left nerve intact as control. We determined ChAT activity as previously described (3)in the frog vestibule after 3,7 and 15 days of surgery. For morphological studies the right and left vestibules obtained from denervated frogs were fixed "in situ" with cacodylate buffered-1% osmium tetroxide, dehydrated and embedded in epoxy resins. One micrometer thick sections were collected on glass slides and stained with toluidine blue for examination under light microscope.
We observed gradual decreased of the activity with time after denervation until it reached 50% of ChAT present in the control side. Morphological study of vestibular nerves in the vecinity of receptor zones revealed a Wallerian degeneration of some nerve fibers randomly distributed among normal looking fibers. Various button-like nerve endings appeared markedly basophilic at the basal portion of receptor zones. No structural alterations were seen at both, the receptor areas and the vestibular nerve trunks of the non-denervated vestibule of operated frogs, of both vestibules obtained from non-operated animals. Thus apparently the only affected structures are the efferent endings. These biochemicals and morphological results show that ChAT in the inner ear of the frog appears to be localized at least in 50% of efferent terminals which probably use Ach as mediator at the level of the sensory periphery of vestibular system.

207.15 Effects of Utricular and Semi-circular Canal Stimulation on Selected Central Nervous System Reflexes of Children with Severe Developmental Disability. M. A. Boyle, Program in Occupational Therapy, Washington University Medical School, St. Louis, Missouri 63110.

Vestibular stimulation is frequently used in remediation of brain injured for improvement of motor control. Previous reports of vestibular stimulation have indicated short term improvements in motor function of normal and neurologically impaired children. The only study examining the long term treatment effect on developmentally delayed children found no significant improvement in motor performance creditable to vestibular stimulation. This study was developed to evaluate short and long term treatment effects of vestibular stimulation on selected central nervous system postural reflexes.

Institutionalized, severely developmentally disabled children (n=20), aged 6 to 16, with motor disability, spasticity, seizure disorders, and profound mental retardation were evaluated pre-treatment, post-treatment, and at follow-up (six weeks following the last treatment): on a battery of six central nervous system postural reflexes: symmetrical tonic neck reflex, asymmetrical tonic neck reflex, tonic labyrinthine neck reflex (supine and prone), labyrinthine neck righting (vertical), and optical neck righting. Subjects were randomly assigned to a treated and control group. The treated group (n = 10) received five minutes of vigorous utricular and semi-circular canal stimulation daily for six weeks. The control group (n = 10) received five minutes of slow movement with minimal utricular and semi-circular canal stimulation daily for six weeks.

Within-group analysis of the median difference scores demonstrated no significant difference between the median scores of the post-treatment and pre-treatment tests in either the control group or the treated group. Moreover, there was no significant difference between the follow-up and pre-treatment scores of the control group. However, the interval between the pre-treatment and follow-up score of the treated group was significant ($0.005<p<0.01$). Between-group analysis of difference scores also demonstrated a significant change ($p = 0.01$) between the treated group's pre-treatment and follow-up score.

Utricular and semi-circular canal stimulation was found to be effective over a long term period in increasing development level of motor function as indicated by performance on central nervous system reflexes.

207.16 BLIND POINTING TO VISUAL TARGETS DURING BODY ROLL AS POSSIBLE OTOLITH FUNCTION INDICATOR ?
D.Ott*, R.Eckmiller and O.Bock*. Division of Biocybernetics, University of Düsseldorf, D-4000 Düsseldorf, FRG.

Vestibular otolith function is presently best being evaluated by measurements of ocular counterrolling during relative changes of the gravitation vector (Diamond & Markham, Neurology,33:1460,1983), although the exact relationship between the ipsi-and contralateral otolith organs and the angle of counterrolling of either eye is still unknown. We report on a sensori-motor task which also depends on the direction of the gravitation vector.

Pointing to visual targets without seeing the pointing hand (blind pointing) was studied in healthy subjects as a function of static body tilt angle α (roll) in a swing chair. Sequences of 42 visual targets, appearing(30 deg left to 30 deg right) on the inner surface of a hemispherical screen(r=23 cm) in the horizontal plane of the tilted head coordinate system were presented monocularly at various roll angles(55 deg left to 55 deg right). Blind pointing positions of the upper hand(e.g. right hand for left ear down tilt) on the outer surface of the screen were measured in two dimensions by means of a modified joy stick device.
1)For a given subject the blind pointing characteristic(see schemes) with significantly different features for the ipsilateral vs. contralateral hemifield was highly reproducible and depended on both the roll angle α and the eye stimulated. 2)The most prominent parameter depending on α was the rotation angle π (see schemes) between α and the angle of the ipsilateral half of the blind pointing characteristic. 3) π reached values up to π =25 deg with increasing α. 4)When the lower eye was stimulated, π was typically larger by at least 5 deg as compared with stimulation of the upper eye.
5)Comparative measurements with a retinal reference paradigm(subjects were fixating a green light dot in the primary position while pointing at the extrafoveally occurring red light dots) yielded qualitatively similar changes for $\pi = f(\alpha)$.

The possible correlation between π and ocular counterrolling will be discussed.

207.17 PROPRIOCEPTIVE INFLUENCES ON VESTIBULAR NYSTAGMUS AND THE DISPLACEMENT COMPONENT OF THE OCULOGYRAL ILLUSION. J. N. Evanoff and J. R. Lackner. Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, Massachusetts 02254.

Several studies have demonstrated a potential contribution of proprioceptive information about limb position to visual direction and voluntary oculomotor control. Proprioceptive information specifying the location of an object in relation to the body has been shown to affect the apparent visual direction of the object and to enhance fixation responses (Lackner, J. R. and Levine, M. S., Neuroscience Letters, 7: 207, 1978; Levine, M. S. and Lackner, J. R., Experimental Brain Research, 36: 275, 1979).

We examined the influence of brachial, proprioceptive information on vestibular nystagmus in the dark using six trapezoidal velocity profiles ranging from $2^o/s^2$ to $25^o/s^2$. Nystagmus was induced by exposing subjects to clockwise, angular acceleration with their longitudinal (Z) body axis aligned with the axis of chair rotation. Subjects fixated a target light that was extinguished five seconds prior to the onset of chair acceleration, they then attempted to maintain fixation of the former position of the light for the duration of the trial. These base-line measures of vestibular nystagmus were then compared to conditions in which subjects touched the target light mount with the unseen index finger of their right hand throughout an entire velocity profile.

Brachial proprioceptive information under these conditions was found to be of sufficient fidelity to contribute to a fixation response adequate to suppress both the fast and slow phase of vestibular nystagmus for all acceleration rates, ($p<.01$). Clearly, a sensory input adequate to override vestibular nystagmus need not originate in the visual modality.

This finding allowed us to assess the contribution of reflexive oculomotor signals to perceptual illusions associated with vestibular stimulation, such as the oculogyral illusion (OGI) in which a visual target, stationary in relation to the body, is seen to move and displace relative to the body in the direction of acceleration (Graybiel, A. and Hupp, D., Journal of Aviation Medicine, 17: 1, 1946). Whiteside, Graybiel, and Niven, (Brain, 88: 193, 1965) have suggested that the OGI results from monitoring a fixation command that is necessary to override the latent vestibular nystagmus so as to maintain a retinally stable image. We found that if subjects touch the visual target with their unseen index finger the illusory displacement component of the OGI is attenuated by an amount comparable to the diminution of their nystagmus that occurs when they fixate their finger in the dark, ($p<.05$). Increases in the magnitude of the OGI displacement were observed if the finger was positioned as little as 8 cm. from the target.

207.18 DIRECTIONAL SENSITIVITY OF CAT FORELIMB AND SHOULDER MUSCLES TO VESTIBULAR AND NECK STIMULATION. R.H. Schor, V.J. Wilson, I. Suzuki* and B.R. Park*. The Rockefeller University, New York, NY 10021.

Combinations of sinusoidal roll and pitch stimuli were used to study the spatial organization of vestibular and tonic neck reflexes acting on forelimb (medial, lateral and long heads of triceps brachii) and shoulder (supraspinatus and infraspinatus) extensor muscles of the decerebrate cat. Neck reflexes were studied in preparations having intact labyrinths as well as those having acute or chronic labyrinthectomies. Reflexes, studied with EMG recording, were described by response vectors whose orientation component is aligned with the optimal excitatory direction of tilt or head rotation. Repeated testing over a period of many hours showed that a muscle's response vector remained reasonably stable, although there was sometimes drift at the beginning or end of an experiment, and sometimes an apparent change of vector during locomotor-like activity. Stimulus frequencies were from 0.05-2 Hz. Over this range, the orientation of muscle response vectors did not change in a systematic fashion with stimulus frequency for either neck or vestibular reflexes. For the latter, this is so despite the fact that reflex dynamics are consistent with convergent input from semicircular canals and otolith organs: the otolith and canal components are apparently aligned. This contrasts with the results of Baker et al. (Soc. Neurosci. Abstr. 10: 162, 1984) on vestibulocollic reflexes. Although there was interexperiment variation, a consistent reflex pattern emerged. For all muscles tested, vestibular reflexes are characterized by response vector orientation near ear-down roll. Neck vector orientation lies in the opposite direction from the vestibular vector, but typically does not lie as close to the roll plane: for the shoulder muscles and the medial and lateral heads of triceps nose up pitch is excitatory, while for the long head of triceps, nose down excites. The pattern of response to neck stimulation generally agrees with the scheme proposed by Roberts (Neurophysiology of Postural Mechanisms, Butterworths, 1978), but the pattern of response to vestibular stimulation does not. Roberts' scheme describes a consistent response to vestibular pitch which we did not see. We suggest that muscle response vectors are produced by vectorial addition of the signals of an array of premotor neurons, each with its own directional sensitivity, and that peripheral and central modulation of this pool of neurons determines which of them are active, and ultimately determines motoneuron vectors. Supported in part by grants from NIH (NS02619) and NASA (NSG2380).

207.19 CONTROL OF LIMB POSITION DURING EXPOSURE TO INCREASED AND DECREASED GRAVITOINERTIAL FORCE LEVELS. John D. Fisk*, J. R. Lackner and P. DiZio* (SPON: Minna Levine). Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254.

We had 5 subjects reproduce practiced flexion and extension positions of their unseen, unrestricted right forearm while exposed to alterations in the magnitude of the gravitoinertial force vector. Parabolic flight maneuvres in a Boeing KC-135 aircraft generated repeated, alternating periods, each approximately 20 s in duration, of increased G-force and free fall. While seated and restrained by a seat belt, the subjects attempted to move their forearms between 110° and 145° end points (full extension = 180°) during the high force (> 1.7 G) pull-up phase and the free fall (0 G) phase of each parabola.

Pre-flight and in-flight practice of this task was provided, both with and without visual feedback. Two orientations of the arm were studied: a "vertical" orientation requiring rotation of the forearm through the line of action of the G-force vector, and a "horizontal" orientation with the plane of forearm rotation orthogonal to the G-force vector. Two speeds were examined: slow movements (approximately 1 s for flexion or extension), and rapid movements (< 500 ms duration). Forearm position and velocity were measured with a light-weight (200 g) electrogoniometer and recorded on FM tape.

We compared movements made in the high force and free fall phases of flight. Slow movements made during free fall had a significantly lower amplitude than high force phase movements with an average reduction for both arm orientations of approximately 20% of the high force amplitude. The decreased movement amplitude in free fall was accompanied by a 13.5% reduction in the peak velocity of "horizontal" movements and by a 23.5% reduction in peak velocity of "vertical" movements. For rapid movements, no significant differences in movement amplitude were found with changes in the magnitude of the G-force vector. However, a significant reduction in peak velocity of 12.5% was found for "vertical" movements made during free fall.

The data suggest that awareness of limb position is altered by changes in the magnitude of the G-force vector, independent of its orientation with respect to the limb. The rapid movements were less affected by the altered G-force level, perhaps because afferent information is not relied on to the same extent for the determination of end-points as with slow movements. However, the orientation of the moving limb with respect to the G-force vector clearly influenced the velocity of the rapid movements. Together our findings indicate that the position sense representation of the body normally is calibrated to a 1 G terrestrial force level.

REFLEX FUNCTION II

208.1 QUANTITATION OF ELECTROMYOGRAM (EMG) PATTERNS OF CLONIC-LIKE MUSCLE CONTRACTIONS IN DECEREBRATE CATS. E. K. Stauffer and R. S. Pozos. Department of Physiology, University of Minnesota-Duluth, Duluth, MN 55812.

A feature of clonic-like muscle action is an EMG that exhibits relatively discrete bursts of activity followed by periods of almost complete silence. In spite of its striking qualitative nature, little data exists describing this bursting pattern. In order to gain further insights into the nature of the motor systems' operation during this type of action, the present study was undertaken to examine the quantitative characteristics of this oscillatory activity.

The left hindlimb of decerebrate cats (pre- and midcollicular) was denervated except for the plantaris muscle. Mechanical and EMG activity were recorded during spontaneous contractions. Data included: (1) EMG burst duration; (2) silent period duration; and (3) area (arbitrary units) of the full-wave rectified EMG burst.

Average burst durations ranged (± S.D.) from 17.3 (± 2.7) to 26.9 (± 3.3) ms for the animals with a mean (± S.D.) of 22.0 (± 3.4) ms across animals. Average silent periods ranged (± S.D.) from 17.0 (± 6.8) to 34.0 (± 5.0) ms with a mean (± S.D.) of 26.8 (± 7.9) ms, but they were more variable than the burst durations (mean coefficients of variation [CVs] = 12.1 versus 19.7 respectively, $p < 0.05$). EMG areas were highly variable from burst to burst (CVs ranging from 44.7 to 100.7 with a mean value (± S.D.) of 63.1 (± 20.0). Small extraneous EMGs appeared occasionally throughout the clonic sequences; these were randomly timed with respect to the primary burst.

These data indicate that the muscle's pool of active motor units (MUs) is probably firing only once or twice ("doublets", Zajac & Young, J. Neurophysiol. 43: 1221) per burst, but that this population is brought to firing threshold within a very narrow time "window" for each burst. However, the fact that the burst areas are so variable suggests that the number of active units is not constant from burst to burst. Thus, even though the time of occurrence of discharges within the ensemble of active units is tightly locked into a narrow time frame (but not precisely in-phase with each other), the mechanism(s) responsible for the synchrony may not operate to recruit identically the same motor units from contraction to contraction, and it does not appear to entrain all MUs of the firing zone.

(Supported by Minn. Med. Found., Univ. Minn. Grad. Sch., and grant #N00014-84-K-0224 from ONR)

208.2 TOPICAL ANESTHESIA: EFFECT OF DESENSITIZATION OF THE SKIN OF THE UPPER LIMB ON THE EXCITABILITY OF THE FLEXOR MOTONEURON POOL Mohamed A. Sabbahi, Carolyn R. Mason,* and Peggy B. Gleeson.* Texas Woman's University, School of Physical Therapy, Houston, TX.

Desensitization of the skin of the lower limb, with topical anesthesia, resulted in modulation of the excitability of the extensor motoneuron pool (MNP) (Sabbahi & DeLuca, 1982). This previously reported modulation was dependent on the desensitized skin area. This report investigates the effect of desensitization of the skin on the excitability of the flexor α-MNP in the upper limb.

The H-reflex of the flexor carpi radialis (FCR) was recorded, using surface electrodes, after stimulation of the median nerve at the arm. Electrical stimulation parameters were 1 msec. duration pulses, 0.2 pps at maximum H-reflex threshold. H-reflexes were monitored by the M-response throughout the experiments. Topical anesthetic (10% Lidocaine) or a placebo was applied on the appropriate skin area in normal adult subjects, and the H-reflexes were recorded at intervals up to 40 minutes post application. The following skin areas were desensitized and sprayed with placebo at separate recording sessions: Anterior arm (AA), Anterior forearm (AF), Posterior arm (PA), Posterior forearm (PF). The percent change in the peak-to-peak amplitude of the H-reflex post anesthesia and placebo were compared.

Results showed that the peak-to-peak amplitude of the H-reflex was slightly decreased immediately post anesthetic application to all skin areas except PF. The changes appear to be due to cold receptors stimulation by the applied anesthetic. The H-reflex was significantly increased in amplitude 10 minutes after application of the anesthesia to AA, AF and PA skin areas. Significant reduction in the H-reflex amplitude was recorded post anesthesia to PF skin area. These changes continued to increase 40 minutes post anesthesia. The degree of reflex facilitation or inhibition varied between subjects. No measurable changes were recorded in the M-response or in the H-reflex post placebo.

These results indicate that the skin receptors of the upper limb modulate the excitability of the flexor α-MNP. All skin areas of the upper limb except that over the antagonist muscles (PF) supply inhibitory inputs to the α-MNs of the FCR. Skin overlying the antagonist muscles appear to supply excitatory inputs to the FCR α-MNP.

208.3 SHORT LATENCY REFLEXES FROM CUTANEOUS AFFERENTS IN THE CHRONIC SPINAL CAT. D. McCrea, S. Hochman*, L. LaBella*, & J. Kehler*. Dept. of Physiology, Univ. of Manitoba, Winnipeg, Canada R3E-0W3.

The present study reports changes in short latency reflexes following single shock stimulation of hindlimb cutaneous nerves recorded in lumbar motoneurons after chronic (six week) total transection of the upper lumbar spinal cord in adult cats. Cats were spinalized by blunt dissection with fine forceps under barbiturate anesthesia. Nursing care consisted of twice daily manual emptying of the bladder. For the acute experiment, dissection was carried out under halothane anesthesia: hindlimb nerves were dissected and the animal prepared for intracellular recording. All recordings were obtained under chloralose anesthesia using electrodes filled with potassium citrate. Compared to animals with intact spinal cords, the earliest latencies of EPSPs and IPSPs from cutaneous afferents tended to decrease in the chronic spinal preparation. This probably reflects increased efficiency of synaptic transmission in these pathways and not a reduction of the minimum number of interneurons interposed between cutaneous afferents and motoneurons. The incidence of short latency (<5mS) EPSPs was increased for stimulation of sural, superficial peroneal, cutaneous caudo-femoralis and tibial nerves in the chronic spinal cats. In addition, chronic spinalization results in the appearance of short latency, low threshold (1.1 threshold) excitation of hamstrings motoneurons when the Tibial nerve (cutaneous and motor to the foot) was stimulated.

Motoneurons in both chronic spinal and unlesioned animals show a variety of IPSPs and EPSPs when either high or low threshold cutaneous afferents were stimulated. In some cells different cutaneous nerves produced similar PSPs but in other motoneurons, different nerves produced quite different PSPs. The chronic spinal animals tended to display greater variations in the cutaneous PSPs than the unlesioned animals. High threshold stimulation often produced the pattern of PSPs expected from the flexion reflex (Eccles & Lundberg, Arch.Ital.Biol.97:22,1957) but there were many examples of effects opposite to those of the classic flexion reflex(ibid).

In summary, even though there is great variation in cutaneous PSPs in intact cats, chronic spinalization results in increased incidence of cutaneous EPSPs, a tendency to shorter latencies and the appearance of a powerful excitation from tibial nerve to hamstrings motoneurons not seen in the intact animal.

208.4 MEASUREMENT AND CHARACTERIZATION OF RECURRENT IPSPS PRODUCED BY STIMULATION OF SINGLE MOTOR AXONS. C.-S. Yuan*, T.M. Hamm, S.-I. Sasaki*, U. Windhorst*, S. Vanden Noven and D.G. Stuart, Dept. of Physiology, Univ. of Arizona, Tucson, AZ 85724.

The spike-triggered averaging technique has been combined with methods for stimulating single axons to determine the features of recurrent inhibitory postsynaptic potentials (RIPSPs) produced in spinal motoneurons by activation of single motor axons. Motoneurons innervating the medial gastrocnemius (MG) muscle were impaled with glass microelectrodes in cats anesthetized with chloralose-urethane (C-U) or allowed to become unanesthetized following ischemic decapitation under halothane anesthesia. Simultaneously, single MG motor axons were activated at rates of 6-8 Hz either by intraaxonal/intramyelin stimulation using glass microelectrodes (Yuan et al, Soc. Neurosci. Abstr. 9:863, 1983), or by intramuscular stimulation using fine bipolar EMG electrodes (Taylor and Stephens, Brain Res. 117:331-335, 1976). The RIPSPs so evoked were collected in a signal averager for measurement. In our sample to date, RIPSPs were recorded in 43% (12/28) of the cells in the C-U preparations and in 65% (17/26) of the ischemic decapitate preparations. These single axon RIPSPs are generally characterized by small amplitude and a prolonged time course similar to that of composite RIPSPs. In some instances, RIPSPs were recorded which consisted of two components, a brief hyperpolarization followed by a second, more prolonged hyperpolarization. The characteristics of the RIPSPs are summarized in the following table:

Characteristics of Single-Axon RIPSPs - Mean ± SD (Range)

Preparation	Amplitude (μV)	Latency (ms)	Rise-time (ms)	Half-width (ms)
C-U	12.0 ± 6.7 (3.1-27.7)	3.8 ± 2.2 (1.0-7.3)	5.9 ± 3.3 (1.0-9.9)	24.1 ± 12.4 (8.6-41.8)
Ischemic Decapitate	35.3 ± 28.0 (13.3-134.3)	3.2 ± 2.1 (0.7-9.2)	5.7 ± 2.4 (3.6-10.5)	23.1 ± 14.7 (7.6-51.2)

Not included in these data are two exceptionally large RIPSPs recorded in cells adjacent to the motoneuron whose axon was being stimulated (see accompanying abstract by S.-I. Sasaki). These RIPSPs were of similar time course to the rest in the sample. In addition to providing the characteristics of single-axon RIPSPs, these results demonstrate the feasibility of determining the distribution of recurrent inhibition within a motor nucleus using such measurements.

Supported by USPHS grants HL07249, NS07888, NS17887 and a grant from the Smith Kline Dauelsberg Foundation.

208.5 TOPOGRAPHIC DISTRIBUTION OF RECURRENT IPSPS TO MOTONEURONS SUPPLYING THE MEDIAL GASTROCNEMIUS MUSCLE OF THE CAT. S.-I. Sasaki*, C.-S. Yuan*, T.M. Hamm, U. Windhorst*, S. Vanden Noven and D.G. Stuart, Dept. of Physiology, Univ. of Arizona, Tucson, AZ 85724.

We have tested the possibility that recurrent inhibitory postsynaptic potentials (RIPSPs) to motoneurons are distributed according to topographic factors within a motoneuron pool. Single motor axons supplying the medial gastrocnemius (MG) muscle were stimulated while recording intracellularly from MG motoneurons, as described in the accompanying abstract (C.-S. Yuan et al, this volume). The locations of motoneurons and motor axons were approximated to the rostral or caudal part of the L7 segment or the S1 segment of the spinal cord by recording their actions potentials extracellularly with electrodes on the respective ventral root divisions or by referring the site of motoneuron penetration to the boundaries of the ventral-root segments. Motoneuron-axon pairs were classified as "proximate" or "distant" according to whether the two axons were contained in the same or different ventral root divisions.

We have collected a total of 42 such pairs to date (27 proximate, 15 distant). RIPSPs were obtained in 20 pairs, while no response could be discerned in the other 22 cases. These RIPSPs and non-responses were distributed as follows:

	Proximate Pairs	Distant Pairs
RIPSPs	N=17	N=3
Non-responses	N=10	N=12

These results demonstrate a significant dependence of the occurrence of RIPSPs upon the proximity of the motoneuron-axon pair (χ^2=5.52; p<.025).

There were no clear cut differences between RIPSP obtained from proximate and distant pairs. However, we have excluded from this sample two RIPSPs which were of clearly different amplitude than the rest. Both RIPSPs were recorded in response to stimulating a motor axon whose cell body had been located by penetration with the recording microelectrode. Stimulating the axon of this motoneuron produced RIPSPs of 420 μV and 202 μV in motoneurons in the same microelectrode tract as this cell and in a tract 200 μm away, respectively. Recordings from two other motoneurons 1 mm away from this site yielded RIPSPs (included in the present sample) of 41 and 38 μV in response to stimulating the same motor axon. This anecdotal observation suggests that the amplitudes of single-axon RIPSPs as well as their incidence may be dependent upon topographic factors.

Supported by USPHS grants NS07888, NS17887, HL07249 and a grant from the Smith Kline Dauelsberg Foundation.

208.6 DIFFERENTIAL CONTRIBUTIONS OF RECTUS FEMORIS AND VASTUS MEDIALIS TO CROSSED EXTENSION REFLEX: PROLONGED CENTRAL SUMMATION. J. A. McMillan, P. R. Hannon* and L. M. Stevenson*, Biol. Dept., Montana State Univ., Bozeman, MT 59717.

Several lines of evidence have suggested a differential, and somewhat independent, contribution of fast and slow motor units to voluntary and reflex motor activities. The differences have (i) been consistent with the size principle of recruitment of motor units and (ii) have supported a model of separate reflex pathways projecting to fast and slow motor unit pools.

We examined prolonged central summation (PCS) of the crossed extension reflex (CER) recorded from the vastus medialis (VM) and rectus femoris (RF), which are relatively fast and slow heads of the quadriceps femoris group respectively. PCS is a feature of nocifensive reflexes associated with repetitive stimulation (f > 0.2 - 0.3Hz) and may be mediated by nociceptive dorsal horn interneurons. It has also been proposed that these interneurons may simultaneously contribute to nociception and to segmental nocifensive reflexes.

Reflexes were monitored in acute decerebrate cats. The left sciatic nerve was stimulated (1 ms, 2-4mA) and isometric tension was recorded from the right VM and RF. VM typically exhibited more pronounced PCS than did RF. The differences were especially evident when the cat was placed with the left body side on the table. First, VM usually began to summate at lower frequencies (down to 0.17 Hz) than did RF. Second, VM typically continued to summate after RF had reached plateau tension. In most cases the long-latency contraction evoked by each shock summated much more than did the short-latency contraction.

Our results do demonstrate that motor neuron pools supplying relatively fast and slow muscles receive differential inputs mediating what has classically been considered to be a singular reflex mechanism. However, the results presented here are not consistent with the size principle of recruitment. Since RF is slower than VM, and since slower muscles have been reported to be recruited at slower rates of rhythmic voluntary contractions, it would be reasonable to predict that RF would summate at lower frequencies of stimulation than would VM. Just the opposite happened. The discrepancy might suggest that responses monitored by recording muscle tension, which is the appropriate index in terms of motor behavior, are different than those monitored by recording electrical activity of individual motor neurons.

Supported by NSF Grant #ISP-8011449 and NIH Grant #RR08218

208.7 **DIFFERENTIAL CONTRIBUTIONS OF VASTUS MEDIALIS AND RECTUS FEMORIS TO CROSSED EXTENSION REFLEX: EFFECTS OF BODY POSITION.** P. R. Hannon*, J.A. McMillan and L. Stevenson* (SPON: D. Phillips) Biol. Dept., Montana State Univ., Bozeman, MT 59717

In another paper presented at this meeting (McMillan, Hannon & Stevenson) we reported that vastus medialis (VM) and rectus femoris(RF), relatively fast and slow heads of quadriceps femoris respectively, do not always act in concert in mediating the crossed extension reflex (CER). In the present study we examined effects of body position on two characteristics of the CER recorded from the two muscles: threshold and response to supramaximal stimulation. Body position has been shown to strongly affect excitability of the CER recorded from intact quadriceps femoris (McMillan and Koebbe, (Exp'l. Neurol. 73,233- 242,1981). We report here that body position affects VM differently than it does RF.

Reflexes were monitored in acute decerebrate cats. The left sciatic nerve was stimulated with indwelling electrodes (1 ms, 2-4mA) and isometric tension was recorded from the right vastus medialis (VM) and rectus femoris (RF).

Threshold for CER from VM was higher than from RF when single shocks were given. However, with high-frequency (20 Hz) stimulation, especially when the cat was placed with the left body side on the table surface, there was usually little, if any, difference in threshold intensity. The only difference was, in some preparations, a longer latency for VM. In one instance threshold for VM was, in fact, slightly lower than for RF. Recruitment of additional motor units in RF near threshold intensity was often accompanied by simultaneous recruitment of additional motor units in VM. These results suggest that the motor neuron pools supplying the two muscles do share some common integrative substrates.

Sustained reflexes, evoked by high frequency trains of supramaximal shocks (10-20 Hz, 2-4 mA), from RF were much more sensitive to changing body position than were those from VM. Both muscles exhibited strong responses when the cat was placed on the right body side. However, when the cat was placed on the left body side the response from RF was strongly inhibited whereas little change was usually seen in the response from VM.

These results are in agreement with other observations that fast and slow muscles can contribute differentially to motor behavior. In this case, the contribution of VM was quite consistent, whereas that of RF was much more variable, with different proprioceptive and/or mechanoreceptive inputs.

208.8 EFFECTS OF A CONDITIONING PATELLAR TENDON REFLEX ON CONTRALATERAL REFLEX CHARACTERISTICS. D.M. Koceja*, G. Kamen and H.H. Morris*. Motor Control Lab, Indiana University, Bloomington, IN 47405.

In an attempt to determine the effects of a conditioning tendon reflex stimulus on the contralateral reflex arc, bilateral patellar tendon reflexes (PTR) were elicited in 5 college-age subjects (SS). The SS were tested over a two day period. On each day the S was seated with each limb independently secured to restrict movement. Two electromagnetic solenoid-driven hammers were positioned so as to deliver a tap to each patellar tendon with a force of approximately 24.5 N. The forces of these hammers were monitored using a digital storage oscilloscope. Peak Force (PF) and Time to Peak Force (TPF) were recorded using two strain gauges positioned at each ankle and the force was recorded using a pen recorder operating at a speed of 200 mm/sec. For the control (C) condition three left limb (LL) and three right limb (RL) PTR were separately elicited. Three bilateral reflex trials were elicited using intertap intervals of 0, 50, 75, 100, 125 and 150 msec. In all bilateral (B) conditions the LL PTR was elicited first. An intraclass reliability ANOVA model incorporating SS, days and trials revealed reliability coefficients ranging from .79-.98 for PF and .42-.96 for TPF. A 2 X 3 (Days X Trials) ANOVA revealed no significant differences between days, trials or days by trials for PF and TPF; therefore data from Day 2 was analyzed. For the C condition, PF revealed no significant differences between the LL and the RL ($t=1.97$, $p > .05$), but a significant difference existed for TPF between the two limbs ($t = 2.11$, $p < .05$). Both PF and TPF analyses (Subj X Cond) revealed no significant changes for the LL across conditions. A similar analysis revealed significant differences among these conditions for the RL (test leg), as shown in the Table.

		Intertap Interval (msec)						
		control	0	50	75	100	125	150
LL:	PF(N)	19.92	17.64	17.47	19.11	18.45	16.82	17.47
LL:	TPF(msec)	72.50	74.58	73.33	74.58	73.75	75.41	73.91
RL:	PF(N)	24.50	22.97	21.31	29.29	30.70	29.18	31.03
RL:	TPF(msec)	65.83	67.08	65.41	64.16	58.33	59.58	57.08

These results suggest a distinct period of depression of PF and a delay in TPF for the second reflex extending until approximately 50-75 msec, after which both PF and TPF were markedly enhanced. Post hoc power analyses revealed that a sample size of approximately 10-12 SS would be sufficient to detect significant differences with power greater than .85.

208.9 REFLEX AND KINEMATIC ADAPTATION IN HUMANS DURING THE LEARNING OF A PERTURBED ARM MOVEMENT. C. Dugas*, J.S. Frank* and A. Nativ*. (Spon: A. Baylor) Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, N2L 3G1, CANADA

Few attempts have been made to examine reflex and kinematic adaptation as a function of learning (i.e., Christakos et al., Neuroscience Letters, 41:295-300, 1983). These have been confined to the study of monkeys over extended periods of learning. The general finding from these studies was that the M2 response decreased while the M1 response to perturbation increased with learning. The purpose of this study was to examine the adaptation of the reflex behavior in humans during learning of a perturbed goal-directed movement.

Two subjects were required to perform a 65 deg forearm extension movement in 900 ms to a visual target. A perturbation in the flexion direction (90 ms, 23 N.m peak torque) was introduced 500 ms after the onset of movement on every training trial. The subjects performed 100 trials per day for four consecutive days. The position of the manipulandum and the EMG signals from triceps and biceps were recorded for the first, middle and last ten trials of each day.

Results demonstrated both changes in subject strategy and reflex adjustment to the perturbation. The kinematic data indicated that with learning, both subjects increased the slope of their displacement-time function in the period preceding the perturbation. This was accompanied by a greater deflection of the limb following the perturbation. This strategy permitted the limb displacement to approach the correct trajectory resulting in an improvement in performance accuracy with learning.

The reflex component was analyzed first by looking at the mean level of EMG for the M1 (20-30 ms) and the M2 (60-90 ms) components. This analysis demonstrated a reduction of the reflex activity (M1 and M2) with learning in both subjects. This is consistent with the greater limb deflection following perturbation. However, in one subject, this reduction was related to the background level of EMG activity, for both the M1 and M2 response. In the other subject there was a reduction in the M1 response during the course of learning which was independent of the background decrease in EMG activity. The M2 response showed a sharp decrease over days one and two, followed by a gradual increase over days three and four.

Compared to previous animal studies, the results suggest a more complex relationship between learning and reflex adjustment. (Supported by NSERC scholarship to C.D.)

208.10 REFLEX MODIFICATION OF THE RABBIT'S NICTITATING MEMBRANE RESPONSE FOLLOWING HIPPOCAMPECTOMY. A. G. Romano, R. L. Port and M. M. Patterson. Dept. of Psychology and Coll. of Osteopathic Med., Ohio Univ., Athens, OH 45701.

The topography of the rabbit's nictitating membrane (NM) response can be modified by preceding the reflex-eliciting stimulus with an auditory stimulus (Ison & Leonard, 1971; Young, Cegavske, & Thompson, 1976). In general, reflex amplitude tends to increase with increases in the interstimulus interval (ISI) and yields a function which closely parallels the ISI-conditioning function. Two lines of evidence suggest that the latter function is mediated at least in part by the hippocampus. Hippocampectomy has been shown to alter conditioned response topography as well as the ISI-conditioning function (Port, Mikhail, & Patterson, 1985). Moreover, conditioned increases in hippocampal activity have been shown to be sensitive to manipulations of the ISI (Hoehler & Thompson, 1980). Because unit activity precedes the behavioral response and conditioned increases occur very early in training, it has been suggested that hippocampal activity might modulate lower brain structures and alter reflex excitability. Thus, the present study sought to determine if the reflex modification function would be altered by hippocampal damage.

Surgical procedures were carried out on nine rabbits anesthetized with halothane. Bilateral hippocampal ablations were performed on four of the animals. In the remaining animals, only the cortex overlying the hippocampus was removed. An additional five animals served as unoperated controls. Behavioral testing began 3-4 weeks post-surgery. The NM reflex was elicited by a 50 ms, 1 mA ac shock delivered via wound clips to the periorbital region of the eye. The auditory stimulus was a 1250 ms, 90 db, 1 kHz pure tone. Six trial-types were programmed to occur 3 times in each of 5 blocks of trials. Shock-alone trials were used to assess baseline NM amplitude and area. The ISI's on tone-shock trials were 75, 150, 300, 600, and 1200 ms. Response measures on these trials were expressed as absolute measures and as percentages of the measures obtained on shock-alone trials.

Repeated-measures analyses of variance failed to indicate a significant difference among the groups' reflex modification functions. Thus, there is no evidence to suggest that the hippocampus influences reflex excitability. Our reflex modification functions for all three groups are in general agreement with those reported by others (Ison & Leonard, 1971; Young et al., 1976). Both absolute and relative measures of response amplitude indicated reflex inhibition at the shortest ISI and increasing levels of reflex facilitation over the longer ISI's. Absolute and relative measures of response area yielded similar results although response area tended to decline at the 1200 ms ISI.

208.11 REFLEX RESPONSES OF THE HUMAN JAW-CLOSING SYSTEM DEPEND ON THE SITE OF INTRAORAL STIMULATION. A. Smith*, C.A. Moore*, D.H. McFarland*, and C.M. Weber* (SPON: C.A. Pratt). Dept. Audiology and Speech Sciences, Purdue Univ., W. Lafayette, IN 47907.

Our ability to understand the principles underlying control of human oral-motor behaviors such as speech is limited by a lack of knowledge of the basic physiological properties of the human oral-motor system. An important aspect of motor systems is the organization of reflex pathways. We have investigated reflex responses in human jaw-closing muscles. Results of earlier studies have demonstrated that activity in human jaw-closing muscles is typically suppressed by high-level mechanical or electrical stimulation of cutaneous afferent pathways. The reflex effects of innocuous mechanical stimulation of cutaneous receptors, such as that produced during speech, have not been explored. Thus, the aim of the present investigation was to determine if activity in jaw-closing muscles could be significantly modulated by application of brief, innocuous stimuli and to assess whether the spatial parameters of stimulation were important in determining the nature of the responses.

Mechanical stimulation was accomplished by displacement of a smooth metal disk probe (5 mm diameter) that was under servo-control. The probe excursion was a single cosine-shaped pulse of .7 mm amplitude and 10 ms duration. The disk was placed in light contact with the intraoral mucosa, and stimuli were applied to eight sites on the tongue dorsum and palate. During stimulation subjects used feedback to maintain a constant isometric biting force. Reflex responses were measured as changes in biting force and in EMG's recorded from right and left masseter muscles.

The nature of the reflex responses observed strongly depended on the site of stimulation. Stimulation of the palate tended to produce suppressions of ongoing activity, while stimulation of the tongue most often resulted in excitatory EMG responses and increases in jaw-closing force. Stimulation of the right side of the tongue produced asymmetric reflex responses in right and left masseter muscles, while stimulation of the right side of the palate produced bilaterally symmetric responses.

208.12 PROPERTIES OF THE HUMAN ABDOMINAL MONOSYNAPTIC REFLEX. B. Bishop, C. Shaw* and T. Kondo*. Dept. of Physiology. State Univ. of NY at Buffalo, Buffalo, NY 14214.

Occasionally in the past the abdominal monosynaptic reflex (AMSR) has been used to assess the corticospinal tract. Otherwise this reflex has been neglected as a tool for assessing abdominal motoneuron excitability. The purpose of this study was to define standardized conditions for eliciting the AMSR, analyze its intrinsic properties, and identify sources which are facilitatory and inhibitory to it. The EMG of the right external oblique abdominal muscle was recorded from surface electrodes while a subject (S) stood with or without trunk rotation. Taps were delivered by way of a solenoid driven plunger. Tap force was measured with a piezotransducer placed at the tap site on a 12" ruler held against the abdomen in line with the linea alba. A relaxed, standing S had no AMSR unless he stood tall to stretch his abdominal muscles or voluntarily contracted them. To generate and maintain a constant low-level of abdominal activity the S rotated his trunk and monitored a meter displaying his abdominal EMG. Now each tap evoked an AMSR whose latency ranged from 15 to 22 msec among subjects. Once abdominal motoneurons were activated by trunk rotation, the amplitude of the AMSR was independent of the level of background activity. In contrast, the AMSR was proportional to tap force. To test the effects of static lung volume, the AMSR was evoked while S held his breath at different prescribed lung volumes. At lung volumes from one liter below total lung capacity to reserve volume the AMSR was inversely proportional to the static lung volume, showing that vagal-volume feedback from pulmonary receptors modulates abdominal motoneuron excitability. To test the effects of phasic lung volume, the AMSR was evoked at different times in the respiratory cycle. Their probability of occurrence and the amplitudes of their responses evoked at end-expiration were significantly larger than those evoked at any other phase of respiration, suggesting that abdominal motoneurons, like intercostal motoneurons, are recipients of central respiratory drive potentials. In conclusion, abdominal motoneurons resemble those innervating limb muscles in that they receive strong segmental control from somatic proprioceptors and they resemble those innervating intercostal motoneurons in that they receive strong control from pulmonary proprioceptors via central respiratory neurons.

208.13 PUDENDAL NERVE REFLEXES IN THE MALE AND FEMALE RAT. Kevin E. McKenna and Irving Nadelhaft. VA Medical Center and Depts. of Pharmacology and Neurosurgery, Univ. of Pittsburgh, Pittsburgh, PA., 15240.

As part of a study investigating the spinal cord control of pelvic organs in the rat, recordings were made from pudendal nerve efferents while electrically stimulating pudendal nerve afferents. Male and female rats (200-300 g) were anesthetized with Dial-urethane or α-chloralose. The rats were paralyzed and artificially ventilated. Some rats were spinalized at C1, 3 to 5 hours prior to recording.

In the rat, the axons of pudendal nerve afferents and efferents are contained in separate branches (SN Abstracts 264.9, 1984). The sensory and motor branches were dissected bilaterally and placed on hook electrodes. In the sensory branch, conduction velocities of myelinated fibers ranged from 32.1 to 15.3 m/sec (mode 23.7 m/sec) in the male and 29.8 to 10.4 m/sec (mode 17.0 m/sec) in the female. In the motor branch the velocities were 26.7 to 13.0 m/sec (mode 20.0 m/sec) in the male and 26.2 to 8.9 m/sec (mode 18.5 m/sec) in the female. These velocities are consistent with measurements of axon diameters in these nerves. Unmyelinated fibers in both branches had conduction velocities of 1.2 to 0.5 m/sec.

Stimulation of the ipsilateral sensory branch elicited a reflex in the motor branch. It consisted primarily of a single myelinated volley with an onset latency of 10-12 msec and duration of 3.5-5.0 msec. A smaller, more variable component, probably representing unmyelinated axons, occurred with an onset latency of 80-100 msec and a duration of 25-30 msec. Both components were elicited by stimulation of myelinated afferents. The reflex was not different in intact or spinalized rats. Reflexes in males and females differed only in a slightly shorter onset latency in males. The reflex amplitude was maximal at stimulus repetition rates of 0.5/sec and below and was virtually absent above 10/sec. Calculated central delays were 5-7 msec. It is concluded that this reflex is polysynaptic and organized at spinal levels.

Stimulation of the contralateral sensory nerve elicited a reflex virtually identical to the ipsilateral reflex except that its onset latency was 1-1.5 msec longer. The contralateral reflex was also maximal at low stimulus repetition rates and abolished above 10/sec. When the ipsilateral and contralateral sensory branches were stimulated simultaneously at maximal intensity, the resulting reflex was indistinguishable from the reflex evoked by stimulation of either branch alone. This implies that the reflex evoked from either side involves a common pool of interneurons. This conclusion is supported by HRP experiments which showed that a major projection of pudendal afferents in the spinal cord is a midline terminal field in the dorsal gray commissure.

209.1 KINEMATIC PROPERTIES OF HUMAN LOCOMOTOR MOVEMENTS. J.R. Flanagan*, D.J. Ostry*, T.B. Hoshizaki*, and M.P. Gelinas* (SPON: F. Wilkinson). McGill University, Montreal, Quebec.

Kinematic invariances have been reported by several researchers interested in human gait. These include invariances in the relative timing of different phases in walking and running and invariances in joint angle patterns. We have pursued the problem of regularities in human locomotion by examining kinematic characteristics of different locomotor gaits over a wide range of velocities. This included an evaluation of the differences in gait in terms of the form of the joint angular velocity profile. The analysis of velocity profiles has proven to be productive in studying both voluntary arm movements and speech motor control.

Cinematographic and metabolic records were obtained from subjects locomoting on a treadmill. Measurements were taken at walking speeds which ranged from 4 to 11 km/hr and for running speeds from 4 to 26 km/hr. Performance was sampled at 1 km/hr intervals. The kinematic data were obtained for movements about the elbow, knee and hip.

Gait cycles were divided into knee angle flexion and extension for both support and recovery phases. Unimodal velocity profiles characterized each flexion and extension movement. The form of the velocity profiles was examined as a function of gait and speed. In both support and recovery phases of locomotion the geometric form of the flexion and extension velocity profiles was found to be invariant across changes in speed but differed for walking and running gaits.

In addition, we observed a number of systematic changes across the range of velocities. As reported previously, in both walking and running, stride rate and stride length increased with velocity. The contribution of stride length to velocity was greater at lower speeds whereas the contribution of stride rate was greater at higher speeds. In running, the duration of the support phase decreased more with increases in velocity than the duration of the recovery phase. In walking, the duration of the support phase and the recovery phase decreased proportionately.

We also found that the ratio of peak knee flexion during recovery to peak knee flexion during absorption (support phase) decreased as walking velocity increased. However, in running, this ratio increased with velocity.

The contribution of these kinematic patterns to transitions between gaits will be discussed.

209.2 ELECTRICAL STIMULATION OF "LOCOMOTOR" SITES IN THE NUCLEUS PEDUNCULOPONTIS AND ZONA INCERTA ACTIVATED LIMBIC PALLIDAL NEURONS ANTIDROMICALLY. M. Wu* and G. J. Mogenson, Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Neural projections have been demonstrated from the limbic pallidal area to the nucleus pedunculopontis, the site of the mesencephalic locomotor region (MLR), which may mediate the locomotor component of adaptive behaviors involving the forebrain limbic system (Swanson, Mogenson, Gerfen and Robinson, Brain Research, 295:161-178, 1984). Blocking these neural projections by injecting procaine into the zona incerta reduced locomotor activity initiated by injections of picrotoxin into the limbic pallidal area or by injections of dopamine into the nucleus accumbens. In the present study, the possible functional significance of this limbic pallidal-MLR projection was investigated using behavioral and electrophysiological recording techniques. Rats with chronic bipolar electrodes in the MLR or zona incerta were tested in an open-field apparatus equipped with photo-cells and counters. Locomotor activity was increased by electrical stimulation of the MLR (from 10.8 ± 2.9 to 128.8 ± 26.1 in 10 min, $p<0.01$) and of the zona incerta (from 24.8 ± 5.5 to 92.2 ± 9.6 in 10 min, $p<0.01$). Subsequently, these rats were anesthetized with urethane and standard electrophysiological recording techniques used to record action potentials from single neurons of the substantia innominata of the limbic pallidal area. In a sample of 212 limbic pallidal neurons, 65 (30.7%) were activated antidromically by single pulse stimulation of the MLR. In another sample of 111 limbic pallidal neurons, 27 (24.8%) were activated antidromically by single pulse stimulation of the MLR and 19 (17.1%) were activated antidromically by single pulse stimulation of the zona incerta. Nine of these neurons responded to the stimulation of both zona incerta and MLR. The mean latency of antidromic responses of limbic pallidal neurons was 17.6 ± 1.8 ms in response to MLR stimulation and 10.8 ± 1.1 ms in response to zona incerta stimulation. These observations provide evidence that neural projections from the limbic pallidal area to the MLR via the zona incerta may contribute to the initiation of locomotor activity.

(Support by the Natural Sciences and Engineering Research Council of Canada).

209.3 EMG PATTERNS IN RESPONSE TO POSTURAL PERTURBATIONS AND THEIR INTERACTIONS WITH VOLUNTARY MOVEMENT IN DEAF SUBJECTS. C.S. Layne*, L.D. Abraham and D. Brunt*. Dept. of Physical Education, Univ. Texas, Austin, TX. 78712. Univ. of Otago, New Zealand.

Normal standing subjects display a distal-to-proximal pattern of muscle activation in response to horizontal displacement (Nashner, Exp. Br. Res.,30,1977). Patterns of activity in the lower limb muscles have also been described prior to the activation of the prime mover in arm raising tasks (e.g. Lee, J. Mtr. Beh.,12,1980). We examined these patterns in deaf subjects of varying motor ability. In addition, we examined the interaction between reflexly initiated activity and voluntary movement. In these analyses we compared "highly skilled" (HS) subjects with "low skilled" (LS) subjects (as assessed by the Barrow motor ability test) to reveal possible neuromuscular correlates of the wide range in motor ability of deaf individuals. Nine deaf males (aged 15-19) were selected as subjects; four were classified as HS, five were classified as LS. Three experimental conditions were employed: (A) postural perturbations, (B) voluntary arm movement, and (C) a combination of A and B. Backward horizontal displacement of the standing subjects served as the postural perturbation, while reaching forward for a ball in response to a stimulus light served as the voluntary movement. In Condition C, the perturbation occured 100 ms after the stimulus. Surface electrodes were used to record EMG activity bilaterally from the gastrocnemius, biceps femoris, and anterior deltoid muscles. Ten trials of data in each condition were averaged for each subject. Latencies of EMG onset and peak activity were analyzed to identify response patterns. Reaction time (RT), movement time (MT), and total response time (TRT) for the reaching task were also measured. In Condition A both groups displayed a distal-to-proximal pattern of activation with the LS subjects responding with earlier bursts of activity than the HS subjects. In Condition B both groups displayed a proximal-to-distal pattern. However, although the HS subjects displayed tonic activity in the lower limbs, no bursts of activity were seen prior to deltoid onset, while the LS subjects had clear bursts of activity in addition to tonic activity prior to deltoid activation. Although there were no differences in the latency of the deltoid onset between the two groups, the HS group had faster RTs, MTs, and TRTs in this condition. In Condition C, 3 of 4 HS and 2 of 5 LS subjects displayed a muscle activation pattern which appeared unaffected by the perturbation. Within each group the behavioral measures were the same as in Condition B, but longer latency bursts of muscle activity in the lower limbs were faster with the imposed perturbation, especially in the HS subjects. Thus, HS subjects seemed better able to adapt their responses to the perturbation imposed during voluntary movement.

Supported in part by BRSG grant from UT/Austin.

209.4 **SYNCHRONIZATION OF MOTOR UNIT FIRING IN DIFFERENT MUSCLES RECORDED DURING VOLUNTARY ISOMETRIC CONTRACTIONS IN MAN.** **A.K. Datta, Jean R. Fleming*, T. Hortobagyi*, and J.A. Stephens, Dept. Physiology, Middlesex Hosp. Med. Sch. London W1P 6DB.**

Experiments were performed on 18 healthy volunteers aged 18-33 years. Recordings were made from intrinsic hand muscles, particularly first dorsal interosseous muscle (1DI) and from large limb muscles including Medial Gastrocnemius (MG), Soleus and Tibialis Anterior (TA). The muscles under study were immobilised by placing the subject's hand or leg in a frame. Two needle electrodes were inserted in to the muscle for recording the activity of two motor units A and B. The subject made a gentle steady isometric contraction such that both units fired continuously, with one, A, firing at 10 impulses/s.

Histograms (bin width 390 μsec) were constructed of the times of firing of unit A relative to the times of firing of unit B. The strength of synchrony was defined as those extra discharges of unit A for each discharge of unit B.

Typically histograms showed a narrow central peak (duration 4-12 msec) centred about the time of firing of unit B superimposed on a slow rising base. Synchrony was always observed and was strongest between pairs of units in intrinsic hand muscles, and in 1DI varied from 0.040 to 0.331 (mean 0.095, SD 0.059, n=25). In the large limb muscles synchrony was sometimes absent, and when observed was weaker than in 1DI, e.g. TA (range 0.016 to 0.094, mean 0.056 SD 0.022, n=18) MG (range 0 to 0.043, mean 0.016 SD 0.013, n=29, absent in 7 pairs). The discharge of a reference unit B in one muscle was correlated with units A from other muscles. Synchrony was greater between units in adjacent intrinsic hand muscles (1DI and 2DI) than between more widely separated hand muscles (1DI and 3DI) which was greater than that between an intrinsic hand muscle and a forearm muscle (1DI and Flexor Digitorum Superficialis, 1DI and Extensor Digitorum Communis) or between adjacent synergist forearm muscles (Ext Carpi Ulnaris and Ext Carpi Radialis Longus).

Significant synchrony was observed between a reference unit B in one muscle and units A in antagonist muscles, in the hand (1DI and first palmar interosseus) and in the leg (MG/soleus and TA).

The close relationship between the distribution of synchrony in different muscles and the function of those muscles in different tasks, taken together with the presence of synchrony between agonist/antagonist pairs is consistent with our hypothesis of the central rather than peripheral origin of short term synchronization in human muscles, probably involving activity of long descending pathways and possibly from branched fibres of the corticospinal tract (Datta et al. 1985, J. Physiol. proc in Press).

209.5 THE CONTRALATERAL LIMB RESPONSE TO PERTURBATIONS DURING HUMAN LOCOMOTION. M. Belanger and A.E. Patla, Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

The response to stimulation (20 ms train, 10-1 ms pulses, 4-5 X threshold), applied to the right (ipsilateral) foot at five points in the stepcycle, was examined for six muscles of the contralateral limb. The area under the EMG curves for both the normal and perturbed cycles were determined for 150 ms, starting 20 ms after the onset of the stimulus. Five trials, each containing a normal and a perturbed stride, of each stimulation point were averaged together. The averaged normal EMG activity was then subtracted from the averaged perturbed EMG activity, yielding the reflex response from which the latency could be digitized. The ipsilateral limb response has been reported elsewhere (Belanger & Patla, Neuroscience Lettr, 49:291-295, 1984). The functional significance of the contralateral limb responses are discussed with respect to stimulation points in the ipsilateral limb.

At heel contact, knee collapse was prevented by an increase in knee extensor response. In addition, an increased plantarflexor response provided quick push-off for the forward progression. An increase in rectus femoris (RF) and vastus lateralis (VL) at early stance allowed for hip flexion and knee extension while an increased tibialis anterior (TA) response allowed for better ground clearance by the contralateral foot. Shortly thereafter, the knee and ankle were prepared for landing by an enhanced biceps femoris (BF) and plantarflexor response respectively. The late stance response was similar to the ES response, with the leg being brought through at a faster rate by enhanced hip flexor and knee extensor activities and increased TA for ground clearance. At toe-off, there was an enhanced TA and plantarflexor response which acted to stabilize the ankle while an increase in the BF and VL activity acted to stabilize the leg and support the body. During midswing, the activity of the knee extensor was enhanced in order to prevent knee collapse. The activity of the plantarflexors was also increased to provide push-off. The activity of the flexors (TA & BF) was also increased, priming up for the upcoming swing phase.

Thus, the contralateral limb response is dependent on the phase of the stepcycle, and is well coordinated with ipsilateral limb response to provide support and stability as well as maintain the ongoing task of locomotion.

Supported by an NSERC grant #A00070.

209.6 MODIFICATION OF THE AMPLITUDE OF ESSENTIAL TREMOR BY TOPICAL ANESTHETIC. R.S. Pozos, J. Beaty*, and T. Long*. Dept. of Physiology, Univ. of Minn., and Dept. of Physical Therapy, College of St. Scholastica, Duluth, MN 55812.

Essential tremor is an overt tremor characterized by a) being absent at rest, b) present on maintaining a posture particularly of the outstretched arms, c) not made strikingly worse by movement, d) not associated with parkinsonian or cerebellar tremor (Marsden, C. D. Movement Disorders: Tremor, edited by Findley & Capildeo, Oxford University Press, New York, 1984, Chapter 5). The mechanism for essential tremor is uncertain; however, it has been reported that peripheral input can reset essential tremor (Lee, R. G. & Stein, R. B. Ann. Neurol. 10: 523-531, 1981). The purpose of this paper is to study the differences between essential tremor and physiological tremor by the addition of weights or the application of topical anesthetic. Previously we have reported that the amplitude of ankle clonus can be decreased by application of local anesthetic (Pozos, R. S., Mills, W., & Iaizzo, P. Neuroscience Abstract 14, #213.7, 1984).

Six control subjects and four essential tremor patients who had the characteristics mentioned above plus a familial history of the disease were used. All signed human subject consent forms prior to the experiments. Surface electrodes were placed on extensor and flexor muscles of the wrist and an accelerometer was placed on the hand. Signals were recorded on a FM tape recorder and later analyzed on a Micro PDP II.

For the weight experiments 100, 200, 300, 500 gms. were placed sequentially on the dominant hand after initial measurements were made of their rest tremor. Topical anesthetic was applied at the end of the weight experiments to the forearm for a period of 20 minutes, after which measurements were taken. Frequency and amplitude analysis were done of these tremors recorded during these experiments. Essential tremor had a range of frequencies from 6-12 Hz. The physiological tremor range was at 6-7 Hz. The addition of weights caused an insignificant change in amplitude in essential tremor whereas 300 and 500 gm on normal subjects caused a significant increase. Topical anesthetic caused a significant decrease in amplitude of both essential tremor and physiological tremor.

The topical anesthetic studies indicate that sensory feedback is used to influence the amplitude of both essential tremor and physiologic tremor.

209.7 OCCURRENCE AND TIMING OF MOVEMENT-RELATED EMG ACTIVITY DEPENDS ON MOVEMENT PROFILE. S.H. Brown and J.D. Cooke. Department of Physiology, Univ. of Western Ontario, London, Canada.

A characteristic pattern of EMG activity is associated with voluntary step-tracking movements. An initial burst of activity in the agonist muscle (Ag1) is followed sequentially by a burst in the antagonist muscle (Ant1) and a second agonist burst (Ag2). Ag1 begins 40-50 msec before movement onset and is complete before peak velocity is reached. Ant1 occurs at or near the time of peak velocity and, as movement speed increases, occurs earlier in the movement. Recently, we have shown that the duration of Ag1 increases in multiples of 70 msec as movement amplitude increases. In general, such temporal relationships have been described only for movements with symmetrical profiles. The present study investigated the dependence of phasic EMG activity on movement profile, in particular, the relative durations of acceleration and deceleration phases.

Subjects grasped a manipulandum handle pivoted above the right elbow and performed flexion-extension movements in the horizontal plane. The tracking task was presented to the subject as an audio signal (target tone) which varied in frequency with target position. Movement of the handle also produced modulation of the audio signal. Subjects were instructed to move in such a way so as to reproduce the target tone. Changes in movement profile were accomplished by changing the ratio of acceleration duration to deceleration duration which, in turn, produced a change in the target tone. For a given movement amplitude, duration of the target tone (movement duration) remained constant.

Typical triphasic EMG patterns were associated with symmetrical movements. As acceleration duration shortened and the subject was required to accelerate more rapidly, Ag1 duration decreased and Ant1 occurred earlier. In some cases Ag1 and Ant1 were coactive. Ag2 was not present in these movements. In short deceleration movements Ag1 was replaced by a gradual increase in tonic activity. The deceleration phase was associated with contraction of both muscles with Ag2 occurring shortly after Ant1. Coactivation of both Ant1 and Ag2 in these movements paralleled the activation of Ag1 and Ant1 seen in short acceleration movements.

These findings indicate that the occurrence and timing of phasic EMG activity are intimately related to the movement profile. Ag1 duration depends upon the duration of the acceleration phase and, similarly, the timing of Ant1 depends not on movement speed per se, but rather on the timing of peak velocity. In addition, the coactivation of Ag2 with Ant1 in short deceleration movements suggests that Ag2 may function to increase limb stiffness and thus assist in terminating the movement.

209.8 ACTIVATION PATTERNS OF ANKLE MUSCLES DURING ONTOGENY OF HUMAN GAIT. F. Dumas*, C.L. Richards* and M. Filion. (SPON: C. HARNOIS). Lab. of Neurobiology, Fac. Med., Laval Univ., Québec, Can., G1K 7P4.

During the ontogeny of human gait, the movement of the ankle changes from a digitigrade to a plantigrade pattern (heel contact followed by plantarflexion at the beginning of the gait cycle). To examine changes in muscle activation that could be related to this more mature pattern, we studied ankle movements and EMG activity of the triceps surae (TS) and tibialis anterior (TA) during gait in 33 children aged 1 to 4 years. The children were separated into three groups on the basis of the frequency of the plantarflexion movement during 5 gait cycles. In children lacking the plantarflexion, the TS is activated in early stance and has a lower peak which declines slowly in late stance and also is activated in late swing phase. In contrast, children with predominantly plantarflexion had lower TS activation in early stance followed by a higher peak ($p<.01$) with a more rapid decline in late stance and suppression of the activation in late swing. In the third group with occasional plantarflexion, the shape and the amplitude of the EMG curve of the TS was intermediate. The TA EMG activity at foot contact ($p<.05$) and the stance peak activation ($p<.025$) were higher in the group with predominant plantarflexion. In these children, the TA amplitude decreased less in mid-swing ($p<.025$), relative to the stance peak, and increased earlier in late swing. The changes in TS and TA activation in swing, in the children with predominant plantarflexion were related to more dorsiflexion in late swing to permit foot contact with the heel at the beginning of the gait cycle.

These results provide evidence of changes in TS and TA activation related to the progressive changes from a digitigrade to a plantigrade pattern. Such changes in muscle activation most likely reflect increased supraspinal modulation of the "spinal locomotor set" during the ontogeny of human gait.

209.9 THE COORDINATION OF LIMB MOVEMENTS WITH DIFFERENT KINEMATIC PATTERNS. S.P. Swinnen*, C.B. Walter* and D.C. Shapiro. Motor Control Lab, Department of Kinesiology, UCLA, Los Angeles, CA 90024 and Katholic Univ. of Leuven, Belgium.

Interlimb coordination was investigated to ascertain the behavioral coupling between the limbs as a function of practice. In the first session, subjects performed unidirectional movements with the same spatial and temporal requirements. In the second session, subjects were required to perform reversal movements in one limb while the other limb performed the unidirectional movement practiced in the first session. Changes in the unidirectional movement as a result of performing a movement with different kinematic properties in the contralateral limb were examined, as was the nature of the coupling between the limbs.

Two sessions consisting of 75 trials each were performed. In the first session, subjects were trained to produce horizontal flexion movements of 72° with both forearms in 500 ms. In the second session, subjects were required to perform the same movement in the left limb while the right limb produced a double reversal task. Both movements were to be performed in the same movement time (500 ms) and to end in a similar position. To examine changes as a function of practice, the initial, middle and final five trials of session two were selected for further analyses. Displacements were indicated by potentiometers connected at the base of the levers, and EMG activity of the biceps and triceps was recorded using surface electrodes.

The results of session two indicated a relationship in final position and movement time between the limbs as they performed together, and these values became more similar to those of session one as a function of practice. The displacement data of the left limb indicated that subjects were successful in performing a unidirectional and not a reversal movement. To examine the relationship between the movements as they were being generated, the acceleration patterns in the right and left limbs were plotted against each other, and cross correlations were computed for the second session. These data demonstrated individual differences in achieving the goal. Some subjects produced high correlations initially, followed by reduced correlations as a function of practice. For others, this trend was reversed. However, regardless of the strategy, there was a tendency for the acceleration patterns to be related. The EMG data demonstrated additional activity in the left limb relative to session one. The results suggest that although the overt behavior of the two limbs appears to be independent, the coupling between the limbs is manifested at the higher time derivatives, indicating that force-producing actions are not independent between the upper limbs.

209.10 MODELING POSTURAL SWAY IN MAN: EXPERIMENTAL EVIDENCE FOR A RANDOM PROCESS MODEL OF QUIET STANDING. S.H. Roy*, M.T. Bailin*, M.M. Stecker*, and C.J. De Luca. (SPON: J. Kucera). NeuroMuscular Research Center, Boston University, Boston, MA 02215 and Liberty Mutual Research Center, Hopkinton, MA 01748.

Current methods of evaluating postural instability during quiet standing include the use of a force platform which measures the excursion of the center of pressure (COP) over the plane of support. The stabilogram (SBG) is the plot of the COP path over time, and is modulated by intrinsic postural control mechanisms, vestibular, proprioceptive and visual cues. In order to obtain greater insight into postural control mechanisms, we have developed a mathematical model for sway path movement which may explain the sway patterns of normal subjects as well as patients with abnormal postural instability.

The movement of the COP during quiet standing is the result of many neuromuscular interactions. Although the movement of the COP is deterministic, it is well known, in systems with many degrees of freedom, that deterministic processes may appear random on a large scale. In this light, we suggest that the motion of the COP during standing can be modeled as a random process following the laws of diffusion within boundaries specified by postural control centers. In particular, as the diffusing COP approaches the limits of stability, the musculoskeletal conformation will be corrected through the motor functions of the appropriate muscle groups. This returns the COP to the stable zone in which large scale coordinated corrections of posture are not required.

Analysis of SBG in normal subjects demonstrates that the average distance of the COP movement from a specified point varies as the square root of time over short distances. We propose that normal subjects display a characteristic diffusion pattern of the COP, which results from central nervous system influences.

Pilot studies on neurologically impaired subjects yield diffusion pattern plots that are distinctly different from normal subjects. The nature of the deflection process and the geometry of the barrier are being investigated.

209.11 SELECTION OF HUMAN POSTURAL SYNERGIES DIFFERS WITH PERIPHERAL SOMATOSENSORY VERSUS VESTIBULAR LOSS. L. M. Nashner, H. C. Diener, and F. B. Horak. Neurological Sciences Institute of Good Samaritan Hospital and Medical Center, Portland, OR 97209

This study compares human postural movements executed with peripheral vestibular inputs and somatosensory inputs from the feet and ankle joints selectively disrupted. We identify the influence of each type of loss on response latency, muscle contractile patterns or synergies, and organization of the senses in relation to the conditions of the task. Peripheral vestibular losses were studied in 4 neurologically normal patients lacking VOR and caloric responses. Somatosensory inputs from the feet and ankle joints were disrupted in 4 normal subjects by applying ankle pressure cuffs bilaterally.

Postural movements were elicited by brief constant velocity horizontal displacements of the support surface. Movements were measured by recording EMG's in 6 leg and trunk muscles, the forces exerted by each foot on the surface, the antero-posterior (AP) sway of the body center of mass and videotaped joint angle changes. The sensory conditions were altered by rotating the visual surround, the support surface, or both in direct proportion to body sway, termed "sway-referenced" visual and support conditions, respectively.

During standing under normal conditions, the onset latencies and the temporal and spatial structure of postural synergies were unaltered by disruption of either the somatosensory or the vestibular inputs. Loss of sensory inputs, however, caused subjects to select synergies differently: (1) Normals deprived of somatosensory inputs from the feet and ankles used the hip synergy, regardless of the size of the perturbation or the properties of the surface (with intact somatosensory inputs the ankle synergy was used on a normal surface, the hip synergy, on a narrow beam). (2) Patients lacking vestibular inputs used the ankle synergy, even when attempting to stand on a narrow beam.

Under different combinations of sway-referenced visual and support surface conditions, normals performed the same with and without somatosensory inputs from the feet and ankles. Vestibular patients maintained balance when sway-referenced visual or support surface conditions were imposed one at a time, but lost balance with the two conditions combined.

Our results indicate that peripheral sensory losses can alter the selection of postural synergies, while not disturbing the organization of muscle activities within the synergies. Furthermore, somatosensory inputs from the feet and ankles are not required for the normal triggering of postural movements, regardless of the sensory conditions. 209.12 INFLUENCE OF STIMULUS PARAMETERS AND SET ON HUMAN POSTURAL SYNERGIES. F.B. Horak, H.C. Diener, and L.M. Nashner. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, Oregon 97209

Automatic postural responses to support surface displacements are partly triggered, central programs and partly determined by the characteristics of the stimulus. We examined the effects of the influence of stimulus size, speed and duration and the influence of set on the parameterization of synergic postural muscle activity.

Ten normal standing subjects were exposed to a series of 120 backward ramp translations of the suppport surface under 12 conditions of varying velocities (constant amplitude) or varying amplitudes (constant velocity). Displacement durations ranging from 34-900 msec had no independent effect on the responses. The effect of perturbation size and speed on body kinematics and on the latencies, patterns, burst durations and integrated areas of surface EMG activity in six trunk and leg muscles were examined. Integrated EMG activity was normalized across subjects and the early (first 75 msec), middle (second 75 msec) and late (last 350 msec) components analyzed separately. The influence of motor set-dependence due to prior experience was examined by comparing responses to practiced and unexpected perturbations.

Platform translations lasting only 75 msec evoked a single burst of muscle activity (75-100 msec duration) in Gastrocnemius, Hamstrings, and Paraspinals (and sometimes Abdominals). Response parameters were unrelated to the size or speed of the perturbations, suggesting a triggered central pattern. For translations lasting longer than 75 msec, the size of the early synergic EMG bursts were best correlated with stimulus velocity (r=.46-.68). The size of later components of the EMGs were best correlated with stimulus amplitude (r=.45-.71). A small, set-dependent influence of ramp amplitude on early Gastrocnemius EMG activity disappeared when perturbation sizes were randomized. Depending upon practice and expectation, very large and fast perturbations resulted in additional activation of antagonist muscles Quadriceps and Tibialis.

The significant gain relations of early burst EMG area with velocity and late, tonic EMG area with amplitude held not only for the muscle stretched by the perturbation but also for proximal muscle components of the synergy. The absolute latencies (98 ± 9 msec), intersegmental latencies (23 ± 12 msec), and burst durations (87 ± 22 msec) were not influenced by the characteristics of the ramp stimulus. These results suggest that centrally organized postural muscle burst patterns are triggered as a synergic unit, fine-tuned by the characteristics of the perturbations and dependent upon prior experience and expectation as well as by concurrent sensory inputs. (NIHF32NS06926,R01NS12661)

209.13 THE EFFECT OF VISION ON NEUROMUSCULAR RESPONSES UNDERLYING POSTURE CONTROL IN CHILDREN. M.H. Woollacott, M. Mowatt*, B. Debû* and E. Keshner. Inst. of Neuroscience and Dept. of P.E. and Human Movement Studies, U. of Oregon, Eugene, OR 97403.

Previous research concerning the influence of vision on body sway in children has indicated that movement of the visual environment, by itself, can cause a newly standing child to compensate for perceived (but nonexistent) sway, and fall in the direction of optical movement. This has led to the hypothesis that vision is the dominant input controlling body sway in the young child (Lee,D. and Aronson, E., Percept. Psychophys.,15:529, 1974). Contrasting studies in adults, which used a moveable platform to cause body sway and analyzed the effects of vision and ankle proprioception on balance control have shown that ankle inputs activate leg muscle responses that are organized into functional synergies specific to the direction of induced sway. Neck muscles have been shown to be activated antagonistically to the leg synergy, possibly via vestibular or neck proprioceptive inputs. Visual inputs have no effect on the latency of these responses in adults. This study aimed 1) to determine the relative influence of visual and ankle proprioceptive inputs on the latencies of postural muscle responses in children, and, within the visual system, 2) to determine the relative influence of peripheral vs. central retinal inputs on posture control.

Postural responses of standing children of 2 age groups (2-3 yrs and 4-6 yrs) were compared to adults using anterior or posterior displacements of a moveable platform. Surface electromyograms were recorded from muscles of the leg, trunk and neck. The relative dominance of postural response activation by proprioceptive vs. visual inputs was determined by comparing response latencies with eyes open vs. closed. In a subset of children, goggles, which blocked either the central or peripheral visual fields, were used to test the roles of the respective visual inputs in posture control.

The youngest group of children tested, the 2-3 yr. olds, showed a consistent reduction in ankle and neck muscle response latencies in the no vision condition. For posterior platform movements causing anterior sway, response latencies were: Vision. gastrocnemius (G): 72+8ms, neck flexors (NF): 126+54ms; No Vision. G:55+16ms, NF: 59+15ms, These changes were not present in the 4-6 yr. olds or adults. No differences were found in the latencies of postural responses for either of the age groups when the peripheral vs. central visual field was preferentially blocked. Thus, it appears that when any portion of the visual field is present, it can be utilized in postural stabilization. The decreased latencies seen in the 2-3 yr. olds with vision removed could imply a shift from the use of longer latency visual inputs with eyes open, to shorter latency proprioceptive inputs with eye closure. It is concluded that 2-3 yr. olds show a visual dominance in the activation of postural responses, which shifts to proprioceptive dominance by the age of 4-6 yrs.

209.14 AN ANALYSIS OF SLOW WALKING IN MAN. R.G. Borkowski*, R.L. Craik, W.F. Freedman, Dept. of Biomedical Engineering, Drexel University, Phila., PA 19104, and Dept. of Physical Therapy, Beaver College, Glenside, PA 19038.

Two modes of ambulation have been described in man, walking and running. The change between the two modes occurs primarily by altering the type of limb movement: in walking,the heel strikes the ground first and knee angle changes during the swing phase are small; in running, the front part of the foot often strikes the ground first and knee flexion is dramatically increased. Although walking and running differ kinematically, a monotonic relationship is maintained between the flexion cycle (swing) and cycle duration and the extension cycle (stance) and cycle duration. At very slow velocities it appears that the relationships between the flexion and extension cycles and cycle duration are no longer linear. The purpose of this study was to determine if the changes observed at very slow walking velocities are indicative of increased variability in performance associated with an unpracticed task or whether the observed changes indicate a third form of ambulation.

Ten men, ranging in age from 16 to 40 years, participated in this study. Pre- and post-training data were collected as subjects walked at the following velocities: 1.7,1.3,1.0,0.7, and 0.3 ms^{-1}. The parameters which were measured included cycle duration, swing and stance duration and support length. A tachometer monitored walking velocity. Four hundred walking cycles at 0.7 and at 0.3 ms^{-1} were practiced over two days; a metronome was used to ensure constant cadence during the practice sessions.

Practice did not alter slow walking performance. No significant difference in pre- and post-test performance was demonstrated by the subjects. Data from all velocities (including 0.3 ms^{-1}) demonstrate a hyperbolic relationship between the flexion phase and cycle duration or the extension phase and cycle duration. Because practice did not change the slow walking performance, it is assumed that the behavior demonstrated at this speed is another mode of bipedal ambulation. This is supported by results of previous study in which changes in the frequency relationship between upper and lower extremity motion were reported with decreasing walking speed. A change in shoulder and hip sequencing was also noted with decreased speed (Craik et al,Adv. Beh. Bio., 1976). Therefore, while the change from walking to running appears to involve a change in limb movement, it appears that the change from walking to "slow walking" is accomplished by a different type of strategy.

209.15 SELECTION OF MOTOR PROGRAMS DURING FUNCTIONAL TASKS IN HUMANS. W. Freedman, L. Kent*. Moss Rehabilitation Hospital, 12th Street and Tabor Road, Philadelphia, PA 19141.

This study was designed to identify factors that determine motor program selection during functional, human tasks. Subjects selected a heel-strike (HS) motor program (as used during level surface walking) or a toe-strike (TS) motor program (as used during stair descent). The task of descending a step of adjustable height followed by level surface walking offered a binary choice of motor program to the subject. Specifically examined was whether the presence or absence of vision or a change in step height influence selection of a TS or a HS motor program for task execution. Ankle angle, muscle activity (tibialis anterior (TA) and triceps surae (TRI)), initial foot contact (HS or TS), and stepdown force of the stepdown limb were measured.

Eleven healthy adult subjects (6M,5F), participated in this study. The experiment for each subject consisted of a set of 50 trials (25 vision, 25 no-vision) with step height randomized at 5 discrete heights (0,2.5,5,10,20 cm). Subjects were informed of step height under all conditions, but were completely naive to the task of interest, i.e., the toe-first or heel-first initial stepdown.

The height of the step did influence whether the subject stepped down toe-first or heel-first, while visual information did not alter the selection of the motor program. Under both visual conditions, all subjects landed heel-first at 0 cm. By 20 cm, the majority of the subjects in this sample had switched solely to toe-first contact. The threshold for switching to the TS program was indistinct, i.e., there were intermediate step heights for which half of the subjects stepped down toe-first or heel-first.

One of two distinct movement patterns was used for any particular trial in this experiment. HS trials were characterized by TA activity and TRI inactivity during swing, with a dorsiflexed ankle at substrate contact. The converse was true for the TS trials, i.e., TRI activity and TA inactivity during swing with a plantarflexed ankle at substrate contact. The selected variables correctly predicted the touchdown motor program by midway through the swing period. The TA and TRI pre-contact EMG bursts and subsequent ankle movement before substrate contact for HS and TS trials appear to be part of pre-programmed movement patterns (i.e., motor programs) which are presumably of central origin.

Movement is controlled through a biological amalgam of voluntary, stereotypic and reflex actions. The particular mixture for any specified movement is based on the intent or functional outcome desired. The switching to the TS motor program as step height increased presumably results in the most efficient and stable movement.

209.16 NEURONAL ACTIVITY CHANGES RELATED TO THE ADVANCE INFORMATION ABOUT BIOMECHANICAL PARAMETERS OF AN INTENDED MOVEMENT. **A.Riehle*, J.Requin.**Dept.of Exp.Psychobiology, Inst.of Neurophysiol.Psychophysiol., C.N.R.S.,F - 13402 Marseille 09, France.

Preparatory processes contributing to the building of the motor program were studied by means of recordings of single-cell activity within motor cortical areas (area 4 and 6) of awake monkeys (**Macaca fascicularis**) during the execution of a wrist flexion-extension movement triggered by a visual stimulus. The animals were trained in a so-called "movement dimension advance information" paradigm the principles of which are as follows: in a choice reaction time (RT) task including a preparatory signal (PS) which provides complete, partial or no information about the biomechanical parameters of the movement, analyses of RT-changes allow one to make inferences about the independence, the timing and the order of processes which underly the preselection of motor program subroutines.

The behavioral results obtained during training and recording sessions show that RT is directly correlated with the type of advance information (complete-direction-extent-none), but movement time is not. This indicates that advance information about movement parameters intervenes at the motor programming and not at the execution level. RT decreases when the amount of advance information is increased. In the situation where the animal is provided with information about only one parameter and is uncertain about the other one, information about direction (flexion or extension of the wrist) shortens RT more markedly than information about the extent of the movement. This result suggests that programming of the movement direction takes longer than programming of the extent.

Various types of neurons were recorded the responses of which could be related to the preparatory processes: (1) neurons responding direction-specifically to the PS which are possibly involved in a process responsible for specifying the activity of the particular muscles by modifying the excitability of the preceding neuronal elements; (2) neurons with slowly developing activity during the preparatory period (PP) (which is partly related to the advance information) that may preset the responsiveness to the response signal; (3) neurons showing sustained activity changes during the PP irrespective of the informative value of the PS, which could play a role in a cortical mechanism underlying the reinforcement of the postural stability of the moving limb; (4) neurons showing activity changes which are strongly time-locked to the response signal but not to the movement onset, indicating a possible mechanism linking the visual information with the motor output.

Supported by the European Training Programme and the Fondation pour la Recherche Médicale (A.R.).

209.17 DIVERGENCE OF PREPARATORY TUNING FROM MOTONEURONAL ACTIVATION AS A FUNCTION OF TASK COMPLEXITY IN MAN. C.W.Y. Chan and M.W. Rogers*. School of Physical and Occupational Therapy, McGill University, Montreal, Quebec, Canada H3G 1Y5

Facilitation of the spinal reflexes prior to rapid limb movements is thought to reflect a preparatory "tuning" of the motoneurons. However, in spite of the well known prolongation of reaction time (RT) as a function of complexity/choice of movement strategies, comparatively little information is available on the preparatory tuning processes preceding different motor tasks. To resolve this issue, we compared the profile of H-reflex excitability prior to an ankle plantarflexion performed under simple ballistic (SRT-B) and complex tracking reaction time (CRT-T) paradigms.

Two groups of nine normal subjects, who were similar in age and mean RT latencies in the ballistic task, participated in the two experimental series. They were instructed to plantarflex the right ankle in response to a visual signal (RS), following a tone burst (WS) at 1000 msec. The ballistic task in series I involved a rapid 20° ramp movement (SRT-B). The tracking task in series II consisted of accurately following either a slow ramp or a bell-shaped oscilloscope trace with (CRT-T) or without choice (SRT-T). EMGs were recorded from the soleus and tibialis anterior simultaneously with ankle movement. For a comparison of the preparatory process between the SRT-B and CRT-T tasks, changes in the excitability of the spinal reflex arc were measured at predetermined intervals following the WS by means of the H-reflex technique.

Three principal findings emerged:

(1) The mean soleus EMG and movement onset latencies were significantly longer ($p<.01$, by some 100 msec) for the SRT-T than the SRT-B task. In contrast to some previous reports, there was no difference in the onset latencies between tracking tasks with (CRT-T) and without choice (SRT-T).

(2) The agonist (soleus) EMG response patterns for the ballistic movements were characterized by a brief, high amplitude burst; whereas those for the tracking tasks tended to be more continuous and slowly graded.

(3) Facilitation of the spinal reflex pathway commenced more than 100 msec earlier relative to the agonist EMG onset, and reached a higher maximum level of excitability for the complex tracking task than that preceding the simple ballistic movement.

These results suggested an earlier AND enhanced tuning of the spinal reflex pathway in association with motor tasks requiring greater complexity. Of particular interest is the demonstrated divergence of preparatory tuning from motoneuronal activating processes, under different task conditions.

209.18 DIFFERENTIALLY TIMED, PROPRIOCEPTIVE INPUT PRODUCES TONIC CHANGES OR TRIGGERING OF VOLUNTARY TORQUE RESPONSES. P. J. Cordo, M. Flanders* and J. G. Anson, Good Samaritan Hospital & Medical Center, Portland, OR 97210.

Isometric torque production at the human elbow joint has been studied in order to identify visual and proprioceptive control mechanisms. Visual control takes the form of a triggered response followed by a series of adjustments aimed at improving accuracy. We now report possible proprioceptive contributions to voluntary torque responses.

Adult, human subjects produced fast and accurate step increases in horizontal flexion torque (24 and 30 Nm) in response to a visual stimulus. In some trials which were randomly selected, the forearm (screened from the subject's view) was briefly displaced at a velocity of 50 deg/s, at various times between presentation of the visual trigger and response onset, and during the voluntary response. In 10% of the trials the expected visual trigger was not provided, however, the proprioceptive perturbation was still imposed.

Effects of perturbations on voluntary torque responses were strongly dependent on the timing of limb movement onset. When perturbation onset occurred during or up to 40 ms prior to the onset of voluntary responses, the torque production system responded like a spring: tonic increases in agonist EMG and elbow torque to extension displacements and decreases to flexion displacements. Reaction times were prolonged by approximately 10 ms following flexion (unloading) limb displacements. These effects are consistent with the expected responses of muscle spindles to joint displacements such as these. When perturbation onset occurred prior to about 40 ms before voluntary response onset, the limb movement (independent of direction) caused an increase in the amplitude of the initial open-loop component of voluntary responses. Furthermore, limb perturbations imposed in the absence of the expected visual stimulus, nonetheless produced triggering of a typical voluntary torque response. The results are consistent with the idea of a proprioceptive control system that is separate and additive to the visual control system. Depending on the specific timing of an imposed limb movement, it can either produce a spring-like response of the limb or trigger the voluntary motor command. In neither case does the proprioceptive control system appear to function as a error correcting mechanism. (NIH RO1 AM31017-02)

209.19 CYCLIC VOLUNTARY FINGER MOVEMENTS: KINEMATIC AND EMG PATTERNS. D. Hahs* and R. Stiles. Dept. Physiology and Biophysics, Univ. Tenn. Center for the Health Sciences, Memphis, TN 38163.

Because much voluntary movement is rhythmical, the question arises as to the ability of the skeletal motor control system to produce smooth oscillations of a body part. Of particular interest in this study are the electromyographic and kinematic patterns obtained during cyclic voluntary movement of a finger.

Normal human subjects were instructed to make self-paced oscillatory movements of the index finger in a parasaggital vertical plane at about 1 Hz. The movement was detected by an AVR-250 accelerometer mounted on a styrofoam sleeve placed over the entire finger. Velocity and displacement records were obtained by digital integration. Jerk was obtained by digital differentation. Bipolar surface EMGs were detected from extensor digitorum and flexor digitorum superficialis muscles. Each EMG signal was full-wave rectified and digitally smoothed. Movement and EMG data were analyzed in the time as well as frequency domain.

Factors entering into the production of the movement were the mechanical-reflex oscillations (tremor) of the finger and the reciprocal- and co-activation pattern of the control signal. Acceleration-related feedback pulses correlated with the tremor, as well as biphasic AGl-ANTl pulses, could be identified in computer-averaged EMG epochs. These latter pulses were correlated with corresponding pulses in the averaged acceleration traces. Position epochs demonstrated that the agonists were being activated (and antagonists deactivated) at or near the extremes of finger position, e.g., the flexor muscle was activated near peak extension. Power spectral density functions of EMG and acceleration both contained bands at the self-paced frequency and contained prominent bands at the second, third, and fifth harmonics.

209.20 THE COORDINATION OF SIMULTANEOUS KEYPRESSES FOR ALL FINGER PAIRS IN HUMANS. C.L. MacKenzie. Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

The preparation and coordination of finger movements are constrained by the structure and functional organization of the motor system. These constraints are dynamic and task specific; that is, they vary with the temporal phase dependence of the finger movements (MacKenzie, 1985). Past research provided a description of the selection and intention gradients when the task required a choice between one of two fingers to make a single, discrete keypress (MacKenzie, Neuroscience Abstracts, 1984).

This research examined coordination processes for a task requiring simultaneous keypresses (chords) with two fingers. Ten, female, right-handed undergraduates performed two replicates of 20 trials for each of 28 finger pairing conditions (excluding thumbs). On each trial, after a constant foreperiod of 2 s, an imperative stimulus (.8 probability) or a no-go stimulus (.2 probability) light indicated to respond with a two finger chord or not to respond respectively. The fingers were resting on eight telegraph keys, and the keypresses were made without vision of the hands. Light-response mappings were counterbalanced across subjects.

The reaction time (RT) analysis revealed significant differences in RT to initiate "simultaneous" keypresses. Further, RT for a given finger changed with the context of the paired finger in the chord. For example, RT for a given finger was longer when paired with a ring finger than when paired with an index finger. Overall, RT for between hand finger chords (239 ms) were faster than within hand finger chords (250 ms). For within hand chords only, the left hand fingers (247 ms) were faster than fingers on the right hand (253 ms). Finger gradients on the left and right hands differed for between and within hand chords. A final gradient in the data revealed a significant departure from simultaneity in the initiation of two keypresses; the keypress for the leftmost finger of the pair was initiated consistently 2-5 ms earlier. This was most pronounced in right hand data and was parallelled by the error analysis. These data and their implications for understanding the activity of the underlying neural networks will be further described.

209.21 **ACTIVATION LEVELS OF TWO ELBOW FLEXORS UNDER ISOMETRIC CONDITIONS.** J.D. Howard*, J.D. Hoit*, R.M. Enoka, and Z. Hasan. Depts. of Physiology, Exercise & Sport Sciences, and Speech & Hearing Sciences, University of Arizona, Tucson, AZ 85724.

In dynamic conditions with varying angular velocities of elbow flexion, it has been shown that the integrated EMG in brachioradialis (BR) and biceps brachii (BB) is highly correlated. This relationship has given rise to the concept of the Flexor Equivalent (Bouisset et al., Electroenceph. Clin. Neurophysiol. 42: 543, 1977). However, Hasan and Enoka (Soc. Neurosci. Abstr. 10: 334, 1984) have observed that changes in the dynamic versus steady-state EMG in the elbow flexors are independent and can go in opposing directions. In elbow flexion movements, they noted a dynamic increase in BR EMG followed by a steady-state EMG that could be either greater than or less than that of the pre-movement EMG.

In light of these studies, the present investigation examined the isometric steady-state activation patterns of BB and BR over a range of elbow angles from 35 to 170°. Each muscle was held at constant activation levels corresponding to 5, 10, 15, and 20% of maximal-effort EMG. The constant activation of one muscle across angles allowed for comparison of the simultaneous activation level in the other muscle. The rectified and filtered EMG signals of both muscles were sampled by computer. A pair of LED lights provided feedback to the subject to activate the test muscle at the prescribed levels. Subjects were unaware of which muscle was the test muscle, and, in fact, typically assumed the feedback related to the torque exerted. The mean coefficient of variation of the test-muscle EMG about the target levels for the entire data pool was 0.08.

The results revealed three features: (1) When the test-muscle EMG was held constant, the EMG pattern of the non-test muscle varied widely across joint angles. When BR was the test muscle, five subjects showed an increase in BB EMG over an elbow-angle range of 65 to 170°. However, the other five subjects showed either a decrease or no discernable directional trend. (2) The activation patterns of the two muscles were inversely related in 9 of 10 subjects. For example, when BR EMG was held constant across angles, five subjects showed an increasing EMG in BB with increasing joint angle. All five of these subjects then demonstrated a decreasing trend in BR EMG when it was the non-test muscle. (3) The four target levels revealed that the correlation between the EMG's of BR and BB varied widely at different angles. Only rarely were the systematic increases in the test-muscle EMG accompanied by corresponding systematic increases in the non-test muscle EMG.

These results caution against the generalization of the Flexor Equivalent hypothesis to isometric conditions. In particular, investigators should use caution in making inferences regarding the activation levels of all elbow flexors when recording from just one.

PHYSIOLOGICAL EFFECTS OF PEPTIDES I

210.1 ELECTROPHYSIOLOGICAL EVIDENCE FOR SUBSTANCE P AS A NEUROTRANSMITTER IN THE CILIARY GANGLION. S.E. Dryer and V.A. Chiappinelli. Dept. of Pharmacol., St. Louis Univ., St. Louis, MO 63104.

The chick ciliary ganglion contains two populations of postganglionic cells, called ciliary neurons and choroid neurons. These neurons differ in size, location within the ganglion and location of target organ. Nerve terminals synapsing onto both populations of cells contain substance P, which is colocalized with acetylcholine (Erichsen et al., J. Neurosci. 2:994, 1982). We have used intact ganglia in an in vitro chamber for intracellular recording from ciliary and choroid neurons.

Ciliary neurons are singly-innervated, contain dual electrical-chemical synapses, and can transmit action potentials at frequencies exceeding 100 Hz. Ciliary neurons do not display slow EPSPs, and are not affected by substance P. In contrast, choroid neurons are multiply-innervated by purely chemical synapses which fail at frequencies above 30 Hz. Following repetitive preganglionic stimulation, choroid neurons display a non-cholinergic slow EPSP which is associated with an increase in input resistance. This slow EPSP is closely mimicked by superfusion with 1-3 μM substance P, and the two responses have the same apparent reversal potential (~ -90 mV). Moreover, the response to substance P desensitizes within minutes, at which time the slow EPSP is blocked, suggesting that substance P is the mediator of the slow EPSP.

Intracellular recordings were also made from calyciform nerve terminals synapsing onto ciliary neurons. These units are also depolarized by substance P. The physiological significance of this response is unknown. Thus, in the chick ciliary ganglion, substance P produces presynaptic effects at one type of synapse and postsynaptic effects at another.

Leu-enkephalin is also found in nerve terminals synapsing onto both ciliary and choroid neurons (ibid.). We have therefore examined the effects of this peptide in the ciliary ganglion using intra- and extracellular recording techniques. Intracellular recordings in the presence of 20 μM leu-enkephalin reveal a small reduction in nicotinic EPSP amplitude in both populations of cells. In ciliary neurons, however, this decrease was never sufficient to block action potentials. Superfusion of leu-enkephalin at concentrations up to 100 μM had no effect on the extracellular compound action potential associated with ciliary neurons. In contrast, 20 μM leu-enkephalin produced a 15% reduction in the choroid neuron compound action potential. This effect was blocked by naloxone. Studies are currently underway to determine the mechanism of this effect of leu-enkephalin.

210.2 THE EFFECTS OF NEUROTENSIN ON TRANSMISSION AT THE FROG NEUROMUSCULAR JUNCTION. K. Alkadhi and R. Clothier*. Department of Pharmacology, University of Houston, University Park, Houston, TX 77004.

Neurotensin is a tridecapeptide unevenly distributed in the central nervous system (CNS) and gastrointestinal tract of various animals including man. Neurotensin is known to have multiple central and peripheral actions such as hypothermia, analgesia and hypotension. On the basis of its presence in the CNS and because of certain characteristics, neurotensin has been suggested as a possible chemical mediator in synaptic transmission. Electrophysiological investigation of the effects of neurotensin on central neurons (J.L. Henry, Ann. N.Y. Acad. Sci. 400: 216-227, 1982) showed variable results. Both depression and excitation were observed in sensory and sympathetic preganglionic neurons. Possible synaptic effect of neurotensin was investigated in the present experiments using the frog neuromuscular junction as a model.

Magnesium-blocked isolated cutaneous pectoris muscles were used for intracellular recording. Neurotensin (0.1, 1, 5μM) had no apparent effect on the resting membrane potential. At 0.1μM neurotensin failed to affect transmission. However, at higher concentrations (1, 5μM) neurotensin decreased the amplitude of the endplate potential (EPP) without affecting that of the miniature EPP (MEPP; 0.61 ±0.07 mV before, 0.59 ±0.06 mV after 5μM neurotensin). The quantal content (m) of the EPP was slightly decreased (m: 86± 3% of control after 5μM of neurotensin, 99±5% of control after 20-40 min wash). Neurotensin slightly but consistently reduced (about 17%, 5μM neurotensin) the frequency of MEPP. This effect was also reversed on prolonged washing. Varying the frequency of nerve stimulation (0.3 - 6 Hz) did not seem to influence the effects of neurotensin on transmission.

These preliminary findings showed that neurotensin affects transmission at the frog neuromuscular junction by acting presynaptically.

210.3 ACTION OF VASOPRESSIN ON NEURONS AND MICROVESSELS IN THE RAT HIPPOCAMPAL SLICE. T. Smock and A. Topple*. Department of Psychology, University of Colorado, Boulder, CO 80309.

A complete analysis of the central action of vasoactive transmitter candidates entails a consideration of possible influences on microvasculature as well as direct effects on neurons. To this end we have used a standard hippocampal slice preparation to evaluate the electrophysiological and microvascular response to substances of this kind. Arginine vasopressin (AVP) was chosen for this study as previous reports show it to be contained in central neurons that make vascular contacts, to be released by depolarization in the presence of calcium and to be capable of producing excitation of central neurons that is fully blocked by a specific structural antagonist for AVP's pressor receptor (Muhlethaler et al, Nature 296:749 and Jojart et al, Neurosci. Lett. 51:259).

For electrophysiology 103 neurons in the CA1 region were impaled and intracellular recordings were obtained (avg.V_m=55+/-2mv, avg. spike size =93+/-2mv). Lack of spontaneous activity indicated that most were pyramidal cells. 55% of the cells responded to AVP (1μM) by displaying an increase in excitability without a major change in V_m or r_m. Confirming previous reports, no effect was obtained in saline media that lacked calcium (Mizuno et al, Brain Res. 309:241). No change in epsp or ipsp frequency was observed.

Inspection and time-lapse microphotography of 62 slices revealed that most slices contained vessels that beat spontaneously, indicated by periodic pulsatile movement ranging in frequency from 0.25 Hz to once a minute or longer. Most vessels within a slice lacked the spontaneous movement, however. Some quiescent vessels could be induced to contract by AVP (1μM). In three slices studied at high magnification (field size 450x700μm) four vessels responded to AVP and ten did not. In seven slices studied at lower magnification only large vessels were resolved. Of these, two responded to AVP and fourteen did not. Intracardial injection of an impermeant dye (Evan's Blue, 0.4g/10ml) before slice preparation labeled many more vessels than were apparent in slices from uninjected animals and permitted an estimate of microvessel density in the slice (one vessel every 29 μm).

Three hypotheses are suggested by the observed action of AVP on neurons and blood vessels. First, the neurons alone could express the pressor receptor for AVP, the blood vessel response being a consequence of increased neuronal activity. Second, the vessels alone could express the receptor, producing a secondary neuronal response by mechanical means. Finally, both neurons and vessels could express pressor receptor populations and respond independently to the applied vasoactive compound.

210.4 **THE EFFECT OF FMRFAMIDE ON FREQUENCY - DEPENDENT SPIKE BROADENING.** D. Doerner* and L.D. Partridge. Dept. of Physiol., Univ. of New Mexico School of Medicine, Albuquerque, N.M. 87131.

The invertebrate neuropeptide FMRFamide (Phe-Met-Arg-Phe-NH_2) has previously been shown to alter the beat frequency and contractility of cardiac muscle (Gen. Pharmacol. 11:237, 1980), to modulate central pattern generation in stomatogastric neurons (Neurosci. Abst. 45.4, 1984), and to modify adaptive behaviors and possibly mediate behavioral state in Aplysia (Neurosci. Abst. 151.9, 1984). The work reported here suggests that FMRFamide may act as a neuromodulatory agent by producing alterations in frequency - dependent spike broadening.

Superfusion of FMRFamide (10 pM - 1 μ M) over the circumesophageal ganglion complex of Helix aspersa or Lymnaea stagnalis consistantly provoked an increase in the percentage broadening. Spike broadening in the presence of the peptide was an average 53% greater than that recorded in Ringer solution. The effect was shown to be dose - dependent and reversible. Changes in spike broadening were accompanied by small (2 - 10 mV) voltage - dependent shifts in membrane potential. The polarity of these shifts reversed near the expected potassium equilibrium potential. Preliminary data suggest that FMRFamide's effect on spike broadening may be due to a modulation of membrane K^+ currents.

Since the amount of transmitter released by a presynaptic neuron should be a function of spike duration, changes in synaptic efficacy will accompany alterations in frequency - dependent spike broadening. One important mechanism for the neuromodulatory action of FMRFamide may result from the ability of the peptide to mediate the extent of spike broadening.

210.5 CALCITONIN (CT) AND CALCITONIN GENE-RELATED PEPTIDE (CGRP) ENHANCE CALCIUM - DEPENDENT POTENTIALS. M. NOHMI*, P. SHINNICK-GALLAGHER, P.W. GEAN*, J.P. GALLAGHER, and C.W. COOPER* (SPON: D. EATON) Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550.

The indication that CGRP is produced in central neurons utilizing acetylcholine as a neurotransmitter and the finding of CGRP immunoreactivity in sacral areas of the spinal cord and in nerve terminals of parasympathetic ganglia of the urinary bladder suggests that CGRP or CT may serve as neurotransmitters or neuromodulators in vesical neurons. We used conventional intracellular recording methods to test the effects of synthetic salmon CT and synthetic human CGRP in cat vesical parasympathetic ganglia. CT (5nM-1μM) had no effect on the resting membrane potential or membrane conductance but prolonged the duration of the afterhyperpolarization (a.h.p.) of an action potential (AP; 36.5%; 0.5μM) without affecting the amplitude of the AP. We also analyzed the effects of CT on the Ca-spike recorded in the presence of tetrodotoxin (TTX, 1μM) and tetraethylammonium (TEA, 20mM) to block sodium and potassium channels respectively. CT (1μM) prolonged the duration but did not affect the peak amplitude or amplitude of the a.h.p. of the Ca-spike. The effect of CT on the calcium spike was reversible and concentration-dependent (5nM-1μM). These effects of CT on the Ca-spike were also observed in the presence of other agents known to block potassium conductance (intra- and extracellular Cs_4SO_4 and 4-aminopyridine; 4-AP). Synthetic human CGRP (1μM) also prolonged the calcium spike under both previous conditions (15.7% and 17.2%, respectively) but CGRP was 3-4 fold less potent than salmon CT. Like CT, CGRP (1μM) did not affect the resting membrane potential or membrane conductance. Forskolin (25μM), an activator of adenylate cyclase known to prolong Ca-spikes in other tissues, prolonged the duration of the Ca-spike (16.1%) recorded in TTX and TEA but not in the presence of TTX, TEA, Cs_2SO_4 and 4-AP. These data suggest that forskolin acts on potassium rather than calcium channels and that CT and CGRP action may not involved cyclic AMP. We report here the first evidence that the neural mechanism of CT and CGRP action is to enhance a calcium conductance. With the exception of ATP (Yatani et al. Nature 296: 169), CT or CGRP appear to be the only known endogenous substances thusfar which enhance Ca conductance. The prolongation of the Ca-spike suggests that CT or CGRP may act as neuromodulators by enhancing the release of neurotransmitter. These data suggest that the fundamental effects of CT, both neural and endocrine, appear to have a common mediator, namely calcium. (Supported by NS16228 to PSG and AM32060 to CWC).

210.6 VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) PRODUCES A NONCHOLINERGIC DISCHARGE AND ENHANCES SLOW EXCITATORY MECHANISMS IN CHRONICALLY DECENTRALIZED CAT SUPERIOR CERVICAL GANGLIA (SCG). M. Rutigliano*, M. Kawatani, and W.C. de Groat, Dept of Pharmacology and Center for Neuroscience, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261

Previous experiments have shown that vasoactive intestinal polypeptide (VIP) elicits a depolarization of cat sympathetic and parasympathetic ganglia cells in vitro. VIP also facilitates muscarinic excitatory mechanisms in ganglia without altering either nicotinic transmission or the response to nicotinic agonists. VIP does not elicit a discharge in normal SCG. The present experiments were undertaken on chronically decentralized SCG to determine if the effects of VIP would be altered by the elimination of preganglionic nerve terminals.

Experiments were performed on SCG in vivo in dial urethane anesthetized cats. Multiunit firing was recorded on postganglionic nerves in normal ganglia acutely decentralized (2-10 hrs) and in chronically decentralized ganglia where the cervical sympathetic trunk was sectioned 14-21 days prior to experimentation. Drugs were administered by injection (0.1 ml) into the common carotid artery.

VIP (5-50 μg) produced a slow onset (30-60 sec), prolonged (2-5 min) discharge in the chronically decentralized SCG. The threshold for the response was 5 μg and the discharge was reproducible when the peptide was given at 20-30 min intervals. VIP did not produce a discharge in the normal SCG even at doses 10-15 times the threshold for the decentralized ganglia. The discharge was resistant to muscarinic antagonists (atropine, 40-70 μg and pirenzepine, 5-200 μg) as well as the nicotinic antagonist hexamethonium (5 mg). However, the discharge was rapidly and reproducibly blocked by agents with a direct postsynaptic depressant action (GABA, 10-100 μg and L-ENK, 10-50 μg). Low doses of VIP also enhanced slow excitatory mechanisms in chronically decentralized SCG. The late (muscarinic) component of the ACh (2-20 μg) induced discharge as well as the late component of the 5-hydroxytryptamine (2-10 μg) induced discharge were both significantly enhanced by VIP (1-5 μg).

In conclusion, the present results indicate that the effects of VIP on the SCG are entirely attributable to a direct postsynaptic action on noncholinergic receptors. The unmasking of VIP-induced postganglionic firing in ganglia could be related to denervation supersensitivity and an enhanced depolarizing action of VIP following the loss of normal excitatory cholinergic inputs. These findings raise the possibility that VIP may function as both a neuromodulator and a neurotransmitter in autonomic ganglia.

210.7 NEUROPEPTIDES REGULATE GUANOSINE TRIPHOSPHATE CYCLOHYDROLASE ACTIVITY IN CULTURED BOVINE ADRENAL CHROMAFFIN CELLS. R. J. Slepetis*, M. M. Abou-Donia, C. D. Unsworth*, W. Haynes*, C. A. Nichol* and O. H. Viveros. Department of Medicinal Biochemistry, The Wellcome Research Laboratories, Research Triangle Park, NC 27709.

We have previously presented evidence that tyrosine hydroxylase (TH) and guanosine triphosphate cyclohydrolase (GTP-CH) activities and tetrahydrobiopterin (BH_4) levels in chromaffin cells of adrenal medulla are regulated by changes in catecholamine levels and by cAMP-dependent mechanisms mediated through nicotinic cholinergic receptors (Viveros et al., Science, 213:349, 1981; Abou-Donia and Viveros, Proc. Natl. Acad. Sci. U.S.A., 78:2703, 1981; Abou-Donia et al., Chemistry and Biology of Pteridines (J. A. Blair, ed.), de Gruyter, Berlin, p. 777, 1983). Recent evidence indicates that in addition to cholinergic fibers, the adrenal medulla is innervated by fibers that contain vasoactive intestinal peptide (VIP) and substance P. Furthermore, catecholamines, opioid peptides, and a number of other neuropeptides are costored in and cosecreted from the chromaffin cell. In order to determine whether these neuropeptides may also be involved in the regulation of BH_4 synthesis, the effects of VIP, substance P and opiate agonists and antagonists on GTP-CH activity and catecholamine levels were investigated in cultured bovine adrenal chromaffin cells. After 24 to 72 hours of exposure to 0.5-10 μM VIP, a small but significant dose-dependent increase in GTP-CH activity was observed (maximal effects were 20-40% above basal activity), and cellular catecholamine content was unchanged by this treatment when values were expressed per 10^6 cells. However, since VIP treatment also stimulated protein synthesis, GTP-CH activity was unchanged, and catecholamine content significantly declined, when expressed in terms of total cellular protein. Treatment of the cells with substance P (0.5 μM-10 μM) for 72 hours resulted in a significant elevation in GTP-CH activity. The maximal increase (75%) was elicited by 1 μM substance P. Total catecholamine levels and cellular protein content were unaffected by substance P treatment. Treatment of the cells with [D-ala^2]-[D-leu^5]-enkephalin (1 μM) and/or naloxone (5 μM) for 24 to 72 hours had no consistent effect on TH and GTP-CH activity. The alterations in GTP-CH activity observed following VIP and substance P treatment suggest that the peptidergic fibers innervating the adrenal medulla may contribute to the modulation of BH_4 biosynthesis.

210.8 EFFECTS OF SYSTEMIC ADMINISTRATION OF A SYNTHETIC ACTH(4-9)-ANALOGUE (HOE 427) ON ACETYLCHOLINE AND CYCLIC NUCLEOTIDE LEVELS IN RAT BRAIN. G. Wiemer* , H. Gerhards* and R. Geiger*. (SPON: H. Braak). Hoechst AG, 6230 Frankfurt/M. 80, FRG

Increases in hippocampal acetylcholine (ACh)-turnover after intracerebroventricular (1 - 30 mcg) administration of ACTH-related peptides have been described (P.L. WOOD et al., J. Pharmacol. Exp. Ther. 209, 97 - 103 (1979) and L.J. BOTTICELLI & R.J. WURTMANN, J. Neuroscience 2, 1316 - 1321 (1982). Since the various behavioral effects of these peptides described by the deWIED group were observed after much lower systemic doses (0.1 - 1 mcg/kg s.c.), we were interested to see whether changes in ACh-metabolism, 3',5'-cAMP and 3',5'-cGMP levels as well as in glucose metabolism also could be detected after behaviorally active systemic doses of short chain ACTH-analogues.

Hoe 427 is an ACTH(4-9)-analogue which shows an increased potency in behavioral tests and an improved metabolic stability in comparison to other short chain ACTH-analogues. Since in ACTH, 11-Lysine contributes strongly to the biological activity (R. GEIGER & H.G. SCHRÖDER, Hoppe-Seyler's Z. Physiol. Chem. 354, 156 - 162, (1973), a similar group was introduced into an analogous position of the molecule.

Male Wistar rats (120 - 140 g) were given various doses (range: 0.01 - 10 mcg/kg) of Hoe 427 s.c. or i.p. and sacrificed at various times (range: 0.5 - 24 hrs) by a microwave beam (4.8 KWsec) focused on the head. Determinations of ACh, cAMP and cGMP were performed by radioassays. Glucose utilisation was measured by using the glucose analogue ^{3}H-2-deoxyglucose (^{3}H-2-DG).

Systemic administration of Hoe 427 in a dose range from 0.01 to 10 mcg/kg produced decreases in ACh-levels mainly in the striatum. The decrease in ACh was more pronounced and found additionally in the hippocampus and hypothalamus when the animals were pretreated with dexamethasone for 1 week (1 mg/kg i.p., daily). The decrease in ACh levels suggests that Hoe 427 increases the utilisation (release) of ACh. This could be further supported by a potentiation of the ACh-depletion induced by pretreatment with the choline-uptake inhibitor hemicholinium-3 (HC-3). In parallel, the levels of 3',5'-cAMP were increased in the hippocampal and hypothalamic areas; 3',5'-cGMP levels were reduced in the cerebellum and elevated in the striatum. Moreover, Hoe 427 enhanced the accumulation of ^{3}H-2-DG in various brain areas.

These results indicate, that short chain ACTH-analogues like Hoe 427 are able to cause potent modulatory effects presumably on cholinergic pathways in different brain areas after systemic administration.

210.9 SINGLE DOSING OF MIF-1 OR TYR-MIF-1 AFFECTS DOPAMINERGIC FUNCTION IN THE BRAIN. C. Hara* and A.J. Kastin. VA Medical Center and Tulane Univ. Sch. Med., 1601 Perdido St., New Orleans, LA 70146.

MIF-1 (Pro-Leu-Gly-NH_2) and Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH_2), brain peptides, were active in the forced swimming test, a screening method for antidepressants (Kastin et al., Pharm. Biochem. Behav. 21:767, 1984). Accumulating evidence has suggested that MIF-1 has a potentiating effect on central dopaminergic (DA) function and may be effective clinically in some CNS disorders. In addition, it has recently been suggested that both peptides may act as opiate antagonists (Kastin et al., Pharm. Biochem. Behav. 21:937, 1984). However, the mechanisms of actions of these peptides in the CNS are still unclear. The present study examined single doses of MIF-1 and Tyr-MIF-1 on haloperidol (HAL)-induced catalepsy and apomorphine (APM)-induced stereotypy in rats in order to study the effects of both peptides on DA function in the brain. Male albino rats (10-11 weeks old) were tested between 9:00AM-12:00PM. All rats were used only once in an experiment. Catalepsy was tested 60 min after HAL administration (1.0 mg/kg, s.c.) with a standard bar test in which catalepsy was defined by rats keeping the imposed posture for over 30 sec (Hara et al., Pharm. Biochem. Behav. 18:423, 1983). The peptides (0.1-10 mg/kg, s.c.) were administered 30 min before the testing for catalepsy. In the APM experiment, MIF-1 and Tyr-MIF-1 (0.2-5.0 mg/kg, s.c.) were injected 10 min before the APM (0.1-2.0 mg/kg, s.c.). Ten min after the APM, each rat was rated for the degree of stereotypy on a 0-4 scale based on 30 sec observations every 10 min (Nakano et al. Pharm. Biochem. Behav. 12:459, 1980). In the catalepsy test, MIF-1 showed the inverted U-shape response found for this peptide in several other situations. Doses of 1.0 and 2.0 mg of MIF-1 suppressed the catalepsy, but doses of 0.1, 0.5, 5.0 and 10 mg did not exert this effect. Tyr-MIF-1 (0.5 and 1.0 mg) showed a suppressive effect similar to that of MIF-1. In the APM experiment, 0.5 mg of MIF-1 potentiated the stereotypy induced by 0.5 and 1.0 mg APM. The 1.0 and 5.0 mg doses of MIF-1 enhanced the stereotypy induced by 0.5 mg of APM, whereas the same doses suppressed that induced by 2.0 mg of APM. However, MIF-1 did not induce stereotypy in the rats that were sedated as a result of receiving only 0.1 mg of APM. Tyr-MIF-1 also seemed to enhance the stereotypy induced by 0.5 mg of APM and suppressed that by 2.0 mg APM, although these results are preliminary. Thus, MIF-1 and Tyr-MIF-1 appear to exert a biphasic effect on the stereotypy induced by APM. The results suggest that MIF-1 and Tyr-MIF-1 exert different responses depending upon the amount of DA neuronal activity. Therefore, MIF-1 and Tyr-MIF-1 may play a role in the indirect regulation of DA neuronal activity.

210.10 POTENTIATION OF ARGININE VASOPRESSIN'S (AVP) CONVULSIVE-LIKE ACTIONS BY SOMATOSTATIN (SS): POTENTIAL MECHANISMS OF ACTION. D.M. Burnard, Q.J. Pittman and W.L. Veale, Department of Medical Physiology, University of Calgary, Calgary, Alberta T2N 4N1.

AVP and SS produce severe motor disturbances when administered into a lateral cerebral ventricle (icv) of the rat. A single injection of AVP or SS increases the likelihood of a convulsive-like episode upon subsequent administrations of AVP. The present work examined: 1) whether SS would potentiate the convulsive-like actions of AVP in rats unable to synthesize AVP (HODI); 2) whether a vasopressor antagonist would block cross-sensitization between SS and AVP; and 3) whether SS/AVP cross-sensitization would occur in the ventral septal area (VSA); a site where AVP is thought to elicit these motor disturbances.

For these experiments, behaviors were recorded and scored over a 10 min period according to a predetermined behavioral code. When male HODI rats (n=6) and the parent Long Evans (LE) strain (n=6) received 2.5 micrograms SS icv on day 1, the behavioral scores did not differ significantly between the two groups. Following 1.0 microgram AVP icv on day 3, both HODI and LE rats displayed barrel rotations (spinning along the long axis of the body) and/or myoclonic/myotonic convulsive-like movements. These behaviors are normally seen following a second icv injection of AVP. When male LE rats received either 5.0 microlitre vehicle (n=8) or 1.0 microgram vasopressor antagonist [d(CH$_2$)$_5$Tyr(Me) AVP] (n=10) icv 5 min prior to 2.5 microgram SS icv on day 1, behavioral responses to SS were not significantly different. In contrast, most rats pretreated with vehicle on day 1 displayed barrel rotations and convulsive-like movements following AVP (1.0 microgram icv) on day 3, whereas antagonist-treated animals showed only minor behavioral anomalies. When male LE rats (n=5) were microinjected bilaterally into the VSA with 250 ng SS on day 1 and 100 ng AVP on day 3, a sensitization process similar to that following icv injections was observed.

The present work demonstrates that SS is able to potentiate the convulsive-like actions of AVP in animals which cannot synthesize AVP, thus sensitization does not appear to rely on endogenous AVP release. Furthermore, SS/AVP cross-sensitization can occur in the VSA, where AVP is thought to trigger these motor disturbances. Since SS-induced potentiation of AVP's convulsive-like effects can be prevented by pretreatment with a potent antagonist of the AVP vasopressor receptor, it is conceivable that SS may interact with the AVP receptor in some unknown manner to elicit this effect.

This work was supported by MRC of Canada. DMB is an MRC student and QJP is an MRC scientist.

210.11 CHOLECYSTOKININ: POTENTIAL MODULATOR OF CLIMBING AND MOSSY FIBER INPUT TO CEREBELLAR PURKINJE CELLS. D.J. Steel*, P.L. Wood and B. Petrack (SPON: B.S. Barbaz). Neuroscience Research, Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, NJ 07901.

Zetler reported that cholecystokinin (CCK) octapeptide (CCK8) blocks seizure activity in response to tremorogenic agents such as harmaline (Zetler, Neuropharmacology 22:757, 1983). Harmaline-induced tremors are associated with marked increases in cerebellar cGMP levels (Wood, Neuropharmacology 21:1235, 1982). We, therefore, explored the possibility that CCK8 also might reduce the harmaline-elevated cGMP.

Mice were injected with CCK8 (.02, .2 and 1 mg/kg s.c.), followed by harmaline (40 mg/kg i.p.). The mice were killed by microwave irradiation; the cerebella were removed, extracted with 1 N HCl, and assayed for cGMP via RIA (New England Nuclear Kits).

We confirmed the observation that CCK8 blocks harmaline-induced tremors. Furthermore, CCK8 dose-dependently reduced the harmaline-elevated cGMP levels. The CCK8 effect was maximal at 10 minutes but still significant at 20 minutes. CCK8 also suppressed basal levels of cerebellar cGMP in a dose-dependent manner. The effects of CCK8 on cGMP levels were not blocked by proglumide (160 mg/kg i.p.), naloxone (50 mg/kg i.p.) or benzotript (150 mg/kg i.p.). Cyclic AMP levels were not affected.

In addition to harmaline, cerebellar cGMP levels are elevated by amphetamine, apomorphine and pentylenetetrazol. We found that CCK8 suppressed the rise in cGMP caused by each of these agents except pentylenetetrazol, indicating that the antagonist actions are not directly at the level of the cerebellum. These results suggest a role for CCK8 in modulation of afferent inputs to the cerebellar Purkinje cells.

210.12 A NEUROPEPTIDE AUTORECEPTOR MEDIATES CHANGES IN NEURONAL EXCITABILITY. J.A. Kauer and L.K. Kaczmarek. Yale University School of Medicine, Departments of Pharmacology and Physiology, New Haven, CT 06510.

Although the bag cell neurons of Aplysia are ordinarily silent, brief electrical stimulation or elevated intracellular cAMP produces a long-lasting afterdischarge. In addition, agents which elevate cAMP levels in the bag cell neurons significantly increase the afterdischarge duration. We now demonstrate that ∝BCP (Rothman et al. PNAS 80:5753-5757, 1983), one of the neuropeptides released during the afterdischarge, alters both the electrical and biochemical properties of the neurons which release it.

We have found that a brief pressure ejection of ∝BCP [1-7] over intact clusters of bag cell neurons at the beginning of an electrically stimulated afterdischarge prematurely terminates the afterdischarge. Two different effects of ∝BCP which may explain this termination have been observed: 1) an alteration in bag cell cAMP metabolism and 2) an autoreceptor-mediated electrical inhibition.

Brief exposure to ∝BCP (1 uM) attenuates the ability of the adenylate cyclase activator forskolin to elevate bag cell neuron cAMP levels. A similar attenuation of forskolin stimulated cAMP levels is seen at the end of a normal electrically stimulated afterdischarge. Measurements of adenylate cyclase activity in bag cell membranes suggest that ∝BCP does not produce its effects directly on this enzyme.

Using isolated cells maintained in primary culture we have shown that ∝BCP also has a direct electrical effect on the bag cell neurons. Pressure ejection of luM ∝BCP near the cell body of a cultured bag cell neuron caused a hyperpolarization (as large as 35 mV in some neurons), accompanied by a drop in input resistance. When the cell was hyperpolarized below E_K, the response to ∝BCP reversed, now appearing as a depolarization. The hyperpolarization in response to ∝BCP ejection was unaffected by 100 mM TEA, while 5 mM CsCl completely abolished it. These observations suggest that ∝BCP produces an autoreceptor activated increase in a potassium conductance.

Our data demonstrate that ∝BCP modulates the excitability of the bag cell neurons which release it, and suggest that release of this peptide during a normal afterdischarge is likely to play a role in determining the firing pattern and duration of the afterdischarge.

210.13 A VOLTAGE-INSENSITIVE POTASSIUM CONDUCTANCE IN APLYSIA NEURONS IS ENHANCED BY FMRFamide AND DEPRESSED BY ELEVATION OF cAMP. C. Erxleben*, V. Brezina* and R. Eckert. Dept. of Biology, UCLA, Los Angeles, CA 90024.

Application of the endogenous neuropeptide FMRFamide or its analogue YGG-FMRFamide to certain Aplysia neurons suppresses the Ca current activated by depolarization, and hence indirectly depresses the Ca-activated K current (Brezina et al. and Erxleben et al., 1985; Biophys. J. 47:435a). Additionally, these peptides have been reported to hyperpolarize Helix (Cottrell et al., 1984, J. Physiol. 356:315) and Aplysia (Ruben et al., 1984, Soc. Neurosci. Abstr. 10:1116) neurons by an increase in K conductance. Using two-electrode voltage clamp and puffed application of peptide dissolved in a solution identical to that in the bath, we have attempted to identify this K conductance, which in the Aplysia abdominal ganglion is enhanced by these peptides in cells L2, L3, L4, L6 and R2, but not in cells L7, L11, R14 and R15. Puffed application of 1-50 μM FMRFamide or YGG-FMRFamide (but not FMRF) to one of the sensitive cells clamped close to the resting potential (-30 to -50 mV) produced a slow outward current that reversed at -70 to -75 mV. The reversal potential shifted with altered K_o(but not Na_o, Cl_o or Ca_o) in the manner predicted for a K-selective conductance. The FMRFamide-induced current was blocked weakly by external TEA or 4-aminopyridine. Apart from constant-field rectification, the conductance was insensitive to membrane voltage. This behavior is inconsistent with the conductances responsible for either the delayed rectifier, inward rectifier, 'A' current, or the Ca-dependent K current. In addition, the increase in K conductance seen in response to FMRFamide and YGG-FMRFamide applications was diminished significantly (by up to 75%) by treatments that elevate intracellular cAMP, such as superfusion with the adenylate cyclase activator forskolin or the phosphodiesterase inhibitor RO 20-1724, and by direct injection of cAMP. All the characteristics of the FMRFamide-sensitive conductance we have determined thus far are consistent with those reported for the 'S' current conductance that is diminished by action of serotonin, elevated cAMP and certain endogenous peptides (SCP's) in Aplysia sensory neurons (Siegelbaum et al., 1982, Nature 299:413; Abrams et al., 1984, PNAS 81:7956). Thus, it appears that the 'S' current conductance may be subject to both 'up' and 'down' modulation mediated by peptidergic mechanisms. The effect of serotonin and SCP in closing the 'S' channel appears to be mediated by a cAMP-dependent protein kinase. Our results suggest that FMRFamide stimulates a mechanism that counteracts this at some level. Supported by NSF BNS 83-16417 and USPHS NRSA GM07185.

210.14 EFFECTS OF NATURAL AND SYNTHETIC PEPTIDES ON APLYSIA NEURONS. M.K.Rock, S.B.Shope, J.E.Blankenship and D.H.Schlesinger. Marine Biomedical Inst., Univ. Tx. Med. Br., Galveston, TX. 77550 and Dept. Medicine, NYU Med. Center, NY 10016.

The atrial gland (AG) and bag cells of A. californica contain peptides capable of inducing egg laying. We have examined the effects of the following peptides on identified neurons of the abdominal ganglion: those released from the bag cells during an afterdischarge, the synthetic 8-amino acid alpha-bag cell peptide (α-BCP), those extracted from the AG, and the synthetic amidated 9-amino acid C-terminal portion of AG peptides A/B/ERH (B_{26-34}). The two synthetic peptides differ in primary structure in only 2 of 8 residues. Peptides were applied by superfusion, arterial perfusion, or pressure ejection from micropipettes placed over specific neurons or by inducing a bag cell afterdischarge. Protease inhibitors were used to prevent peptide degradation.

Inhibition of the left upper quadrant (LUQ, L2-L6) cells follows a bag cell afterdischarge, and this effect is duplicated by application of α-BCP at 10^{-7} to 10^{-4} M and by B_{26-34} at $5x10^{-4}$ M. B_{26-34} at 10^{-6} to 10^{-4} M has either no effect or a slight inhibitory effect on LUQ cells. Inhibition of R2 follows a bag cell afterdischarge, and this effect is duplicated by application of α-BCP at 10^{-7} to 10^{-4} M and by B_{26-34} at 10^{-6} to $5x10^{-4}$ M. AG extract has a powerful excitatory effect on R2. Inhibition of the white cells (R3-R14) follows a bag cell afterdischarge, and this effect is duplicated by α-BCP at 10^{-4} M and B_{26-34} at $5x10^{-4}$ M. AG extract has a powerful excitatory influence on R3-R14. α-BCP and B_{26-34} applied to the soma of LUQ cells, R2, and white cells increase membrane conductance. L10 undergoes a biphasic response (inhibition followed by prolonged excitation) following a bag cell afterdischarge, α-BCP duplicates the inhibitory but not the excitatory response. AG extract has an excitatory effect on L10.

Thus, peptides released by the bag cells inhibit LUQ cells, R2, and R3-R14 and produce an inhibition followed by excitation on L10. AG extract has a mild to powerful excitatory effect on these cells. All inhibitory effects are mimicked by α-BCP. The excitatory effects of the AG extract can not be duplicated by B_{26-34}, suggesting that the C-terminal portion of the AG peptides A/B/ERH are not responsible for these effects. Rather, B_{26-34} at comparatively high concentrations seem to mimick α-BCP (with which it shares homologies) and inhibit these neurons. Preliminary data indicates L10 is initially inhibited by α-BCP while the prolonged excitation may be due to ELH. Supported by NIH: NS-11255, NS-07185 (SBS), NS-18109 (DHS); NSF: PCM 82-15185 (JEB).

210.15 THE SUPPRESSIVE EFFECTS OF SCP_B ON THE ISOLATED GILL OF APLYSIA CALIFORNICA MAY BE MEDIATED BY A CHOLINERGIC MECHANISM. D.R.L. Cawthorpe*, W.F. Colmers and K. Lukowiak* (SPON: W.L. Veale). Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

The endogenous neuropeptide, SCP_B, when perfused at concentrations as low as 10^{-13}M through the isolated gill of Aplysia californica, is a potent, reversible inhibitor of the gill withdrawal reflex (GWR) evoked by a mechanical stimulus to the gill. The classical neurotransmitter acetylcholine (ACh), also has inhibitory, as well as excitatory, effects on the GWR. The suppressive effects of ACh, which can be mimicked by the ACh agonist carbachol, are blocked by the nicotinic blocker curare. In this study, we examined whether the suppressive effects of SCP_B on the GWR could be mediated via a cholinergic mechanism by examining whether these effects could be blocked by co-perfusion of the peptide and curare.

Preparations consisted of the siphon, mantle and gill of 150-300 g Aplysia californica, with the abdominal ganglion and opaline and gametolytic glands removed. The preparation was pinned to the Sylgard base of a lucite dish, filled with artificial seawater (ASW; Instant Ocean) maintained at 15°C. The perfusate, ASW, was delivered to the afferent branchial gill vein via a glass cannula. A suture thread, tied to a single gill pinnule, was attached to an isotonic force transducer (Grass FT03C), connected to a Grass polygraph. The GWR was evoked by a mechanical stimulus to the gill by a mechanical trapper.

Perfusion of 10^{-13} to 10^{-9}M SCP_B through the isolated gill induced a suppression of the evoked GWR. After washout and recovery, SCP_B at the same concentration was co-perfused with curare (10^{-9} to 10^{-5}M). Under these conditions, SCP_B did not cause a suppression of the GWR (n=8). Curare concentrations above 10^{-5}M appeared to be equally effective in blocking the SCP_B suppression for all peptide concentrations tested. After complete washout with ASW, perfusion of SCP_B alone again caused suppression of the GWR.

The results show that curare at concentrations of 10^{-9} to 10^{-5}M completely blocks the suppressive effects of SCP_B on the isolated Aplysia gill. Even concentrations of 10^{-9}M SCP_B, which cause a profound, long-lasting suppression of the GWR in this preparation, were without effect in the presence of curare. The suppressive effects of ACh are blocked by curare, indicating their mediation by a nicotinic cholinergic receptor. Thus, it appears that the observed SCP_B effects on the GWR are mediated via this cholinergic mechanism. Experiments are in progress to test the interaction of the central excitatory and peripheral inhibitory effects of SCP_B on this preparation with the CNS attached.

210.16 PHYSIOLOGICAL ACTIONS OF PROCTOLIN IN THE VENTILATORY SYSTEM OF CRAYFISH AND LOBSTER. V.M. Pasztor, R. Katz*, S. Weizner* and B.M.H. Bush. Biology Department, McGill University, Montréal, Canada, and Physiology Department, Bristol University, England

Proctolin-like immunoreactivity has been demonstrated in both motor and sensory neurons of the lobster ventilatory appendage, (collaborative work with K.K. Sewicki). Several motor axons to ventilatory muscles stain for proctolin as do afferent fibers and the peripheral dendritic arbor of the oval organ, a mechanoreceptor subserving ventilation. This finding suggests that the 75-90 nm dense cored vesicles seen earlier in electron micrographs of neuromuscular synapses on ventilatory muscles (Moody-Corbett and Pasztor. J. Neurobiol. 11, 1980) and of oval organ sensory endings (Pasztor, Zoomorphol. 193, 1979) contain proctolin.

Motor effects. Both central and peripheral motor effects resulted from proctolin application. When injected into intact crayfish it caused acceleration in ventilatory beat frequency and increased beat amplitude. These excitatory effects were confirmed by recording from ventilatory motor roots of isolated perfused subesophageal ganglia. Proctolin initiated rhythmical motor output in quiescent preparations and caused both decreased burst cycle periods and recruitment of motorneurons in active ganglia. Bath applied proctolin (10^{-7}M) produced 20-40% potentiation of contractions from semi-isolated coxal levator muscles in response to electrical stimuli delivered to the motor nerve in a simulated ventilatory pattern. No increase in the duration of contraction was observed nor any change in amplitude or shape of junctional potentials. Bishop et al. (Soc. Neurosci. Abst. 10, 151, 1984) report similar findings for crayfish abdominal flexor neuromuscular preparations.

Sensory effects. Afferents from the oval organ carry both impulses and graded potentials to the neuropil (Pasztor and Bush, Science 215, 1982). Responses to stretch stimuli were enhanced after 10^{-8}M Proctolin application, involving changes in receptor potential amplitude and spiking threshold.

210.17 GAMMA-AMINOBUTYRIC ACID INHIBITS THE POTASSIUM-STIMULATED RELEASE OF SOMATOSTATIN-LIKE IMMUNOREACTIVE SUBSTANCE FROM RAT SPINAL CORD SLICES. M.R. Vasko, S. Cartwright*, and V. Harris*. VA Med.Ctr., Univ. Texas Hlth. Sci. Center, Dallas, Texas 75216

Although somatostatin is localized, in part, in primary afferent neurons that synapse in the dorsal horn of the spinal cord, few studies have been performed to determine the regulation of somatostatin release from the spinal cord. Since gamma-aminobutyric acid (GABA) receptors have been localized on afferent nerve terminals in the dorsal horn, we studied whether GABA would affect the potassium (K+)-stimulated release of somatostatin-like immunoreactive substance (SOLI) from rat spinal cord slices.

Male Sprague-Dawley rats (250-400g) were decapitated and a 2 cm segment of lumbosacral spinal cord was removed, chopped into 0.5x0.5 mm pieces, weighed, placed in a perfusion chamber at 37°C and perfused with oxygenated Krebs-bicarbonate solution (0.5ml/min) containing BSA (0.5%), bacitracin (20μM) and dithiothreitol (6μM). To evoke SOLI release, 50mM KCl was substituted for equimolar NaCl for 8 mins during the perfusion. Drugs were administered starting 4 to 6 mins prior to 50mM KCl and throughout the high K+ period. Perfusates were collected every two minutes into glass test tubes, extracted through octadecylsilylsilica cartridges (Sep-Pak), lyophilized and assayed for SOLI using radioimmunoassay. The anti-serum for somatostatin did not cross react with numerous other peptides and the assay was not affected by any drug manipulations. Serial dilution of spinal perfusate resulted in a linear decrease in assayable substance suggesting that a non-specific contaminant was not released from the spinal cord tissue.

Exposure of spinal tissue to 50mM KCl resulted in a significant increase in release of SOLI from a basal level of 0.15 pg/min/mg tissue to 0.43 pg/min/mg tissue (n=14, $p<.001$). This evoked release (2.8 pg/mg tissue/10 min; defined as released during 10 min period after exposure to 50mM KCl minus the 10min period prior to exposure to 50mM KCl) was calcium dependent since exposure of tissue to high extracellular K+ in perfusate containing 0mM calcium and 3mM EGTA did not increase release of SOLI. GABA (10^{-5}M) did not alter basal release but significantly ($p<0.01$) reduced evoked release from 2.84 ± 0.38 pg/mg tissue/10 min to 1.07± 0.15 pg/mg tissue/10 min(n=10). A lower concentration of GABA (10^{-6}M) also reduced evoked release (1.92± 0.63 pg/mg/10min;n=4)but this reduction was not statistically significant. Bicuculline(10^{-5}M)did not antagonize the GABA induced inhibition of SOLI release. Evoked release in tissues exposed to bicuculline and GABA was 0.78 ± 0.12 pg/mg tissue/10 min (n=6).

These results suggest that GABA-containing neurons in the spinal cord may be important in regulating somatostatin release. Furthermore, since the GABA induced inhibition of SOLI release appears to be bicuculline insensitive, the GABA effect may be mediated by GABA-B receptors. (Supported by the Veterans Administration)

210.18 HORMONAL ACTIONS OF BAG CELLS AND NEUROPEPTIDES ON THE ARTERIAL SYSTEM OF APLYSIA. S.H. Ligman*, E.D. Tripp* and P.H. Brownell (SPON: M.I. Schimerlik). Dept. of Zoology, Oregon State University, Corvallis, OR 97331.

One component of the complex physiological response associated with egg-laying behavior in Aplysia californica may be a prolonged change in the pattern of blood circulation. In innervated, semi-intact preparations of the pericardial organs and major arteries, we found that stimulated bursts of bag cell activity increased periodic contractions of the gastroesophageal (GE) and anterior (Ant) arteries without affecting the abdominal artery. Arterial vasoconstriction lasted 30 to 90 min and appeared to be mediated by hormonal action of a transmitter(s) released from bag cell neurons. Since bag cells discharge just prior to ovulation in Aplysia, the induced pattern of vasoconstriction may function to alter circulation in accordance with tissue-specific metabolism during egg-laying.

The bag cells synthesize and release several peptides which may mediate the vasocontractile response of the GE and Ant arteries. To identify the transmitters involved, we attached 2-4 cm sections of the arteries to a tension transducer and immersed the tissue in mineral oil, thereby reducing the perfusion volume to a thin aqueous layer surrounding the artery. The artery was then perfused by a continuous stream (170 ul/min) of aerated, buffered seawater into which small volumes (80 ul) of transmitters could be introduced without interrupting flow. Our preliminary results indicate that oil-immersed arteries respond to acetylcholine (10 uM) and serotonin (100 nM) in the same manner observed by others. Additionally, we observed that brief (20-30 sec) exposures of the arteries to alpha bag cell peptide (10-30 uM threshold) had a stimulatory effect on contractile activity, while another endogenous peptide, FMRF-amide (10-300 nM threshold), inhibited contractions. These pharmacological studies of the isolated arteries suggest that some neuropeptides act directly on vascular muscle, and that artery-specific actions of peptide transmitters may regulate the pattern of blood flow during egg-laying. Supported by NIH grant NS18681.

210.19 EFFECTS OF ∝-BCP AND FMRF-NH_2 ON RESPIRATORY AND VASCULAR MOTOR SYSTEMS IN APLYSIA. J.L.M. Morgan*, S.H. Ligman*, and P.H. Brownell. Dept. of Zoology, Oregon State University, Corvallis, Oregon 97331.

Neurons in the abdominal ganglion of Aplysia californica synthesize and release several neuropeptides including the cardioactive peptide FMRF-NH_2 and bag cell peptides ELH and ∝-BCP. These putative transmitters affect the activities of identified neurons in the ganglion but the behavioral significance of these neuronal actions is undetermined. To investigate possible behavioral functions, we used a semi-intact preparation of branchial (gill and siphon) and pericardial (heart, kidney and major arteries) organs innervated by the abdominal ganglion. With this preparation, it is possible to record the responses of motor neurons and the organs they regulate while infusing small quantities of peptides into the ganglionic vasculature.

Preliminary studies using this system indicate that ∝-BCP (0.7-10.0 uM) strongly inhibits most of the motor neurons innervating the gill (L7, L9gl,2, LDgl,2, RDg) and siphon (LDsl,2,3, LBsl,2,3), but does not affect siphon motor neuron RDs. These inhibitory effects are similar to the inhibition observed following afterdischarge of the bag cell system suggesting that -BCP is the transmitter that mediates this component of the response. Inhibition of gill and siphon motor neurons by ∝-BCP was correlated with changes in the pattern of spontaneous gill and siphon contractions (respiratory pumping) mediated by these cells. In contrast to these inhibitory actions, ganglionic infusion of FMRF-NH_2 (0.1-10.0 uM) uniformly excited all of the gill motor neurons and caused tonic contraction of the gill.

The arterial vasoconstrictor motor neurons, LBvcl,2,3, were strongly inhibited by FMRF-NH_2 and ∝-BCP, but this neuronal response was not correlated with changes in arterial tonus. Other studies (Ligman et al., this volume) suggest these transmitters also act directly on vascular muscle. Together, these studies indicate that motor neurons are common targets of neuropeptide transmitters in the abdominal ganglion, but that the behavior of organs innervated by these cells are not always directly related to these central actions. Supported by NIH grant NS18681.

CATECHOLAMINES: DOPAMINE RECEPTORS II

211.1 A NEUROCHEMICAL ASSAY FOR DOPAMINE AUTORECEPTOR AGONIST ACTIVITY USING RESERPINIZED MICE. C.B. Davis*, R.P. Shank, G.E. Martin (SPON: P.E. Setler) Department of Biological Research, McNeil Pharmaceutical, Spring House, PA 19477-0776.

The concept of dopamine autoreceptors has been confirmed by numerous laboratories. There are receptors on dopaminergic neurons from the nigro-striatal pathway which, when activated, function to decrease the synthesis and release of dopamine. It is possible that selective dopamine autoreceptor agonists may serve a therapeutic value as antipsychotics. We have developed a neurochemical procedure to test for dopamine autoreceptor agonist activity using a reserpinized mouse model. Our assay is based on the ability of dopamine autoreceptor agonists to inhibit the synthesis of DOPA in striatal tissue. Reserpine (5.0 mg/kg i.p.) is administered 18 hours prior to administration of the test compound. Thirty minutes after the test compound a DOPA decarboxylase inhibitor, NSD-1015 (100.0 mg/kg i.p.) is administered. In between the test compound and the NSD-1015 injections, the mice are observed for behavioral effects that are indicative of potential postsynaptic effects. The mouse is sacrificed by cervical dislocation 45 minutes post NSD-1015. The striatum is excised and homogenized in 2% perchloric acid. Analysis of DOPA is performed by HPLC using electrochemical detection.

The content of DOPA in striatum of control mice (which received reserpine, saline and NSD-1015) was 13.9 ±2.69 pmol/mg tissue (n=48) which is approximately 100 times the amount of DOPA in untreated mice. The maximum inhibition of DOPA accumulation by dopamine autoreceptor agonists was 80-90%. The ED_{50} value is the dose at which 50% inhibition of DOPA accumulation is achieved. ED_{50} values were generated for seven compounds known to be active at dopamine autoreceptors. These compounds and their ED_{50} values are: apomorphine (0.102 mg/kg i.p.); n-propyl norapomorphine (0.0028 mg/kg i.p.); EMD 23448 (0.227 mg/kg i.p.); (+)-3PPP (2.68 mg/kg i.p.); (+)-3PPP (5.63 mg/kg i.p.); (-)-3PPP (4.85 mg/kg i.p.); and (+)-PHNO (0.0066 mg/kg i.p.). Pentobarbital and phenobarbital, compounds which are not known to be dopamine autoreceptor agonists, were active in this test. The compounds that were inactive in our assay include haloperidol (0.2 mg/kg i.p.); proglumide (10.0, 40.0 mg/kg i.p.); d-amphetamine (4.0 mg/kg i.p.); morphine (16.0 mg/kg i.p.); clonidine (1.0 mg/kg i.p.); SKF 38393A (1.0, 3.0, 10.0 mg/kg i.p.); THIP (10.0 mg/kg i.p.); quipazine (1.0 mg/kg i.p.); and SCH 23390(0.3,1.0,3.0,10.0 mg/kg i.p.). Dopamine autoreceptor agonist activity for compounds that are active can be confirmed by using a D-2 antagonist such as haloperidol to reverse inhibition of DOPA accumulation. The apparent activity of pentobarbital and phenobarbital was not reversed by haloperidol indicating that these compounds are not direct-acting autoreceptor agonists.

211.2 ROBUST MODULATION OF ^{3}H-DOPAMINE RELEASE FROM RAT STRIATAL SLICES BY D-2 DOPAMINE RECEPTORS. Linda P. Dwoskin* and Nancy R. Zahniser (SPON: N. Weiner). Dept. Pharmacol., Univ. Co. Hlth. Sci. Ctr., Denver, CO 80262.

It has been difficult to demonstrate D-2 dopamine (DA) receptors that modulate stimulated release of ^{3}H-DA in rat striatal slices. The effect of a selective D-2 receptor agonist, pergolide (PERG), and antagonist, S-sulpiride (SUL), were systematically studied at different rates and durations of electrical stimulation both in the absence and presence of the DA uptake inhibitor nomifensine (NOMI). We now report that robust modulation of the stimulated release of ^{3}H-DA by D-2 DA receptors from rat striatal slices depends on the stimulation parameters used as well as whether or not an uptake blocker is included.

Electrical stimulation of rat striatal slices prelabeled with ^{3}H-DA produced a calcium-dependent increase in transmitter overflow. The amount of ^{3}H-DA released by 15 pulses of electrical stimulation was not dependent on the frequency of stimulation (0.25-3.0 Hz). In contrast, highly significant positive correlations were obtained between the total number of pulses (6-300) applied and the amount of tritium released. NOMI (10 uM) increased ^{3}H-DA release at each level of stimulation without affecting spontaneous release. PERG produced a dose-dependent inhibition of stimulation-evoked ^{3}H-DA release and was maximally effective at 30 nM. The inhibition produced by 30 nM PERG was greater when low numbers of pulses were delivered and in the absence of NOMI. PERG (30 nM) in the absence of NOMI completely blocked tritium overflow evoked by 15 pulses and inhibited overflow evoked by 60 pulses to 6.5±5% of control and that evoked by 300 pulses to 34±5%. In the presence of NOMI, overflow was inhibited to 47±6%, 80±4% and 76±10% of control at 15, 60 and 300 pulses, respectively. SUL produced a dose-dependent potentiation of stimulated ^{3}H-DA release and again was most efficacious at low levels of stimulation but, in contrast to the agonist, in the presence of NOMI. At a maximally effective concentration of SUL (1 uM) in the presence of NOMI, ^{3}H-DA release evoked by 15 pulses was stimulated by 370±50% over control while that evoked by 300 pulses was stimulated by 210±4%. In the absence of NOMI, increases of 200±60% and 150±10% were observed at 15 and 300 pulses, respectively. Interpretations are (1) higher synaptic concentrations of DA achieved at higher stimulation frequencies and in the presence of NOMI account for the reduced efficacy of the agonist, but that a low level of DA must be present in the synaptic cleft for the antagonist to be most efficacious; (2) D-2 receptors are most effective during periods of low stimulation. The results underscore the importance of the selection of the experimental conditions for studying D-2 receptor modulation of DA release from rat striatal slices. (Supported by grants AM 07391 and NS 09199)

211.3 DEPLETION OF ENDOGENOUS DOPAMINE CAN ENHANCE THE INHIBITION OF STIMULATION-EVOKED RELEASE OF ^{3}H-DOPAMINE FROM RAT STRIATAL SLICES BY D-2 DOPAMINE RECEPTOR AGONISTS. Nancy R. Zahniser and Linda P. Dwoskin*. Department of Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262.

We have observed that pergolide, a D-2 dopamine (DA) receptor agonist, causes a greater inhibition of electrically-stimulated release of ^{3}H-DA from rat striatal slices when low levels of stimulation and no uptake blockers are used. One explanation of these data is that D-2 receptor agonists appear more efficacious if the concentration of endogenous DA in the synapse is low. Thus, it was expected that if endogenous DA were depleted, pergolide would produce an inhibition of ^{3}H-DA release of greater magnitude as compared with control tissue for any given stimulation. In order to test this hypothesis, rats were treated 16 hr before sacrifice with alpha-methyl-p-tyrosine methyl ester HCl (AMPT; 300 mg/kg, i.p.) to deplete endogenous DA levels. This treatment produced an 85% decrease in the striatal DA concentration (control: 8.5 ± 0.43 ug/g tissue; treated: 1.3 ± 0.10). Modulation of electrically-stimulated ^{3}H-DA release by a maximally effective concentration of pergolide (30 nM) was measured in the absence and presence of nomifensine (10 uM) in striatal slices from control and treated animals. Despite the profound decrease in DA levels following AMPT treatment, ^{3}H-DA was taken up and released in response to stimulation to essentially the same extent by the slices from both groups of animals. When 60 pulses (1 Hz) were used to stimulate ^{3}H-DA release in the absence of nomifensine, the inhibition of release produced by pergolide was close to maximal in slices from both control (6.6 ± 4.7% of stimulated release, N = 4) and AMPT-treated animals (17 ± 5.7%, N = 3). In contrast, in the presence of nomifensine, the maximal inhibition produced by pergolide following AMPT treatment was twice that produced in control slices (control: 80 ± 4.2% of stimulated release, N = 4; AMPT: 43 ± 2%, N = 3). With 300 pulses (5 Hz) there was approximately 3-fold more ^{3}H-DA released during the stimulation period. In this case, however, no significant differences were observed in the control versus the AMPT-treated slices whether nomifensine was absent (control: 35 ± 3.7% of stimulated release, N = 4; AMPT: 45 ± 4.2%, N = 5) or present (control: 80 ± 8.2%, N = 4; AMPT: 73 ± 12%, N = 5). The greater inhibition of release by pergolide in the AMPT treated animals at 60 pulses in the presence of nomifensine suggests that lower levels of endogenous DA remained in the synapse in the slices from the AMPT-treated animals. This is consistent with the idea that D-2 receptor agonists produce a greater inhibition of ^{3}H-DA release if the concentration of DA in the synaptic cleft is low. (Supported by grants NS 09199 and AM 07391)

211.4 EFFECTS OF SELECTIVE DOPAMINE AGONISTS ON SUBSTANTIA NIGRA PARS RETICULATA ACTIVITY ARE INCONSISTENT WITH EXCLUSIVE MEDIATION OF DOPAMINE POSTSYNAPTIC EFFECTS BY D-2 RECEPTORS. B.G. Weick and J.R. Walters. NINCDS, NIH, Bethesda, MD 20205.

The substantia nigra pars reticulata (SNpr) is one of the major output nuclei of the basal ganglia complex. Dopamine (DA) neurons are in a position to influence SNpr neurons by indirect effects mediated through the striatum and direct effects mediated through release of DA from DA dendrites which extend into the SNpr. In earlier investigations, the mechanism of the modulation of basal ganglia output by DA and drugs which interact with DA receptors has been explored by observing the changes in tonic activity in the SNpr produced by DA receptor stimulation[1,2,3]. In normal rats, systemically administered apomorphine (APO), presumably acting through both direct and indirect mechanisms, induces variable changes in the tonic activity of SNpr neurons[1]. In rats with supersensitive DA receptors due to 6-hydroxydopamine (6-OHDA) induced lesions of the substantia nigra pars compacta (SNpc) DA neurons, systemic APO consistently induces a decrease in SNpr activity[2]. Iontophoresed DA, on the other hand, increases the activity of about 50% of the SNpr neurons and very consistently attenuates the inhibitory actions of GABA on these cells in normal rats[3]. Most of these effects have been presumed to be mediated by postsynaptic D-2 receptors. In the present study, the nature of the DA receptors mediating these effects has been investigated using DA agonists selective for the D-1 and D-2 DA receptor subtypes.

Extracellular, single unit activity of SNpr neurons was monitored in rats which were either anesthetized with chloral hydrate or paralyzed, artificially respired and locally anesthetized. Although APO and the D-2 agonist, LY 171555, have been shown equipotent at inhibiting the activity of the SNpc DA neurons[4], neither LY 171555 (1.0 umol/kg, i.v., n=11) nor the selective D-1 agonist, SKF 38393 (35.0 umol/kg, i.v., n=11), produced, in normal rats, the magnitude of variability of SNpr responses comparable to that induced by APO (1.0 umol/kg). As seen in behavioral studies, a high dose of SKF 38393 (35 umol/kg, n=11) did induce changes in SNpr activity like those of APO (1 umol/kg) in 6-OHDA lesioned rats (10-12 weeks). Activity was reduced 40 and 57% 5 to 10 min after SKF 38393 and APO, respectively. However, in the DA supersensitive rat, neither 1.0 umol/kg (n=12) nor 4.0 umol/kg (n=7) LY 171555 induced decreases in SNpr activity.

When iontophoretically applied, LY 171555 was considerably more potent than SKF 38393 at inhibiting the activity of SNpc DA cells, and, like DA[3], frequently increased activity and consistently attenuated the effects of iontophoretically applied GABA on SNpr cells. However, SKF 38393 also increased rate and modulated the effects of GABA on some SNpr cells. The results indicate that classic D-2 receptors do not exclusively mediate the effects of systemic APO and iontophoretic DA on SNpr cells.

211.5 INVESTIGATION OF PHARMACOLOGICAL DIFFERENCES BETWEEN RAT SUBSTANTIA NIGRA DOPAMINE AUTORECEPTORS AND POSTSYNAPTIC D-2 DOPAMINE RECEPTORS. J.H. Carlson, D.A. Bergstrom and J.R. Walters. NINCDS, Bethesda, MD 20205 and George Washington University Dept. of Pharmacology, Washington, D.C. 20037.

Dopamine (DA) agonists inhibit substantia nigra pars compacta (SNpc) DA neuronal firing and stimulate globus pallidus (GP) activity. These effects are believed mediated by pre- and postsynaptic DA receptors, respectively. Both these receptor types have been postulated to be of the D-2 subtype, as the D-1 agonist, SK&F 38393, does not alter tonic SNpc or GP activity. To compare the pharmacological characteristics of pre- and postsynaptic D-2 receptors, the effects of the DA agonists, apomorphine (APO) and pergolide, and the selective D-2 agonists, LY 171555 and RU 24926, on SNpc and GP activity were examined utilizing extracellular, single unit recording techniques.

The 4 DA agonists were comparably efficacious and potent in inhibiting SNpc DA neuronal firing in chloral hydrate anesthetized rats. Each agonist caused a dose-dependent, haloperidol-reversible, complete inhibition of cell firing. The ED_{50}'s for i.v. APO, pergolide, LY 171555 and RU 24926 were 22±6, 25±4, 25±5 and 28±4 nmol/kg, respectively (n=8-12).

As an index of postsynaptic DA receptor stimulation, GP neuronal activity was recorded in gallamine-paralyzed, locally anesthetized, artificially respired rats. We have previously shown that APO and d-amphetamine induce dose-dependent, haloperidol-reversible increases in GP activity, while drugs such as l-amphetamine, clonidine, LSD and SK&F 38393 induce minimal changes. Like APO; pergolide, LY 171555 and RU 24926 caused dose-dependent, haloperidol-reversible excitation of GP activity. However, in the GP, the dose-response curve slopes and maximal efficacies of APO and pergolide were significantly greater than those of the selective D-2 agonists. APO and pergolide were of similar efficacy, inducing maximal rate increases of 113 and 165% (n=6-18), respectively; the D-2 agonists LY 171555 and RU 24926 induced significantly lower maximal rate increases of only 62 and 54% (n=6-14), respectively.

Since APO and pergolide interact with both D-1 and D-2 receptors, it seemed possible that their greater effects on pallidal activity could be due to their stimulation of both receptor subtypes, even though D-1 receptor stimulation alone is without effect on GP activity. However, coadministering SK&F 38393 with LY 171555 did not significantly enhance the excitatory effects of LY 171555. Moreover, coadministration of LY 171555 and APO did not attenuate the effects of APO, indicating that LY 171555 is not acting as a partial agonist at postsynaptic sites. In addition, pretreatment with 0.3 μmol/kg LY 171555 did not attenuate the effects of 1.0 μmol/kg APO as low doses of APO have been shown to do.

These results suggest that the effects of APO and pergolide (and d-amphetamine) on GP activity may involve, in part, interactions with haloperidol-sensitive receptor sites which may be pharmacologically different from the receptors which mediate the effects of the D-2 agonists. These sites appear dissimilar to the D-2 autoreceptors mediating the inhibitory effects of DA agonists on SNpc neurons.

211.6 DOPAMINE AUTORECEPTOR REGULATION OF STRIATAL TYROSINE HYDROXYLASE. K.S. Strait* and R. Kuczenski (Spon: D. Schmidt) Tennessee Neuropsychiatric Institute and Dept. of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN 37232.

Tyrosine hydroxylase (TH), isolated from striatal synaptosomes, exhibits biphasic Lineweaver-Burke kinetics for its tetrahydrobiopterin cofactor (BH_4), consistent with multiple K_m forms of the enzyme. Incubation of striatal synaptosomes with forskolin (EC_{50} 0.47 μM), or db cAMP (EC_{50} 1.3 mM), results in activation of TH, isolated from these synaptosomes, via conversion of the enzyme to a single low K_m form (K_m 40 μM). The activation of synaptosomal TH by forskolin or db cAMP is not additive and is similar to activation seen with cAMP dependent protein kinase phosphorylation of purified TH (Vulliet et al. PNAS 77, 92, 1980). The addition of dopamine (IC_{50} 1.0 μM) (with nomifensine and pargyline), or apomorphine (IC_{50} 30 nM), to the synaptosomal incubation medium blocks the activation of TH by forskolin. This effect of dopamine and apomorphine can in turn be blocked by preincubation of the synaptosomes with the dopamine receptor antagonists haloperidol (IC_{50} 4.5 nM), or chlorpromazine (IC_{50} 50 nM). In contrast to the forskolin data above, dopamine failed to block the activation of TH by db cAMP. Similarly, addition of dopamine to the TH assay, in amounts equivalent (as measured by HPLC) to that carried over from the synaptosomal incubation with the TH, had no effect on forskolin activated enzyme. The observations that dopamine and apomorphine can block forskolin activation of TH, that this blockade can in turn be prevented by preincubation with haloperidol or chlorpromazine, and that the amount of dopamine required for blockade of forskolin activation in synaptosomes has no effect on TH when added to the enzyme assay, supports the existance of a presynaptic dopamine receptor (autoreceptor), which regulates the activity of TH by altering the enzyme's K_m for its BH_4 cofactor, probably through a decrease in the phosphorylation state of the enzyme. Failure of dopamine to block db cAMP activation of TH suggests that, if forskolin and db cAMP activate TH through identical changes in phosphorylation state, then autoreceptor regulation of TH must occur through a decrease in cAMP levels. The autoreceptor could accomplish this decrease in cAMP through negative coupling to adenylate cyclase, or stimulation of phosphodiesterase activity, or both. 211.7 INTERACTIVE EFFECTS OF D-1 AND D-2 DOPAMINE RECEPTOR BLOCKADE IN VIVO. C. F. Saller and A. I. Salama. Dept. of Pharmacology, Stuart Pharmaceuticals, Div. of ICI Americas Inc., Wilmington, DE 19897.

The possible interactive effects of D-1 and D-2 dopamine (DA) receptor blockade in vivo were assessed by measuring the concentrations of the two major DA metabolites: 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), in rat striatum. We had previously found that the D-1 agonist SKF 38393 attenuates the decrease in DOPAC and HVA elicited by D-2 agonists and potentiates the increase in these two DA metabolites produced by D-2 receptor blockade (Saller and Salama, Eur. J. Pharmacol., 109:297-300). We report here that the D-1 antagonist SCH 23390 can attenuate the effects of D-2 blockade on striatal DOPAC and HVA concentrations. Thus, very low doses of SCH 23390 (< 1 µg/kg, i.p.), injected 30 min. prior to sacrifice, attenuated the increase in DOPAC and HVA produced by either haloperidol or spiperone (100 µg/kg, i.p.), injected 60 min. before SCH 23390. SCH 23390 also attenuated the increase in plasma prolactin concentrations produced by haloperidol. Therefore, these observations, along with other in vitro data (Salama and Saller, this meeting), suggests that a functionally important interaction exists between D-1 and D-2 DA receptors.

211.8 INTERACTIVE EFFECTS ON D-1 AND D-2 DOPAMINE RECEPTOR BLOCKADE IN VITRO. A. I. Salama and C. F. Saller. Dept. of Pharmacology, Stuart Pharmaceuticals, Div. of ICI Americas Inc., Wilmington, DE 19897.

Several studies have suggested that a functional interaction exists between striatal D-1 and D-2 dopamine (DA) receptors. For example, D-2 receptor stimulation by LY 141865 can antagonize the effects of D-1 receptor stimulation (SKF 38393) on adenylate cyclase activity (Stoof and Kebabian, Nature, 294:366, 1981). These observations have been extended to demonstrate that low concentrations of haloperidol (< 25 µM), a D-2 DA receptor antagonist, enhanced the stimulation of adenylate cyclase activity produced by SKF 38393 in striatal membrane preparations. No enhancement was observed when DA, which stimulates both D-1 and D-2 receptors, was used to stimulate adenylate cyclase activity. Haloperidol (< 10 µM) also potentiated the K^+-evoked release of ^{3}H-Ach from superfused striatal tissue slices. Both of these effects of haloperidol were blocked by low (nM) concentrations of the D-1 antagonist SCH 23390. In addition, SCH 23390 reduced the ability of haloperidol to antagonize the inhibition of ^{3}H-Ach release produced by the DA agonist apomorphine. By itself, SCH 23390 did not affect either basal adenylate cyclase activity or K^+-evoked release of Ach. These findings suggest that D-1 receptor blockade may attenuate the response to D-2 DA receptor blockade (refer to abstract by Saller and Salama, this meeting, for in vivo effects).

211.9 A NEW D-1 SELECTIVE RADIOLIGAND FOR AUTORADIOGRAPHY: SKF-83566. Sally J. Boyson[1,2], Kathryn E. Flaim[3*], and Perry B. Molinoff[1]. Departments of Pharmacology[1] and Neurology[2], University of Pennsylvania School of Medicine, Philadelphia, PA 19104; and Smith Kline and French Labs[3], Philadelphia, PA 19101.

Binding characteristics of (N-methyl-^{3}H)-R-7-bromo-8-hydroxy-3-methyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine (SKF-83566), including its high affinity and selectivity for the dopamine-1 (D-1) receptor, were described by Flaim et al. (FASEB Abstract 8305, 1985). We now report the use of (^{3}H)-SKF-83566, with a specific activity of 85 Ci/mmol, in quantitative autoradiographic studies of the distribution of the D-1 receptor in rat brain. Autoradiographic images were analyzed on an IBM-based image processing system. Kinetic parameters of the binding of (^{3}H)-SKF-83566 to 32 µ slices of a mash made by homogenization of the striata from several rats and to 32 µ coronal sections through the striatum of individual rats were similar. Slices of striatal mash were therefore used to define pharmacologic parameters. The binding of (^{3}H)-SKF-83566 (0.1-2.0 nM) to slices incubated in buffer (50 mM Tris, 10 mM $MgSO_4$, 2 mM EDTA, 154 mM NaCl; pH 7.4) at 37°C reached equilibrium by 80 minutes. A wash in buffer at 4°C for 20 minutes reduced nonspecific binding to less than 3% of total binding. Scatchard analysis of saturation curves determined in both mash slices and coronal sections yielded a K_d of 1.0 nM and a B_{max} of approximately 4,000 fmol/mg protein in the striatum. K_d values calculated by the method of Cheng and Prusoff from IC_{50} values determined in the presence of 0.2-0.3 nM (^{3}H)-SKF-83566 were as follows: SCH-23390, 0.80 nM; spiroperidol, 500 nM; (+)-butaclamol, 15 nM; (-)-butaclamol, 45 µM; sulpiride, 70 µM; ketanserin, 300 nM; and propranolol, 250 µM. Serial coronal sctions of rat brain were incubated in 1.7 nM (^{3}H)-SKF-83566, washed, and apposed to LKB ultrofilm for one week to determine the distribution and densities of D-1 receptors. The highest densities of the D-1 receptor were found in the caudate-putamen, nucleus accumbens, olfactory tubercle, substantia nigra, and structures in the third and fourth ventricles. Moderate densities were found in several nuclei of the septum and amygdala, the subthalamic nucleus, caudal hippocampus, zona incerta, endopeduncular nucleus, claustrum, and superior colliculus. D-1 receptors were present in all layers and regions of the cerebral cortex, but were most prominent in the auditory and entorhinal cortices, and layer 6 of the prefrontal and parietal cortices. There were no D-1 receptors detectable in the cerebellum or brainstem. (Sponsored by The Huntington's Disease Foundation and GM 34781)

211.10 COMPARISON OF THE DISTRIBUTION OF D-1 AND D-2 DOPAMINE RECEPTOR SUBTYPES IN RAT BRAIN USING QUANTITATIVE AUTORADIOGRAPHY. Paul McGonigle, Sally J. Boyson and Perry B. Molinoff. (SPON: Rodney B. Murray). Departments of Pharmacology and Neurology, University of Pennsylvania, Phila., Pa. 19104.

To help elucidate the different roles of D-1 and D-2 dopamine receptor subtypes in the regulation of movement and behavior, the anatomical distribution of these receptor subtypes in the same animals was measured. D-1 receptors were visualized with (^{3}H)-SKF-83566 (85 Ci/mmol) according to the method of Boyson et al. (Neurosci. Abst., 1985) and D-2 receptors were labelled with (^{3}H)-spiroperidol (77-100 Ci/mmol). Uniform sections of caudate-putamen mash were used to optimize the assay conditions for labelling D-2 receptors. Caudate-putamen mash provided a virtually unlimited number of homogeneous sections that contained a high density of D-2 receptors. These mash sections were incubated with the appropriate concentration of radioligand and drugs; washed, and then wiped off the glass slide for direct counting in a scintillation counter. Nonspecific binding was measured in the presence of 100 µM sulpiride. At 25°C, the binding of 0.3 nM (^{3}H)-spiroperidol reached equilibrium by 70 min. Washing the sections for 80 min. at 4°C following incubation reduced nonspecific binding to 30% of total binding. Scatchard analysis of the equilibrium binding of (^{3}H)-spiroperidol (0.05-3 nM) resulted in linear plots and yielded a K_d of 1 nM. At 0.3 nM (^{3}H)-spiroperidol, there was no detectable labelling of serotonin (5-HT2) receptors since the selective 5-HT2 antagonist ketanserin had a uniformly low affinity (IC_{50} = 3.5 µM) for these binding sites.

The distribution of D-1 and D-2 receptors was measured in adjacent 32 micron thick coronal and horizontal sections from a total of six rats. For the coronal maps, 38 sections corresponding to Paxinos and Watson (The Rat Brain in Stereotaxic Coordinates, Academic Press, 1982) plates 4 to 42 were examined. Similarly, horizontal sections corresponding to Paxinos and Watson plates 54 to 65 were studied. Sections labelled with 1.7 nM (^{3}H)-SKF-83566 or 0.3 nM (^{3}H)-spiroperidol were apposed to LKB ultrofilm for one to two weeks and then developed. Quantitative autoradiography with computer assisted densitometry was used to determine the densities of binding sites labelled with (^{3}H)-SKF 83566 or (^{3}H)-spiroperidol. The highest densities of both D-1 and D-2 receptors were measured in the caudate-putamen, nucleus accumbens, olfactory tubercle and substantia nigra. In contrast, relatively high densities of D-1 receptors but low densities of D-2 receptors were found in the subthalamic nucleus, the third and fourth ventricles, the superior colliculus, layer VI of the prefrontal cortex and the medial amygdaloid nucleus. Thus, these regions that exhibit markedly different densities of dopamine receptor subtypes represent promising targets for future study. (Supported by USPHS NS 07272 and GM 34781 and The Huntington's Disease Foundation)

211.11 IN VIVO BINDING OF THE NEUROLEPTIC [^{18}F]-N-METHYLSPIROPERIDOL TO HUMAN CAUDATE-PUTAMEN OVER TWELVE HOURS. C.D. Arnett, A.P. Wolf*, C.-Y. Shiue*, J.S. Fowler*, R.R. MacGregor*, and M. Smith*. Department of Chemistry, Brookhaven National Laboratory, Upton, NY 11973

As part of a program to evaluate positron-emitting radioligands for use in studying neurotransmitter receptors by positron emission tomography (PET), we have synthesized and studied several carbon-11 (Biol. Psychiat. 19:1365, 1984) and fluorine-18 (J. Neurochem. 44:835, 1985) labeled radioligands. The most promising of these compounds for imaging dopamine receptors in humans is [^{18}F]-N-methylspiroperidol (Life Sci. 36:1359, 1985).

This radioligand was synthesized from cyclotron-produced [^{18}F]fluoride in 2 h with a radiochemical yield of 10-15% and a specific activity greater than 10 Ci/μmol (EOB). Initial PET studies of this radioligand in normal human volunteers confirm our earlier conclusion as to its suitability for studying dopamine receptors in humans. Following intravenous administration of this compound, decay-corrected radioactivity in the caudate-putamen (a brain region which contains a high concentration of dopamine receptors) increased over a period of more than 4 h and did not decline for the entire 12 h duration of the study. This is consistent with essentially irreversible binding of this radioligand to dopamine receptors in vivo. By comparison, radioactivity declined rapidly in the cerebellum, a brain region which contains virtually no dopamine receptors. At times longer than 2 h after injection, the cerebellum radioactivity curve closely paralleled the blood plasma radioactivity curve. The very long retention of radioactivity in the human caudate-putamen suggests that very little metabolism of this compound takes place in this brain region. Rat studies demonstrated virtually no metabolism of this compound in the rat brain for up to 4 h (Life Sci. 36:1359, 1985).

Because fluorine-18 has a longer physical half-life than carbon-11 (109.8 min vs. 20.4 min), [^{18}F]-N-methylspiroperidol seems superior to N-[^{11}C]methylspiroperidol (Science 221:1264, 1983) for imaging dopamine receptors, since these results indicate that PET studies may need to be carried out for more than 2 h for good definition of in vivo kinetic constants. [^{18}F]-N-Methylspiroperidol thus appears to have fulfilled the basic requirements for a PET neuroreceptor radioligand of: (1) an appropriate radionuclide physical half-life, (2) a rapid radiochemical synthesis and purification to produce a high specific activity product, (3) a significant brain penetration following peripheral administration, (4) little metabolism within the brain during the study, (5) a highly specific distribution to the dopamine receptor, and (6) a slow dissociation from the receptor.

211.12 IN VIVO [H-3]SPIPERONE BINDING REQUIRES DOPAMINE. Diane C. Chugani*, Robert F. Ackermann and Michael E. Phelps. Department of Pharmacology and the Division of Nuclear Medicine and Biophysics, UCLA School of Medicine, Los Angeles, California, 90024, USA

In a previous experiment to determine whether dopamine competes with [H-3]spiperone ([H-3]SP) binding in rat corpus striatum in vivo, we performed unilateral substantia nigra electrical stimulation in order to increase dopamine release. Then left and right striatal [H-3]SP accumulations were compared after intravenous administration. We expected to find decreased [H-3]SP accumulation ipsilateral to the stimulation if dopamine does in fact compete with [H-3]SP. Paradoxically, we found increased, not decreased, ipsilateral [H-3]SP accumulation (Ipsilateral: 324 ±1.4 dpm/mg ±SEM, Contralateral: 286 ±3.2 dpm/mg ±SEM). We hypothesized that this in vivo accumulation of [H-3]SP was due to trapping in endocytotic vesicles following agonist-induced internalization of receptors. Increased dopamine release, according to this scheme, would result in increased [H-3]SP accumulation, as we observed. Depletion of dopamine, according to this scheme, should result in a large decrease in [H-3]SP accumulation in striatum. Therefore, we administered reserpine (5 mg/kg) to rats 24 hours before [H-3]SP injection in order to deplete dopamine in striatum. We sacrificed the rats 1 hour after [H-3]SP injection (250 μCi/kg, i.v.) and rapidly dissected striata and cerebella. The brain regions were homogenized in 10 volumes ethanol, and aliquots were counted. The reserpine treatment resulted in a large, significantly decreased [H-3]SP accumulation in striatum (Control: 271.7 ±5.4 dpm/mg ±SEM, Reserpine pretreatment: 143 ±6.4 dpm/mg ∓SEM, $p<.001$), and in one rat, [H-3]SP concentration in striatum fell to cerebellar levels (Striatum: 105 dpm/mg, Cerebellum: 108 dpm/mg); the cerebellum contains no dopamine receptors. This profound reduction in [H-3]SP binding following reserpine pretreatment supports our hypothesis that, in vivo, [H-3]SP is trapped in regions containing dopamine receptors through dopamine-mediated receptor internalization.

211.13 IN VIVO OBSERVATION OF REGIONAL ACTIVITIES OF FLUORINATED NEUROLEPTICS BY ONE DIMENSIONAL ^{19}F NMR ZEUGMATOGRAPHY. I. L. Kwee*, T. Nakada, and C. B. Conboy* (SPON: M. P. Remler). Neurochem. Res. Lab., VA Med. Ctr., Martinez, CA 94553 and Dept. of Neurology and NMR Facility, Univ. of California, Davis, CA 95616.

Local contents of fluorinated neuroleptics in rat brain were studied noninvasively in vivo using one-dimensional 19-fluorine (^{19}F) nuclear magnetic resonance (NMR) rotating frame zeugmatography. Adult Sprague-Dawley rats (200-300g) were given intraperitoneal injection of fluphenazine (20mg/kg), haloperidol (15mg/kg) or trifluoperazine (20mg/kg) four times at thirty minutes intervals. Subsequently, the animal was lightly anesthetized and placed in the NMR probe which contained a one turn oval (2.5 x 3.5 cm) surface coil centered over the rat calvarium. ^{19}F NMR signals were obtained using a spectrometer operating at 4.69T (Nicolet NMR System NT-200) at 188.2 MHz. Sets of free induction decays (FIDs) were obtained with consecutively incremented pulse width. Standard two dimensional Fourier transfomation of data sets provided sets of spectra representing regional contents of each compound. Activities of these fluorinated neuroleptics showed a similar differential distribution in the brain maximal in the deep structures presumably within the basal ganglia. These observations suggest the feasibility of performing studies of regional pharmacologic activities of fluorinated neuroleptics by means of ^{19}F NMR spectroscopic analysis and hence studies of regional neurotransmitter activities in vivo.

This work was supported by UCD grants D-1921 (ILK) and NMR-8540 (TN).

211.14 INTRASTRIATAL VARIATION IN DOPAMINE RECEPTOR DENSITY AS MEASURED BY IN VIVO BINDING OF N-PROPYLNORAPOMORPHINE. L.D. Loopuijt*, J.B. Sebens*and J. Korf* (SPON: ENA). Division of Biological Psychiatry, Psychiatric Clinic, Oostersingel 59, 9713 EZ Groningen, the Netherlands.

Neuroleptics exert their antipsychotic action by means of blockade of dopamine receptors, but occupy binding sites, that are different from those which are occupied by dopamine and its agonists. Since anatomical localization of receptors determine their function, we studied the localization of the dopamine agonist N-propylnorapomorphine (NPA) to compare our results with those obtained with neuroleptics. So we employed light microscopic autoradiography to localize (3H)NPA, that binds selectively to dopamine receptors under in vivo conditions (van der Werf,J.F. et al.,Eur. J. Pharmacol.,87(1983)259, Köhler, C. et al., Eur.J. Pharmacol.,72(1982)397.

Seven rats were injected into the tail vein with 200 uCi (3H)NPA, were sacrificed 1 h and 10 min later by decapitation. Brains were quickly removed and frozen, cryosections were cut, autoradiograms were prepared using Ilford G5 emulsion. Rats were divided into 3 groups: group 1 received 4 days before (3H)NPA injection reserpine (5mg/kg/day), group 2 received an injection of 6-hydroxydopamine (8ug) into the substantia nigra 3 weeks before (3H)NPA injection, group 3 received an intraperitoneal injection of haloperidol (2mg/kg) 30 minutes before (3H)NPA, and group 4 received only a (3H)NPA injection.

The autoradiograms, obtained in this way show a high silver grain density in the caudate-putamen, a moderate density in the olfactory tubercle and nucleus accumbens and a slight labeling in the frontal cortex. No detectable label was found in the substantia nigra, both compacta and reticulata nor in the hippocampus. The above mentioned labeling was absent after haloperidol treatment (group 3). The caudate-putamen showed a heterogeneous distribution of silver grains: the head of the caudate was most densily labeled dorsally, in more caudal direction the lateral part was heavily labeled, while at the level of the globus pallidus, the highest concentration silver grains was found more ventrally, adjacent to the claustrum. This intrastriatal distribution of label is present in animals with reserpine treatment, with 6-hydroxydopamine lesions as well as with single (3H)NPA injection. So this differential silver grain density does not represent the heterogeneous distribution of presynaptic receptors on nigral afferents nor a selective post-mortem release of endogenous dopamine in separate neuronal pathways. Presumably this striatal pattern is due to differences in postsynaptic dopamine receptor density.

211.15 D-1 AND D-2 DOPAMINE RECEPTOR QUANTITATIVE AUTORADIOGRAPHY USING [^{3}H]-N-PROPYLNORAPOMORPHINE. E. K. Richfield, A. B. Young and J.B. Penney. Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104.

A method of labelling both the D-1 and D-2 dopamine receptors in rat brain for analysis by quantitative autoradiography was developed. The dopamine agonist [^{3}H]-N-propylnorapomorphine (NPA) was selected because of its high affinity for dopamine receptors.

Twenty micron sections of rat brain were thaw mounted onto subbed microscope slides. Sections were pre-washed in 4°C buffer 2x5 min before incubation. Slides were incubated for 120 minutes in varying concentrations of [^{3}H]-NPA from 0.2 to 4.0 nM. The buffer used contained 50 mM sodium phosphate (pH 6.8), NaCl 65 mM, $CaCl_2$ 1 mM, $MgCl_2$ 1 mM, ascorbate 0.01%, and pargyline 1 μM. After incubation, slides were given 2x10 min washes in 4°C buffer, a 3 second dip in 4°C distilled water and fan dried.

Saturation studies revealed binding to a single site in striatum with a K_D of 0.62 nM and a B_{max} of 1.52 pmol/mg protein. This K_D value is similar to values seen in homogenate studies. The B_{max} value exceeds the number of sites reported for many homogenate assays using various tritiated dopamine agonists and exceeds the number of sites seen with tissue sections using labeled D-2 antagonists. This suggests that a high percentage of dopamine receptors are in the high affinity state in tissue sections and that [^{3}H]-NPA labels both D-1 and D-2 receptors.

Competition studies using nonselective dopamine agonists including dopamine and NPA, as well as a selective D-1 agonist SKF-38393 and a selective D-2 agonist LY171555 demonstrated curves with a Hill coefficient of one. This indicates that agonists may not be able to distinguish D-1 from D-2 receptors in tissue sections.

Competition studies using the selective dopamine antagonists sulpiride, domperidone, SCH-23390 and cis-flupenthixol demonstrated Hill coefficients less than one and had biphasic curves. Thus, use of appropriate concentrations of domperidone or sulpiride allowed selective studies of the high affinity D-1 receptor, while appropriate concentrations of SCH-22390 allowed the high affinity D-2 receptor to be studied. The approximate ratio of D1:D2 receptors in striatum was 30:70.

The advantage of using quantitative autoradiography to study dopamine receptors is the ability to study the relationship between D-1 and D-2 receptors in multiple brain regions innervated by dopamine and to correlate changes in receptors with other studies using tissue sections such as ^{14}C-deoxyglucose determination of regional metabolic activity. In addition, properties of the high affinity state of both the D-1 and D-2 sites can be studied directly and correlated with other properties of dopamine function.

211.16 DOPAMINE D_1 AND D_2 RECEPTOR INTERACTIONS.

A. Dumbrille-Ross, H.B. Niznik and P. Seeman
Pharmacology Dept., Univ. of Toronto, Toronto, CANADA M5S 1A8

Biochemical and electrophysiological studies have shown that dopamine D_1 and D_2 receptors have opposing roles. Although some in vivo studies suggest an interaction between the D_1 and D_2 receptors, it is not known whether different nerve cells or the same neuron is involved in this interaction.

1) We studied the in vitro effects of the D_2 agonist N-propylnorapomorphine (NPA) and the D_2 antagonist spiperone on the binding of the agonist ^{3}H-SKF-38393 to D_1 receptors. Canine caudate nucleus was used. The receptor density (B_{max}) and dissociation constant (K_D) were determined by Scatchard analysis.

The density of the D_1 agonist ^{3}H-SKF-38393 increased by about 60% from 14 to 23 fmoles/mg wet tissue in the presence of 0.1 nM NPA; the K_D was also increased. The B_{max} decreased about 50% in the presence of 0.1 nM spiperone.

2) We also examined in vitro effects of the specific dopamine D_1 agonist SKF-38393 and the antagonist SCH-23390 on the binding of the D_2 agonist ^{3}H-NPA to D_2 receptors. The density of D_2 agonist ^{3}H-NPA sites increased about 20% from 13 to 15 fmoles/mg tissue when incubated in the presence of 0.1 nM SCH-23390; it decreased by about 25% in the presence of SKF-38393.

These results suggest that dopamine D_1 agonists decrease agonist binding to D_2 receptors, and that D_2 agonists increase agonist binding to D_1 receptors. Intact neurons may further enhance this interaction.

211.17 PERIPHERAL DOPAMINE RECEPTORS ARE INVOLVED IN THE REGULATION OF ALDOSTERONE PRODUCTION. C. Missale, P. Liberini*, M. Pizzi*, M. Memo, M.O. Carruba*, P.F. Spano. Inst. of Pharmacol. Exp. Ther. Sch. of Med., Univ. of Brescia; Dpt. of Pharmacol., Chemiother., Med. Toxicol., Univ. of Milano, Italy.

There is growing evidence for an influence of dopamine on adrenal glomerulosa production of aldosterone. This effect has been suggested to be mediated by peripheral dopamine receptors, namely DA_1. However, in this study we show that two different receptors for dopamine are present in rat adrenal glomerulosa, on the basis of the paradigm that stimulated or inhibited adenylate cyclase are indices of dopamine receptor function.

The cyclic AMP generating system in the adrenal cortex is stimulated by dopamine (EC_{50} = 7.2 μM) as well as by different dopamine agonists such as NPA (EC_{50} = 20 μM) and SKF 38393 (EC_{50} = 2 μM) and these effects are blocked by haloperidol, but not by (-)sulpiride, which slightly potentiates the stimulatory effect of dopamine. On the other hand, when the selective D_1 antagonist SCH 23390 is present in the incubation medium, dopamine induces a concentration-dependent inhibition of adenylate cyclase (IC_{50} = 10 μM); similarly, the dopaminergic ergot derivatives, bromocriptine (IC_{50} = 2 μM), dihydroergotoxine (IC_{50} = 6 μM) and lisuride (IC_{50} = 4 μM) decrease the cyclase activity; (-)sulpiride, in contrast to (+)sulpiride, completely blocks these effects.

In vivo studies in the rat indicate that sulpiride stereospecifically enhances plasma aldosterone levels, haloperidol is less active than (-)sulpiride and SCH 23390 is completely inactive on plasma aldosterone, thus suggesting an involvement of D_2 dopamine receptors in the regulation of aldosterone secreting system.

These data provide direct evidence for the presence of D_1 and D_2 dopamine receptors in the adrenal cortex with opposing roles in the formation of cyclic AMP; the pharmacological profile of this receptor system is identical to that described for D_1 and D_2 dopamine receptors in the corpus striatum. The D_2 receptor, linked to the inhibition of adenylate cyclase, may be functionally involved in the regulation of aldosterone production.

212.1 LACK OF ATTENUATION OF METHYLPHENIDATE-CONDITIONED PLACE PREFERENCES BY HALOPERIDOL. M.T. Martin-Iverson, S. Mithani* and H.C. Fibiger, Div. Neurol. Sci., Dept. Psychiat., University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

It has previously been demonstrated (Martin-Iverson et al., Brain Res. 332:59, 1985) that neither haloperidol (HAL) pretreatment nor catecholamine depletion induced with 6-hydroxydopamine attenuate place preferences conditioned with methylphenidate (MPD), while HAL pretreatment does block place preferences produced with d-amphetamine (AMPH - Spyraki et al., Brain Res. 253:185, 1982). These earlier experiments were conducted in an apparatus in which rats exhibit robust initial preferences for one compartment of a 2 compartment box, and the drugs were associated with the least preferred compartment. As preferences in this apparatus may result from drug effects on processes such as habituation or aversion, the present study examined the effects of HAL (0.2 mg/kg, i.p.) pretreatment on place preferences in rats induced with MPD (5.0 mg/kg, i.p.) or AMPH (1.5 mg/kg, i.p.) in a 2 compartment apparatus in which no initial preferences were apparent. In addition, extinction trials were conducted in a group of rats that had been conditioned with MPD to determine whether or not place preferences were the result of conditioning or some as yet unspecified drug-habituation interaction.

Place preference conditioning was observed following both MPD and AMPH, but not in a group treated only with vehicle (n=10 per group). Repeated testing of rats conditioned with MPD revealed that preferences undergo extinction, suggesting that learning, not habituation, underlies the observed place preferences. HAL signifcantly attenuated place preferences induced with AMPH, but not those produced with MPD. Thus, MPD appears to produce a rewarding action via a mechanism, and possibly a locus of action, that is distinct from that of AMPH.

Other groups of rats were tested for locomotor activity during drug treatments following a protocol identical to that used for place preference conditioning. The results from these experiments, which ascertain if differences in the effects of HAL on stimulant-induced place preferences relate to differences in actions on motor stimulation, will be presented.

212.2 SUPPRESSION OF OPERANT RESPONDING PRODUCED BY BLOCKADE OF DOPAMINE D1 RECEPTORS WITH SCH 23390. S. Nakajima. Department of Psychology, Dalhousie Univ., Halifax, Nova Scotia, Canada.

Recent experiments in our laboratory demonstrated that a depamine D1 receptor blocking agent, SCH 23390, completely suppressed bar-pressing response for brain stimulation. Sulpiride, a dopamine D2 blocking agent, did not interfere with self-stimulation. A question was raised as to whether a similar receptor specificity exists in other types of reinforcement. The present study shows that the specificity is present in the reinforcement produced by food.

Albino rats were maintained on a food regimen at 85% of free-feeding weight. They were trained to press a bar for food pellets under either continuous reinforcement (CRF), fixed interval of 1 min (FI-1), or fixed interval of 3 min (FI-3). The FI-1 group showed a high level of response rate and maintained the same level for 30 min under a no-drug condition. The performance of this group, however, was highly susceptible to the drug effect. Injection of SCH 23390 maleate (0.05 mg/kg, IP) immediately prior to testing suppressed responding in about 20 min. The animals remained active, showing no signs of sleep or paralysis, but they showed drastic decline in response rate, and many of them stopped responding completely for more than 10 min.

The FI-3 group did not show as high level of performance as in the FI-1 group, and the drug effect was more pronounced. The CRF group was most resistant to the drug effect. Only a few animals stopped responding completely, and others pressed the bar from time to time and ate all of the pellets earned. The fact that the same motor response, bar-pressing, was suppressed under one condition but not under the other indicates that the suppression was not a simple motor interference.

Sulpiride (50 mg/kg, IP) was injected 4 hours prior to testing so that the animals could be tested at the peak of the drug effect. It had no effect on the responding under CRF or FI-1. Performance under FI-3 was slightly reduced with sulpiride.

These results suggest that the D1 receptors are critically involved in producing the rewarding effect of food, as they are in producing brain-stimulation reward. The D2 receptors seem to play only a minor role in this regard.

212.3 EFFECT OF AROUSAL ON THE SPONTANEOUS DISCHARGE AND SENSORY EVOKED ACTIVITY OF NIGRAL DOPAMINERGIC NEURONS. Robert E. Strecker and Barry L. Jacobs. Dept. of Psychology, Princeton University, Princeton, N.J. 08544.

Single dopaminergic (DA) neurons were recorded in freely moving cats by means of low impedance movable microwires. Dopaminergic neurons were identified by their electrophysiological characteristics, their response to the DA agonist drug apomorphine, and by histological localization of the recording site in the substantia nigra. Unit activity was examined during several different behaviors in order to examine DA involvement in arousal/stress, sensory integration, motor/postural control, and selective attention. None of the following tonically presented arousing/stressful conditions had an effect on neuronal discharge rate relative to baseline discharge rate: inaccessible food, feeding, grooming, inaccessible rats, immersion of feet in ice water, tail pinch, white noise, and somatosensory stimulation. Further, no relationship was found between DA unit activity and manipulations involving movement (treadmill locomotion), immobilization, or posture.

In contrast, repeated presentation of phasic auditory or visual stimuli during quiet waking behavior typically produced brief (<200 msec) excitatory neuronal responses, as has been previously reported (Steinfels, et al., Brain Res., 258, 217, 1983). Systematic changes in head orientation, or simultaneous exposure to tonic loud white noise had no effect on these observed neuronal responses to phasic clicks or light flashes. However, simultanous presentation of the other tonic environmental stimuli (e.g., inaccessible food, feeding, grooming, somatosensory stimulation, restraint, and ice bath) dramatically attenuated the DA neuronal responses to phasic clicks and flashes. This contrasts with the inability of these same conditions to influence spontaneous discharge rate.

In conclusion, during the various behaviors tested, DA neurons appear to provide a remarkably constant input to their target neurons in the caudate. However, the presentation of phasic sensory stimuli can change DA discharge dramatically, and this sensory response can be blocked during various active behaviors. This pattern of sensory responsiveness may provide a mechanism for the modulation of sensorimotor processing or attentional mechanisms in the caudate, which in turn influence information processing in the rest of the brain.

212.4 VENTRAL TEGMENTAL AREA DOPAMINE SYSTEM: LOCOMOTOR AND COGNITIVE PERFORMANCE FOLLOWING 6-HYDROXYDOPAMINE-INDUCED DAMAGE. Brundin*, P., Gage, F.H., Dunnett, S.B., and Björklund, A. Department of Histology, University of Lund, Sweden and Department of Experimental Psychology, University of Cambridge, UK. (SPON: European Neuroscience Association).

Rats with extensive bilateral 6-hydroxydopamine (6-OHDA) lesions in the mesostriatal dopamine (DA) system display a DA-deficiency syndrome which includes akinesia, bilateral sensorimotor neglect and disturbances in feeding and drinking behaviour. In Parkinson's disease there is a reduction of DA-levels in the mesostriatal, but also in cortical and limbic regions. The mesolimbocortical DA-neurons which originate in the ventral tegmental area (VTA, A10 of Dahlström and Fuxe) and project, e.g., to the nucleus accumbens, olfactory tubercle, prefrontal cortex, anteromedial striatum and septum have been implicated in a variety of behavioral functions including regulation of locomotor activity, stress and cognition in rats. Extensive bilateral 6-OHDA lesions of the VTA have been shown to produce a persistent reduction of spontaneous locomotor activity, a blockade of amphetamine-induced locomotor activation, hyperactivity in response to apomorphine, impairments in active avoidance tasks, and disruption of hoarding behavior.

We have studied the effects of large bilateral injections of 6-OHDA in the VTA of rats on locomotor activity and cognitive behaviour in the Morris' watermaze. Rats with extensive lesions showed a prolonged latency to find the escape platform in the watermaze and often exhibited reduced swim speeds. In addition, these animals showed little indication of using spatial cues to find the hidden platform. These findings were reproduced in a subsequent experiment when noradrenergic neurons were partially protected from the 6OHDA effect by administration of desmethylimipramine prior to 6OHDA injection. The extent of DA depletion in different projection areas was assessed neurochemically and correlated with behavioural deficits. It was found that the extent of regional DA depletion was directly related to the magnitude of cognitive deficit. In ongoing experiments we have attempted to alleviate the lesion-induced syndrome by transplantation of a dissociated cell suspension containing fetal DA neurons to VTA projection target areas.

212.5 CONDITIONED PLACE PREFERENCE INDUCED BY INTRACEREBROVENTRICULAR MICROINJECTIONS OF COCAINE: POSSIBLE INVOLVEMENT OF CENTRAL DOPAMINE. M.A. Morency* and R.J. Beninger (SPON: M.W. Donald). Dept. of Neuroscience, McMaster Univ., Hamilton, Ont. L8N 3Z5 and Dept. of Psychology, Queen's Univ., Kingston, Ont. K7L 3N6

Behavioral studies have shown that cocaine is a potent reinforcing stimulus. Although it is often assumed that cocaine's local anesthetic actions are unrelated to its reinforcing properties, Spyraki et al. (Brain Res., 1982, 253: 145) reported that cocaine-induced conditioned place preference (CPP) was unaffected by manipulations which disrupted central dopamine (DA) and norepinephrine function. In addition, systemic injections of procaine, a local anesthetic which does not share cocaine's potent central stimulant effects, produced CPP. The present study was undertaken to evaluate the possible role of DA in cocaine-induced CPP. The apparatus consisted of a shuttle box in which the two end compartments were distinguished by brightness, odor and texture. The neutral central area served as a choice point. In the preconditioning phase, rats were allowed to explore the 3 compartments for 15 minutes; on the 3rd day, the time spent in the end compartments was recorded. During the conditioning phase, rats injected with cocaine were immediately confined for 30 minutes to the initially less prefered end compartment. On alternate days, rats received saline injections and were confined for 30 minutes to the opposite compartment. After 4 cocaine and 4 saline pairings, undrugged amimals were given access to the entire apparatus and time spent in the end compartments was recorded. Experiment 1 consisted of a partial replication of Spyraki et al. (1982). As expected, systemic administration of cocaine (5.0 mg/kg, i.p.) produced a significant CPP ($p<.02$) that was not disrupted in a second group of rats pretreated 4 hours prior to conditioning with pimozide (1.0 mg/kg, i.p.), a specific DA antagonist. In experiment 2, cocaine was microinjected unilaterally into the lateral ventricles to eliminate peripheral local anesthesia. Cocaine (50.0 ug in 1 ul, i.c.v.) produced CPP ($p<.001$). In this case, however, the CPP effect was blocked in rats pretreated with 1.0 mg/kg pimozide ($p>.20$). Results support the involvement of central DA in cocaine reward. (Supported by the Natural Sciences and Engineering Research Council.)

212.6 ELEVATION OF MEDIAL FOREBRAIN SELF-STIMULATION THRESHOLDS FOLLOWING MICROINJECTIONS OF DOPAMINE IN VENTRAL TEGMENTUM. O. Kofman, J. Yeomans and S. Whitfield*. Dept. of Psychology, University of Toronto, Toronto, Ontario, M5S 1A1.

Medial forebrain bundle self-stimulation is due mainly to the direct activation of myelinated fibers which pass from basal forebrain to ventral tegmental area (Bielajew and Shizgal, 1982; Yeomans, 1982). The involvement of ventral tegmental area dopaminergic neurons in medial forebrain bundle self-stimulation has been inferred from experiments which showed blockage of self-stimulation following injections of dopamine antagonists systemically (e.g., Fouriezos and Wise, 1976), or in mesolimbic terminal regions (e.g., Mora, Sanguinetti, Rolls & Shaw, 1975).

The present experiment tested this idea more directly by microinjecting dopamine directly into ventral tegmentum. Stimulation of autoreceptors on dopamine cells inhibit their spontaneous or glutamate-induced firing (e.g., Grace and Bunney, 1984). Rats were implanted with bilateral monopolar electrodes in the lateral hypothalamus and a single 28 gauge injection cannula aimed at the ventral tegmental area. They were trained to bar press for 0.5 sec trains of cathodal pulses (0.1 msec duration). Current was held constant and pulse frequency was varied until 20 min of stable baseline frequency thresholds were obtained. Dopamine or artificial CSF was then injected into the ventral tegmental area, and frequency thresholds for self-stimulation measured for up to one hour following injection (Yeomans, Kofman and McFarlane, 1985). Elevations of thresholds were observed for both ipsilateral and contralateral stimulation sites, peaking at about 10 min following the injection of 2, 5 or 10 ug of dopamine. Motor deficits were not observed, except at doses of 10 ug. No threshold changes were seen after injections of CSF. The duration of these effects was shorter than previously found for atropine (Yeomans, Kofman and McFarlane, 1985).

Testing the animals repeatedly over a period of one week resulted in a decline of the dopamine effect. This effect is consistent with previous studies (Antelman and Chiodo, 1981; Antelman, Chioda & de Giovanni, 1982) which found decrements of the behavioral and physiological effects of dopamine autoreceptor stimulation over several days due to the development of subsensitivity.

212.7 6-OHDA LESION OF THE CAUDATE NUCLEUS BUT NOT NUCLEUS ACCUMBENS PRODUCES DISRUPTION OF COMPLEX MOTOR FUNCTION IN RATS. M. Amalric, R.E. Lintz, and G.F. Koob. Div of Preclinical Neuroscience and Endocrinology, Scripps Clinic and Research Foundation, La Jolla, CA 92037.

Impairment of the dopaminergic system in the brain induced by neuroleptics or by specific lesion result in motor disturbances in rats. In humans, neuroleptics often produce Parkinson-like neuromuscular side effects which are attributed to dopamine (DA) receptor blockade in specific anatomical loci in the extrapyramidal motor system. Lesions to the terminals of the mesolimbic system (destroyed by 6-hydroxydopamine 6OHDA injections aimed at the nucleus accumbens) but not of the striatal system produce an attenuation of spontaneous locomotor activity. In order to further specify the role of the two main DA pathways in the brain on motor function, we studied the effects of a neuroleptic, α-flupenthixol, administered systemically and specific lesion of DA activity by 6OHDA perfusion in the nucleus accumbens or nucleus caudate in rats performing a motor task for food reinforcement. Rats were trained to press a lever and release it as fast as possible after a light cue (conditioned stimulus CS). Four different time periods (0.25, 0.5, 1.0, 2.0 sec) delivered at random preceded the CS. In order to be rewarded by a food pellet, the rats had to wait long enough for the light to come on and to release the lever within 1 sec after the C.S. Reaction time was measured from the CS to the release of the lever for each trial. Daily sessions ended after 100 trials. Results were expressed in percent of success for the reaction times (successful trials both for the delay period and for the response latency within 1 sec) and for the delay period (whatever the reaction time value). α-flupenthixol (0.1, 0.2 and 0.4 mg/kg) injected intraperitoneally 2 1/2 h before the training session impaired the performance of the rats. Reaction time values were significantly lengthened for the 0.2 mg/kg dose. At the highest dose (0.4 mg/kg) rats stopped the task after 2 to 10 trials. When dopaminergic neurons were destroyed by 6OHDA injection differences in the two systems were observed. While disruption of the dopamine activity in the nucleus accumbens did not affect the performance of the rats, lesions of the dopaminergic neurons in the nigrostriatal pathway significantly affected the reaction time performances. Rats showing 95 to 99% success for the reaction time restriction before lesion decreased to 68-75% success 3 weeks post lesion. Reaction time values increased more than 4 sec. No changes were seen in the delay period. Results support the hypothesis that whereas the nucleus accumbens is involved in locomotor activation the corpus striatum has a role in the initiation of complex goal directed responses.

212.8 AMPHETAMINE-INDUCED REBOUND IN PLAY. J. Cox*, T. Strohe* & J. Panksepp. Dept. Psych., Bowling Green State University, Bowling Green, OH 43403

It is now well established that acute amphetamine (AMPH) administration reduces the play behaviors of young rats, although the mechanism of this effect remains obscure. We now report that repeated AMPH treatment (5mg/kg) produces a "rebound" in pinning behaviors and also markedly increases the average duration of each pin within a play session. In a initial experiment, using much milder AMPH treatment (1mg/kg once daily for 8 days) we did not see AMPH-induced rebound during the regimen or during withdrawal. However, under these conditions we did see a mild amount of tolerance to the play-reducing effects of a test dose of AMPH.

Subsequently, we administered AMPH (5mg/kg) every 8 hours to individually housed animals. We tested them daily, 7 hours following the preceeding AMPH treatment. Rebound emerged following 4 successive injections and persisted at least 16 hours after the final treatment. Rebound emerged concurrently with marked tolerance to a test dose (1mg/kg) of AMPH given before testing and with apparent cross-tolerance to fenfluramine (5mg/kg). Replications have indicated that AMPH-induced rebound emerges regardless of whether or not the rats are tested during the regimen and regardless of whether the injections are given every 8 or every 12 hours.

Repeated AMPH treatment is known to produce subsensitivity of dopamine autoreceptors as well as marked norepinephrine depletion. In preliminary tests of the neurochemical specificity of AMPH-induced rebound, we have found that rebound is attenuated in rats with 6-OHDA lesions of the nucleus accumbens. Since we found that these lesioned rats played normally in baseline tests, mesolimbic DA activity does not appear to be critical for play. Nevertheless, repeated AMPH appears to be acting through a DA mechanism to amplify play.

212.9 COMPARISON OF THE ABILITY OF (+)-AMPHETAMINE AND CAFFEINE TO PRODUCE ENVIRONMENT SPECIFIC CONDITIONING. R.S. Herz* and R.J. Beninger. Dept. Psychology, Queen's University, Kingston, K7L 3N6, Canada

A Pavlovian paradigm was used to assess the ability of two stimulant drugs, (+)-amphetamine or caffeine to produce environment specific conditioning. Based on evidence gathered from previous research dopamine appears to be involved in environment specific conditioning produced by many drugs including (+)-amphetamine, cocaine and morphine. The present experiment attempted to examine the hypothesis that direct activation of dopaminergic neurotransmission is critical to this phenomenon by comparing stimulant drugs with different mechanisms of action. Thus, the stimulant properties of (+)-amphetamine have been shown to be medi ated by dopamine, whereas the stimulant properties of the methylxanthine, caffeine are not thought to be directly medi ated by dopamine. Rather, the primary mechanism of caffeine's stimulant effects is thought to be the inhibition of adenosine receptors. As it was important for comparison that these drugs produce similar stimulant effects, pilot work established that doses of 30.0 mg/kg of caffeine and 2.0 mg/kg of (+)-amphetamine were appropriate. Forty-eight male Wistar rats were assigned to four groups of 12 rats each. Animals experienced four conditioning days with either drug or saline injected intraperitoneally prior to a 60 minute session in the photocell activity monitors and the alternate substance, saline or drug, respectively, injected in the home cage following the session. The fifth day was the test day, when all animals received saline in the activity monitors. This procedure was repeated so that days six to nine were the same as days one to four, and a second test session was conducted on day ten. Results revealed significant group differences on conditioning days between the experimental drug animals and their controls for both locomotor activity and rearing/jumping. It was also consistently found that on test days only the experimental animals previously receiving amphetamine in the activity monitors exhibited significantly higher activity scores than their controls. The hypothesis that environment specific conditioning may require the direct activation of dopaminergic neurotransmission was supported by the results. This does not exclude the possibility that caffeine may be able to produce conditioned effects at different doses or in different conditioning paradigms. However, these results show that the production of increased locomotor activity seen repeatedly with stimulant drugs in a conditioning paradigm is not sufficient to produce conditioning. (Funded by the Natural Sciences and Engineering Research Council.)

212.10 RAT ENDOCRINE RESPONSE TO PHYSOSTIGMINE IN A NOVEL ANIMAL MODEL OF DEPRESSION. N. Downs[1*], K. Thatcher Britton[2], G. Koob[2], D. Gibbs[1] and N. Swerdlow[3]. [1]School of Med., UCSD, San Diego, CA 92093; [2]PCN, Scripps Clinic and Res Fnd., La Jolla, CA 92037; [3]Dept Neurosci. and MST Program, UCSD, San Diego, CA 92093.

Previous workers (Risch et al, J Clin Psychopharm 1981) reported an abnormal endocrine response in clinically depressed patients compared to matched controls following administration of the acetylcholinesterase inhibitor physostigmine (PS). In these studies, depressed patients demonstrated a supersensitive increase in serum ACTH and prolactin (PRL) following PS challenge. Based on these findings, we examined the ACTH and PRL response to PS in rats following destruction of brain monoamine systems which have been implicated in the etiology of depression.

Thirty-three male Wistar rats were handled daily for 7 d and then injected with PS (0 - 0.6 mg/kg sc). After 20 min, animals were decapitated and trunk blood was collected for RIA analysis of plasma ACTH and PRL content. PS produced a dose-dependent increase in plasma ACTH, and both decreased (low doses) and increased (highest dose) plasma PRL levels.

Sixty-eight rats were then divided into 5 groups that received stereotaxic injections of saline or amine-selective neurotoxins so as to deplete brain levels of dopamine (DA), norepinephrine (NE) or serotonin (5HT). After 7 d, most animals were tested for the effect of these lesions on gross motor activity, using a standard pencil catalepsy test. One wk later, all animals were injected with PS (0 or 0.1 mg/kg sc), trunk blood was collected as above for RIA analysis, and brains were dissected for HPLC analysis of regional neurotransmitter content.

Compared to sham-lesioned controls, only DA-lesioned animals exhibited catalepsy. Analysis of plasma PRL levels in saline- and PS-injected animals revealed that 0.1 mg/kg PS increased plasma PRL in all groups with no between-group differences. Analysis of plasma ACTH levels in saline- and PS-injected animals revealed that 0.1 mg/kg PS increased plasma ACTH levels in all groups. ANOVA with repeated measures on lesion group revealed a significant main effect. Newman-Keuls individual means comparison revealed that, compared to sham-lesioned controls, ACTH levels following PS were significantly elevated in DA-lesioned rats, but not NE- or 5HT-lesioned animals. The effect of PS on plasma ACTH levels in DA-lesioned rats corresponded to a 6-fold increase in sensitivity to PS in these animals.

These results suggest intriguing parallels between the supersensitive increase in the plasma ACTH response to PS in clinically depressed patients and that seen in rats following depletion of central DA, but not NE or 5HT levels.

212.11 PROGESTERONE DECREASES 5-HT (SEROTONIN) RELEASE FROM ESTROGEN-PRIMED RAT HIPPOCAMPAL SLICES., Laura Imig and Peter Lipton, Dept. of Physiology, Univ. of Wisconsin, Madison, WI (Sp: H. Karavolas).

Progesterone (P) administration to ovariectomized, estrogen (E)-primed rats increases sexual receptivity. A large body of data implies this may be mediated by decreased activity of the serotonergic system, possibly due to an increase in monoamine oxidase (MAO) activity. Although these effects have been studied largely in the hypothalamus, hippocampal P implants and serotonergic receptor blockers also facilitate lordotic behavior.

We determined (E+P)'s effect on 5HT metabolism and release in hippocampal slices. Rats (210-220g) were ovariectomized. About one week later they were injected with 2.5µg E_2B, for two days, then sacrificed. Slices were depolarized in 60mM or 30mM K^+. When added to buffer, P was at 2µg/ml. Tissue and buffer 5HT and 5HIAA were measured by HPLC and used to calculate release and synthesis (per mg protein) for 50' periods.

P decreased 5-HT release in E-primed rats by 30% at both 30mM and 60mM K. (30 mM: + P, = 1.97 ± 0.18 ng/mg; - P = 3.30 ± 0.14 ng/mg. 60mM K, + P = 3.42 ± 0.14 ng/mg; - P = 4.66 ± 0.24 ng/mg.) 5HIAA release from P-treated slices was decreased by approximately 20% at both 30mM and 60mM K. Progesterone had no significant effect on 5HT or 5HIAA release in non E-primed animals depolarized by 30mM K^+. (5HT: + P = 2.53 ± 0.18 ng/mg; - P, 2.81 ± 0.18 ng/mg.)

5HT synthesis was reduced by 30% in slices incubated with P at 30mM K. However, P did not decrease 5HT synthesis at 60 mM K. (30 mM: + P, = 6.55 ± 0.71 ng/mg; - P = 9.31 ± 0.63 ng/mg. 60mM K: + P = 8.50 ± 0.54 ng/mg; - P = 8.74 ± 0.99 ng/mg.) 5HIAA synthesis was reduced by 13% at 60 mM K and 16% at 30mM K.

Thus, P decreases 5HT and 5HIAA release in E-primed rats, but has no effect on non E-primed rats. This suggests that the hippocampal slice could well be a model for studying the mechanism of action of P on sexual behavior.

The effects of P are most easily explained by a decrease in Ca^{++} entry into serotonergic terminals during depolarization. This would account for decreased release. It would also account for the reduction in synthesis at 30mM but not 60mM K as Ca^{++}-activated synthesis is apparently saturated at low concentrations of Ca^{++} (Auerbach and Lipton, J. Neurosci. 1985). The absence of 5HT cell bodies in the hippocampus suggests two possible modes of P action: 1) direct action on 5HT terminals to decrease Ca^{++} entry, ii) activation of an inhibitory interneuron transmitter (e.g. GABA) which would act presynaptically to inhibit Ca^{++} entry.

The first hypothesis would imply P action independent of the genome while the second would be consistent with an action on the genome (of the inhibitory interneuron).

212.12 GRADED LESIONS OF THE NIGROSTRIATAL PATHWAY. TOPOGRAPHIC DISTRIBUTION OF DOPAMINE DEPLETIONS, AND CORRELATION WITH AMPHETAMINE INDUCED ROTATIONAL BEHAVIOR. G.Pasinetti*, D.G. Morgan and C.E. Finch, (SPON: V. Henderson). Andrus Gerontology Center, and Dept. of Biol. Sciences, Univ. Southern Cal., Los Angeles, 90089-91.

Graded lesions of the nigrostriatal pathway were made in male rats to determine the threshold lesion size for induction of striatal dopamine (DA) supersensitivity. Male rats were pretreated with 25 mg/kg imipramine and a series of graded unilateral lesions were made by injecting 8,4, or 2, ug 6-OHDA (2 µl volume in 0.1% ascorbic acid) through a cannula stereotactically placed in the anterior portion of the right substantia nigra, pars compacta. Three weeks after the lesions, rats were injected with amphetamine sulfate (5.0 mg/kg) and tested for rotational behavior. One week after behavioral testing, animals were sacrificed by decapitation.

To estimate the topographic distribution of DA depletion, one mm punches were collected from anterior, middle and posterior levels of the striatum. At the middle level, punches from the dorsal, ventro-medial, and ventrolateral aspects of the striatum were pooled separately. The concentrations of DA, NE and DOPAC in these punches were measured by reverse-phase HPLC.

The DA depletions in these animals were proportional to the amount of 6-OHDA injected. The overall DA depletions using 8, 4, and 2 ug 6-OHDA were 95%, 89%, and 57% of the contralateral striatum (mean concentration in control side = 155 ± 12 ng/mgprotein; not different than uninjected animals). The range of overall depletions was 13% to 98%. In general, the depletions were less in the ventromedial aspect of the striatum than in the dorsal, or ventrolateral aspects. The depletions at the posterior level of the striatum tended to be slightly greater than those at the anterior or middle levels.

The rotational behavior produced by amphetamine injections correlated significantly with the severity of overall DA depletion (r= -0.67, $p<0.05$). When anterior, middle, or posterior levels of the striatum were considered separately, the depletions at both the anterior and middle levels correlated with the number of turns (r= -0.64, and r= -0.59, respectively; both $p<0.05$). In the posterior striatum, where all but 2 depletions were greater than 90% of control, no significant correlation was found (r= -0.51).

Thus, amphetamine induced rotation can be used as an index of the severity of DA depletion for unilateral depletions of 50-90%. This is of importance for a second experiment, already in progress, examining the regulation of both D-1 and D-2 striatal DA receptors following graded lesions such as these. The amphetamine induced turning can be used to pool animals with similar depletions for neurochemical analyses.

212.13 INVOLVEMENT OF THE SEPTO-HIPPOCAMPAL PATHWAY IN THE TIMING BEHAVIOR OF RATS: THE EFFECT OF DIFFERENT NEUROTOXINS. J.D. Steketee, P.B. Silverman, C.M. Davis* and C.A. Harrington. Neuropsychopharmacology Section, Texas Research Institute of Mental Sciences and University of Texas Graduate School of Biomedical Sciences at Houston, Texas Medical Center, Houston, Texas 77030 USA

The differential reinforcement of low rates (DRL) operant schedule was used to study the involvement of the septo-hippocampal pathway in the time behavior of rats. Electrolytic lesion of the septum or hippocampus have been shown to disrupt the performance of rats on a DRL schedule. Little has been done to determine the neurochemical basis of the septo-hippocampal involvement in rat DRL performance.

After four days of DRL 1 bar press training, rats received either electrolytic lesions or lesions induced by 6-hydroxydopamine (6-OHDA), 5,7-dihydroxytryptamine (5,7-DHT), ibotenate or ethylcholine aziridinium ion (ECA) in the medial septum or hippocampus. The rats continued DRL 1 bar press training until they had recovered from surgery, at which time they were placed on a DRL 15 schedule for 30 days. Total responses, reinforcements, and efficiency (reinforcements/responses) were recorded. Temporal distribution of responses in 5 second bins was also recorded. Following DRL 15 training, the rats were sacrificed. The septal area and hippocampus were dissected out and used for choline acetyltransferase (CAT) assay or monoamine assay via high performance liquid chromatography (HPLC).

Electrolytic lesions of the medial septum or hippocampus significantly ($p < 0.5$) altered performance on the DRL 15 schedule. Electrolytically lesioned rats responded more frequently and received fewer reinforcements, thus demonstrating decreased efficiency. Of the chemical septal lesions only those made with ibotenic acid significantly affected DRL performance. Ibotenic lesioned rats responded at the same rate as controls, but received fewer reinforcements and exhibited a lower efficiency. Ibotenic acid lesions also had a significant effect in the hippocampus. Rats with ibotenate lesions in the hippocampus responded at a higher rate than controls during the last half of DRL 15 training. They received fewer reinforcements and were less efficient than controls throughout the 30 days of training. 5,7-DHT and 6-OHDA induced hippocampal lesions resulted in a decreased number of reinforcements and decreased efficiency. The effect of 5,7-DHT lesions on reinforcement rate and efficiency occured after 10 days of training, while 6-OHDA affected reinforcements from Day 1 and efficiency from Day 10 of training.

Biochemical data are being used to verify lesion placement and will ultimately be used in an attempt to delineate the role of specific neurotransmitters in DRL deficits resulting from septo-hippocampal damage.

212.14 XYLAZINE EMESIS, YOHIMBINE AND MOTION SICKNESS SUSCEPTIBILITY IN THE CAT. J.B. Lucot and G.H. Crampton. Depts. Pharmacology and Psychology, Wright State Univ., Dayton, OH 45435

The mechanism of emetic action of drugs whose emetic potency correlates with motion sickness susceptibility may suggest the receptor types involved in the systems mediating motion sickness. The emetic potency of xylazine, an alpha-2 adrenoceptor agonist, was tested for correlation with motion sickness susceptibility. The role of alpha-2 adrenoceptors in both emetic stimuli was then evaluated using the alpha-2 antagonist, yohimbine.

Cats were divided into two groups according to motion sickness susceptibility and were observed following subcutaneous injections of xylazine. The incidence of vomiting increased with the dose and at each dose, the high susceptibility group had a greater emetic incidence than the low susceptibility group. In another experiment with cats divided into two groups according to motion sickness susceptibility, s.c. administration of yohimbine effectively antagonized the xylazine-induced emesis in both susceptibility groups. These latter cats were then challenged with a motion sickness stimulus after s.c. pre-treatment with yohimbine. Yohimbine failed to prevent motion sickness, but did occasion an unexplained varibility in response rates. These findings establish that the emetic effect of xylazine is a function of alpha-2 adrenoceptors, but that these receptors are not involved in feline motion sickness. The fact that susceptibilities to xylazine emesis and to motion sickness are correlated suggests a point of interaction other than the area postrema, which, in cat, is known to be essential for xylazine-induced vomiting but not for motion sickness. 212.15 STUDIES ON THE HYPERACTIVITY PRODUCED BY INJECTION OF MORPHINE OR MUSCIMOL INTO THE MEDIAN RAPHE NUCLEUS. M. Klitenick, D. Wirtshafter and K.E. Asin, Dept. Psychology, Univ. Il at Chicago Chicago, IL. 60680.

Recent studies have demonstrated that various manipulations of the median raphe nucleus (MR) are able to produce hyperactivity. For example, large increases in locomotion have been observed following electrolytic lesions of the nucleus, as well as after intra-MR injections of particular compounds.

We report here that rats with indwelling cannulae terminating in the MR display a pronounced increase in photocell cage activity following injections of the GABA agonist muscimol (100 ng/0.5 ul), confirming the results of Sainati & Lorens (1982). In order to examine whether or not serotonergic mechanisms play a role in this response, we examined muscimol-induced hyperactivity in rats pretreated with either 1 or 2 systemic injections of the serotonin synthesis inhibitor PCPA (300 mg/kg). Despite the fact that these injections depleted serotonin in several forebrain structures by 80-90%, they did not alter the hyperactivity induced by intra-MR muscimol.

In other, preliminary, studies we have found that intra-MR injections of 10ug serotonin fail to produce hyperactivity. Since electrophysiological studies have shown that iontophoretic application of serotonin inhibits the firing of serotonergic cells within the MR, these results, like those of the study using PCPA, fail to support a model in which ascending serotonergic fibers mediate the hyperactivity produced by intra-MR injections of muscimol, as suggested by Sainati & Lorens (1982).

Since recent reports have demonstrated the presence of opiate receptors within the MR, we next examined the effects of intra-MR injections of morphine (0.1,0.5,1.0,5.0 & 10.0 ug/0.5 ul) on locomotor activity. Morphine injections were found to increase activity at all of the above-mentioned doseages, although the response was not as large as that seen following muscimol. The response to the 5ug dose of morphine could be blocked in a dose-dependent fashion by naloxone (1,2.5 & 5 mg/kg). These results suggest that opiate receptors within the vicinity of the MR may play a role in the control of locomotor activity.

212.16 REWARD SUMMATION FUNCTIONS SEPARATE PIMOZIDE'S MOTOR AND HEDONIC EFFECTS IN RATS LEVER-PRESSING FOR SUCROSE. C. S. Bailey, S. Hsiao and J. E. King*. Department of Psychology, University of Arizona, Tucson, AZ 85721.

Dopamine (DA) is implicated in hedonic processing, possibly in the mesolimbic DA system. However, DA's involvement in the nearby nigrostriatal motor system indicates that motor effects must be separated from hedonic effects before accurate interpretation can be made. Attempts to separate these effects have had mixed success, and no attempt has been made to quantify the relative hedonic value of reinforcers.

Reward summation functions (RSF), a plot of rate of behavior versus log concentration of reinforcer, typically are a positive slope ending in a peak rate of responding. RSF's have been used to separate motor and hedonic effects using brain stimulation reinforcement (Edwonds, D. E. & Gallistel, C. R., J. Comp & Physl. Psych., 87:876, 1974). The RSF paradigm has not been used with other reinforcers.

Male Sprague-Dawley rats (n=18) lever-pressed for sucrose solutions of varying molarity in an easy task condition (30 g of weight required to press the lever) and then in a difficult task condition (60 g of weight required to press the lever). The peak of the RSF showed a vertical increase but the slope of the function did not shift. Thus, a motor impairment was reflected in the peak and not the slope of the function. That the rate of responding increased, rather than decreased, may be due to increased frustration which causes an increase in drive.

The same rats then lever-pressed for sucrose molarities laced with 0.05% quinine. The peak of the RSF did not change, but the slope of the function showed a horizontal increase when compared to the RSF for sucrose only. Thus, a hedonic change was reflected in the slope but not the peak of the function.

The rats were then injected with 0.2 mg/kg pimozide, a DA antagonist, and four hours later responded for sucrose solutions. The RSF for pimozide showed no change in the peak, but did show a horizontal increase in the slope, similar to the RSF for quinine-sucrose. A RSF for 3% tartaric acid injection, the pimozide vehicle, was not different from the RSF for sucrose.

Thus, RSF's represent motor effects as a vertical change in peak of the function and hedonic effects as a horizontal change in slope of the function. Pimozide's effects at this dose are hedonic and not motor. RSF slopes are different for brain stimulation, sucrose and sucrose-quinine reinforcers and thus may indicate quantitatively the relative hedonic value of the three reinforcers.

212.17 GENETIC APPROACHES TO STUDY RELATIONSHIPS BETWEEN BRAIN AND BEHAVIOR. C. Vadasz*, I. Sziraki*, L.R. Murthy* and A. Lajtha (SPON: N. Marks). Lab. of Neuro-behavior Genetics, Neurochemistry Div., Nathan Kline Inst., Orangeburg, N.Y. 10962.

One of the central goals in neurobiology is to find and analyse relationships between behavior and its neural substrate. There are several useful genetic methods which are applicable to establish these relationships (Vadasz, Cs. et al. In: I. Lieblich, Ed., Genetics of the Brain, Elsevier, p. 127, 1982).

Recently it has been reported that strain differences in tyrosine hydroxylase (TH) activity in midbrain dopamine (DA) systems are entirely attributable to differences in number of dopamine neurons in the substantia nigra - A10 (SN) area (Ross, R.A. et al. Nature, 264: 654, 1976) and such strain differences in enzyme activity and neuron number can be found in the hypothalamus (HT) also (Baker, H. et al., The J. of Neurosci., 3: 832, 1983). DA mediated spontaneous or amphetamine induced locomotor activities were paralleled with TH activities in SN, corpus striatum (CS) and HT in our experiments on reciprocal F1 hybrids (Vadasz, Cs. et al. J. of Neurogenet. In press). This was consistent with the hypothesis that some of the genes which control central DA systems contribute also to the expression of these motor activities.

In the present work, we studied highly inbred strains, their F1 hybrids and F2 segregating populations to further investigate the genetically based relationships between central DA systems and various types of ostensible behavior.

TH activity was measured in SN, CS and HT and correlated with behavioral variables used to assess emotionality, territorial marking, exploration and spontaneous motor activity. Factor analysis, a multivariate technique, was used to analyze the data. The resulting environmental, genetic and phenotypic factor matrices were significantly different from each other and gave further support to our hypothesis that multivariate genetic factor analysis can be a powerful method in constructing genetic maps of the brain or brain-behavior relationships.

AGING: NEURAL BASIS OF BEHAVIOR

213.1 INCREASED DYE COUPLING IN HIPPOCAMPAL NEURONS OF SENESCENT RATS. G. Rao, C.A. Barnes, B.L. McNaughton and J. Baldwin*. Dept. Psych., Univ. of Colorado, Boulder, CO 80309.

Several studies have examined the electrical characteristics of mammalian neurons in advanced age and a number of rather specific changes have been described. One such change is an apparent increase in the excitability of both pyramidal (Landfield and Pitler, Science, 226, 1089, 1984) and granule cells (Barnes and McNaughton, J. Physiol. (Lond.) 309, 473, 1980) of the hippocampus which appears in the absence of an altered resting potential or input impedance. In granule cells, it was found that this excitability change was more pronounced following synaptic activation than following intracellularly applied depolarizing current. One mechanism that could account for this observation is an increase in the extent of electrotonic coupling. MacVicar and Dudek have shown that both granule and pyramidal cells exhibit clusters of 2-3 units which transfer low molecular weight dyes freely and exhibit high electrical coupling ratios. If the extent of coupling increased with aging, this would result in an apparent decrease in the mean synaptic activation threshold since this would be set by the most excitable cell in an ensemble. This possibility is addressed by the present investigation.

Hippocampal slices were prepared from 6 old (25 mo) and 5 young (10 mo) Fischer-344 retired breeder rats, obtained from the NIA breeding colony. Intracellular recordings were made from pipettes containing a 5% solution of carboxyfluorescein in 0.1 M K^+Ac. Hyperpolarizing current pulses (1 nA, 100 msec, 5 Hz) were passed through the recording pipette to eject the dye. While ejection times varied, there were no age differences in the mean ejection times nor was there a correlation between ejection time and the number of filled cells. After filling, the slices were mounted in a 5% solution of n-propyl-gallate in glycerol (pH 8.0), observed using epi-fluorescence optics, and photographed.

Successful impalements were obtained from 43 cells in the young group and 38 cells in the old group. The old animals showed a statistically significant increase over the young animals in the average number of cell bodies observed per impalement ($\bar{x}$ old=1.67 ± 0.14 S.E.M.; $\bar{x}$ young=1.25 ± 0.08 S.E.M., $p < .05$). As many as four cells per cluster were observed after impalements from old animals. Coupled cells were frequently observed as far apart as 50 to 100 µm with an obvious point of contact only between adjacent dendrites. In addition, field potential recordings from the same slices revealed an increase in the ratio between population spike to field EPSP similar to that found in the fascia dentata.

These data strongly suggest a more extensive electrotonic coupling of hippocampal neurons in old animals which may have profound consequences for the information processing capability of these neurons. Supported by PHS grant AG 03376.

213.2 AGE-RELATED DIFFERENCES IN THE DECAY OF ENVIRONMENTALLY-INDUCED HIPPOCAMPAL PLASTICITY. P.E. Sharp, C.A. Barnes and B.L. McNaughton. Dept. Psych., Univ. of Colorado, Boulder, CO 80309.

Cells in the dentate gyrus (FD) show an activity-dependent long-term enhancement (LTE) of synaptic strength, which has become a promising candidate mechanism for information storage. In a recent study FD responses exhibited a persistent increase in amplitude as a result of exposure to a spatially complex environment. This suggests that an LTE-like phenomenon can be induced by environmental as well as electrical stimulation.

The present study compared this environmentally induced plasticity in young and old rats. Old rats show deficits in learning on spatial tasks and also show faster decay rates of artificially induced LTE in hippocampus (Barnes and McNaughton, D. Stein (Ed.), Psychobiology of Aging: Problems and Perspectives, 1980). If spatial information storage shares a common mechanism with LTE, it was reasoned that the environmentally induced plasticity might also show faster decay rates in old rats.

In this study 8 old (32 mo) and 8 young (14 mo) rats were implanted with electrodes for chronic recording of extracellular field responses in hippocampus. After recovery from surgery, perforant path evoked granule cell responses could be measured in the unanesthetized, freely-moving state. The experiment consisted of three phases. Phase I (lasting 15 days) provided baseline response measures. Animals lived in standard individual colony cages, as they had for many weeks prior to the start of the experiment. During Phase II (11 days) the rats were given daily exposure (from 5:00 PM to 9:00 AM) to a spatially complex enriched environment. Phase III was identical to Phase I; environmental enrichment was discontinued, and the animals spent all time except for recording sessions in the standard colony cages.

While no consistent or significant changes were seen in the synaptic component of the response, the population spike amplitudes for both old and young animals showed significant increases during Phase II (fractional change 1.37 ± .34 S.E.M. and 1.01 ± .48 S.E.M. for the young and old groups respectively). During Phase III, population spike amplitudes slowly decreased toward baseline, reaching fractional changes of .81 ± .25 S.E.M. (Young) and .26 ± .25 S.E.M. (Old) by day 15. The slope of the exponential decay function was significantly greater for the old animals.

These results indicate that a long-lasting increase in perforant path evoked granule cell response can be induced by environmental stimulation. Young and old animals showed asymptotic levels of change which did not differ statistically in magnitude but which decayed at different rates. These results are very similar to those of Barnes and McNaughton (1980) for the synaptic component of artificially-induced LTE. They support the idea that these two forms of plasticity may play a role in memory. Supported by PHS AG 03376.

213.3 AGING AND SELECTIVE ATTENTION: VISUAL EVENT RELATED POTENTIALS
M.M.Schroeder* and M.R.Harter* (SPON:C.J.AINE). Department of Psychology, University of North Carolina at Greensboro, Greensboro, N.C., 27412.

The performance of the normally aging individual on selective attention tasks is typically slowed, particularly when the number of irrelevant stimuli are increased or when the location of the relevant stimulus is uncertain. The purpose of this study was to investigate the effects of age on two types of selective attention as indicated by event related potentials: the effects of attending a particular location (interlocation) and particular feature (intralocation) of visual stimulation. It was predicted that the ERP indicants of both types of selective attention in older, as compared to younger subjects, would reflect a slowing and reduced selectivity of neural information processing.

Healthy normal subjects, inexperienced in ERP studies, were recruited for the study from the community. The mean age of the younger group was 25 yrs.: the mean age of the older group, 76yrs. The stimuli consisted of two color flashes, (red and blue), presented at two locations, (central and 16 deg. in the right visual field). These four stimulus conditions were presented in random order. For a given relevance condition, subjects were instructed to count one of these four conditions. There were four relevance conditions: red center, blue center, red right, blue right. ERPs from the occipital midline were averaged to 50 red flashes in the central and in the right visual field for all four relevance conditions. The amplitude and latency of the largest delfection in two time windows of the ERP components associated with interlocation and intralocation effects were measured: 200-350 msec. (N200-350), and 350-512 msec. (P350-512).

As predicted, the ERP indicants of selective attention, (N200-350 and P350-512), had a longer latency for the older, as compared to the younger group. The nature of the two types of selective attention, as reflected by P350-512, depended on age. The intralocation attention effect was greater for the younger subjects than for the older subjects: in contrast, there was no significant difference between the two groups in the magnitude of the interlocation effects. For both groups, the interlocation effect occurred earlier in time than the intralocation effect, replicating earlier findings.

The results were discussed in the context of neurophysiological mechanisms that might underlie these two types of selective attention, and how these mechanisms might change with age.

213.4 STIMULUS EXPECTANCY ASSESSMENT: POSSIBLE AGE EFFECTS ON THE EVOKED POTENTIAL.
G. W. Lewis and M. R. Blackburn. Navy Personnel Research and Development Center, San Diego, CA 92152.

Attention may be assessed through comparison of evoked brain activity to predictable versus unpredictable events and may be related to age. The objective of the present research was to examine the effects of stimulus presentation within and between modalities [same vs. random order of visual, auditory, and bimodal (simultaneous visual and auditory)] on groups of individuals differing on age.

The average age for the younger group (N=11) was 19.3 (SD=1) years and for the older group (N=11) was 33.5 (SD=8.3) years. Evoked potentials were obtained from F3, F4, T3, T4, P3, P4, O1, and O2 referenced to nose. Visual stimuli were 17 minute visual angle (VA) checks in a checkerboard pattern subtending 9 degrees VA, 5 ftL. Auditory stimuli were 65dB(A) clicks about 30 ms duration. All stimuli were presented aperiodically with a 2 second interstimulus interval. A 512 ms post stimulus epoch was averaged (N=20 stimuli) and μVrms of the average obtained.

Analysis of variance demonstrated: greater EP amplitudes in the younger group overall; greater amplitudes to randomized than to same mode presentation; greater parietal than frontal amplitude; and a significant presentation-by-site-by-age interaction. There was a greater difference between same and random presentations for the younger group in the parietal, but a greater difference for the older group in the frontal region.

Possible explanations include: (1) greater arousal in the younger group related to test anxiety, (2) age related decline in reactivity, and (3) differential control of attention related to experience or maturity.

213.5 AGE-RELATED DETERIORATION OF LEARNING ABILITY IS ACCELERATED IN AUTOIMMUNE MOUSE STRAINS.
M.J. Forster, K.C. Retz, M.D. Popper*, and H. Lal. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107.

Deterioration in the abilities of young C57BL/6 mice to acquire an avoidance response occurs following immune system manipulations which produce senescence-like increases in serum brain-reactive antibodies (BRA) (Nandy, K. et al., Neurosci. Abs., 10:721, 1984). Similar learning deficits occur in association with heterochronic formation of BRA over the life spans of C57BL/6 and autoimmune New Zealand Black (NZB) mice (Nandy, K. et al., Life Sci. 33:1499, 1983). Recent findings have indicated that deficient memory for avoidance learning may also be related to BRA formation in those strains (Harris, C.M. et al., Neurosci. Abs., 10:451, 1984). In order to further test the relationship between BRA and avoidance learning or memory, an additional autoimmune mouse strain was tested. Inbred mice of the MRL/Mp-lpr strain are known to exhibit BRA formation just following puberty, whereas genetically related, non-autoimmune mice (MRL/Mp-+ strain) are without this characteristic. Learning/memory abilities of the autoimmune MRL mice were expected to deteriorate beginning after 1.5 months of age, in parallel with the formation of BRA. Male MRL/MpJ-lpr (autoimmune) or MRL/MpJ-+ (non-autoimmune control) mice aged 1.5 or 3 months were tested for acquisition of a one-way active avoidance response until an avoidance had occurred on at least 8 of the last 10 trials. Separate groups of these mice were retrained to the same criterion either 1 or 48 hours following acquisition. Performance of the mice during the 1- and 48-hour retention tests indicated little difference between the strain or age groups. On the other hand, the control MRL mice showed an improvement in avoidance learning between 1.5 and 3 months, whereas the autoimmune MRL mice exhibited a marked deterioration within the same time period. The age-related learning deficits shown by the autoimmune MRL mice were qualitatively similar to those associated with elevated BRA in C57BL/6 and NZB mice. The current findings provide added support for the hypothesis that immunologic mechanisms related to the formation of BRA are involved with senescence-related learning dysfunctions. (Supported by a research grant from Miles Institute for Clinical Pharmacology).

213.6 ACCURATE SPATIAL MEMORY IN EXPERIENCED OLD RATS SURVIVES TEN MONTHS WITHOUT TRAINING.
W.W. Beatty, R.A. Bierley*, A.I. Troster* and G.J. Rixen*. Dept. of Psychology, North Dakota State Univ., Fargo, ND 58105

If a win-shift food searching strategy is required, young rats rapidly learn to enter each of the arms in a radial maze only once. Imposing a delay of several hours between their 4th and 5th choices does not degrade performance on this working memory (WM) task. Aged rats that receive their first training on the maze when they are already old acquire accurate spatial memory more slowly than young rats although once criterial performance is attained old and young animals perform equally well even at retention intervals of several hours. By contrast, 26 month old rats that had learned the radial maze problem while young and performed the task almost daily until 22 months of age displayed highly accurate WM, even at long delays (e.g., 96% correct at 5 hours), as soon as they were reintroduced to the task after 3 months without training (Beatty, et al., in press).

Bahrick and his colleagues have shown in humans that memory for some kinds of information is maintained with little loss for 30 years or more. To determine whether or not spatial memory in rats might be similarly long-lived we studied the reacquisition of accurate spatial WM at various delay intervals by a group of 21-5 month old rats that had received 225 radial maze tests between 3-11 months of age but received no testing during the intervening 10 months. The old rats regained accurate performance very quickly (Mdn sessions to criterion including 5 criterial sessions = 7, 7 and 5 for 0, 1 hour and 5 hour delays respectively). Their reacquisition was more rapid than the original acquisition of a group of 3 month-old rats tested concurrently (Mdn sessions to criterion = 13, 19, and 22 for the same rentention intervals). The old rats maintained highly accurate WM without employing response strategies. Forcing them to enter a randomly selected set of 4 arms had no effect on retention after a 5 hour delay (89% correct vs 91% under free choice conditions). These results show that the skills required for accurate spatial WM persist with little loss in aged rats. Spatial WM in rats may provide a model system for studying the neurobiology of enduring memory.

213.7 A CRITICAL EVALUATION OF SPATIAL LEARNING DEFICITS IN SENESCENCE. P.R. Rapp, M. Gallagher, and R.A. Rosenberg*. Dept. of Psychology, Univ. of North Carolina at Chapel Hill, Chapel Hill, N.C. 27514

The identification of behavioral testing procedures which are sensitive to age-related cognitive dysfunction has received considerable attention recently. Although a number of investigations have reported that the performance of aged animals is impaired in tasks which young animals solve on the basis of spatial information (e.g., the 8-arm radial maze), the degree to which spatial learning, per se, is compromised in senescence remains undetermined. The following experiments were therefore designed to critically evaluate age-related changes in spatial learning using the Morris water maze task.

In Experiment I, young (6mos., n=11), middle-age (12mos., n=11), and senescent (22-28mos., n=11) male Long-Evans hooded rats were tested for 32 trials, 2 trials per day, in the Morris task. During training an escape platform was submerged in clouded water in a fixed location within the maze for each subject. During the first 32 trials the escape latencies of all groups eventually decreased to equivalent asymptotic levels. Subsequent analyses, however, revealed that acquisition among senescent subjects was significantly impaired during the first half of training relative to young and middle-age animals ($p<.01$). This acquisition deficit was observed to occur in a reliable pattern such that aged subjects were relatively more impaired on the first trial of each day compared to performance on the second trial of the same day.

In Experiment II, naive young (n=13), and senescent (n=11) animals were tested (2 trials/day) for their ability to swim to a visible escape platform placed in a fixed location for individual subjects over 13 trials. This experiment was thereby designed to assess sensory and motoric factors which might contribute to age-related impairments in task performance. Although aged subjects were initially slower to escape in this cued version on the Morris task, both groups rapidly reached equivalent levels of learned performance. All subjects were subsequently observed in the maze for 90secs. with the escape platform removed. During this trial young animals spent significantly more time in the quadrant of the maze which had previously contained the platform compared to any other quadrant of the apparatus ($p<.01$). Aged subjects, conversely, showed no spatial bias. Similarly, other measures of behavior indicate that during cue training young animals acquire a significant amount of spatial information while senescent subjects show no such acquisition. These findings strongly support the interpretation that age-related impairments in acquiring spatial information contribute importantly to senescent learning deficits in the Morris water maze.

213.8 OLFACTORY, VERBAL AND VISUAL RECOGNITION: AGE-RELATED CHANGES IN SECONDARY MEMORY PERFORMANCE. P.J. Moberg*, G.D. Pearlson, L.J. Speedie*, J.R. Lipsey*. (SPON: K.L. Kubos). Johns Hopkins Med. Inst., Dept. of Psychiatry and Behav. Sci., Baltimore, MD 21205

Perceptual losses appear to accompany the normal aging process. Previous research has documented age decrements in verbal and visual recognition (Schoenfield & Robertson, Can. J. Psych., 20: 228-236, 1966), and in olfactory identification ability (Doty, et al., Science, 226: 1441, 1984); however, declines in olfactory recognition memory have not been similarly examined.

One hundred and ten normal controls were administered three similarly structured recognition tasks. Visual and verbal recognition were measured implementing abbreviated forms of the Rey Auditory Verbal Task (1964) and Kimura's Figures (1963). The third recognition task was an olfactory paradigm of the authors' design (Moberg, Pearlson, et al., Neurosci. Abstr., 10: 318, 1984). All subjects were screened, and performed normally on an odor discrimination task to assess olfactory acuity. They were then presented with a series of 10 target odorants in identical masked bottles. The subjects were asked to remember, without naming, the target odors. After administration of a short cognitive battery, the Mini-Mental State Exam (MMSE) (Folstein, et al., J. Psychiat. Res., 12: 189, 1975), they were presented with 20 odorants including the original 10, plus 5 odors similar to 5 of the target odors, and 5 which were dissimilar. Subjects were asked to indicate which odorants they had been previously presented. Recognition accuracy for all tasks was represented using d' scores.

All participants scored in the normal range (≥ 25) on the MMSE. Results indicate significant age-related declines in all recognition modalities, with olfactory recognition being least affected ($r=-.27$, $p<.01$) compared to verbal ($r=-.43$, $p<.001$) and visual ($r=-.36$, $p<.001$) modalities. Of the three tasks, only the olfactory paradigm was not significantly correlated with educational level. Gender, smoking and prescribed medication effects were insignificant. These data indicate a decline in olfactory recognition with age, but at a lower rate than that for visual or verbal modes. The lack of strong educational, age and gender influences suggests that olfactory recognition may be a modality specific type of memory that is relatively culture-free. Such a test may allow for easier detection of pathological changes while avoiding the bias seen in other memory paradigms.

213.9 THE BEHAVIORAL AND PHYSIOLOGICAL CONSEQUENCES OF RIGHT MIDDLE CEREBRAL ARTERY LIGATION IN RATS FOLLOWING TREATMENT WITH NIMODIPINE, A CALCIUM VOLTAGE-OPERATED CHANNEL BLOCKER. C-A. Hardy and R.L. Isaacson. Dep't of Psychology and the Center for Neurobehavioral Sciences, SUNY-Binghamton, Binghamton, N.Y. 13901.

Preventing calcium influx in ischemic cells of the brain has been demonstrated to limit neuropathological changes associated with the loss of functioning in neural tissue (e.g. edema, EEG changes). The present experiment was designed to test the potential ability of nimodipine (NIM), a calcium voltage-operated channel blocker, to limit cerebral infarct size and aid in behavioral and physiological recovery in rats subjected to ligation of the right middle cerebral artery (MCA). Subjects were 57 adult male Long-Evans rats, who received either: no-surgery (n=20), control-surgery (n=19), or right MCA ligation (n=18). Approximately half of each surgery group was injected with a single systemic dose of NIM (3 mg/kg,i.p.), or a volume equivalent of the saline vehicle. The drug and/or vehicle was administered 10 min after ligation was completed in the MCA animals, 10 min after the control-surgery damage, or 100 min after the anesthesia in the no-surgery animals. Beginning on the day after surgery (i.e. post-surgery day 1= PS1), and on PS7, PS14, and PS21, all animals were tested in (1) a 10 min open field activity/exploration test, (2) a 6 min cool water swim test, (3) a 10 min post-swim grooming observation test in the home cage, and (4) sensory-motor tasks. The behavioral changes shown by the MCA animals were imperceptible in the majority of responses examined, and the observation of hyperactivity in the open field by Robinson (1979) was not replicated. However, the MCA animals did show an increased preference for left-sided grooming across test days in the home cage observation test, as well as a decreased likelihood of removing an alligator clip attached to the fur in one of the sensory-motor tasks. NIM had a pronounced behavioral effect only in the MCA animals. Specifically, the drug tended to decrease the amount of responding on a variety of behaviors only in the MCA rats (e.g. duration of hole-pokes and the number of central hole-pokes in the open field, right-sided flank grooming, orientation to a visual stimulus, & removal of a clip to the fur). The effect of NIM on behavior of MCA rats changed from PS1 to PS21, with certain behaviors becoming more frequent (e.g. right & left sided grooming, removal of clips from the fur), and other behaviors becoming less frequent (e.g. Duration of peripheral hole-pokes, number of central hole-pokes). It is proposed that the abnormal behaviors produced by NIM in the MCA rats is due to the administration of the drug after the ligation of the MCA, since NIM analogues have been previously demonstrated to have beneficial effects on the recovery of physiological functioning when given prior to the onset of ischemia. Future studies should examine the differential effects of calcium voltage-operated channel blockers when given before vs after the onset of ischemia.

213.10 COMPARISON OF DIAZEPAM PHARMACOKINETICS AND PHARMACODYNAMICS IN HEALTHY YOUNG AND ELDERLY ADULTS. A.M. Nikaido*, E.H. Ellinwood, Jr. and D.G. Heatherly*. Department of Psychiatry, Duke University Medical Center, Durham, NC 27710.

A number of pharmacokinetic and receptor kinetic studies have indicated age-related changes in the activity of benzodiazepines. Previous research has reported no or weak correlations between diazepam plasma levels and psychomotor or cognitive impairment in both young and elderly adults. However, only a few studies have attempted to examine directly the relationship between the pharmacokinectics and pharmacodynamics of diazepam. The present set of studies examines the effects of an acute 10 mg dose of diazepam on the performance of 8 healthy young and 8 healthy elderly men. Prior to the drug sessions all subjects were trained to a plateau level of performance on several behavioral tasks. Each test session started with a predrug battery followed by an oral dose of the drug or placebo and repeated performance testing for 4 to 5 hrs. Blood samples were drawn concurrently with the task batteries.

Both young and elderly volunteers demonstrated significant ($P < .05$) impairment at the 10 mg dose as compared to placebo. On the other hand, significant ($P < .05$) age differences were evident for the two primarily motor coordination tasks of tracking and standing steadiness but not for any of the cognitive tasks, such as digit symbol substitution (DSS) and keyboard reaction (KRT).

The following linear model based on one proposed by Ellinwood et al. (in press) was used to examine the change over time in the relationship between drug serum levels and behavioral scores:

$$E = A + [(FF \times P) \times KATC]$$

where E = performance score, FF = free fraction, P = serum drug concentration, A = constant term for KATC and KATC = linear regression coefficient relating performance to drug concentration over time. In general, the KATC values for tracking (Young: -.464; Old: -.252) and sway (Young: -.569; Old: -.493) were higher than those for DSS (Young: - .258; Old: -.3218). The data indicated that there was a faster decline in impairment relative to serum concentration for the motor than cognitive tasks.

The indication of task specific effects supports hypotheses of physiological tolerance. In summary, the results of the present experiment indicated that the behavioral effects of diazepam in the elderly cannot be accounted for only by the corresponding drug serum concentrations and emphasize the necessity of considering the pharmacodynamics of benzodiazepines when prescribing and designing drugs for this age group.

213.11 3,4-DIAMINOPYRIDINE IMPROVES SPATIAL WORKING MEMORY BUT NOT SPATIAL REFERENCE MEMORY IN AGED RATS. C. Eppich*, C.A. Barnes, and J. Baldwin*, Dept. of Psych., Univ. of Colorado, Boulder, CO 80309.

A recent study (Davis, et al., Exp.Ag.Res. 9, 1983) has suggested that an age-related deficit in short-term memory on an 8-arm radial maze may be attenuated by pretreatment with 3,4-diaminopyridine (3,4-DAP). There were two questions raised by this work that the present experiment was designed to address: 1) Is the memory improvement age-specific or will 3,4-DAP improve radial maze performance in young animals as well? 2) Is the memory improvement specific to the spatial working memory problem, or will 3,4-DAP improve spatial reference memory as well?

Two different tasks were used to examine the effects of 3,4-DAP on spatial memory. Spatial working memory was assessed using the 8-arm radial maze, where optimal performance requires that an animal remember which arm it has obtained food from on any given trial. Spatial reference memory was assessed on the circular platform, a task involving escape from a brightly illuminated surface into a concealed goal tunnel.

Fifteen young (10 mo) and 15 old (28 mo) male Fischer rats were used in this study. The animals were further divided into 3 drug groups: saline, low-dose (750 pmole/kg) 3,4-DAP, and high-dose (2750 pmole/kg) 3,4-DAP. For the present analysis the low-dose and high-dose animals were treated as one group. Rats were injected daily, approximately 10 min prior to being placed on the maze. Training took place on the circular platform first. The animals were tested for 16 trials at 24 hr intervals. After the completion of this test, the animals were food-deprived to 85% of their ad libitum weight and were then trained to a criterion of 4 errors or less on 3 consecutive trials on the radial arm maze.

The finding of Davis et al. was confirmed by the present experiment, as 3,4-DAP was found to improve the performance of old rats, relative to saline-treated animals, on the radial maze. This result appears to be a selective improvement of the older animals, however, since the drug did not improve young animals' performance.

The results from the reference memory task were quite different. 3,4-DAP did not change the number of errors made by old rats on the circular platform, and, in fact, it led to an increase in errors made by the young rats. Interestingly the decrement in performance on this task in the young group was not due to repetitive errors in the same incorrect hole but to a less accurate approach to the escape tunnel.

Our results suggest that 3,4-DAP may be specific in its effects on spatial memory. It appears selectively to improve memory of the older animals and, within that age group, improves only working memory and not reference memory. This result may have important implications for the clinical use of 3,4-DAP in the treatment of certain age-related memory impairments. Supported by AG03376.

213.12 PREFERENCE DIFFERENCES FOR SUCROSE SOLUTIONS IN YOUNG AND AGED SQUIRREL MONKEYS. R. R. Michels*, J. E. KING* and S. Hsiao. Department of Psychology, University of Arizona, Tucson, Az. 85721.

We measured licking patterns and molarity preferences of six young and six aged squirrel monkeys in response to two sets of sucrose molarities (0.0,.25,.5,.75,1.0,1.25,1.5 and 1.75 or 1.0, 1.5,2.0,2.5 and 3.0). In addition to conventional measures of lick rate and consumption, several microbehavioral measures of licking performance were recorded. Sucrose preference thresholds were determined for aged and young animals, using four sucrose solutions ranging from a .025 to .1 molar concentration.

Sucrose preference thresholds for aged and young monkeys were virtually identical. The concentration at which 75% of the total test volume consumed was sucrose, was estimated to be .033 molar for the old and .049 molar for the young animals.

In the licking experiment, consumatory activity by both aged and young monkeys increased monotonically with sucrose concentrations below 1.0 M. At molarities higher than 1.0, consumatory activity of the young animals decreased, while that of the aged animals continued to increase until sucrose solutions were above a 1.5 molar concentration. Increases in consumption by both young and aged animals were effected by increasing the number of licking bursts, length of licking bursts and number of licks.

Aged monkeys displayed a greater within animal variability of tongue-on times, a constant and exponentially decreasing rate of licking at high molarities and a constant efficiency decrement in amount drunk per lick and amount drunk per second of licking. These age dependent behaviors opposed, but could not eliminate, the expression of a sucrose molarity preference shift in the aged animals. These results are consistent with the hypothesis that aged animals suffer decrements in perception of hedonic value.

213.13 BEHAVIORAL AND NEUROPHYSIOLOGICAL EFFECTS OF BASAL FOREBRAIN LESIONS. K. Perryman*, J. Fitten and A. Kling (SPON. M.K. Menon). Dept. of Psychiatry, Sepulveda V.A. Med. Cen., Sepulveda, CA 91343.

The magnocellular basal forebrain nuclei are cholinergic cells of origin for widespread neocortical areas and limbic structures. The decline in this cholinergic innervation is reasoned to be instrumental in the development of neuritic plaques and neurofibrillary tangles in the cerebral cortex and hippocampus that has been associated with the cognitive decline of Alzheimer's disease. Our group is presently examining the behavioral-neurophysiological aspects of the cholinergic hypothesis of senile dementia of the Alzheimer type (SDAT) using non-human primates that have kainic acid lesions of the nucleus basalis (nBm) and diagonal band (dB). Preliminary performance data on simultaneous and delayed matching-to-sample tasks suggest that the integrity of the cholinergic basal forebrain is necessary to acquisition and short-term retention. Monkeys with bilateral kainic acid lesions involving nBm and dB required more trials to reach 90 percent criterion on a red/green color color discrimination than unoperated controls and could not master the 3 second delayed comparison of the same stimuli. The operated animal's cortical and hippocampal EEGs were shifted from a predominantly delta-theta (1-7 Hz) activity profile during the performance of the tasks prior to the lesions to a theta-alpha (4-12 Hz) type spectrum. We were also no longer able to elicit visual evoked potentials from the frontal cortex to the onset of the discriminanda following destruction of nBm and dB. Although one of the neurophysiological markers of SDAT in the later stages is a reduction in alpha frequencies, our observations of an early post-lesion upward shift in the EEG spectrum may reflect some sort of compensatory mechanism associated with increased production of cholinetransferase (CAT) by intrinsic cortical neurons. We are taking weekly samples of EEG cortical activity to observe if and when there is a swing back in the predominant EEG frequency toward the delta and theta bands that has been associated with SDAT.

213.14 ASSOCIATION OF SLEEP PARAMETERS AND MEMORY IN INTACT OLD AND NUCLEUS BASALIS LESIONED YOUNG RATS. W. S. Stone[1,2], H.S. Altman[2], D.F. Caldwell[2], R.F. Berman[1], M.M. Kilbey[1]. [1]Dept. of Psychology, Wayne State University, Detroit, MI 48202; [2]Lafayette Clinic, Detroit, MI 48207.

The purpose of the present experiment was to examine whether young rats with nucleus basalis of Meynert (NB) lesions, which are suggested as a model of Alzheimer's Disease (AD) because retrieval of passive avoidance is shown to be impaired, also show sleep disturbances similar to those reported in AD (Prinz, 1982).

In order to test this we examined whether sleep parameters in young rats with NB lesions are similar to those of intact older rats. In addition, we employed a passive avoidance paradigm to determine if sleep parameters were related to retention scores, and whether young lesioned and old intact rats showed similar sleep-retention relationships. Young (6 months) and old (24-26 months) animals were divided into 4 groups. All Ss were implanted with EEG electrodes. One young and one old group did not receive any other surgical treatment while the other two groups, both young, also received bilateral implantation of cannulas aimed at the region of the nucleus basalis. After recovery, 24 hour sleep-wake recordings were obtained from all animals by placing them on activity platforms in sound attenuation chambers. The activity record and EEG were recorded on a polygraph machine and scored in 30 sec. epochs as awake, paradoxical sleep (PS) or non-PS (NPS). One young group then received bilateral injections of ibotenic acid dissolved in artificial rat CSF, while another young group received only vehicle injections. Two weeks later all animals had 24 hr. sleep recordings retaken. The Ss were then trained with one trial on a 2 compartment passive avoidance (PA) apparatus and tested for retention 24 hrs. later.

The results indicate that prior to lesioning, the 3 young groups did not differ from each other on any of the sleep parameters. Among the age differences, young animals slept significantly more than old animals, and had significantly: fewer brief arousals (3 sec. and 15 sec.), higher PS/total sleep ratio, longer PS periods, and larger differences in day-night sleep percentages After the injections, the lesioned animals resembled the old animals on a number of dimensions. As in previous studies PA scores declined in both the old and NB lesioned young rats. Significant sleep-wake cycle disturbances and fragmention of sleep bouts were also seen in the young lesioned group. When sleep parameters were compared with PA scores, the closest association was found between retention and mean length of PS bouts. Shorter length PS bouts which were most common in old and lesioned animals were related to decreased retention, while longer PS periods were more closely related to intact and, mainly, younger animals.

213.15 BRAIN CT AND DST IN ELDERLY DEPRESSIVES. R.C. Young, G.S. Alexopoulos, M. Brown*, Shamoian, C.A., R. Roe*, and M. Deck*. Cornell University Medical College and Westchester Division, The New York Hospital, 21 Bloomingdale Road, White Plains, N.Y. 10605.

Depressive illness is prevalent among the elderly. Brain neurotransmitter dysfunction may be especially prominent in late life depression. For example, hyperactivity of the hypothalamic-pituitary adrenocortical axis, as reflected in an abnormal dexamethasone suppression test (DST), is more common in elderly than in young adult depressed patients. Atrophic changes on brain computerized tomography (CT) can occur with normal aging and are prominent in some depressed patients.

Patients admitted to a geriatric psychiatric service were studied. Subjects were included who were 60 years of age or older and met DSM III criteria for major depression, and who had both pretreatment DST and brain CT performed as part of their evaluation. Plasma samples were obtained at 0800, 1600, and 2300 hours on the day following 1 mg of dexamethasone orally at 2300 hours. Cortisol was determined by radioimmunoassay. Cortical sulcal widening, lateral and third ventricular enlargement were each rated as: 0-absent; 1-minimal or slight; or 2-definite, at least moderate. CTs were evaluated blind to DST results.

A preliminary sample (n=10) had a mean age of 74.5 years $\pm$ 5.1 years; all were Caucasian and nine were female. Their age at the time of their first depressive episode ranged from 28 to 75 years and was not related to index age (r_S=0.05). Seven of ten had abnormal DST by the criteria of Carroll et al.

Rating of ventricular enlargement was strongly positively correlated post-dexamethasone plasma cortisol at 0800 (lateral ventricular: r_S=0.80, $p<.01$, two-tailed; third ventricle: r_S=0.69, $p<.05$) and 1600 (lateral ventricle: r_S=0.64, $p<.10$; third ventricle: r_S=0.36 N.S.), but not at 2300 hours. The relationship with sulcal widening was not as strong (0800: r_S=0.55, N.S.). All three CT measures were strongly related to age (sulci: r_S=0.76, $p<.05$; lateral ventricle: r_S=0.64, $p<.10$; third ventricle: r_S= 0.62, $p<.10$). Their correlation with age of illness onset was weaker but positive (sulci: r_S=0.19; lateral ventricle: r_S=0.34; third ventricle: r_S=0.57, $p<.10$). Except for age and post-dexamethasone plasma cortisol at 0800 hours (r_S=0.45), age and age at illness onset were only weakly related to cortisol levels within this sample.

These preliminary results suggest that further investigation of relationships between measures of brain structure, clinical course, and neuroendocrine function in late life depression is warranted.

213.16 **INCREASED CHROMOSOME 21 MARKER (SOD-1) IN ALZHEIMER'S DISEASE FIBROBLASTS.** **O.J. Thienhaus*, F.P. Zemlan and H.B. Bosmann* (SPON: J.B. Suszkin). Lab. of Geriatrics Research, Univer. of Cincinnati College of Medicine, Cinti., OH 45267.**

Based on the hypothesis that excessive chromosome 21 material may play a pathogenetic role in Alzheimer's disease (AD), we measured superoxide dismutase-1 (SOD-1) activity in skin fibroblasts from an AD patient and compared them with SOD-1 activities in trisomy 21 fibroblasts (Down's Syndrome) and a normal control.

SOD activity was assayed according to the xanthine oxidase/nitroblue tetrazolium method developed by Beauchamp and Fridovich (Anal. Biochem. 44:276, 1971), i.e. a spectrophotometric assay at 560 nm. After identifying the fibroblast cell concentration range where small changes in protein concentration would not cause appreciable changes in the rate of absorbance, further determinations of SOD-1 activity were made employing protein concentrations thus determined, i.e. 13.33+ 0.36 ug/tube, representing approximately 166,000 cells/tube. Measured SOD-activities were standardized against commercially available, purified SOD. Addition of 2nM sodium cyanide, a specific inhibitor of SOD-1, eliminated all SOD activity, indicating that the activity measured was indeed due to the chromosone 21-coded SOD-1, and not to random superoxide scavanger activity.

We found that SOD-1 activity in AD fibroblasts was approximately 1.3 times greater than in an age-matched normal control ($p<0.01$). SOD-1 activity in trisomy 21 fibroblasts was 1.92 times greater than in the control ($p<0.001$), a finding replicating earlier studies (Feaster, W.W., et al., Am. J. Hum. Genet. 29:563, 1977). All enzyme determinations were done after the same number of cell culture passages.

Analysis of enzymatic activity in the three diagnostic groups (each comprising 42 samples) employed multivariate analysis of variance utilizing a general linear model. Post-hoc individual comparisons used Tukey's Honest Significant Difference Test.

213.17 CEREBROSPINAL FLUID ACETYLCHOLINESTERASE AND CEREBRAL ATROPHY IN ALZHEIMER DEMENTIA. G.D. Pearlson and L.E. Tune. Dementia Clinic, Johns Hopkins School of Med., Baltimore, Maryland 21205.

In 16 patients with the diagnosis of senile dementia of the Alzheimer type (SDAT), computed tomography head scans were rated blind to clinical and laboratory data, and lateral ventricular-to-brain ratios (VBR's) calculated planimetrically. Lumbar cerebrospinal fluid (CSF) acetylcholinesterase (AChE) activity was measured by radioenzymatic assay in all patients (Tune,L.E. et al, Ann. Neurol. 13: 46, 1985). The degree of dementia was quantified using the Mini-Mental Status Examination (Folstein,M.F. et al. J. Psych. Res. 12: 189, 1975). Significant correlations existed between cerebral atrophy as assessed by VBR, and CSF AChE activity (Pearson's r= -0.59, $p<.01$). Cognitive impairment, as quantified by the MMSE score, also correlated significantly with VBR (r=-.46, $p<.05$). These correlations were not accounted for either by age or by duration of illness. This relationship between VBR and AChE activity demonstrates an association between two independently determined clinical measures in senile dementia of the Alzheimer's type.

213.18 DECLINE IN CORTICAL $GABA_A$ AND $GABA_B$ SITES IN ALZHEIMER'S DEMENTIA. D.C.M. Chu, J.B. Penney and A.B. Young. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48109.

Cortical atrophy is one of the pathological hallmarks of senile dementia of the Alzheimer's type (SDAT). GABA is a major inhibitory neurotransmitter of cortical interneurons. Using a quantitative autoradiographic method, we have assayed $GABA_A$ and $GABA_B$ receptors in postmortem human frontal cortex from 4 persons with SDAT and 4 persons without neurologic disease. Blocks of frozen cortex were cut at -18°C in 20um sections, thaw-mounted onto gelatin-coated slides and air-dried. The slides were prewashed for 20 min at 4°C in 50 mM Tris-HCl + 2.5 mM $CaCl_2$ (pH 7.40) and blow-dried. $GABA_A$ receptors were assayed by incubating the tissue sections with ^{3}H-GABA (20 nM, 79 Ci/mmol) in the presence of increasing concentrations of isoguvacine to obtain IC_{50} and K_I values for isoguvacine. $GABA_B$ binding was performed by incubating tissue sections with ^{3}H-GABA in the presence of increasing concentrations of baclofen with 10 uM isoguvacine also present to block binding to $GABA_A$ sites. Assay conditions for both $GABA_A$ and $GABA_B$ receptors involved 30 min of incubation at 4°C with the ligand in 50 mM Tris-HCl + 2.5 mM $CaCl_2$, pH 7.40. Tissue sections were then rinsed once with ice-cold buffer and once with cold 2.5% glutaraldehyde in acetone and immediately blown-dry. Slides were mounted in an X-ray cassette and exposed to LKB Ultrofilm-^{3}H for 3 weeks at 4°C. Film densities were measured in cortical layers 2 and 4 by spot densitometry. Log-logit plots were constructed to yield IC_{50} values for isoguvacine and baclofen.

In SDAT cortex, layer 2 displayed a 43.1% decrease in total isoguvacine-sensitive $GABA_A$ binding (0.281 $\pm$ 0.053 pmol/mg tissue for SDAT vs. 0.494 $\pm$ 0.134 for control, $p<0.05$ by two-tailed, unpaired t-test) and a 60.9% decline in baclofen-sensitive $GABA_B$ binding (0.054 $\pm$ 0.010 for SDAT vs. 0.138 $\pm$ 0.055 for control, $p<0.05$). There was no statistically significant difference in either $GABA_A$ or $GABA_B$ binding in layer 4 between SDATs and controls. No clear trend in IC_{50} values for isoguvacine or baclofen was observed in the two groups. $GABA_A$ binding in human frontal cortex from both groups represented 80% of total ^{3}H-GABA bound whereas $GABA_B$ binding comprised 20%. This differs with our finding in rats in which $GABA_A$ and $GABA_B$ sites appear to be present in equal amounts in the cerebral cortex.

This study represents the first demonstration of a decline in both $GABA_A$ and $GABA_B$ receptors in layer 2 of frontal cortex from SDAT individuals.

213.19 **EFFECT OF AGE ON GLYCINE RECEPTOR BINDING IN THE RAT.** C. Hunter,* E. Chung and M.H. Van Woert. Graduate Program in Neurobiology. Departments of Neurology and Pharmacology, Mount Sinai School of Medicine, New York, N.Y. 10029

The concentration of the inhibitory neurotransmitter GABA in the CNS is reduced in epilepsy (1) and ^{3}H-GABA receptor binding has been reported to decrease with aging in the rat. (2) Glycine is another major inhibitory transmiter which also may play a role in convulsive disorders, (3) as well as spasticity (4). In the present study, the effect of aging on glycine levels, ^{3}H-Strychnine binding and ^{3}H-GABA binding was investigated in the medulla and spinal cord of 2, 10 and 24 month old Fischer 344 rats.

^{3}H-Strychnine and ^{3}H-GABA receptor binding decreased in both the medulla and spinal cord of 10 and 24 month old rats compared to the two month old animals.

	Specific Binding (fmoles/mg protein)	
	^{3}H-Strychnine	^{3}H-GABA
Medulla		
2 mo	265.3±17.5	32.01±2.7
10 mo	232.8±11.1	29.93±1.7[a]
24 mo	165.5±7.2[ab]	22.36±2.1[a]
Spinal Cord		
2 mo	269.24±10.7	41.46±1.6
10 mo	199.64±7.9[a]	21.51±1.0[a]
24 mo	177.23±5.6[ab]	16.63±1.23[ab]

Each value is the mean ± SE of 8 rats.
a) P< .05 compared to 2 mo old. b) P < .05 compared to 10 mo old.

Scatchard analysis of ^{3}H strychnine binding in the spinal cord of 24 month old rats showed a reduction in B_{max} of 25 percent compared to the 2 month old controls. Glycine, threonine and serine levels in the medulla did not change with age.

The relevance of decreased ^{3}H-strychnine binding in older rats to glycine receptor function and seizure threshhold will be reported. (Supported by USPHS grant NS 12341)

213.20 AGE-DEPENDENT CHOLINE UPTAKE IN RAT BRAINS. H. Goldman, S. Murphy* and H. Altman . Dept. of Pharmacology and Lafayette Clinic, Wayne State Univ. Detroit, MI 48201.

The blood-to-brain transfer of ^{3}H-choline relative to a ^{14}C-butanol reference indicator was measured by a single capillary-transit technique in conscious, unrestrained rats, as a function of age. Standard caged Sprague-Dawley male rats were studied at 6, 12 and 24 months of age. Indicator dilution of butanol in arterial blood provided the estimate of cardiac output. Regional brain vascular spaces and plasma/red blood cell choline levels were measured in subsets of animals from each age group. The results from these studies indicate that there was a significant reduction in regional cerebral blood-to-brain transfer rates of choline in the aging rat brain. The decline was seen in all regions examined. In seven of these, the decline between 6 and 24 mo was significant at less than the 0.05 level, e.g., pons-medulla-30%, basal ganglia-20%, parietal cortex-18%, pyriform cortex-amygdala-21%, septal region-18%, inferior colliculus-24%, olfactory bulb-24%. Least affected were the hippocampal and frontal cortical areas-7%. The decline in most regions was progressive, with the exception of the pyriform cortex-amygdala, in which a decrease of 20% was observed mainly between middle and old age. These decrements occurred in the absence of significant changes in cardiac outputs, in regional brain vascular spaces, plasma choline or RBC choline levels. Furthermore, the age-dependent regional reductions in choline transport occurred in the absence of changes in the uptake of sucrose, a marker of simple blood-to-brain diffusion. Our data strongly suggest that the transport and/or permeability of choline in most areas of the brain decreases with age. The diminished availability of this substrate for the synthesis of acetylcholine and membrane phospholipids may be important in the reduced cerebral functions associated with aging in the rat and other animals.

Supported, in part, by grant AG03571 from the NIA.

213.21 LOSS OF COMPLEX-SHAPED AXOSPINOUS SYNAPSES IN THE DENTATE GYRUS AS AN ANATOMICAL MARKER OF AGE-DEPENDENT SPATIAL MEMORY DEFICIT IN F344 RATS. Y.Geinisman, L. de Toledo-Morrell* and F.Morrell. Dept. of Cell Biol. & Anat., Northwestern Univ. Med. Sch., Chicago, IL. 60611 and Depts. of Neurol. Sci. and Psychol., Rush Med. Coll., Chicago, IL. 60612.

Most but not all aged F344 rats exhibit a profound spatial memory deficit when tested in the 8-arm radial maze (de Toledo-Morrell, L. et al.,Behav. Neurosci., 98:902, 1984). Accurate performance in this task in young animals depends on the integrity of the hippocampal formation (HIF) or its afferent supply (Olton, D.S. et al.,Brain Res., 233:241, 1982). A possible anatomical substrate of this spatial memory deficit in aged rats was assessed by electron microscopic examination of synapses in the dentate gyrus (DG) of HIF, at the perforant path-granule cell junction; i.e., the termination site of entorhinal afferent input to HIF. Animals were given one trial a day in the maze and trained to a criterion of 3 consecutive trials with no errors (no repeated entries into a given arm) or to a maximum of 30 trials. Three groups of rats (N=6 in each) were examined morphologically: 1) 5 mos. old animals that reached criterion, 2) 27 mos. old rats that reached criterion and 3) 27 mos. old rats that failed to reach criterion (memory-impaired group). The morphologist (Y.G.) was "blinded" with respect to age and behavioral history. The tissue preparation consisted of perfusion fixation with aldehydes, osmication and routine processing. Two tissue blocks from the dorsal HIF (right side) whose rostral face was 1.5 or 3.5 mm caudal to the HIF septal pole were used. From the rostral face of each block, serial ultrathin sections, which included the molecular layer of the DG hidden blade, were prepared and stained with uranyl acetate and lead citrate. Axospinous synapses were quantified in the middle of the molecular layer. The postsynaptic density was employed as the counting and measuring unit. The synaptic numerical density per unit volume of neuropil (N_V) was estimated stereologically, using the method of Fullman (J.Metals, 5:447, 1953). The minimum sample size was evaluated by the technique of progressive means. Axospinous synapses were divided into simple- and complex-shaped ones; the latter included both perforated and nonperforated synapses. No differences in synaptic N_V were found between the groups of young adult and aged rats that reached the criterion. N_V values were lower by 16% (n.s.) for simple-shaped synapses and by 33% ($p<.005$, two-tailed U test) for complex-shaped synapses in memory-impaired aged rats as compared to aged rats without memory deficits. The differential magnitude of changes in N_V of the two synaptic types is indicative of an absolute loss of complex-shaped synapses and cannot be explained by a change in volume. It appears, therefore, that a loss of complex-shaped axospinous synapses in DG may underlie age-related deficits in spatial memory.

213.22 AGING AND A NOVEL NEUROTOXIN, MPTP(1-METHYL-4-PHENYL-1,2,5-6-TETRAHYDROPYRIDINE) ELICIT DEFICITS IN BRAIN DOPAMINE TRACTS AND INCREASES IN DUODENAL ULCERS. J.Z. Fields, Research Service (151), Hines IL 60141

This report describes a new animal model of duodenal ulcer disease that implicates deterioration in a brain dopamine (DA) tract as an etiologic factor. MPTP is a novel neurotoxin that appears to be specific for lesioning only the nigrostriatal (NS) DA tract and induces parkinsonism in man, primates and some rodent species. Although the extensive NS lesions (>80%) required for overt signs of parkinsonism have not yet been elicited in rats, large decreases in levels of nigral and striatal DA and DA metabolites have been observed. Recently, Szabo et al reported (Fed Proc 43 <1984> 945) that MPTP induces duodenal ulcers (DU) in rats. At 2 mg/100g, s.c., X3/day for 4 days, DU were consistently elicited in 80 to 100% of animals (Sprague Dawley females). There was diminished output of gastric acid and duodenal/pancreatic base, little or no mortality and no neurlogical signs. We repeated thse experiments and extended them to an evaluation of the effect of aging on MPTP-induced DU. We confirmed that MPTP (same schedule) can induce severe DU. In the first experimnt (age = 3 mos) we saw a fall in striatal DA (-15%) and DOPAC (-45%, $p<.01$). The diminished DOPAC/DA ratio ($p<.01$) suggests a decrease in DA turnover. In a 2nd experment, nigral DOPAC ($r=-.69, p<.0002$), nigral DA ($r=-.46$, $p<.01$) and striatal DOPAC ($r=-.47$, $p<.02$) decreased as the dose of MPTP (0 to 4 mg/100g) increased. In a third experiment (ages=1,2,3 mos) frequency and severity of MPTP-induced DU increased with age as has been reported for cysteamine-induced DU. Since there is a strong age-related correlation in man between decreases in NS DA and increases in the incidence of DU, both of which change linearly across a large portion of the human lifespan - ages 15 to 75 - these two correlates of human aging may be mechanistically related, presumably through neuroendocrine and/or autonomic changes. MPTP-inuced DU may be a useful model not only for the pathophysioloy of DU but also for the involvement of brain catecholamines in aging.

213.23 DECREASED CEREBRAL BLOOD FLOW AND IMPAIRED LEARNING IN RATS ASSOCIATED WITH AGING. Berman, R. F.[1], Goldman, H.[2], and Altman, H. J.[3] [1]Dept. Psychology, [2]Dept. Pharmacology, Wayne State University, Detroit, MI 48202 [3]Lafayette Clinic, Detroit, MI 48207.

The relationship between reduced cerebral blood flow and impaired learning in aged rats was examined. Male, Sprague-Dawley rats, aged 6, 12, and 24 months were housed either in standard cages or in an enriched environment, and then trained to traverse a 14 arm sequential T-maze (i.e., Stone maze) for food reward. An age-related progressive decline in maze learning was found, with 24 month old rats making significantly more errors and requiring significantly more trials to reach criterion then either 6 or 12 month old rats. After training, regional cerebral blood flow was measured in 14 brain regions, including pons-medulla, hypothalamus, basal ganglia, midbrain, hippocampus, occipital cortex, parietal cortex, frontal cortex, olfactory bulbs, septal region, inferior colliculi, superior colliculi, and amygdala-pyriform area. There was an overall mean decrease in cerebral blood flow of 19.7% in middle-aged rats (12 months) and 17.9% in old rats (24 months). A regional analysis indicated that the decrease was present in all of the brain regions examined at both 12 and 24 months of age. The range of decreases in cerebral blood flow was from approximately 7% to 27%. These data support the possibility of a relationship between impaired learning and reduced cerebrovascular functioning in aged animals. Furthermore, 12 and 24 month old animals exposed to an enriched environment for 2 months prior to training and cerebrovascular measurements, showed better learning (i.e., reduced errors and fewer trials to criterion) and higher regional cerebral blood flows then similar aged standard housed animals. Thus, environmental enrichment appears to minimize some of the effects of aging on both learning and cerebral circulation. These findings emphasize the importance of environmental conditions in behavioral and physiological studies conducted on aged animals.

213.24 ACCELERATED ENHANCEMENT OF SENSITIVITY TO ETHANOL IN AGING NEW ZEALAND BLACK (NZB/BlNJ) MICE. K.C. Retz, M.J. Forster, N.J. Ashford* and H. Lal. Dept. of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107.

Relatively young NZB/BlNJ mice exhibit several characteristics of senescence, including deficiencies in learning and memory processes, elevations of brain reactive antibodies, and alterations in CNS-mediated drug effects (Nandy et al., Life Sci. 33:1499, 1983; Retz et al., Fed. Proc. 43:624, 1984; Harris et al., Soc. Neurosci. Abstr. 10:451, 1984; Nandy et al, Soc. Neurosci. Abstr. 10:721, 1984). We now report the effects of ethanol upon motor impairment of these mice. Male NZB/BlNJ and C57BL/6J mice 2-3, 4-6, or 10-14 months old (Jackson Labs; Bar Harbor, ME) were given ethanol 1.25, 1.88, 2.50 g/kg, i.p. prepared in saline vehicle (10 ml/kg). Fifteen min following EtOH the mice were placed on a 3.33 rpm constant velocity rotorod. The mice were permitted to remain on the rotating rod until they fell or 120 seconds had elapsed. The degree of motor impairment was estimated by the following equation: "% Motor Impairment" = [(120 sec. - latency on rotorod) x 100%] / 120 sec. All animals used in the studies were tested before receiving drug and found to have 0% motor impairment. A 3-way ANOVA on the data indicated that, overall, motor impairment varied as a function of: strain $F(1,30)=35.6, p<0.005$; age $F(2,30)=13.3, p<0.005$; and EtOH dose $F(2,60)=78.8$, $p<0.005$. However, the overall effect of strain was primarily a reflection of differential age-related changes in EtOH sensitivity among the strains occurring after 2-3 months of age. Whereas no strain difference in the effect of EtOH was apparent for 2-3-month-olds, the older groups of NZB mice were more sensitive than age-matched C57 mice following 1.25 and 1.88 g/kg EtOH. These age-related sensitivity changes were reflected in significant strain by dose $F(2,60) = 11.0, p<0.005$ and strain by age by dose $F(4,60)=2.6$, $p<0.05$ interactions. These data demonstrate an accelerated age-dependent enhancement of sensitivity to ethanol in NZB/BlNJ relative to C57BL/6 mice, a "reference" mouse strain widely employed in aging and EtOH studies. (Supported by USPHS grant AG03623 to H.L. and Texas College of Osteopathic Medicine grant 34144 to K.C.R.)

DEVELOPMENT AND PLASTICITY I: AGING

214.1 AGE-RELATED CHANGES IN SEROTONIN TURNOVER IN THE MEDIAN EMINENCE (ME) OF OVARIECTOMIZED ESTROGEN-TREATED RATS. I.R. Cohen-Becker and P.M. Wise. Dept. of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201.

Cyclic reproductive function is intimately timed to the photoperiod and thus is dependent upon the presence of normal circadian rhythmicity. Previous reports have demonstrated an age-related delay in the onset of cyclic release of LH in ovariectomized rats following the initiation of estrogen-treatment (Wise, P.M. Endocrinol., 115:801,1984). Recently, reports have indicated that changes in the normal circadian rhythm of serotonin can alter the timing and amplitude of LH surges (Walker, R.F. Neuroendo., 36:468, 1983). Therefore, we studied the effects of age on ME serotonin turnover rates in estrogen-treated, ovariectomized rats at various times during the day.

Studies were performed in young (3 mo) and middle-aged (8 mo) female Sprague-Dawley rats maintained on a 14 L: 10 D photoperiod with lights on at 0400h. All animals were ovariectomized and 7 days later received Silastic implants containing estradiol. These implants maintained physiological levels of estradiol in the circulation. Two days later animals were given either pargyline (75 mg/ kg body weight, ip) or were untreated at 0800, 1200, 1800 and 2400h. Controls were killed at 0800, 1200, 1800 and 2400h. Pargyline-treated animals were killed at 0810, 1210, 1810 and 2410h. Brains were removed, frozen and sliced at 300 microns. The ME was microdissected and analyzed for serotonin (5HT) and 5-hydroxy-indole-acetic acid (5HIAA) by HPLC. Both a comparison of the ratio of 5HIAA/5HT prior to and following pargyline treatment as well as 5HIAA/5HT ratios by themselves were examined as indicators of changes in serotonin turnover rates.

Age-related differences were found in the diurnal pattern of ME-5HT. Young animals exhibited low 5HT turnover in the morning (0800 and 1200h) compared to the afternoon (1800h) and night (2400h) when turnover was high. This diurnal pattern was apparent regardless of which of the two methods were used to determine turnover. In contrast, no diurnal change in 5HT turnover was seen in middle-aged rats. Turnover rates in these animals remained high at all times examined.

These data indicate that there is no deficit in serotonin turnover in middle-aged animals. Moreover, these animals failed to exhibit a diurnal pattern of serotonin turnover which may be necessary for normal cyclic release of LH. These data also demonstrate that the ratio of 5HIAA/5HT alone is as good an indicator of serotonin turnover rates as a comparison of ratios following pargyline treatment. (Supported in part by NIH AG-05351 to IC-B and NIH AG-00168 and AG-02224 to PMW).

214.2 PERGOLIDE SLOWS AGE-RELATED DETERIORATION OF THE DOPAMINERGIC NIGROSTRIATAL SYSTEM IN FISCHER 344 RATS. D. L. Felten, S. Y. Felten, T. Romano*, D. T. Wong, M. J. Schmidt, R. W. Fuller, and J. A. Clemens. Dept. of Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642, and The Lilly Research Laboratories, A Division of Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285.

Pergolide is a dopamine (DA) agonist with both presynaptic and postsynaptic action. We administered pergolide chronically in the diet (0.5 mg/kg/day) to male Fischer 344 rats to study its effects on nigrostriatal DA neurons. Four groups of rats were studied: (1) Rats fed pergolide from 3 mo. of age to 27 mo. of age; (2) Rats pair-fed from 3 mo. of age to 27 mo. of age, as pair-fed controls for pergolide administration; (3) Rats fed ad lib to 27 mo. of age; and (4) 3 mo. old untreated control rats. Fluorescence histochemical observations showed aging changes in substantia nigra (SN) at 27 mo. of age, including a marked decrease in fluorescent intensity in both perikarya and dendrites, increased accumulation of lipofuscin pigment in perikarya, and a reduced density of neurons in SN pars compacta (3 mo.controls--100% ± 12.6% (mean ± S.D., n=8); 27 mo. pair-fed controls--68.3% ± 14.0%, n=8, compared with 3 mo. old controls). Pergolide treatment enhanced the intensity of DA fluorescence in both perikarya and dendrites, led to increased density of neurons in SN pars compacta (27 mo. old pergolide treatment--85.1% ± 11.4%, n=8, compared 3 mo. old controls), but did not prevent lipofuscin accumulation in neurons. Rank order evaluation demonstrated significant differences in fluorescent intensity in both the SN pars compacta and striatum (3 mo. controls, 27 mo. pergolide, 27 mo. pair-fed, $p < .01$). Uptake of ^{3}H-DA into striatal synaptosomes was increased significantly (178%) in animals receiving pergolide compared with 27 mo. old pair-fed controls ($p < .05$). ^{3}H-Spiperone binding studies with striatal membranes in 21 month old rats fed pergolide for 18 months was no different than binding in pair-fed animals. These findings suggest that chronic dietary administration of pergolide to Fischer 344 rats slows the normal age-related deterioration of DA nigrostriatal neurons, and does not produce chronic down-regulation of DA receptors in striatum. Pergolide, therefore, may offer an important advantage in the treatment of Parkinson's disease by preserving the integrity of remaining DA nigrostriatal neurons.

214.3 BETA NOREPINEPHRINE RECEPTORS IN THE SENSORIMOTOR CORTEX OF THE FISHER 344 RAT: CHANGES AS A FUNCTION OF AGE AND CHRONIC CARDIOVASCULAR EXERCISE. R.E. Wilcox (1), M. Limb* (1), J.A. Severson (2), G. Cartee (3), W.W. Spirduso (1 and 3), J. Fineg*(1), and R.P. Farrar (1 and 3). (1) Dept. of Pharmacology, College of Pharmacy, Univ. of Texas, Austin TX 78712 (UT). (2) Med. Sch. Univ. of Southern California, Los Angeles, CA 90033. (3) Dept. of Health & Phys. Ed., UT 78712.

Age and exercise appear to produce opposite patterns of adaptation of dopamine (DA) receptors in the basal ganglia (P.E. Gilliam et al., Pharmacol. Biochem. Behav., 20, 863-867, 1984; P.E.Gilliam et al., Soc. Neurosci. Abstr., 11, 1985). We were interested in the response of beta norepinephrine (NE) receptors in sensorimotor cortex to age vs. exercise to determine the extent to which the reciprocal pattern shown for DA would apply to another central processing area in the control of movement.

Male Fisher 344 (F344) rats 4 or 18 mo. old were subdivided into untrained and endurance trained (treadmill) groups. All rats maintained their exercise program up to 48 hr before and were fasted 12 hr before sacrifice. At the conclusion of the 6 mo. training program half of the animals from each group were sacrificed immediately while the remaining subjects were given a 30 min treadmill test at 75% of the maximal oxygen consumption immediately prior to sacrifice. Saturability of 3H-dihydroalprenolol (DHA; 6 concentrations from 0.1 to 5nM) and NE displacement of 3H-DHA binding (20 NE concentrations from 1nM to 0.1 mM) in "sensorimotor" cortex (neocortex minus frontal and occipital pole regions) were determined in tissue from individual rats (n = 32) as described in O'Donnell et al. (J. Pharmacol. Exp. Ther., 228, 640-647, 1984). dl-Propranolol (10uM) was used as a blank. Initial analyses of the data by LIGAND (Munson and Rodbard, Anal. Biochem., 107, 220-239, 1980) were supplemented by analysis of variance (ANOVA) and Kruskal-Wallis ANOVA by ranks.

The major results were as follows. (1) NE binding in the cortex of 10 mo. old F344 rats was best described by a 2-site (high and low affinity agonist state) model. (2) By 24 mo. the binding had altered so that a 1-site (a single low affinity agonist state) model provided the best fit. (3) In contrast, neither the overall Kd nor Bmax of 3H-DHA binding were altered by age or exercise from 10 to 24 mo. (4) Chronic exercise increased the affinity of the low affinity agonist state (Kl) in young and old rats and decreased the affinity of the high affinity agonist state (Kh) in the young animals. (5) A 30 min exercise bout was able to alter the NE binding to the same extent in 10 and 24 mo. old animals regardless of training status.

(Supported by grant NS20827 to REW and WWS and UT and Pharmacy BRSG grants to REW.)

214.4 THE EFFECTS OF AGE ON REACTIVE CAPACITY AND NIGROSTRIATAL DOPAMINE FUNCTION IN SPRAGUE-DAWLEY RATS. P. Gilliam MacRae[a], R.E. Wilcox[b], W.W. Spirduso[c]. [a]Dept. of Sports Medicine, Pepperdine University, Malibu, CA 90265. [b]Dept. of Pharmacology and [c]Dept. of Physical and Health Education, University of Texas, Austin, TX 78712.

Twenty young, 3 month, and twenty old, 18 month, male Sprague-Dawley rats were shaped in a reactive capacity test to quickly release a lever, in response to auditory and visual stimuli, in order to avoid footshocks. The animals were tested for 50 trials a day for 7-14 days (Session 1). The animals that met the preset performance criterion level were tested again 3 months (Session 2) and 6 months (Session 3) later for consecutive 5 days. The animals were then sacrificed and their striata dissected for biochemical assays. [^{3}H]-Spiperone receptor binding assays were performed to determine the density and affinity of striatal D_2 receptors. Concentrations of dopamine and two of its major metabolites, DOPAC and HVA, were measured using high performance liquid chromatography with an electrochemical detector.

Significant age differences in reactive capacity indicated that the young (9 month) animals were more successful at the task and responded with faster latencies than the old (24 month) animals. Further analysis however indicated that the age differences in reactive capacity were significant only on the first two days of each testing session. The young animals demonstrated a greater retention of reactive capacity performance across sessions than the old animals. In this well-learned task, retention of performance across sessions, and not the capacity to react, was most affected by the aging process.

Receptor binding results showed that the young animals had a significantly greater number of dopamine D_2 receptors than the old animals. No significant age differences were found in receptor affinity (1/Kd) or concentrations of dopamine, DOPAC, or HVA. When the concentrations of dopamine, DOPAC, and HVA were expressed as a ratio of DOPAC+HVA/dopamine the old animals had a significantly higher ratio than the young animals.

Further support for the relatonship between reactive capacity and nigrostriatal dopamine function was found in that significant positive correlations were found between reactive capacity performance and receptor density (r=.67) as well as between reactive capacity and the ratio of DOPAC+HVA/DA (r=.47).

Sponsored by grants to P. Gilliam MacRae, N01-AG-3-2104, W.W. Spirduso & R.P. Farrar, AG020271-03, R.E. Wilcox & W.W. Spirduso, NS20827, W. Riffee & R.E. Wilcox, MH33442.

214.5 Alterations of neurotransmitters with aging in coho salmon (Oncorhynchus kisutch, Walbaum). S.O.E. Ebbesson, J.E. Smith, G.T. Bazer*, R.P. Bailey*, and J.B. Reynolds*. Depts. of Anatomy and Psychiatry, Louisiana State Univer. Sch. of Med., Shreveport, LA 71130 and Dept. of Med. Sci. and Alaska Cooperative Fishery Unit, University of Alaska, Fairbanks 99701.

Whole brain content of several biogenic amines and amino acids was determined in two age groups of coho salmon using HPLC techniques. Brains of presmolt salmon (about 4-5 months old) were compared to brains of homeward migrants (about 4-5 years old). Levels of dopamine and serotonin were significantly higher in the homeward migrants than in presmolts, while glutamine and GABA were significantly lower in the older age group. Levels of other amino acids, such as aspartate, glutamate, serine, glycine and taurine were the same in the two age groups.

Biogenic Amine Content (^{pmoles}/mg protein)

	Presmolts n=5		Adult's n=6		
*Dopamine	4.8	(±1.5)	14.8	(±4.9)	***
*Serotonin	4.5	(±1.2)	15.2	(±3.9)	**

Amino Acid Content (^{nmoles}/mg protein)

GLN	61.46	(±7.64)	43.26	(±4.52)	**
*GABA	38.17	(±2.34)	28.18	(±3.87)	**

*Known neurotransmitter

Values are means ± standard deviations.
The significance of the differences determined with Student's t-tests were: ** p<0.001; *** p<0.01

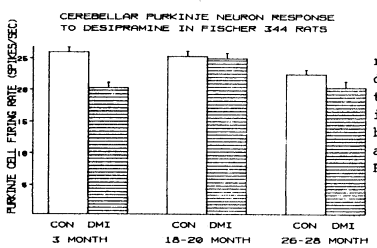
These findings point to selective changes in neurotransmitters with aging and perhaps with changes in behavior, but whether this relates to qualitative alterations in circuitry remains to be seen.

The brains were collected October 4, 1984, at the Crooked Creek Hatchery, Kenai Peninsula, Alaska.

214.6 **AGE-RELATED DECREASE IN CEREBELLAR PURKINJE NEURON RESPONSE TO DESIPRAMINE IN FISCHER 344 RATS** P.C. Bickford[1,2,3], K. Parfitt[1,*], B.J. Hoffer[1,2,], and R. Freedman[1,2,3,*]. [1]Departments of Pharmacology and [2]Psychiatry, University of Colorado Health Sciences Center, and [3]VAMC, Denver, CO 80262.

Depression is a significant problem in the elderly population and antidepressant drugs are frequently administered to alleviate the symptoms. Enhancement of noradrenergic (NE) neurotransmission is thought to be important in the mechanism of action of tricyclic antidepressants. In aged rats the effects of locally applied NE on neuronal discharge are markedly diminished. We therefore have investigated whether the tricyclic antidepressant desipramine (DMI) can augment neurotransmission in these animals. DMI (10 mg/kg/day) was administered for 3 weeks via Alzet minipumps implanted subcutaneously in young (3 month), and old (18-20 month or 26-28 month) Fischer 344 rats. Effects on noradrenergic neurotransmission were monitered by measuring cerebellar Purkinje neuron firing rate which is regulated primarily by NE (Hoffer et al, Brain Res. 30:425-430, 1971). Increases in NE neurotransmission slow Purkinje cell firing rates, while decreases result in increased firing rates.

No effect of DMI was observed with a single acute dose of 20 or 40 mg/kg i.p. in young rats. However, chronic DMI administration produces a decreased cerebellar Purkinje neuron discharge rate. This change was observed as early as three days of treatment and continued for up to 21 days of treatment. The effect of DMI on discharge rate was reversed by propranolol (5 mg/kg ip). DMI induced slowing could not be observed in animals pretreated with 6 hydroxydopamine. In contrast to young rats, at 18-20 or 24-26 months the decrease in cerebellar Purkinje neuron firing rates after treatment with DMI for 21 days was not observed (see figure below). There was a significant age-drug response interaction at p<0.05 using an analysis of variance. There was a slight elevation of DMI levels in cerebellar tissue of the older rats.



Taken together these results suggest a decreased efficacy of tricyclic antidepressants in aged rats. (Supported by USPHS grant AG04418 and the VA Medical Research Service.)

214.7 **AGE-RELATED ALTERATIONS IN MONOAMINE RELEASE FROM RAT STRIATUM: AN IN VIVO ELECTROCHEMICAL STUDY.** G. Rose[1,2], G. Gerhardt[1], G. Conboy[1*] and B. Hoffer[1]. [1]Dept. of Pharmacology, University of Colorado Health Sciences Center and [2]Medical Research, VAMC, Denver, CO 80262

Deficits in psychomotor performance are a consequence of normal aging. Current evidence suggests that one CNS substrate for this behavioral abnormality involves a decline in striatal dopaminergic transmission. While postsynaptic modifications of striatal dopaminergic connections during aging (e.g., reductions in striatal dopamine receptor density) have been well documented, presynaptic changes have been less well defined. Therefore, in the present study, in vivo electrochemistry was used to examine presynaptic alterations in dopamine release in the striatum of aged rats.

Chronoamperometric determinations of monoamine release, induced by local micro-pressure applications of K^+, were made using Nafion-coated graphite epoxy electrodes; these electrodes minimize any signal derived from ascorbate or urate, or acidic monoamine metabolites. Recordings were made from the striatum of urethane-anesthetized Fisher 344 rats at 6, 24, and >29 months of age. Following the in vivo electrochemical experiments, the animals were sacrificed and the caudate nucleus removed for analysis of whole tissue levels of monoamines and their metabolites using standard HPLC techniques.

Overall, mean amplitudes of K^+-evoked releases from the striatum of 6 mo. and 24 mo. F344 rats did not differ significantly (6.8 uM $\pm$ 0.38 (S.E.M.) vs 6.0 uM $\pm$ 0.36; $p > 0.1$). However, this result was complicated by the observation that the mean values obtained from two separate groups of 24 mo. animals, recorded 6 months apart, were significantly different from each other (group 1--8.0 uM $\pm$ 0.64; group 2--4.8 uM $\pm$ 0.34; $p < 0.001$). Mean releases for the latter 24 mo. group were significantly less than for the 6 mo. group ($p < 0.01$). No difference was found in the release magnitudes of 6 mo. animals recorded contemporaneously with the two groups of 24 mo. rats. Release amplitudes for the >29 mo. group (4.0 um $\pm$ 0.37) were clearly less than from the 6 mo. animals ($p < 0.001$). Both groups of 24 mo. rats, as well as the >29 mo. animals, also showed significant prolongation in the timecourses of the K^+-evoked releases when compared to the 6 mo. group ($t_{1/2}$ values in sec: 6 mo.--87 $\pm$ 7.1; 24 mo.--130 $\pm$ 15; >29 mo.--130 $\pm$ 11; 6 vs 24, $p < 0.02$; 6 vs >29, $p < 0.01$). Whole tissue levels of the monoamines and their principal metabolites did not differ between ages (striatal dopamine levels $\pm$ 8500 ng/gm for all groups; DA/DOPAC ratios $\pm$ 5.5:1). Thus, dynamic alterations in presynaptic monoamine function, which are not reflected in whole tissue levels, occur in rat striatum with aging. (Supported by USPHS grant AG04418 and the Veterans Administration Medical Research Service.)

214.8 REDUCTION IN SOMATOSTATIN CONTENT IN THE SCIATIC NERVE OF THE AGING FISHER RAT. S.F. Lewis, A. Brodish and D.B. MacLean (SPON: P. Smith), Dept. of Med. and Physiol., Wake Forest Univ. Med. Ctr., Winston-Salem, NC 27103.

Somatostatin (SS) and substance P (SP), two widely distributed neuropeptides, are synthesized in primary sensory neurons within sensory ganglia and transported bidirectionally, towards the CNS and peripherally towards sits of innervation. Substance P may mediate nociception and chemoreception at synapses within the CNS, while peripherally it partly mediates neurogenic inflammation and perhaps other related (e.g. immune) responses. Although the functions of sensory neuron SS are undefined, it may inhibit both the release and actions of SP. The roles of these two peptides in altered autonomic and somatosensory responses that have been described with aging are unknown.

Male Fisher rats, either young (4 months), middle aged (12 months) or old (25 months) were decapitated and the sciatic and vagus nerves rapidly removed. Nerves were cut into equal 3mm segments and subsequently extracted. Neuropeptide content was determined using specific RIA's. The content of neuropeptide (pg, mean $\pm$ SEM) and protein (ug), expressed per 3 mm nerve segment, are shown below:

		SP	SS	Protein	SP	SS	Protein
	(n)	Vagus			Sciatic		
Young	(22)	56±4	0.8±0.1[a]	23±2	78±4	16±1[b]	151±6[b]
Middle	(26)	60±5	1.3±0.2[a]	29±3[b,c]	74±4	11±1[b,c]	194±5[b]
Old	(24)	60±6	0.9±0.1	31±3[b,c]	77±4	9±1[b,c]	227±8[b]

[a] $P<.05$ vs other groups [b] $P<.01$ vs younger group(s)
[c] NS vs middle aged group

These findings demonstrate: 1) that there is an increase in vagal and sciatic protein content with age that is not matched by an equal increase in neuropeptide content; 2) that SS content in the sciatic nerve declines as a function of age, unlike the vagus nerve in which peptide content is maintained or increased; and 3) most of the age related changes occur relatively early with a declining rate of change thereafter. The differential effect of aging on SS vs SP content in the sciatic nerve is similar to our observations in the chronic diabetic rat (Diabetes, suppl. 1985, #406). Further studies are in progress to determine whether the decline in content reflects increased neuropeptide turnover within the nerve, decreased synthesis/transport, or both.

Studies were supported by grant AG-04207 from the NIA.

214.9 CHOLINE ACETYLTRANSFERASE IN HUMAN CEREBROSPINAL FLUID: FACT OR ARTIFACT? L.I. Szweda*, D.D. Bloom*, J.L. Dahl, M.E. Salinsky*†, and C.D. Johnson*‡ (SPON: T.A. Rudy). Departments of Pharmacology, Neurology†, and Zoology‡, University of Wisconsin-Madison, Madison, WI 53706.

The activity of the enzyme choline acetyltransferase (ChAT), a specific marker for cholinergic neurons, is much reduced in cortical biopsy material from patients with Alzheimer's disease. There have been numerous suggestions that the activity of this enzyme in the cerebrospinal fluid (CSF) might be a useful indicator of the degree of central cholinergic deficiency and of the effectiveness of potential treatment strategies. However, reports of ChAT levels in the CSF have provided conflicting results. We therefore examined assay procedures for specific measurement of the activity of the enzyme in the CSF.

CSF was obtained by lumbar puncture from ten patients, eight with no evidence of neurologic disease, two with a diagnosis of Alzheimer's dementia. We used the radiometric assay of Fonnum [J. Neurochem. 24, 407 (1975)] to measure ChAT activity. In this assay [^{3}H]acetylcholine (ACh) synthesized from [^{3}H]acetyl CoA is extracted into an organic phase as a complex with tetraphenylborate (TPB). We obtained evidence for the CSF-dependent formation of an extractable radiolabeled product. However, the formation of this product was not affected by the presence of acetylcholinesterase in the assay or by boiling the CSF prior to assay. It was further observed that its extraction into the organic phase did not require TPB. These results indicated that the radiolabeled product was not ACh, and indeed in subsequent experiments we observed that the reaction product did not comigrate with authentic ACh when subjected to high-voltage paper electrophoresis at pH 1.9 [J. Neurochem. 2, 231 (1971)]. Similar results were obtained when CSF samples were dialyzed, frozen, or concentrated prior to assay.

Thus we could find no evidence for either the enzymatic or non-enzymatic production of ACh by CSF. Neither did we find any evidence for ChAT inhibitory activity in the CSF as it did not inhibit the enzyme isolated from chick brain. Our results call attention to the dangers inherent in the use of radiometric assays for assessing ChAT activity unless careful attention is paid to possible artifactual production of extractable radiolabeled material. They further suggest that if there is ChAT in lumbar CSF, the levels are too low to be detected by a conventional radiometric assay. On the other hand, they do not rule out the presence of ChAT in CSF from intracranial sites. Supported by funds provided by the Research Committee of the Graduate School of the University of Wisconsin to JLD.

214.10 PROPERTIES OF SINGLE MOTOR UNITS IN THE MEDIAL GASTROCNEMIUS MUSCLE OF MIDDLE-AGED AND OLD RATS. K.Kanda*, K.Hashizume*, E.Nomoto*, and S.Asaki* (SPON: H.Washio). Dept. of Physiol., Tokyo Metropolitan Institute of Gerontology, Tokyo 173, Japan.

Age-related changes in the mammalian neuromuscular system have been studied using physiological, histological, and histochemical techniques. Interpretation of the data from whole-muscle studies is difficult, however, because most muscles consist of motor units with widely varying properties. Our study therefore was directed at individual motor units; we examined various properties of such units in middle-aged (11-14 months) and old (26-30 months) male Fischer rats anesthetized with urethane and chloralose. The distal portion of the medial gastrocnemius (MG) muscle was carefully dissected from the surrounding tissues. The tendon of the muscle was attached to a strain gauge through a small steel hook. The mechanical properties of the motor units were studied by stimulating single MG axons in the dissected ventral root filaments. After the physiological experiments, the MG muscle was excised for histochemical studies. The wet weight of the MG muscle in the old rats decreased by about 24% compared with that in the middle-aged rats (0.63 g vs. 0.83 g). Data of 132 motor units taken from 8 middle-aged rats and 93 units from 6 old rats were analyzed. It was possible to classify all the motor units into 4 types (FF, FI, FR and S) using similar criteria ("sag" property in unfused tetani and fatigability) to those previously applied to cat hindlimb muscles. The composition by type for middle-aged rats was FF (fatigue index < 0.5) and FI (0.5-0.75) units, 37.2%; FR (> 0.75), 48.5%; and S, 14.4%. The MG muscle in old rats exhibited a relatively high proportion of S units (28.4%) and type I muscle fibers, but fewer FR units (35.8%). The twitch contraction time after maximum post-tetanic potentiation was shortened in FF and FI units (15.1 $\pm$ 2.1 ms for old rats vs. 17.0 $\pm$ 2.0 ms for middle-aged rats, t test, $P < 0.001$), but not in FR (15.4 $\pm$ 2.7 ms vs. 15.3 $\pm$ 2.1 ms) and S (27.9 $\pm$ 4.5 ms vs. 28.2 $\pm$ 5.5 ms) units. Post-tetanic potentiation of FF, FI and FR units was significantly less in the old rats. There was a large increase in the tetanic tension for S units (3.0 $\pm$ 1.7 gwt vs. 1.6 $\pm$ 0.6 gwt, $P < 0.001$), but a slight decrease for FF and FI (14.7 $\pm$ 6.9 gwt vs. 17.9 $\pm$ 8.1 gwt, $P > 0.05$) and FR (6.7 $\pm$ 4.0 gwt vs. 9.5 $\pm$ 4.3 gwt, $p < 0.002$) units. Conduction velocity of axons slowed down in all unit types (50.9 $\pm$ 11.2 m/s vs. 62.9 $\pm$ 4.2 m/s, $P < 0.001$ for FF and FI; 44.1 $\pm$ 10.3 m/s vs. 66.3 $\pm$ 3.5 m/s, $P < 0.001$ for FR; 46.1 $\pm$ 8.2 m/s vs. 57.6 $\pm$ 5.4 m/s, $P < 0.001$ for S). These results suggest that motor unit reorganization takes place in the late stage of the animal's life. However, the underlying mechanisms of the changes found in this experiment must await further studies.

214.11 SPECIFICITY OF INTRAHIPPOCAMPAL GRAFT-INDUCED IMPROVEMENTS ON COGNITIVE PERFORMANCE IN AGED RATS. F.H. Gage and Anders Björklund. Department of Neurosciences, University of California, San Diego, and Department of Histology, University of Lund, Sweden.

We have recently demonstrated that, a subgroup of aged rats are severely impaired in spatial reference memory, using the Morris swim maze, and that this impairment is selectively and specifically correlated with decreases in 2-deoxyglucose utilization in the hippocampal formation and the prefrontal cortex (Gage et al., J. Neurosci. 1984). We have subsequently reported that grafting of cholinergic neurons to the hippocampus of these age-impaired rats will result in a significant post-graft amelioration of this cognitive deficit (Gage et al., Science 1984). In order to better understand the nature of the functional recovery observed, both in terms of the extent of the behavioral recovery, and the mechanism by which the grafts induce restoration of function, we have replicated and extended our previous results. First, we have modified the behavioral test situation, so that both spatial and non-spatial memory can be measured. Secondly, we have administered pharmacological probes with physostigmine and atropine to determine the specificity of the cholinergic involvement, both with the initial deficit and with the recovery induced by the graft. Our results reveal that aged rats that are impaired are impaired on both spatial and non-spatial reference memory. However, the majority of aged rats are not impaired in either spatial or non-spatial reference memory. Those aged animals that are impaired show a transient and small improvement in non-spatial reference memory with a single injection of physostigmine. Only a small performance decrement was observed following atropine injections in the young control animals, while those aged animals that normally showed no reference memory impairments, were significantly impaired only in spatial reference memory following injections of atropine. Suspension grafts of basal forebrain rich in cholinergic neurons once again resulted in amelioration of the deficits in the age-impaired animals. The improvement was observed in both spatial and non-spatial reference memory. Injections of atropine reversed the positive effects of the grafts on both the spatial and non-spatial components of the task. These results suggest that the grafts are having their functional effects at least partly through the cholinergic system.

214.12 FORMATION OF CHOLINERGIC SYNAPSES IN THE DENTATE GYRUS OF BEHAVIORALLY-IMPAIRED YOUNG AND AGED RATS BY GRAFTED BASAL FOREBRAIN NEURONS. D.J. Clarke, F.H. Gage, and A. Björklund. University Department of Pharmacology, Oxford, UK (DJC), Department of Neurosciences, UCSD, La Jolla, California (FHG) and Department of Histology, Lund, Sweden (AB).

Previous studies have indicated that fetal cholinergic basal forebrain neurons grafted into the hippocampal formation can ameliorate learning and memory impairments in either young rats with lesions of the septo-hippocampal pathway or aged rats with age-related behavioral deficits. This study investigated the ultrastructural characteristics of the graft/host cholinergic connections in young and aged rats with graft-induced recovery in spatial learning (as assessed in the Morris' water-maze), using choline acetyltransferase immunocytochemistry.

The results showed that grafted ChAT-immunoreactive neurons were capable of forming extensive synaptic contacts with neuronal targets in the dentate gyrus. In young control rats, the majority of cholinergic boutons are known to be synaptic onto dendritic shafts. In the young grafted animals with lesions of the septo-hippocampal pathway, the quantitative relationship between somatic and dendritic synapses of the graft-derived fibers was abnormal such that somatic contacts predominated. In the aged rats, after completion of the behavioral testing (3 months after grafting), the intrinsic cholinergic afferents were removed 1 week prior to tissue processing by a fimbria-fornix lesion. Choline acetyltransferase immunostaining revealed grafts rich in cholinergic perikarya and fiber outgrowth into the host hippocampal formation. Ultrastructurally, the graft-derived boutons were seen to have formed predominantly symmetrical synaptic contacts with neuronal elements in the dentate gyrus.

The results suggest, therefore, that the ability of cholinergic grafts to compensate for behavioral impairments in both young and aged rats may be mediated via direct synaptic actions on host hippocampal target neurons.

214.13 AN ANIMAL MODEL OF HUMAN-TYPE MEMORY LOSS IN AGING BASED ON AGING, DRUG, AND LESION STUDIES WITH THE RAT. J.M. Ordy, R.C. Griffith, Pennwalt Corporation, Rochester, NY 14623, G. Thomas, University of Rochester, Rochester, NY 14624, and W. Dunlap, Tulane University, New Orleans, LA 70118.

Loss of recent memory represents an inevitable manifestation of aging, particularly of Alzheimer's disease. These age and disease related memory impairments have been related to degeneration and/or loss of neurotransmitter-specific neurons in the basal forebrain, and the septo-hippocampal entorhinal circuit. Research strategies for the development of effective drug treatments for human type memory loss in animal models have focused on the essential criteria for measuring trial-specific working memory for correlation with neural changes in neurotransmitter-specific memory circuits produced by aging, drugs, and lesions. The goals of this research program were to develop a valid test of trial-specific working memory with concomitent measures of motivation and neuromuscular performance for the rat in a T-Maze. Specific aims were to examine the effects of: 1) age, 2) basal forebrain, septal, amygdala lesions, and 3) physostigmine, scopolamine, and piracetam on memory, motivation, and motor performance of young, middle aged, and old rats. Aging significantly impaired working memory, motivation, and motor performance. Memory of septally lesioned rats was significantly more impaired than that of basal forebrain, or amygdala lesioned rats. Physostigmine improved, whereas scopolamine impaired memory. Physostigmine also blocked scopolamine impairment of memory. The "nootropic" drug piracetam did not improve memory, nor block scopolamine impairment of memory. The experimental findings of this geriatric research program provide direct support for the emerging view that clarification of age, lesion, and drug effects on transmitter-specific neural memory circuits in animal models represents a very important step in the research strategies for the development of effective drug treatments for recent memory loss in senile dementia and Alzheimer's disease.

214.14 NEUROENDOCRINE AND GENETIC ASPECTS OF AGING IN PLATYFISH. M. P. Schreibman, L. Halpern-Sebold* and H. Margolis-Nunno*. Biology Department, Brooklyn College, Brooklyn, NY 11210.

Age-related changes in the distribution of immunoreactive (ir-) luteinizing hormone releasing hormone (LHRH), serotonin (5HT) and tyrosine hydroxylase (TH) and in the size of cells where LHRH is localized were studied in brains of 8 to 30 (average life span) mo. old platyfish (Xiphophorus maculatus) genetically "constructed" to become sexually mature at two ages (early maturing males (E), 18 wks.; late maturing males (L), 59 wks.). The intensity of ir-LHRH in nucleus olfactoretinalis (NOR) perikarya and fibers in E is similar at 8, 24, and 30 mos.; it increases somewhat at 12, and more at 18 mos. The area of NOR cells in E decreases between 8 and 24 mos. and then shows a minor increase at 30 mos. In L, ir-LHRH in the NOR is most intense at 8 mos. when L are beginning puberty (stage 2). At all other ages there is considerably less NOR ir-LHRH with no elevation at 18 mos. as in E. NOR cell body area in L is smaller than E at 8 and 18, but larger at 12 mos. Ir-LHRH in nucleus preopticus periventricularis (NPP) perikarya of E increases at 18, decreases at 24, and is lowest at 30 mos. Ir-LHRH in L remains constant between 12 and 30, and is lowest at 8 mos. In E, NPP cell body area is maximum at 12 and lowest at 18 and 30 mos. NPP cell areas in L are not elevated at 12 mos. Ir-LHRH in the nucleus lateralis tuberis (NLT) is greatest at 18 mos. in E. In L, although ir-NLT perikarya are never seen, pale ir-fibers are present in the NLT at 12, 24 and 30 mos. In E, NLT perikaryal area decreases between 8 and 30 mos.; in L, it increases between 8 and 12 mos. and then decreases.

In E, ir-5HT in the forebrain is found in the wall of the third ventricle and its paraventricular organ (PVO) and in the pineal gland. Ir-5HT first appears in cell bodies of the nucleus preopticus (NPO) at 18 mos. in E. In L at all ages, ir-5HT is paler than, but similar in distribution to, E; however, ir-5HT is never seen in NPO perikarya of L.

In 12 mo. old E, ir-TH is localized in the NOR, NPO, and PVO. In NOR perikarya, ir-TH is greatest at 12 mos. and absent at 8 and 30 mos.; in the NPO it is highest between 12 and 24 mos. and in the PVO it is at low levels between 8 and 24, and absent at 30 mos. In L, low levels of ir-TH are found in the PVO only between 8 and 24 mos. and no ir-TH perikarya are localized in the NOR or NPO at any age.

Our report suggests that distinct changes occur throughout life in the distribution and relative quantities of the neuropeptides and neurotransmitters regulating the reproductive system and that the profiles of these changes are not similar in fish which differ in genotype for the time of sexual maturation. (Supported by NIA (AGO-1938) and PSC-CUNY).

214.15 AN AGE-RELATED DECLINE IN HIND-PAW SHOCK INDUCED ANALGESIA. R. J. Hamm and J. S. Knisely*. Department of Psychology Virginia Commonwealth University, Richmond, VA 23284.

In order to examine the function of an endogenous, nonopioid system of pain inhibition during aging, rats (3,14, and 24 mo old) were shocked on their hind paws. Rats were exposed to 90 sec of scrambled electric shock delivered to their hind paws. Because the 14 mo old and the 24 mo old rats had approximately a 0.1 mA higher shock threshold than the 3 mo old rats, the 3 mo old rats were exposed to a 1.6 mA shock intensity to induce analgesia while the 14 and 24 mo old rats were exposed to a 1.7 mA shock. After shock termination, tail-flick latencies were measured at 0,1,2,4,6,8,10,12 and 14 min.

To investigate the pharmacology and anatomy involved in the production of hind-paw shock induced analgesia, the effects of naltrexone (7 mg/kg), scopolamine (5 mg/kg), saline (1 ml/kg), and adrenalectomy were examined across age groups. A 3(Age) x 9(Time) analysis of variance of the tail-flick latencies following saline treatment revealed that there was an age-related reduction in the degree of analgesia produced by hind-paw shock ($p < 0.0001$). An analysis comparing naltrexone-treated animals and saline-treated animals demonstrated that naltrexone did not attenuate the analgesia observed following hind-paw shock in any age group. A similar analysis of the analgesia observed following adrenalectomy also found that adrenalectomy did not reduce hind-paw shock induced analgesia in any age group. An analysis of analgesia following saline and scopolamine treatment revealed that scopolamine significantly attenuated the analgesia produced by hind-paw shock ($p < 0.001$). In addition a measure of the effectiveness of scopolamine's blockade of analgesia revealed that there was an age-related decline in the degree to which scopolamine reduced hind-paw analgesia.

These results confirm that hind-paw shock activates a neurally mediated, nonopioid analgesic system that involves cholinergic sites. The results also demonstrate that as age increased there was a progressive reduction in the degree of analgesia induced by hind-paw shock. The age-associated changes in the effectiveness of scopolamine suggest that the decline in hind-paw shock induced analgesia is the result of an alteration in the function of the cholinergic system during aging.

214.16 OXOTREMORINE-INDUCED ANALGESIA IN MATURE AND SENESCENT RATS. J. S. Knisely* and R. J. Hamm (Spon: D. J. Mokler). Dept. of Psychology, Virginia Commonwealth University, Richmond, Virginia 23284.

In order to investigate the role of the central muscarinic cholinergic system in the production of analgesia during aging, rats (3-mo, 10-mo and 23-mo-old) were subcutaneously injected with oxotremorine (0.025, 0.05 or 0.10 mg/kg) in conjunction with 0.19 mg/kg scopolamine methylbromide (dose equimolar to 0.10 mg/kg oxotremorine). Before drug administration, baseline pain thresholds were determined using 3 tail-flick trials (1 minute ITI). Following the injections, tail-flick latencies were measured at 5 minute intervals through 30 minutes and at 45, 60, 75 and 90 minutes.

Post-drug TF latencies were converted to percent maximum possible effect (% MPE) and were analyzed by a 3(Age) x 3(Dose) x 11(Time) analysis of variance. The analysis revealed no age-related differences in oxotremorine-induced analgesia. However, there were main effects of Drug ($p < 0.001$) and Time ($p < 0.0001$) and a significant Drug x Time interaction ($p < 0.0001$). Thus increasing the dose of oxotremorine enhanced analgesia and the analgesia displayed, varied across time.

To more closely examine the dose-related analgesic effects of oxotremorine, a least-squares linear regression line was calculated for each age-group independently using % MPE scores at the peak-effect time (usually 15 to 25 minutes) for each dose of the muscarinic agonist. From this analysis, the correlation coefficient, slope and y-intercept of each regression line were determined and age groups compared. For the regression analysis, doses were converted to μg/kg. It was found that oxotremorine (plus methylscopolamine) produced analgesia in a dose-related fashion: correlation coefficients were 0.65, 0.77 and 0.59 for 3-mo-old, 10-mo-old and 23-mo-old rats, respectively. This analysis also revealed that 10-mo-old animals were slightly more sensitive to oxotremorine-induced analgesia than the other 2 age groups tested.

These results demonstrate a lack of age-related differences in analgesia produced by the stimulation of central muscarinic cholinergic receptors. This finding is supported by other research which has revealed that aged animals show an equivalent or increased pharmacological responsivity to exogenous cholinomimetics.

Supported in part by a Grant-in-Aid of Research from Sigma Xi, The Scientific Research Society and NIA Dissertation Grant.

214.17 AGE-RELATED DECREASE IN THE CATECHOLAMINERGIC INNERVATION OF THE MOUSE SPLEEN. A. Capocelli*, D.L. Bellinger, D.L. Felten and P.D. Coleman. Department of Anatomy, University of Rochester, Rochester, NY 14642.

Age-related alterations in immune function have been described in a number of mammals, including human and rodent. We are examining whether these alterations in immune function in mice may be related to possible changes in the catecholaminergic innervation of the organs of the immune system as a function of age. Male C57Bl/6 mice were obtained from the NIA colony at Charles River Breeding Laboratories and sacrificed at 6 ages from 7 to 38 months. Usually there were three mice at each age, with the exception of the oldest ages. The spleen, thymus, lymph nodes and brain were removed quickly, weighed, frozen on dry ice and placed in liquid nitrogen. Frozen sections of spleen were subsequently cut at 10 um and processed for induced fluorescence by the sucrose-phosphate-glyoxylic acid (SPG) method of de la Torre (1983). The sections were examined in a Nikon Biophot fluorescence microscope using epi-illumination. All microscope fields containing observable fluorescent fibers were photographed at 160x. Blind, qualitative examination of complete sets of micrographs permitted us to distinguish abundant innervation, moderate innervation, or sparse innervation of the spleen. These judgments in C57Bl/6 mice correlated with age. Younger animals showed abundant plexuses of varicosities surrounding both large and small vessels of the central arterial system in the white pulp, linear and punctate strands of varicosities in the parenchyma of the white pulp, and arrays of fibers associated with the splenic capsule and trabeculae. Age-related changes in older mice included progressive diminution of the size and fluorescent intensity of plexuses associated with blood vessels, diminished fluorescent parenchymal profiles in white pulp, and reduced presence of arrays of varicosities associated with the splenic capsule and trabeculae. In addition, the number of intensely autofluorescent cells in the splenic white pulp increased with age. Quantitative evaluation of fluorescent varicosities is under way. We tentatively conclude that catecholaminergic innervation of the spleen decreases with increasing age in the C57Bl/6 mouse.

214.18 Mechanism of Nerve Resistance to Ischemic Conduction Failure with Increasing Age

J. D. Schmelzer*, K. K. Ward* and P. A. Low

Human peripheral nerve is more resistant to ischemia-anoxia with increasing age but the mechanism of this resistance to ischemic conduction block (RICB) is not known. We found that peripheral nerve of the Sprague Dawley rat also had increasing RICB with age and related RICB to oxygen consumption (VO_2), nerve ATP, creatine phosphate (CP) and lactate at rest and after anoxic stress (table; n>6).

Parameters	100 g	300 g	500 g
Time to 50% conduction block	8.1±0.5[a]	11.9±1.1[b]	25.9±1.8[c]
O_2 consumption (VO_2)(ml/kg/hr)	800.6±29.9	609.1±17.7[c]	386.2±17.1[c]
nerve ATP(nmol/mg)-at rest	1.07±0.07	0.69±0.05[c]	0.45±0.02[c]
- 15 min. anoxia (% of resting)	24.5±2.1	51.0±2.6[c]	70.5±2.8[c]
nerve CP(nmol/mg)-at rest	2.27±0.09	1.74±0.04[c]	1.32±0.05[c]
- 15 min. anoxia (% of resting)	4.7±1.0	13.9±1.4[c]	32.5±1.2[c]
nerve lactate(nmol/mg)-at rest	1.85±0.14	1.49±0.11[c]	0.93±0.06[c]
- 15 min anoxia (% of resting)	447.5±12.5	562.8±25.1[c]	588.6±20.5[c]

a = SEM
b = $0.001 < P < 0.01$
c = $P < 0.001$

The ages for 100 g., 300 g. and 500 g. rats were 30.3±0.6, 66.5±0.9 and 232.5±6.2 days respectively. Rat peripheral nerve underwent progressive RICB with age. Time to 50% block of conduction was increased by 47% and 220% for 300 g. and 500 g. rats respectively, as compared to the 100 g. rats. The major mechanism of RICB is a progressive reduction in energy requirements as indicated by a progressive reduction in O_2 consumption and in ATP and CP utilization of sciatic nerve with increasing age. An additional mechanism appears to be a slight increase in anaerobic metabolism as indicated by a greater percent increase in endoneurial lactate under anoxic stress.

214.19 EXPERIMENTAL ISCHEMIA IN AGED RATS: EFFECT ON BRAIN MICROVESSEL ß-ADRENERGIC RECEPTORS (ß-R). M.S.Magnoni*, S.Govoni and M.Trabucchi. Inst. of Pharmacol. and Pharmacognosy, Univ. of Milan and Chair of Toxicology, 2nd Univ. of Rome, Italy.

Right carotid occlusion (RCO) induces in the rat a more pronounced and persistent decrease in the density of ß-R located on cerebral capillaries of the controlateral hemisphere. On the other hand, the occlusion of the left carotid induces a greater ipsilateral decrease in ß-R number, suggesting that the left side of the brain is more sensitive to the ischemic insult, independently of the side of carotid occlusion. Corpus callosum section partially prevents the controlateral neurochemical changes induced by RCO, suggesting that the effects of ischemia in brain areas distant from the insult are mediated by transneuronal mechanisms. Thus, the different response of microvasculature of the two hemispheres to ischemia may be due to asymmetries in neuronal pathways controlling cerebral microcirculation. Along this line, the effect of ischemia on microvessel ß-R function was studied during aging, a condition associated with altered patterns of both neuronal activity and vascular regulation. Aged S.D. rats (24 months) underwent 48 hrs RCO and ß-R were measured in brain microvessels using the specific radioligand ^{125}I-iodocyanopindolol. The results indicate that aged rats show a reduced density of capillary ß-R. In addition the RCO does not induce a decrease of ß-R density in the controlateral hemisphere of old rats. The altered pattern of neuronal regulation of brain capillaries which occur during aging may lead to the reduced basal level of ß-R and to the loss of the asymmetric response of cerebral microvasculature to the ischemic insult. The qualitative difference in the brain microvascular reactivity to ischemia during aging may be of potential interest for the study of the acute cerebrovascular disease in the elderly.

This study was supported by CNR contract N° 8402557.56 . The gift of aged rats by the Italian Study Group on Brain Aging is aknowledged.

214.20 THE INTERACTION OF AGING AND ENDURANCE EXERCISE UPON SKELETAL MUSCLE OF PREDOMINANTLY DIFFERENT FIBER TYPE. R.P. Farrar[1,2], T.J. Walters[1], G. Cartee[1], and H.L. Sweeney[1]. [1]Dept. of Physical Education and [2]Division of Pharmacology, Univ. Texas at Austin.

Does aging induce an intrinsic decline in physiological function or are the declines observed as a result of decreased activity? This experiment was designed to control for the amount of exercise young and old rats were engaged in, and measure changes in aerobic capacity and myosin isozyme patterns in a predominancly slow twitch muscle, soleus (SOL), and a predominantly fast twitch muscle, extensor digitorum longus (EDL). Male, F344 rats were divided into 4 groups; young sedentary (YS), young trained (YT), old sedentary (OS), old trained (OT). YT and OT initiated training at 4 and 18 mo of age, respectively. Both groups trained at the same absolute workload throughout the study running 5 d/wk, up to 60 min/d, and up to 20 m/min. At the end of 6 mo of training both trained and age-matched sedentary groups were sacrificed. Training produced significant increases in oxidative enzyme activity over their age matched controls, and this increased activity was not significantly different between YT and OT. The EDL on the other hand showed no significant changes in any oxidative enzyme marker due to age or training. Electrophoresis of the myosin light chain patterns demonstrated no changes in the SOL, but a shift in the light chain patterns due to aging in the EDL. The young groups contained higher LC_3 content than the old groups. The OT showed higher LC_3 content than OS and this would infer a higher percentage of IIB fibers being maintained by training in the OT group, but still less than the young groups, trained or sedentary.

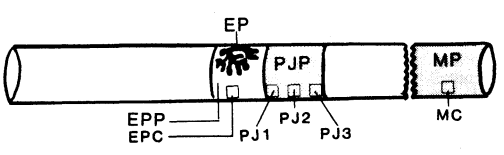
214.21 METABOLISM OF ACETYLCHOLINE AT THE NEUROMUSCULAR JUNCTION OF MATURE ADULT AND AGED RATS. M. H. Weiler and D. O. Smith. School of Pharmacy and Department of Physiology, Univ. of Wisconsin, Madison, WI 53706.

In rat diaphragm neuromuscular junctions, acetylcholine (ACh) levels and quantal size decline but evoked release remains constant during aging. This is associated with increased leakage of ACh from the cytoplasmic pool in aged animals. The causes of declining ACh levels are further examined in this study of ACh synthesis and release. Hemidiaphragms from rats aged 10 (mature adult controls) and 28 (aged) mos were dissected and preincubated in circulating oxygenated saline (37°C) containing physostigmine (50 uM). Endogenous and labeled ACh and choline (Ch) were then monitored using gas chromatography-mass spectrometry at various times following addition of $^2H_4$-Ch (10 uM) to the medium. In the older rats, endogenous Ch levels and efflux were consistently higher; moreover, incorporation of $^2H_4$-Ch was also greater. This incorporation must involve diffusion pathways, for uptake (V_{max}) by the high-affinity pathway has been shown to decrease with age. During stimulation, the synthesis of $^2H_4$-ACh equilibrated more rapidly in the 28-month animals, resulting in a 2-fold higher specific activity of labeled ACh within 8 min; in separate experiments, we found choline acetyltransferase activities unchanged with age. After 20 min, however, similar steady-state specific activities were reached. (Synthesis in noninnervated tissue was negligible). Thus, synthesis appears to occur at a more rapid rate in the aged rats. At rest and during stimulation, though, release of total ACh (endogenous plus tracer) was greater in the older animals. This was due to greater leakage of endogenous ACh during aging, because the specific activity of the released ACh was less in the aged group. Thus, ACh is synthesized more rapidly in the older preparations, but the newly synthesized ACh is not released as readily. We conclude that reduced ACh levels during aging are due primarily to increased leakage of the transmitter. Since this cannot be due to a larger concentration gradient in the older animals, it may be attributed to an age-related increase in membrane permeability to ACh. Supported by PHS grants AG01572 and MH17691 and a starter grant from the Pharmaceutical Manufacturers Association Foundation.

214.22 MICROLOCALIZATION OF ACH RECEPTORS IN YOUNG AND OLD C57 MOUSE MUSCLE. N.A.Anis* and N. Robbins, Dept. of Dev. Genetics & Anatomy, Case Western Res. Schl. of Med., Cleveland, OH 44106.

In limb muscles of aged C57 mice, min. end-plate potential (mepp) amplitude increases but there is no change in input resistance (Anis & Robbins, Neurosci. Abst. 10, ,1984). An accurate measure of AChR per endplate is necessary to elucidate this result, but the usual method of quantitating junctional AChR involves error due to the subtraction of the perijunctional component. Also, perijunctional AChR itself is of interest because it changes with disuse and denervation, and may relate to increased sprouting with age. Therefore, we carried out microdissection of individual muscle fibres combined with I-125 alpha-bungarotoxin (*BTX) labelling to assess junctional and perijunctional AChR in young (8-12 mo) and old (24-25 mo) C57 mice.

After incubation in and washout of *BTX, soleus muscles were teased into individual fibers, which were each cut in 3 pieces (see Fig.). Gamma counting, measurement of surface area, cholinesterase staina, and autoradiography were used to compute results. In both young and old mice, EPC and PJ1 grain counts were similar but PJ2 and PJ3 were less, so that a modified method of subtraction of gamma counts (EPP minus PJP) could be used to find true endplate AChR densities (sites per sq. micra). These were 7,975 +/-1235 S.E. and 7,301 +/-992 at old and young endplates respectively (total counts per endplate were also similar). The corresponding perijunctional values were 201 +/- 51 and 313 +/-97.



Thus, endplate AChR density does not change with age, and increased mepp amplitude must be due to other factors. Perijunctional AChR in old mice shows no changes characteristic of disuse or denervation.

214.23 TRANSMITTER RELEASE AND ULTRASTRUCTURE OF YOUNG AND OLD MOUSE NEUROMUSCULAR JUNCTIONS IN LOW CALCIUM SOLUTIONS. M.A.Fahim and N.Robbins, Gerontology Research Center, University of So. California, Los Angeles, CA 90089 and Department of Developmental Genetics & Anatomy, Case Western Reserve School of Medicine, Cleveland, OH 44106.

Transmitter release increases at hindlimb neuromuscular junctions (nmj's) of aged CBF-1 mice, (Banker, Kelly & Robbins, J. Physiol., 339: 355, 1983) but the mechanism is unknown. Therefore, we studied the relation between external Ca and quantal content (mean EPP/mean mepp) in soleus muscles of young mature (7 mo.) and old (29 mo.) mice. In addition, we examined synaptic vesicle density in junctions fixed in zero Calcium solutions to minimize offects of fixation-induced release.

At Ca concentrations of 0.3 to 1.0 mM (with 2.75 mM Mg), quantal content was greater at nmj's of old mice, and a plot of quantal content vs. log Ca was similar but shifted to the left in old mice. This finding was consistent with a quantitative rather than a qualitative difference in transmitter release with age. In order to determine if this difference was related to the number of vesicles ready for release (i.e. within 200 nm of the nerve terminal membrane), morphometry was carried out on electron micrographs of 15-18 nmj's per age group, in muscles fixed either in 0 or 2.5 mM Ca. In 2.5 mM Ca, vesicle density was reduced in old muscles, as previously reported for the whole terminal (Fahim & Robbins, J. Neurocytol., 11: 641,1982). However, in muscles fixed in 0 Ca., there was no age difference in synaptic vesicle density (135 +/- 10 vs. 129 +/- 13 vesicles per unit area in young and old nmj, respectively).

We conclude that greater vesicle availability is not the source of increased transmitter release at the old soleus nmj. Rather, the previously reported age-related decrease in vesicle density in conventionally fixed muscles may reflect increased transmitter release of old nmj's during fixation. Since soleus muscles normally fire continuously in vivo, it is moot whether the conventionally fixed or the low-Ca-fixed nmj approximates the true in vivo situation.

214.24 CALCIUM ENTRY, UTILIZATION AND CLEARANCE AT THE NEUROMUSCULAR JUNCTION OF AGED RATS. D. Blumberg, J.L. Rosenheimer, and D.O. Smith. Department of Physiology, University of Wisconsin, Madison, WI. 53706.

Confluent evidence from diverse preparations indicates that Ca^{2+} regulation in nerve cells may be less effective in aged animals. These possibilities were tested in the phrenic nerve of rats aged 10 and 28 mos.

Release requirements for calcium were indirectly assessed by measuring the magnitude of the postsynaptic response while varying extracellular [Ca^{2+}]. Double logarithmic plots of these data had slopes of 2.7 and 2.9 in the 10- and the 28-mos animals, respectively, indicating similar cooperativity in the action of Ca^{2+} in the release process of both age groups.

The frequency histogram of synaptic delays was used to determine the time course of transmitter secretion and, therefore, the kinetics of Ca^{2+} entry near the active zone. Synaptic delays were recorded at single end plates using focal extracellular recording techniques. The histogram of delays in the aged rats was shifted to significantly longer values; the average values were 0.28 and 0.40 ms in the 10- and the 28-mos animals, respectively.

The extent of synaptic facilitation provides an indirect measure of intracellular Ca^{2+} levels in the immediate vicinity of the transmitter release sites. To determine whether clearance of this residual Ca^{2+} is affected during aging, paired pulses were delivered to the phrenic nerve in Mg^{2+}-blocked preparations, and the magnitude of the synaptic facilitation was measured. The decay in facilitation as the inter-pulse interval became longer was well described by an exponential expression, and the time constants in 10- and 28-mos rats were 36 and 39 ms, respectively. Thus, Ca^{2+} clearance at the release site is apparently not affected during aging.

Indirect evidence obtained in a separate study further argued against major changes in intracellular free Ca^{2+} levels in this preparation. Neurofilament triplet proteins are readily degraded by a Ca^{2+}-dependent protease. The presence of these individual neurofilament subunits in the phrenic nerve was compared using SDS gel electrophoresis and immunoblot techniques. No quantitative age-related changes were seen.

Collectively, these results suggest that there are no significant age-related changes in intracellular free Ca^{2+} levels in peripheral axons. Longer synaptic delays, though, may indicate altered Ca^{2+} channel properties in the older animals. Supported by NIA grant AG01572.

SENSORY SYSTEMS: AUDITORY PATHWAYS III

215.1 FUNCTIONAL ORGANIZATION OF THE MUSTACHED BAT INFERIOR COLLICULUS: REPRESENTATION OF FM_2 FREQUENCIES CARRYING TARGET RANGE INFORMATION. W.E. O'Neill and R.D. Frisina, Center for Brain Research, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

The mustached bat, Pteronotus parnellii, emits multiharmonic, ultrasonic signals consisting of a long constant frequency (CF) terminated by a short frequency modulation (FM). Although it follows the basic mammalian plan, parts of the auditory system are specialized to process these two components of the biosonar signal. Target range information, coded by the time interval between FM components of the emitted pulse and echo, is processed in two cortical fields (FM-FM and DF). Neurons in these fields respond only to pairs of FM signals with specific time delays, and are thereby range-tuned. Target distance is represented by the locus of activity in these regions of cortex (O'Neill W.E. & Suga N., J. Neurosci. 2, 1982). To define subcortical pathways providing inputs to these cortical regions, we have studied the representation of FM frequencies of the second harmonic of the biosonar signal (FM_2:48-60 kHz) in the central nucleus of inferior colliculus (ICC). Unlike cortical units, units in ICC are not facilitated by pairs of FM signals (O'Neill W.E., J. Comp. Physiol., in press).

In the present study, we recorded from 884 neurons in 11 mustached bats. The locations of these units were reconstructed from stereotactic coordinates in each ICC studied. In the last four bats after detailed mapping of the ICC, we made focal iontophoretic injections of HRP to localize the physiologic maps and to trace the afferent and efferent connections of the FM_2 projection (companion abstract). Our results show that FM_2 frequencies are at the caudal border of the anterolateral division confined to a large slab which stretches across almost the entire width of the ICC. The slab measures about 1.4 mm dorsoventrally, 1.3 mm mediolaterally, and 0.6 mm rostrocaudally. The large region representing the reference frequency (61-62 kHz) lies just dorsocaudal to the FM_2 representation, while frequencies above 62 kHz are ventromedial. These findings are consistent with a previous study (Zook et al., J. Comp. Neurol. 231, 1985).

The injections of HRP made in the middle of the FM_2 region, in DAB sections, ranged from 200 to 750 μm in the a-p direction, and 300-950 μm in the other planes. The deposits did not exceed the physiologically-defined representation of FM_2 frequencies and clearly spared the cytoarchitectonic boundaries of the doroposterior and ventromedial divisions of ICC. Our reconstructions indicate that the cytoarchitectonic borders between these divisions correspond to the physiological borders between the FM_2, reference frequency, and high frequency representations. These borders thereby divide the ICC into functionally distinct pathways processing different aspects of sonar information reaching the bat's ears. Supported by NSF grant BNS 8311627 to WEO and NIH-NRSA NS07343 to RDF.

215.2 FUNCTIONAL ORGANIZATION OF MUSTACHED BAT INFERIOR COLLICULUS: CONNECTIONS OF THE FM_2 REGION. R.D. Frisina and W.E. O'Neill. Center for Brain Research, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

The FM components of the multi-harmonic, CF-FM biosonar signal used by the mustached bat for echolocation are important for encoding target-range information. We have mapped in detail the representation of the second harmonic component (FM_2) in the central nucleus of the inferior colliculus (ICC) (companion abstract). Here we report the afferent and efferent connections of this region as visualized by anterograde and retrograde transport of focally-injected HRP.

In TMB sections, regions contained darkly-stained Golgi-like cell bodies clearly organized into a laminar arrangement: Ipsilateral to the injection site - dorsal nucleus of lateral lemniscus (DNLL), intermediate nucleus of lateral lemniscus (INLL), dorsal and ventral divisions of ventral nucleus of lateral lemniscus (VNLL), lateral superior olive (LSO) and medial superior olive (MSO); Contralateral - DNLL, LSO, fusiform-cell layer of dorsal cochlear nucleus (DCN) and anterior and marginal divisions of anteroventral cochlear nucleus (AVCN). This laminar arrangement of cell bodies suggests that these nuclei are tonotopically organized. Other regions contained darkly-labeled cell bodies that were less clearly organized: Ipsilateral - all periolivary nuclei and ventral and lateral nuclei of trapezoid body; Contralateral - ventromedial periolivary nucleus (VMPO) and medial division of posteroventral cochlear nucleus (PVCN). Lightly-labeled cell bodies were found contralaterally in MSO, deep layers of DCN, posterior division of AVCN, and lateral division of PVCN.

In contrast to the inputs to the FM_2 region, its outputs are relatively uncomplicated. Heavily-labeled terminal ramifications were found ipsilaterally in an anteromedial region of the medial geniculate body of thalamus (MGB), dorsolateral MGB, posteromedial MGB, lateral pontine nuclei and deep layers of superior colliculus. Some darkly-labeled cell bodies and terminal ramifications were observed in contralateral ICC in a region roughly corresponding to the effective area of the injection site, and outside the effective area of the injection site in ipsilateral ICC. These findings suggest that some intracollicular processing takes place.

No labeling was observed in auditory cortex, cerebellum, nucleus of the brachium of inferior colliculus; contralaterally in MGB, INLL, VNLL, periolivary nuclei (except VMPO), nuclei of trapezoid body, and octopus cell region of PVCN; and ipsilaterally in medial nucleus of trapezoid body and cochlear nucleus. In sum, by confining our HRP injections within physiologically-defined borders of the FM_2 representation in ICC, we have identified pathways from cochlear nucleus to MGB which are critical for range information processing in this species. Supported by NSF grant BNS8311627 to WEO and NIH-NRSA NS07343 to RDF.

215.3 ANATOMICAL PROJECTIONS TO A SINGLE ISOFREQUENCY REGION: BASIS FOR AN ORGANIZATION OF BINAURAL RESPONSE PROPERTIES IN THE MUSTACHE BAT. L.S. Ross*, J.J. Wenstrup, and G.D. Pollak (SPON: L. Edds). Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Like other mammals, the mustache bat's inferior colliculus displays a tonotopic organization of frequencies, but there is an enlarged isofrequency region in which the 60 kHz component of its echolocation call is processed. This enlarged isofrequency region corresponds to the anatomically defined dorsoposterior division (DPD) of the central nucleus of the inferior colliculus (Zook et al., J. Comp. Neurol., 231:530,1985). Within the DPD, neurons having similar binaural response properties are found clustered together, and each binaural class occupies a specific region of the DPD. The central nucleus receives ascending projections from at least seven brainstem auditory nuclei, and the present study was undertaken to determine which brainstem nuclei project to the isofrequency region.

We began by placing large deposits of HRP (500 micron diameter) within the boundaries of the DPD as defined physiologically. These experiments have shown that the DPD receives a complete set of afferents from the lower brainstem auditory nuclei; that is, all of the nuclei projecting to the central nucleus also send projections to the DPD. The major projections to the DPD include contralateral projections from the cochlear nucleus, ipsilateral projections from the medial superior olive and intermediate and ventral nuclei of the lateral lemniscus, and bilateral projections from the lateral superior olive and dorsal nucleus of the lateral lemniscus. In addition, these projections appear to originate in the appropriate 6o kHz isofrequency regions of the brainstem nuclei. Thus, an isofrequency region receives a full set of afferents from the corresponding isofrequency regions of the brainstem nuclei.

Previous experiments have shown that these projections are not uniformly distributed within the central nucleus, suggesting that the organization of binaural regions occurs as a result of segregation of afferents. To investigate this possibility, small deposits of HRP (200 micron diameter) were placed in physiologically defined binaural regions within the DPD. The arrangement of binaural regions within the DPD is generally consistent with the observation of anatomical projections to the DPD. For example, deposits in regions of monaural EO cells results in the labeling of cells in monaural nuclei such as the cochlear nucleus and intermediate and ventral nuclei of the lateral lemniscus while the binaural brainstem nuclei tend to project to more binaurally dominated portions of the DPD.

215.4 PREDICTING AN AUDITORY NEURON'S SOUND LOCATION SELECTIVITY. Z.M. FUZESSERY and J.J. WENSTRUP. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

A sound originating at a particular point in space generates a characteristic set of monaural and binaural spatial cues. A neuron's selectivity for that sound location is dictated by its selectivity for these spatial cues. Many auditory neurons exhibit complex monaural and binaural response properties. They may be excited by monaural input to one or both ears, and their responses facilitated or suppressed when these inputs are combined. Such neurons may be facilitated at certain interaural timing and/or intensity difference values, and suppressed at others. These influences may also vary with absolute stimulus intensity. To understand the mechanisms underlying the representation of auditory space, it is necessary to dissect out the influences exerted by a neuron's monaural and binaural response properties.

The present study examines the determinants of the spatial selectivity of the various binaurally excited neurons (E-O/F, E-O/F,I, E-E/O, E-E,F and O-O/F types) in the inferior colliculus of the mustache bat, and delineates a method for predicting their sound location selectivity from their monaural and/or binaural response properties. First, the directional properties of the external ears were determined to construct a matrix of the intensity levels reaching the cochlea from various points in the sound field, as well as the interaural intensity disparities generated throughout the sound field. Second, using dichotic stimulation, the response magnitudes of inferior colliculus neurons were documented over a relevant range of interaural intensity disparities and absolute stimulus intensity levels. From these data, the neuron's response magnitude at any point on the spatial matrix could be determined, allowing a prediction of the neuron's spatial selectivity. Finally, using free-field stimulation, the actual spatial selectivity of these same neurons was tested to measure the accuracy of the predictions.

In general, the experimental and predicted results were in close agreement. A feature observed in many neurons is that the various monaural and binaural properties of a neuron can exert opposing influences on spatial selectivity. They tend to shift a neuron's spatial sensitivity toward different points in the sound field, and the neuron is often most sensitive at an intermediate point. Predictions of spatial selectivity therefore require that the monaural and binaural influences acting on a neuron be evaluated in concert.

215.5 THE DESCENDING AUDITORY PATHWAY AND THE COCHLEAR NUCLEUS IN THE MUSTACHE BAT. J.M. Zook. Dept. of Zoological and Biomedical Sciences and OUCOM, Ohio University, Athens, OH 45701.

To date, most attention given to the centrifugal or descending auditory system has centered on the prominent olivocochlear projection from the superior olivary complex to the cochlea. However most, if not all of the principle nuclei of the auditory pathway receive centrifugal input in the form of cholinergic fibers descending from a more central auditory center. The cochlear nucleus is intriguing: although it contains cells and fibers which stain positive for Acetylcholinesterase (AChase) and is the target of descending auditory projections, there is no direct projection descending from cochlear nucleus to cochlea. This study focuses upon the AChase-positive regions of the cochlear nucleus of the mustache bat, Pteronotus parnellii, to suggest a way by which the cochlear nucleus may contribute indirectly to the descending auditory system.

Unlike other mammals, where AChase-positive cells and fibers are lightly scattered throughout the ventral cochlear nucleus, the cochlear nucleus of the mustache bat contains a circumscribed, densely AChase-positive region along the medial and posterior borders of the anteroventral cochlear nucleus. Named the marginal zone, this region contains an almost completely homogeneous population of large multipolar neurons which, along with the surronding fibers, are uniformly AChase-positive.

Single unit recordings were made to characterize the best-frequency response both in and around the marginal zone. Small deposits of horseradish peroxidase (HRP) or a peroxidase conjugate with wheat germ agglutinin (WGA-HRP) were placed at physiologically characterized loci from the recording micropipettes. In related experiments the retrograde transport of HRP was also traced from the cochlea to the cells of origin of the olivocochlear bundle. Retrograde transport of HRP from the cochlear nucleus confirmed that the marginal zone is the target of descending projections from more cells of the superior olive, lateral lemniscus and inferior colliculus than any other part of the ventral cochlear nucleus. Units with best frequencies between 50 and 80 kHz were recorded within the boundaries of the marginal zone. This range of best frequencies includes, but is not limited to the frequency band near the predominant frequency of the echolocation cry (which is disproportionately represented in most auditory nuclei of this species). These data suggest that the descending auditory input to the marginal zone might be specifically targeted to influence information carried by this 50-80 kHz band. Anterograde tracing of WGA-HRP and HRP suggest that some of the same cells of the periolivary nuclei which project to the cochlea may also receive input from the marginal zone. These data raise the possibility that the cochlear nucleus may have an indirectly descending contribution to the cochlea via the projecting cells of the superior olivary complex.

Supported by NIH Grant NS 20986.

215.6 FUNCTIONAL LAMINAR AND COLUMNAR ORGANIZATION OF THE AUDITORY CENTERS IN ECHOLOCATING JAPANESE HORSESHOE BATS. I. TANIGUCHI, N. SAITO* and O. ARAI*. Dept. Auditory Disorders, Med. Res. Inst., Tokyo Med. and Dent. Univ., Tokyo 113, Japan.

Functional macroscopic structures of the brain of echolocating bats were visualized by the autoradiographic 2-[^{14}C]deoxyglucose (DG) method. We used the Japanese greater horseshoe bat, Rhinolophus ferrumequinum nippon (Taniguchi, I., J. Comp. Physiol., 156, 185, 1985). This species emits an orientation sound (pulse) from the nostril, which consists of a long constant frequency (CF) component followed by a short downward frequency-modulated (FM) component. Duration of pulses is about 30 ms and the CF of resting pulses is about 65.5 kHz. Their hearing is most sensitive to around 66 kHz, slightly higher than the CF. When the bats are stimulated by the frequency near the optimal frequency as a mimetic echo, they vocalize frequently orientation sounds even in an experimental room.

Bats were injected peritoneally with 2 µCi DG in 0.2 ml normal saline, while they were unanesthetized. After injection, each animal hung from a toe-hold in a small bird-cage in a sound-proof room, with or without sound stimulation. To stimulate bats to vocalize, a train of tone bursts of 66 kHz was used. The duration and rise-fall time were 30 ms and 2 ms, respectively. The stimulus level was fixed at 60 dB SPL as measrured at the animal's head. Eighty minutes after the DG injection, the animal was killed by an overdose of sodium pentobarbital. The frozen brain was sectioned at 30 µ. The sections were exposed to a single emulsion X-ray film (Sakura, ^{3}H type) in X-ray film cassettes for 4 days. Autoradiographs made at the level of the inferior colliculus revealed an active laminar structure in the central nucleus of the inferior colliculus in echolocating bats, but such a structure was not readily detected in resting bats. One of the active laminae seems to consist of a cluster of neurons that respond to the optimal frequencies around 66 kHz. These laminae represent tonotopical organization of the inferior colliculus. A non-active lamina was also observed just above the active one. The neurons in the non-active lamina may optimally respond to frequencies slightly lower than 66 kHz. Probably the activity of these neurons was suppressed by lateral inhibition. The DG uptake to the medial geniculate body and the auditory cortex increased with echolocation. Furthermore, the columnar organization appeared in the auditory cortex during echolocation. They were arranged alternately active and less active. These results suggest that the auditory centers are influenced by vocalization and are organized in a laminar or columnar manner. Inputs to them may be sent from the sensory feedback via the auditory pathways or from the vocalization centers.

215.7 VISION GUIDES THE DEVELOPMENT OF AUDITORY LOCALIZATION IN BARN OWLS. Eric I. Knudsen and Phyllis F. Knudsen, Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

To localize sounds, the auditory system associates sets of auditory cues with locations in space. However, during development, these auditory cues change as the head and ears grow. How, then, does the auditory system establish correct associations? We found that, in barn owls, visual experience guides the development of auditory localization and fine-tunes both its accuracy and its precision.

Sound localization was measured from head orienting responses to auditory stimuli. Noise bursts were presented from random locations in a darkened, sound attenuating chamber. The response of the owl was indicated by the position of an infrared beam that reflect from a mirror mounted on its head, and was quantified in degrees of error relative to the location of the target. The owls were tested beginning at 3 months of age.

Two owls that were raised with their eyes occluded oriented to sounds with significantly poorer precision (F - test; $p < .01$) than did birds raised with normal vision. In fact, the data from one bird indicated that it could not localize the vertical locations of sound sources at all. After the visual occluders were removed, the owls demonstrated normal precision in orienting to visual stimuli but not to auditory stimuli. The results imply that vision is required for owls to develop normal auditory localization precision.

Two additional owls were raised with Fresnel prisms in front of their eyes. The prisms deviated vision 10^{o} to the right. By 3 months of age both owls were orienting approximately 10^{o} to the right of acoustic stimuli. That is, they had adjusted their auditory localization to match the visual errors induced by the prisms. After the prisms were removed, the owls corrected their auditory localization errors over a period of about 3 weeks. Thus, during development the visual system supplies spatial information which can alter and fine-tune auditory localization.

215.8 ORGANIZATION OF NUCLEUS LAMINARIS IN THE BARN OWL. C. Carr, N.Brecha and M. Konishi. Dept. of Biology, California Institute of Technology Pasadena, CA 91125 and CURE, VA Medical Center, Wadsworth, Los Angeles, CA 90073.

Sensitivity to interaural temporal disparities underlies aspects of sound localization. The first place where it appears is nucleus laminaris (NL), which is also the first recipient of binaural input. An analysis of the structure and connections of NL has been undertaken in an attempt to identify morphological correlates of the emergent sensitivity to interaural temporal disparities. The Golgi technique, immunocytochemical techniques and in vivo and in vitro intracellular dye injection were used.

In the barn owl, NL is a greatly hypertrophied brainstem nucleus, surrounded by afferent fiber tracts. NL contains numerous large (30-50 um) neurons in a central neuropil area, and these cells have many short stubby dendrites, from 10 to 50 um in length. NL neurons receive afferent input from both the ipsilateral and contralateral cochlear nucleus magnocellularis. Nucleus magnocellularis receives eighth nerve input via end bulbs of Held directly onto the unipolar somata of its neurons. Each neuron projects bilaterally to nucleus laminaris, and their terminals within NL are large, stubby and have few branches. These terminals end closely apposed to the large cells of NL.

Immunocytochemical methods have revealed that Calcium binding protein (CaBP) immunoreactivity is localized to both the neurons of nucleus magnocellularis and NL, although the target for NL efferents, nVLVa (anterior part of the ventral nucleus of the lateral lemniscus), which is also sensitive to interaural temporal disparities, displays no immunoreactive product. Glutamic acid decarboxylase (GAD) immunoreactivity has demonstrated the presence of a second afferent input to NL. GAD-positive terminals surround the somata of the large cells of NL. They are of unknown origin, and suggest that inhibitory processes may act in NL.

Sensitivity to a particular temporal disparity is conferred by the simultaneous arrival of afferent magnocellular inputs onto the cells of NL. The time difference in the incoming signals is compensated for within NL (Sullivan and Konishi, 1985). Physiological and ultrastructural techniques will be used to analyse how the required temporal advances and delays are produced.

215.9 CONSTRUCTION OF A NEURAL MAP OF INTERAURAL PHASE DIFFERENCE IN NUC. LAMINARIS OF THE BARN OWL. W. E. Sullivan and M. Konishi, Division of Biology, California Institute of Technology, Pasadena, CA 91125.

We studied the mechanisms underlying neuronal sensitivity to interaural phase difference in the barn owl's nuc. laminaris, the first-order binaural nucleus in the avian brainstem. Using microelectrodes, a large sinusoidal response to tonal stimuli, or "neurophonic" response, is recorded in this nucleus. The neurophonic has a 2 to 3 msec latency and is sharply tuned to frequency. These and other properties show its physiological origin. The neurophonic is probably due to the synchronized, phase-locked activity of a population of neurons. In the owl, neurophonic potentials can be recorded at frequencies of up to 8.5 kHz. and can be driven by monaural excitation of either ear or by binaural stimulation.

As the electrode moved ventrally within the nucleus, the neurophonic response to a contralateral stimulus showed a progressive phase advance whereas a phase delay was seen in successive ipsilateral ear responses. Binaural responses were sensitive to interaural time delay, a maximum response occurring when the monaural responses would be in phase and a minimum response occurring when they would be out of phase. Binaural tuning curves shifted towards a greater ipsilateral time lead with depth.

The results are consistent with the bilateral innervation pattern of nuc. laminaris by the cochlear nuclei and support a simple model for the genesis of binaural phase tuning and a neural map of interaural phase difference. Ipsilateral cochlear nucleus fibers enter nuc. laminaris from the dorsal side and contralateral fibers enter ventrally. The electrode moves towards the contralateral and away from the ipsilateral source as it advances ventrally, thus causing an earlier contralateral and a later ipsilateral response.

In our model, fibers from the two cochlear nuclei project through nuc. laminaris in opposite directions, representing the opposing "delay lines" proposed by Jeffress. This generates a dorsal-ventral gradient of neural delay difference. For coincidence of monaural signals to occur, increases in neural delay must be balanced by decreases in acoustic delay. Thus, a ventral movement causes binaural neurophonic tuning curves to shift towards a smaller acoustic delay in the ear for which a longer neural delay is seen: i.e., the ipsilateral ear. Laminaris neurons also respond maximally when the two monaural inputs coincide. This "coincidence detection" transforms the neural delay difference gradient into a map of interaural phase (or time) difference. (Supported by a Del Webb Fellowship to W.E.S. and PHS Grant NS-14617 to M.K.)

215.10 INTRACELLULAR RECORDINGS FROM OWL INFERIOR COLLICULUS. Andrew Moiseff, Department of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06268.

The activity of space selective and space specific neurons were recorded from the inferior colliculus of adult barn owls (Tyto alba). Owls were tranquilized (Diazepam) and anesthetized (Ketamine), and placed in a stereotaxic frame with the animal's body suspended horizontally. A small craniotomy was performed to access the brain, a slit was made in the dura mater, and glass microelectrodes filled with 2M K-Acetate were advanced into the inferior colliculus under stereotaxic guidance.

Dichotically presented auditory stimuli were delivered through magnetic earphones mounted in each auditory meatus. It was often possible to record extracellular activity before impaling a cell. At such times the binaural parameters (interaural time difference and interaural intensity difference) were adjusted to maximize the unit's spike rate. Since receptive fields of closely located units are very similar this insured that the stimuli would be properly adjusted for exciting units when impaled intracellularly (even if the impaled cells were not the same as those recorded from extracellularly).

A standardized stimulus paradigm subjected the unit to various interaural time and intensity differences, monaural stimulation, and frequency tuning. Units showed strong, tonic, hyperpolarization (inhibition) in response to certain time and intensity differences. Inhibition lasted well beyond the duration of the 'offending' stimuli. 'Acceptable' stimuli elicited tonic depolarization above threshold for spiking. When the stimulus ended excitation ceased and the unit was inhibited for approximately 20 msecs.

The occurence of inhibitory and excitatory binaural parameters correlate with the center-surround organization of auditory receptive fields reported by Knudsen and Konishi (Science 202 :778) and demonstrate that this organization is, at least in part, the result of interactions at the level of space-selective and space-specific neurons. The temporal extent of inhibitory interactions, which far outlast the actual stimulus, is being further investigated. They may result in sharper receptive fields in response to moving auditory stimuli.

215.11 PROJECTIONS FROM THE ACOUSTIC TUBERCLE TO OTHER AUDITORY BRAIN STEM NUCLEI IN THE RED-EARED TURTLE, CHRYSEMYS SCRIPTA ELEGANS. R.H. Browner, DM. Pierz, and D. Marbey. Department of Anatomy, New York Medical College, Valhalla, NY 10595.

It is important to determine the acoustic tubercle (AT) connections relative to the ability of the turtle's 8th nerve to regenerate to the cochlear nuclei (Marbey and Browner, Hearing Res. 15: '84). The interaction of these structures can effect the process of regeneration.

Ten red-eared turtles were anesthetized with Brevital Sodium (0.5 to 0.8%). Following this the animals were placed in a stereotaxic apparatus (Kopf) and anesthetized with Halothane, Nitrous Oxide, and Oxygen. The dorsolateral portions of the crania were drilled open, the dura mater opened and the cerebellum moved medially, exposing the surface AT. Glass micropipettes (tips: 15-30 µm) were placed in the AT. Injections were made rostal to caudal in the AT. 25% HRP or 20% HRP-WGA was iontophoretically (2.5 µamps) injected for seven minutes. The turtles survived for 5 days and then were perfused with Reptilian Ringers and the fixative for HRP (TMB Method). The brains were removed, embedded in gelatin-albumin, and sectioned at 40 µm in the standard planes. Three tracts were traced from AT. A dorsal tract coursed ventrally and medially under the 4th ventricle through both MLF. The fibers turned dorsally and entered the contralateral AT. It formed a band of terminals and fibers between the ependymal cells and the nuclei magnocellularis and laminaris. An intermediate smaller tract left the AT and crossed the midline, obliquely, ventrally to the contralateral ventrolateral superior olive (SO). The ventral pathway coursed ventrally and laterally and followed the outer contour of the brain stem to the ipsilateral SO. The fibers crossed the midline and joined the intermediate pathway in the area of the contralateral SO. These AT fibers entered the lateral lemniscus and coursed rostrally and dorsally, to enter the central nucleus (CN) of the torus semicircularis (TS). In the caudal portion of the CN the axons terminated in the large cell region. Some axons entered the medial smaller cell area. Ipsilaterally a small number of AT fibers coursed rostrally in the lateral lemniscus to enter the CN. There were no axon terminals in either laminar nucleus.

In the ipsilateral SO there were multipolar neurons retrogradely filled with HRP reaction product. In the contralateral nucleus magnocellularis there were HRP filled cells; in the contralateral SO there were axons and axon terminal fields. The cells in the nucleus of the lateral lemniscus had few axonal terminals; most fibers continued to enter CN of the TS.

Injections limited to the nucleus magnocellularis had fewer fibers entering the 3 tracts and terminating in the contralateral CN. Research supported by the Culpeper Foundation.

215.12 **REPRESENTATION OF COOPERATIVE FIRING ACTIVITY AMONG SIMULTANEOUSLY RECORDED NEURONS, G. Gerstein, A. Aertsen*, Dept. of Physiology, Univ. of Pennsylvania, Philadelphia PA 19104.**

Technical development of electrode structures and of spike shape sorters have made increasingly practical the simultaneous and separable recording of activity from some 20 to 30 neurons, thus allowing direct study of static and dynamic properties of neuronal assemblies. Analysis of such data is usually based on variants of cross-correlation of PAIRS of spike trains, and for combinatorial reasons requires examination of thousands of correlograms in order to draw conclusions about the neuron assembly. An analysis that treats the entire observed neuronal assembly as an entity rather than as a combination of pairs is clearly needed.

We examine here a new transformation of multiple simultaneously recorded spike trains (1) which represents each of the N observed neurons as a particle in an N space. Initially all particles are equidistant in the N space. Particle movements are governed by the timing of the neuronal spikes by the following rules. Each spike train is converted into a time varying "charge" for the associated particle, usually using a low pass filter. The force between any two particles is a vector proportional to the product of their charges, and is directed along the line between their positions. At each time step the movement of each particle in turn is determined by the vector sum of all pair forces acting upon it. As the calculation proceeds, particles representing neurons with correlated firing will tend to aggregate. Thus the developing spatial arrangement of the particles reflects the logical interactions of the neurons.

This simple representation can be modified in several ways for other emphasis (2). Change of sign in the charge product during the calculation produces spatial aggregation of those particles representing neurons which interact through inhibitory processes. Extension to a two-charge definition based on both forward and backward exponentials allows inference of causality (synaptic direction) rather than just correlated firing, as in the original version. Sensitivity of the "gravity" calculation is extremely high; typical data of 30 sec. duration produce interpretable aggregations.

Performance of this representation is best seen by projection from the original N space to a plane. Both "time exposures" of the particle trajectories and "snapshots" of the projected positions can identify the interactions within a neuronal assembly. Movies are useful to determine the dynamics of the aggregation process; this may reflect time or stimulus varying interactions within the observed assembly.

HORMONAL CONTROL OF BEHAVIOR

216.1 THE ROLE OF THE ALPHA ADRENERGIC SYSTEM IN THE MALE RING DOVE'S COURTSHIP BEHAVIOR. S.R.Barclay*and M.-F.Cheng.(Spon: M. Dalsass) Institute of Animal Behavior,Rutgers University,Newark,N.J.07102

We previously reported (Neuroscience Abstracts,1984) that an androgen dependent courtship behavior,the bow-coo, was depressed when male ring doves were treated with the alpha-adrenergic agonist, phenylephrine, and elevated when the males were treated with prazosin, an alpha-adrenergic antagonist. The purpose of the present study is to determine whether the modulation of the bow-coo behavior is mediated solely by the alpha-adrenergic system or whether the beta-adrenergic system is also involved.

In the present studies we followed the same experimental paradigms previously used to determine the effects of alpha-adrenergic agonists and antagonists on courtship behavior in the ring dove. In the first group of experiments we determined a dose response curve for each drug. Intact males were administered the drugs intramuscularly one to two hours prior to testing. Males were then paired with a receptive female in a breeding cage and observed for fifteen minutes. The second group of experiments determined whether a specific drug effect was hormone-dependent. Castrated males were primed with various steroids or vehicle administered in Silastic capsules for a week prior to behavioral observations. The primed animals were then treated with the lowest effective dose of the drugs and tested for courtship behavior with a receptive female. The third set of experiments attempted to show whether the observed drug effects were centrally mediated. Chronic cannulae were implanted in the third ventricle of intact males and drugs were infused into the ventricular fluid. A female was introduced into the male's cage thirty minutes after the infusion and courtship behavior was measured for fifteen minutes.

Consistent with our previous findings,methoxamine,an alpha-adrenergic agonist,also inhibited the bow-coo without affecting other androgen-dependent courtship behavior such as nest-coo. Norepinephrine reuptake blocker, desipramine,blocked all expression of male sexual behavior,including the bow-coo.

These results suggest that inhibition of the alpha-adrenergic system is part of the normal induction of courtship behavior in the male ring dove.

216.2 PROGESTERONE ANTAGONIST DOES NOT PREVENT CHOLINERGIC FACILITATION OF LORDOSIS. G. Richmond* and L. G. Clemens. Dept. of Zoology, Michigan State University, E. Lansing, MI 48824

The sexual behavior of many female rodents is dependent upon sequential release of the ovarian steroids estrogen and progesterone (P). We have demonstrated that receptivity (lordosis) can be induced by intracerebral administration of muscarinic cholinergic agonists in estrogen-primed female rats. This effect is not enhanced by prior P administration, suggesting that while the facilitation is estrogen-dependent, it is independent of P. In Experiment 1 we investigated this possibility directly by blocking lordosis with a P antagonist (RU 38486) and examining whether the muscarinic agonist oxotremorine (OXO) can reverse this inhibition. We also examined whether the drugs affect behavioral desensitization to additional P. In a second study we investigated whether RU itself interacts with progestin receptors to cause desensitization to P given 25 hr later.

In Experiment 1 ovariectomized rats were implanted with stainless-steel cannulae in the lateral ventricles. They were treated for 3 days with .5ug estradiol benzoate (EB) and on Day 4 injected with RU (.5mg) or oil. One hr later they received P or oil. Three, 4, and 5 hr after this injection they were tested for lordosis; infused with OXO (.5ug/cannula) or vehicle; and tested again 5 and 20 min after infusion. On Day 5, 24 hr after the first P/oil injection, all females received .5mg P and were tested for lordosis 4, 5, and 6 hr later. RU blocked receptivity in animals receiving P. This inhibition was reversed 5 min after OXO infusion and disappeared by 20 min. Females that received EB + P on Day 4 showed a diminished response to a second P injection on Day 5. However, an even greater decrease in response to P was observed in animals that received RU on Day 4.

In Experiment 2 ovariectomized animals were treated for 3 days with EB. On Day 4, RU or oil was injected, followed an hr later by one of two concentrations of P (.5 or 1.5mg) or oil and 3 tests for lordosis (3, 4, and 5 hr after the last injection). A second P injection (.5mg) was given 24 hr after the first injection (on Day 5), followed 4, 5, and 6 hr later by lordosis tests. Animals that had been given RU with P again displayed little receptivity. After the second P injection, little or no receptivity was shown by females that had received RU alone as well as in combination with P on Day 4.

These experiments offer direct evidence for the hypothesis that the mechanism by which the cholinergic system facilitates lordosis is P-independent. The results also suggest that RU acts like a competitive antagonist to P, thus preventing P administered 1 hr and/or 25 hr after RU from inducing sexual receptivity.

216.3 **DIFFUSION PATTERN OF CHOLINERGIC COMPOUNDS INFUSED INTO THE VENTRAL MEDIAL HYPOTHALAMUS OR MIDBRAIN CENTRAL GRAY.** T.C. Meyers*, G. Richmond* and L.G. Clemens (SPON: J. Zacks). Zoology Department and Neuroscience Program. Michigan State University, East Lansing, MI 48824.

Infusion of cholinergic agonists into the midbrain central gray (MCG) or the ventral medial hypothalamus (VMH) facilitates feminine sexual behavior (lordosis) in ovariectomized, estrogen-primed facilitate lordosis is uncertain due to the possibility of diffusion away from the MCG or VMH. In order to more thoroughly evaluate this possibility we have examined the diffusion pattern of a cholinergic compound infused into either the MCG or VMH.

Ovariectomized Sherman female rats were implanted with stainless steel cannulae terminating in the lateral ventricle and either the MCG or VMH. Animals were then injected with a dose of estradiol benzoate (EB) shown to be effective as a priming dose for facilitation of lordosis by infusion of a cholinergic agonist. EB was administered daily for three days. On the fourth day, tritiated scopolamine, a muscarinic cholinergic antagonist, was infused at a volume of .5ul into either the MCG or VMH. Cerebral spinal fluid (CSF) was extracted from the lateral ventricles at 5 and 15 minute and again at 3, 5, and 6 hours. CSF was then analyzed for presence of the isotope. The label was not found in the CSF at any of the above times. We therefore believe that cholinergic compounds infused into the MCG or VMH do not diffuse into the lateral ventricle.

In a subsequent experiment, we infused tritiated scopolamine into the MCG or VMH and determined the spread of the label through non-ventricular tissue. Animals were sacrificed by decapitation 5 or 15 minutes after infusion. The brains were removed and the MCG, VMH, cortex and various brainstem areas were dissected. When infused into the VMH, the label was found in VMH and MCG but no in cortex or brainstem. When the volume of scopolamine infused into the VMH was reduced to half the original, diffusion still occurred, but with a latency of 15 minutes.

These experiments indicate that at volumes and concentrations used in behavioral research, diffusion occurs from the VMH to the MCG, and perhaps to other periventricular areas. This may be an important consideration in attempting to localize the brain sites involved in the cholinergic regulation of lordosis.

216.4 DORSAL MIDBRAIN LESIONS WHICH IMPAIR HAMSTER LORDOSIS ALTER THE RESPONSIVENESS OF REMAINING MIDBRAIN NEURONS. M.D. Havens and J.D. Rose, Dept. of Psychol. Univ. of Wyoming, Laramie, WY 82071

The midbrain provides a critical degree of control over the expression of lordosis by golden hamsters. Bilateral deep superior colliculus lesions in the hamster abolish lordosis and unilateral collicular lesions selectively impair elicitation of the response by stimulation of the contralateral flank. While central gray and ventral tegmental lesions sometimes impair lordosis, the effects of these lesions are not as consistent or as pronounced as those seen with tectal lesions. Neurons which respond to lordosis-triggering forms of somatic stimulation are widespread in the hamster's midbrain and the responsiveness of these neurons is enhanced by the synergistic effects of estrogen and progesterone. These findings imply that both tectal and nontectal neurons play an important role in the sensorimotor control of hamster lordosis and raise the possibility that tectal lesions impair lordosis by altering the sensory responsiveness of subtectal midbrain neurons. To evaluate this hypothesis, the responsiveness of single midbrain neurons to lordosis-controlling forms of somatic stimulation was assessed in three groups of ovariectomized, estrogen-progesterone treated hamsters. One group had received lordosis-blocking bilateral tectal lesions. The second group had received unilateral tectal damage and showed impaired lordosis responsiveness to contralateral flank stimulation. The third group consisted of surgical control animals. A total of 319 cells was recorded in the three groups of animals under urethane anesthesia. The percentage of cells which responded to some form of somatosensory stimulation was significantly higher in the bilaterally-lesioned group than in the unilaterally-lesioned or surgical control groups. In addition, more of the responsive cells were located in the ventral tegmentum of bilaterally-lesioned animals than in either of the other two groups. Also, the spontaneous firing rate was decreased by the bilateral lesions, relative to the unilateral lesion and surgical control groups. The tactile receptive fields of the cells were also altered by the lesions. A greater percentage of units in the unilateral lesion group responded to facial stimulation, whereas, a greater percentage of units in the bilateral lesion group responded to flank stimulation. Thus, dorsal midbrain lesions which impair the elicitation of lordosis by somatosensory stimulation also alter the responsiveness of remianing midbrain neurons. Functionally, the elevated responsiveness of ventral tegmental neurons in bilaterally-lesioned animals may result in the elicitation of locomotion rather than lordosis by flank stimulation, since ventral midbrain neurons in hamsters tend to show locomotion-related firing. (Supported by NIH Grant NS 13748)

216.5 EFFECTS OF PROGESTERONE ON MONOAMINE TURNOVER IN DISCRETE BRAIN NUCLEI: RELATIONSHIP TO SEXUAL BEHAVIOR. K.J. Renner, L.C. Krey and V.N. Luine. Lab. of Neuroendocrinology, Rockefeller University, New York, N.Y. 10021.

Progesterone facilitation of sexual behavior in the female rat is believed to be regulated, in part, by central monoaminergic systems. However, central sites for progesterone-monoamine interactions in regulation of behavior remain largely unknown. In the present study the effect of progesterone on monoamine levels and turnover were evaluated in brain nuclei in estrogen-primed rats.

One week after ovariectomy rats were injected s.c. with 0.5 mg progesterone (P) or oil vehicle 21 h. after s.c. treatment with 5 ug of estradiol benzoate. The initial levels of norepinephrine (NE), dopamine (DA), 5-hydroxyindole acetic acid (5-HIAA) and serotonin (5HT) were measured in animals injected i.p. with saline 3 hr after the administration of P. To estimate NE and DA turnover, oil or P treated animals (3h.) were injected with α-methyl-p-tyrosine (400 mg/kg) and sacrificed 2 h. later (5 h. after oil or P). Serotonin turnover was estimated in animals injected with pargyline (75 mg/kg) 20 minutes prior to sacrifice. Amine content was measured by high performance liquid chromatography with electrochemical detection in the following brain nuclei: lateral septum, vertical nucleus of diagonal bands (vDB), medial preoptic nucleus, anterior hypothalamic, periventricular region (PVE, anterior hypothalamic level), ventromedial hypothalamuis (VMN), midbrain central grey (MCG), arcuate-median eminence, and dorsal raphe. In addition, sexual behavior (lordosis response) and plasma LH were measured under these steroid-priming conditions.

Estrogen-primed rats treated with P showed high levels of lordosis responding and elevated plasma LH when compared with estrogen only primed rats indicating that the lag-time following E priming was sufficient for P to exert neuroendocrine effects.

Progesterone did not significantly affect initial levels of NE, DA, 5-HIAA or 5HT in any of the brain nuclei studied. In the PVE, P resulted in decreased NE turnover. DA turnover was elevated in the vDB of P treated rats. Progesterone treatment resulted in decreased 5HT turnover in the VMN and MCG. No other changes in monoamine turnover following P were noted.

These results suggest that progesterone influences monoaminergic activity in a few discrete brain nuclei of E-primed rats. The relationship of the changes in PVE NE and vDB DA turnover to sexual receptivity are not known. However, both regions have been implicated in the regulation of gonadotropin secretion. The decreased serotonin accumulation in the VMN and MCG following P treatment is consistent with the hypothesis that 5HT exerts tonic inhibitory modulation of lordosis behavior.

216.6 SEROTONIN IN THE MEDIAL BASAL HYPOTHALAMUS MEDIATES SEX DIFFERENCES IN HORMONE-FACILITATED LORDOSIS OF MALE RATS. J.Moreines, D.Pfaff, and B.McEwen, Rockefeller Univ., NY, NY 10021.

Developmental effects of perinatal androgens render adult male rats refractory to the activation of feminine sexual behavior (lordosis) by estradiol (E2) and progesterone (P). Recent evidence suggests that serotonin (5HT) may inhibit hormone mediated lordosis responding of female rats at the level of the ventromedial hypothalamus (VMH) (Luine,et al.,1984. Science 226: 1436). The hypothesis that this inhibitory input contributes to sex differences in behavioral responsiveness to hormones was assessed in gonadectomized adult male rats deprived of 5HT following bilateral stereotaxic injections of the neurotoxin, 5,7 dihydroxytryptamine (5,7 DHT) into the region of the VMH. Lordosis quotients (LQs) were determined at mating tests conducted 48 hr following sc insertion of Silastic capsules producing physiological E2 levels both before and 4 hr after P injection (0.5mg).

The results show that 5,7 DHT treatment enhances the effects of E2 in the absence of P. Increased sexual responsiveness was displayed at times when this treatment is known to reduce 5HT levels in the VMH of females (Luine,et al.,1984) (i.e., days 18 to 52 post surgery). The mean LQ achieved by these animals was 71 (N=4), which is comparable to that typically obtained by E2-primed females; in contrast, control animals attained a mean LQ of 25 (N=4) ($p=.01$). In addition, the 5,7 DHT treatment appeared to reverse the insensitivity of males to synergistic P effects. LQs of hyper-responsive males were elevated to 81 when P was injected 48 hr following E2 ($p<.05$). In contrast, LQs of controls (LQ=23) remained unaffected by P administration. Evidence that P potentiates E2-induced lordosis following 5,7 DHT injections was further demonstrated when E2-priming was reduced to 6 hr. This E2 stimulation was sufficient to induce lordosis 24 hr later only after exogenous P in 2 of 4 hyper-responsive males (LQ=40).

While 5,7 DHT injections appear to reverse sexually dimorphic responses to hormone-facilitated lordosis, this treatment fails to alter sex differences in gonadotrophin effects of E2 and P. Neither control, nor lesioned males, displayed a surge of luteinizing hormone following E2 and P treatment sufficient to mediate behavior of hyper-responsive males.

These results suggest that 5HT input into the VMH interferes with hormone-responsive lordosis mechanisms in males as in females. Interestingly, some lesioned males remain hyper-responsive more than 50 days post 5,7 DHT, i.e., when behavioral function and 5HT levels in the VMH of females have recovered (Luine,et al.,1984). Whether basal levels of 5HT are reinstated in these latter males, and what particular cellular mechanisms mediate the reversal in sensitivity to E2 and synergistic P are under investigation. Supported by grant NS07030.

216.7 INTRACEREBRAL DOPAMINERGIC CONTROL OF MASCULINE SEXUAL BEHAVIOR IN RATS. E.M. Hull, D. Bitran, E.A. Pehek, R.K. Warner, L.C. Band, and G.M. Holmes. Dept. of Psychology, State Univ. of New York at Buffalo, 4230 Ridge Lea Rd., Amherst, NY 14226.

Systemically administered dopaminergic drugs have been reported to facilitate sexual behavior of men and male rats. The locations within the brain that contribute to this facilitation have not previously been determined, though the caudate-putamen (CP), nucleus accumbens (NA), and lateral septum (LS) have been suggested as candidates. In addition, the medial preoptic area (MPOA) is important for masculine sexual behavior and receives dopaminergic terminals of incertohypothalamic (A14) neurons. In order to localize dopaminergic effects on copulation, we microinfused the dopamine agonist apomorphine (APO) into each of the sites noted above, as well as into the lateral ventricle (LV) as a control placement.

The lowest dose of APO (0.2 µg) infused into the LV decreased the number of ejaculations, the rate of intromitting and the percentage of mounts on which the male gained vaginal intromission. The higher two doses (0.5 and 2.0 µg) infused into the MPOA and, in some cases the LV, increased the number of ejaculations and the percentage of mounts with vaginal intromission, and decreased the latency to begin copulating, the latency to ejaculate, and the postejaculatory interval before resuming copulation.

Infusions into the CP and the LS did not affect any aspect of behavior. Infusions into the NA produced only a slight, dose-related decrease in latency to begin copulating.

The copulatory impairments associated with infusions of the lowest dose into the LV may have resulted from stimulation of dopamine autoreceptors; the facilitative effects of the two higher doses into the MPOA and LV may have been due to stimulation of postsynaptic receptors.

216.8 GENETIC INFLUENCES ON COPULATORY AND AGGRESSIVE BEHAVIORS IN MICE. B. E. F. Wee, D. R. Weaver, K. L. Sinchak*, and L. G. Clemens. Neuroscience Program and Department of Zoology, Michigan State University, East Lansing, MI 48824.

While castration results in reduction of a variety of hormone-dependent behaviors, McGill and Manning (Anim. Beh. 24:507-518, 1976) have shown that one hybrid strain of mice, the B6D2F1, continues to copulate up to one year after castration. The purpose of this study was to examine the effects of castration on copulatory and aggressive behaviors in this hybrid and the parental strains : C57Bl/6J and DBA/2J.

In experiment 1, sexual behavior was measured in adult male mice of the three strains : B6D2F1 (F1) (resulting from a cross between a C57 female and a DBA male), DBA, and C57. Sexually experienced males of each strain were castrated or sham operated. Following surgery, males were tested for an additional 25 weeks.

Castrated F1 males showed high levels of copulatory behavior, and some F1s continued to show the ejaculatory pattern 25 weeks after castration, thus confirming the observations by McGill and Manning. Neither parental strain retained the ability to ejaculate in the absence of testicular androgens.

To determine whether other "hormone-dependent" behaviors also persist after castration in B6D2F1 males, the effects of castration on aggression were examined. In experiment 2, DBA, C57, and B6D2F1 males were tested for aggressive behavior. After four biweekly aggression tests with an olfactory bulbectomized, stimulus male, the mice were either sham operated or castrated. Four additional biweekly aggression tests followed the surgery. Aggression was measured as the number of attacks by the experimental male within a 5 minute test session.

Levels of presurgical aggressive behavior were as follows : DBA > C57 > B6D2F1. Aggression was maintained at precastration levels after sham operation, but castration reduced aggressive behavior in all strains. However, when tested 7 weeks after castration, 60% of the DBA males continued to show aggressive behavior, while less than 20% of the C57 and F1 males were aggressive.

The results indicate that retention of copulatory behaviors by B6D2F1 castrates may be mediated by a nonhormonal mechanism. However, the effect of castration on aggressive behaviors does not follow this same pattern.

216.9 ESTROUS CYCLE DEPENDENT VARIATION IN BALANCE BEAM PERFORMANCE IN FEMALE RATS. Melissa M. Miller*, Sara A. Westgate*, Peter J. Snyder*, Mary A. Kalafut* and Jill B. Becker (SPON: D.G. Green). Psychology Dept. and Neuroscience Laboratory Bldg., The University of Michigan, Ann Arbor, MI 48104-1687

During the estrous cycle in female rats, the amphetamine-stimulated release of striatal dopamine (DA) is greater on estrus than on proestrus or diestrus 1. Amphetamine-stimulated or electrical stimulation-induced rotational behavior show a very similar pattern of change across the estrous cycle. In the experiment reported here, we examined the influence of estrous cycle on a natural behavior requiring the active integration of sensori-motor information. Given what is known about the normal function of the nigro-striatal DA system, we hypothesized that fluctuations in striatal DA activity would be reflected in balance beam performance.

Female Holtzman rats were maintained on a 14:10 light:dark cycle (N=9). Estrous cycle phase was monitored by daily vaginal smear examinations. The ability of each rat to walk lengthwise across a balance beam 0.5" X 4.0 ft was tested daily, on two separate trials. Prior to each trial, the front and back feet were painted with different colors of tempera paint. The animal was placed on the beam and the time it took to walk the length of the beam for cookie mash reward was recorded. Footfaults were scored by an independent observer, blind to the estrous condition of the animal, at the end of each day by examining the footprints on each beam. A footfault was scored for each footprint that extended off the top of the beam onto the side of the beam. Animals were tested over 2 complete estrous cycles, 3-4 h after the lights went on in the animal room. Then animals were given 6 weeks to adapt to a reversed light:dark cycle and the procedure was repeated 3-4 h after lights off (under red light conditions).

There was a significant effect of estrous cycle on balance beam performance. When testing occurred 3-4 h after lights on, female rats made significantly fewer footfaults on estrus than on proestrus ($p<0.001$) or diestrus ($p<0.007$). When testing occurred during lights off, female rats made fewer total footfaults on estrus than on diestrus ($p<0.035$). Under both lighting conditions, fewer footfaults were consistently made with the front feet than with the back feet. In addition, there was no effect of estrous cycle on the time it took to walk the length of the beam.

It is intriguing to note that estrous cycle dependent variation in balance beam performance corresponds to the pattern of striatal DA release across the estrous cycle. However, further research is necessary to determine the underlying neural basis of the estrous cycle dependent variation in footfaults on the balance beam.

216.10 EFFECTS OF ESTRADIOL (E_2) ON PROTEIN SYNTHESIS IN VITRO, IN THE VENTROMEDIAL HYPOTHALAMIC NUCLEUS (VMN) AND PREOPTIC AREA (POA) OF THE FEMALE RAT. K.J. Jones, B.S. McEwen, and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

It is generally thought that the functional consequences of steroid hormone action on target tissues are effected via mechanisms which include protein synthesis. Early changes in cell nuclear morphology in VMN neurons during behaviorally-relevant paradigms of E_2 exposure are consistent with this view(Jones et al.,1985). In this study, we examined, after similar paradigms, effects of E_2 on protein synthesis in 2 E_2-concentrating regions of female rat brain, VMN and POA.

Ovariectomized rats (OVX) were either implanted with E_2 for 2h or for a discontinuous schedule of 2h-on-E_2/7h off/2h on-E_2, or sham-implanted for controls. Punches of VMN and POA were collected and in vitro labelled with ^{35}S-methionine and -cysteine for 4h. Proteins were separated by 2-dimensional gel electrophoresis, fluorographed, and exposed to autoradiographic film. The fluorograms were quantified by computerized scanning densitometric and normalization procedures.

In the VMN, 2h of E_2 produced increases in intensity of labelling in some proteins and decreases in intensity of labelling in other proteins, normalized and relative to the controls. After 2h-on/7h-off/2h-on of E_2, intensity of labelling changed in a different set of proteins, normalized and relative to the controls. The populations of proteins increased by E_2 did not overlap in the 2 paradigms, whereas, approximately 1/2 of the populations of proteins decreased by E_2 were the same in both treatment groups. In the POA, 2h of E_2 also produced increases in intensity of labelling of some proteins and decreases in intensity of labelling of others, normalized and relative to the controls. After 2h-on/7h-off/2h-on of E_2, intensity of labelling changed in a different set of proteins. Approximately 1/2 of the populations of proteins increased and decreased by E_2 were the same in both treatment groups. Most of the proteins in VMN affected by E_2 differed from those proteins in POA affected by E_2.

Differential effects of E_2 on protein synthesis in the VMN are in accord with ultrastructural data suggesting a cascade of events from the first 2h of E_2, and later through the second 2h of E_2. Taken together, these data support the hypothesis that estrogen has more than one phase of action on the VMN. The differences in the population of proteins affected by E_2 action in the VMN vs. POA imply regional specificity of steroid hormone action on protein synthesis in the brain. For example, these differences could contribute to VMN/POA differences in the control of female sex behavior, male behavior, parental behavior, and ovulation. Supported by MH-15125 and HD-05751.

216.11 THE EFFECTS OF IC ADMINISTRATION OF OXYTOCIN ON PUP-DIRECTED BEHAVIOR AND SELF-GROOMING IN PREWEANLING AND WEANLING RATS.
G. Peterson*, G. Mason*, J.D. Caldwell*, P.J. Brooks*, A.J. Prange, Jr. and C.A. Pedersen. Biological Sciences Research Center, Neurobiology Curriculum and Department of Psychiatry, University of North Carolina, Chapel Hill, NC 27514

Intracerebroventricular (ICV) administration of oxytocin (OXY) has been shown to increase maternal behavior in estrogen-primed adult female and also to increase self-grooming in intact adult male and female rats. Weaning rats (18-24 days of age, female and male) have been reported to display rapid onset maternal-like behavior towards young rat pups. The latency of onset of maternal-like behavior towards pups increases markedly after age 24 days concimitant with an increase in general neophobia. We have tested the effects of central administration of OXY on behavior directed towards young pups in rats at various ages before and during weaning.

Preweanling or weanling Sprague-Dawley rats (18, 22 or 26 days of age) were each allowed to habituate to a mouse cage for four hrs the day prior to behavioral testing. On the day of testing each animal received either 2 ug of OXY in normal saline (NS) or NS vehicle alone intracisternally (IC) while under light ether anesthesia. Fifteen minutes after IC injection, three 1-4 day old rat pups were placed in each cage. Each animal was observed for a one-minute period every ten minutes over the next two hrs. Behavior occurring during each five-second interval of observation was recorded. Among a large number of behaviors that were scored were forepaw holding with and without licking (FHL) of pups and self-grooming. Rats 22 days of age displayed far more FHL of pups after OXY than did those after NS injection ($F = 27.64$, $p < .0001$, Student's t test). In rats 18 days of age there was a trend towards more FHL of pups after OXY ($F = 3.41$, $p < .08$), but in rats 26 days of age there was no difference between OXY and NS recipients ($F = 1.39$, $p < .26$). Self-grooming behavior, however, was significantly increased in OXY recipients in each age group ($p < .0001$). Thus age, stage of weaning or the onset of neophobia appears to influence sensitivity to a pup-directed behavioral effect of OXY but does not alter sensitivity to a self-directed behavioral effect of OXY.

216.12 COMBINED CENTRAL PLUS PERIPHERAL IMPLANTS OF DIHYDROTESTOSTERONE INCREASE SEXUAL BEHAVIOR OF MALE RATS
P.C. Butera* & J.A. Czaja (SPON: L.J. Pellegrino), Laboratory of Behavioral Endocrinology, Purdue University

The inability of dihydrotestosterone (DHT), a nonaromatizable androgen, to stimulate sexual behavior in castrated rats is usually taken as support for the hypothesis that male sexual motivation is primarily influenced by estrogenic metabolites of testosterone (T). However, reports that DHT can facilitate mating in castrated monkeys, guinea pigs, and some strains of rats and mice have raised questions about the generality and validity of this idea. Although the mechanism for this species difference is unknown, it is possible that reduced bioavailability of DHT to the rat brain may contribute to its ineffectiveness in this species, since exogenous DHT is metabolized rapidly by male rats. The present experiment was therefore designed to bypass potential problems of biotransport by directly stimulating the medial preoptic area (MPOA) with DHT.

Fifty-two adult, male rats (Long-Evans), prescreened for sexual behavior, were castrated (Day 0) and implanted subdermally with either a blank implant or a silastic capsule of DHT. On day 21, subjects received bilateral guide cannulae (22 ga.) stereotaxically aimed at the MPOA. Males were given mating tests on days 28 and 31 to assess the effects of peripheral DHT alone on sexual behavior. On day 32, inner cannulae (28 ga.) containing 1 mm pellets of crystalline cholesterol, DHT, or T were lowered into the brain of males treated with peripheral DHT. Mating tests were conducted 12 and 15 days after central hormone application.

The number of rats mounting or ejaculating in response to peripheral DHT alone did not differ significantly from untreated controls. In contrast, more of the males treated with intracranial DHT displayed mounting and ejaculatory behaviors than those receiving central implants of cholesterol ($\chi^2(1) = 14.672$, $p<.001$, and 5.392, $p<.05$, respectively). The behavior of the males given central DHT was not significantly different than the behavior of males treated centrally with T. Analyses performed on the implant site coordinates revealed no significant differences in cannula placement between the groups, which clustered around the medial portion of the POA and anterior hypothalamus.

The fact that combined treatment with central and peripheral DHT is sufficient in itself to significantly increase male sexual behavior is inconsistent with the hypothesis that androgens must be aromatized to estrogens for the activation of male reproductive behavior. These results are more consistent with the idea that the relative ineffectiveness of peripheral DHT in male rats is due to decreased bioavailability of this hormone to the brain regions necessary for the expression of mating behavior.

216.13 COPULATION-ILLNESS ASSOCIATIONS FACILITATED BY AN ODOR CUE: NORMAL BLOOD LEVELS OF LUTEINIZING HORMONE.
G. J. Lawrence, S. W. Kiefer, T. L. Steele, and S. K. Quadri*. Depts. of Psychology/Anatomy-Physiology, Kansas State Univ., Manhattan, KS 66506.

Normal copulatory behavior in male rodents consists of a relatively stereotyped sequence of behaviors that are accompanied by specific endocrinological responses. For instance, there is a surge of luteinizing hormone (LH) in male mice when they are exposed to an estrous female (Coquelin et al., J. Neuro., 1984, 4). Copulatory behavior of male rats can be modified by using illness as punishment, and avoidance of copulation can be enhanced if a novel almond odor is present on the female (Lawrence & Kiefer, Neurosci. Abst., 1984, 8). The present study was conducted to determine whether alterations in LH response were present in male rats trained to avoid copulatory behavior.

Male rats were trained to avoid copulatory behavior by pairing copulation with lithium chloride (LiCl) induced illness; males were made ill after each encounter with an estrous female, noncontingent on mating responses. Males in the AO group (n=13) were trained with estrous females sprayed with an almond odor and rats in the NO group (n=16) were trained with estrous females without the almond odor. Controls (n=8) for odor, illness, and test environment were included. Eight training trials were conducted; on the ninth trial males were tested as before but without illness. Immediately following the ninth trial males were sacrificed and trunk blood was collected. The blood was assayed for LH levels as described by Fayez et al. (Proc. Soc. Exp. Bio. Med., 1985, 178).

On the ninth trial, males in the AO group showed a significant avoidance of copulatory behavior (85% failed to initiate copulatory behavior on the last trial compared with 38% in the NO group and 0% of controls). Males in both experimental groups showed significantly longer latencies for each mating response (mount, intromission, and ejaculation) compared with controls. No differences were found in the LH blood levels between males in the AO, NO, and control groups. Correlations between LH levels and avoidance or response latencies were nonsignificant. These data tentatively suggest a dissociation between normal endocrinological response of male rats to the presence of estrous females and the normal behavioral response of copulation.

216.14 THE ROLE OF ANDROGENS IN BEHAVIORAL MASCULINIZATION OF RATS.
K. L. OLSEN. Dept of Psychiatry and Behavioral Science, State University of New York, Stony Brook, NY. 11794.

A critical question is the identity of the active differentiating hormone or combination of hormones that mediate behavioral masculinization. This is important for our eventual understanding of the neural mechanisms underlying differentiation of sexual behaviors. Problems associated with exposing rats to either testosterone or estradiol can be overcome by giving the synthetic steroid, methyltrienolone (R1881 = 17β-hydroxy-17α-methyl-estra-4,9,11-trien-3-one). R1881 binds with high affinity to putative neural androgen receptors and doesn't compete for neural estrogen binding. Moreover, it is not presumably metabolized into either estrogens or other behaviorally less potent androgens.

Experiments were carried out to determine whether perinatal exposure to androgens, independent of estrogen stimulation, could mimic the differentiating action of the testes. In these studies, neonatal exposure to R1881 was combined with prenatal aromatase inhibitor (ATD) and neonatal castration. The rationale is that the combination of an aromatase inhibitor and neonatal castration should eliminate estrogen stimulation during the differentiating period.

Pregnant Spraque-Dawley rats were injected with either the ATD (5 mg/.1 ml/day) or vehicle from Day 10 of gestation until parturition. Males were castrated at birth and implanted with Silicone capsules containing R1881 or cholesterol; the implants were removed 10 days later. Another group of neonatally castrated males was given daily injections of 100 ug of hormone for the first five postnatal days. Some males, exposed prenatally to ATD or vehicle, were castrated at 60 days of age. At 90 days of age, rats received daily injections of 200 ug of testosterone propionate; testing began 10 days later.

Rats exposed prenatally to ATD or vehicle and castrated after the developmental period exhibited ejaculatory behavior following androgen treatment in adulthood. Males castrated at birth, irrespective of the prenatal treatment, did not show high levels of mating behavior as adults. As compared with neonatally castrated males, postnatal exposure to R1881 enhanced the ability to display masculine behavior (increased mounts and intromissions) but the rats did not ejaculate.

These results suggest that estrogen is necessary for the masculinzation of the ejaculatory system but not the mounting system. Based on this outcome, we are now determining whether exposure to estrogen in combination with R1881 mimics the masculinizing action of the testes.

216.15 AUTORADIOGRAPHIC LOCALIZATION OF ANDROGEN AND ESTROGEN CONCENTRATING CELLS IN THE BRAIN OF THE JAPANESE QUAIL. J.T. Watson and E. Adkins-Regan. Field of Neurobiology, and Department of Psychology, Cornell Univ., Ithaca, NY, 14853

The autoradiographic method was used to identify cells in the quail brain which accumulate testosterone(T) and two of its meatabolites: estradiol(E) and dihydrotestosterone(DHT). Adult (6wks.-8mons.) male and female Japanese quail (Coturnix coturnix japonica) were photically castrated and implanted with T or E implants to induce normal sexual behavior. The implants were removed, and 48 hrs. later the birds were injected with 250uCi per bird tritiated E, T, or DHT. 90 minutes after injection, the birds were decapitated, and their brains were processed for autoradiography. Following exposure for 3 to 19 months, sections were developed, stained with cresyl violet, and examined with light microscopy. One half of each of 20 coronal sections from each bird was examined in entirety for labelled cells. The number of silver grains over a cell was compared to the expected number of grains for an area of the same size assuming a Poisson distribution for the background grain level estimated in each field of view.

Labelled cells were found following all three steroid treatments, but their distribution differed between treatments. Labelled cells were found in preoptic area(POA), nucleus taeniae (TN) of the archistriatum, the lateral posterior nucleus of the hypothalamus(PHL), the periventricular magnocellular nucleus (PVM), the lateral septal region(SL), the infundibulum(INF), and nucleus intercollicularis(ICo) of the midbrain. The distribution of labelled cells by treatment was: (++=many labelled cells, +=few labelled cells, 0=no labelled cells; * indicates a group significantly different from other steroid groups)

NUCLEUS	E	T	DHT
POA	++	++	0 *
TN	++	++	0 *
PHL	++	++	+ *
PVM	++	++	+ *
SL	+	+	+
INF	++	++	+ *
ICo	+ *	++	++

These results, taken with previous studies on the specificity of activation of sexual behavior with androgenic and estrogenic metabolites of testosterone, suggest that the metabolites act at different sites in the quail brain to activate the various components of sexual behavior.

Supported by NIH grant 1 R03 MH39295-01.

216.16 RESTORATION OF MASCULINE COPULATORY BEHAVIOR AND BINDING OF TESTOSTERONE, ESTRADIOL, AND DIHYDROTESTOSTERONE TO ANDROGEN AND ESTROGEN RECEPTORS IN MALE RATS. M.Y. McGinnis* and R.M. Dreifuss* (SPON: J.E. Shriver) Dept. of Anatomy, Mt. Sinai School of Medicine, CUNY, New York,N.Y. 10029.

The purpose of this study was to examine the effects of physiological doses of testosterone (T), its two major metabolites dihydrotestosterone (DHT) and estradiol (E_2), and DHT in combination with E_2, on masculine copulatory behavior, and on cell nuclear androgen and estrogen receptor binding in brain and pituitary of male rats.

For behavioral studies, all animals were required to complete two ejaculatory series on the pretest for inclusion in the study. Copulators were then castrated and three weeks later tested for the absence of copulatory behavior. Non-copulators, randomly divided into 5 treatment groups, received Silastic capsules inserted under the abdominal skin as follows: 1) 2 10mm T, 2) 1 5mm 10% E_2 (diluted with cholesterol), 3) 1 5mm DHT, 4) 1 5mm 10% E_2 plus 1 5mm DHT, 5) 1 10mm Blank (Bk) capsule. Tests for restoration of copulatory behavior were given 2-4, 5-7, and 14-16 days post-treatment. Most of the rats receiving T treatment completed 2 ejaculatory series by 5-7 days. Treatment with 10% E_2 + DHT also restored copulatory behavior by 5-7 days, but not as effectively as T. In rats receiving 10% E_2 copulatory behavior was restored only after 14-16 days of exposure. DHT and Bk capsules had no effect on restoration of copulatory behavior.

For cell nuclear androgen receptor and estrogen receptor binding assays, tissues from 6 animals in each treatment group were pooled. Pituitaries were removed, and brain samples were taken from hypothalamus, preoptic area, amygdala and septum. Half the pituitaries and samples from one half of each brain area were assayed for androgen receptors, the other half for estrogen receptors. For all tissues, high levels of androgen receptor binding, were found only in the T treatment group, and high levels of estrogen receptor binding were found only in 10% E_2, and 10% E_2 plus DHT treatment groups. Our results suggest that in physiological doses, T is the major gonadal steroid that binds to androgen receptors and E_2 is the major gonadal steroid that binds to estrogen receptors. Thus, restoration of copulatory behavior in castrated rats appears to be correlated primarily with testosterone binding to androgen receptors, and it is not correlated with DHT or E_2 binding to androgen receptors or with T binding to estrogen receptors either as estradiol or as testosterone.

216.17 CYTOSOL ANDROGEN RECEPTORS IN GUINEA PIG BRAIN AND PITUITARY. M. Bonneau*, H.B. Ahdieh*, J. Thornton and H.H. Feder. Institute of Animal Behavior, Rutgers University, Newark, New Jersey 07102.

In contrast to the rat, male sexual behavior of castrated male guinea pigs is fully restored after treatment with 5α-dihydrotestosterone in the absence of exogenous estrogen (Alsum & Goy, Horm. Behav., 5:207, 1974). This suggest that guinea pig brain may be highly sensitive to non-aromatizable androgens, yet there are no reports of the characteristics of androgen receptors in brain of this species. In addition, the possibility that noradrenergic transmission may influence the concentration and/or distribution of brain androgen receptors has not been investigated, although such an influence of adrenergic transmission on progestin and estrogen receptors has been demonstrated (Nock & Feder, Neurosci. Biobehav. Rev., 5:437, 1981; Clark et al., Brain Res., 1985, in press).

Brain and pituitary "cytosol" receptor had an apparent K_D of 0.04nM and was androgen specific (methyltrienolone > 5α-dihydrotestosterone > testosterone = estradiol > progesterone). The concentrations of "cytosol" androgen receptors in castrated adult male guinea pigs (N=8) were 12.2±1.5, 11.6±0.9, 6.9±0.6, 2.6±0.3, 1.3±0.3 femtomoles/mg protein (mean±s.e.m.) in anterior pituitary, hypothalamus, medial preoptic area, amygdala and cerebral cortex respectively. No significant difference in the concentration of receptors was observed between castrated adult male and female guinea pigs. The systemic injection of 5mg/kg of Prazosin (an α_1-adrenergic antagonist) had no significant effect on the concentration of receptors in castrated adult males in any brain area.

The very high affinity of guinea pig brain "cytosol" androgen receptors and their localization to brain areas involved in reproductive processes is consistent with the previous report that non-aromatizable androgens stimulate masculine sexual behavior in this species. These results suggest that, at least in guinea pigs, brain androgen receptors might be crucially involved in the regulation of male sexual behavior.

216.18 ESTROGEN INCREASES CYTOSOLIC ANDROGEN RECEPTOR IN PITUITARY AND SPECIFIC BRAIN NUCLEI OF THE MALE RAT. R.J. Handa*, C.E. Roselli and J.A. Resko*. Dept. of Physiology, Oregon Health Sciences Univ., Portland, OR 97201 and Dept. of Reproductive Biology and Behavior, Oregon Regional Primate Res. Center, Beaverton, OR 97006

In the rat, estrogen synergizes with androgen to facilitate male reproductive behavior. To determine the biochemical basis of this synergism, we examined the in vitro binding of the synthetic androgen, R1881, to brain and pituitary (PIT) cytosol of male rats exposed to estrogen for 7 days. Animals were castrated 7 days before implanting 2.5 cm Silastic capsule containing crystalline 17β-estradiol (E). Controls were sham implanted. Purified cytosols were prepared from PIT or hypothalamus-preoptic area (HPOA). Incubation with increasing concentrations of [^{3}H]-R1881 revealed the presence of a single, saturable, high affinity receptor with a K_d of 0.9 X 10^{-10}M in both PIT and HPOA. Triamcinolone acetonide (10 μm) was added to the incubation tube to prevent binding to the progesterone receptor. Competition studies using excess radioinert steroids showed that the binding of [^{3}H]-R1881 was specific for androgen receptor (AR). Single point determination of AR in PIT cytosol showed significantly greater amounts in E-treated males (42.2 ± 3.0 fmol/mg protein [mg], n=9) compared with controls (26.4 ± 1.65 fmol/mg n=11; $p<0.01$). Values were comparable when [^{3}H]-DHT was substituted as the radioligand (43.0 ± 2.4 vs 24.0 ± 1.0 fmol/mg n=5, $p<0.01$). In addition, we measured AR in discrete brain nuclei and subregions from animals perfused with 10% cold DMSO. Brains were frozen, sliced at 300 μm and 16 brain nuclei were punched according to the method of Palkovits. Nuclei from 5-6 animals were pooled for each determination. Highest levels of AR were found in the ventromedial n. (17.2 ± 0.6 fmol/mg), medial preoptic n. (MPOA, 12.8 ± 1.6 fmol/mg) bed n. of the stria terminalis (BNST 11.6 ± 1.5 fmol/mg), lateral septum (12.4 ± 1.8 fmol/mg) and medial amygdala (MA, 10.6 ± 0.7 fmol/mg). E treatment increased ($p<0.05$) AR in the MPOA (15.5 ± 0.5 fmol/mg), BNST (15.6 ± 0.8 fmol/mg) and MA (14.9 ± 1.5 fmol/mg). No differences were detected in nuclei with intermediate levels of binding (5-10 fmol/mg; suprachiasmatic n., periventricular preoptic n., lateral preoptic n., periventricular ant. hypothalamic n., ant. hypoth. n., arcuate/median eminence, or hippocampal CA_1) or in 4 nuclei with low levels of binding (1-5 fmol/mg). These data demonstrate that E can modify AR numbers and that these increases are restricted to the pituitary and specific brain regions which appear to mediate male reproductive behavior. Supported by HD 06731, HD 18196. HD 07133.

216.19 TESTOSTERONE BLOCKS THE AUTORADIOGRAPHIC LABELING OF NEURONS BY [^{3}H]ESTRADIOL IN THE BRAINS OF FEMALE RHESUS MONKEYS. H.D. Rees and R.P. Michael. Dept. of Psychiatry, Emory Univ. Sch. of Med., and Georgia Mental Health Inst., Atlanta, GA 30306.

The administration of testosterone (T), either systemically or intracerebrally, increases female sexual receptivity and motivation in ovariectomized rhesus monkeys. The aromatization of T to estrogenic metabolites may play a role in its behavioral actions. The activity of aromatizing enzymes varies widely in different regions of the brain. Autoradiography was used to localize precisely the brain regions in which aromatized metabolites of T may influence estrogen target neurons in female rhesus monkeys. Five females, weighing 5.9-7.6 kg, were ovariectomized and injected sc with either vehicle (controls) (N=2), 2 mg testosterone propionate (TP) (N=2), or 2 mg dihydrotestosterone propionate (DHTP) (N=1) daily for 4 days beginning the day of ovariectomy. Four hours after the last injection, each female received 1 mCi [2,4,6,7-^{3}H]17β-estradiol iv (Amersham; 93 Ci/mmol). One hour later, the animals were killed and the left halves of brains and samples of peripheral tissues were frozen and stored in liquid nitrogen. Frozen sections were cut at 4 μm in a cryostat and thaw-mounted on emulsion coated (NTB3) slides. After exposure for 20 weeks at -19^{o}C, the slides were developed and stained with methyl green-pyronin. A cell in the brain was considered labeled if its nucleus had a silver grain density at least twice that of adjacent neuropil background.

Labeled neurons in the vehicle-treated controls were located in the medial preoptic nucleus (n.), anterior hypothalamic area, arcuate n., ventromedial n., paraventricular n., premammillary n., supramammillary n., lateral septal n., bed n. of stria terminalis, medial, cortical and accessory basal amygdaloid n., and claustrum. In the brains of the TP-pretreated females, the labeling of neurons was virtually abolished except in the arcuate n. and lateral septal n., where the percentage of neurons labeled remained high and similar to that of the controls. In contrast to TP, pretreatment with the non-aromatizable androgen DHTP did not affect labeling in any brain region. Neither TP nor DHTP pretreatment had any effect on the labeling of cells in the pituitary gland, uterus, vagina, or clitoris. These data suggest that metabolites of T occupy nuclear estrogen binding sites in estrogen-concentrating brain regions, except the arcuate n. and lateral septal n. Thus, T appears to act as a regionally specific estrogen in the female primate brain.

Supported by USPHS grants MH 33766 and MH 19506. General support was provided by Georgia Department of Human Resources.

216.20 SOCIAL STIMULI INCREASE PROGESTIN RECEPTOR LEVELS IN HYPOTHALAMUS BUT NOT IN PREOPTIC AREA OF THE FEMALE PRAIRIE VOLE, AN INDUCED OVULATOR. M.Cohen-Parsons, C.S.Carter* and E.J.Roy. Depts. of Psychology and Ecol., Ethol., and Evol., University of Illinois, 603 E. Daniel, Champaign, IL 61820.

Cross-species comparisons reveal a general pattern of steroid target cell distribution in the vertebrate brain. In female animals, high concentrations of estrogen (E) concentrating cells are found in the medialbasal hypothalamus (MBH), preoptic area (POA) and the limbic forebrain. In intact laboratory rats, the binding of E to brain cell nuclei fluctuates with the secretion of ovarian E over the estrous cycle. In these females, E induces the synthesis of receptors for progesterone (P), thereby priming the female for maximal responsivity to P in areas of the brain which are known to regulate sexual behavior and ovulation.

In contrast to the spontaneous ovulators, in prairie voles E and P do not synergize to facilitate behavioral estrus. Female sexual behavior in prairie voles is E-dependent, and pheromonal and tactile stimulation from males cause an increase in cell nuclear E receptor binding in the brain. Although the level of cytosol progestin receptors increases in the MBH of sexually activated females, no difference in progestin receptor levels occurs in the POA. These results indicate that although the presence of E-accumulating cells is a general characteristic of the vertebrate brain, the ability of cells in different brain regions (MBH vs POA) to respond to E may differ among species. These differences may be related to the differential control of sexual behavior and/or ovulation among species.

216.21 ACTION OF ESTROGEN IN MALE HIPPOCAMPUS. Y.L.T. Ting* and T.J. Teyler (SPON: D. Riccio). Neurobiology Program, N.E. Ohio Univerisities College of Medicine, Rootstown, OH 44272.

A crossed hormone effect on tissue excitability has been demonstrated in hippocampal slice preparations. Active forms of estradiol increases the population spike amplitude of hippocampal slices taken from male rats by as much as 250%. A less prominent effect of testosterone on slices from female rats has also been observed (increase of 150%) (Teyler et al., Science, 209:1017, 1980). Such changes appeared rapidly, occuring within 5 minutes after drug administration. To demonstrate that such electrophysiological changes are not limited to slice preparations, the experiment has been replicated in intacts.

Varying doses of beta-estradiol-3-benzoate dissolved in safflower oil was injected I.P. into male hamsters weighing 95-130 grams. I.V. injections of 17-beta-estradiol suspended in PVP were also used. Stimulation of the Schaffer collaterals and recoridng from CA1 pyramidal cells of the hippocampus was achieved with tungsten electrodes. A constant level of anesthesia was maintained with an infusion pump of nembutol-saline solution. After baseline determinations, the tissue response to the drug was tracked for 45 minutes.

Preliminary data shows that intact hippocampus excitability has a dose dependant property parallel to that of slice preparations. In addition, the changes occurred rapidly as in the slice, suggesting the operation of a mechanism of action other than that of the classical steroid hormone.

217.1 CHOLECYSTOKININ MODULATION OF DOPAMINE-MEDIATED BEHAVIOR: IMPLICATIONS FOR TOURETTE SYNDROME. H.K. Kulmala, J.W. Boja*, and J.A. Nielsen, Dept. of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272

Tourette Syndrome (TS) is a developmental disorder which appears to involve a hypersensitivity of striatal dopamine (DA) systems. Unilateral asymmetries in DA, itself, or in DA receptor concentrations in rodent striata are reflected by circling behavior. Thus, changes in rotational activity can be used to predict the efficacy of agents for treating TS. We have utilized this behavior to determine the possible efficacy of cholecystokinin-8 (CCK) in TS.

Rats received injections of 2ul of artificial CSF or 100 ng CCK in this vehicle through indwelling right lateral ventricular cannulae 1 hr. prior to testing. Two and four days later, animals received artificial CSF, followed by testing. Rotational activity was evaluated every other day in darkened, computerized circular chambers. Total left versus right, one-quarter and full turns were determined for 15 minutes before and 30 minutes after rats received either 2.5 mg/kg d-amphetamine (AMPH) or saline administered intraperitoneally. Once baseline behavior returned, a second dose of CCK or CSF was administered and animals were tested as above.

Animals acclimated to the chambers by the second or third trial. Some rats showed an inherent left or right turning bias, whereas others showed little bias. Saline injections did not significantly change the direction or quantification of circling. The effects of AMPH were consistent in any one animal, but varied across the group. Left-biased animals showed little change in total rotational activity or directional preference, whereas right turning was significantly amplified. Intraventricular CCK had differential effects on left- and right-biased rats. Rotation was decreased or changed to right-turning in previously left-biased animals, an effect still seen at 2 days after CCK. In right-biased animals, a decrease in right-turning was evident.

CCK had been reported to decrease DA receptor number. Thus, following unilateral intraventricular injection, we expected to create a hyposensitive striatum, resulting in spontaneous or amphetamine-revealed right-turning. The data in left-turning animals is consistent with this expectation. The data in right-biased animals indicates that CCK also may have effects not related to the action on DA receptors. Further experiments are in progress to expand upon these findings.

Supported by a research grant from the Tourette Syndrome Association to H.K. Kulmala.

217.2 **GABAERGIC AND CATECHOLAMINERGIC SYNAPTIC INTERACTIONS IN THE MACAQUE HYPOTHALAMUS: DOUBLE LABEL IMMUNOSTAINING WITH PAP AND COLLOIDAL GOLD.** K.K. Thind, T. Song* and P.C. Goldsmith. Dept. of OB/GYN and Repro. Sci., U.C.S.F., San Francisco, CA 94143.

Gamma-aminobutyric acid (GABA) has been implicated as an inhibitory neurotransmitter in control of gonadotropin secretion. In this study, we analyzed GABA-CA neuronal interactions in the anterior ventral periventricular area (AVPV), and the arcuate nucleus (ARC) and adjacent periventricular zone (ARC-PVZ) of the primate hypothalamus.

Adult male Rhesus monkeys were perfused with aldehydes. Coronal Vibratome sections (40 microns) were immunostained sequentially for tyrosine hydroxylase (TH) with the peroxidase anti-peroxidase (PAP) technique, and for glutamate decarboxylase (GAD) with immunogold (15 nm), so that the location of both enzymes could be visualized simultaneously at the light microscopic (LM) and electron microscopic (EM) levels. Rabbit anti-TH (#16) and sheep anti-GAD (#1440-4) were generously supplied by A.W. Tank and V. Weise respectively. At the **LM level**, TH-immunoreactive (-IR) perikarya (brown) were observed in the ARC, ARC-PVZ, and the AVPV, where positive fibers were plentiful. GAD-IR processes (red), present throughout the hypothalamus, appeared to contact some TH-IR neurons. GAD staining was especially dense in the AVPV, where a substantial overlap of TH and GAD fibers occurred. At the **EM level**, PAP was present in perikarya, dendrites, axons, and axon terminals of TH-IR neurons. Colloidal gold particles were found only in dendrites and axon terminals of GAD-IR neurons. Labeled GAD terminals typically contained small, clear synaptic vesicles, while TH terminals contained these and sometimes one or two dense core vesicles. No evidence for cross-labeling was observed, and appropriate controls confirmed the specificity and selectivity of the method. In the **ARC and ARC-PVZ**, asymmetrical (Gray I) axo-dendritic synapses occurred between GAD and TH-IR profiles, with TH/GAD directionality more prevalent. Symmetrical (Gray II) synapses were less common, with either TH or GAD pre-synaptic in axo-dendritic and dendro-dendritic contacts. GAD/GAD interactions were not seen, but TH/TH contacts appeared to be dendro-dendritic. In the **AVPV**, only symmetrical synapses were observed, and their directionality was difficult to determine. GAD- and TH-IR dendrites frequently formed dendro-dendritic synapses, but GAD/TH dendro-somatic synapses were rare. Again no GAD/GAD interactions were seen, but TH/TH contacts were often dendro-dendritic and rarely dendro-somatic.

These results illustrate the complex interactions of GAD and TH containing elements in the neuroendocrine hypothalamus. Since both GABA and CA neurons concentrate estrogens, they also suggest how their connections might affect gonadotropin secretion in primates.

217.3 VIP STIMULATION OF SECRETION AND ADENYLATE CYCLASE IN RAT PAROTID ACINAR CELLS. M.K. McMillian*, M.M. Freiden* and B.R. Talamo. Neurosciences Labs, Tufts Medical School, Boston, MA 02111

Vasoactive intestinal peptide, VIP, and acetylcholine are co-localized to nerves in the rat parotid gland. As with acetylcholine and α-adrenergic agonists, VIP is a weak stimulator of exocytosis of amylase from parotid acinar cells, cell aggregates or tissue fragments. Unlike these agonists, however, it does not stimulate increases in calcium levels as measured by 22Na+ uptake.

It has been suggested that VIP stimulates exocytosis via cAMP. VIP also has been reported to elevate cAMP in rat parotid acinar cells, but at maximally active concentrations it does not detectably elevate cAMP accumulation in our system. However, under some conditions VIP can activate adenylate cyclase in parotid cells, albeit far less effectively than do β-adrenergic agonists, which are also more potent stimulators of exocytosis. Forskolin or a phosphodiesterase inhibitor, RO 20-1724, greatly potentiate VIP effects on cAMP level and amylase release. Forskolin enhances the secretory response without significantly shifting the EC50 for VIP, which is about 1nM for cell aggregates. Although cAMP accumulation can be boosted (4 fold) by using a combination of VIP and phosphodiesterase inhibitor, maximal amylase release comparable to that elicited with isoproterenol cannot be achieved. Paradoxically, VIP is as effective as isoproterenol in activating adenylate cyclase in a membrane preparation. The EC50 for enzyme activation is comparable to that for stimulating cAMP accumulation or amylase release from intact cells.

This association of very low cAMP accumulation with amylase release parallels the effects seen with isoproterenol, where the capacity to stimulate cAMP accumulation can be shown to be far in excess of the amount of cAMP which accumulates under conditions of maximal exocytosis. Unlike isoproterenol, with VIP there do not appear to be spare receptors for the secretory response; the amylase release curve parallels the cAMP accumulation dose-response curve (detected in the presence of forskolin).

Muscarinic and α-adrenergic agonists, which inhibit adenylate cyclase stimulation by isoproterenol in the heart, do not inhibit either the accumulation of cAMP or the release of amylase stimulated by VIP or isoproterenol in this system. This work is supported by NIH grants RO1-NS17331 and PHS P30AM39428.

217.4 ROLE OF CHOLINERGIC NEURONS IN THE CENTRAL CARDIOVASCULAR ACTIONS OF SUBSTANCE P. G.R. Trimarchi*, W.C. Glisson*, W.M. Thompson*, J.C. Van Lingen* and J.J. Buccafusco (SPON: R. Borison). Dept. Pharmacology and Toxicology, Medical College of Georgia and Veterans Administration Medical Center, Augusta, GA 30912.

The role of cholinergic neurons in central cardiovascular regulation is not well understood, however, activation of brain cholinergic neurons in several species evokes a hypertensive response. It also has been reported that central cholinergic blockade in hypertensive animal models produces an antihypertensive response. It is possible that brain acetylcholine may, at least in part, play a role in the maintenance of elevated blood pressure. As with central cholinergic stimulation, intracerebroventricular (icv) injection of substance P (sP) elicits a pressor response in unanesthetized rats. The purpose of this study was to determine whether the cardiovascular effects following icv injection of sP are mediated by central cholinergic neurons. Male, Wistar rats were anesthetized, and chronic indwelling arterial and icv cannule were implanted. Mean arterial pressure (MAP) and heart rate (HR) were recorded from unanesthetized, unrestrained animals. Icv injection of sP (0.05, 0.5 and 5 ug) produced a dose-related increase in MAP of 21 ± 7, 27 ± 3 and 41 ± 2 mmHg, respectively and an increase in HR of 110 ± 44, 145 ± 8 and 178 ± 13 beats/ min, respectively. The maximal increase in MAP occurred between 5 and 25 min after injection, as the dose administered was increased. For the highest dose, MAP was significantly elevated even 45 min after injection. HR increased rapidly just after injection, the response peaked with 5 min, and then returned towards baseline by 30 min. Hemicholinium-3 (HC-3), when administered centrally, causes a marked depletion of brain acetylcholine. One hr following HC-3, icv injection of sP (0.5 - 5 ug) elicited a pressor response significantly reduced in magnitude and duration. For example, an increase of only 7 ± 6 mmHg was observed following 5 ug of sP, and this was maintained only briefly. HC-3 pretreatment did not significantly alter the entire course of the sP-induced tachycardic response, however, there was a significant inhibition in the initial rise in HR, and an increase in the time to peak of the response. These findings indicate that functioning cholinergic neurons are required for the full expression of the cardiovascular response to central injection sP. Since HC-3 is a presynaptic inhibitor of cholinergic neurons, it is possible that sP elicits its central pharmacological actions through the enhanced release of acetylcholine. Supported by HL30046 and the Veterans Administration.

217.5 CHOLECYSTOKININ BLOCKS EFFECTS OF GABA ON HIPPOCAMPAL POPULATION SPIKE. J.D. Stittsworth, Jr. and W.J. Giardina
Dept. of Neuroscience and Dept. of Pharmacology, Abbott Laboratories, Abbott Park, IL. 60064

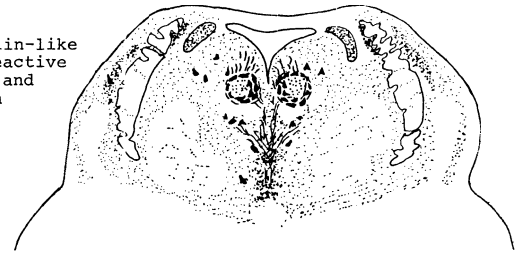
Cholecystokinin (CCK) and GABA immunoreactive material has been reported to coexist in hippocampal neurons (Somogyi et al., The Journal of Neuroscience, 1984). Bradwejn and deMontigny (Nature, 1984) reported that i.v. administration of benzodiazepines reversed CCK-induced activation of CA1 or CA3 hippocampal neurons. The benzodiazepine receptor is thought to be coupled with the GABA receptor. Because CCK and GABA immunoreactive material coexist in hippocampal neurons and because of the CCK-benzodiazepine interaction, a question of functional significance is raised. We have studied the effects of CCK_8, CCK_4, bicuculline (BIC) and GABA on the population spike (PS) recorded from CA1 hippocampal pyramidal neurons.

The PS was recorded from 400 µm thick hippocampal slices prepared from brains of guinea pigs. The slices were placed in a recording chamber at the gas-fluid interface, in a noncirculating bath. A stimulating electrode was placed in Schaffer Collaterals and a recording electrode was placed in the pyramidal cell layer of CA1. The stimulus was delivered at a rate of once every 10 seconds. The PS was averaged (n=2) once every min. When the amplitude of the PS was stable, ten control recordings were made and their average amplitude calculated (control = 100%). Compounds were added to the chamber by micropipetting (20 µL) near, but not on, the slice. The PS amplitude was recorded every min for 65 min following administration of the test compound. 100 nM CCK_8 had no effect on the PS amplitude. 1 µM CCK_8 caused a slow increase in the amplitude of the PS, beginning 25 min after application to the bath; the amplitude, after 65 min, was 150% over control. The effect of 10 µM CCK_4 could be seen earlier beginning 10 min after bath application. At the end of the 65 min, the CCK_4-induced enhancement was 220% over control. The effect of the GABA antagonist BIC (300 nM) was an immediate enhancement of the PS to 150% over control. Application of 100 µM or 30 µM GABA caused a suppression of the PS. At 100 µM the GABA-induced suppression was seen immediately, and 30 µM GABA caused an initial enhancement (70% over control) followed by nearly total suppression within 45 min. When CCK_8, CCK_4 or BIC were added to the bath 15 min prior to GABA application, the GABA-induced suppression was blocked. 100 nM CCK_8, a concentration which has no effect on the PS, also blocked the GABA-induced suppression. The interaction of CCK and GABA is similar to that of BIC and GABA. These data suggest that CCK may affect GABA neurotransmission in the hippocampus.

217.6 RELATIONSHIP BETWEEN CATECHOLAMINE, ENKEPHALIN, SUBSTANCE P AND NEUROTENSIN IMMUNOREACTIVE NEURONAL SYSTEMS IN THE INFANT HUMAN BRAIN. N. Sakamoto*, J-P. Michel*, K. Kitahama*, N. Kopp* and J. Pearson. Osaka Univ., Japan, Faculté de Médecine and Hôpital Neurologique, Lyon, France and NYU Medical Ctr., New York, NY 10016.

Three human infant brains were studied after perfusion fixation with formalin using an immunoperoxidase technique modified to greatly improve sensitivity and to reduce background to virtually zero. High dilution of primary antibody, very prolonged incubation, extended rinses, blocking of nonspecific absorption by normal serum at all 3 stages involving antibodies, and metallization using nickel ammonium sulfate in the final incubation mixture give superior results.

In the medulla substance P and enkephalin axons are present in a newly demonstrated aggregate of adrenergic (phenylethanolamine N-methyl transferase-reactive) neurons dorsal to the main part of the solitarius nucleus. In the upper pons an enkephalinergic nucleus lies dorsal to the medial longitudinal fasciculus and is particularly richly innervated by substance P. Substance P-immunoreactive cell bodies are present in large numbers in the upper pontine tegmentum and junction with the mesencephalon. Substance P, enkephalin and catecholamine fibers have complex, sometimes complimentary relationships in the basal ganglia. Neurotensin neurons are prominent in thalamic and limbic systems; in the latter they are related to substance P neurons. Multiple catecholamine and peptide neurons are present in the subcortical white matter of the cerebral hemispheres. Basal ganglia and cortical terminal pattern distributions are distinctive for each substance. Preliminary data indicate that developmental changes may result in different patterns of terminal density for some transmitters in the adult.



Enkephalin-like immunoreactive neurons and axons in human infant pons.

217.7 DENERVATION SUPERSENSITIVITY TO CHOLECYSTOKININ AND DOPAMINE IN THE RAT NUCLEUS ACCUMBENS: MICROIONTOPHORETIC STUDIES. X-T. Hu* and R.Y. Wang (SPON: H. Benzinger). St. Louis Univ. School of Medicine, Department of Pharmacology, St. Louis, MO 63104.

Hökfelt et al (Nature 285:476-478, 1980) reported that approximately 40% of the dopamine (DA) neurons in the ventral tegmental area (VTA or A10) also contain cholecystokinin (CCK). These DA/CCK neurons send their projections primarily to the medial and caudal parts of the nucleus accumbens (NAc). To study the interaction between DA and CCK on NAc cells, we have shown that iontophoresis of sulfated CCK octapeptide (ionto-CCK) activated primarily cells in the medial NAc. Concurrent ionto-DA reversed CCK-induced activations and suppressed the activity of NAc cells (White and Wang, Brain Res. 300:161-166, 1984). The purpose of the present study was to investigate the development of denervation supersensitivity to DA and CCK on NAc cells after lesions of DA fibers in the medial forebrain bundle (MFB).

Rats were pretreated with desipramine, a norepinephrine (NE) uptake blocker, 30 min prior to the direct injection of 6-hydroxydopamine (6-OHDA, a relatively selective neurotoxin for catecholamine systems) in the MFB to protect the NE systems. Two other groups of rats were injected with either the vehicle or 5,7-dihydroxytryptamine (5,7-DHT, a relatively selective neurotoxin for serotonin systems) and served as controls. Five to seven days after the injection, rats were anesthetized with chloral hydrate and prepared for single cell recording and microiontophoretic studies. The ejecting current of CCK needed for increasing the discharge rate of spontaneously active cells to 80% above their basal rate (ED_{80}) or the current needed to activate quiescent cells to 2 Hz was compared in control vs. experimental groups. ED_{80} was selected because not all cells can be driven by CCK to 100% above basal rates. Glutamate was also used to activate those quiescent cells to 2 Hz of firing rate. ID50s for DA were systematically compared on spontaneously active cells as well as on those quiescent cells activated by glutamate in both 6-OHDA pretreated and control rats.

The sensitivity of NAc cells to iontophoretically applied DA or CCK was markedly enhanced (approximately 3 fold) in 6-OHDA pretreated rats but not in vehicle or 5,7-DHT pretreated groups. In addition, the enhanced sensitivity to CCK was more obvious on cells in the medial NAc than in the lateral part. No such regional differences were detected for DA. Interestingly, the number of spontaneously active cells increased in the medial but not the lateral part of the NAc.

In conclusion, the results indicated that lesions of DA/CCK fibers by 6-OHDA were effective in inducing the development of denervation supersensitivity to both CCK and DA on NAc cells. (This research was supported by USPHS grants MH-34424, MH-38794 and a RSDA MH-00378.)

217.8 DOES CHOLECYSTOKININ POTENTIATE DOPAMINERGIC ACTION IN THE NUCLEUS ACCUMBENS? R.Y. Wang and X-T. Hu*. Department of Pharmacology, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

Recently Crawley et al. (Neurochem. Int., 6:755-766, 1984) reported that cholecystokinin (CCK) injected directly into the nucleus accumbens (NAc) of the rat potentiated apomorphine-induced stereotypy and dopamine (DA)-induced hyperlocomotion. Because this facilitation of DA receptor mediated behavior by CCK was not observed when CCK was injected in the neostriatum, Crawley et al. suggested the potentiation of DA by CCK may be specific to the mesolimbic neurons, where CCK and DA coexist. We have previously shown that iontophoresis of sulfated CCK octapeptide (ionto-CCK) activated the cells in the medial but not the lateral NAc. Furthermore, concurrent ionto-DA would reverse CCK-induced activation (White and Wang, Brain Research, 300:161-166, 1984). The purpose of this study was to determine whether CCK would potentiate the effect produced by DA on NAc cells by using single cell recording and microiontophoretic techniques.

The rat was anesthetized with chloral hydrate and then mounted on a stereotaxic apparatus. Standard electrophysiological techniques were used.

As previously described (White and Wang, 1984) many NAc cells had very low discharge rates or were quiescent. Therefore, the effect of CCK on DA was studied on spontaneous activity as well as glutamate (GLU) activated cellular activity in the NAc. DA suppressed both the spontaneous as well as GLU-activated activities. However, the GLU-activated quiescent NAc cells appeared to be more sensitive to DA inhibition. Consistent with our previous finding, CCK was much more effective in activating medial than lateral NAc cells. In the medial NAc when CCK concurrently iontophoresed with DA, the ejecting current was adjusted so that CCK by itself did not have direct effect on the cellular activity, CCK attenuated markedly DA-induced inhibition. CCK was also effective in reversing DA-induced inhibition on lateral NAc cells. Of 15 NAc cells studied, under no circumstance was there any sign of potentiation of DA by CCK. Furthermore, when CCK was applied concomitantly with GLU (n=7), CCK enhanced GLU-induced excitation.

In conclusion, CCK potentiated GLU-induced excitation and attenuated DA-induced inhibition on NAc cells, suggesting that CCK and DA have opposite roles in modulating the activity of NAc cells. Our results, therefore, do not support the view that CCK potentiates DA at cellular level. (This research was supported by USPHS grants MH-34424, MH-38794 and a RSDA MH-00378.)

217.9 EFFECTS OF NALTREXONE ON MONOAMINES IN ESTROGEN-PRIMED RATS. D. L. Allen and V.N. Luine. (SPON: I. Wajda)
Rockefeller University, New York, NY 10021.

Opiates are known to be involved in the hormonal control of gonadotropin release and male sexual behavior, and may have a role in the control of female sexual behavior. We have recently shown (Allen, et. al., Hormones and Behavior 19:98, 1985) that the opiate antagonist, naltrexone (NTX, 3 mg/kg s.c.) facilitates lordosis responding in estradiol benzoate (EB)-treated female rats. The facilitation of behavior was blocked by pargyline, a monoamine-oxidase inhibitor, suggesting a possible interaction of monoamines and opioids in the regulation of female sexual behavior. The purpose of the present experiment was to further investigate possible opiate-monoamine interactions in the regulation of sexual behavior.

The effect of naltrexone on monoamine levels and serotonin turnover in discrete brain regions was investigated. Ovariectomized rats were injected with EB (5 ug), and 48 hours later with naltrexone (3 mg/kg) or saline. Three hours later, when naltrexone-treated rats would be sexually receptive, all rats were injected with pargyline (75 mg/kg) or saline, and sacrificed twenty minutes later in the dark. Discrete brain regions were analyzed by the punch technique. The brain regions sampled were the dorsomedial nucleus and the lateral portion of the ventromedial nucleus of the hypothalamus, anterior hypothalamic nucleus, arcuate-median emminence, medial preoptic area (POA), medial nucleus of the amygdala, and the dorsal and lateral mesencephalic central gray. Levels of monoamines were detected by HPLC with electrochemical detection.

Naltrexone in estradiol-primed female rats produced limited effects on monoamine levels and serotonin accumulation. There was no effect on dopamine, norepinephrine or serotonin levels in any of the brain regions. Naltrexone treatment decreased the rate of accumulation of serotonin after pargyline in EB-primed female rats only in the preoptic area (14.0 $\pm$ 3.4 pg/ug protein/hr in EB vs. -1.1 $\pm$ 3.7 in EB + NTX, $p < .01$), suggesting decreased turnover.

Thus, estradiol and naltrexone, in doses that facilitate sexual behavior, result in limited effects on monoamine levels and serotonin accumulation in the areas examined. The only change was a dramatic decrease in 5-HT accumulation after pargyline in the POA, a region involved in the control of female sexual behavior. Possible interactions between opiates and monoamines in the control of sexual behavior need to be further examined.

Supported by USPHS Grant HD12011 (VNL) and NSF Graduate Fellowship (DLA).

217.10 THE SAME POTASSIUM CONDUCTANCE IS INCREASED BY ACTIVATION OF μ-OPIOID RECEPTORS AND α_2-ADRENOCEPTORS. J.T. Williams and R.A. North. Neuropharmacology Laboratory, 56-245, M.I.T., Cambridge, MA 02139.

Intracellular recordings were made from neurons in the locus coeruleus in slices cut from rat pons and maintained in vitro. Membrane currents were recorded with a single electrode voltage-clamp amplifier. Opioids and catecholamines produced outward currents at membrane potentials between -40 and -110 mV; these currents have been shown previously to result from opening of membrane potassium channels. The receptors activated by the opioids and catecholamines on locus coeruleus neurons have been shown by determinations of dissociation equilibrium constants for antagonists to be μ and α_2 types respectively. The purpose of the present experiments was to test the hypothesis that the different cell surface receptors were coupled to different populations of potassium channels. Addition of quinine (50 μM - 1 mM), substitution of barium for calcium, or substitution of rubidium for potassium, in the superfusion solution decreased the outward currents induced by both opioids and α_2-adrenoceptor agonists to a similar extent. The maximum outward currents produced by [Met]enkephalin (30 μM), normorphine (10 μM) and clonidine (1 μM) were the same (279 $\pm$ 28 pA, n = 13). The currents induced by a combination of any two agonists ([Met]enkephalin and normorphine; [Met]enkephalin and clonidine; noradrenaline and normorphine; [Met]enkephalin and noradrenaline) were not larger than the maximum current observed in the same neuron in response to any agonist applied alone. For example, the outward current observed during application of [Met]enkephalin (10 μM) was not further increased when the superfusion solution was changed to one which contained both [Met]enkephalin (10 μM) and clonidine (100 nM or 1 μM), or to one which contained both [Met]enkephalin and normorphine (1 or 10 μM). The results indicate that α_2-adrenoceptors and μ-opioid receptors activate the same potassium conductance in an individual neuron, presumably through a shared intracellular second messenger.

Supported by U.S. Department of Health and Human Services grant DA03161.

217.11 CCK-8 PEPTIDES ALTER THE RELEASE OF ENDOGENOUS DA FROM THE RAT NUCLEUS ACCUMBENS IN VITRO. M.M. Voigt, R.Y. Wang and T.C. Westfall. Dept. of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

We have previously demonstrated that sulfated CCK-8 (CCK-8S) can alter the release of DA from the nucleus accumbens (NAc) in vivo. The purpose of the present study was to examine the effect of CCK-8 on DA release in vitro in an attempt to further explore the interaction between CCK and DA release.

Male Sprague-Dawley rats (270-320 g) were decapitated and the brain quickly removed and placed into an aluminum brain mold on ice. The NAc was dissected out in two consecutive 1 mm slices which were kept separated and designated the anterior (ANT) and posterior (POST) portions, respectively. The NAc was dissected from the frontal sections using the landmarks of Horn et al (1974). 300 μm slices were prepared and incubated in a Krebs-Ringer bicarbonate buffer (KRB). Using a previously published basket method, release of endogenous DA from slices was quantitated using HPLC coupled with electrochemical detection. Slices were subjected to two 5 min pulses of high-K^+-containing KRB separated by 20 min. The effects of the indicated drugs were tested during the 5 min preceeding the second stimulation period (A2) as well as during the second stimulation period (S2).

CCK-8S was found to alter basal release from the POST section of the NAc only, whereas the unsulfated octapeptide (CCK-8US) had no effect on basal release from either region. Marked differences between the ANT and POST NAc were observed with respect to their responses to CCK-8S section on K^+-evoked DA release. CCK-8S caused a dose-dependent decrease in evoked release from the ANT NAc (1 nM to 1 μM) whereas it attenuated release from the POST NAc at only very low concentrations (0.1 and 1.0 nM). CCK-8US also attenuated release from the ANT NAc at a concentration of 1 nM, whereas in the POST NAc this concentration enhanced release. At 100 nM, this peptide had no effect on release from either region. Additionally, this peptide (at 100 nM) could block the effects of CCK-8S in both regions. Proglumide (PRG) also decreased release by itself in the ANT NAc and could not block the effect of CCK-8S in this region of the NAc. However, PRG had no effect of its own on release from the POST NAc and could block the action of CCK-8S in this region. The DA antagonist sulpiride had no effect on CCK-8S action in either region of the NAc.

These results suggest that there may be two forms of CCK receptors in the NAc that differ with respect to PRG and CCK-8US. In addition, it appears that CCK-8S does not act via the DA autoreceptor. Finally, there also seem to be major differences between ANT and POST NAc in the regulation of DA release.

217.12 *IMMUNOCYTOCHEMICAL VISUALIZATION OF DOPAMINE, NORADRENALINE, ACETYLCHOLINE, SEROTONIN, TRYPTAMINE AND 5-METHOXYTRYPTAMINE IN THE RODENT CENTRAL NERVOUS SYSTEM.* *A. McRae-Degueurce, J. Dulluc* and M. Geffard. IBCN-CNRS, 1 rue Camille Saint-Saëns, 33077 Bordeaux cedex France.*

Antisera were raised against dopamine (DA), noradrenaline (NA), acetylcholine (ACh), serotonin (5-HT), tryptamine (T) and 5-methoxytryptamine (MT) by conjugating each molecule to bovine serum albumin and to human serum albumin via glutaraldehyde. Antibody specificity was tested in vitro with the ELISA method. A perfusion mixture composed of glutaraldehyde, allyl alcohol in a cacodylate buffer at pH 11 allowed immunocytochemical visualization of DA, NA, ACh, 5-HT, T and MT in the same rodent brain. No cross-reactivity was found among the various antisera.

This immunocytochemical approach allowed the visualization of DA cell bodies and ACh fibers in the substantia nigra (SN). ACh cell bodies were found in the striatum, medial septum and the cortex. 5-HT fibers were equally noticed in the SN. NA-containing cell bodies were restricted to the locus coeruleus and other noradrenergic cell body regions (A1, A2, A5). Neuronal populations containing HT, T and MT were found in the raphe dorsalis (RD), raphe centralis superior (RCS) and the B9 group. Specific neurotoxins such as 6-hydroxydopamine (6-DHDA) and AF64A were used to further examine the specificity of the antisera. Ten months following a unilateral injection of 6-DHDA in the medial forebrain bundles no immunoreactive DA cells were found in the SN ipsilateral to the injection site. However ACh fibers were still present. One to 3 weeks following a unilateral injection of AF64A in the SN a substantial loss of ACh fibers was noted, but the DA cell bodies were still present.

Visualization of these neurotransmitters is also possible at the ultrastructural level. This immunocytochemical approach should further our knowledge concerning the distribution, localization and synaptic organization of these neurotransmitter systems in the CNS.

217.13 NICOTINIC- AND MUSCARINIC-INDUCED RELEASE OF DOPAMINE IN CAT AND RABBIT CAROTID BODY. B.G. Dinger, L. Almaraz* and S.J. Fidone. Dept. of Physiology, Univ. of Utah School of Medicine, Salt Lake City, UT 84108.

The arterial chemosensory tissue of the carotid body consists of morphologically distinct parenchymal cells in synaptic association with afferent terminals of the carotid sinus nerve (CSN). Type I parenchymal cells contain multiple neuroactive substances, including catecholamines and acetylcholine. Natural stimuli, such as hypoxia, induce a calcium dependent release of dopamine (DA), a major catecholamine of the carotid body. Because type I cells possess cholinergic receptors (which bind ^{3}H-QNB and ^{125}I-α-BGT), and cholinergic agents have a profound effect on CSN discharge, we have investigated the possibility that DA release from the carotid body is modulated by nicotinic and muscarinic agents.

In the present experiments the release of ^{3}H-DA (synthesized from ^{3}H-tyrosine) was monitored in the in vitro cat and rabbit carotid body preparations in response to nicotinic and muscarinic agonists and antagonists. Cat carotid bodies superfused with 100% O_2 equilibrated media responded to 100 μm ACh with a 5 fold increase in ^{3}H-DA release. Atropine (0.5 μM) partially inhibited ACh evoked release, and the addition of 50 μM mecamylamine further reduced release to near basal values. Conversely, release was elevated by both nicotinic and muscarinic agonists.

In the rabbit carotid body, on the other hand, nicotinic and muscarinic receptors appear to have divergent effects on ^{3}H-DA release. In 100% O_2-equilibrated superfusion media, basal release was unaffected by bethanechol (100 μM), and ACh stimulated release only in the presence of atropine (0.5 μM). Under hypoxic conditions, however, bethanechol resulted in a 30% decrease in evoked release, suggesting that muscarinic receptors are primarily inhibitory to DA release. In contrast, nicotine produced a 50% increase in release, and preliminary data suggest that this nicotinic component can be abolished by ACh (100 μM) or bethanechol (100 μM).

Our data imply fundamentally different actions for muscarinic receptors in cat vs. rabbit carotid bodies. Interestingly, the increase in ^{3}H-DA release produced by both nicotinic and muscarinic receptors in the cat, and their mutually antagonistic effects in the rabbit carotid body, correspond precisely to the actions of nicotinic and muscarinic agents on CSN impulse activity in these two species. We are currently studying the possibility that endogenous ACh may influence DA release evoked by natural stimuli.

217.14 THE EFFECTS OF ALPHA-ADRENERGIC AGENTS ON CALCIUM ANTAGONIST BINDING SITES. H.Matsubayashi*, S.Kito, S.Katayama, and R.Miyoshi (SPON:M.Shimoyama). Third Dept. of Int. Med., Hiroshima Univ. School of Med., 1-2-3 Kasumi Minami-ku, Hiroshima, 734, Japan.

Ehlert and Itoga described the specific ^{3}H-nitrendipine(^{3}H-NTD) binding to neurons themselves. At the last meeting of Society for Neuroscience, the authors showed that there was an interaction between the alpha-adrenoceptor and Ca antagonist binding sites. In Ca antagonist binding experiments, ^{3}H-nitrendipine has been exclusively used as radioactive ligand. In this study, ^{3}H-verapamil (^{3}H-VER) and ^{3}H-diltiazem (^{3}H-DIL), which were structually different from nitrendipine, were used to characterize binding sites of these drugs in the brain. In addition, the authors tried to study how alpha-adrenergic agents modulated Ca antagonist binding. The effects of Ca antagonists on brain adenylate cyclase activity was also studied. The 10% synaptosomal fraction of the rat cerebral cortex was prepared. In the ^{3}H-VER and ^{3}H-DIL binding experiments, the buffer was 50mM Tris/HCl, pH 7.4 (0.1% bovine serum albumin) and the incubation condition was 60min at 25°C. Adenylate cyclase activity was measured following the method of Salomon et al. The standard assay mixture consisted of 50mM Tris/HCl, 11mM creatin-phosphate, 10mM $MgCl_2$, 8mM theophylline, 0.035units/ul creatin-phosphokinase, 0.1mM ATP, 0.19uM ^{3}H-ATP and synaptosomal membrane pretreated with 100uM Gpp(NH)p for 30min at 30°C. The incubation was performed at 30° C for 10min. Through these experiments, the following results were obtained. 1) Saturation analysis of ^{3}H-VER binding in the rat cerebral cortex revealed a single binding site whose Kd value was 1.26nM and Bmax 19.4fmol/mg protein. As for ^{3}H-DIL binding sites they were not detected in our experimental conditions. 2) The inhibition experiments of ^{3}H-VER by various Ca antagonists revealed inhibitory potency of the drugs in order of diltiazem, nicardipine and nifedipine with IC_{50} values $3.5X10^{-7}$, $1.9X10^{-6}$ and $2.6X10^{-4}$ (M) respectively. 3) Yohimbine and prazosin inhibited ^{3}H-VER binding with IC_{50} values $3.5X10^{-5}$ and $3.3X10^{-5}$ (M) while they did ^{3}H-NTD binding with IC_{50} values $2.0X10^{-5}$ and $7.9X10^{-4}$ (M). Clonidine was much less potent to inhibit ^{3}H-VER binding with 30% inhibition at 10^{-4}M and it had no effect on ^{3}H-NTD binding. 4) Gpp(NH)p had no effect on ^{3}H-VER binding whereas ^{3}H-NTD was considerably inhibited. 5) Of these four kind of Ca antagonists, nifedipine was only drug to inhibit adenylate cyclase activity. The inhibition rate was 20% at the concentration of 10^{-3}M. All these results showed that there was heterogenecity of Ca antagonist binding sites in the brain and these heterogenious characters were interacted each other. Futhermore, these binding sites are deeply associated with alpha-adrenoceptor. It was also assumed that nifedipine and nitrendipine binding sites were coupling with Gi protein.

217.15 CHANGES IN BETA-ADRENERGIC RECEPTOR NUMBER AND FUNCTION FOLLOWING SELECTIVE LESIONS OF SEROTONIN AXONS. C.A. Stockmeier, A.M. Martino* and K.J. Kellar, Department of Pharmacology, Georgetown University, Washington, DC 20007.

Functional relationships between central serotonin (5-HT) and norepinephrine (NE) systems have been proposed based on anatomical, electrophysiological and biochemical evidence. We have measured the effects of selective lesions of 5-HT axons with p-chloramphetamine (PCA) or 5,7-dihydroxytryptamine (5,7-DHT) on adrenergic receptor binding and function in several areas of rat forebrain.

Rats received PCA (5 mg/kg, i.p.) on days one and three, or 5,7-DHT (7 ug free base) was injected into both the dorsal and median raphe nuclei of anesthetized rats that had been pretreated with desipramine. Five to seven weeks later the extent and specificity of the lesions were determined by measuring the uptake of [^{3}H]5-HT and [^{3}H]NE into fresh homogenates from various forebrain areas. The uptake of [^{3}H]5-HT was reduced by PCA (60-70%) and by 5,7-DHT (> 90%) in both frontal cortex and hippocampus. In contrast, neither the uptake of [^{3}H]NE nor the NE content in either area was significantly reduced by the lesions.

Lesions with PCA resulted in a 33% increase in the binding of [^{3}H]dihydroalprenolol ([^{3}H]DHA) to beta-adrenergic receptors in the hippocampus and an equivalent increase in isoproterenol-stimulated production of cyclic AMP. The binding of [^{3}H]DHA was also increased in the frontal cortex (26%). In a similar manner, lesions with 5,7-DHT increased [^{3}H]DHA binding to beta-adrenergic receptors in the frontal cortex (40%), hippocampus (46%) and hypothalamus (21%). Scatchard analyses indicated that the number of beta-adrenergic receptors was increased by 30% and 80% in the frontal cortex and hippocampus, respectively, following the lesions of 5-HT axons with 5,7-DHT. There was no change in the affinity of [^{3}H]DHA for the receptors, nor was the Hill coefficient of binding altered by the lesion. Competition studies indicated that L-isoproterenol was 2 to 3 times less potent in competing for [^{3}H]DHA binding sites in cortex from rats lesioned with either PCA or 5,7-DHT than in cortex from control rats. A similar shift in affinity of isoproterenol for beta receptors following lesions of 5-HT axons has been reported previously by Manier et al., 1983. In contrast to the increase in beta-adrenergic receptors, neither the binding of [^{3}H]prazosin to $alpha_1$-adrenergic receptors nor [^{3}H]p-aminoclonidine to $alpha_2$-adrenergic receptors was altered by either type of 5-HT lesion. These results indicate that 5-HT neurons may regulate beta-adrenergic receptor number and function in brain. This regulation offers a possibly critical link between these two neurotransmission systems, both of which have been implicated in depression and other CNS disorders.

218.1 AUTORADIOGRAPHIC MAPPING OF PROTEIN KINASE C IN RAT BRAIN WITH A PHORBOL ESTER, ^{3}H-PDBU: EFFECTS OF NEUROTOXIN LESIONS. P.F. Worley*, J.M. Baraban and S.H. Snyder. (SPON: R. Schnaar). Johns Hopkins Univ., Dept. of Neuroscience, Baltimore, MD 21205.

Protein kinase C is a calcium and phospholipid stimulated, phosphorylating enzyme present in high concentrations in the brain. Its activity appears to be linked closely to the phosphoinositide (PI) cycle, since diacylglycerol which is generated by the PI cycle may be an endogenous activator of protein kinase C. Phorbol esters are potent tumor promoters which bind to specific receptor sites with high affinity. Several lines of evidence indicate that the phorbol ester receptor is identical to protein kinase C (Niedel et al., Proc. Natl. Acad. Sci. USA 80:36-40, 1983). Accordingly, one can assess the distribtuion of protein kinase C by monitoring the binding of the potent phorbol ester ligand [^{3}H]phorbol 12,13-dibutyrate [^{3}H]PDBU). Quantitative autoradiography of rat brain sections demonstrates marked heterogeneity with dense binding in the cortex, hippocampus, striatum, cerebellum and substantia gelatinosa. To ascertain the cellular localization of receptor binding sites, we examined the effects of neurotoxin lesions upon grain densities in various areas of the brain. Administration of ibotenic acid unilaterally near the substantia nigra produces no loss of [^{3}H]PDBu binding in either the nigra or the caudate despite extensive destruction of nigral neurons. However, unilateral injections of quinolinic acid into the caudate deplete binding of [^{3}H]PDBu markedly in the ipsilateral substantia nigra as well as in the caudate itself. Accordingly, most phorbol ester receptor binding in the substantia nigra appears to be associated with terminals of the descending striatonigral fibers rather than intrinsic nigral neurons. Unilateral injections of quinolinic acid into the hippocampus produce a marked loss of grains in both the stratum oriens and stratum radiatum ipsilateral to the injection. By contrast, receptors are unchanged in the ipsilateral molecular layer of the dentate gyrus following the lesion. Thus, the loss of [^{3}H]PDBu binding in the stratum oriens and stratum radiatum reflects phorbol ester receptors associated with intrinsic neurons while the preserved binding in the molecular layer may be associated with afferent terminals. Localized injections of kainic acid into the cerebellum produce regions where Purkinje cells are destroyed with no apparent loss of granule cells. In regions of Purkinje cell loss, lower grain density in the molecular layer coincides with Purkinje cell degeneration. Accordingly, a large portion of phorbol ester binding sites in the molecular layer of the cerebellum appear to be associated with dendrites of Purkinje cells. These experiments indicate that protein kinase C is largely associated with neurons and is concentrated in both pre- and post-synaptic elements.

218.2 Ca^{2+}-ACTIVATED, PHOSPHOLIPID-DEPENDENT PROTEIN KINASE (C-KINASE) ACTIVITY IN THE HERMISSENDA NERVOUS SYSTEM. J.T.Neary, S.Naito*, and D.L.Alkon. Lab. Biophys.,NINCDS-NIH,MBL, Woods Hole, MA 02543.

Long-lasting reductions in early and late K+ currents are correlated with associative learning in Hermissenda (Alkon, Science 226, 1037, 1984). These currents can be reduced by increasing the cytosolic Ca^{2+} concentration, $[Ca^{2+}]c$, and a series of experiments suggest that an increase in $[Ca^{2+}]c$ is an early event in conditioning. However, the rise in $[Ca^{2+}]c$ is likely to be brief, whereas the physiological response is sustained. We are interested in biochemical mechanisms that underlie the sustained response to the Ca^{2+} transient, and one possible mechanism involves the activation of C-kinase by Ca^{2+} and diacylglycerol (DG), a product of phosphoinositide metabolism. In mammalian systems, DG increases the sensitivity of C-kinase for Ca^{2+} and phospholipid, thus converting it to a form which is active at low $[Ca^{2+}]c$ in a membrane environment (Nishizuka, Science 225, 1365, 1984). Here we report on C-kinase activity in the Hermissenda nervous system.

Enzyme activity is measured by the phosphorylation of endogenous substrates (Mr=20K, 28K, 54K, 56K, 71K, 82K, 87K, and >200K) and lysine-rich histone, a substrate for mammalian C-kinase. After homogenization in Tris, pH 7.0, EGTA, DTT, and centrifugation at 23,000xg for 30 min, 80-85% of the C-kinase activity is in the supernatant and 15-20% in the particulate fraction. This centrifugation step isolates cytosolic C-kinase from calmodulin kinase because the latter is present almost entirely in the membrane fraction. Cytosolic C-kinase activity is dependent on phosphatidylserine (PS) and is increased by Ca^{2+} and DG; without PS neither Ca^{2+} nor DG is effective. PS + 5-20 μM Ca^{2+} and PS + <0.5 μM Ca^{2+} stimulate ^{32}P incorporation in lysine-rich histone 10- and 3-fold, respectively, over basal control (EGTA) or Ca^{2+}. Most endogenous substrates are phosphorylated by PS + <0.5 μM Ca^{2+}, but 56K and 71K require higher Ca^{2+}. As with the mammalian enzyme, addition of DG, in the presence of PS, increases C-kinase activity, particularly at free Ca^{2+} levels of 0.5-5.0 μM. DG or 1-oleoly-2-acetylglycerol (OAG) is more effective than triacylglycerol. The major endogenous substrate for cytosolic C-kinase is Mr 56K; a protein with a similar Mr is a major substrate of endogenous cAMP-dependent protein kinase, and in intact ganglia depolarization with high external K+ increases phosphorylation in this band (S. Naito et al., this volume).

Recently it has been shown that treatment of Hermissenda photoreceptors with both a C-kinase activator (OAG) and a Ca^{2+} load produces reductions in K+ currents which last longer than those obtained with either treatment alone. This effect, which is likely to be mediated by C-kinase and calmodulin kinase, may be important for long-term storage of associative memory. (We thank L. Kaczmarek and S. DeRiemer for their C-kinase assay method.)

218.PO ELEVATED EXTERNAL POTASSIUM CAUSES PERSISTENT CHANGE OF SPECIFIC PROTEIN PHOSPHORYLATION IN HERMISSENDA NERVOUS SYSTEM. S.Naito*, J.T.Neary, M.Sakakibara*, and D.L.Alkon. Lab. of Biophysics, NINCDS-NIH, MBL, Woods Hole, MA 02543.

Electrophysiological studies have indicated that protein phosphorylation plays a crucial role in reducing two potassium currents (I_A and $I_{Ca^{2+}\text{-}K^+}$) in type B photoreceptors; this reduction is similar to that observed following associative learning in Hermissenda. Recent evidence (Acosta-Urquidi et al., Science 224:1254, 1984; Alkon et al., in press; Sakakibara et al., in press) suggested that Ca^{2+}/calmodulin-dependent protein kinases and C-kinase are involved in the regulation of these potassium channels. Since it was demonstrated that membrane depolarization in the type B cell accumulated during acquisition of associative learning and that depolarization alone in type B cell induced behavioral modification in animals (Alkon, Science 210:1375, 1980; Farley et al., Science 221:1201, 1983), the effect of high external K+ induced depolarization on protein phosphorylation was examined in this study. Protein phosphorylation in Hermissenda nervous system (NS) was studied by incubating NS in artificial sea water (ASW) containing ^{32}P for 3 hr and treating it under test conditions for appropriate duration, then phosphoproteins in NS were analyzed by SDS-PAGE and autoradiography (Neary et al., Nature 293:658, 1981). High K+ (100 or 300 mM) was found to increase the state of phosphorylation of Mr 56K protein and decrease that of 25K; the latter had previously been described to be affected by 4-aminopyridine or high K+ (Neary and Alkon, J.B.C. 258:8979, 1983). High K+ also increased to a lesser degree the state of phosphorylation of 24.5K and decreased that of 20K protein. Experiments using a broken cell preparation suggested that among these proteins the 56K was phosphorylated by endogenous cAMP-dependent protein kinase and C-kinase (Neary et al., Soc. Neurosci. Abstr. 10:805, 1984; ibid., 11: in press). The reversibility of high K+ effect on protein phosphorylation was studied by transferring NS to a normal ^{32}P-containing ASW after high K+ treatment. Interestingly, the state of phosphorylation of 25K did not increase to a control level (15 out of 19 cases) for up to 30 min after removal of high K+. In contrast to the effect on 25K, the high K+-induced changes in state of phosphorylation of 56K, 24.5K and 20K did not persist after removal of high K+. Thus it is plausible that depolarization of NS causes lasting change(s) in protein kinase and/or protein phosphatase activity which specifically affect 25K phosphorylation. The role of Ca^{2+} on the depolarization-induced reduction of 25K phosphorylation is now being investigated. The present findings may provide a useful model for examining biochemical learning mechanisms in the medial type B cell previously shown to be a primary locus for long-lasting storage of associative memory (Alkon, Science 226: 1037, 1984).

218.4 PERFORMANCE CHARACTERISTICS OF THE DFPase/F^- (ENZYME) ELECTRODE IN ACETYLCHOLINESTERASE INHIBITORS OF THE ORGANOPHOSPHATE TYPE. K. S. Rajan and S. Mainer*, IIT Research Institute, Chicago, IL 60616, F. C. G. Hoskin, Illinois Institute of Technology, Chicago, IL 60616, and L. Luskus, Brooks AFB, TX

The enzyme electrode composed of DFPase attached to a fluoride ion specific electrode reported earlier (Rajan, K. S., Mainer, S., Hoskin, F. C. G. and Luskus, L., Biophys. Jl. 47, 9a, M.AM.B12, 1985) has been investigated with regard to its response characteristics in aqueous solutions of organophosphonates in the presence of cations such as Ca^{2+} and Mg^{2+} and anions such as diisopropylphosphate, NO_3^-, SO_4^{2-}, F^- and metal chelating agents. In the presence of 10^{-4}M to 10^{-2}M concentrations of the divalent ions, the electrode responds linearly to solutions of diisopropylphosphorofluoridate (DFP) in the concentration range 10^{-6} to 10^{-2}M with an efficiency of 95-98%. In the presence of 10^{-3}M NO_3^- and SO_4^{2-}, the electrode responses to DFP solutions (10^{-5}M - 10^{-2}M) are linear with an efficiency of 91%. Diisopropylphosphate and F^- ions (10^{-5} - 10^{-4}M) do not interfere with the efficiency and linear response of the electrode in DFP solutions. The effect of metal chelating agents such as EDTA, DTPA and citric acid on the performance of the electrode are being investigated in connection with their use as masking agents for trivalent cations such as Al^{3+} and Fe^{3+}. The results are considered from the point of view of the effects of the different cations and anions studied on the activity of the electrode-bound enzyme, DFPase.

218.5 ANALYSIS OF THE β SUBUNIT OF TRANSDUCIN (TD) AND IDENTIFICATION OF THE β SUBUNIT OF GUANINE NUCLEOTIDE REGULATORY PROTEINS (GNRPs) FROM RAT, HUMAN AND BOVINE BRAIN ON TWO-DIMENSION POLYACRYLAMIDE GELS. Heydorn, W.E. , Creed, G.J.*, Gierschik, P.*, Spiegel, A.M.*, Milligan, G.* and Jacobowitz, D.M. Lab. Clinical Science, NIMH, Bethesda, MD 20205

GNRPs are a family of proteins involved in signal transduction across cell membranes. All four GNRPs identified to date (TD, G_s, G_i and G_o) are heterotrimers with α, β and γ subunits. Previous studies have shown peptide map identity and immunochemical crossreactivity between the β subunit of TD and the other GNRPs. We have studied the mobility of the β subunit of purified TD using two-dimensional gel electrophoresis (2DE). In addition, we have identified the location, MW and pI of the β subunit of the GNRPs in rat, human and bovine brain on 2D gels.

In the initial experiment, 1 µg of purified TD β/γ isolated from bovine rod outer segment membranes was subjected to 2DE, then stained with silver. The majority of the protein migrated as a doublet (in the MW dimension) with approximate MWs of 36kDa and 34kDa (values similar to those determined previously for the β subunit of the GNRPs), and a pI about 5.8. In addition, small amounts of slightly more acidic forms of the β subunit could also be detected. The major 36kDa and 34kDa protein of TD β/γ separated by 2DE reacted on immunoblots with antiserum raised against both TD β/γ and the β subunit of bovine brain GNRPs, demonstrating that the β subunit of TD consists of two major polypeptides of MW 36kDa and 34kDa, and pI of 5.8. Subsequently, proteins contained within rat hippocampus, freshly dissected (during surgery) human cortex and bovine cerebral cortical membranes were studied by 2DE and immunoblotting using antisera raised against both TD β/γ and the β subunit of bovine brain GNRPs. In all three cases, the primary proteins visualized were a doublet of MW 36kDa and 34kDa and pI 5.7-5.8. Comparision of these results with those obtained using TD β/γ revealed that this doublet co-migrates with the β subunit of TD. Restaining the brain blots to identify orientation markers (e.g., actin), showed that in the rat the β subunit of the GNRPs corresponds to protein #43 of the rat brain atlas of Heydorn et al (J. Neurosci. 3:2597, 1983). In human, this protein is #M85 according to the system of Narayan et al (Clin. Chem. 30: 1989, 1984).

In summary, these results demonstrate: 1) The β subunit of TD migrates on a 2D gel as 2 polypeptides of MW 36kDa and 34kDa, and pI 5.8. 2) Rat, human and bovine brain all contain 2 polypeptides that co-migrate with the β subunit of TD and cross-react with antiserum raised against both TD β/γ and the β subunit of bovine brain GNRPs. This suggests that these are the β subunits of the GNRPs in brain. 3) The β subunit of the GNRPs is one of the major proteins present in brain.

218.6 POTENTIATING EFFECT OF PHORBOL ESTERS ON CYCLIC AMP ACCUMULATION IN RAT BRAIN CORTICAL SLICES. E.W. Karbon*, R.S. Duman* and S.J.Enna. (SPON: G.A. Robison). Depts. Pharmacol. and of Neurobiol. and Anat. Univ. Texas Med. School, Houston, Texas 77025.

Experiments were undertaken to examine the ability of phorbol esters, compounds known to stimulate protein kinase C, to influence neurotransmitter- and forskolin-stimulated cAMP accumulation in rat brain. cAMP production was studied in slices of rat brain cerebral cortex using a prelabeling technique. 12-O-Tetradecanoyl phorbol--13-acetate (TPA) markedly potentiated cAMP production induced by isoproterenol (ISO) or 2-chloroadenosine, while having little effect on cyclic nucleotide formation alone. The EC_{50} for TPA was approximately 1 µM. TPA also potentiated the cAMP response to VIP, PGE_2, and forskolin, suggesting that it influences the adenylate cyclase system at some point beyond the neurotransmitter receptor recognition site. The potentiating effect of TPA on ISO was additive with other agents known to facilitate cAMP responses such as α-adrenergic and $GABA_B$ receptor agonists. Also, these latter substances had no effect on the potency of TPA to facilitate ISO-stimulated cAMP production. The potentiating effect of TPA was not influenced by EGTA or quinacrine, which have been shown to diminish the interaction between ISO and α-adrenergic/$GABA_B$ receptor agonists. It was found that a preincubation period with TPA was necessary to observe a maximal response to this agent, a finding that is consistent with the notion that TPA is not directly modifying the receptor system. Moreover, RO 20-1724, a phosphodiesterase (PDE) inhibitor, did not alter the potentiating response to TPA with regard to ISO-stimulated cAMP production, indicating that the phorbol ester is not inhibiting PDE. Other tumor promoting phorbols such as 4 β-phorbol 12, 13-dibutyrate were also found to possess potentiating properties, whereas phorbols known not to stimulate protein kinase C such as 4 α-phorbol and 4 α-phorbol 12, 13-didecanoate did not. The results suggest that activation of protein kinase C modifies some component of the brain receptor-coupled adenylate cyclase system, resulting in an increased production of cAMP in response to neurotransmitter stimulation. It is possible that activation of this enzyme enhances the coupling between proteins involved in cAMP production or modifes adenylate cyclase to prolong its catalytic action. (Supported in part by grants from the National Science Foundation, the National Institute of Mental Health and Bristol-Myers, Inc.).

218.7 PHORBOL ESTERS: OPPOSING EFFECTS ON CALCIUM-DEPENDENT ACTION POTENTIALS OF DORSAL ROOT GANGLION NEURONS. M. A. Werz and R. L. Macdonald, Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104.

Stimulation of membrane inositol phospholipids has been suggested as a mechanism by which neurotransmitters mediate cellular actions. One of the products of membrane phospholipid turnover is diacylglycerol, which stimulates protein kinase C. Protein kinase C has been implicated in receptor transducing mechanisms in multiple systems. We have investigated the effects of phorbol esters, compounds that can stimulate protein kinase C at the same site as diacylglycerol, on action potentials of dorsal root ganglion (DRG) neurons grown in primary dissociated cell culture using intracellular recording techniques. Action potentials evoked from DRG neurons bathed in a tris buffered solution and impaled with microelectrodes filled with 4 M KAc have a duration of about 2 msec and have a convex inflection on the repolarizing limb. The initial component of action potentials is sodium-dependent with the convex inflection calcium-dependent. The phorbol esters, TPA (12-O-tetradecanoylphorbol-13-acetate) and PDBu (phorbol 12,13-dibutyrate), did not have visible effects on the configuration of these brief action potentials. However, when the calcium-dependent component of action potentials was augmented to durations of 20-80 msec by reduction of repolarizing potassium conductances, by either intracellular injection of the potassium channel blocker cesium or by addition of 5 mM tetraethylammonium to the recording medium, phorbol-mediated effects were observed. At membrane potentials larger than -50mV, PDBu (10 nM - 1 µM) and TPA (1 nM - 100 nM) augmented calcium-dependent action potential duration dose-dependently. The increased action potential duration produced by phorbol esters was associated with a decrease of after hyperpolarization and was blocked when intracellular cesium injection produced action potentials with durations greater than 400 msec and without after hyperpolarizations, consistent with substantial blockade of potassium conductance. With either membrane depolarization to about -35 mV or substantial blockade of potassium conductance, PDBu and TPA decreased calcium-dependent action potential duration dosedependently. The ester 4 α-phorbol was inactive at all concentrations tested (up to 50 µM). We suggest that the phorbol esters affect calcium-dependent action potential duration in two ways: by decreasing a calcium conductance and by decreasing a potassium conductance. These effects of the phorbol esters on calcium influx may have relevance for the intracellular events occurring at presynaptic terminals following neurotransmitter binding to surface receptors.

218.8 CALCIUM, cAMP, AND pH DEPENDENT PHOSPHORYLATION OF PLEUROBRANCHAEA NEURAL PROTEINS. J.M.Connor*, R.Gillette, and M.U.Gillette. (SPON: A.E.Applebaum). Dept. of Physiology and Biophysics, University of Illinois, Urbana, IL 61801

Endogenous calcium and cAMP dependent protein phosphorylation of neural tissue affects several specific ion conductances in molluscan neurons, thereby changing their excitability. Recently small changes in intracellular pH (0.05-0.2 units) have also been shown to have profound effects on ion conductances and cAMP metabolism of the opisthobranch Pleurobranchaea (Calhoon, R. D. and R. Gillette Brain Research 271:371 1983; see Green and Gillette, this volume). In order to characterize the phosphoproteins of the nervous system we studied endogenous phosphorylation in calcium, cAMP, and pH stimulated homogenates of CNS. Phosphoproteins were identified by separation on one-dimensional polyacrylamide gel electrophoresis after $^{32}PO_4$ labeling of proteins. Calcium and cAMP stimulated phosphorylation was notable in 45 and 30 kilodalton proteins respectively. An 80 kilodalton protein was phosphorylated in the presence of either cAMP or calcium but only at pH 7.0 and not at pH 7.5 or 8.0. Phosphorylation of the 45 and 30 kilodalton proteins was not markedly sensitive to pH. The unique substrate specific pH sensitivity of the phosphorylation of the 80 kilodalton protein may relate causally to to the pH sensitivity of the excitability of many neurons. These studies provide the basis for future attempts to link changes in the excitability of Pleurobranchaea neurons to intracellular protein modification. This work was supported by NSF BNS 8308551 to R. G.

218.9 **THE KINASE C ACTIVATOR 1,2-OLEOYL ACETYL GLYCEROL MIMICKS NOREPINEPHRINE'S EFFECT ON THE VOLTAGE DEPENDENT CALCIUM CURRENT OF EMBRYONIC CHICK DORSAL ROOT GANGLION NEURONS.**
S.G. Rane and K. Dunlap. Physiology Dept., Tufts Med. Sch., Boston, MA 02111.

Diacylglycerol (DAG), a product of hormone-induced polyphosphoinositide turnover, is a second messenger which initiates protein kinase C-dependent phosphorylation. The membrane-permeable analogue of DAG, 1,2-oleoyl acetyl glycerol (OAG), has been shown to induce kinase C activity in whole cells when applied extracellularly. We have tested the effects of OAG on voltage-dependent macroscopic currents recorded from embryonic chick dorsal root ganglion (DRG) neurons grown in tissue culture.

Ca currents were recorded with the whole-cell variation of the patch clamp technique. The patch pipette solution contained (in mM): 150 CsCl, 10 HEPES, 5 MgATP, 5 BAPTA and the external solution contained (in mM): 133 NaCl, 1 $CaCl_2$, 10 TEA, 25 HEPES, 0.3 uM TTX.

OAG (25 ug/ml) reduced Ca current in all cells tested (mean decrease 49.8 + 4.5%, 22 cells), an effect similar, if not identical, to that produced by 10 uM NE which reduced Ca current by an average 41.9 + 6.7%, 14 cells. I-V plots showed that NE and OAG affected only the amplitude of the peak Ca current. Neither compound changed the voltage threshold for current activation, the potential at which current was maximal, or the null potential for the current.

To determine whether NE and OAG-induced decreases in Ca current share a common pathway, the additive effects of the two drugs applied together were tested. One drug was first applied to give a maximal decrease in Ca current, after which the second drug was instantaneously applied in the continued presence of the first drug. Application of the second drug caused no further decrease in Ca current, regardless of the order in which NE and OAG were applied. This result is consistent with the idea that both NE and OAG act through a common, saturable pathway.

It appears unlikely that the NE- and OAG-induced decreases in net inward current result from an increase in an outward current. When Ca was replaced with Ba in the external solution (thereby further decreasing the likelihood of activating Ca-dependent outward current), NE- and OAG- induced decreases in inward current were even greater (OAG mean 87.9 + 4.2%, NE mean 75.9 + 7.2%, 4 cells each). Furthermore, in an external solution containing 10 mM Co and TTX (to block all inward current), OAG did not affect the voltage-dependent outward current recorded with 150 mM KCl in the patch pipette (5 cells). Similar results have been previously described for NE (Dunlap and Fischbach, J.Physiol. 317, 519-535, 1981).

In some non-neuronal cells OAG has a secondary effect (besides kinase C activation) of raising intracellular Ca concentration. The minimal concentration of OAG required to elicit this effect (50 ug/ml) is double the concentration used for this study. Furthermore, for DRG neurons the actions of OAG and NE were unaffected when intracellular Ca was buffered to either very low (less than 10^{-8} M) or very high (greater than 10^{-6} M) levels with either BAPTA or EGTA in the patch pipette solution. It is doubtful that the decreaes in Ca current due to either OAG or NE can be attributed to an elevation of intracellular Ca.

The experiments described for this study provide evidence that the diacylglycerol/protein kinase C system may mediate the NE-induced decrease in voltage-dependent Ca current of embryonic chick DRG neurons. This second messenger/kinase system could have general applicability in the study of how neurotransmitters modulate voltage-dependent ion channels.

218.10 INCREASED PLASMA CALMODULIN LEVELS FOLLOWING STRESS. K. Fliegner*, C.C. Loullis, D.D. Davis*, S.R. Dunlop*, P.A. Shea, H.C. Hendrie* and B. Beer. (SPON: S.K. Fisher). Dept. of CNS Research, Medical Research Div. of American Cyanamid, Lederle Labs, Pearl River, NY 10965 and Dept. of Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN 46222.

The prevalence and importance of calcium as a regulator of biochemical activity is by now well established. Little, however, is known about the presumed role played by this ion in mediating the body's mobilization of resources in response to stress. Preliminary data from our laboratory indicated that calmodulin (CaM), an ubiquitous calcium-binding protein, could be measured in human plasma using a radioimmunoassay procedure. Hypothesizing that any special stress-related function of calcium may be reflected by changes in CaM levels, we have measured plasma CaM levels in high and low trait anxious subjects under baseline and stressful conditions.

Blood samples were drawn from 18 low anxious and 19 high anxious students three days prior to and then just before a mid-term examination in their undergraduate psychology course. Subjects were assigned to low and high anxiety groups on the basis of their scores on the Trait Anxiety Inventory (Spielberger et al., 1970). Both baseline (three days pre-exam) and stress (morning of exam) plasma CaM levels were then determined for both groups by radioimmunoassay.

A 2 x 2, two-way (Anxiety x Stress) analysis of variance with repeated measures on stress revealed that plasma CaM levels increased with stress ($p < 0.05$) irrespective of anxiety group. Mean $\pm$ S.E.M. values for baseline and stress levels were 334 $\pm$ 45 and 498 $\pm$ 72 ng/mL, respectively.

These preliminary results indicate that appreciable circulating levels of CaM are present in the periphery and that plasma CaM levels are modulated by stress. Interestingly, these same subjects exhibited a similar pattern of change in whole blood serotonin (5-HT) levels (Davis et al., in press). In light of these findings and the known involvement of CaM in central neurotransmission, further examinations of these stress-related changes would be important. Such investigations might reveal that peripherally circulating CaM levels can serve as a marker for central neurochemical changes that occur in psychiatric disorders and following behavioral and/or pharmacological manipulations.

218.11 INCORPORATION OF CALMODULIN INTO CENTRAL NEURONS: IMPLICATIONS FOR NEUROTRANSMISSION. C.C. Loullis, K.H. Fliegner*, J.A. Joseph, C. Sus-Binderwald* and D.H. Hellhammer. Dept. of CNS Research, Medical Research Div. of American Cyanamid, Lederle Labs, Pearl River, NY 10965 and Psychology Inst., Munster Univ., 4400 Munster, Fed. Republic of Germany.

Calmodulin (CaM), a small, ubiquitous, acidic, thermostable calcium-binding protein, plays a crucial role in cell function by virtue of its calcium-dependent ability to regulate a wide variety of enzyme systems. In brain, CaM has been shown to be involved in neurotransmission and receptor responsiveness. The role of CaM in neuronal function has been presumed, thus far, to be mediated only through its intracellular actions.

However, initial observations from in vivo push-pull experiments in our laboratories indicated the presence of CaM in brain extracellular fluid and its modulation by peripheral administration of testosterone. Data from both push-pull and slice experiments revealed that perfusion of CaM into the extracellular fluid could modulate the release and metabolism of neurotransmitters. Moreover, the amount of continuously perfused CaM recovered through the cannula was considerably less than expected, suggesting that extracellular CaM may be incorporated into neurons. To investigate this possibility, we incubated whole brain crude synaptosomes with ^{125}I-CaM at 0° C and 37° C. Cytosolic and particulate fractions were separated by centrifugation and radioactivity quantified in a γ-counter. Results indicated a temperature- and time-dependent incorporation of CaM. This incorporation was Ca^{2+}-dependent and could be abolished by the addition of excess cold CaM.

These data provide preliminary evidence that CaM exists in extracellular fluid, that its extraneuronal levels can be manipulated pharmacologically, and that CaM can be incorporated into neural cells. This incorporation process may be partially responsible for CaM's ability to modulate neurotransmitter release and metabolism. Although the precise role of extracellular CaM is only beginning to be elucidated, these preliminary data suggest the possibility that this extracellular pool, in addition to intracellular stores of CaM, is important for proper neuronal function.

218.12 INCREASED BRAIN FATTY ACID CYCLOOXYGENASE ACTIVITY IS ASSOCIATED WITH DRUG INDUCED CLONIC CONVULSIONS. T.W. Lysz, M. Centra, and P. Keeting, Depts. of Pharmacology and Biochemistry, UMDNJ-New Jersey Medical School, Newark, N.J. 07103.

We recently reported that drug-induced convulsions produced a marked increase in brain fatty acid cyclooxygenase (CO) activity. (Federation Proceedings 1985, Abs. #6184). The resulting increased activity of the CO may play a role in the enhanced prostaglandin (PG) formation measured at the onset of the first clonic convulsion. This study was undertaken to determine whether the elevated CO activity induced by pentylenetetrazol (PTZ) could be reversed by anticonvulsants.

Adult Swiss Webster mice (25-30 Gm) were injected with either 500 mg/kg ethosuximide (ESM) (ip) or saline, followed 1 hour later with 85 mg/kg PTZ (ip). Two minutes after the onset of clonic convulsions (or 4 minutes following convulsant administration if no convulsions were observed), the mice were decapitated and brain microsomes were prepared as previously described (Lysz and Needleman, J. Neurochem. 38 (1982) 1111-1117). Microsomal CO from PTZ treated mice, determined by RIA after a 5 minute incubation at 37 °C with 17 µM arachidonic acid (AA), 1 mM epinephrine, and 1 mM reduced glutathione, consistantly generated 60 to 90% more PGE_2 then did the microsomes from saline injected controls (56.8 $\pm$ 6.1 pmoles/mg protein for PTZ treated mice ($\bar{x}$ $\pm$ S.E.M., N=4) versus 31 $\pm$ 5.6 pmoles/mg protein in controls ($P < .05$). ESM effectively eliminated the clonic convulsions induced by PTZ and prevented the increase in brain CO activity associated with the PTZ challenge (38 $\pm$ 7.8 pmoles/mg protein). ESM administered ip to control mice did not affect microsomal CO activity nor did addition of the anticonvulsant in vitro. Similar results were obtained for $PGF_{2\alpha}$ production, the other major AA metabolite produced by the brain microsomes.

CO activity was significantly ($P < .05$) elevated 2 minutes after the onset of clonic convulsions. An increased, though not significant, activity of CO was measured 30 seconds after the injection of PTZ but before observable clonic convulsive activity. The CO activity returned to control levels by two hours after the last observed clonic convulsion.

These results, together with our previous findings, suggest that mouse brain fatty acid CO undergoes modification with seizure activity. The enhanced activity of the CO can be effectively reversed by anticonvulsant pretreatment. Supported by NIH grant NS-19478.

218.13 MODULATORY EFFECTS OF ASCORBIC ACID ON NEURONAL ACTIVITY IN THE NEOSTRIATUM DURING IONTOPHORESIS OF DOPAMINE AND GLUTAMIC ACID. T.W. Gardiner* and G.V. Rebec. Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Although little is known about the functions of ascorbic acid (AA) in the brain, recent data suggest that this compound plays an important -- perhaps neuromodulatory -- role in CNS regulation. To assess the potential for AA to influence neuronal activity directly, we have begun to examine the effects of administering AA iontophoretically to neurons in the neostriatum of chloral hydrate anesthetized rats. Iontophoresis was performed using a glass, multibarreled pipette that was glued to the tip of a tungsten recording electrode. Drug solutions (0.5 M) were administered from the outer barrels of the pipette, whereas the center barrel (containing 4M NaCl) was used routinely for current balancing. In more than 30 neostriatal units examined thus far, about one-third responded to AA (15-80 nA) with a marked, dose-dependent excitation of firing rate. Moreover, when AA was administered to neurons during simultaneous activation by glutamic acid (GLU), more than two-thirds showed excitatory responses to AA. Many of these GLU-activated cells did not respond to AA alone. Ejection of AA with higher currents (80-120nA) usually produced an even greater excitation of neuronal activity, although occasionally an inhibition of activity was observed. Ejections of anodal or cathodal current alone did not produce these effects, whereas administration of isomeric AA produced effects that usually were less pronounced than those of AA.

In 10 additional neurons, AA antagonized the inhibitory effects of iontophoretically-applied dopamine (DA) in an additive manner. Although other data suggest that AA may modulate DA-receptor binding, the additivity of these responses suggests that AA and DA exert their effects upon neostriatal unit activity via independent mechanisms. Further work will explore this issue, as well as attempt to characterize the mechanisms underlying AA's neuronal effects in the neostriatum.

218.14 SIGNIFICANT BIOPTERIN CONCENTRATIONS IN NUCLEAR FRACTIONS OF REGIONAL RAT BRAIN PREPARATIONS. S. Knapp and M. Merwin.* Dept. of Psychiatry, UC San Diego Sch. of Med., La Jolla, CA 92093

Tetrahydrobiopterin (BH_4), the required cofactor for tryptophan and tyrosine hydroxylases (TPOH and TOH), regulates the activities of these key enzymes in the biosynthesis of three neurotransmitters serotonin (5-HT), dopamine (DA), and norepinephrine (NE). Its cofactor role of making molecular oxygen available to the mixed-function oxidases has provided BH_4 with a critical functional role in the brain. However, few relevant neurochemical measures have been correlated with changes in regional BH_4 levels, and none have been examined in regional subcellular fractions. We have recently demonstrated (Knapp, S. and Merwin, M., Fourth Winter Workshop on Biochemical and Clinical Aspects of Pteridines, 1985) that the fractional distribution of BH_4 in neurotransmitter-specific regions did not correlate with previously determined TPOH activity distributions (Knapp, S., et al., JPET 189: 676, 1974).

Significant portions of regional brain BH_4 are associated with the nuclear (P_1), synaptosomal (P_2), and cytosolic (S_2) fractions rather than occurring selectively in fractions associated with neurotransmitter systems, the synaptosomal and supernatant fractions. The localization of BH_4 in other than neurotransmitter-specific fractions is consistent with the existence of multiple pools of BH_4 that may be differentially sensitive to pharmacological manipulations.

Of 30 psychoactive drugs examined, only d-amphetamine, and neither cocaine nor methylphenidate, reduced striatal BH_4 levels (Mandell, A., et al., JPET 213: 569, 1980). Amphetamine also reduces protein synthesis in cell-free systems in vitro, probably via decreased tRNA acylation (Nowak, T., and Monroe, H., BBRC 77: 1280, 1977), and disaggregates brain polysomes (Moskowitz, M., et al., PNAS 72: 834, 1974). D-amphetamine disassociates polysomes in rat brain with a time course similar to ones describing loss and recovery of TPOH activity, certain behavioral responses, and striatal BH_4 levels. We now report that most of the BH_4 decrement observed in total striate preparations after treatment with d-amphetamine (1.0 mg/kg) occurs in the S_2 cytosolic fraction. These data are consistent with there being a pool of BH_4 particularly sensitive to amphetamine's interference with tRNA acylation and/or polysomal-dependent protein synthesis.

218.15 ISOLATION OF A PLASMA ACID PROTEIN MODULATOR FOR THE HUMAN PLATELET IMIPRAMINE BINDING SITE. K.I. Abraham*and L.R.Meyerson. CV-CNS Research Section, Medical Research Division of American Cyanamid Co., Lederle Labs, Pearl River, NY 10965. Recently a substantial effort has been implemented in search of mammalian circulating modulators. The serotonin (5HT) system is an excellent target for an endogeneous modulator due to the observed diurnal variations in serum 5HT levels, platelet 5HT uptake velocity and tricyclic binding. Fresh human platelet rich plasma was obtained from normal volunteers and the platelets and plasma separated for binding assays. Platelet free plasma (PFP) when added back to platelet membranes dose responsively inhibited [3H]-imipramine(IMI) binding. In purifying the plasma modulator, PFP was applied to a blue sepharose CL-6B column to remove albumin and other plasma proteins. The unbound effluent from this column contained >75% of original IMI binding inhibitory activity. The blue sepharose CL-6B effluent was then subject to chromatography on a concanavalin A sepharose 4B column in order to remove complex carbohydrates and select glycoproteins. The effluent from this procedure contained >66% of the original IMI binding inhibitory activity and was then subject to ion exchange chromatography on a FPLC Mono Q HR 10/10 column. One peak of IMI binding inhibitory activity was eluted across a linear NaCl gradient with peak inhibitory activity eluting at 0.22 M NaCl. This peak was then chromatographed on tandem gel permeation columns (Zorbax Bio-Series GF-250) using 200 mM sodium phosphate pH 7.4 as the eluant. The apparent molecular weight of the single active fraction was ca. 48 kdal. This peak of inhibitory activity was then applied to a Mono P HR 5/20 chromatofocusing column and found extremely acid in nature (pI<4.0). Purity of the fractions containing inhibitory factor was assessed by SDS-PAGE at each step. The GF-250 fraction was insensitive to heat and acid exposure. The purified GF-250 fraction was immunoreactive with rabbit antiserum to human alpha-1-acid glycoprotein, although this does not necessarily confirm positive identity as such. The relevence of a modulator of this type is noteworthy with respect to control of the 5HT transporter.

218.16 EFFECTS OF INTRACEREBROVENTRICULAR ADMINISTRATION OF FORSKOLIN AND 2'-5'-DIDEOXYADENOSINE ON SLEEP IN RATS. S.R. Glaum, G.M. Yanik, N.M. Porter, E.H. Chen*, and M. Radulovacki. Depts. of Pharmacology and Biometry Program, University of Illinois College of Medicine, Chicago, IL 60612.

Adenosine (Ado) and related compounds are thought to affect sleep through Ado A_1 and A_2 receptors linked to adenylate cyclase (AC). Ado and Ado analogs administered in nanomolar quantities activate A_1 receptors, reduce AC activity and decrease the formation of cAMP. Activation of A_2 receptors requires micromolar quantities of Ado and Ado analogs, which stimulate AC and increase formation of cAMP. Systemic administration of low doses of Ado analogs increases deep slow-wave sleep (S_2) in rats, presumably by acting at A_1 receptors. In contrast, higher doses decrease sleep, possibly through action at A_2 receptors (Radulovacki, M., et al. JPET 228: 268, 1984).

To test the hypothesis that sleep is mediated by changes in the levels of cAMP, forskolin and 2'-5'-dideoxyadenosine (2'-5'-DDA), two compounds that interact directly with the catalytic subunit of AC, were administered to rats. Forskolin is a potent activator of AC and increases cAMP in rat brain membranes (Seamon, K.B. and Daly, J.W., J. Cyc. Nuc. Res. 7(4): 201-204, 1981), whereas 2'-5'-DDA is an antagonist of the AC catalytic subunit and decreases formation of cAMP (Londos, C., Wolff, J., and Cooper, D.M.F., In: Purinergic Receptors p. 289-322, ED. G. Burnstock, Chapman and Hall, London 1981).

Male Sprague-Dawley rats (300 gm) implanted with EEG and EMG electrodes were polygraphically recorded for 6 h following intracerebroventricular administration of 2.4, 24.0, 120.0, 300.0 or 600.0 nmoles of forskolin or .098, 0.98 or 9.8 nmoles of 2'-5'-DDA over 2 minutes. Records were analyzed as waking, light slow-wave sleep, S_2, REM and total sleep (Radulovacki, M., op. cit.).

Forskolin at all doses produced no significant change from control in the amount or quality of sleep. Similar results were obtained with 2'-5'-DDA at all doses. The results indicate that generalized stimulation or inhibition of AC is insufficient to mediate sleep in the manner of specific A_1 and A_2 agonists. We conclude from these results that non-specific modulation of cAMP levels cannot account for the alteration in sleep as seen with administration of Ado analogs. These results suggest the importance of receptor-specific changes in cAMP on the regulation of the sleep-wake cycle. (Supported by ONR Contract N000 14-79-C-0420)

218.17 MODULATION OF ADRENOMEDULLARY SECRETION OF CATECHOLAMINES AND ENKEPHALIN-LIKE PEPTIDES BY OPIATES. T. D. HEXUM AND B. A. BARRON. Dept. of Pharmacol., University of Nebraska Medical Center, Omaha, NE 68105

[Met^5]-enkephalin immunoreactive material (ME-IRM) and catecholamines are co-stored and co-released from the adrenal medulla. Splanchnic nerve stimulation brings about the secretion of these agents by releasing acetylcholine onto chromaffin cell nicotinic receptors. The presence of ME-IRM in splanchnic nerve [Hexum et al, J. Neurochem. 43 1500 (1984)] and opiate receptors on chromaffin cell membranes [Saiani and Guidotti, J. Neurochem. 39 1669 (1982), Castanas et al, Mol. Pharmacol. 25 38 (1984)] suggests that opiates may influence adrenomedullary secretion [Costa et al, Fed. Proc. 40 160 (1981)]. The effect of the opioid agonist, etorphine, and the antagonist, diprenorphine, on the release of catecholamines and [Met^5]-enkephalin-immunoreactive material (ME-IRM) from bovine adrenal glands was investigated using retrograde perfusion. Etorphine (5×10^{-7} M) inhibited the spontaneous outflow of ME-IRM by approximately 10 percent but had no significant effect on spontaneous catecholamine release. Acetylcholine (ACh) and 1,1-dimethyl-4-phenylpiperazinium (DMPP) stimulated catecholamine and ME-IRM release at concentrations ranging from 1 to 100 µM. The acetylcholine (5×10^{-5} M) and DMPP (5×10^{-5} M) stimulated release of ME-IRM and catecholamines was significantly decreased by the addition of etorphine. Diprenorphine (5×10^{-7} M) had no significant effect on the spontaneous outflow of either ME-IRM or catecholamines. However, diprenorphine reversed the inhibition of the DMPP-stimulated release caused by etorphine. After submaximal stimulation of the gland with DMPP (1×10^{-5} M), a further stimulation of release of ME-IRM and catecholamines was observed after the addition of diprenorphine alone, i.e., in the absence of etorphine. These results provide further evidence supporting the contention that opiates modulate the secretion of catecholamines and ME-IRM from the adrenal gland.

SOMATOSENSORY CORTEX

219.1 THE THALAMOCORTICAL AND THE TRANSCALLOSAL BARREL-FIELD SLICE PREPARATIONS: PRESERVING EXTRINSIC CONNECTIONS IN VITRO. A. Agmon*, and B.W. Connors (SPON: M.W. Siegel). Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Layer IV in the rodent primary somatosensory cortex contains discrete clusters of neurons and neuropil (barrels), forming an array that is topologically equivalent to the pattern of sinus hairs in the mystacial pad. Indeed, each barrel receives its main sensory input from the corresponding contralateral vibrissa. This unique structure-function relationship makes the barrel field an attractive region for investigating sensory information processing in the neocortex, and the synaptic circuitry underlying it. We chose to address these questions using the in vitro slice technique. In addition to the well-established technical advantages of the slice preparation (more stable intracellular impalements, direct access to all cortical layers, control over the extracellular environment), we have found it to offer another significant benefit: direct visualization of the barrels in the living, unstained tissue (Agmon and Connors, Soc. Neurosci. Abst. 10:493, 1984). A major drawback of the slice technique has been, so far, loss of connections with extrinsic structures. We report here two new slice preparations that include intact afferent/efferent pathways with their structures of origin: the thalamocortical and the transcallosal barrel-field slice preparations.

Rat barrel-field slices (500 µm thick) were prepared and viewed as described, with the following modifications. To preserve the thalamocortical pathway, the block of tissue to be sectioned included both the parietal cortex and the underlying striatum and thalamus, and was vibratomed in a vertical plane running anterolateral to postero-medial, approximately 45° from the coronal plane. To preserve the callosal pathway, a two-hemisphere block of parietal cortex was sectioned coronally. The afferent/efferent connectivity was assessed by extracellular stimulation and recording. In the thalamocortical preparation, responses in the barrel field were elicited by stimulation of the ventrobasal nucleus of the thalamus (VB), and vice-versa; responses in both VB and the barrel field were elicited by stimulation in the internal capsule. In the transcallosal preparation, responses lateral to the barrel field were elicited by stimulating the corpus callosum in both the ipsi- and the contralateral hemislices.

We believe that the unique opportunity to record from the barrel field in vitro under direct visual control, while stimulating specific input/output pathways, promises to make the barrel-field slice a preparation of choice for probing the synaptic circuitry of the neocortex.

219.2 THE ROLE OF A CORTICAL BARREL IN VIBRISSAL SENSATION. R. B. Masterton and K. A. Hutson*. Department of Psychology, Florida State University, Tallahassee, FL 32306.

Three graded tactile discriminations, each requiring transduction by a single vibrissa, were investigated in rats with or without prior ablation of the vibrissa's cortical barrel. Behaviorally-derived psychophysical functions show that a single vibrissa's cortical barrel makes no measurable contribution to its vibrissa's sensitivity to sinusoidal oscillations, nor to the vibrissa's acuity for detecting changes in the frequency of oscillation. Extending the cortical ablation to include almost the entire barrel-field either contralaterally or bilaterally also has no appreciable effect on these tests of a vibrissa's spatial and temporal acuity.

In contrast, a task requiring vibrissal palpation of an object to detect its presence is completely abolished after ablation of the cortical barrel. In this latter test, the loss of a cortical barrel is indistinguishable from the loss of the vibrissa itself. Therefore, the barrel deficit in rats seems to be more of a vibrissa-specific agnosia than a vibrissa-specific anesthesia.

The similarity of the barrel deficit both to clinical astereognosis and to experimentally-derived deficits in "active" discriminations following somatosensory cortex ablations in rats and other mammals suggests that a cortical barrel's contribution to its vibrissa may not be qualitatively different than the contribution of any other (non-barrel) patch of somatosensory cortex to its (non-vibrissal) receptors.

219.3 CELLULAR PATTERNING OF METABOLIC ACTIVATION IN MOUSE SI VIBRISSAL CORTEX FOLLOWING SINGLE-WHISKER STIMULATION IN BEHAVING ANIMALS. J.S. McCasland and T.A. Woolsey. James L. O'Leary Division of Experimental Neurology and Neurological Surgery and The McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, Saint Louis, MO 63110.

The one-to-one representation of whiskers in functional columns of mouse somatosensory cortex offers an excellent opportunity to analyze the detailed spatial organization of mammalian cerebral cortex. The purpose of these experiments is to map the detailed spatial activity of a single cortical column. An in situ fixation method for cellular resolution of stimulus-dependent 2-deoxyglucose labeling (Durham et al.,1981) has been modified to achieve a ten-fold improvement in label retention. The results are consistent with the notion that the fixed 2DG is in glycogen.

Subjects had all large whiskers clipped except C3, and behaved freely for 45 minutes after 2DG injection. They were then anesthetized with phenobarbitol for 4 to 5 hours, a treatment which results in a doubling of brain glycogen. All perfusion steps are carried out at 0-4^{0}C, at pH 4, and in the presence of the glycolytic inhibitor iodoacetate. Under these conditions virtually no breakdown of 3H-2DG in glycogen can occur after the perfusion fluid has penetrated and cooled the brain. The labeling patterns obtained using this fixation scheme were very similar to those obtained with the Durham et al., '81, protocol, despite the ten-fold improvement in label retention. In control animals (no whiskers clipped) the vast majority of layer IV cells as well as adjacent neuropil regions in SI vibrissal cortex are labeled. The stimulus-dependent localization of the fixed label is seen in an isolated column of heavy label in the appropriate cytoarchitectonic zone after C3 stimulation in the behaving animal. In C3-only experimental animals, a much larger percentage of neurons are labeled in the stimulated C3 barrel than in adjacent "unstimulated" barrels. Taken together, these results indicate that the vast majority of active cells are labeled in our material.

These materials lend themselves to a detailed regional and cellular analysis of labeling patterns with respect to cortical depth and the identified columnar boundary of the barrel. Zones of heavy metabolic activity are correlated with the incidence of heavily-labeled single cells within a barrel. A regional analysis of these materials indicates a columnar correlation between patches of heavy label within the C3 barrel in serial 50u sections. The analysis also shows that the adjacent C4 and C2 barrels are differentially activated by C3 stimulation in the behaving animal such that labeling in C2 is heavier than that in C4.

219.4 DISTRIBUTION AND FORMS OF GABAergic NEURONS IN RAT BARREL CORTEX: A COMPARATIVE IMMUNO- AND HISTOCHEMICAL STUDY OF GAD, GABA AND GABA-TRANSAMINASE. S. Lyon* and B.W. Connors (Spon: K.L. Chow). Dept. of Neurol., Stanford Univ. Sch. of Med., Stanford, CA 94305.

γ-aminobutyric acid (GABA) is an important inhibitory neurotransmitter in neocortex. Neurons utilizing GABA are presumed to contain uniquely high levels of glutamic acid decarboxylase (GAD, the GABA synthesizing enzyme), GABA-transaminase (GABA-T, the GABA degradative enzyme) and GABA itself. We have attempted to identify GABAergic neurons in the barrel area of rat SmI cortex by using immunocytochemical methods to localize GAD and GABA, and a histochemical technique to localize neuronal GABA-T (Nagai et al., J. Comp. Neurol. 218:220, 1983).

Each stain labelled a very similar population of neurons, as judged by the nearly identical distributions of soma size and position and primary dendritic orientation. GAD, GABA, and GABA-T positive somata had maximal diameters ranging from 6-30 μm, with a mean of 14.4-15.8 μm in coronal sections. The largest cells tended to be in or near layer IV, although soma size was not strongly correlated with laminar position. On average, stained cells had a vertical orientation. In coronal sections the mean angle by which primary dendrites deviated from the normal to the pia was 30°; further, within layer IV cell profiles displayed significantly more primary dendrites in the coronal plane than in the tangential plane. However, clearly multipolar cells were commonly observed with each staining technique. The densities of GAD, GABA and GABA-T positive cell bodies were highest in layer IV, and lowest in layer I and the subcortical white matter. The distribution of stained cell bodies within barrels was examined in tangential sections through layer IV. Cell density (i.e. # of somata per unit area) was 20 to 100% higher near the wall of the barrel than in the centermost area.

All three methods stained clearly delineated punctate structures, interpretable as GABAergic terminals, whose density was highest in layer IV and lowest in layer I and upper layer V. In tangential sections through layer IV, each barrel was visible as a dense patch of stained puncta. The interbarrel septa were relatively unstained. Within single barrels there was no obvious gradient of specific terminal staining that could distinguish walls from hollows.

These results suggest that a high concentration of either GAD, GABA or GABA-T is a useful marker for GABAergic neocortical neurons. It seems likely that each histochemical method labelled the same set of neurons. Within rat barrel cortex, GABAergic neurons have diverse sizes and forms but relatively specific spatial distributions of somata and terminals.

We thank Donald Schmechel for providing the GAD antiserum. This work was supported by NIH grants NS 12151 and NS 19510.

219.5 ANGULAR SENSITIVITIES OF SMI BARREL NEURONS AND THE EFFECTS OF FENTANYL ANESTHESIA. D.J. Simons and P.W. Land. Center for Neuroscience, and Dept. of Physiology and Dept. of Anatomy and Cell Biology, Univ. of Pittsburgh Sch. of Medicine, Pittsburgh, PA 15261.

More than 200 single units in the layer IV barrels of the rat SmI cortex have been examined to quantitatively assess their responses to single vibrissa movements in eight different angles (i.e. in 45° increments relative to the horizontal alignment of the whisker rows). The vast majority of cells in the barrels responded to deflections of only one whisker; cells located in the septa between barrels responded to two or three adjacent hairs. Most cells responded maximally to whisker movements at one or two adjacent angles. For more than half of the units, responses at the "best" angle were significantly greater than to movements in 4 or more other directions; less than 20% of the units displayed no angular preference, i.e. their polar plots were circular. Among moderate to highly tuned cells, more responded best to up or up-and-back whisker displacements (42%) than to down or down-and-forward deflections (17%); less than 5% of tuned cells responded best to down-and-forward displacements. These findings may reflect a non-random distribution of mechanoreceptive endings in the whisker hair follicles.

Units recorded successively within a vertical electrode penetration through lower layer III and layer IV display qualitatively similar angular preferences. Small horizontal displacements of the recording electrode, on the order of 50-75 um, often are accompanied by a slight shift in the cells' overall angular preference. The horizontal distance required to observe a substantial shift in angular preference (i.e. through more than 270°) is considerably less than the full diameter of a barrel. In addition a single barrel does not appear to contain a simple "clock-like" distribution of best angles. One possibility is that there are two, or three, representations of angular space within a barrel each of which may correspond to one of the several metabolically active regions in the barrel centers revealed by cytochrome oxidase histochemistry.

Moderate doses of Fentanyl, a morphine analogue, increase spontaneous activity and mean discharge to whisker displacments; for a given cell the degree of angular tuning is reduced but the overall angular preference is unaffected. At low doses (4 ug/kg/hr) unit responses more closely resemble the unanesthetized state. By contrast Nembutal (sodium pentobarbital, 15-30 mg/kg) diminishes unit responsiveness and greatly reduces the ability to isolate responsive cells using fine-tipped glass microelectrodes.

Supported by NIH grant NS-19950.

219.6 INTRACELLULARLY RECORDED RESPONSES OF RAT SmI CORTICAL NEURONS TO CONTROLLED STIMULATION OF THE MYSTACIAL VIBRISSAE George E. Carvell* and D. J. Simons. (SPON: T. Plant). Center for Neuroscience and Dept. of Physical Therapy and Dept. of Physiology, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Extracellular recording studies have shown that cells in the SmI barrel cortex respond selectively to temporally and spatially patterned stimulation of the vibrissae. Intracellular recording techniques were used to examine membrane potential changes that may underly the neuronal integration of multi-whisker inputs. To date, data have been obtained from more than 40 neurons. Results show: 1) Whisker displacements elicit short-latency (7-10 ms) EPSP's of 10-15 ms duration. 2) The columnar whisker elicits the shortest latency EPSP's and, typically, action potentials (AP's). Adjacent and more distant whiskers elicit longer latency EPSP's that are smaller in amplitude and have a slower rise time. Such subthreshold EPSP's are observed even in the middle cortical depths where only a single whisker elicits AP's. 3) EPSP's with or without AP's are followed by longer-latency hyperpolarizations of the membrane potential (IPSP's) whose amplitudes are reduced with hyperpolarizing current. 4) IPSP amplitudes may be as large as 10 mV and are maximal 20-30 ms after stimulus onset; the membrane potential repolarizes over a 50-75 ms period (i.e., up to 100 ms post-stimulus). 5) Termination of IPSP's is often associated with a rebound depolarization and occassionally AP's. 6) The appearance of IPSP's coincides with an absence of spontaneous AP's. 7) AP's from deflection of a second (or third) adjacent whisker are abolished when that whisker is displaced during the period of maximal IPSP amplitude. Such response suppression can be observed even when the first (i.e., conditioning) deflection fails to elicit an AP. 8) The magnitude, and in some cases the presence, of IPSP's is related to certain spatial aspects of the sensory stimulus; these include the angle in which a single whisker is deflected, which particular whisker is stimulated, and the combination of vibrissae comprising a patterned multi-whisker stimulus.

These membrane potential changes parallel the results of extracellular studies which have suggested that the responses of cortical neurons to patterned stimulation of the vibrissae can be understood in terms of excitatory and inhibitory components of their receptive fields. The present findings also have important implications for interpreting alterations in receptive field properties of cortical neurons following peripheral deafferentation or sensory deprivation.

219.7 RECEPTIVE FIELDS OF VIBRISSAE-DRIVEN UNITS IN THE AWAKE RAT SI CORTEX: EFFECTS OF ACTIVE MOVEMENT AND ANESTHETICS. J.L.U. Guise and J.K. Chapin. Dept. of Cell Biology and Anatomy, U. of Texas Health Sci. Cntr., Dallas, Tx. 75235.

We have evaluated sensory responses of single units in the whisker region of the SI cortex (the "barrelfield") of unanesthetized, unrestrained rats. Standardized mechanical whisker stimulation techniques were employed for this purpose. Major reasons for utilizing this awake preparation were to: 1) observe the effects of spontaneous whisker movement on responses to applied whisker stimulation, and 2) compare responses of the same single neurons to equivalent stimulation in the awake, and halothane anesthetized states. A hand-held rotary motor-driven device was used to mechanically stimulate the whiskers in a relatively natural fashion by moving a bar at a constant speed and constant displacement across the whisker field. This bar was brought across the whiskers once every second in alternating directions. Rats were habituated to this procedure so that they remained relatively still.

Perievent histograms of the response to such stimulation when the whiskers were not spontaneously moving generally showed a 20ms duration peak, followed by an inhibition lasting from 20-100ms. During low amplitude spontaneous whisking movements these peaks were often unchanged in amplitude, but the post-excitatory inhibitions were markedly reduced, or even replaced by excitatory peaks. Occasionally, especially during greater amplitude whisker movements, even the short latency response peaks were facilitated or suppressed. Some cells were directional, a property which appeared to interact in complex ways with movement.

Halothane was used to test anesthetic effects because it may be quickly administered and reversed. When a neuron was isolated in the awake rat, administration of halothane typically severely reduced responses, even in low doses. Nevertheless, spontaneous activity was even more sharply reduced, thus greatly increasing the signal/noise ratio. These effects persisted for at least 30 minutes, even in the absence of behavioral effects.

To conclude, the direct, short latency responses to whisker stimulation appear to be modifiable by behavioral and drug manipulation. However, these are much less modifiable than either the longer latency responses to the whisker stimulation, or the spontaneous discharge.

219.8 ANESTHETIC EFFECTS UPON RESPONSE PROPERTIES OF NEURONS IN THE SUPERFICIAL SI CORTEX. J.D. Greenspan and D.A. Dreyer*. Dept. of Physiology and Dental Research Center, Univ. of North Carolina, Chapel Hill, NC 27514.

A previous report described a class of neurons located in the upper laminae (I-III) of cat SI cortex which had unusual response properties, including 1) a preference for slowly moving stimuli across the skin (<5.0cm/s), and 2) suppression of activity by fast, repetitive stimuli (McKenna, et al, J. Neurophysiol., 51, 1984). This report futher describes the response properties of these "slow brush" neurons, both before and after the administration of nitrous oxide or alpha-chloralose.

Many of these units exhibited a directional preference in their sensitive range of excitatory stimulus velocities. With repeated application of computer-controlled stimuli, units would show inconsistent responses to initially excitatory stimuli. In some cases responses grew in intensity, and in other cases responses decreased in intensity with repeated brushing. Even in cases where there was no apparent trend in response across trials, the variability in a unit's response was considerably greater than that observed in the more typically described SI neurons.

Preliminary data indicate that these superficial "slow brush" neurons are very sensitive to anesthetics. Two units have been tested before and after nitrous oxide administration. A 33% concentration of nitrous oxide eliminated directional selectivity but retained velocity selectivity in one unit. A 75% concentration of nitrous oxide almost entirely eliminated another unit's responsivity.

Three out of three slow brush units were entirely suppressed by I.V. administration of 40mg/kg chloralose. In contrast, one of one layer IV "fast brush" neuron was unchanged following the same dose of chloralose. More data will be presented to futher delineate the relationship between these units' physiological and pharmacological properties.

219.9 ACTIVITY OF POSTCENTRAL SOMATOSENSORY CORTICAL NEURONS CHANGES PRIOR TO ACTIVE MOVEMENT. R.J. Nelson. Dept. Anatomy, Univ. Tennessee, Ctr. Hlth. Sci., 875 Monroe Ave., Memphis, TN, 38163.

Previous observations have shown that many neurons in primary somatosensory cortex (SI) that respond to vibrotactile stimuli serving as the "go-cue" for hand movement also exhibit decreases in activity 60-80ms before movement even though the stimulus remains present (Nelson, Exp. Brain Res., Suppl. 10, 1985). These, and other observations, suggest that SI neurons may have their activity modulated by centrally originating inputs. This study sought to determine if other SI neurons which do not respond to the go-cue also changed activity prior to movement.

Rhesus monkeys flexed or extended their wrists in response to a vibrotactile cue (27,57 or 127Hz sine wave) delivered to their hands via a manipulandum after they maintained a fixed wrist position for a randomized hold time (0.5, 1.0 or 1.5s). The stimulus remained until the animal's hand moved 5 degrees from the held position in this self-paced task. Muscle activity was periodically monitored by placing EMG wires into nine forelimb muscles. Single cortical neuronal activity was monitored by conventional means. Of 619 SI task related cells, 103 neurons (23 from area 3a; 18 from area 3b; 46 from area 1; 16 from area 2) were chosen because: 1) each did not change activity for at least 60ms after stimulus onset and 2) each exhibited a significant change in activity prior to movement onset. A limited number of area 4 neurons were also recorded. Phasic activity changes in these occurred between 70-110ms before movement onset. Of the SI neurons, 65% responded to palpation of muscles or movement of a single joint, 20% had cutaneous receptive fields and the remainder were not tested. Both increases and decreases in activity were observed ranging from 20-170ms prior to movement onset. One possible source of modulating influences upon these cells is from peripheral receptors activated by changes in muscle activity prior to movement. It was determined that 40 of 103 cells changed activity after onset of forelimb muscle activity. Therefore it is possible that changes in activity for these cells were due to peripheral inputs. The remaining 63 neurons might receive inputs from other body regions that contribute to the observed activity changes prior to movement. This was not confirmed by natural stimulation. Of these neurons, (19 from area 3a; 3 from area 3b; 31 from area 1; 10 from area 2), 67% had changes of the same sign (increase or decrease) for both directions of movement; 10% had changes of different sign and the rest showed changes for one movement direction only.

These observations suggest that in addition to peripheral inputs, many SI neurons also receive central modulatory inputs that influence their activity prior to movement and do so at about the same time as presumably centrally originating influences modulate the responsiveness of other SI neurons to peripheral sensory input as previously described.

219.10 DYNAMIC TACTILE DISPLAYS EXCITE SI CORTICAL NEURONS. S. Warren, H. Hamalainen, P. Genduso*, J. Davis*, and E.P. Gardner. Dept. of Physiology and Biophysics, NYU Sch. Med., New York, NY 10016.

The sensation of motion across the skin can be elicited by sequential activation of a linear series of closely spaced probes, such as the OPTACON tactile array. These dynamic tactile displays have the advantage that one can precisely locate the specific elements activated at a particular moment, and can independently vary the spatial and temporal characteristics of the moving pattern. Humans can recognize letters of the alphabet displayed on the OPTACON, but accuracy of performance depends upon the mode of presentation and stimulus duration. We have adapted the tactile array of the OPTACON for use with a PDP-11/23 computer, to allow computer activation of each of 144 miniature probes arranged in a matrix of 6 columns and 24 rows separated by 1.1 mm. Rhesus monkeys have been trained to place their hands over the entire array, and to signal detection of probe activation using a RT paradigm. Single unit recordings were made in areas 3b, 1 and 2 of SI cortex from trained, fully alert animals. Over 70 cortical neurons have been studied with single bar stimuli swept over the tactile array at spatial periods of 1.1, 2.2 and 4.4 mm, and at temporal frequencies of 25, 50 and 100 Hz, in both distal and proximal directions. Cortical responses seemed most strongly influenced by the temporal frequency of probe activation, and the apparent direction of motion across the skin. At low stimulus frequencies, rapidly-adapting and motion sensitive neurons fired one or more impulses in a brief burst, with 15-18 ms latencies. While adaptation conferred directionality to the initial burst, responses during the remainder of the sweep appeared independent of the number of rows previously activated, or the direction from which individual rows were approached. Moderate stimulus frequencies (50 Hz) evoked one impulse/stimulus, but at 100 Hz such frequency following was degraded. Slowly-adapting neurons usually responded more vigorously to low frequency stimuli, but did not demonstrate one-for-one entrainment to the stimulus pulses. Direction sensitive neurons preferred high frequency stimulation, and showed decreased ON-direction responses as the temporal frequency declined, suggesting that slowly moving stimuli may be more vulnerable to inhibition than rapidly moving ones. These findings show that the 240 Hz rate of stimulation used clinically by the OPTACON may not be the most appropriate for obtaining good resolution of spatial detail by cortical neurons. They also demonstrate that dynamic tactile displays provide a useful means for comparing cortical responses to spatial patterns, applied at a variety of temporal frequencies, and at different receptive field locations.
