The use of a microcomputer for image processing can greatly aid in mapping glucose utilization in the brain. The use of pseudocolor display techniques and reconstruction algorithms allow data gathered by [14C] 2-deoxyglucose (GU) mapping techniques as well as from other autoradiographic techniques to be meaningfully displayed and analyzed. We have developed software which has allowed us to relate quantitatively reconstructed GU data directly to the cat cytoarchitectonic atlas. The analysis of the autoradiographic data is initiated by digitizing the films using a scanning microscope equipped with a photomultiplier tube having a resolution to 10 microns square. The optical density data is stored on disc and then converted to GU values using the Sokoloff equation and appropriate measurements of plasma parameters and [14C] standards. The majority of our analysis programs work with two-dimensional GU images. A program was recently developed to reconstruct the brain using a series of up to 140 serial sections of scanned brain sections. Once alligned a vertical or horizontal cursor can be used to slice through the reconstructed brain and a computer generated horizontal or sagittal image will be displayed. This new image can then be analyzed quantitatively in a manner identical to the original transverse images. Before the slice is created, the sections which will make it up must be aligned. This is done by choosing three corresponding points on each of the two images. Using this information, the program rotates the outline of the second image so as to provide a best fit and displays it over the first image. The operator can then translate and rotate the outline, alligning it visually. The second section is then rotated to fit the first and the process is repeated for each section until all are in register. Slices are then created using a weighted average smoothing algorithm in which the data value in the new slice at a particular point is determined by the average of the corresponding data points in the two sections which lie in front of and behind the point, inversely weighted by their respective distances to the point. This algorithm does not require that the existing sections be evenly spaced throughout the length of the new slice, nor does it limit the length of the new slice to a multiple of the number of sections which make up the slice. We have written another program which allows the user to trace one or more areas on a GU data section, either reconstructed or original, and compute the mean and standard deviation over that area. This program can also interface with a high resolution sonic digitizing tablet which utilizes a photograph of the corresponding histological section that represents the anatomy of the scan being analyzed. Using a scaling program one can outline a histologically defined area within the photograph using the cursor from the sonic digitizer and the same area will be analyzed on the computerized scan. This type of analysis greatly reduces the experimentor bias in the interpretation of the so-called "hot spots" in the autoradiographic record. In addition another program allows the user to select any point on the scan using a movable cursor and displays the GU and location in stereotaxic coordinates, which is computed from the step size of the microscope and location of a reference point. These two programs can be used together to provide a quantitative mapping of GU in the cat brain. The theoretical accuracy of the process is determined both by the shrinkage of the histology in the autoradiological process, as well as by the resolution of the scanner. Most sections are scanned at a resolution of 100 microns/pixel, allowing localization of a point within 100 microns in a particular animal. This accuracy is not as useful in making comparisons between animals because of differences in brain size; scaling programs under development will allow comparison between two brains with this accuracy. The programs do allow the publication of data in tabular and statistical as well as graphical form, and allow the possibility of a quantitative composite map of brain activity. This analysis has been extremely useful in identifying areas of the cat brain that are influenced by physiologically and electrically stimulated cardiovascular reflexes. 61.12 CENTRAL PROJECTIONS OF VAGAL AFFERENTS IN THE CAT: A [14C]2-DEOXYGLUCOSE MAPPING STUDY. D.R. Kostreva
Dept. Anesth. Med. Col. Wis. and VAMC, Wood, WI 53193.

Fourteen adult cats 2-4 kg were anesthetized with pentobabital sodium and placed on positive pressure ventilation. EKG was monitored along with systemic blood pressure. A femoral artery was cannulated for blood measurements of glucose, PCO_2, PO_2, pH and scintilation counting. A femoral vein was cannulated for injection of the single bolus of 100 uCi/kg of [14C]2-deoxyglucose. The cervical vagi were exposed in all animals. The cats were divided into two groups. One group had the cervical vagi sectioned bilaterally and the left cut central end of the vagus was placed across a pair of stimulating electrodes connected to a stimulator. The parameters were a frequency of 10 Hz, a pulse width of 0.5 ms and a current strength of 5 mA. These parameters produced a 20-50 mmHg pressor response in the cat. A pattern of periodic stimulation was used so as not to fatigue the response. In most of the non-stimulated control cats the vagi were sectioned, however, in a few they were exposed surgically but left intact. Ventilation was adjusted to insure an arterial PCO_2 as close to 23 mmHg as possible. The animals were then given a single bolus injection of [14C]2-deoxyglucose. The stimulated group were stimulated periodically. During the 45 minute period, 16 paired blood samples were taken for scintilation counting and blood glucose measurements. The animals were then sacrificed and the brains removed and frozen rapidly. The brains were then serially sectioned using a cryostat, and covered with film for autoradiography. After 12 days of exposure the films were developed and scanned and converted to glucose utilization values using the Sokoloff equation. The results indicate that stimulation of vagal afferents unilaterally in the cat result in primarily an ipsilateral increase in glucose utilization by the medial subnucleus of the nucleus tractus solitarius. Other areas of the brainstem that appear to be effected by stimulation of vagal afferents are effected bilaterally, these include the external cuneate nuclei, and the inferior olives. This study demonstrates that stimulation of vagal afferents not only produces profound physiological effects but that these effects also produce marked changes in glucose utilization by specific nuclei and synaptic regions of the brainstem. (Supported by NIH Grants NS18037, HL27968, RCDA HL00959 and the VA)

61.13 ROSTRAL VENTROLATERAL MEDULLA MEDIATES THE CENTRAL HYPOTENSIVE ACTION OF PROPRANOLOL. P.J. Privitera*, A.R. Granata, D.J. Reis, R.L. Tackett* and T.E. Gaffney*. Depts. of Pharmacology & Medicine, Medical Univ. of South Carolina, Charleston, SC 29425 and Cornell Univ. Med. Coll., New York, NY 10021.

We previously observed in the dog that the hypotensive response to centrally administered propranolol was correlated with elevations in cerebrospinal fluid norepinephrine levels. Furthermore, central α-adrenergic blockade prevented the propranolol-induced hypotension (Science 213: 911,1981). Collectively, these studies supported the concept that the centrally mediated hypotensive response to propranolol results from drug-induced release of norepinephrine which then stimulates central α-adrenergic receptors to decrease peripheral sympathetic nerve activity and lower arterial pressure. The present studies were designed to localize the central site(s) at which propranolol acts to produce its hypotensive effect. In pentobarbital-anesthetized dogs, perfusion of propranolol (25 ug/kg/min for 30 min) through the brain ventricular system resulted in 25 $\pm$ 8 mmHg decrease in arterial pressure. Selective perfusion of the same drug dose through the fourth ventricle resulted in a comparable hypotensive response (-24 $\pm$ 5 mmHg) whereas perfusion through the forebrain ventricles (lateral-third ventricle) resulted in a much reduced effect (-8 $\pm$ 2 mmHg). These results suggested that the central hypotensive action of propranolol was localized to the hindbrain region. Experiments were then conducted in urethane-anesthetized rats to determine the effect of bilateral microinjections of propranolol into the region of the rostral ventrolateral medulla (RVL) containing adrenergic neurons of the C1 group. This region was selected because it is known to contain noradrenergic nerve terminals and participate in cardiovascular regulation. In addition, we have previously demonstrated that tyramine, a drug which releases catecholamines from adrenergic nerve terminals, produces hypotension and bradycardia when injected into the RVL (Fed. Proc. 43(3):400, 1984). Bilateral microinjections of propranolol (0.25 to 2.0 nmoles) into the RVL produced an initial pressor response followed by a sustained decrease in arterial pressure which persisted for the course of the experiments (120-180 min). Heart rate was not consistently altered by the drug. The injection site was verified pharmacologically by injecting tyramine, 10 nmole, at the end of each experiment and observing a decrease in arterial pressure and heart rate and by histologic localization of the injection track. In those experiments in which propranolol produced no hypotensive response, tyramine likewise was without effect suggesting that the response to propranolol is anatomically localized to the C1 area in the RVL. The results suggest that an action of the drug in the C1 region of the RVL contributes to the hypotensive effect of centrally administered propranolol.

61.14 STIMULATION OF NEURONS OF C1 AREA OF THE ROSTRAL VENTRAL LATERAL MEDULLA INCREASES REGIONAL CEREBRAL BLOOD FLOW IN THE RAT. M.D. Underwood*, C. Iadecola and D.J. Reis (SPON: T. Meikle). Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Neurons in an area of the rostral ventral lateral medulla (RVL), containing adrenaline neurons of the C1 group (C1 area), maintain normal levels of blood pressure (Ross et al., J. Neurosci., 4:474, 1984) and mediate baroreceptor reflexes (Granata et al., Am. J. Physiol., 248:H547, 1985). We sought to determine whether RVL neurons also participate in the regulation of the cerebral circulation.

Studies were undertaken in 56 adult male Sprague-Dawley rats anesthetized with chloralose (40 mg/kg, s.c.), paralyzed (tubocurarine) and artificially ventilated. Arterial pressure (AP), heart rate and blood gases were monitored and controlled. The RVL was stimulated electrically (1 sec on/1 sec off; 100 Hz, 100 uA, 10 min) with microelectrodes or chemically by microinjection of the excitatory amino acid, kainic acid (KA). The evoked hypertension was controlled to keep AP in the autoregulated range of regional cerebral blood flow (rCBF). rCBF was measured using 14C-iodoantipyrine as indicator with bilateral dissection of 11 brain regions. Placements of electrodes or cannulae were always localized histologically post-mortem.

In controls rCBF ranged from 57 ml/min x 100g in corpus callosum to 105 in inferior colliculus. Unilateral electrical stimulation of RVL increased rCBF ($p < 0.05$, n=6) bilaterally and symmetrically in inferior colliculus (160% of unstimulated control), superior colliculus (150%), hypothalamus (135%), thalamus (164%), caudate nucleus (143%), hippocampus (140%), frontal cortex (152%), parietal cortex (136%), occipital cortex (138%), and corpus callosum (132%). Bilateral adrenalectomy did not change resting rCBF (n=5) nor the elevations elicited by electrical stimulation (n=5). KA microinjected into RVL unilaterally (n=6) or bilaterally (n=4) at a dose producing sustained elevation in AP (5 nm in 100 nl), elicited changes in rCBF comparable in magnitude and pattern to those elicited by electrical stimulation, suggesting that the responses are elicited from local neurons and not fibers of passage in the C1 area. Bilateral electrolytic lesions placed in the RVL area after spinal cord transection with AP maintained in rCBF autoregulated range by i.v. phenylephrine infusion, had no effect on resting rCBF (n=6) nor on the magnitude of increases in rCBF elicited by elevation of arterial pCO_2 to 64.4 + 0.5 mmHg (n=5). We conclude that: (a) excitation of neurons in RVL increases rCBF globally: this increase is not attributable to substances released from the adrenal glands, (b) in contrast to their tonic role in the systemic circulation, neurons in RVL do not contribute to maintaining resting rCBF and do not participate in the cerebrovasodilation elicited by hypercarbia. Neurons within the RVL, possibly those of the adrenergic C1 group, can initiate a global cerebrovasodilation, largely through neural pathways intrinsic to the brain. (Supported by NIH Grant numbers HL18974 and NS03346 and by US DOD DAMD 1784C4185.)

61.15 DEPRESSION OF SYMPATHETIC PREGANGLIONIC NEURONS (SPGNs) BY METHYLDOPA IS PREVENTED BY INHIBITION OF PNMT. Parley W. Madsen and Donald N. Franz. Department of Pharmacology, University of Utah, Salt Lake City, Utah 84132.

The possibility that the central vasodepressor effect of methyldopa is produced by methylepinephrine (mEPI) instead of methylnorepinephrine (mNE) is supported by studies showing that mEPI is highly bound to central alpha-2 receptors (Goldberg et al., Eur. J. Pharmacol. 69:95, 1981) and depresses SPGNs by potent activation of alpha-2 receptors (Guyenet and Stornetta, Brain Res. 235:271, 1982). In further support of this hypothesis, we have previously found that a selective PNMT inhibitor, SKF 64139, prevents the marked depression of SPGNs by reserpine (5 mg/kg) 3 hr after infusion of 150 mg/kg of methyldopa (Soc. Neurosci. Abstr. 8:426, 1982). The depressant effect of methyldopa is attributed to synthesis and release of mEPI from bulbospinal EPI pathways that terminate in the SPGN neuropil. The present study was designed to avoid the use of reserpine to reveal the depressant effect of methyldopa and to use a more selective PNMT inhibitor, LY 134046 (Fuller et al., Biochem. Pharmacol. 30:1345, 1981), to prevent this depression.

Sympathetic discharges, recorded from upper thoracic preganglionic rami, were evoked by stimulation of descending excitatory pathways in the cervical dorsolateral funiculus (intraspinal) or thoracic intercostal nerves (spinal reflex) in unanesthetized spinal cats. After pretreatment with 20 mg/kg of carbidopa, methyldopa (100 mg/kg) gradually depressed sympathetic discharges evoked through each pathway to about 50% of control values by 2 hr. The depression produced by methyldopa was rapidly antagonized by yohimbine (0.5 mg/kg). Pretreatment (4 hr) with LY 134046 (20 mg/kg) completely prevented the depression of transmission by methyldopa/carbidopa. Instead, the evoked responses were gradually enhanced to greater than 200% of control. The effect of LY 134046 was not due to blockade of alpha-2 receptors because clonidine (25 ug/kg) produced its typical depression that was rapidly antagonized by yohimbine.

The ability of PNMT inhibitors to prevent depression of SPGNs by methyldopa supports the proposal that mEPI released from bulbospinal EPI pathways is the functional inhibitory metabolite of methyldopa at this site. The enhancement may be due to release of NE or mNE from descending excitatory NE pathways. (Supported by HL-24085, GM-07579, and Utah Heart Association)

61.16 NEURONS CONTAINING THE ADRENALINE-SYNTHESIZING ENZYME PNMT IN THE CAT BRAIN. P.J. Gatti*, D.A. Ruggiero, R.A. Gillis, M. Anwar*, W.P. Norman, D.H. Park and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 and Depts. of Pharmacology and Anatomy, Georgetown Univ., Washington, D.C. 20007.

Neurons containing the adrenaline synthesizing enzyme, PNMT (phenylethanolamine-N-methyltransferase) are located in the ventrolateral (VLM) and dorsomedial (DMM) medulla in rat but have not yet been mapped in the cat. In this study we demonstrate, for the first time, the distribution of neurons containing PNMT in the brainstem of cat. Adult cats were anesthetized (pentobarbital (40 mg/kg i.p.)) treated with cerebroventricular injections of colchicine (0.5 mg/200 ul), reanesthetized and perfused transcardially with 4% paraformaldehyde in 0.1M phosphate buffer. In control animals vehicle alone was administered intraventricularly. Sections (40 um) were cut on a sliding microtome and then stained with antibodies to PNMT by using peroxidase-antiperoxidase immunocytochemistry. Twenty-four hours after colchicine injections, cells containing PNMT were intensely labeled in VLM and DMM. In VLM, labeled cells extended from the level of the facial nucleus to the calamus scriptorius. Most cells were stained at the level of the rostral third of the inferior olive in an area equivalent to the nucleus reticularis rostroventrolateralis of rat (Ross et al., J. Comp. Neurol. 228, 1984). Farther caudally, cells were adjacent to the lateral reticular cerebellar relay nucleus, and at the level of the calamus, lined the ventral surface. In DMM, cells were restricted to the caudal nucleus tractus solitarii (NTS) including subpostremal, medial and commissural subdivisions.

In this study we have observed major differences in the distribution of PNMT labeled cells in cat when compared to data from rat. In cat: 1) the cell group in VLM was more elongate vertically, and not clearly differentiated into subdivisions; 2) few or no cells were labeled in the rostral DMM (i.e. in rostromedial NTS, periventricular grey, medial longitudinal fasciculus or nucleus paragigantocellularis dorsalis); 3) few cells with horizontal axes of orientation or dendrites entering the raphe were labeled; 4) the organization of PNMT labeled neurons in the caudal NTS differed topographically and extended farther caudally into the commissural region; and 5) unlike rat, cells were clearly labeled in the area postrema and subpostrema.

We conclude: 1) in cat (as in rat) neurons are labeled with PNMT in two areas of medulla associated with visceral (e.g., cardiorespiratory) control; and 2) species differences exist between cat and rat in the organization of the PNMT cell systems.

61.17 A STUDY OF PRESUMPTIVE NEURONAL INPUTS TO THE A5 NORADRENERGIC CELL GROUP. Christopher E. Byrum* and Patrice G. Guyenet, (sponsor C.E. Creutz). Univ. of Virginia School of Medicine, Department of Pharmacology, Charlottesville, VA 22908.

The A5 noradrenergic (NE) cell group is located in the ventrolateral reticular formation of the pons. These cells project massively to the intermediolateral cell column of the spinal cord and play a still incompletely understood role in central autonomic regulation. The purpose of the present experiments was to determine which brain areas project to the portion of the reticular formation in which these cells are located.

Small deposits of wheat germ agglutinin-conjugated HRP (HRP-WGA) were made in the rostral portion of the A5 NE cluster by either iontophoresis or pressure injection. The overlap of the deposit with the A5 cell group was confirmed by photographing the location of fluorescent NE cells in vibratome sections obtained throughout the injection area (Faglu technique) before the sections were processed for HRP localization. Since the main A5 cell cluster lies within the rubrospinal tract, the presence or absence of neuronal labeling in the red nucleus was taken as evidence for or against damage to axons of passage.

In all cases where the HRP-WGA deposit (diameter 0.75 to 1.5 mm) overlapped with the A5 NE cell group and did not damage the rubrospinal tract (N=5), significant retrograde labeling was found in the following structures: Kölliker-Fuse nucleus, ventral midbrain periaqueductal gray (PAG), posterior parvocellular part of the paraventricular nucleus of the hypothalamus, lateral and perifornical hypothalamic areas, zona incerta, dorsal parabrachial area, vestibular complex, ventrolateral medullary reticular formation, intermediate and commissural portions of the nucleus tractus solitarius, and locus coeruleus.

Although it is unclear which of these inputs to the A5 area make synaptic contact with A5 NE cells, the nature of the inputs strongly supports the assertion that the A5 area is primarily involved in autonomic regulation.

61.18 STIMULATION OF THE NORADRENERGIC CELLS OF THE LOCUS COERULEUS IN RAT DECREASES BLOOD PRESSURE. A.F. Sved. Neurology Service, V.A. Medical Center, East Orange, NJ 07019, and Dept. Neurosci., UMDNJ, Newark, NJ 07103.

Previous studies have demonstrated that electrical stimulation of the locus coeruleus (LC) elicits a marked increase in arterial pressure (AP). However, the conclusion that stimulation of the LC produces a pressor response is based totally on electrical stimulation, which activates nerve cells in a region as well as the fibers passing through that region. In the present study, we examined the effect of stimulating specifically the noradrenergic cells of the LC on AP. Male Sprague-Dawley rats anesthetized with α-chloralose (60 mg/kg iv) following induction with halothane had cannulas placed in a femoral artery and vein and were mounted in a stereotactic instrument. Burr holes were drilled through the skull to allow placement of electrodes and micropipettes into the LC. Electrical stimulation of the LC (50 μA, 50 Hz, 10 sec train of 0.2msec pulses) increased AP more than 30 mmHg. This pressor response to electrical stimulation was not effected by pretreatment of the LC with 6-hydroxydopamine (2μg in 0.2 μl injected slowly into the left LC of rats treated with pargyline 10 days before study); the 6-hydroxydopamine treatment destroyed all (>90%) noradrenerigic neurons in the region of the LC, as demonstrated by histofluorescence using the FAGLU method. In contrast to electrical stimulation, microinjection of the neuroexcitatory agent L-glutamate into the LC decreased AP. The depressor response to L-glutamate was dose-related with 0.5nmol (in a 0.1ul injection volume) being the minimum dose to elicit a significant response (-10±2 mmHg, n=6) and 4.0 nmol producing the maximal response, a decrease in AP of 34±4 mmHg (n=6). The depressor response to 2.0 nmol L-glutamate injected into the LC was totally prevented by pretreatment with 6-hydroxydopamine. In addition, carbachol (1.0 nmol), a cholinergic agonist which has ben deomonstated to increase the activity of LC neurons, decreased AP (-16±3, n=5) when injected into the LC. These results suggest that stimulation of the LC decreases AP and that the pressor response elicited by electrical stimulation is not due to stimulation of noradrenergic cells of the LC.

Supported by funds from the Foundation of the University of Medicine and Dentistry of New Jersey and the Veterans Administration.

61.19 EFFECT OF BLOOD PRESSURE ALTERATIONS ON NEUROTRANSMITTER TURNOVER IN LOCUS COERULEUS AS MEASURED BY IN VIVO ELECTROCHEMISTRY. D. Bhaskaran,* and C.R. Freed, Depts. of Med. and Pharm., Univ. of Colo. Health Sci. Ctr., Denver, CO 80262.

Locus coeruleus contains the majority of noradrenergic cell bodies in the brainstem and may play a role in blood pressure (BP) regulation. Our laboratory has reported changes in neurotransmitter turnover in nucleus tractus solitarius (NTS) and dorsal raphe nucleus (DRN) following manipulations of BP with drugs (Neurosci. Abs. 91.1, 1984, Life Sci. 34: 1581, 1984). We have now studied the effect of drug-induced hypertension and hypotension on neurotransmitter metabolism in the LC. Urethane anesthetized male Sprague-Dawley rats weighing 250-350 g had carbon paste in vivo electrochemical (EC) electrodes placed in LC and linear sweep voltammetry was performed from -0.2 V to +0.5 V at a rate of 10 mV/sec using a DCV-5 cyclic voltammetry apparatus (Bioanalytical Systems). Peaks were seen at 0.15 V and at 0.28 V. Studies with alpha-methylparatyrosine, fusaric acid, and pargyline showed that the first peak was produced by extracellular fluid DOPAC while the second peak was 5-HIAA. Phenylephrine was infused i.v. to raise BP by 50 mm Hg and nitroprusside was used to reduce BP by 20 mm Hg. To confirm the EC findings, other groups of rats were decapitated during and after hypertensive and hypotensive drug infusions and the LC assayed for norepinephrine (NE), dopamine (DA), DOPAC, serotonin (5-HT) and 5-HIAA using HPLC with EC detection. Results showed that during phenylephrine-induced hypertension, there was no significant change in extracellular fluid DOPAC concentration during the first 40 min of drug infusion. However, as the hypertension continued for 60 min, the signal increased to 160 % of baseline and the increase persisted even after the infusion. The extracelluar fluid concentration of 5-HIAA increased with the onset of the infusion and remained elevated at 210 % of baseline after the infusion. Nitroprusside-induced hypotension did not change the catechol peak but it did lead to a 190 % increase in 5-HIAA. Direct tissue assays confirmed that DOPAC and 5-HIAA were changed as predicted by the EC electrodes. Tissue NE and 5-HT did not change in any experiment but tissue DA was decreased during nitroprusside infusion. These experiments show that hypertension and hypotension lead to changes in catecholamine and indoleamine metabolism in locus coeruleus. We have found in NTS and DRN that the carbon paste in vivo EC electrode measures extracellular fluid NE and 5-HIAA. By contrast, LC appears to have DOPAC and 5-HIAA as the primary electrochemically active species measured by carbon paste and carbon fiber electrodes (Brain Res. 273: 197, 1983). Changes in DOPAC are associated with hypertension but not hypotension. DA and 5-HT in LC may be important for cardiovascular regulation.

61.20 THE ORGANIZATION OF DORSAL MEDULLARY PROJECTIONS TO THE AMYGDALOID CENTRAL NUCLEUS AND PARABRACHIAL NUCLEUS IN THE RABBIT. B.S. Kapp, J.S. Schwaber,[1] C.G. Markgraf* and T. Bilyk-Spafford.* Dept. of Psychology, Univ. of Vermont, Burlington, VT 05405 & [1]Dupont Central Research Neurobiology Group, Glenolden, PA 19036.

Both the amygdaloid central nucleus (ACE) and the parabrachial nucleus (PBN) have been implicated in cardiovascular regulation in the rabbit (Kapp et al., 1982; Hamilton et al., 1981). Since both areas are reciprocally connected, and receive direct projections from the nucleus of the solitary tract (NTS)/vagal dorsal motor nucleus (DMN) complex (Ricardo & Koh, 1978; Nordgren, 1980), they appear to be important components of a larger forebrain system involved in cardiovascular regulation. The present experiment was designed to further examine the anatomical organization of this system by determining the extent to which neurons of the NTS/DMN complex which project to the ACE also project via collaterals to the PBN.

Twenty New Zealand rabbits received injections of Fast Blue (FB; 10%; 40-150 nl) aimed at the ACE. Two to four weeks later, injections of Bisbenzimide (Bb; 40-80 nl) were aimed at the lateral parabrachial region. One to three days thereafter the animals were perfused, and 30 µm frozen sections were taken throughout the rostral-caudal extent of the NTS/DMN complex and examined using fluorescent microscopy for the presence of single and double-labeled neurons.

Less than two percent of labeled neurons within the NTS/DVN complex contained both FB and Bb. Neurons containing either FB or Bb demonstrated a similar, predominantly ipsilateral topographical distribution, with the majority located caudal to obex. At caudal levels FB and Bb labeled neurons were located within the DMN and commissural subnucleus of the NTS. More rostrally, labeled neurons were located within the DMN as well as within the parvocellular, medial, dorsomedial and intermediate subnuclei of the NTS.

To assure that retrogradely-labeled neurons in the NTS were not a function of transport by injured fibers of passage, injections of ^{3}H-leucine/proline were made into the NTS/DMN complex caudal to the level of obex in five rabbits. Transported label was concentrated within the medial component of the ACE as well as within the PBN where it was most dense lateral to the brachium conjunctivum.

These results suggest that separate populations of neurons within the NTS/DMN complex project to the ACE and PBN, and that these populations demonstrate similar topographical distributions within the dorsomedial medulla. These distributions are quite similar to the distribution of catecholamine-containing A2 neurons recently demonstrated to project to the hypothalamic paraventricular nucleus in the rabbit (Blessing et al., 1982). 61.21 ADRENAL MEDULLARY HORMONES AND BETA-ADRENORECEPTORS ARE INVOLVED IN THE GLOBAL CEREBROVASODILATION ELICITED BY STIMULATION OF THE DORSAL MEDULLARY RETICULAR FORMATION IN RAT. P.M. Lacombe*, C. Iadecola, M.D. Underwood*, K. Chida* and D.J. Reis. (SPON: M.E. Ross). Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Electrical stimulation of the dorsal medullary reticular formation (DMRF) in rat, globally increases regional cerebral blood flow (rCBF) and metabolism. The finding that acute removal of the adrenal glands markedly reduces the elevations in rCBF suggests that part of the vasodilation depends upon substance(s) released from adrenals (Iadecola et al., Soc. Neurosci. Abstr. 10, 168, 1984). Although the most likely candidates are the adrenal catecholamines (CA), other substances released from the adrenal cortex or medulla, could be involved. In this study we sought to determine: (a) whether these substance(s) are released from the medulla and (b) whether beta-adrenergic receptors are involved in the cerebrovasodilation. Rats were anesthetized (chloralose 40mg/kg), paralyzed (tubocurarine) and artificially ventilated. Arterial pressure (AP) and heart rate were monitored and blood gases were kept in physiological range. DMRF was stimulated (50 Hz; 50 uA; 1 sec on/1 sec off) and AP kept in the autoregulated range for rCBF. rCBF was measured by the 14-C-iodoantipyrine technique in 13 dissected brain samples. In unstimulated rats (n=5) rCBF ranged from 64±4 (ml/100g x min) in corpus callosum to 110±11 in inf. colliculus. Acute total adrenalectomy (n=5) did not change resting rCBF. In intact rats (n=5) DMRF stimulation elicited an increase in rCBF in all areas with maximal responses in cerebral cortex (frontal cortex, Fcx to 206%; parietal, Pcx to 208%; occipital, Ocx to 189% of control; $p < 0.01$). After acute total adrenalectomy (n=6), DMRF stimulation increased rCBF only in Fcx (144%), Pcx (161%) and Ocx (171%) ($p < 0.02$), the increases being significantly lower than those obtained in intact stimulated rats ($p < 0.05$; analysis of variance). Comparable effects were elicited by acute removal of only the adrenal medulla (Fcx 164%, Pcx 164%, Ocx 158%; $p < 0.05$ from unstimulated and from intact stimulated). Administration of the beta-adrenergic receptor blocker propranolol (1.5 mg/kg, i.v.), 30 min prior to rCBF measurement, did not affect resting rCBF (n=5), however it abolished the increase in rCBF elicited by DMRF stimulation in intact animals, with a regional pattern and magnitude similar to that elicited after adrenalectomy or adrenal demedullation (rCBF increases: Fcx 144%, Pcx 146%, Ocx 136%; $p < 0.05$ from unstimulated and from intact stimulated). We conclude that substance(s) released from the adrenal medulla contribute to the cerebrovasodilation elicited by DMRF stimulation. The cerebral vasodilation is, in part, mediated by beta-adrenergic receptors, presumably within CNS. It is therefore probable that CA mediate the adrenal-dependent component of the cerebral vasodilation elicited by DMRF stimulation. However, since CA do not cross the intact blood-brain barrier, the mechanism through which they increase CBF and metabolism remains to be established. (Supported by NIH NS03346)

61.22 A VASODEPRESSOR RESPONSE ELICITED BY CHEMICAL STIMULATION OF INTRINSIC NEURONS OF ROSTRAL FASTIGIAL NUCLEUS (THE FASTIGIAL DEPRESSOR RESPONSE). K. Chida*, C. Iadecola, M.D. Underwood*, and D.J. Reis (SPON: R.P. Friedland). Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Electrical stimulation of the rostromedial pole of the cerebellar fastigial nucleus (rFN), in rat as in other species, elicits highly coordinated cardiovascular (the fastigial pressor response) and behavioral responses. Since electrical stimulation excites both neurons and their processes, these responses could originate from excitation of neurons within rFN or from stimulation of neuronal processes originating elsewhere and passing through rFN. In this study we sought to determine by chemical stimulation whether the hypertension and tachycardia elicited from rFN stimulation in rat, are due to excitation of local neurons. An unexpected vasodepressor response was found. Rats were anesthetized (chloralose, 40 mg/kg), paralyzed and artificially ventilated. Arterial pressure (AP) and heart rate (HR) were continuously monitored and recorded. rFN was stimulated electrically, with 8 sec trains of pulses (duration: 0.5 msec), or chemically, by the excitatory amino acids kainic acid (KA) , l-glutamic (l-glu), l-aspartate (l-asp), dl-homocysteate (dl-hom) locally microinjected (volume 100 nl) through micropipettes. Placements were histologically verified. Electrical stimulation of the rFN (n=17) produced a stimulus-locked elevation in AP and HR, graded with the intensity and frequency of the stimulus (threshold current: 14 ± 1.2 uA, at 50 Hz). At 5 times threshold AP rose 46 ± 2 mmHg. Microinjection in rFN of l-glu (n=5), at doses effective in elevating AP when microinjected in the rostral ventrolateral medulla (0.01-100 nmole), or l-asp (1-10 nmole) (n=5) had no effect. Chemical stimulation of the rFN with KA (n=10) produced a sustained (< 10 min), dose-dependent (0.05-5 nmole) reduction in AP and HR (AP reduction: 56 ± 6 mmHg, HR reduction: 103 ± 9, at 5 nmole; $p < 0.001$). Microinjection of KA (5 nmole) into the overlying cerebellar vermis (n=5), dentate nucleus (n=5) or fourth ventricle (n=4), failed to evoke a similar response. Microinjection of dl-hom (1-100 nmole) (n=5) also elicited a dose-dependent reduction in AP and HR (AP reduction: 34 ± 7 mmHg at 100 nmole; $p < 0.01$. To destroy the intrinsic neurons in rFN sparing the fibers of passage, the excitotoxin ibotenic acid was unilaterally injected in rFN (15 ng in 1.5 ul). In 7 days, neuronal perikarya completely disappeared in the rostral and intermediate portion of FN, with extensive gliosis. Electrical stimulation of the lesioned rFN (n=3), elicited elevations in AP and HR, not different from those obtained from the rFN of intact rats (AP elevation at 5 x threshold (<100 uA): 47 ± 4 mmHg; $p > 0.05$ from intact group). We conclude that: (a) the cardiovascular changes elicited by electrical stimulation of the rFN are not due to excitation of neurons intrinsic to rFN, but, most likely, to excitation of neuronal processes, originating elsewhere; (b) neurons in rFN responsive to KA and dl-hom, but not l-glu or l-asp, can initiate a potent and heretofore unrecognized vasodepressor response, the fastigial depressor response.

61.23 CEREBRAL CORTICAL NEURONS ARE REQUIRED FOR THE CORTICAL CEREBROVASODILATION ELICITED BY STIMULATION OF THE FASTIGIAL NUCLEUS IN RAT. C. Iadecola, S. Arneric, L.W. Tucker, H. Baker and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Electrical stimulation of the cerebellar fastigial nucleus (FN) increases local cerebral blood flow (lCBF) globally in brain and in cerebral cortex, independently of local metabolism (Nakai et al., Brain Res. 260, 35, 1983). Lesions of the basal forebrain (BF) abolish the cortical vasodilation (Iadecola et al., Brain Res., 279, 41, 1983) suggesting that the cortical vasodilation is mediated by pathways originating in or passing through BF. However it is not known whether these pathways affect CBF directly or via interposed cortical interneurones. To determine whether local neurones in cerebral cortex participate in the cortical cerebrovasodilation elicited by FN stimulation, rats were anesthetized with halothane and a local lesion produced by using the excitatory neurotoxin ibotenic acid (IBO) (10 ug in 1 ul) microinjected into the left primary sensory cortex. Five days later, rats were anesthetized (chloralose), paralyzed and artificially ventilated. Blood gases were controlled and arterial pressure was kept within the CBF autoregulated range. FN was electrically stimulated (1 sec on/1 sec off) at 50 Hz and 100 uA. lCBF was measured autoradiographically in 30 brain regions by the 14-C-Iodoantipyrine technique. IBO microinjection resulted, within 5 days, in lesions highly reproducible with respect to size, location and chemistry. Histologically, the lesion was characterized by neuronal loss over a cortical area of 3-5 sq. mm with variable gliosis and capillary proliferation. HRP-WGA (n=3) microinjected into the lesion, was transported retrogradely into the neurons of the BF and ventrobasal thalamus, indicating that major afferent pathways to the lesioned area were preserved. Biochemically, the activity of glutamic acid decarboxylase (GAD) was reduced to 26±9% of control (n=7; $p < 0.01$), while the activity of choline acetyltransferase was unchanged. These observations indicate loss of intrinsic GABAergic and probably other neurons, with preservation of the afferent cholinergic fibers,mostly from BF. IBO treatment (n=5) did not alter resting cortical lCBF when compared with the contralateral side (113±25 vs. 123±7; ml/100g x min; NS) nor with the corresponding area of unlesioned controls (125±8; NS). FN stimulation (n=6), in untreated rats increased lCBF significantly and symmetrically in most brain regions. However, lCBF did not increase within the lesion (122±8% of control; NS) in contrast to the lCBF in contralateral homologous site wherein it rose to 171±9% ($p < 0.005$). The absence of vasodilation within the lesion was not due to vasoparalysis since hypercarbia (pCO_2: 63±4 mmHg) (n=5) increased lCBF in the cortical target area bilaterally and symmetrically (lesion: 330%, contralateral: 327%; NS).

We conclude that local cortical neurones do not substantially contribute to resting lCBF or to the cerebrovascular reactivity to CO_2. However such neurons are required for cortical cerebrovascular vasodilation elicited by FN stimulation. (Supported by NIH NS03346 and DOD DAMD17-84-C-4185)

61.24 PUTATIVE PATHWAYS LINKING THE FASTIGIAL PRESSOR AREA AND THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS IN THE RAT. A.Del Bo and A.Rosina*, Clin.Medica IV,Univ.di Milano and Ist.Fisiologia Centri Nervosi, CNR, Milano, Italy.

Electrical stimulation of the pressor site of the fastigial nucleus (FN) in the rat induced secretion of vasopressin (VP) into the plasma which could be modulated by afferents from the baroreceptors (Del Bo et al., Circ.Res.,54:248, 1984). Aim of the present study was to disclose the pathways which might subserve such a functional control of rostral FN on neurosecretory cells in the hypothalamus.

A technique which combines retrograde and anterograde fluorescent tracing(Rosina,Neurosci.Lett.,33:217,1982) was used. In urethane anesthetized rats the anterograde tracer Fast blue (FB) was microinjected (0.1 µl, 2% w/v) into the left rostromedial FN while the paraventricular nucleus of the hypothalamus (PVN) was centered on both sides with the retrograde tracer Diamidino yellow (DY) (0.1 µl, 1% w/v). After 10 days survival, animals were perfused with 20% formalin buffered at pH 7.2. 25 µ frozen sections were analyzed under a Leitz Ploemopak,by a filter system providing excitation light of 360 nm.

FB axons and axon terminals leaving the rostral FN through the superior and inferior cerebellar peduncles distributed bilaterally to several regions in the brainstem: the vestibular complex, the nucleus reticularis gigantocellularis, the nucleus parasolitarius, the lateral reticular nucleus. FB ascending fibers and terminals were found through the periventricular and central grey, the locus coeruleus and parabrachial complex. Brainstem DY neurons projecting to PVN were traced in the ventral medulla, tractus solitarius, raphe nucleus, dorsal tegmental nucleus, locus coeruleus, central grey and parabrachial nucleus. Among the above mentioned structures, which are known to be involved in direct and reflex control of circulation, FB terminals and DY cells were found to overlap in only two regions: scattered in the ventral medulla and more numerous in the locus coeruleus-parabrachial complex. The observed effect of FN stimulation on VP secretion may well be mediated by polysynaptic pathways but the present data suggest that a disynaptic link may also be possible.

61.25 CORTICOTROPIN-RELEASING FACTOR: EFFECTS ON BAROREFLEX CONTROL OF HEART RATE. L.A. Fisher. Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Corticotropin-releasing factor (CRF), by virtue of its central nervous system (CNS) distribution and actions, is suspected of being a physiologic mediator of the integrated endocrine and autonomic responses to stress. Simultaneous elevations of mean arterial pressure (MAP) and heart rate (HR), indicative of altered baroreflex function, are observed both during exposure to various physical and psychological stressors (e.g., exercise, cold) and after intracerebroventricular (icv) administration of CRF. Therefore, the CNS effects of CRF on baroreflex control of HR were examined in detail by constructing complete stimulus-response curves relating MAP to pulse interval (PI; reciprocal of HR) over a wide range of MAP.

All experiments utilized conscious, unrestrained male rats (200-250 gm) fitted with lateral cerebroventricle cannulae and femoral artery and vein catheters. After measurement of basal MAP and HR, the rats received icv injections of saline (10 µl) or CRF (1.5 nmoles). Baroreflex testing began 10 min later, when MAP and HR reached stable plateaus. MAP was raised or lowered by alternating intravenous infusions (1 min, 20 sec duration) of graded doses of phenylephrine and nitroprusside. MAP and HR were recorded just prior to the onset and again during the last 20 sec of each infusion. MAP and HR were allowed to recover to preinfusion levels between each infusion. After conversion of HR to PI, all resting and response values were fitted to an S-shaped curve with nonlinear regression analysis.

The relationship between MAP and PI was clearly modified after CRF treatment. As previously demonstrated, CRF-treated rats displayed concurrent elevations of MAP and HR causing the MAP-PI curves to be shifted downward and to the right. Moreover,response range and reflex gain were markedly reduced while threshold MAP and MAP at midrange were increased following CRF treatment. These changes in curve parameters suggest that CRF alters transmission in CNS pathways involved in processing baroreceptor information. The pronounced effects of CRF on baroreflex function are likely to cause, acutely, enhanced cardiovascular performance and thus support the rise in metabolic rate that attends various stressful conditions. However, if such cardiovascular activation is sustained chronically, the potential for deleterious consequences is great.

61.26 ORGAN BLOOD FLOW DISTRIBUTION FOLLOWING CENTRAL INJECTIONS OF ANGIOTENSIN II IN CONSCIOUS RATS. R. Rettig, F.C. White* and M.P. Printz*. University of California, San Diego, School of Medicine, La Jolla, CA 92093.

Intracerebroventricular (icv) injections of angiotensin II (ANG II) are well documented to elicit pressor responses and bradycardia in rats and other species. The exact hemodynamic mechanisms underlying these responses have not yet been completely identified. The dipsogenic effect together with a recent report of a decrease in splanchnic nerve activity following central ANG II stimulation have been interpreted to suggest that ANG II elicits a centrally integrated behavioral and autonomic response pattern that resembles a classical "feeding response" and that is associated with a redistribution of organ blood flow away from the skeletal musculature and in favor of the mesenteric vascular bed.

In order to test this hypothesis we have measured blood flow in several vascular beds prior to and 2 min after icv injections of ANG II (100 ng) in 10 adult, conscious, freely moving Sprague-Dawley rats, using the tracer microsphere technique (diameter of spheres: 15 ± 3 µm; labels: Ce-141, Sn-113). Ten additional rats received icv injections of vehicle only. Central ANG II injections reduced blood flow significantly in the skin (-59%), stomach (-57%), bronchial circulation (-46%), small intestine (-43%), kidneys (-22%) and colon (-11%). There were no significant blood flow changes in the skeletal musculature, heart and brain, whereas blood flow increased slightly in the hepatic artery vascular bed. Injections of vehicle only did not significantly alter blood flow in any of the vascular beds, except for an unexplained increase in hepatic artery flow.

These data suggest that the central ANG II-induced pressor response in conscious rats is mediated to a major extent by vasoconstriction in the mesenteric vascular bed and the kidneys, whereas skeletal muscle blood flow does not change significantly. This organ blood flow distribution pattern is not compatible with the classical "feeding response".

61.27 INTERRUPTION OF THE THALAMIC MD-PREFRONTAL PROJECTION HAS NO EFFECT ON STIMULATION-ELICITED CARDIAC CHANGES OR LEARNED BRADYCARDIA IN THE RABBIT. Shirley L. Buchanan and D. A. Powell. WJB Dorn VA Hospital, and University of S.C., Columbia, SC 29201

New Zealand albino rabbits, anesthesized with ketamine and thorazine, received knife cuts (Kopf Scouten assembly) either medial or lateral to the mediodorsal nucleus (MD) of the thalamus. A third group of control animals received sham cuts. A stimulating electrode was implanted in all animals. After a 1 to 2 week recovery period cardiovascular responses elicited by electrical stimulation through the previously implanted electrode were assessed in conscious animals. Heart rate (HR), blood pressure (BP), electromyographic activity (EMG) and respiration were measured in response to 2-sec trains of biphasic stimulation (40-200 μA). In addition, the HR component of the Orienting Reflex (OR) was measured in response to 10 presentations of a 4-sec, 75 db, 1216 Hz tone. HR was measured on a beat-by-beat basis for 10 beats prior to tone onset, for the duration of the tone, and for 10 beats following tone offset. Following OR assessment, rabbits received 2 sessions of differential classical conditioning, during which either the 1216 Hz tone, or a 304 Hz tone, was consistently paired with a 3 mA paraorbital electrical shock. HR was measured as during orienting assessment.

As previously found, electrical stimulation of MD elicited large bradycardiac responses, accompanied by pressor responses and respiration increases. Neither medial nor lateral knife cuts appeared to affect this response. The OR to the tone stimulus was a HR deceleration, which declined across trials. The HR CR was also a bradycardiac response, with larger decelerations occurring in response to the tone followed by shock (CS+) than to the non-reinforced tone (CS-). Both the OR and the CR were intact following either medial or lateral cuts. Since these cuts interrupt efferent fibers from MD to prefrontal cortex, these results suggest (a) that the autonomic changes elicited by electrical stimulation of MD are not mediated by MD-prefrontal connections, and (b) similarly, that the bradycardia elicited by Pavlovian conditioning contingencies is not dependent on the integrity of these connections.

61.28 APPLICATION OF GLUTAMATE AND CARBACHOL TO THE MEDIODORSAL NUCLEUS OF THE THALAMUS ELICITS AUTONOMIC CHANGES IN CONSCIOUS RABBITS. D. A. Powell and Shirley Buchanan, Neuroscience Lab., WJB Dorn VA Hospital and Univ. of South Carolina, Columbia SC

Chronic indwelling cannulas were implanted in the mediodorsal nucleus (MD) of the thalamus in albino rabbits under ketamine and thorazine anesthesia. After a 1-2 wk recovery period the medial ear artery was cannulated under a local anesthetic and several autonomic measures, including heart rate (HR), mean blood pressure (BP), respiration, and electromyographic activity (EMG) were recorded subsequent to the injection of μl amounts of glutamate, GABA and carbachol. All drugs were dissolved in .9% saline. At the conclusion of testing the animals were sacrificed by nembutal and perfused transcardally with saline and 10% formalin. Histological verification of cannula tips was then assessed after cryostat sectioning and staining with thionin.

It was found that dose-related decreases in HR and increases in BP were obtained with both glutamate and carbachol at doses in the nmol and μmol range. However, GABA did not have an effect when injected into MD. Some injections also produced increases in respiration and EMG. Control injections through cannulas chronically implanted in the overlying hippocampus or adjacent ventricles revealed a different pattern of responding, suggesting that the effects obtained with MD placements were due to chemical stimulation of MD. Moreover, assessment of diffusion of methylene blue around the cannula tip in acutely sacrificed animals revealed that at the injection and time parameters employed, the drug remained in MD. Saline injections produced only a minimal effect, and control injections of carbachol and glutamate into other thalamic nuclei, i.e. AV and the reticular nucleus, did not produce similiar autonomic changes.

Responses elicited from MD in the present experiment were similar, but not identical, to those produced by electrical stimulation of MD. They suggest that the bradycardia and pressor responses produced by electrical stimulation are due to stimulation of MD cells and not fibers of passage. One troublesome feature of these findings, however, is that the changes produced were somewhat smaller than those produced by electrical stimulation. These differences may reflect the fact that a smaller population of MD cells is activated by chemical stimulation compared to those activated by electrical stimulation.

61.29 CORRELATION BETWEEN RESPIRATORY AND CARDIAC AUTONOMIC NERVE ACTIVITIES. M. Kollai* and K. Koizumi. Department of Physiology, State University of New York, Downstate Medical Center, Brooklyn, NY 11203

The aim of the study was to obtain information about the nature of relationships between respiratory and cardiac autonomic nerve activities in spontaneously occurring situations and in those evoked by superior laryngeal nerve stimulation. The time course of activities recorded from phrenic, expiratory-intercostal muscle, cardiac sympathetic and parasympathetic nerves was analyzed in chloralose anesthetized and artificially ventillated dogs. We found that: 1) The pattern of cardiac autonomic nerve discharges in relation to the respiratory cycle varied in different experiments, depending on how transition from inspiration to expiration occurred; this was detected by monitoring changes in phrenic activity; 2) When the amplitude of integrated phrenic discharges varied, a similar pattern of variations appeared in the sympathetic but not in the vagal discharges; 3) During the rising phase of slow wave blood pressure oscillations, phrenic firing increased during inspiration and was maintained at a moderate level also during expiration; simultaneously sympathetic activity level was enhanced and vagal activity level was diminished; 4) Stimulation of laryngeal afferents produced total silence in phrenic activity and steady firing of the expiratory muscle nerve as well as discharges of both vagal and sympathetic nerves. The alternating discharge pattern between the two cardiac autonomic nerves previously present was lost.

From these observations it has been concluded that the primary factor in creating different autonomic activity patterns is the changing qualities of central inspiratory activity; its time course defines the period when vagal activity is inhibited, and its intensity determines whether and when the sympathetic activity is facilitated. (Supported by grant from USPHS, NS-00847).

61.30 CAN ARTERIAL CHEMORECEPTORS INFLUENCE BARORECEPTORS? J. T. Hansen. Dept. Cellular and Structural Biology, Univ. Texas Health Science Center, San Antonio, TX 78284.

Peripheral arterial chemoreceptors, such as the carotid and aortic bodies, lie in close proximity to baroreceptor regions located on the carotid sinus and aortic arch. The carotid body and sinus are innervated by the carotid sinus nerve, which possesses both chemosensory and baroreceptor afferents which terminate in the NTS. These two cardiovascular receptors generally are viewed as separate reflex systems; the carotid body initiates respiratory reflexes in response to changes in blood gases while the baroreceptors mediate cardiac and vasomotor reflexes in response to an elevated blood pressure. However, recent ultrastructural evidence demonstrates that these two receptor systems share a common blood supply (McDonald, D.M., and Larue, D.T. J. Neurocytol., 12:117, 1983). Vascular cast preparations of the carotid sinus show that the blood supply to the sinus vasa vasorum comes from small arterioles in the carotid body. This vasa vasorum is intimately associated with clusters of baroreceptor nerve endings on the carotid sinus. Additionally, isolated glomus-like cells, typical of those seen in the carotid body, occasionally are observed in the sinus wall adjacent to baroreceptor nerve endings. The carotid body glomus cells contain catecholamines and several neuropeptides, which may be released onto adjacent nerve endings or into the carotid body vasculature. Therefore, these neuromodulatory substances may have access to the baroreceptor nerve endings and smooth muscle of the carotid sinus via the vasa vasorum, or directly via paracrine secretion from isolated glomus-like cells in the sinus wall.

61.31 ROLE OF THE CAROTID SINUS BARORECEPTORS AND THE INTERNAL AND EXTERNAL CAROTID ARTERIES IN THE CEREBRAL ISCHEMIC RESPONSE OF THE RABBIT. William G. LeBlanc,* Barry E. Hurwitz,* Philip M. McCabe & Neil Schneiderman. (SPON: Lincoln Potter) Dept. Psych., Univ. of Miami, Coral Gables, FL 33124

The cerebral ischemic response (CIR) in the rabbit, produced by interruption of the blood supply to the head, consists of elevated arterial pressure, bradycardia, apnea, and a shift in regional blood flow. It is normally produced by permanently occluding the two vertebral arteries and temporarily occluding the two common carotid arteries (CCAs). Since previous studies have typically involved occlusion of the CCAs below the carotid sinus (CS), questions remain concerning the relative roles played by the internal (ICAs) and external (ECAs) carotid arteries and about the influence of the CS baroreceptors upon the reflexive bradycardia.

It has been reported that the carotid sinus (CS) baroreceptors are not involved in the reflexive bradycardia of the CIR (Dampney et al., 1979, Circ. Res., 45, 48-57). However, we found that after aortic nerve transection, the contribution of the CS baroreceptors was masked when the CIR was produced by occluding the CCAs below the CS, but was observed when the CIR was produced by occluding the ICAs and the ECAs separately at a point above the CS.

Although there are anastomoses between the ICAs and the ECAs, no blood flow from the ECAs into the intracerebral circulation is observed during resting conditions (Scremin et al., 1982, J. Cerebral Blood Flow & Metabolism, 2, 55-66). In contrast, we found that these anastomoses are patent under certain occlusive conditions, allowing blood flow from the ECAs to the intracerebral circulation. Simultaneous occlusion of ICAs and ECAs elicited a CIR. Release of either one ICA or one ECA during the CIR resulted in a reversal of the CIR. Occlusion of only the ICAs or ECAs was not sufficient to produce a CIR. When the ICAs but not the ECAs were occluded, blood flow from the ECAs was sufficient to raise intracerebral arterial pressure to a level capable of preventing the initiation of the CIR or reversing the effects of an ongoing CIR. Dye injected into one ECA did not enter the cerebral circulation when one ICA was patent, but did enter the cerebral circulation when both ICAs were occluded, suggesting that flow can occur from the ECAs to the intracerebral circulation given a favorable pressure gradient.

61.32 ADRENAL MODULATION OF CEREBRAL VASODILATION ELICITED BY ELECTRICAL STIMULATION OF THE CENTROMEDIAN-PARAFASCICULAR COMPLEX IN RAT. S. Mraovitch, F. Lasbennes,* Y. Calando* and J. Seylaz.* Lab. of Physiologie et Physiopathologie Cérébrovasculaire, INSERM U 182, CNRS UA 641, Université Paris VII, Paris, France.

Recently it has been discovered that electrical stimulation of the cerebellar fastigial nucleus (FN) increased cerebral cortical blood flow (Nakai et al., Am. J. Physiol. 343 (Heart Circ. Physiol. 12) H:226-H235, 1982). Since monosynaptic projections from FN were found to terminate in the centromedian-parafascicular complex (CM-Pf) but not in the cortex, it is conceivable that increase in cortical cerebral blood flow (Cx CBF) elicited by FN stimulation may be in part mediated via diffuse CM-Pf projections through the cortex. In the present studies we sought to examine in rat whether electrical stimulation of the CM-Pf would modify regional Cx CBF (rCBF) and if so, whether the changes are mediated through neural pathways intrinsic to brain. Rats were anesthetized (chloralose), paralyzed (tubocurarine) and artificially ventilated. Arterial pressure (AP), heart rate and body temperature were continuously monitored and blood gases were measured and controlled. CM-Pf was electrically stimulated with intermittant trains (1 sec on/1 sec off) at 200 Hz and with an intensity (50-100 μA) corresponding to 3x the threshold current required for a 10 mm Hg AP elevation. At all times, AP was maintained within the autoregulated range ($<$150 mm Hg) for rat rCBF. rCBF was measured in right and left samples of 10 brain regions by the ^{14}C-iodoantipyrine technique with regional dissection. In all animals, histological localizations of stimulated sites were carefully reconstructed. In unstimulated and sham operated rats (n=7) rCBF ranged from 40$\pm$3 (ml/100g/min) in corpus callosum to 99$\pm$16 in inferior colliculus. During stimulation of CM-Pf (n=7) rCBF increased bilaterally in all cerebral regions ranging from + 118% in parietal cortex ($p<0.001$) to +38% ($p<0.001$) in cerebellum. rCBF was significantly increased in medulla, pons, inferior colliculus, superior colliculus, frontal cortex, occipital cortex, caudate-putamen and corpus callosum. The cerebral vasodilation persisted after unilateral transection of the cervical sympathetic trunk without differences in rCBF between innervated and denervated sides. In 6 rats, stimulation of sites adjacent to the CM-Pf, including the posterior nucleus of the thalamus, and ventrobasal nucleus of the thalamus, failed to modify rCBF. In contrast, acute adrenalectomy (n=6) significantly ($p<0.05$) decreased elevated rCBF during CM-Pf stimulation in all cortical regions (frontal -36%, parietal -34%, and occipital -27%) and in caudate nucleus (-37%). We conclude: (1) electrical stimulation of CM-Pf increase CBF, (2) the response is anatomicaly specific and not affected by ipsolateral cervical sympathectomy, (3) adrenal hormones probably catecholamines and circulating glucocorticoids considerably contribute to cerebral vasodilation elicited by CM-Pf stimulation. Thus, excitation of neurons originating in, or fibers passing through the CM-Pf can elicit a powerful cerebral vasodilation which appears to be mediated by intrinsic neural pathways and modulated by the adrenal hormones.

61.33 ACUTE MYOCARDIAL DAMAGE AND PLASMA CATECHOLAMINES AFTER OCCLUSION OF THE MIDDLE CEREBRAL ARTERY IN THE CAT. K.E. Smith*, V.C. Hachinski, M.D. Silver*, C. Gibson and J. Ciriello. Departments of Physiology, Clinical Neurological Sciences and Pathology, University of Western Ontario, London, Canada N6A 5C1.

Focal cerebral ischemia in humans has been shown to result in increases in plasma norepinephrine levels and cardiac arrhythmias (Stroke, 12:200, 1981; Stroke, 13: 838, 1982). In addition, systemic administration of catecholamines has been shown to cause myocardial damage (Arch Pathol., 93:356, 1972). Furthermore, we have recently shown that plasma levels of norepinephrine are elevated after occlusion of the middle cerebral artery (MCA) (Stroke, 6:136, 1985). Taken together, this evidence suggests that cerebral ischemia may produce myocardial damage as a result of activation of the sympathetic nervous system. In the present study, experiments were done in chloralosed, paralyzed and artificially ventilated cats to investigate the effects of occluding the left MCA on acute cardiac damage and its relationship to plasma catecholamine levels. The hearts were removed from the perfused cats and examined for histopathological changes. After occlusion of the MCA for 8-10 hours, 43% (8) of the hearts examined (n=19) were found to have either acute myocardial necrosis (4/8), focal hemorrhage (3/8) or both (1/8). The levels of plasma norepinephrine (+46 ± 20%) and dopamine (+143 ± 73%) were increased significantly ($p<0.025$) from pre-occlusion values (-4 ± 10% and -14 ± 19%, respectively) in these cats with acute myocardial damage compared to the cats without acute myocardial changes. These data suggest that a rise in plasma catecholamines due to increased sympathetic activity following MCA occlusion may be a causal factor for myocardial damage. (Supported by the Heart & Stroke Foundation of Ontario).

61.34 BLOOD FLOW IN THE CAUDATE NUCLEUS HAS DIFFERENT REGULATORY MECHANISMS THAT IN OTHER STRUCTURES. E. Pinard,* S. Puiroud,* and J. Seylaz* (Spon: G. Bilotto). Lab. of Physiologie et Physiopathologie Cérébrovasculaire, INSERM U 182, CNRS UA 641, Université Paris VII, Paris, France.

In view of the discrepancy related to the effect of amines or other vasoactive agents on cerebral blood flow (CBF), further studies were performed in 16 rabbits by means of a new method based on mass spectrometry (Seylaz et al., Am. J. Physiol. 245, H513-H518, 1983). This technique enables local, quantitative and continuous measurement of partial pressures of oxygen and carbon dioxide (PO_2, PCO_2) and local, quantitative and sequential (each 3 minutes) measurement of CBF. Helium was chosen as tracer gas. CBF measurements by means of this technique were validated by a systematic comparison with the results obtained in the same experimental conditions with the ^{14}C-ethanol tissue sampling technique. Several days before the experiment, gas sampling cannulas were chronically implanted in two different structures: either caudate nucleus (n=7), or thalamus (n=5), or parietal cortex (n=5), or putamen (n=8), or hippocampus (n=8). The day of the experiment, the animal was freely breathing and not anaesthetized. The cannulas were connected to the mass spectrometers, arterial pressure (AP) was recorded, and blood gases were controlled.

Previous studies (Aubineau et al., Brain Res., 61, 153-161, 1973) from our laboratory had demonstrated that: 1) isoprenaline increased blood flow in caudate nucleus (CN) and not in thalamus, 2) noradrenaline markedly decreased blood flow in CN without affecting thalamic or cortical blood flow, without any disruption of the blood brain barrier. The tentative conclusions of these studies were that these effects were due to the heterogeneity of adrenergic receptors distribution on cerebral vessels with a much higher density in the carotid territory. It was unlikely that a metabolite proposed by Berne et al. (Circ. Res. 35, 262-271, 1974) to be a link between metabolism and blood flow had regional effects on CBF, comparable to those of adrenomimetics. Nevertheless, our results expressed as mean $\pm$ SEM are the following: intravenous injection of adenosine at a dose (0.1 mg/kg/min) which induced a small decrease in AP -8.7$\pm$0.8%) caused a highly significant vasodilation in the CN (+48.0$\pm$3.0%), did not affect significantly blood flow in thalamus, cortex and putamen and had little effect on hippocampus blood flow (+12.5$\pm$4.0%).

In conclusion, the specificity of the vascular reactivity of the CN to sympathomimetic agents has been also found for adenosine. In view of the weak permeability of the blood brain barrier (BBB) to this nucleoside it is tempting to bring together the mechanism of action of all these vasoactive agents: a possible mechanism could be an indirect action via receptors located in structures devoid of a BBB and specifically related by intrinsic nervous pathways to the cerebral vessels of the CN.

61.35 CALCIUM CHANNEL BLOCKER SPECIFICITY FOR CEREBRAL VS. PERIPHERAL RESISTANCE ARTERIES IN VITRO. F.W. Marcoux and J.M. Weaver*. Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

The action of calcium channel blockers on vascular smooth muscle is now well documented. Indeed, clinical trials are ongoing as efforts to establish therapeutic utilities for these inhibitors of vasoconstriction. Few studies, however, have compared the activities of these compounds on arterial resistance segments from different vascular beds. We examined in vitro the activity of 4 structurally different calcium channel blockers, diltiazem, flunarizine, nimodipine and verapamil, on cerebral and peripheral arterial resistance segments which were taken from the same rat. Middle cerebral (MCA) and mesenteric arterial resistance (MTR) segments (<200μ in diameter) were mounted in parallel myographs and equilibrated in artificial CSF. The arterial segments were constricted with their respective EC_{90} concentrations for K+ and then exposed in a non-recirculating manner to increasing concentrations of one of the calcium channel blockers (10^{-10} - 10^{-4}M in ½ log increments). Concentration-inhibition curves constructed from the geometric mean $IC_{5,10,50,90}$ and 95_S for each calcium channel blocker in MCA and MTR segments were compared.

All 4 calcium channel blockers inhibited K+-induced constrictions in a concentration dependent fashion. Diltiazem and verapamil inhibited K+-induced constrictions in MCA and MTR segments in 2 phases, affecting first the secondary plateau phase of the contractile response and then, at higher concentrations, the initial peak phase. With diltiazem, the initial peak phase of the contractile response was inhibited more potently in MTR than in MCA segments. With verapamil, the secondary plateau phase of the contractile response was inhibited more potently in MTR than in MCA segments. Flunarizine and nimodipine showed single phase inhibition of the K+-induced response and both were approximately 5 times more potent in MCA than in MTR segments.

Thus, diltiazem and verapamil inhibited K+-induced vasoconstriction in a fundamentally different way than did flunarizine and nimodipine. Flunarizine and nimodipine showed clear specificity for middle cerebral vs. mesenteric arterial segments. Whether these differences in activity demonstrated with resistance arterial segments invitro will contribute to our understanding of the relative therapeutic benefits for each of the drugs in vascular disease will require further study, both experimentally and in the clinic.

61.36 INNERVATION OF CEREBRAL BLOOD VESSELS BY PEPTIDERGIC NERUONS Kunio Nakai,Toru Itakura*, Kazuo Nakakita*,Hideyoshi Yokote*, Yutaka Naka*, Ichiro Kamei,Harumichi Imai* and Norihiko Komai*. Dept. of Neurological Surgery,Wakayama Med. College,Wakayama 640 Japan

Evidences that peptide-containing neurons as well as aminergic neurons may be involved in regulating the cerebral blood flow have recently been cumulating(Edvinsson,TINS.,5.425,1982;8:126,1985; Eckenstein and Baughman.Nature,309:153).Present study further investigated peptide-containing neurons along the cerebral blood vessels comparing with other neurotransmitter system such as noradrenaline using PAP-immunohistochemistry and hydrogen clearance method.Guinea pigs weighing 200-300 g were perfused through ascending aorta with 4% paraformaldehyde , 0.5% glutaraldehyde and 0.2% picric acid in cold phosphate buffer(pH=7.4) under deep anesthesia with Nembutal (50 mg/kg). After postfixation pial arteries and cryocut brain sections(20μ) were placed in 0.1% triton X-100 in phosphate buffered saline until the day of immunostaining using anti-VIP,-SP or dopaminebeta hydroxylase(DBH) as primary antibodies. In general nerve fibers within vascular adventitia showed denser distribution in the anterior part of circle of Willis. Nerve plexus gradually decreases its density as caliber of the vessel decreases. VIP immunopositive fibers along pial arteries characteristically showed spiral running pattern throughout the intracranial pial arteries. Ultrastructural observation of VIP positive fibers along pial arteries demonstrated that about 80% of VIP positive fibers within vascular adventitia lay very close to vascular smooth muscles(within one micron).Within the cerebral cortex VIP positive cell bodies and fibers are numerous (Morrison et al.,Brain Res.,292:269,1984). Some of those VIP neurons were found very close to intraparenchymal blood vessels. In contrast, SP immunopositive fibers along pial arteries run in a mesh-work pattern and lay relatively apart from the vascular smooth muscles. Neither a nerve terminal nor a cell some immunostained with SP was found within the cerebral cortex. DBH immunopositive fibers along pial arteries showed mainly spiral pattern in the arteries near the bifurcation of middle cerebral arteries, although they tended to show mesh-work running pattern as the vessel caliber decreased. Some of DBH immunopositive fibers within the cerebral cortex showed close contact with intraparenchymal blood vessels.

Using hydrogen clearance method we have observed a significant increase of regional cerebral blood flow(r-CBF) by intracortical injection of VIP,a significant decrease by injection of noradrenaline and no significant change by SP.

Above results suggest that VIP neuron plays an important role in regulating cerebral blood flow by increasing it through a direct action on both pial and parenchymal vessels and further suggest a possibility of VIP being a useful therapeutic drug for an ischemic stroke of the central nervous system.

61.37 RECOVERY OF CARDIOVASCULAR FUNCTION AFTER CHEMICAL SYMPATHECTOMY WITH 6-HYDROXYDOPAMINE. S.J. Fluharty*, M.J. McCann*, S.A. Meyers*, R.R. Vollmer*, M.J. Zigmond and E.M. Stricker. Depts. of Biological Sciences, Pharmacology and Psychology, Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Catecholamine (CA)-containing neuronal systems can sustain substantial damage without severe disturbance of function. We have proposed that such plasticity results from adaptations to the injury that occur in residual elements of the damaged system, and have been evaluating this hypothesis by examining cardiovascular function in pithed rats after systemic treatment with 6-hydroxydopamine (6-HDA). Although sympathetic innervation of the heart was decreased by >90% for several weeks, chronotropic responses to thoracolumbar stimulation were normal within 3 days of 6-HDA treatment. Bilateral adrenalectomy had no significant effect on chronotropic responses elicited by 20 sec pulses of increasing frequency, either in control animals or in 6-HDA-treated rats. Restoration of function therefore may have resulted from enhanced synthesis and release of norepinephrine (NE) from surviving sympathetic terminals. Indeed, tyrosine hydroxylase activity in undamaged neurons of the heart was increased 3-fold relative to NE levels at this time. Moreover, blockade of CA biosynthesis with alpha-methyltyrosine (AMT; 300 mg/kg) substantially reduced the heart rate responses in 6-HDA-treated rats with intact adrenals, whereas it had no such effect in control animals.

Similar results have been obtained using continuous preganglionic stimulation with 0.5 Hz for 20 min. Heart rate increased rapidly during the first 5 min, and by 20 min it was elevated by almost 150 beats/min in control animals (more than twice the increase after 20 sec of stimulation with 0.5 Hz). AMT treatment had little effect on this response either in control animals or in adrenalectomized rats. Although prolonged preganglionic stimulation also increased heart rate in 6-HDA-treated rats, to levels that were 60% of normal despite cardiac NE depletions greater than 95%, this tachycardia was reduced significantly by AMT treatment and it was eliminated completely if AMT was given to 6-HDA-treated rats that also had been adrenalectomized.

These results suggest that biochemical adaptations allowing enhanced synthesis and secretion of CA within residual sympathetic nerves may have an important functional impact on the heart after near-total denervation induced by systemic 6-HDA treatment. Moreover, they indicate that adrenal medullary CAs make a significant contribution to cardiac responsivity after 6-HDA treatment when the capacity for NE synthesis in the surviving sympathetic nerves had been exhausted.

61.38 **THE INTRACARDIAC INNERVATION OF THE CARDIAC VENTRICLES IN THE RAT - A RETROGRADE FLUORESCENT TRACER STUDY.** **B.J. Pardini, P.G. Schmid, and D.D. Lund. Veterans Administration Medical Center and Cardiovascular Center, Department of Internal Medicine, University of Iowa, Iowa City, Iowa 52240.**

Prior studies from this laboratory have described the topographic location and number of intracardiac ganglion cells in the rat - sites of termination for cardiac vagal preganglionic neurons (Soc. Neurosci. Abstr. 10:607, 1984). The ganglion cells are located in four distinct regions of the heart, all above the atrio-ventricular groove: 1) between the superior vena cava and aorta, 2) superior and posterior to the interatrial septum, 3) posterior to the left atrium, and 4) posterior to the right atrium. The high degree of interanimal reproducibility and localization of the ganglion cells to these topographic areas suggest a certain amount of anatomic organization. The purpose of the present experiments was to determine if the organization of the intracardiac ganglion cells extended beyond the location of their somata to include the sites at which they terminate. The fluorescent dyes, Fast Blue and rhodamine-labeled microspheres, were used to retrogradely label cell somata which projected to the free wall of the left ventricle in the rat. Equithesin-anesthetized rats were intubated and respired by positive pressure. After a right thoracotomy, multiple injections of Fast Blue or rhodamine-labeled microspheres were made in the ventricular wall with a glass micropipette attached to a Hamilton 10 ul syringe. Three to four injections of 1 to 2 ul each were made into the ventricular wall. After closure of the chest, the rats were extubated, and allowed to survive for 48 to 96 hrs. Rats were perfused with saline followed by 10% buffered formalin; hearts were excised and 25 um frozen sections were cut on a Cryostat. Sections were viewed through an Olympus microscope with fluorescent attachment. After injections into the left ventricle, clusters of labeled ganglion cells were seen in the area of the interatrial septum and posterior to the left atrium (areas 2 and 3, above). No labeled somata were seen in the vicinity of the aorta and superior vena cava (area 1) or posterior to the right atrium (area 4). Preliminary experiments indicate that there are no labeled cells in the parasympathetic preganglionic areas of the medulla, providing evidence that vagal preganglionic neurons probably do not terminate in ventricular regions which are void of ganglion cells, and that dye did not spread to atrial regions or through the blood to artifactually label neurons. The data indicate that individual loci of intracardiac ganglion cells may have organized projections to specific sites of termination at the neuroeffector junction in the ventricle.

62.1 REGIONAL SPECIALIZATION OF THE BASAL GANGLIA: THE CORTICOSTRIATO-PALLIDAL SYSTEM IN THE RAT OLFACTORY TUBERCLE. D.S. Zahm[1] and Lennart Heimer. Department of Neurology, Univ. of Virginia School of Medicine, Charlottesville, VA. 22908. [1]Currently: Department of Anatomy, St. Louis Univ. Sch. of Medicine, St. Louis, MO. 63104.

The stability in the fundamental organization of the cortico-striatopallidal (CSP) system, despite the diversity of relationships of its various levels with different parts of the brain, leads us to suspect that CSP circuitry provides a cellular mechanism indispensible to neural processing as it is carried out by nearly the entire forebrain. Understanding, however, has been impeded by the absence of a suitably simple model in which input-output relationships might be investigated. The part of the CSP system in the olfactory tubercle (OT) is unique because of the direct and profound influences exerted upon it by responses to olfactory stimuli. OT striatum receives a dense projection from mitral and tufted cells in the olfactory bulb and a massive input from primary olfactory cortex. Other afferents which buttress OT striatal character include tyrosine hydroxylase and cholecystokinin immunoreactive fibers from the midbrain, serotonergic fibers from the raphe, and projections from the amygdala and thalamic intralaminar nuclei.

We have provided additional details about this most ventral part of the basal ganglia using contemporary light and electron microscopic tract tracing methods in combination with immunocytochemical analysis. Despite its diverse input, the output of OT striatum as demonstrated by transported Phaseolus vulgaris-leucoagglutinin appears to end topographically and exclusively in typical striatopallidal synaptic configurations within the polymorph layer of the OT and subcommissural ventral pallidum (VP). Correspondingly, VP in the polymorph OT has fewer efferent targets than more dorsal, subcommissural parts of VP, globus pallidus (GP), or entopeduncular nucleus (EP), projecting significantly only to mediodorsal thalamus and the midbrain ventral tegmental area. As the whole extent of VP, by virtue of dense terminal staining with antisera against glutamate decarboxylase, enkephalin, and substance P, is regarded as neurochemically distinct from GP and EP, VP in the OT polymorph layer can be further distinguished because it lacks terminal staining against neurotensin antiserum, which is a moderate to heavy marker of the subcommissural part of VP and a medial-most strip of GP. Although the origin of neurotensin axon terminals in pallidum requires further investigation, the absence of that marker in the most ventral part of VP further supports our impressions that it is organized more simply than more dorsal parts of the CSP system. Further investigations into the potential offered by the OT as an experimental model of basal ganglia cellular mechanisms are warranted. Supported by NIH grants NS17743 and NS 01799.

62.2 **Functional compartments of the cat striatum.** **A.Jayaraman.** Dept. of Neurology, Louisiana State University School of Medicine, NewOrleans, Louisiana, 70112,USA.

A precise knowledge of the organization of the projections from functionally defined cortical areas is fundamental to our understanding of the functions of the striatum (and the basal ganglia). Recent studies have shown that the rat caudatoputamen may be divided into a medial limbic and a lateral nonlimbic compartment. A detailed analysis of the projections from cytoarchitectonically defined cortical areas suggests that the nucleus accumbens (NA) and caudate nucleus (CN) may have several functional subcompartments. Stereotaxic injections of 0.05 µl of 2% WGA-HRP were placed into the NA and CN in 27 cats. After 24 -36 hrs, the animals were deeply anesthetized, sacrificed, the 40µ thick brain sections were processed for HRP histochemistry. These sections were studied using dark- and brightfield microscopy. Injections in medial NA resulted in selective labeling of cells of CA 1 and subicular regions thereby confirming the hypothesis that the medial NA is the **"hippocampal district"(HD)** of the striatum. Lateral NA injections led to labeling of cells in the prelimbic cortex (area 32), infralimbic cortex (area 25), the entorhinal cortex (area 27), the perirhinal cortex (areas 35 and 36), and the agranular insular cortex. These cortical areas are known to be reciprocally connected with each other. The agranular insular cortex and the infralimbic cortex, the cortical representation areas for gustatory, cardiac, respiratory, and gastric responses, project monosynaptically to the nucleus of tractus solitarius, a major center for visceral responses in the brain stem. This connectivity pattern suggests that the lateral NA receives major projections from cortical areas that are concerned with visceral responses. This sector of the striatum may be called the **"autonomic" or "visceral striatum"(AS)**. Medial caudate injections labeled cells of area 6 aß, the ventro- and dorsolateral orbital cortex, the granular insular cortex, the ventral retrosplenial cortex, the cingulate gyrus, areas 7, 21a, 21b of the suprasylvian gyrus, the dorsoposterior and ventral regions of the posterior ectosylvian gyrus, and the posterior sylvian gyrus. The medial CN is called the **"cognitive striatum"(CS)** since it receives projections from these complex multimodal association areas of frontal, parietal, insulotemporal, and occipital cortex,which are involved in integrative, language and cognitive functions. Since the medial CN receives projections from several cortical areas which have neurons with oculomotor properties, viz., area 6 aß (the frontal "oculomotor" area), area 7, insular cortex, this area of the striatum may also subserve oculomotor functions. The lateral CN receives major projections from the primary motor cortex (area 4), and less dense projections from areas 6 aß, 3,1, and 2 and this region is called as the **"sensory-motor striatum" (SMS)**.

62.3 **CIRCUITRY OF THE PEDUNCULOPONTINE NUCLEUS REVEALED WITH FLUORO-GOLD. EVIDENCE FOR A PALLIDAL-TEGMENTAL-SPINAL PROJECTION.** By L.C. Schmued and J.H. Fallon, Dept. of Anatomy, Univ. of California, Irvine.

This study employed a novel fluorescent dye useful for demonstrating retrograde axonal transport. This tracer exhibits numerous advantages over other similarly used compounds in terms of sensitivity, extent of cellular label, permanence, emission intensity, limited uptake by intact axons, compatability with other histochemical techniques, and wide latitude of survival times. This dye, Fluoro-Gold (Fluorochrome Inc. P.O. Box 4983, Englewood, Colorado 80155) was pressure injected as a 3.5% solution. Survival times ranged from one day to one month. Short survival times resulted in gold colored granules in the cytoplasm with frequent axonal label. Longer survival times resulted in extensive staining of dendritic processes.

Initially, the gray matter of the upper thoracic spinal cord of albino rats was injected with Fluoro-Gold. Many nuclei known to project to the spinal cord contained retrograde label. Of particular interest was the retrograde label seen in the pontine tegmentum region corresponding to the areas described physiogically as the mesencephalic locomotor region and anatomically as the pedunculopontine nucleus.

This area was subsequently injected with the dye to determine its afferents. The following regions were found to project to these mesencephalic regions: substantia nigra (especially in pars lateralis, and to a lesser extent, in pars compacta and pars reticulata, subthalamic nucleus, zona incerta, globus pallidus (ventral caudal portion), entopeduncular nucleus, bed nucleus of the stria terminalis, and central nucleus of amygdala.

The third phase of this study involved injecting the above structures with an anterograde tracer (^{3}H-adenosine or PhA-L lectin) to verify these connections. Tissue injected with ^{3}H-adenosine was processed for autoradiography and resulted in silver grains over potential postsynaptic neurons. Tissue injected with PhA-L lectin was processed for immunocytochemistry and demonstrated entire axons and terminals.

The last phase of the experiment involved combining anterograde transport from the aforementioned pallidal regions with retrograde dye transport from the spinal cord. In these cases, anterogradely labeled axons from the globus pallidus or substantia nigra could be seen in close proximity to, and sometimes running alongside of the dendrites of cells in the pedunculopontine nucleus retrogradely labeled from spinal cord injection. Although it is not possible to prove the existence of synaptic terminals with light microscopy, this evidence supports the notion of a direct motor output from pallidum to mesencephalon to spinal cord. Conceptually, these pathways may provide a significant route whereby information exits loops of the extrapyramidal motor system to ultimately innervate motor neurons of the spinal cord. Methodigically, we feel this work demonstrates the superiority of Fluoro-Gold as a retrograde tracer. Supported by grant NS 15321.

62.4 PROJECTIONS FROM THE NUCLEUS TEGMENTI PEDUNCULOPONTINUS TO THE THALAMUS IN THE RAT. B.M. Spann and I. Grofova. Department of Anatomy, Michigan State University, E. Lansing, MI. 48824.

In the rat, the nucleus tegmenti pedunculopontinus (PPN) has been demonstrated to correspond to the mesencephalic locomotor region. The nucleus has been shown to have reciprocal connections with various basal ganglia nuclei and to give rise to a descending projection to the spinal cord. In addition, it provides a prominent cholinergic input to the intralaminar nuclei of the thalamus. Several retrograde transport studies have indicated that the PPN-thalamic connection is both crossed and uncrossed but neither the extent of crossing nor the presence of axonal collateralization have been established.

In the present study a series of experiments were carried out to determine the distribution of thalamic projecting neurons in PPN and to test for the presence of collateralization. In the first set of experiments 0.05µl of 2% HRP-WGA solution was stereotaxically injected into the parafascicular nucleus (Pf) and also involved other intralaminar nuclei. The majority of labeled neurons were located ipsilaterally in a dorsolateral region of PPN which has been identified by Sugimoto and Hattori as the nucleus tegmenti pedunculopontinus pars compacta (PPNc), (Neuroscience, 11, 931-946, 1984). The present study confirmed the presence of a prominent contralateral PPN projection to thalamus. Of the labeled neurons projecting to intralaminar nuclei, 21% were located contralaterally while the remaining 79% were ipsilateral. Furthermore, the contralateral neurons exhibited the same distribution pattern as that seen ipsilaterally. Thalamic projecting cells were either fusiform or multipolar in shape and varied in sizes from 19 to 42µm along the longest axis.

In the second set of experiments Granular Blue (GB) and Diamidine Yellow Dihydrochloride (DYD) were stereotaxically injected ipsilaterally and contralaterally, respectively in the Pf of the rat. The dyes also diffused to adjacent thalamic regions but did not extend to subthalamus. The distribution and morphology of the labeled neurons were similar to that described above. While approximately 85% of the labeled neurons in PPNc projected ipsilaterally to the intralaminar nuclei, the remaining 15% projected contralaterally. Furthermore, no distinct separation of the two populations of PPNc projection neurons was observed. Less than 5% of the PPNc projection neurons possessed collaterals branching to both the ipsilateral and contralateral intralaminar nuclei.

62.5 TOPOGRAPHIC DISTRIBUTION OF CONNECTIONS FROM THE PRIMARY MOTOR CORTEX TO THE CORPUS STRIATUM IN THE OWL MONKEY. H.J. Gould, III and R.H. Whitworth, Jr.* Dept. of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70119.

Projections from motor cortex to corpus striatum were studied in a new world monkey, Aotus trivirgatus. Microstimulation mapping techniques were used to identify specific portions of the primary motor map (Gould et al., '83, Soc. Neurosci. Abst., 9:309). Identified stimulation sites were subsequently injected with wheat germ agglutinin conjugated to horseradish peroxidase. After survival times of 36 to 48 hours, the animals were perfused and the brains were removed from the skull, blocked and cut frozen in the coronal plane. Sections processed with tetramethyl benzidine for peroxidase activity were mounted on slides and examined with the light microscope.

All injection sites were confined primarily to cortical Area 4 and were responsive to current levels between 1.0 and 5.0 μA when presented in trains of 24 pulses. Each pulse in a train was 0.2 msec in duration and was presented at a frequency of 300-350 Hz. The major projections from the primary motor cortex to the corpus striatum terminate bilaterally in the putamen. The general topographic orientation of the representation of body parts presents with the hindlimb located dorsally, adjacent to the cortical white matter and the head ventrally. The most ventral portion of the putamen is free of labelled terminations. The densest terminations are organized into bands that extend between the subcortical white matter laterally and the internal capsule throughout the rostral to caudal length of the putamen. More broadly distributed, sparser terminations are also found to form a much more complex pattern. Contralateral projections to the putamen are found in the same general distribution but are much less dense and appear to be somewhat more restricted in rostrocaudal extent.

Dense terminations in the caudate nucleus are discontinuous and restricted to cell islands located along the medial aspect of the internal capsule. Less dense terminations are confined to fewer cell islands along the medial aspect of the contralateral caudate nucleus. Sparse labelling is also observed in the dorsal-most aspect of the ipsilateral claustrum.

These results are consistent with those reported earlier for old world monkeys (Kunzle, '75, Brain Res., 88:195; Jones et al, '77, J. Comp. Neurol., 173:53; Liles and Updyke, '85, Brain Res., in press) and suggest that there is a general topographic organization in the primate putamen. The differences in the pattern of dense versus sparse terminations within the putamen may reflect differences in the function of the corticostriate projection.

62.6 SOMATOMOTOR, OCULOMOTOR AND HIGH-ORDER PATHWAYS THROUGH BASAL GANGLIA OF CAT. I.M. Jeffers and C.R. Olson, Psychology Department, Princeton University.

INTRODUCTION. The aim of the experiments reported here was to characterize neural connections between the basal ganglia and cortical areas serving somatomotor, oculomotor and high-order functions. In neuroanatomical tracer experiments, connectional topography was analyzed at each stage of the loop leading from cerebral cortex to caudate nucleus to entopeduncular nucleus to ventral thalamus to frontal cortex.

(1) Cortico-caudate topography. In 7 cats, we placed deposits of nuclear yellow (NY) and bisbenzimide (Bb) at separate sites in the head of the caudate nucleus, then analyzed the distribution of retrogradely labeled cells in cerebral cortex. Dorsolateral caudate injections gave rise to retrograde labeling of primary motor cortex and of cortical areas to which it is linked. Dorsomedial injections gave rise to retrograde labeling of the medial frontal eye field and of cortical areas projecting to it. Ventromedial injections labeled prefrontal cortex and related cortical areas.

(2) Caudate-entopeduncular topography. In the same cases, we charted anterogradely labeled axon terminals in the entopeduncular nucleus. Tracer deposits in dorsolateral, dorsomedial and ventromedial divisions of the caudate nucleus produced terminal labeling in lateral, intermediate and medial divisions of the entopeduncular nucleus respectively.

(3) Entopeduncular-thalamic topography. In 5 cats, we placed deposits of NY and Bb in ventral thalamus, systematically varying the mediolateral placement of the deposit. More medial thalamic deposits gave rise to more medial retrograde labeling in the entopeduncular nucleus.

(4) Thalamo-cortical topography. In 8 cats, we placed deposits of NY and Bb in a cortical zone encompassing the ventral bank of the cruciate sulcus and the adjacent medial face of the frontal pole. As injection-sites moved from somatomotor cortex (deep in the cruciate sulcus) through the medial frontal eye field (close to the sulcal lip) to prefrontal cortex (on the medial face of the hemisphere), labeled cells in the ventral thalamic complex assumed progressively more medial locations.

CONCLUSION. Topographic connectional patterns revealed by this study are compatible with the notion (first proposed for primate by DeLong) that cortical areas with somatomotor, oculomotor and high-order functions project in parallel through the basal ganglia and thalamus to separate divisions of the frontal lobe serving those functions.

62.7 LOCAL PROJECTIONS WITHIN THE DIAGONAL BAND DEMONSTRATED BY ANTEROGRADE TRANSPORT OF PHASEOLUS VULGARIS - LEUCOAGGLUTININ (PHA-L). H.R. Brashear*, D.S. Zahm*, and L. Heimer (SPON: F.E. Dreifuss). Department of Neurology, University of Virginia School of Medicine, Charlottesville, Virginia 22908.

Studies of axonal transport from neurons in the nuclei of the diagonal band (DB) with tritiated amino acids or wheatgerm agglutinin-horseradish peroxidase have emphasized long projections. Golgi impregnated material, however, reveals that many DB neurons have extensive local axon arborizations and suggests that longer intranuclear connections are present as well. Immunohistochemical demonstration of the anterogradely transported plant lectin Phaseolus vulgaris - leucoagglutinin (PHA-L), introduced by Gerfen and Sawchenko (Brain Research, 290:219-238, 1984), permits further investigation of short DB projections.

Iontophoretic injections of PHA-L were placed in the nuclei of the vertical and horizontal limbs of the DB and the anterogradely transported tracer was localized with the biotin-avidin immunoperoxidase method. The discrete nature of the PHA-L injections frequently allowed the study of neurons limited to the DB, which were impregnated in a Golgi-like manner. Labeled perikarya at the injection sites were medium to large with fusiform to polygonal shapes. The large dendritic arbors of these neurons frequently extended across the entire breadth of the DB. Dendrites and cell bodies had few visible spines. Axons with multiple varicosities extended conspicuously along the longitudinal dimensions of the DB. Some of these axons gave off multiple very short collaterals within the DB. Injections in ventral parts of the DB produced numerous clusters of terminals in dorsal parts of the DB near the medial septal nucleus. Bifurcating axons, one branch of which lacked visible terminals, suggested that some of the terminals present in DB arise from collaterals of longer projections. Other labeled axon segments could be seen ending in multiple terminals close to the injection site. Further study will clarify whether these latter fibers arise as collaterals from projection neurons or if some DB neurons have axonal arborizations which remain entirely within DB. These observations suggest that intrinsic connections play an important role in the organization of the neuronal circuitry of the DB.

62.8 THALAMOSTRIATE PROJECTIONS FROM THE VENTRAL ANTERIOR THALAMIC NUCLEUS IN THE DOG. D. Tanaka, Jr., L. G. Isaacson*, and B.K. Trosko*. Department of Anatomy, Michigan State University, East Lansing, Michigan 48824.

Previous studies using retrograde tracing techniques have demonstrated a projection from the ventral anterior thalamic nucleus (VA) to the neostriatum. However, details concerning the topography and patterns associated with VA thalamostriate terminal fields have not been described. In the present study, we examined the distribution and organization of VA thalamostriate projections and terminal fields using both anterograde and retrograde tracing techniques.

Injections of tritiated leucine and proline were made into the rostrolateral, caudomedial, and caudal-intermediate parts of VA in 3 dogs. In each case, the densest accumulations of label were located adjacent to the internal capsule in the dorsal and lateral parts of the head of the caudate nucleus. Projections from caudal VA were located slightly more caudally and ventrally in the caudate than were those from rostral VA. Dense aggregations of silver grains were scattered throughout areas containing more diffuse and widespread label. At some levels small amounts of label were also noted in the dorsal part of the putamen.

Lectin-conjugated horseradish peroxidase was injected into the head of the caudate nucleus in 4 dogs. Small injections into the dorsolateral corner of the caudate resulted in clusters of retrogradely labeled neurons forming a dorso-ventrally oriented arc in the most lateral part of VA. Larger injections placed mid-laterally in the caudate resulted in a more widespread distribution of neurons located in the mid-region of VA. In both cases, the labeled neurons extended throughout the rostro-caudal extent of VA and into the rostral part of the ventral lateral nucleus. Injections placed medially in the caudate resulted in only a few labeled cells located in the dorsal and medial parts of VA.

These results indicate that VA projects topographically to a widespread region in the head of the caudate nucleus, with the lateral and mid-portions of VA projecting heavily to the dorsal and lateral caudate and medial VA projecting sparsely to medial caudate. Since there is evidence to suggest that VA, the basal ganglia, and cortical area 6 may form part of a neural circuit involved with the sequencing of motor activities, it is of particular interest that the densest VA thalamostriate projections appear to terminate in the same region of the caudate that receives the densest projection from area 6.

(Supported by NIH Grant NS16991 and BRSG funds to the College of Veterinary Medicine).

62.9 INTERRELATED ORGANIZATION OF CORTICOCORTICAL AND CORTICOSTRIATAL PROJECTIONS: A MULTIPLE RETROGRADE LABELING STUDY IN THE CAT. R.S. Fisher, M.K. Boylan, M.S. Levine, C.D. Hull, and N.A. Buchwald. Mental Retardation Research Center, UCLA School of Medicine, 760 Westwood Pl. Los Angeles, CA 90024.

Multiple retrograde labeling methods were used to demonstrate the axonal branching and crossing of the corticocortical and corticostriatal projections of 10 adults cats. Single markers (lectin-bound horseradish peroxidase, nuclear yellow and/or fast blue) were pressure-injected into area 4 of the precruciate gyrus of the neocortex (Cx) and into one or both of the caudate nuclei (Cds). Labeled neurons were demonstrated by combined brightfield and epifluorescent illumination in the uninjected area 4 of the Cx.

Both single and multiple labeled neuronal somata were most prevalent in area 4 of the uninjected Cx. All possible combination of labeling including triple-labeled cells (3 collaterals: commissural corticocortical fibers, decussated corticostriatal fibers and undecussated corticostriatal fibers) were evident. Both the corticocortical and corticostriatal projections originated from a single line of small-to-medium size pyramidal neurons (somatic areas = 129$\pm$ 5μm^2; nuclear areas = 33 $\pm$2 μm^2). These somata were located in both the supra- and infragranular laminae and composed up to 40-50% of all Cx neurons in the regions of the greatest density of labeled cells.

Thus, corticofugal projections to the neocortex and neostriatum demonstrated a rich variety of complex axonal branching and decussation. Collateralized afferents to the Cx and Cd arise from cortical as well as subcortical neurons. The branched corticofugal projections are important because they may subserve intra- as well as interhemispheric connectivity. Supported by USPHS Grant AG 01558, HD 05958.

62.10 THE ROLE OF N-METHYL-D-ASPARTATE (NMDA) MEDIATED EXCITATION, AND CHOLINERGIC MUSCARINIC AND GABAERGIC NEUROTRANSMISSION WITHIN THE RAT VENTROMEDIAL THALAMIC NUCLEUS (VM) IN MOTOR CONTROL. T. Klockgether*, M. Schwarz*, L. Turski*, K.-H. Sontag*. (SPON: J. Noth). Max-Planck-Institute for Exp. Medicine, Hermann-Rein-Str. 3, 3400 Göttingen, F.R.G.

The rat ventromedial thalamic nucleus (VM) is a point of convergence of several anatomical pathways involved in motor function. This nucleus receives GABAergic fibers from the substantia nigra pars reticulata, cerebellar fibers, which possibly use acetylcholine and cortical fibers which use glutamate as their transmitter. The VM is the source of a widespread projection to almost the entire neocortex. To investigate the role of neurotransmitters within the VM in motor control behavioural tests were performed in rats receiving microinjections of transmitter specific drugs into the VM. In addition, electromyographic (EMG) signals were registered from several muscles in awake, unrestrained rats.

The GABA agonist muscimol (MSC) (10-50 ng) and the N-methyl-D-aspartate (NMDA) antagonist 2-amino-7-phosphonoheptanoic acid ((-)AP7) (25-250 ng) injected bilaterally into the VM induced a state of immobility which is generally referred to as catalepsy, whereas the muscarinic antagonist N-methyl-scopolamine (SCOP) (0.5-5.0 µg) was devoid of a behavioural effect. Both, the (-)AP7 (100 ng) and the MSC (25 ng) induced catalepsy were found to be dose-dependent and site specific. The (-)AP7 (100 ng) induced catalepsy was antagonized by both, NMDA (100 ng) and the GABA antagonist bicuculline (BIC) (100 ng). The MSC (25 ng) induced catalepsy was antagonized by both, BIC (100 ng) and NMDA (100 ng).

EMG analysis did not reveal relevant differences between the behavioural state induced by injection of MSC or (-)AP7 into the VM. In both cases, animals displayed a tonic EMG-activity in the gastrocnemius muscle which is considered to reflect limb rigidity. The animals were unable to initiate limb movements or locomotion due to an inability to produce phasic EMG bursts. On the other hand, the muscular reactions which serve to maintain or reinstate the animals static equilibrium were intact.

The present results suggest that the balance between NMDA mediated excitation and GABAergic inhibition within the VM represents a critical factor (1) for the development of limb rigidity and (2) for the animal's motility. The failure of SCOP injected locally into the VM to induce a behavioural effect may be interpreted in terms of a weak cholinergic muscarinic tone in the nucleus.

The study was supported by a grant from the Deutsche Forschungsgemeinschaft (So 136/3-1).

62.11 THREE-DIMENSIONAL RECONSTRUCTION OF THE TOPOGRAPHY OF CORTICO-STRIATAL PROJECTIONS IN THE RAT. J.K. Chapin, M. Sadeq, W.K. Smith, D.S. Schlusselberg, and D.J. Woodward. Dept. of Cell Biology and Anatomy, U. of Texas Health Sci. Cntr., Dallas, Tx. 75325.

The three-dimensional topography of the cortico-striatal projection system in the rat was investigated through use of the orthogradely transported lectin PHA-L. Pressure or iontophoretic injections of PHA-L were made in electrophysiologically and cytoarchitectonically defined subregions of the frontal and parietal cortices. A microscope-computer based system for acquisition and display of neuroanatomical data was used for 3-D reconstruction of the pattern of terminal labelling observed in serial coronal sections.

Overall, injections in the frontal cortex produced a distinctly different pattern of terminal labelling in the striatum than injections in the parietal cortex. Frontal cortico-striatal projections typically coursed posteriorly from the injection site, and terminated in the ventro-lateral quadrant of the striatum. Parietal cortico-striatal projections coursed anteriorly from the injection site and terminated in the dorso-lateral striatal quadrant.

For example, the 3-D pattern of cortico-striatal terminal labelling from the MI forelimb cortex (in caudo-lateral frontal cortex) resembled a rostro-caudally elongated wedge extending posteriorly from the region of the injection site. This wedge was formed by sprays of axons spreading ventro-laterally from the MI corticofugal bundles descending through the striatum. In more caudal coronal sections this labelling could in many cases be observed to divide into an inner core and an outer shell. By contrast, the 3-D pattern of labelling resulting from injections in the caudo-lateral SI cortex resembled an elongated shell following the dorso-lateral border of the striatum up to 4 mm anterior to the injection site. More medially placed SI cortical injections labelled this outer shell, plus a concentric inner shell. Within their respective target zones, projections from both parietal and frontal cortices followed a medio-lateral and a rostro-caudal topography, ie. more rostro-medial cortical injection sites projected to more rostro-medial sites in the striatum.

In conclusion, this investigation revealed markedly different patterns of projection to the striatum from the frontal cortex, as compared with the parietal cortex. Nevertheless, within these categories, a traditional rostro-caudal and medio-lateral topography was maintained. Supported by grants NS18041, AA03901, and the Biological Humanics Foundation.

62.12 COMPUTER-AIDED MAPPING AND RECONSTRUCTION OF THE STRIATO-PALLIDAL PROJECTION IN THE RAT. V.B. Domesick, P.A. Paskevich* and S.W. Matthysse. Depts. of Anatomy and Psychiatry, Harvard Medical School and McLean Hospital, Belmont, MA 02178.

Findings reported during the past decade support a dualism in the innervation of the rostral striatum of the rat. Whereas a large, ventromedial part of the region receives substantial, partly overlapping projections from a variety of structures implicated in the circuitry of the limbic system (hippocampal formation, amygdala, frontocingulate cortex, ventral tegmental area), a smaller dorsolateral sector of the rostral striatum receives only sparse limbic afferents but is densely innervated by the sensorimotor cortex (for a review see Kelley, Domesick and Nauta, 1982). Concurrently, the globus pallidus has been redefined - morphologically as well as histochemically - to include a rostroventral extension, the ventral pallidum of Heimer and Wilson (cf. Haber and Nauta, 1982). The present communication reports an attempt to determine the extent to which the dualism in the innervation of the striatum corresponds to the subdivision of the globus pallidus into a dorsal and ventral pallidum.

In order to study the striato-pallidal projection by the aid of autoradiographic tracing methods, small iontophoretic injections of ^{3}H-Proline^{3}H-leucine were placed throughout the caudatoputamen and nucleus accumbens. The results were mapped and reconstructed on standard rat brain sections by computer-aided methods.

For the purpose of charting the autoradiographic data, an Apple IIe microcomputer was used to control an interactive video imaging and display system which allows us to superimpose computer-generated diagrammatic and densitometric displays over the video transmitted microscopic images. The data thus obtained were used to provide contours for the reconstruction of consecutive sections with a second system using a digitizing tablet linked directly to a 32 bit super mini-computer. The software required to perform three-dimensional reconstructions, calculate volume, surface area, and statistical analysis were developed by us to suit our specific needs.

The results show that the topography of the striato-pallidal projection reflects the dual organization of the striatum. The dorsolateral, non-limbic sector was found to project to the classically defined globus pallidus whereas the limbic, ventromedial sector projects to the ventral pallidum with preservation of the medial to lateral and dorsal to ventral topography. These findings suggest the existence of two parallel trans-striatal conduction lines, one through the dorsal pallidum, the other through the ventral pallidum. Supported by grants NIMH 5P01 MH31154 and NIH 1R01 NS19945.

62.13 **A COMPUTER MODEL OF THE NEOSTRIATAL SPINY NEURON BASED ON HIGH VOLTAGE ELECTRON MICROSCOPIC MEASUREMENTS OF CELL SHAPE.** C.J. Wilson, Dept. of Anatomy, Univ. Tenn. Ctr. Hlth. Sci., 875 Monroe, Memphis TN 38163.

Neurophysiological studies of rat neostriatal spiny cells both in striatal slices and in vivo have yielded puzzling results when analyzed by peeling exponentials from transients recorded at the onset or offset of small intracellular current steps. These experiments give estimates of electrotonic dendritic length ranging from about 1.4 to 1.8 length constants. Because spiny neuron dendrites in the rat range from 150 to 200 µm in length, this implies a length constant in the range of 80 - 150 µm for these neurons. Dendritic diameters for these cells are between 0.35 µm and 1.0 µm over most of their length. Assuming 75 ohm/cm^2 for the intracellular resistivity, these results suggest that the dendritic membrane should have a resistance in the range of 200 to 1500 ohm-cm^2. This range of values produces whole neuron input resistance values that are generally less than that experimentally observed for these cells (20-40 MΩ), and matches the transient data only if very high values of membrane capacitance are assumed (3-6 µF/cm^2). A possible source of error in these calculations is the failure to include a possible contribution from dendritic spines in both the steady state and the transient responses.

These issues were reexamined using a sample of neurons intracellularly injected with horseradish peroxidase after intracellular recording in vivo. The stained neurons were postfixed in osmium tetroxide, and embedded in plastic in preparation for sequential light and electron microscopic study. The entire dendritic tree was reconstructed from serial 50 µm vibratome sections, and the number of dendrites, their lengths, and the occurrences of branch points noted. Selected regions of the cells were then sectioned at a thickness of 5 µm on an ultramicrotome, and sections were placed in folding grids for direct examination in the High Voltage Electron Microscope at 750 or 1000 keV. The resulting images had sufficient resolution to avoid all ambiguities arising from overlapping of spines and silhouetting by the dendrite and allowed measurement of dendrites and spines at 0.01µm precision. These measurements were used in a computer simulation of the steady state and transient responses of the neurons to brief pulses and steps of intracellularly applied current. The spine membrane was found to account for 50 to 75% of the total membrane surface area at all positions along the spiny part of the dendritic tree. As a result, the effect of the spines could be approximated for steady state analysis by increasing the dendritic surface area but maintaining a constant dendritic cross sectional area. The resulting steady state model of the spiny neuron yielded more realistic values for the predicted input resistance of the cells and higher estimates of the membrane resistance. A similar improvement in the model for transient responses was obtained. These results suggest that a large part of the discrepancy between theoretical and observed responses of spiny neurons to intracellularly applied currents may be due to the passive electrical properties of the spines. Supported by NIH grant NS20743.

62.14 SLOW SODIUM AND I_A CURRENTS IN NEOSTRIATAL NEURONS. E. Galarraga, J. Bargas* and J. Aceves*. Dept. Physiology and Neuroscience. Centro de Investigación del IPN. 07000 México, D. F. México.

In the previous Meeting, we presented evidence indicative of the participation of the Ca-activating K conductance determining the firing pattern of neostriatal neurons. Here we have explored the participation of the slow sodium current and of I_A on the firing of these neurons. Using conventional microelectrode techniques, intracellular electrical activity of neostriatal neurons was recorded in slices of rat neostriatum. Long outward current pulses of threshold strength produced a slow and progressively increasing depolarizing potential that, after a long latency, evoked cell firing. TTX (1 µM), but not Co, blocked the slow depolarizing potential. 4-aminopiridine (1 mM) drastically shorthened firing latency and augmented the slow depolarizing potential, which when not reaching firing threshold was seen as a slow oscillation of the membrane potential. The oscillation was not blocked by Co. When the depolarizing pulse was preceded by a conditioning hyperpolarization, the latency for cell firing was prolongued. 4-AP blocked the effect of the conditioning hyperpolarization. In the presence of TTX (1 µM) the depolarizing pulse preceded by conditioning hyperpolarization produced a slow hyperpolarizing potential instead of the slow depolarizing one. TEA (10 mM) did not block the slow hyperpolarizing potential. Conditioning hyperpolarization significantly reduced frequency of neuronal firing. 4-AP also drastically reduced frequency of neuronal firing, but the interval of the two first responses was decreased, and occasionally only slow depolarizing potentials were observed intercalated between the fired potentials. These results strongly suggest that both slow sodium and I_A currents are present in neostriatal neurons, and that both of them play a significant role in determining the firing pattern of the neurons. (Supported by PCCBBNA-020884 grant from CONACyT of México).

62.15 ^{14}C DEOXYGLUCOSE MAPPING STUDIES OF SOMATOSENSORY STIMULI: REGIONAL EFFECTS IN RAT BASAL GANGLIA. L.L. Brown and L.I. Wolfson*. Department of Neurology, Albert Einstein College of Medicine, Bronx, New York 10461.

Previous anatomical, electrophysiological, lesion and behavioral studies suggest that the striatum receives sensory information from cortex which may be important for movement feedback, movement planning, learned movements and the orienting response. We used two simple somatosensory stimuli to determine whether and where they affected basal ganglia metabolism, and whether the magnitude of the response in ventrobasal thalamus and primary cortex was preserved in striatum.

^{14}C Deoxyglucose experiments were carried out in three groups of awake, partially restrained rats: no stimulus control (n=8), tactile stimulus (left side, stroke of the forelimb, 1/2sec, 20g force with a modified von Frey hair; n=3) and passive movement stimulus (left forelimb extension-flexion, 1/4sec; n=3). Glucose utilization (umols/100g/min) and R-L% difference ([R-L/L] x 100) were calculated.

Three striatal regions at each of three anterior-posterior planes were analysed. In the anterior and MID striatum (A8620u - A7890u, Konig and Klippel), the tactile stimulus caused a contralateral increase in glucose utilization over controls (R-L% difference = 21±9%) in a specific dorsal region. The passive movement stimulus caused an increase in glucose utilization (R-L% difference = +32±10%) in a posterior (A7470u) and lateral region of striatum, different from the region of the tactile stimulus effect. Passive movement also increased glucose utilization in the globus pallidus (R-L% difference = +8±4%). Both sides of the substantia nigra compacta and a ventral striatal region were affected bilaterally by both stimuli (+40%), but the reticulata region was affected by the tactile stimulus only. For the tactile stimulus group, the ventrobasal thalamus, sensory cortex and striatum showed similar R-L% differences: +24±8, +22±5 and +21±9% respectively. Although data from a paralysed control group are not yet available, the data emphasize the importance of somatosensory stimuli for basal ganglia function, and emphasize that there is localization of function within basal ganglia which will simplify further analyses of striatal function and the relationship of striatal transmitters to function.

62.16 CYTOCHROME OXIDASE ACTIVITY IN THE RAT NEOSTRIATUM: A LIGHT AND ELECTRON MICROSCOPIC STUDY. G.A. Graveland*, L. Schiff* and M. DiFiglia (Spon: J. Nathanson). Department of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Histochemical studies have shown that the enzyme cytochrome oxidase (CO), which participates in oxidative phosphorylation, can serve as a useful marker for examining metabolic demands in different regions of the central nervous system and within different populations of neurons. CO histochemistry was used to to determine the relative distribution of metabolic activity in neostriatal neurons. Rats (N=5) were anesthetized and perfused with 2% paraformaldehyde and 1-2% glutaraldehyde in phosphate buffer (ph 7.3). Vibratome sections were incubated in 0.15% diaminobenzidine (DAB) for 15 min to 2 hrs. Control sections incubated in DAB plus .1M sodium cynanide failed to exhibit the histochemical reaction. At the light microscopic level a heterogeneous distribution of CO reaction product was observed within caudate neuropil and was characterized by regions of high activity, 200-800 µm in size, surrounded or adjacent to areas of lower activity. At the ultrastructural level CO reaction product was localized to membranes and intracristae spaces of mitochondria. The majority of reactive mitochondria (those containing the densest precipitates of reaction product) were found within distal spiny dendrites in all caudate regions. In areas of high activity the mitochondria within bundles of myelinated fibers and in many axon terminals were also highly reactive whereas those in neuronal somata, primary dendrites and glial cells and processes exhibited relatively little or no activity. The distribution of CO activity was examined quantitatively using a protocol modified from Carroll and Wong-Riley (J Comp Neurol, 222:1984). Mitochondria were rated for their density of CO reaction product as dark, moderate, light, or non-reactive in caudate neuropil taken from CO rich (1506µm^2) and poor (1500µm^2) zones. Results showed that within dendrites greater proportions of the mitochondria were reactive in caudate regions with high CO activity (N=844; 44% dark, 14% moderate, 25% light, and 17% non-reactive) than in regions of low CO activity (N=842; 11% dark, 17% moderate, 39% light and 33% non-reactive). Similarly, greater proportions of the mitochondria localized to axon terminals were reactive in CO rich zones (N= 350; 47% dark, 24% moderate, 20% light and 9% non-reactive mitochondria as compared to areas of low CO activity (N=256; 9% dark 8%, moderate, 23% light, and 60% non-reactive).

The variability in CO activity in caudate may be related to previous anatomical and immunohistochemical observations which show its heterogeneous organization. The processing of numerous synaptic inputs by neostriatal spiny dendrites may be responsible for its high metabolic demands. Supported by grant NS 16367(MD).

62.PO EVIDENCE IN THE CAT THAT THALAMOSTRIATAL FIBERS INNERVATE STRIOSOME OR MATRIX TISSUE ACCORDING TO THEIR SITE OF ORIGIN. C.W. Ragsdale, Jr. and A.M. Graybiel. Psychology Dept., MIT, Cambridge, MA 02139.

By histochemical criteria striosome and matrix compartments can be distinguished in the mammalian striatum. This compartmentalization is observed in the innervation patterns of the major fiber-systems afferent to the striatum. It has not been clear, however, whether, like midbrain and cortex, the thalamus sends fibers to both striosome and matrix compartments; correlative studies of thalamostriatal connections have been limited to those of the posterior intralaminar complex. We report here on the thalamostriatal projections of a range of thalamic nuclei traced from a total of 24 deposits of tracer substances, either a horseradish peroxidase-wheat germ agglutinin conjugate, [35]S-methionine or a mixture of tritiated proline and leucine, made in 14 cats. Adjacent sections from the striatum were processed alternately for autoradiography or peroxidase histochemistry to demonstrate transported label and for acetylcholinesterase (AChE) activity or met-enkephalin- or substance P-like immunoreactivity to show the striosomes. Injection sites were analyzed with reference to maps of thalamostriatal neurons prepared by Beckstead (1984) and Jayaraman (1985).

Injections of the paraventricular nucleus labeled fibers in the caudate nucleus (CN) that traveled in a strip along the ventricular edge of the nucleus and formed patches in the medial and ventral CN. These patches coincided with AChE-poor striosomes identified in adjoining sections. Deposits placed in midline thalamic sites including the rhomboid nucleus also labeled fibers that selectively innervated striosomes in the medial and ventral CN. By contrast, large injections of the posterior intralaminar complex elicited widespread fiber-labeling in the striatum that appeared in the medial CN to be broken up by holes. Comparisons with adjacent sections stained for AChE demonstrated that these gaps in labeling matched the AChE-poor zones. We conclude that the thalamostriatal system is not limited to matrix tissue, that there are thalamic sites that selectively innervate striosomes and that in medial striatum the distributions of fibers from posterior intralaminar and anterior midline thalamus must be at least in part complementary.

Labeled thalamostriatal fibers often were arranged in inhomogeneous patterns that could not be completely accounted for by the histochemical staining. Of special note were fibers labeled by several deposits in the posterior intralaminar nuclei which formed complex patterns in matrix tissue and which, particularly in the dorsal and lateral CN, tended to circumscribe and sometimes to invade the striosomes. Clear instances of 'avoids' of substance P-rich striosomes in the dorsolateral CN (part of the sensory-motor-afferented striatum) were seen following large injections placed near the transition zone between the posterior nuclear group and the ventrolateral nucleus.

Supported by NIH Training Grant MH-15761 and NIH-EY02866-07.

BASAL GANGLIA: IMMUNOCYTOCHEMISTRY

63.1 VARIATIONS IN CHOLINE ACETYLTRANSFERASE DISTRIBUTION WITHIN RAT VENTRAL STRIATUM: AN IMMUNOCYTOCHEMICAL STUDY. P.E. Phelps and J.E. Vaughn. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

The ventral striatal region, defined by Heimer and colleagues to include the substriatal gray, striatal cell bridges, the olfactory tubercle, and nucleus accumbens, contains high levels of acetylcholine and its synthesizing enzyme, choline acetyltransferase (ChAT). Correlated light and electron microscopic studies were conducted to describe variations in ChAT-positive (ChAT+) terminal-like staining that may represent additional neurochemically distinct areas of the ventral striatum. The specificity of the ChAT monoclonal antibodies and the methods used in this investigation have been previously demonstrated.

Light microscopic findings indicated significant differences in the intensity of ChAT+ punctate staining in ventral striatum that ranged from moderate to extremely dense. Most of the substriatal gray and striatal cell bridges, as well as the lateral part of accumbens, contained a moderate number of thin beaded ChAT+ fibers and punctate structures. The most dense ChAT+ fiber and punctate staining was observed within a stripe that extended along the lateral edge of the substriatal gray into the olfactory tubercle, as well as in dense areas along the striatal bridge between accumbens and the tubercle. In counterstained sections, these intensely stained regions were often associated with clusters of ChAT-negative somata. Similar associations of extremely dense ChAT+ staining with unlabeled cell clusters were observed adjacent to all islands of Calleja. Dense concentrations of ChAT+ beaded fibers were also observed among the granule cells of the islands. An intermediate level of ChAT+ staining was found within the molecular and multiform layers of the tubercle, but relatively little was observed within the dense cell layer, giving the tubercle a laminated appearance. Nucleus accumbens also varied in ChAT+ staining, with a medial, oval-shaped region adjacent to the major island of Calleja being more dense than the lateral portion. EM observations made in substriatal gray and the dense stripe revealed that some of the beaded ChAT+ fibers, initially seen by LM, formed synaptic contacts, and were particularly numerous in the striatal stripe. The ChAT labeled boutons contained pleomorphic vesicles, and those forming synapses were usually associated with symmetrical junctions, most often contacting dendrites. ChAT+ boutons also synapsed with unlabeled medium-sized somata characterized by sparse cytoplasm and either smooth, or in the striatal stripe, indented nuclear membranes. These results suggest that variations in density of cholinergic terminals may define unique subregions of the ventral striatum. Supported by NIH grant NS18858.

63.2 ULTRASTRUCTURAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN RAT BASOLATERAL AMYGDALA. J. Carlsen* and L. Heimer (SPON: G.R. Hanna). Department of Neurology, University of Virginia, Charlottesville, VA 22908

It has been amply demonstrated, that the basolateral amygdaloid nucleus (BL) receives a dense cholinergic innervation from the ventral forebrain cholinergic system. Immunocytochemical localization of choline acetyltransferase (ChAT) was used in this study to identify the ultrastructural morphology and synaptic associations of cholinergic terminals in the BL.

A very dense homogenous pattern of ChAT-positive punctate structures and fine varicose fibers were observed throughout the BL. Electron microscopy demonstrated that many of the punctate structures were axon terminals, many of which established symmetric contacts with soma, dendrites or spines. Occasionally, an asymmetric cholinergic axodendritic contact was observed. Whereas both pyramidal and non-pyramidal neurons (nomenclature, according to Millhouse, O.E. and J. de Olmos, Neuroscience, 10: 1269 (1983)) seemed to receive ChAT-positive axodendritic contacts, axosomatic cholinergic synapses were apparently restricted to non-pyramidal neurons.

Furthermore, a group of hitherto unrecognized small ChAT-positive cells (10-14 µm largest diameter) were observed in the BL. Electron microscopy confirmed the presence of small immunoreactive neurons, and revealed that they received both symmetric and asymmetric ChAT-negative synapses on their soma. These features tend to classify them as non-pyramidal intrinsic neurons.

The BL apparently receives a dual cholinergic innervation, one originating in the ventral forebrain, and another in an intrinsic group of cholinergic neurons. A similar dual cholinergic innervation has recently been demonstrated in the cerebral cortex. Likewise, the ultrastructural characteristics of the cholinergic synapses in the BL share many features with those of the cerebral cortex (Houser, C.R., et al., J. Comp. Neurol. 234: 17 (1985)).

63.3 ULTRASTRUCTURAL IDENTIFICATION OF CHOLINERGIC TERMINATIONS ONTO THALAMOSTRIATE PROJECTION NEURONS IN THE DOG. L.G. Isaacson and D. Tanaka, Jr. (SPON: S.T. Sakai) Department of Anatomy, Michigan State University, East Lansing, Michigan 48824

Cholinergic projections from nucleus tegmenti pedunculopontinus (PPN) to the centrum medianum-parafascicular complex (CM-Pf) of the thalamus have been demonstrated in the rat using the retrograde transport of ^{3}H-choline (Sugimoto and Hattori, 1984) as well as in the dog using a combined immunocytochemical and WGA-HRP retrograde labeling technique (Isaacson and Tanaka, 1985). In addition, Sugimoto and Hattori (1984) have shown PPN projections which terminate onto thalamostriate projection neurons in the CM-Pf complex. However, these studies have not directly demonstrated whether cholinergic terminals establish synaptic contacts with thalamostriate neurons. The present study utilizes a combined immunocytochemical and WGA-HRP retrograde labeling technique in an attempt to examine the ultrastructural morphology of cholinergic terminals within CM-Pf and to localize cholinergic terminals making synaptic contact with thalamostriate neurons in the dog.

Thalamostriate projection neurons were localized using the cobalt chloride-glucose oxidase reaction following WGA-HRP injections into the caudate nucleus. The ChAT-immunoreactive terminals (i.e. cholinergic terminals) were visualized using the Avidin-Biotin technique.

Cholinergic terminals within CM-Pf exhibited immunoreactivity associated with the cytoplasmic matrix and synaptic vesicle membrane. The majority of these cholinergic terminals contained populations of pleomorphic synaptic vesicles. Intermediate-type contacts were frequently observed onto dendritic as well as somatic profiles, some of which were identified as belonging to retrogradely labeled thalamostriate projection neurons. This study provides direct evidence of cholinergic terminations onto thalamostriate projection neurons within the CM-Pf complex. In conjunction with previous reports, the results of the present study suggest that thalamostriate neurons in the CM-Pf complex may receive direct cholinergic input from the nucleus tegmenti pedunculopontinus.

SEE SESSION 62.PO

63.5 DIFFERENTIAL DISTRIBUTION OF M1 AND M2 MUSCARINIC BINDING SITES IN THE STRIATUM OF THE ADULT AND IMMATURE CAT. M.A. Nastuk and A.M. Graybiel. Dept. of Psych. & Whitaker Coll.,MIT, Cambridge MA 02139.

Distributions of cholinergic antagonist binding sites in the developing striatum are characterized by dense patches of binding in register with dopamine islands. However, in the mature striatum few clear patches of heightened binding density are visible in sections incubated with ^{3}H-propylbenzilylcholine mustard (^{3}H-PrB; Nastuk and Graybiel'83). This diminished patterning suggested that the early patchiness of binding could be a consequence of developmental events rather than reflecting a nascent functional compartmentalization persisting to adulthood. Alternatively, patterning at maturity could have been masked in the material prepared with ^{3}H-PrB, a nonselective ligand. In an attempt to resolve this question, we examined with ^{3}H-film autoradiography the distributions of muscarinic receptor subtypes in the adult cat's striatum and in a series of fetal and neonatal cats (E40-P4). Binding conditions were chosen to identify M1 and M2 sites according to protocols of Hammer et al.'80 (and pers. comm.) and Potter et al.'84: M1 sites were defined as those labeled with ^{3}H-pirenzepine (^{3}H-PZ;10nM), and M2 sites were defined as those bound with ^{3}H-N-methylscopolamine (^{3}H-NMS;0.3nM) in the presence of 100nM unlabeled PZ (gift of R.Hammer). Binding assays were performed in striatal tissue; K_d's were 7.6nM (^{3}H-PZ) and 0.42nM (^{3}H-NMS), and levels of nonspecific binding were low.

Autoradiograms of mature striatum showed distinct patches of heightened binding density in sections incubated under M1 but not M2 conditions. Patches of putative M1 binding sites matched acetylcholinesterase (AChE)-poor striosomes. Putative M2 binding appeared virtually uniform. At all fetal ages sampled (E40-E58) M1 and M2 sites were distinctly clustered, and both sets of clusters corresponded to AChE-rich patches and to patches rich in tyrosine hydroxylase immunoreactivity (i.e., to dopamine islands). During the perinatal period, both M1 and M2 distributions changed. M2 binding became uniform while M1 binding became less crisply patchy and transiently less tightly linked to local differences in the AChE staining pattern (itself undergoing maturational changes) before becoming resolved into the adult distribution. In all animals there were regional differences in the degree of patterning of M1 binding. For example, in the mature cat the patches were rarely prominent in the dorsolateral caudate nucleus and rarely crisp in the putamen.

The present finding of heightened striosomal muscarinic binding as seen with M1 but not M2 binding conditions suggests that striatal cholinergic function is heterogeneous at maturity. Further, the ontogenetic linkage between dopamine islands and clusters of M1 and M2 subtypes, and the demonstration that dopamine islands match striosomes in the adult cat (Jiminez-Castellanos & Graybiel, in press), suggests that residual clustering of striatal M1 sites may be related to the compartmental distribution of a subset of dopamine containing fibers.Supported by NSF BNS83-19547&the Seaver Inst.

63.6 QUANTITATIVE AUTORADIOGRAPHY OF GABA RECEPTORS IN THE CAT MOTOR THALAMUS. K. Kultas-Ilinsky, J. Fogarty* and I. Ilinsky, Dept. of Anatomy, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

Ventral anterior (VA) and ventral medial (VM) thalamic nuclei are known to receive a massive inhibitory input from basal ganglia (BG) in contrast to the VL whose major input is excitatory and from the cerebellum. Recently it has been demonstrated that intensity and distribution of GAD-immunoreactivity differs in individual subdivisions of the cat motor thalamus (Kultas-Ilinsky et al.,1985. J. Neurosci. in press). Thus, VA and VM contain numerous GAD-immunoreactive axo-dendritic terminals of BG origin whereas GAD-immunoreactive structures in the VL are represented mainly by dendro-dendritic synapses. In light of these findings it was of interest to determine the distribution of different GABA receptors in the cat motor thalamus and to learn whether they correlate with the known topography of BG projections and organization of intrinsic neuronal circuitry. The binding of three ligands specific to different GABA receptors was studied: ^{3}H-muscimol(^{3}HM)-an agonist of high affinity $GABA_A$ sites, ^{3}H-Baclofen(^{3}HB)-an agonist of $GABA_B$ receptors and ^{3}H-flunitrazepam, (^{3}HF)-benzodiazepine agonist that binds to low affinity $GABA_A$ sites. The autoradiographs of tissue sections were digitized using a computer image analysis system calibrated to convert the optical density values into concentrations of ^{3}H per g of tissue.

The density and distribution of the three types of GABA binding sites were compared in different subdivisions of the motor and adjacent nuclei of the rostral thalamus. The highest density of ^{3}HM and ^{3}HF binding sites was found in the midline and limbic nuclei whereas the density of ^{3}HB binding in the midline nuclei was lower and comparable to that in VA and VM. The lowest density of all three binding sites was in intralaminar nuclei and the reticular nucleus did not display any measurable binding. Although overall density of receptors in the motor nuclei was always less than in midline and limbic regions the following distribution pattern was noted: medial and posterolateral VM consistently displayed a high density of binding sites for all three ligands; the VL had the highest number of ^{3}HF-receptors; anterolateral VM and VA had the lowest number of ^{3}HM binding sites, moderate density of ^{3}HF binding sites and high number of ^{3}HB binding sites. The results suggest that the distribution of $GABA_B$ receptors correlates the best with the known topography of GABAergic BG projections in the motor thalamus, whereas low affinity $GABA_A$ binding sites are more likely coupled to GABAergic local neuronal circuits. The hypothesis is now being tested in experiments with unilateral lesions in BG.

Computer image analysis was performed in LONI at Dept. Neurol., Washington Univ., St. Louis. Supported by grants from American Parkinson Disease Association and NIH #NSRO119280.

63.7 A COMBINED GOLGI, DEGENERATION, AND IMMUNOCYTOCHEMICAL STUDY OF THE VENTRAL PALLIDUM IN RAT. L. Záborszky, T. Tömböl*, W.H. Oertel, and L. Heimer. Department of Neurology and Clinical Neuroscience Research Center, University of Virginia, Charlottesville, VA; 1st Department of Anatomy, Semmelweis University, Hungary; and Department of Neurology, Technical University, Munich, FRG.

In order to understand the neural circuits of the ventral pallidum, an attempt was made to characterize some of its neurons in terms of three dimensional structure and afferent connections with special reference to GABA-ergic input.

Lesions were made in the rat nucleus accumbens and olfactory tubercle. Some of the animals received 100 µg colchicine in the lateral ventricle. After a survival time of 30 hours, the animals were perfused by a buffered picric acid-paraformaldehyde fixative (Somogyi and Takagi, 1982). Vibratome sections containing the ventral pallidum were first processed for glutamic acid decarboxylase (GAD) or choline acetyltransferase immunohistochemistry. The sections wer then assembled into agar blocks and reprocessed for Golgi impregnation (Freund and Somogyi, 1983). Impregnated cells were photographed in ventral pallidal areas known to receive projections from the nucleus accumbens or from the olfactory tubercle. The sections were gold toned according to Fairen et al. (1977) and embedded into resin.

The impregnated cells had a triangular or fusiform shape, measuring 25 µm (long diameter). The three to four long primary dendrites were characterized by a smooth outline with occasional beaded or undulated portions. Some of the slender dendrites were unbranched, whereas other divided into two-three branches close to the cell body. Only the initial portion of the axons was impregnated. In a few cases we could observe GAD-positive puncta outlining the distal portions of the dendrites.

An electron microscopic analysis is now being performed in order to determine if Golgi-impregnated neurons do receive GAD-containing and/or degenerating terminals from the ventral striatum. We are also analysing the relative distribution of degenerating terminals on ChAT- and GAD-containing neurons.

63.8 STRIATAL(-LIKE) GABA-ERGIC NEURONAL POPULATIONS IN RAT OLFACTORY TUBERCLE, CENTRAL AND MEDIAL AMYGDALOID NUCLEI. W.H.Oertel and E.Mugnaini. Dept.Neurol.,Technical Univ.,Munich,FRG and Dep.Biobeh.Sci.,U.Conn,Storrs, CT 06268, USA.

It was recently demonstrated by immunocytochemistry for glutamic acid decarboxylase(GAD),the biosynthetic enzyme for GABA that the vast majority of neurons in rat striatum, i.e. in caudate/putamen and accumbens nucleus, are represented by two classes of GAD-positive neurons (Oertel and Mugnaini, Neurosci.Lett.,47:233,1984): A minor category consists of medium to large size neurons.The second category represents the vast majority of the striatal medium size spiny neurons. In the present study, we have investigated the distribution of GAD-immunoreactive nerve cell bodies in the olfactory tubercle (OT), which is considered as the most ventral part of the striatum by Heimer (1978), in the islands of Calleja (IC) and in the amygdala.

Untreated rats and rats pretreated topically with colchicine (10-20 µg) 12-40 hr before sacrifice were used. The animals were perfused with a zinc formaldehyde fixative. Floating cryostat sections were processed for GAD-like immunoreactivity with the PAP-method.

In untreated rats,few medium to large size neurons were GAD-immunoreactive in OT, the central amygdaloid nucleus (AC), the medial amygdaloid nucleus(AM) and the massae intercalatae(MI).The vast majority of medium size neurons in the polymorph layer and pyramidal layer of OT, the neurons in the granule cell clusters in IC and the vast majority of neurons in AC, AM and MI were GAD-immunoreactive in optimally stained specimens of untreated rats and were consistently GAD-positive in specimens of colchicine pretreated animals. The remaining amygdaloid areas contained a medium to low density of GAD-positive neurons.

The data indicate that OT, AC, AM and MI and the granule cell clusters in IC bear some resemblence to striatal areas in respect to the types and distribution of GABAergic neurons. In addition, these areas receive catecholaminergic input. As OT shares a high acetylcholinesterase activity with the caudate/putamen and accumbens nucleus, our data support the view of Heimer (1978) that OT is the most ventral subnucleus of the striatum . In contrast, AC and AM exhibit low acetylcholinesterase activity and therefore are suggested to be subsumed under the denominator "striatal-like" areas.

63.9 ^{3}H-QNB BINDING ON SUBSTANCE P-, AND SOMATOSTATIN-IMMUNOREACTIVE STRIATAL NEURONS. M.A. Ariano & S.L. Kenny.* Department of Anatomy & Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

^{3}H-QNB is a reversible antagonist of muscarinic acetylcholine receptors (mAChr), and has been used to detect binding sites of this neurotransmitter system *in vitro* (Yamamura & Snyder, 1974). Localization of mAChr is very high in the striatum (Nonaka & Moroji, 1984), and we have used a modification of the *in vitro* autoradiographic receptor binding method of Kuhar (Wamsley, et al, 1981) to determine ^{3}H-QNB binding on individual striatal cell bodies. Immunohistochemical characterization of these striatal neurons has been determined prior to analysis of ^{3}H-QNB in an attempt to correlate the distribution of mAChr on perikarya reactive for the undecapeptide, substance P, or the inhibitor of growth hormone release, somatostatin. Both of these compounds have been previously described within neurons of the striatum (Fonnum, et al, 1974; Brownstein, et al, 1977; DiFiglia & Aronin, 1982; Beal & Martin, 1983).

The brains of male Sprague-Dawley rats (200-250 gm) were rapidly removed and frozen in a cryostat at -25°C in the coronal plane. 8 µm sections were thaw-mounted onto chrom alum-coated glass slides. The detection of immunohistochemical reactivity for the two neuropeptide substances was performed first, using the PAP method of Sternberger (1979). The reaction product was visualized using 3,3'-diaminobenzidene as the chromagen. Tissue sections were thoroughly rinsed, followed by incubation with 0.25-0.5 nM ^{3}H-QNB for 2 h at room temperature (Ariano, 1985). The slides were dipped into NTB-3 emulsion (Kodak), dried, and stored for 5-7 days. Sections were developed in D-19 (Kodak), followed by stabilization in fixer. After extensive washing, sections were covered with glycerol, and examined in bright-field optics using a Zeiss Photomicroscope 3.

Regions of densest immunohistochemical staining were chosen for analysis. Preliminary experiments demonstrate a prevalent clustering of ^{3}H-QNB autoradiographic silver grains in the emulsion overlying substance P- and somatostatin-reactive somata within the striatum. Quantitation of the silver grains is currently under examination, comparing the density of mAChr binding sites over the neuropeptide-reactive cells versus the surrounding neuropil.

63.10 THE DEVELOPMENTAL RELATIONSHIP BETWEEN DOPAMINE ISLANDS AND EARLY STRIOSOMAL NEURON CLUSTERS IN THE FETAL CAT STRIATUM. A.M. Graybiel & H. Newman-Gage*, Dept. Psychol. & Whitaker College, MIT, Cambridge, MA 02139. (SPON: F.O. Schmitt).

Striatal neurons lying in the histochemically distinct compartments known as striosomes can be pulse-labeled in the cat by single *in utero* injections of ^{3}H-thymidine at embryonic days E23-30. Such ^{3}H-thymidine labeled neurons are already clustered during the late fetal period, and lie in the striatal compartments innervated by the early-forming "dopamine island" fibers. These findings have raised the possibility of a developmental relationship between the clustering of dopamine island fibers and of striosomal neurons. Here we present evidence that both become clustered during a restricted time-window of development (ca. E35-45), and that there is a progressive and orderly spatial linkage between the two.

Brains from E35-50 fetuses were collected following initial exposure to ^{3}H-thymidine at E24-28. Dopamine-containing afferents were identified with tyrosine hydroxylase (TH) immunohistochemistry and ^{3}H labeled neurons by autoradiography. Striatal cell bodies that were heavily labeled (^{3}H CB) were present at all fetal ages. Light labeling was also prominent up to E45. At E35, TH-positive fibers appeared throughout the putamen, were densest in the cell bridges of the internal capsule, and were just beginning to invade the caudate nucleus (CN). ^{3}H CB had a similar distribution, but a prominent band of ^{3}H CB also appeared along the medial face of the CN immediately next to the ganglionic eminence. The CN had a central core with fewer labeled neurons. By E38, occasional streamers of ^{3}H CB connected the medial band with the ^{3}H CB piled up along the internal capsule, and the arrangement of the ^{3}H CB in the putamen was not uniform. TH immunostaining was distinctly inhomogeneous. Patches of TH extended medially and laterally from the cell bridges and there were hints of clustering in the CN core. By E42, ^{3}H CB were present throughout the width of the CN rostrally, and many were clustered. The medial and lateral ^{3}H CB bands, connected by streamers, still appeared farther caudally. Crisp TH patches were present at all levels, and tended to be aligned with clusters (less crisp) of ^{3}H CB. By E45, ^{3}H CB were organized in distinct clusters in the CN, including in its central core. The ^{3}H CB clusters were well-circumscribed at mid-CN levels but appeared to be still nascent elsewhere in the CN. ^{3}H CB clusters of both types were aligned with TH-positive patches. Faint TH patches appeared in medial regions where ^{3}H CB clustering was not pronounced. At E50, crisp ^{3}H CB clusters matched crisp TH-positive patches. We conclude that from near the inception of striosomal-cell and island-fiber clustering, groups of these elements are in a position to interact. Discrete clustering of the fibers occurs earlier than discrete clustering of the cell bodies but small neuronal clumps are visible as early as fiber groupings can be detected. NSF BNS83-19547 & NIH NS07711-01.

63.11 DEVELOPMENTAL ANATOMY OF DOPAMINE ISLANDS IN THE CAUDATE NUCLEUS OF THE CAT. H. Newman-Gage* and A.M. Graybiel, Dept. of Psych. & Brain Science, MIT, Cambridge, MA 02139. (SPON: Walle J.H. Nauta).

During development, the dopamine-containing innervation of the caudate nucleus (CN) is organized in patches known as dopamine islands. Prenatally, these coincide with patches of dense acetylcholinesterase (AChE) staining. In the adult, the dopamine island regions correspond to the zones of pale AChE staining known as striosomes. There are distinct dorsoventral differences in the islandic innervation and in the neurochemical content of striosomes. We report here an analysis of the development of the dopamine islands in a series of cat fetuses taken at almost daily intervals from embryonic day 27 (E27) to birth as well as in kittens aged P1-P8. The islands were identified with TH antiserum (Dr. T. Joh) and were compared to patterns visible in adjoining AChE-stained sections.

TH or AChE activity was minimal in the CN until after E35. By E38, homogeneous TH staining appeared rostrally but farther caudally faint though definite patches were found in the dorsal CN adjacent to the internal capsule. The non-island (or matrix) TH staining was darkest ventrally. AChE staining was similar to TH staining. At E45, obvious patches of TH and AChE activity were present. These were most distinct laterally, but extended to the medial quarter of the CN. Rostrally, the TH-positive patches appeared broad and often interconnected. In more caudal cross-sections, there were increased numbers of smaller, more discrete patches. The dorsal islands were darker than ventral ones and they appeared to extend farther rostrally and caudally. There were similar rostrocaudal differences in the AChE patches and also a striking extension in background AChE activity from closely surrounding the dense patches to diffusely filling most of the area between dopamine islands. With increasing age, the extent and complexity of the TH and AChE patch systems increased. By E61, TH-positive patches appeared throughout the CN, with dorsolateral patches being darkest and ventral patches most weakly stained. AChE patches showed similar patterns except that ventral AChE patches were not yet present in rostral sections. After birth, matrix TH activity increased and ventrally the TH became more homogeneously dark. AChE-positive regions had begun to coalesce, and ventral staining was as dark as that observed dorsally. By P8, zones lacking AChE stain began to appear though TH-positive patches remained. This was the beginning of the transitional phase to the adult striosomal architecture.

Light microscopic immunohistochemistry of the E58 CN with antibodies to synaptic vesicles (Dr. W. Matthew) indicated a higher density of such vesicles in the dopamine islands. This suggests that synaptogenesis in the island system may precede that in the matrix. Electron microscopic immunohistochemistry substantiated this impression, as TH-positive, vesicle-containing profiles were more common in identified dopamine islands than in the matrix. Supported by NSF BNS83-19547, NIH NS07711-01 and the Seaver Institute.

63.12 TRANSPLANTED DOPAMINE CELLS IN OR PERI-VENTRICULAR REGION GROW BETTER THAN THOSE IN THE CENTRAL PART OF THE CAUDATE NUCLEUS. H. Nishino[1], T. Ono[1], J. Takahashi*[1], M. Kimura*[2], S. Shiosaka*[3] and M. Tohyama*[3]. Dept.[1]Physiol. and [2]Anat., Fac. Med., Toyama Med. Pharmaceut. Univ., Sugitani, Toyama 930-01, and [3]Dept. Neuroanat., Inst. Higher Nerv. Act., Osaka Univ., Osaka 530, Japan.

In several brain sites, transplantation of cerebral tissue or cell suspensions ameliorates functional disturbances that follow electrolytic, chemical or surgical lesions. However, some critical factors (embryo age, transplant volume, injection point etc.) affect the growth of the transplant, and consequently control functional recovery. We report here results of transplanting dopamine (DA) cell suspensions into the caudate nucleus to restore motor balance of rats with unilateral lesions in the nigrostriatal DA pathway, and investigating the relation between growth of the DA cells and behavior recovery.

Unilateral lesions in the nigrostriatal DA pathway of recipient rats were made by microinjection of 6-OHDA. DA cell suspensions prepared from the midbrains of embryos (fetal age, 13-15 days) contained 10^7-5×10^7 cells/ml, more than 90% of which were viable. Transplantations of suspensions (microinjection, total volume less than 10 µl) were made separately in two areas in the head of the caudate nucleus, 1.5mm antero-caudally or latero-medially. Motor imbalance due to lesion or after transplantation was estimated from the number of turns following Met-amphetamine injection (5 mg/kg, i.p.). Motor imbalance (turning to the lesioned side) was ameliorated slightly in the 2nd week and definitely in the 3rd and 4th weeks after transplantation. In the 8th week brains were perfused and removed, and frozen sections were made to stain the tyrosine hydroxylase (TH) activity (PAP method). In behavior recovered rats, TH positive cells were scattered around the injection sites, and it was found that positive cells grew better (extensive axon elongation and dendrite branching) when transplantation was made into the medial part of the caudate nucleus, especially into the periventricular region. The extent of ramification of dendrites and axons was well correlated with the degree of behavior recovery. In well recovered cases, synaptic contacts between the TH positive terminals and recipient caudate neurons were observed.

Data suggest that the growth and ramification of transplanted DA cells is the most critical factor affecting functional recovery, and the amount of growth depends on the site of transplantation.

63.13 TYROSINE HYDROXYLASE IMMUNOHISTOCHEMICAL ANALYSIS OF THE INFERIOR COLLICULUS IN RATS. U.E. Olazábal[1] and J.K. Moore[2]. Depts. of Psychology[1] and Anatomical Sciences[2], SUNY at Stony Brook, New York, 11794.

Previous work from this laboratory has documented a direct projection from the substantia nigra, pars lateralis(SNL) to the inferior colliculus(IC) in rats and cats(1). In the present study, the chemical characteristics of this pathway were investigated in order to further understand its functional significance. In this immunohistochemical study, rats were anesthetized and perfused with 4% paraformaldehyde and 0.5% zinc salicylate as mordant in 0.45% saline(2). Tissue blocks including the superior colliculus (SC), substantia nigra(SN), and inferior colliculus were removed, sectioned, and processed by the Avidin-Biotin variation of the PAP technique, in order to visualize tyrosine hydroxylase(TH-) and glutamic acid decarboxylase(GAD-) immunoreactivity.

Obtained results demonstrated a plexus of varicose tyrosine hydroxylase-positive(TH+) axons in the IC. This plexus of axons and terminals is confined to the external cortex and rostral pole of the colliculus, and is completely absent from its central nucleus. This study has also confirmed the presence of TH+ neurons in two of the areas known to project to the IC, the central gray (CG), and SNL. Tyrosine hydroxylase is the rate-limiting enzyme in the metabolic pathway leading to the formation of both dopamine and norepinephrine. However, neurons exhibiting TH+ activity in central gray and substantia nigra are known to be dopaminergic rather than noradrenergic(3,4,5). The TH+ cells in the SNL appear to be identical as those described by Hökfelt et al. as zone A9L of the dopamine nucleus system(6). These TH+ SNL neurons have the same size, shape, and distribution as cells which backfill from HRP injections in the IC, while glutamic acid decarboxylase-positive(GAD+) cells in this area are markedly smaller and more elongate.

These findings suggets that TH+ neurons in the substantia nigra, pars lateralis are likely to be the source of the terminal field in the external nuclei of the inferior colliculus. Ongoing experiments are further examining the chemical nature of this system, and its possible role in auditory orienting behavior.(Supported by the Deafness Research Foundation).

63.14 REGIONAL DISTRIBUTION OF DOPAMINE, TYROSINE HYDROXYLASE AND DOPAC IN RAT STRIATUM. S. L. Rubinstein*, C. Sarvey* and K. Gale (SPON:M. Bradford). Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

Biochemical studies of the topographical distribution of dopamine (DA) innervation in the rat striatum have yielded conflicting results. Koslow et al. (Neuropharmacology 13: 1123-1130, 1974) reported a biphasic rostrocaudal distribution of striatal DA with peak DA concentrations occurring at the level of the decussation of the anterior commissure and 1.6 mm rostral to this level. Tassin et al. (Brain Research 107: 291-301, 1976) reported DA concentrations and DA uptake activity to be highest in the rostral-most portion of the striatum and decrease progressively in more caudal striatal regions. The latter authors found peak DA concentrations 1-2 mm from the rostral border of striatum. Since both of these studies utilized tissue micropunches which could introduce a sampling error, we examined the rostrocaudal distribution of DA in the striatum by analyzing complete cross sections (500 u thick) of striatum. In addition, we examined the rostrocaudal distribution of tyrosine hydroxylase (TH) activity and DOPAC concentrations utilizing complete striatal cross sections. Fresh-frozen sections of brains, taken from 350g male Spraque-Dawley rats, were made with a cryostat at -15°C. Analysis of DA and DOPAC was performed using HPLC; TH activity was assayed in the presence of saturating concentrations of substrates using a decarboxylase-coupled assay in which the evolution of $^{14}CO_2$ (from 1-^{14}C-L-tyrosine) is measured (Waymire et al., Anal. Bioc. 43: 588-600, 1971).

The distribution of DA was found to be monophasic, showing a peak located between 2 and 3 mm from the rostral border of striatum; the average peak concentration was 900 pmol/mg protein. The DA concentration gradually decreased in both directions from the peak, declining to concentrations approximately 30% - 50% lower at the rostral and caudal ends of the tissue. The distribution of TH coincided with that of DA, with average peak activity of 1.8 umoles L-tyrosine converted to L-dopa/mg prot/hr. DOPAC concentrations did not covary with DA levels, resulting in different DA/DOPAC ratios at different rostrocaudal levels. In general, the highest DA/DOPAC ratios were found midway through the rostrocaudal extent of the striatum and coincided with the region of highest DA content; these values were approximately 35% higher than the DA/DOPAC ratio found in the tail of striatum.

63.15 INTRACELLULAR RESPONSES OF CAT CAUDATE NEURONS TO MICROPRESSURE EJECTION OF SUBSTANCE P, CHOLESYSTOKININ, AND THEIR ANTIBODIES. C.E. Adams, C.D. Hull, M.S. Levine, and N.A. Buchwald. Mental Retardation Research Center, UCLA School of Medicine, 760 Westwood Plaza, Los Angeles, CA 90024.

Immunohistochemical and radioligand binding studies have identified substance P (SP), cholesystokinin (CCK) and their receptors within the basal ganglia (BG). Our investigations of SP and CCK function in BG include an examination of responses of intracellularly-recorded cat caudate neurons to micropressure ejections of SP, CCK, GABA and monoclonal antibodies to SP (A-SP) and CCK (A-CCK). We have observed membrane polarization and/or resistance changes to one or more of the test substances in 56 caudate neurons. Of these 56 cells, 22 cells did not return to original control membrane and/or resistance levels following ejection of a test substance and were not included in our analysis. Ten of the remaining 34 cells were tested with SP. Eight responded with a depolarization of the membrane, 1 exhibited an initial hyperpolarization followed by depolarization while the other showed no membrane change. Fourteen caudate neurons tested with CCK responded with membrane depolarization but only 2 returned to control levels. A decrease in the amplitude of the EPSP and in the amplitude of the inhibitory postsynaptic potential (IPSP) to cortical stimulation was observed in 6/9 caudate neurons tested with GABA. The remaining 3 responded to GABA with a decrease in the amplitude of the EPSP only. Ten out of 13 caudate neurons tested with A-SP exhibited a membrane depolarization. No change in EPSP amplitude was observed. Three of 4 cells examined with A-CCK exhibited membrane depolarization while the fourth showed a hyperpolarization. No changes in EPSP amplitude were observed. Recovery times for recorded membrane and/or resistance changes ranged from less than 20 seconds to as long as 100 seconds after termination of pressure ejection. No consistent interactions resulted from the simultaneous application of a peptide and its antibody. A complex interaction between GABA and SP was observed. SP was found to selectively inhibit spike generation but not the EPSP of cells previously inhibited by GABA. In conclusion, the primary response of cat caudate neurons to application of SP, CCK, A-SP and A-CCK is membrane depolarization, frequently of a prolonged nature. These substances may exert a more complex influence on caudate function as is suggested by the observation of a spike/EPSP dissociation with combined GABA and SP application. Supported by USPHS Grant AG 01558, HD 05958.

63.16 CHARACTERIZATION OF NEUROPEPTIDE Y-IMMUNOREACTIVE NEURONS IN STRIATUM OF CATS AND MONKEYS. Y. Smith, J. Dumas* and A. Parent. Lab. of Neurobiology, Fac. Med., Laval Univ. Québec, Canada.

A detailed study of the distribution of neuropeptide Y (NPY) in the striatum of squirrel monkeys (Saimiri sciureus) and cats was undertaken by means of indirect immunofluorescence and peroxidase-antiperoxidase (PAP) methods.

In monkeys, the NPY-immunoreactivity is homogeneously distributed along the entire extent of caudate nucleus (CD) and putamen (PUT), while in cats marked heterogeneities are noted. In the CD of cats, the NPY-immunoreactive fibers and cell bodies are concentrated in patches of various sizes, which can be readily distinguished from zones of poor NPY-immunostaining. In squirrel monkeys, quantitative measurements reveal that the density of NPY-immunoreactive cell bodies is greater in CD than in PUT, and it increases markedly along the rostrocaudal extent of the striatum. In rostral CD and PUT the densities are 23 cells/mm^2 and 14 cells/mm^2, respectively, whereas the values for caudal CD and PUT are 35 cells/mm^2 and 20 cells/mm^2, respectively. In primate CD and PUT the NPY-positive neurons are either triangular, fusiform or globular, with long and smooth dendrites branching infrequently. Measurements made with a Zeiss modular system for quantitative image analysis show that these NPY-immunoreactive cells belong to a single subset of striatal neurons having a maximum diameter of 19.2 ± 0.1 um and a cross-sectional area of 145.5 ± 0.6 um (Mean ± S.E.M.; N=1238 CD cells and 1169 PUT cells). Furthermore, co-localization studies made with the help of the indirect immunofluorescence technique and Tramu's antibody elution method (Tramu et al., J. Histochem. Cytochem., 26: 322, 1978), demonstrate that the vast majority of NPY-positive striatal neurons in monkey also contain somatostatin (SS). Finally, experiments combining the use of the retrograde tracer WGA-HRP with PAP immunohistochemical method for the visualization of NPY were undertaken to find out if NPY-positive striatal cells are output neurons. The injections of WGA-HRP in substantia nigra and pallidal complex of monkeys and cats produces retrograde labeling of numerous medium-sized striatal neurons, but no HRP granules are found in NPY-immunoreactive cells after such injections. The injection of WGA-HRP in frontal cortex of cats is also ineffective in labeling NPY striatal cells. Thus, the NPY striatal neurons in cats and monkeys do not appear to project outside the striatum.

These results reveal that, in mammalian striatum, NPY is mostly confined to a subpopulation of medium-sized neurons which are intrinsically organized and also contain somatostatin. [The antisera were kindly provided by Drs G. Pelletier (NPY) and R. Benoit (SS). Supported by the MRC of Canada].

63.17 RESPONSES IN DOPAMINE TERMINAL REGIONS TO OLFACTORY AND SOMATOSENSORY STIMULATION IN RATS. Charles H.K. West and Richard P. Michael. Department of Psychiatry, Emory University School of Medicine and Georgia Mental Health Institute, Atlanta, GA 30306.

Dopaminergic neurons in the ventral tegmentum project to various forebrain regions including nucleus accumbens (NAC), olfactory tubercle (OT) and lateral septum (LS). As an initial step towards investigating possible interactions between sensory input and dopamine (DA) neurotransmission, we recorded responses in these three regions evoked by sensory input and by electrical stimulation of the ventral tegmentum. In adult male rats (n=12) anesthetized with chloral hydrate (400 mg/kg, i.p.), single units were recorded with glass micropipette electrodes filled with a solution of 2M NaCl saturated with fast green dye. The olfactory stimuli (ammonia, cedar oil, ethanol, acrylic solvent, rat urine) were applied with cotton swabs placed 1-2 cm beneath the rat's nostrils for 5-10 sec. The somatosensory stimuli used were light touch, tail pressure and foot pinch. Electrical stimuli were applied via bipolar electrodes in the ventral tegmentum and consisted of trains of monophasic square waves (100-400 uA, 0.2 msec duration, 100 Hz). The rates of spontaneous firing (mean ± SEM) for units in NAC, OT and LS were 8.4 ± 1.9, 14.4 ± 3.0 and 7.3 ± 2.6, respectively. Responses consisted of increases or decreases in spontaneous firing rates and were evoked in each brain structure: 11 of 18 units in OT (61%), 11 of 24 units in NAC (46%) and 3 of 13 units in LS (23%). When responses were observed in NAC or OT units, they could usually be evoked by several of the eight types of sensory stimuli used; for responsive units, the mean number of effective stimuli per unit was 4 in OT and 3 in NAC. However, in LS, only cedar oil or acrylic solvent evoked responses in 3 units. The stimuli producing responses in the greatest number of units in NAC were foot pinch and urine, and in OT they were ethanol and solvent. The pattern and direction of the responses to electrical stimulation varied between units. Again, the highest percentage of units responsive to stimulation was found in OT (67%), compared with 38% for LS and 29% for NAC. When present in the same unit (n=13), responses both to sensory and to electrical stimulation tended to be in the same direction. These results demonstrated that olfactory and somatosensory stimulation can evoke responses in a significant proportion of units in DA terminal regions and that many of these units are also responsive to electrical stimulation of the ventral tegmentum. The relationship between DA and sensory evoked responses is currently being investigated.

63.18 **QUANTITATIVE AUTORADIOGRAPHY REVEALS A CORRELATION BETWEEN A HETEROGENEOUS DISTRIBUTION OF DOPAMINE (D-2) SITES AND AChE PATCHINESS IN THE HUMAN STRIATUM.** **J.F. Marshall, J.N. Joyce and D.W. Sapp*. Dept. of Psychobiology, Univ. California Irvine, Irvine, CA 92717.**

Using quantitative autoradiography we have shown that the behaviorally relevant D-2 receptors are organized in a lateral to medial gradient in rat striatum (Joyce et al. Brain Res., 1985) which corresponds to similar gradients of acetylcholinesterase (AChE) stain, cholineacetyltransferase activity, and high affinity choline uptake (Joyce, J.N. and J.F. Marshall, Neurosci. Lett., 53:127, 1985). In human striatum, AChE is also heterogeneously distributed, but takes the form of light and dark patches ('striosomes'). We used quantitative autoradiography to determine whether a corresponding patchy organization of D-2 sites occurs in human caudate or putamen. Thin (20 μM) sections of human striatum, obtained from a 34 year old male with no history of neurological disease, were incubated with [^{3}H]spiroperidol (0.6 - 0.7 nM, 100 Ci/mmol, Amersham) or [^{3}H]sulpiride (19 - 20 nM, 75.4 Ci/mmol, NEN) in the presence of 40 nM ketanserin with or without 1 μM (+)-butaclamol. Adjacent sections were processed for autoradiography or AChE histochemsitry. Autoradiographic sections and a set of ^{3}H-standards were apposed to ^{3}H-sensitive film (LKB). Autoradiographs were digitized, linearized and the resulting images photographed for further analysis, or the density of specific [^{3}H]spiroperidol and [^{3}H]sulpiride binding read from regions of rostral striatum with the aid of an image processor (Altar, C.A. et al., Neurosci. Meth., 100:173, 1984). Clearly identifiable high-density and low-density patches of D-2 binding were visible, and the zones could be followed continuously on adjacent sections for at least 120 μM. The concentration of bound radioligand in the high-density patches was twice that in low-density zones. Importantly, high- and low-density D-2 patches showed a good correlation with, respectively, AChE-rich and AChE-poor patches in adjacent sections stained histochemically. The sections used for autoradiography, and later stained with thionin and luxol-fast, did not show any obvious heterogeneity of cell packing density that corresponded to the patchiness of D-2 receptor density. This work shows that the organization of the D-2 receptor obeys the 'striosomal' pattern of AChE histochemistry, which is consistent with the proposed relationship between this class of dopamine receptors and striatal cholinergic neurons (Joyce and Marshall, ibid).

63.19 STRIATAL AXONS TO GLOBUS PALLIDUS, ENTOPEDUNCULAR NUCLEUS AND SUBSTANTIA NIGRA COME FROM SEPARATE CELLS: RETROGRADE DOUBLE-LABELING WITH HRP AND FLUORESCENT LATEX MICROSPHERES. R.M. Beckstead. Dept. of Anat., Univ. of Virginia Med. Sch., Charlottesville, VA 22908.

The major input to the two segments of the globus pallidus [in the cat, the globus pallidus (GP) and entopeduncular nuc. (EP)] and the substantia nigra (SN) comes from the striatum (caudate nuc. & putamen). Although there exists little direct evidence, it has been implied in several reports that the striatonigral axons are mainly collaterals of striatopallidal fibers. Two recent reports on the primate brain have shown, using double retrograde dye-labeling, that the nigral and pallidal afferent axons originate from separate striatal cells. I tested this finding and the further question of whether the inputs to GP and EP come from separate striatal cells in the cat using a double retrograde method that combines HRP with rhodamine-fluorescent latex microspheres (FLM). These tracers have the advantages that they do not diffuse widely (especially FLM) from the injection site as do the free fluorescent dyes, are unmistakeably distinguishable from one another, and do not fade under excitation light. In each case, two of the three target cell groups were injected, each with a different tracer, until all three possible combinations of two had been obtained several times. Although none of the deposits of either tracer involved an entire target cell group, many deposits were made that covered a large portion of each. In all cases in which the tracer encroached upon a striatal target, there were cells labeled in the striatum that were of a size and shape that is consistent with the observation that they mainly belong to the category of medium striatal cells. Since the striatal projections to GP, EP and SN are each topographically arranged, the zones of cell-labeling within the striatum varied depending upon the portion of the target nucleus involved by the deposit. Thus, in many cases the fields of striatal cells containing one label overlapped only slightly with those in which cells containing the other label occurred. In other cases, however, there was wide overlap of the striatal zones containing cells marked with either tracer. In all cases, very few double-labeled cells could be found, even where hundreds of cells labeled with either tracer were freely intermingled. These findings confirm that, in the cat as in the primate, the striatal axons to SN arise from cells that are largely separate from the striatopallidal population, and further show that the axons to GP and EP also emanate from different cells. These findings are consistent with the recent observation in the cat (and monkey) that the striatal axons to the two segments of the pallidum are histochemically distinct: those to GP contain mainly met-enkephalin whereas those to EP contain substance P. Since GP, EP and SN all receive GABAergic striatal axons, the present findings suggest that individual GABA cells are selective with respect to their pallidal target.

63.20 SOMATOSTATINERGIC INPUTS TO THE REGION OF THE A8 CELL GROUP. M-F Chesselet. Laboratory of Cell Biology, National Institute of Mental Health, Bethesda, MD 20205.

A dense network of fibers expressing somatostatin (SOM)-like immunoreactivity was observed in the rat in a restricted area of the mesencephalic reticular formation (MRF), corresponding to part of the nucleus cuneiformis. The aspect of the labelling at a light microscopic level was compatible with the presence of SOM-positive terminals in this area and was in sharp contrast with a much sparser fiber labelling in surrounding regions, including the pars compacta of the substantia nigra. This SOM-positive region overlapped with an area of dense CRF-, dynorphin- and enkephalin-like immunoreactivity, suggesting that this zone is innervated by multiple peptidergic systems. In addition, part of the SOM-positive region overlapped with the dorso-lateral aspect of the catecholaminergic cell group A8.

In order to determine the origin of this somatostatinergic projection, retrograde tracing with the fluorescent dye fast blue (FB) was combined with fluorescence immunohistochemistry. After injection of the dyestuff into the SOM-positive region of the MRF, but not in adjacent areas, FB was found to be present in cell bodies expressing SOM-like immunoreactivity in the central nucleus of the amygdala and in the rostral and ventral aspects of the zona incerta (but not in the striatum nor the nucleus accumbens septi). The existence of a projection from the zona incerta to the SOM-positive area of the MRF was confirmed by anterograde transport and immunodetection of the lectin phaseolus vulgaris leucoagglutinin (PHA-L)[1].

Taken together, these results suggest that somatostatinergic neurons from the amygdala and from the zona incerta may contribute to the innervation of a region within the MRF including part of the A8 cell group. This is of particular importance considering the broad field of projections of the A8 neurons which includes areas also innervated by A9 (substantia nigra) and A10 (ventral tegmental area) cell groups[2,3]. Therefore, the projections described here could play a strategic role in the regulation of neuronal activity within the basal ganglia.

63.21 STRIATAL HETEROGENEITY IN RESPONSIVITY TO NEUROLEPTICS: CORRELATION WITH AFFERENT INPUT. A.Y. Deutch, M. Goldstein, and R.H. Roth. Depts. of Pharmacology & Psychiatry, Yale School of Medicine, New Haven, CT 06510 and NYU Medical Center, New York, NY 10011.

Recent findings indicate the the striatum exhibits anatomical, biochemical, and functional heterogeneity. There are considerable differences across the telencephalic dopamine (DA) terminal field regions in biochemical responsivity to neuroleptics. We have therefore examined heterogeneity in biochemical responsivity to haloperidol (HPD) by assessing regional differences in biochemical indexes of dopaminergic neuronal activation. We have further attempted to correlate the observed pattern of regional responsivity with the sources of dopaminergic afferents to these regions.

Adult male rats were sacrificed following HPD challenge and ten regions of the striatum (CP) punch-dissected from coronal slices. Two measures of DA neuronal activation were assessed: the ratio of the DA metabolite 3,4-dihydroxyphenylacetic acid (DOPAC) to DA, as an index of turnover, and accumulation of l-DOPA after decarboxylase inhibition as an index of synthesis. The precise source of DA afferents to the striatal subfields as dissected was evaluated by both a combined retrograde tracer-immunohistochemical method and an anterograde (PHA-L) procedure.

Both the magnitude of the HPD-induced increase in DA turnover and synthesis exhibited a two-fold regional variability. The greatest increase in turnover and synthesis was observed in the rostral dorsomedial sector of the CP, whereas the ventrolateral tail of the CP exhibited the least responsivity to HPD. Overall, a dorsal to ventral and medial to lateral gradient running along an oblique rostrocaudal axis was observed in the biochemical responsivity of the CP to HPD. The precise mesencephalic source of the DA innervation of the CP subfields and the biochemical responsivity of these regions was highly correlated. Areas of the CP exhibiting the greatest degree of change in turnover or synthesis received a DA innervation from the medial half of the A9 cell group; areas exhibiting low responsivity were predominantly innervated by A10 and A8 neurons. Those areas intermediate in responsivity received mixed A9-A8 inputs. Areas of the CP receiving DA afferents from the A8 region and pars lateralis exhibited a relatively low degree of responsivity to HPD, suggesting that the pars lateralis may constitute a functional subset of the A8 cell group; this finding is supported by comparative connectivity of the regions. These data therefore suggest that the A9 DA neurons exhibit the greatest biochemical response to HPD challenge of the mesencephalic DA neurons, the A10 neurons the lowest response, with the A8 neurons occupying an intermediate position. The source of the DA afferents to the CP thus appears to be at least one important determinant of the biochemical responsivity of the CP to neuroleptics, a pattern which remains constant across the striatal, mesolimbic, and mesocortical terminal field regions. 63.22 SPONTANEOUS ACTIVITY OF DOPAMINERGIC CELLS IN NUCLEUS TEGMENTI PEDUNCULOPONTINUS, AN AVIAN SUBSTANTIA NIGRA HOMOLOGUE. I. J. Goodman. Dept. of Psychology, West Virginia University, Morgantown, WV 26506-6040.

The avian nucleus tegmenti pedunculo-pontinus (TP), according to evidence regarding its location, connections, neurotransmitter (catecholamine) content and behavioral consequences of its perturbation, appears to correspond to the mammalian substantia nigra. Many details regarding comparative structural and functional similarities and differences await clarification. In an effort to contribute toward that and as part of a program to achieve a better understanding of the role of catecholaminergic structures in avian behavior, the present study investigated characteristics of spontaneous single cell activity in avian TP.

The acute pigeon (Columba livia) preparation, maintained under chloral hydrate (initial dose, 400 mg/kg, i.p.), was employed in this study. Glass micropipettes, filled with 2 M NaCl saturated with fast green, were used to record extracellular unit activity under various drug conditions, i.e., anesthetic alone, anesthetic plus apomorphine (APO, dopamine agonist) and anesthetic plus haloperidol (HAL, dopamine antagonist), all delivered through a cannulated wing vein. These conditions were used as a means of pharmacologically differentiating dopamine and non-dopamine cells within TP, according to criteria established in mammals (Bunney, 1979). The final recording sites in animals were marked by a dye deposit at the electrode tip.

Spontaneously active cells were identified in TP with varying response characteristics across cells. Most cells tended to fire at slower rates (below 15 spikes/sec) with irregular interspike intervals, but with spike durations varying across cells (0.8 - 4.0 ms). Most recorded waveforms were biphasic (pos. - neg.) with a minority being triphasic (pos.-neg.-pos.), usually those with longer durations. The injection of APO (.01 - 0.5 mg/kg) produced a significant decrease in spontaneous firing rates, principally in cells showing longer duration spikes (2-4 ms), multiple spikes (bursts) and lower spike rates (below 8/sec), with inconsistent or no effects seen in other cells. HAL (.01 - 0.5 mg/kg) tended to produce a significant rise in firing rates of cells sensitive to APO and/or with shared electrophysiological response characteristics, while also having inconsistent or no effects on other TP cells. These effects provide a basis for separating TP neurons into dopamine and non-dopamine types, according to electrophysiological and pharmacological criteria. This is not unlike the findings reported for the mammalian substantia nigra. No systematic spatial arrangement of these cell types in TP was established.

63.23 CHARACTERISTICS, DISTRIBUTION, AND INTERRELATIONSHIPS OF SOMATOSTATIN, NEUROPEPTIDE Y, AND NADPH DIAPHORASE NEURONS IN HUMAN CAUDATE NUCLEUS.
N.W.Kowall, R.J.Ferrante*, M.F.Beal,and J.B.Martin. Dept. of Neurology and Neuropathology, Mass. General Hosp and Harvard Med. School, Boston MA 02114.

In the present study we have examined the topography of somatostatin (SS), neuropeptide Y (NPY) and NADPH diaphorase (NADPH-d) neurons in human caudate and their relationship to zones of differential acetylcholinesterase (AChE) activity (striosomes). Twelve blocks of striatum were fixed in neutral buffered formalin at 4 C for 48 hours. Sections were incubated with antisera to SS and NPY followed by amplification and detection using an avidin-biotin peroxidase method or indirect immunoflouresence. Absorption controls were consistently negative. NADPH-d staining was performed as previously reported except for the addition of Triton X-100 (0.8%) and monosodium malate (125mg%) to the incubation medium. These modifications enhanced staining of cell arbors and revealed a heterogeneous pattern of neuropil staining. Large numbers of reactive neurones were uniformly distributed throughout the caudate in bands and clumps which avoided zones of low AChE activity. This was especially striking in AChE, diaphorase double stained sections where neurons often congregated along the margins of high and low AchE activity. The background pattern of neuropil diaphorase activity was identical to that of AChE. The striosomal mosaic was modified in the nucleus accumbens where the elliptical or serpiginous low AChE patches were flattened and oriented into a series of horizontal bands. Colocalization studies, including double diaphorase immunocytochemistry and double simultaneous immunoflourescence, showed that SS, NPY, and diaphorase activities coexist in a single population of neurons in human striatum. The morphology of these neurons is variable and can be divided into 4 categories all of which are typical of aspiny type interneurons. Immunoreactive fibers were more prevalent in ventral caudate and accumbens suggesting that extrinsic projections, possibly from the basal forebrain, may contribute to high levels of SS and NPY in these regions. (NWK is an MRC fellow, supported in part by NS 16367).

63.24 QUANTITATIVE AUTORADIOGRAPHY OF ^{3}H-SPIPERONE BINDING SITES IN RAT STRIATUM FOLLOWING DISCRETE CORTICAL LESION.
J.M. Trugman* and G.F. Wooten, Dept. of Neurology, Univ. of Virginia School of Medicine, Charlottesville, VA 22908.

Using quantitative in-vitro film autoradiography we have studied ^{3}H-spiperone (^{3}H-SP) binding in rat striatum following a discrete cortical lesion. A 3x6 mm rectangular burr hole was made overlying the frontal cortex of one hemisphere and a suction lesion of the cortex was made within these confines. The time course and location of degenerating nerve terminals within the striatum were verified using a silver degeneration stain. At 5-7 days post-lesion, degenerating nerve terminals were localized to the dorsal striatum. Rats were killed at 5, 10, and 20 days after cortical lesion. Serial 20 μ sections were taken through the striatum for binding studies. Sections were incubated at room temperature for 30 min with 2 nM ^{3}H-SP in 50 mM tris-acetate-saline buffer, pH 7.4. Adjacent sections for nonspecific binding were incubated with ^{3}H-SP plus 2 μM d-butaclamol. Alternate sections were incubated for 90 min at room temperature in phosphate buffered saline with 1 nM ^{3}H-QNB, with and without 1 μM atropine. Sections were coexposed with calibrated ^{3}H Microscales (Amersham) to LKB Ultrofilm. Films were analyzed densitometrically with a Leitz MPV variable aperture microdensitometer.

Three areas within the body of the striatum were analyzed: dorsal striatum (1.3x.8 mm), ventral striatum (1.3 x .8 mm) and a dorsomedial area of pure gray matter adjacent to the lateral ventricle (.5x.1 mm). Four sections were analyzed per animal with 3-4 animals per time point. Paired t-tests were used to compare specific binding ipsi- and contralateral to the cortical lesion. ^{3}H-QNB binding served as a control for intrinsic striatal damage and revealed no significant asymmetries. The table below summarizes ^{3}H-SP binding expressed as fmoles/mg tissue wet weight. There were no differences at any time point.

		Control n=3	5 days n=3	10 days n=4	20 days n=4
Dorsal Striatum	Control	153±8	137±17	153±21	132±10
	Lesion	148±15	156±13	139±30	134±2
Ventral Striatum	Control	136±23	143±33	151±19	126±9
	Lesion	143±21	153±28	137±14	131±13
Dorsomedial Gray	Control	171±17	159±19	164±32	166±17
	Lesion	161±14	158±36	168±40	169±11

These results suggest that a discrete frontal cortical lesion which causes degeneration of cortical afferents in the dorsal striatum does not alter ^{3}H-SP binding. These results do not support the existence of D-2 receptors on cortico-striatal terminals.

MUSCLE I

64.1 VARIABILITY OF AXONAL CONDUCTION VELOCITY MEASUREMENTS IN MAMMALIAN MOTOR UNITS.
D.A. Gordon, T.M. Hamm, R.M. Reinking*, R.M. Enoka, and D.G. Stuart. Depts. of Physiology and Exercise & Sport Sciences, University of Arizona, Tucson, AZ, 85724.

The conduction velocity (CV) measurement is an important consideration in studies on the properties of mammalian motor units. The purpose of this investigation was to evaluate methods of determining CV of motor axons and to establish the reliability of these methods.

Single motor axons to the functionally isolated tibialis posterior (TP) muscle of the cat hindlimb were activated by suprathreshold stimulation of cut ventral-root (VR) filaments. Action potentials evoked in the TP muscle-nerve were recorded extracellularly and averaged with three bipolar electrodes at the popliteal fossa level. CV measurements were made from VR to muscle-nerve (conventional CV) and between proximal and distal pairs of muscle-nerve electrodes (muscle-nerve CV).

The comparison of CV measurements revealed that the muscle-nerve CV was 5.7% slower, on average, excluding corrections for stimulus utilization time, than the conventional CV estimate. Considerable variability, from a variety of potential sources, was observed in these values. Contributions to variability in CV could be attributed to variability in time and distance measurements as well as differences in stimulus utilization time, variable axonal branching, and variability in regional CV.

The variabilities inherent in distance and time measurements were estimated by making multiple measurements of these parameters. The combined uncertainty in these measurements alone accounted for much of the variability in measured values of conventional and muscle-nerve CV in individual experiments, indicating that uncertainties in the time and distance measurements account for most, but not all, of the variance of CV estimates in motor axons. We are still investigating interexperimental differences in CV estimates which were not well accounted for by these error estimates.

The uncertainties in the conventional and muscle-nerve CV estimates due to errors in time and distance measurements were calculated to be 0.9% and 4.8%, respectively. Comparison of these values suggests that a greater degree of reliability is provided by the conventional measurement of CV in single motor axons, due to the longer conduction distances and time provided by this method. This is in contrast to sensory axons whose morphology differs from motor axons, and in which other methods of measuring CV are preferable (Rindos et al., Experimental Neurology, 86(2): 208-226, 1985).

Supported by USPHS grants HL07249, NS20544 and NS17887.

64.2 FATIGUE-RELATED CHARACTERISTICS OF THE SOLEUS AND EDL MUSCLES IN SMALL AND LARGE CAGE-REARED FEMALE RATS.
K.A. Volz*, L.L. Rankin*, R.M. Enoka, and D.G. Stuart. (SPON: J.B. Angevine). Depts. of Physiology and Exercise & Sport Sciences, University of Arizona, Tucson, AZ 85724.

Previous studies from this laboratory (Enoka et al., and Rankin et al., Soc. Neurosci. Abstr. 10: 781, 1984) have indicated that the soleus (SOL) and extensor digitorum longus (EDL) muscles of male rats were affected by the size of the cage in which the animal was raised. To continue our investigation into cage-size effects, we have examined some histochemical and fatigue-related characteristics in female rat hindlimb muscle.

Female SD weanling rats were raised for 100-135 days in either a small FDA-approved laboratory cage (SC; 5/cage) or in one 258x larger (LC;15/cage). Subsequently, fatigue-related characteristics were determined in vivo for the muscles SOL and EDL, followed by qualitative histochemical analysis utilizing the stains for NADH and myosin ATPase (Peter et al., Biochem. 11(14): 2627, 1972) and measurement of individual fiber cross-sectional area (CSA) (Van Der Meulen et al., Neurology 27: 355, 1977).

The results indicate that, in contrast to our studies using male rats, the fatigue resistance of SOL and EDL in female rats was not significantly affected by cage size. In addition, cage size did not significantly affect the histochemical composition of either SOL, a predominantly slow-contracting muscle (LC-SOL = 85% SO, 15% FOG; SC-SOL = 78% SO, 22% FOG, n = 4) or EDL, a fast-contracting muscle (LC-EDL = 5% SO, 51% FOG, 44% FG; SC-EDL = 3% SO, 57% FOG, 40% FG, n = 4). The mean CSAs for these fiber types in each muscle were not statistically different either. However, when the mean normalized CSA values of LC-SOL were compared to SC-SOL, a significant difference was revealed ($p < .05$). The same relationship, however, did not hold for EDL, but this is, in part, explained by the significant variation ($F_{12,12} = 11.63$, $p < .0025$) in all fiber-type CSAs for the LC- EDL. Further, when the mean CSAs for type SO fibers in all SOL (LC + SC) were compared to the fatigue index (FI; Burke et al., J. Physiol. 234: 723, 1973), a significant correlation was identified ($r = 0.78$, $p < .05$). Finally, there was no correlation ($r = 0.26$) when the FI of all SOL (LC + SC) were compared to the FI of all EDL.

These results suggest: (1) male and female rats respond differently to the opportunities afforded by cage size, (2) SOL is more affected by cage size than EDL, a consequence perhaps of its presumed usage, (3) the correlation between the SO-CSA of SOL and its FI is developed because of biochemical changes in the SO fibers which enhance fatigue resistance and, (4) since intra-animal fatigue resistance for SOL and EDL is not related, the mechanism of fatigue as demonstrated by the FI may well be different for the two muscles.

Supported by grants from NASA (NAGW 338) and NIH (HL07249).

64.3 **RELATION BETWEEN WHOLE-MUSCLE EMG AND FORCE DURING A FATIGUE TEST.** R.M. Enoka, L.L. Rankin*, K.A. Volz*, M.J. Joyner*, and D.G. Stuart. Depts. of Physiology and Exercise & Sport Sciences, University of Arizona, Tucson, AZ 85724.

In an attempt to identify the mechanisms associated with the decline in force during a standarized fatigue test (Burke et al., J. Physiol. 234: 723, 1973), we have monitored, in vivo, the compound muscle action potential (AP) and the isometric force during a 6-min test in which the test muscle was activated by supramaximal intermittent stimulation of its nerve. Accordingly, the soleus (SOL) and extensor digitorum longus (EDL) muscles of male and female SD rats (4.36 and 2.68 N, respectively; 120-150 days) were subjected to a protocol that included 1 Hz trains of 13 stimuli delivered at a rate of 40 Hz. The APs were recorded with a pair of intramuscular stainless-steel electrodes and were quantified by average measurements of the area and "mean" amplitude (MA) for the 13 APs within each train (Stuart et al., Proc. XXIV IUPS XV: 190, 1983). The fatigability of the muscles was quantified by a measure of fatigue resistance (FR): peak tetantic force at 6 min relative to initial force.

By raising the rats in small and large cages, the FR of both test muscles extended over a range of values such that the muscles clustered into significantly different ($p < .001$) groups of relative high, intermediate, and low FR: for SOL, these values ($\bar{X} \pm SD$) were 112 ± 7 (n = 10), 92 ± 6 (n = 7), and $67 \pm 14\%$ (n = 5), respectively, while for EDL, the values were 48 ± 5 (n = 8), 33 ± 5 (n = 8), and $10 \pm 7\%$ (n = 8), respectively. Despite these differences in FR for EDL, the 3 groups exhibited a qualitatively similar relationship between AP area and force during the course of the fatigue test. In all 3 groups, the relationship was characterized by an initial potentiation and a subsequent parallel decline in both AP area and force. Quantitatively, however, the high FR group displayed the greatest potentiation of both force and AP area. Somewhat similar relationships were apparent between MA and peak force for EDL, although MA did not potentiate initially as did AP area. The changes in area and MA during the test were similar for EDL ($r^2 = 0.85$, $p < .01$). In contrast, the high and intermediate FR SOL groups demonstrated a markedly different area-force relationship than the low FR group in that force essentially remained constant while AP area potentiated for the former groups and, conversely, area remained constant while force declined for the low FR group. In addition, the changes in AP area and MA for SOL, while significant ($p < .01$), were less related ($r^2 = 0.35$) than for EDL.

It was apparent that under these conditions (cf. also Sandercock et al., J. Appl. Physiol. 58: 1073, 1985) both AP area and MA changed during the course of the fatigue test. However, we are uncertain at this point as to whether these AP changes reflect a change in the neural drive, a tissue-filtering effect, or some combination of the two mechanisms.

Supported by grants from NASA (NAGW 338) and NIH (HL07249).

64.4 **COEXISTENCE OF WHOLE-MUSCLE FATIGUE AND TWITCH POTENTIATION IN RAT HINDLIMB MUSCLE.** L.L. Rankin*, R.M. Enoka, K.A. Volz*, and D.G. Stuart. (SPON: A. Kaszniak) Depts. of Physiology & Exercise & Sport Sciences, Univ. of Arizona, Tucson, AZ 85724.

The degree of potentiation of isometric twitch tension is dependent upon activation history and muscle-fiber type (Burke et al., Brain Res. 109: 515, 1976; Jami et al., J. Physiol. 340: 129, 1983). Comparing whole muscle twitches before (pre) and after (post) a 6-min fatigue test, we observed greater tension in post-twitches than in pre-twitches in some muscles despite significant fatigue developed during the intervening test.

These observations were based upon data acquired during a previously reported study on the effects of cage-size on muscle properties in rat soleus (SOL) and extensor digitorum longus (EDL) (Rankin et al., Soc. Neurosci. Abstr. 10: 781, 1984). The protocol included: (1) 32 twitches at 0.5 Hz; (2) 1 100-Hz tetanus (500 ms); (3) 6-min fatigue test (13 stimuli at 40 Hz repeated 1/s); (4) 8 twitches at 0.5 Hz; and, (5) 2 100-Hz tetani. Fatigue resistance was determined by expressing peak tetanic force at 6 min relative to the initial peak force. Mean values (n = 18) for peak tension (P_t), time-to-peak tension (TPT) and one-half relaxation time (½ RT) were determined for the 8 twitches immediately preceding (pre) and the 8 twitches following (post) the fatigue test.

Twitch potentiation (post P_t/pre $P_t > 1.0$) was observed in 61% of EDL muscles despite a mean 52% decline in peak force during the fatigue test. In contrast, only 33% of SOL muscles potentiated while force declined by 17% during the test. Given their fiber-type compositions (EDL = 3% SO, 59% FOG, 38% FG; SOL = 84% SO, 16% FOG; Ariano et al., J. Histochem. Cytochem. 21: 51, 1973), this difference between EDL and SOL is consistent with the previously reported observation, albeit with a different protocol, that the coexistence of fatigue and potentiation occurred most frequently in FR motor units (FOG fibers), less in FF units (FG fibers) and infrequently in S units (SO fibers) in cat peroneus tertius (Jami et al., 1983). However, in contrast to these investigators, we found positive linear correlations between fatigue resistance and twitch potentiation for both EDL and SOL ($r = 0.94$ and 0.86, respectively).

TPT and ½RT times were significantly longer in post-twitches (123% and 170%, respectively) for EDL, providing further evidence of muscular fatigue (Edwards et al., J. Physiol. 251: 287, 1975). No significant changes in these values occurred in SOL. The change in TPT for EDL in association with potentiation is consistent with the notion that repetitive stimulation can alter the state of activation and hence twitch dynamics (Wilkie, Br. Med. Bull. 12: 177, 1956).

The simultaneous occurrence of whole-muscle fatigue and potentiation suggests that the mechanisms underlying these two phenomena affect different sites within the muscle, but the linear relationship suggests that they are not totally independent of one another.

64.5 LONG DURATION MUSCLE FATIGUE CAUSED BY IMPAIRED EXCITATION-CONTRACTION COUPLING. R.G. Miller, H.S. Milner-Brown*, D. Hooper*, R.B. Layzer*, & M.W. Weiner*. Department of Neurology, Children's Hospital of San Francisco, San Francisco, CA. 94118 and Department of Neurology, Radiology and Medicine, University of California/ San Francisco, San Francisco, CA. 94143.

The mechanism of long-lasting muscle fatigue has been studied utilizing simultaneous measurements of 31^P Nuclear Magnetic Resonance spectroscopy, surface rectified integrated EMG(RIEMG) and force from the human adductor pollicis. During a four minute maximum isometric contraction to produce muscle fatigue, pH fell from 7.1 to 6.4, phosphocreatine fell to undetectable levels, and mean maximum force fell by 80%; neuromuscular efficiency (NME) (NME=Force (N), in a 5s, 50% maximal contraction) fell to 45% of RIEMG (mV)
the pre-fatigue value immediately after the four minute fatiguing contraction.

During recovery, pH and high energy phosphates returned to control levels within thirteen minutes and maximum force generating capability returned to 96% of control levels within 15 minutes; however, NME recovered more slowly (mean 70% at fifteen minutes and 85% at thirty minutes).

To test our hypothesis that the delayed recovery of NME was due to persistent impairment of excitation-contraction coupling, post-tetantic potentiation of the twitch was examined before and after fatigue. Post-tetanic potentiation (PTP) was 60% in the fresh muscle, less than 25% after fifteen minutes of recovery from fatigue with gradual return toward baseline levels over a time course that paralleled that of NME. Similarly, the response to low frequency stimulation recovered more slowly (85% of control within 21 minutes of recovery) than the response to high frequency stimulation which was nearly complete (97% after twenty-one minutes of recovery).

These observations support our hypothesis that long duration fatigue is independent of muscle pH and inorganic phosphates. A persistent impairment of excitation-contraction coupling is likely based on these observations.

64.6 **ENDURANCE TIME CHARACTERISTICS OF THE DORSIFLEXOR AND PLANTARFLEXOR MUSCLES OF THE HUMAN ANKLE** A. Vahid Shahidi*, R.E. Kearney and I.W. Hunter (SPON: H. Galiana). Biomedical Engineering Unit, Faculty of Medicine, McGill University, Montréal, Québec, Canada, H3G 1Y6.

Neuromuscular fatigue may be defined as any reduction in the force generating capacity of the neuromuscular system (Bigland-Ritchie & Woods, Muscle & Nerve, 7:691, 1984). The time for which a specified force can be maintained, the **endurance time**, provides a convenient measure of the fatigue resistance of a muscle. It has been sugggested that the ankle plantarflexors are more resistant to fatigue than the dorsiflexors (Belanger et al., Eur J Appl Physiol, 51:381, 1983), but the relative endurance times of these two muscle groups does not appear to have been documented previously. The purpose of the present study was to determine the endurance times of the ankle dorsiflexors and plantarflexors as a function of the level of contraction.

Subjects were required to match a constant target signal by generating an equivalent ankle torque. Subjects were instructed to stop contracting when they could no longer achieve the target level. Target levels ranging from 15% to 90% of the maximum voluntary contraction (MVC) were examined for both plantarflexing and dorsiflexing contractions. Ankle torque and surface electromyograms from tibialis anterior, triceps surae, and lateral gastrocnemius were sampled at 20 hz throughout the contractions. The endurance time was defined as the time at which the ankle torque first dropped below 95% of the target level.

The figure shows endurance time as a function of contraction level for both plantarflexing (triangles) and dorsiflexing (squares) contractions for a typical subject. Endurance time decreased with increasing contraction level in an approximately exponential manner. Indeed, a simple exponential model fitted to the data provided a good fit; the variance accounted for by this model was always greater than 97.5% for the four subjects studied to date. The excellent quality of the fits obtained is shown by the similarity of the symbols (experimental data) and the smooth lines (predicted values) in the figure.

$$T = ae^{-M/b} + c$$

T = endurance time, (s)
M = % MVC,
a,b,c = constants.

64.7 REGIONAL DISTRIBUTION OF THE OXIDATIVE CAPACITY AND ITS RELATIONSHIP TO FATIGUE RESISTANCE OF MOTOR UNITS.
T.P. MARTIN* and V.R. EDGERTON. Brain Res. Inst. and Dept. Kinesiology,UCLA.Los Angeles,CA,90024

The activity of an oxidative metabolism marker enzyme has been observed to be limited in its predictability of the fatigue resistance(FI) of normal and spinal transected muscle(Baldwin JAP 56:1602,1984). Some disassociation of these two parameters is further suggested by essentially a bimodal distribution of FI in tibialis anterior(TA) units while a population of fibers from this muscle displays a unimodal distribution of succinate dehydrogenase(SDH) activity(Roy Neurosci. Abstr. 73,1984). These results imply that other factors inaddition to the absolute oxidative capacity of a muscle unit determine the FI.

Thirteen TA units were isolated by ventral root splitting and identified by glycogen depletion. SDH activity was measured by a quantitative histochemical technique. The regional distribution of SDH activity was calculated from the mean activity of concentric rings(starting from the edge of the fiber and progressing to the center) and expressed as the slope of the activity of each successive ring(radial distance from edge/SDH activity). The FI was calculated from the ratio of the initial tension relative to the tension at 2 min during 40pps for 330msec stimulation.

Units displayed FI's that ranged from .01-1.0 and SDH activities from 31 picoM/min to 88 picoM/min. Units displayed also one of three consistent and unique distributions of SDH. These are characterized as A)homogenious throughout the fiber, no slope B) mean slope = -0.6 um/picoM/min C) mean slope = -1.0 um/pM/min. Profile C was associated also only with fibers that stained lightly for myosin ATPase(pH 8.8). A non-linear relationship was observed between the mean SDH activity of the unit and FI. However when both the absolute SDH activity and its regional distribution(SDHxSlope) were considered a linear relationship was observed with FI. It appears that the combination of the total SDH activity of a unit's fibers and how that activity is distributed throughout the cross-section of the cells is an important determinant of FI. Further, the regional distribution of SDH activity is related to the physiological classification of unit types in the TA.

64.8 NON-CORRESPONDENCE BETWEEN ELECTRICAL AND MECHANICAL PROPERTIES OF DIAPHRAGM MOTOR UNITS.
G.C. Sieck, M. Fournier, D. Hary* and M.J. Belman* Dept. of Respiratory Diseases, City of Hope Medical Center Duarte, CA 91010. Depts. of Anatomy and Kinesiology, UCLA School of Medicine, Los Angeles, CA 90024 and Dept. of Biomedical Engineering, USC, Los Angeles, CA 90089.

If the motor unit action potential (MUAP) is a reliable manifestation of the electro-chemical events leading to force generation and if fatigue results from a failure in these events then changes in the MUAP should correspond with force decline. The purpose of this study was to assess the relationship between electrical and mechanical properties of diaphragm motor units during a commonly used fatigue test. In anesthetized cats, MUAP's were recorded from pairs of fine wire electrodes implanted in the sternal, costal and crural regions of the right hemidiaphragm. After freeing the costal margin from the rest of the rib cage, a force transducer was attached in series with diaphragm fibers. The central tendon was clamped near the fiber insertion and fixed to the frame in which the animal was positioned. Following a cervical laminectomy, the spinal cord was transected at C3, and dorsal roots from C4 to C7 were cut bilaterally. While the C5 ventral root was stimulated supramaximally, muscle fiber length was adjusted so that force measurements were made under optimal isometric conditions. Filaments of the C5 ventral root were then dissected until single motor units in the diaphragm were isolated based on criteria of constant evoked MUAP and twitch force responses. Motor units were classified as either fast or slow based on their twitch contraction times and the presence or absence of sag. To assess motor unit fatigability, ventral root filaments were stimulated at 40 pulses/sec in trains of 330ms duration at 1 train/sec. A fatigue index (FI) was calculated as the ratio of force produced after 2 min of stimulation divided by the initial force. During the fatigue test, evoked MUAP's were plotted in a raster display to determine changes in waveform and peak to peak amplitude. In some fast fatigable units (FI < 0.25), changes in the amplitude and/or waveform of the MUAP corresponded with the reduction in force. Similarly, in some slow and fast, fatigue-resistant motor units (FI > 0.75), little change in MUAP amplitude or waveform occured. However, we encountered a significant number of fast motor units whose evoked MUAP's remained unchanged even in the presence of a substantial decline in force. In other motor units, changes in the MUAP occured with very little decrement in force. We conclude that changes in the MUAP during this particular fatigue test do not consistently correspond with the classification of motor unit types. Thus, these data indicate that motor units classified as the same type may have different mechanisms of fatigue.

64.9 SOMATOTOPIC ORGANIZATION IN THE SEGMENTAL INNERVATION OF THE DIAPHRAGM.
M. Fournier* and G.C. Sieck. (SPON: D. Barnes) Department of Respiratory Diseases, City of Hope Medical Center, Duarte, CA 91010 and Departments of Anatomy and Kinesiology, UCLA School of Medicine, Los Angeles, CA 90024.

The purpose of this study was to determine the topographical organization in the segmental innervation of the diaphragm using the method of glycogen depletion. This technique offers the advantage over previously used methods in that the spatial distribution of muscle fibers innervated by stimulated axons can be identified using histochemical techniques. Adult cats were anesthetized and fine wire electrodes were implanted in the sternal, costal and crural regions of the right hemidiaphragm. The costal origin of diaphragm fibers was freed from the rib cage and attached in series with a force transducer. The central tendon was clamped near the insertion of muscle fibers and fixed to the frame in which the animal was positioned. Muscle fiber length was adjusted so that force measurements were made under optimal isometric conditions. Following a cervical laminectomy, the spinal cord was transected at C3 and dorsal roots from C4 to C7 were cut bilaterally. Ventral roots from C4 to C7 were dissected and evoked EMG and/or force responses determined. Responses were primarily limited to the C5 and C6 ventral roots, although smaller responses were occasionally observed by stimulation of C4. To deplete muscle fiber glycogen, the C5 or C6 ventral root was stimulated at 50 to 75 pulses/sec in trains of 100 ms duration at 2 trains/sec. Stimulation was continued until force reached minimal levels (1 to 2 hrs). The diaphragm was then excised and segments from the entire muscle were rapidly frozen. Alternate muscle cross sections were stained for glycogen using the periodic acid-Schiff (PAS) reaction and for myosin ATPase to classify fiber types. Muscle fiber staining intensity in the PAS reaction was quantified using a computer-based image analysis system. Fibers on the non-stimulated side were used as controls. Approximately 3,000 fibers were sampled in each diaphragm. The glycogen content (PAS optical density) of fast-twitch fibers was distributed bimodally, with no overlap between depleted and control fibers. In slow-twitch fibers, a bimodal distribution of glycogen content was also observed, but there was overlap between stimulated and control fibers. Estimation of proportions of fibers,innervated by each ventral root was therefore based on measurements in fast-twitch fibers. Stimulation of C5 resulted in glycogen depletion in about 90% of fibers in the sternal, ventral costal and ventral crural regions. Stimulation of C6 resulted in a similar depletion of fibers in the dorsal costal and dorsal crural regions. There was a gradual reduction in the numbers of fibers innervated by each ventral root moving toward the mid-costal or mid-crural region. An overlap in innervation occured in the mid-costal region with C5 innervating fibers on the abdominal side and C6 fibers on the thoracic side.

64.10 INNERVATION RATIO, FIBER SIZE AND SPECIFIC TENSION OF TYPE-IDENTIFIED MOTOR UNITS IN THE CAT TIBIALIS ANTERIOR
S.C. Bodine, R.R. Roy, E. Eldred, and V.R. Edgerton. Brain Research Institute, UCLA, L.A., CA. 90024

Types of motor units identified by physiological and histochemical profiles differ in the maximum tetanic force (P_o) produced by the single units. These differences might be related to the number of fibers per unit, i.e., innervation ratio (IR), fiber cross-sectional area (CSA), and/or specific tension (SpT). Previous investigations of type-identified motor units, however, have not included direct measurements of each of these factors, and therefore, information regarding the regulation of P_o in different motor unit types is based on indirect estimations.

In this study, the factor(s) responsible for the variability found in P_o of motor units were determined for units of the tibialis anterior (TA). The TA was chosen because it has relatively long fibers. Units in the TA were characterized physiologically as S, FR, or FF (Burke et al. Science 174, 1971) and subsequently depleted of their glycogen through repetitive stimulation of an isolated ventral root filament. Cross-sections were stained for glycogen using a periodic acid-Schiff reaction and analyzed using an image processing system which allowed for the measurement of single-fiber optical densities and CSA. This system permitted a more precise identification of those fibers belonging to the motor unit (MU) than did visual inspection alone. The number of fibers belonging to the MU was determined in a number of cross-sections taken along the length of the muscle. CSA was measured for each fiber belonging to the MU. Specific tension (SpT) was calculated as the ratio of P_o : total CSA, where total CSA equals the sum of the areas of all the fibers belonging to the MU.

Type	P_o (g)	Mean CSA (um^2)	IR	Total CSA (cm^2)	SpT_o (kg/cm^2)
S	2.3	1935	80	.0015486	1.49
S	4.7	3007	88	.0026463	1.78
FR	8.6	2234	161	.0035968	2.39
FR	9.6	2629	198	.0048387	1.98
FF	11.5	3239	166	.0053766	2.14
FF	16.0	2953	193	.0056991	2.81
FF	27.5	3693	281	.0103799	2.65
FF	28.5	3287	379	.0124592	2.18

These data suggest that type S units in the TA have a somewhat lower SpT and IR than type FF and FR units, and moreover, a lower SpT than the type S units in the cat soleus Neurosci. Abstr., 25.5, 1984). The FF and FR units appear to have similar SpT and IR, but differ considerably in fiber size. This observation might explain the differences in P_o between FF and FR units.

64.11 CORRELATION OF ELECTROPHYSIOLOGY AND HISTOCHEMISTRY OF MURINE MUSCLE FIBER TYPES USING HORSERADISH PEROXIDASE. J.A. Florendo*, J.F. Reger*, and P.K. Law (SPON: R.A. Schreiber), Depts. of Anatomy, Neurology, and Physiology/Biophysics, Univ. of Tennessee Ctr. Hlth. Sci., Memphis, TN 38163

Miniature end-plate potentials (MEPPs) were recorded in vivo at 37°C from surface fibers of the fast-twitch extensor digitorum longus (EDL) and the slow-twitch soleus (SOL) muscles of adult Bar Harbor 129 mice. Previous studies demonstrated that the EDL MEPPs had a significantly higher frequency, smaller amplitude, and shorter duration than the SOL MEPPs (Exp. Neurol. 82:404-412, 1983). To test if these electrophysiologic differences were characteristics of the different histochemical fiber types of these muscles, the electrophysiology and histochemistry of individual muscle fibers were compared using horseradish peroxidase (HRP) for identification. MEPPs from individual fibers of EDL and SOL muscles were recorded and measured for frequency, amplitude, and duration. After each recording, the muscle fiber was injected with HRP by depolarization at 2mA for 30 sec for subsequent cytochemical identification. Each whole muscle was then removed and immediately frozen in methyl-butane cooled by liquid nitrogen. Serial sections (10 μm) were stained for HRP, to identify the fiber from which the recording was made, and for succinic dehydrogenase, phosphorylase, and acidic and alkaline myosin ATPase. The MEPP parameters of each fiber were compared with its cytochemical profile. Muscle fibers exhibiting higher frequencies, smaller amplitudes, and shorter durations corresponded with fast glycolytic or type IIB fibers. Fibers demonstrating lower frequencies, greater amplitudes, and longer durations were found to be slow oxidative or type I fibers. And fibers with overlapping characteristics were shown to be fast oxidative glycolytic or type IIA fibers. Therefore, this study demonstrates a direct correlation between MEPP characteristics and histochemistry of fiber types.

64.12 SEXUAL DIMORPHISM OF MUSCLE FIBER TYPES IN THE LARYNX OF *XENOPUS LAEVIS*. G.E. Gray, D.A. Sassoon, and D.B. Kelley (SPON: W. Walthall) Department of Biological Sciences, Columbia University, New York, NY, 10027.

Sex-specific vocal behaviors of the adult South African clawed frog, *Xenopus laevis*, are sensitive to circulating androgens (Wetzel and Kelley, *Horm. Behav.*, 1983). Males produce mate calls, prolonged bouts of repetitive trills that attract females. Females produce ticking, a brief and intermittent vocalization, signalling sexual unreceptivity. The larynx, which is the vocal organ, is markedly sexually dimorphic in overall size and in muscle mass. Using histochemical methods, we examined adult laryngeal muscle for sex differences in fiber type and studied the effects of circulating androgens.

Laryngeal muscle from sexually mature males and females, one-month castrated males, and one-month testosterone-treated ovariectomized females was cryostat sectioned and histochemically reacted for succinate dehydrogenase (SDH) and ATPase activity . Thigh muscle, which has no apparant dimorphism, was assayed for comparison. Our results show that muscle fiber types differ in the larynx of male and female *X. laevis*. Female laryngeal muscle is composed of a heterogeneous population of fiber types, in which both the SDH and ATPase reactions reveal a population of dark, light, and intermediate-staining fibers. Male laryngeal muscle is composed of a homogeneous population of fibers that stain dark for SDH, intermediate for ATPase at pH 8.5, and light for ATPase at pH 4.5. These results suggest that male laryngeal fibers are of the fast-twitch-oxidative-glycolytic type (terminology of Peters et al., *Biochem.*, 1972). Thigh muscle does not show sexual dimorphism in its fiber type. Its staining pattern for SDH and ATPase is heterogeneous, although SDH activity is lower than in laryngeal muscle of either sex, suggesting an overall greater oxidative capacity in the larynx. In castrated males and testosterone-treated females, the overall pattern of staining was similar to that of intact untreated adults. We therefore are investigating whether regulation of fiber type is due to hormone action at an earlier period of development. The fiber type of the male larynx suggests that it is especially adapted for the demands of mate-calling, which requires fast muscle contraction and high oxidative capacity for prolonged activity.

64.13 MORPHOLOGY-HISTOCHEMISTRY OF INTRINSIC LINGUAL MUSCLES IN MACACA FASCICULARIS. Roxanne De Paul*, Amy Wood*, James Abbs, & Robert Sufit. (Spon. C. Welt) Speech Motor Control Labs.(Waisman Center) & Dept. of Neurology. Univ. of Wisconsin, Madison, WI 53705-2280.

Despite the importance of primate intrinsic tongue muscle functions in speech and feeding, current data consist primarily of gross morphology; there is little or no information on primate tongue muscle fiber types, their inter- or intramuscular distribution, or the nature of the associated connective tissue. These data are basic to the understanding of tongue motor control and associated CNS organization. Likewise, because these muscles coactively manipulate the three-dimensional shape of the tongue, their mechanical inter-relations are also of importance.

Whole tongues were obtained from 10 M. Fascicularis monkeys and variously blocked to permit serial sectioning in the coronal, parasaggital, and horizontal planes. The tissue was mounted with tragacanth gum, quick frozen at 160 degrees C in liquid nitrogen-cooled isopentane, and sectioned serially (8 u) to permit longitudinal and cross-sectional views of superior longitudinal (SL), inferior longitudinal (IL), transverse (T), and vertical (V) muscles and their inter-relations. Sections were processed using modified Gomori trichrome, NADH-tetrazolium reductase, myosin ATPase, reverse ATPase, and Verhoeff Van Giesen methods.

Morphologically, these tongue muscles were notably different from limb muscles. Fiber inter-digitation among the four muscles was striking. Connective tissue (both collagen and elastin) was seen along the length of most fascicles, providing mechanical interfaces to mucosa, other fascicles of the same muscle, and other intrinsic muscles. As such, these muscles were inseparable mechanically; contraction of one intrinsic muscle would appear to change the orientation of other intrinsic muscles, hence yielding complex interdependent actions.

There were fiber type variations both among and within these intrinsic muscles. In the very tip of the tongue, fibers in the four muscles were almost exclusively type II. Slightly more posteriorly, the strong predominance of type II fibers in SL and IL muscles was maintained while, by contrast, there was an abrupt transition in V and T muscles to about 40% Type I fibers. Most posteriorly, Type I and II fibers were distributed about equally in all muscles. These fiber type variations suggest that the anterior and posterior segments of SL and IL may function separately, i.e., type II fiber contractions underlie the characteristic rapid movements of the tongue tip while the slower, postural actions of the posterior tongue body logically are more dependent upon type I fibers. The potential neural correlates of these intra-muscular variations (e.g., motor and sensory cortical fields, XIIth nucleus MN musculotopy) need to be investigated. (Supported by NIH; NS-13274 & HD-03352; & MDA).

64.14 MUSCLE SPINDLE DISTRIBUTION IN THE INTRINSIC TONGUE MUSCLES OF M. FASCICULARIS: RELATION TO MUSCLE FIBER TYPES. Robert L. Sufit, James H. Abbs, Roxanne De Paul*, & Amy Wood*. Speech Motor Control Labs. (Waisman Center) & Dept. of Neurology. Univ. of Wisconsin, Madison, WI 53705-2280.

As described in a companion paper (De Paul et al., this meeting), the intrinsic tongue muscles of M. Fascicularis manifest a nonuniform distribution of type I and type II muscle fibers; Specifically, the most anterior portions of the superior longitudinal, inferior longitudinal, transverse, and vertical muscles (the tongue tip) are comprised almost exclusively of type II fibers, while the posterior portions of these same muscles have approximately equal numbers of type I and type II fibers.

The present study, conducted on five animals also studied in the companion paper, was aimed at determining if muscle spindles were concentrated in regions comprised of type I fibers. Such spindle concentration has been reported for many limb muscles and appears to be paralleled by preferential stretch reflex activation of muscle fibers in the muscle regions where the spindle receptors are located. This possibility has significance for the intrinsic tongue muscles inasmuch as (1) several investigators have reported an absence of a stretch reflex in the anterior tongue muscles, and (2) anterior and posterior segments of the tongue are involved in quite different motor actions, indicating probable differential control.

The whole tongues from the five M. Fascicularis were variously blocked to permit serial sectioning in coronal, parasaggital, and horizontal planes. Tissue was quick frozen at 160 degrees C in liquid nitrogen-cooled isopentane. The serial sections (8 u) were processed to permit identification of muscle spindles using modified Gomori trichrome and Verhoeff Van Giesen methods. Sectioned tissue from each tongue was examined along several representative 4-5 cm segments, always including the very tip. Because muscle spindles in the tongue are reported to be different from those in limb muscles, several criteria were utilized by two independent observers to ensure positive identification.

Spindles were not numerous. However, they were seen almost exclusively in the posterior portions of the four intrinsic muscles examined. That is, there were no spindles in the tongue tip and most were in the posterior one-half. As such, consistent with limb muscles, spindles were absent in the intrinsic tongue muscle regions comprised mainly of type II fibers and identified readily in regions which had a sizable proportion of type I fibers.

These data reinforce the probable independent activation of the anterior and posterior portions of the intrinsic tongue muscles and suggest that stretch reflexes might be discernible if one were to monitor EMG activity posteriorly. (Research supported by NIH; NS-13274 & HD-03352; & MDA).

64.15 HISTOCHEMISTRY OF GASTROCSOLEUS MUSCLES IN THE TWITCHER MOUSE
R.F. Mayer, E. Toyoshima, E. Potes*, A.M. Yeager* and H.W. Moser, Veterans Administration Medical Center, Department of Neurology, Univ. of Maryland Sch. of Med., and Johns Hopkins Univ. Sch. of Med., Baltimore, Maryland 21201

The twitcher mouse (twi) is a recently discovered authentic model of globoid cell leukodystrophy (GLD) and the genetic defect is a deficiency of galactosylcerimadase activity (Kobayashi et al, Brain Res. 1980). The primary pathological lesions involve the meylin of both central and peripheral nervous systems. In peripheral nerve, axons are not involved and remyelination follows demyelination (Duchen et al, Brain, 1980). The disease is progressive and the animals usually die within 8 weeks. In a recent study, A.M. Yeager and associates (Science, 1984) have shown that hematopoietic cell transplantation (HCT) prolonged survival and peripheral nerve remyelination in the twi. Motor conduction velocities remain slow in HCT-treated twi, but the animals remain active (Toyoshima et al, Neurology, 1985). There are limited data on the effects of this disease and prolonged demyelination-remyelination on muscle fibers in hind limbs. Reports in patients with GLD have suggested that congenital muscle fiber type disproportion (CMFTD) occurs and may have a neurogenic mechanism. We have examined soleus, plantaris and gastrocnemius muscles in untreated and HCT-treated twi and controls at 28, 40, 84 and 109 days to determine whether there are any histological-histochemical changes. The muscles were frozen in isopentane and liquid nitrogen, sectioned in a cryostat at 10 µm and reacted for myofilbrillar ATPase at alkaline (pH 9.4) and acid (pH 4.35), NADH diaphorase and modified trichrome using established techniques. Serial cross sections were obtained, photographed and the muscle fibers (mean of 426) typed as I (oxidative), IIA and IIC (oxidative-glycolytic) and IIB (glycolytic). Whole muscles of the twi were smaller than controls. At 34-45 days, the soleus (mean wet weight) was 31% control, the plantaris was 29% control and the gastrocnemius was 25% control. There were no degenerating or regenerating fibers and no target fibers. Muscle fiber atrophy was evident at 40 days and was more prominent in type II fibers than type I. There was no fiber type grouping, group atrophy or CMFTD. Studies in the normal soleus revealed a mean (4 animals) of 33% type I, 65% type IIA and 2% type IIC fibers; no type IIB fibers were observed. In the twi, the mean percent of type I (34%) fibers remained the same, no IIB fibers were seen, somewhat fewer type IIA (59%) fibers and more type IIC (7%) fibers were present. The type IIC fibers were increased at 84 and 109 days only. This study suggests that in the twi, demyelination is not associated with fiber type grouping, but muscle fiber atrophy and some increase in type II fibers occurs.

64.16 INFLUENCE OF NEURAL ACTIVITY ON MORPHOLOGICAL AND HISTOCHEMICAL CHARACTERISTICS OF RAT SKELETAL MUSCLE.
K.E.Misulis*, W-D.Dettbarn, R.C.Gupta*, and G.T.Patterson. Depts. of Neurology & Pharmacology, Vanderbilt Univ. Nashville, TN 37212

In this study we have used three models of altered rat hindlimb muscle activity to determine the factors of neural innervation responsible for intact skeletal muscle structure and function. These were: 1) sciatic nerve crush producing denervation with subsequent reinnervation, 2) spinal cord section with resultant paraplegia, and 3) hypokinesia by hindlimb suspension. All of these resulted in disuse of the hindlimb, but with the lesions at different functional levels of the motor system. At times ranging from 0 to 4 weeks the predominately slow (type 1) soleus and the predominately fast (type 2) extensor digitorum longus (EDL) muscles were removed for analysis. Actomyosin ATPase reactions were performed on mid-belly cross-sections of the muscles for evaluation of fiber number, fiber type proportions, and quantitative morphological analysis. These results were correlated with muscle activity as measured by single unit and whole muscle electromyography.

In the soleus, all of these treatments produced an increase in the proportion of type 2 fibers at the expense of type 1 fibers. Total fiber count showed that this was due to a conversion of reaction characteristics rather than to a drop-out of type 1 fibers. Morphological analysis showed a decreased mean diameter and an increased variation in fiber diameter of all fiber types with all treatments. The EDL was less affected by each of these treatments. These similar histochemical effects were associated with very different patterns of electrical activity. Nerve crush abolished neurally-induced electrical activity until innervation was re-established. In contrast, spinal cord section produced little change in muscle activity, although the hindlimbs were not used for ambulation. Hypokinesia resulted in the muscles becoming virtually electrically silent, but without a structural lesion to the neuraxis.

All of these treatments produced qualitatively similar changes in the morphological and histochemical characteristics of the soleus in spite of very different patterns of muscle electrical activity. This suggests that some feature of these treatments other than activity, per se, is responsible for the normal fiber type characteristics. The common feature of these treatments is the prevention of weightbearing and useful ambulation. These data support the hypothesis that the soleus depends not only on neural activity but also on load-bearing for maintenance of normal muscle characteristics.

Supported by NASA grant #NAG 2-301.

REFLEX FUNCTION I

65.1 MECHANICAL ANALYSIS OF "ANTAGONOGENIC" REFLEX ACTION IN DECEREBRATE CATS.
T.R. Nichols. Dept. of Physiology, Emory Univ. School of Med., Atlanta, GA 30322.

The mechanical response properties of an intact joint should be determined not only by the inherent mechanical properties of the muscles acting at the joint and autogenetic reflexes acting on these muscles and synergists, but also by the actions of pathways which interconnect the antagonists. For example, one would predict from electrophysiological studies that the force response of a muscle stretched by joint rotation should be enhanced by disinhibition through the reciprocal Ia inhibitory pathway from the released antagonist (Hultborn H, et al.,Acta physiol. scand., 96:368, 1976). I evaluated the actions of such "antagonogenic" pathways by making simultaneous mechanical measurements on pairs of antagonists acting at the cat's ankle. Cats were decerebrated at the premammillary level under halothane. The right foot was disarticulated and the tendons of either soleus and tibialis anterior or soleus and extensor digitorum longus were connected through separate myographs to two length-controlled motors. Ramp-and-hold length changes of 0.25 to 8 mm in amplitude were applied either simultaneously or individually. Force responses were measured at ramp termination (dynamic response) or at the end of the 300 ms hold phase (static response). Excitabilities of the two muscles were adjusted by changing the initial length of the flexor relative to the extensor or by coactivating the muscles with stimulation in the red nucleus using tungsten microelectrodes. Force responses in soleus were reduced by up to 50% when soleus stretch was accompanied by stretch of one of the flexors, so long as the flexor was not slack and gave measureable responses to stretch. The inhibition was present over a wide range of initial forces in both muscles. A powerful inhibition of soleus could also be produced by vibrating the flexor at 150 Hz and 50 µm peak-to-peak amplitude. Increases in the responses of soleus due to simultaneous release of a flexor (normal mechanical coupling) were also observed. These antagonogenic effects were abolished by dorsal root section. Antagonogenic effects on flexors due to stretch or release of soleus were seldom observed.

These results show that antagonogenic pathways are potentially quite powerful and suggest that they act to enhance the mechanical stiffness of soleus but not the stiffnesses of ankle flexors in the decerebrate cat. This pattern could possibly be achieved, according to known connections, by a facilitation of transmission in the flexor-coupled Ia inhibitory interneurons (cf. Hultborn, et al., ibid.). It would be presumed that the extensor-coupled Ia inhibitory interneurons are inhibited or activated so intensely by the brainstem that transmission from afferent sources is occluded.

65.2 LACK OF STRETCH REFLEX COMPENSATION FOR FATIGUE INDUCED CHANGES IN STIFFNESS OF THE FLEXOR POLLICUS LONGUS.
P.E. Crago and S.V. Zacharkiw*. Depts. Biomedical Engineering and Orthopaedics, Case Western Reserve Univ., Cleveland, OH 44106.

The hypothesis that stiffness is regulated by feedback from muscle force and length receptors has been supported experimentally by the observation of compensation for both yielding and inherent stiffness asymmetries, and by the small variability of stiffness over a wide range of initial forces. However, in decerebrate cats these properties are achieved without significant force feedback.

The present experiments in humans were designed to test for force feedback and stiffness regulation in the face of internal disturbances to the hypothesized force feedback loop. Stretch reflexes were compared at the same level of motor neuron pool output, but at different forces, and correspondingly different inherent muscle stiffnesses. This was achieved by fatigue.

Joint position disturbances (4 deg. ramp in 150 ms) were applied at the interphalangeal joint of the thumb while normal adult subjects contracted the flexor pollicus longus (FPL) to produce a flexion torque. The subjects were instructed not to react to the disturbances. Joint position and torque and FPL EMG were measured before, during, and after ramp disturbances in joint angle. Stretch reflexes were studied at several initial torques prior to and about 45-60 min. after fatigue. Fatigue was induced by a series of 50 to 100 intermittent isometric contractions at a torque near the maximal torque employed in the reflex studies.

Stiffness was measured before reflex action (0-40 ms after ramp onset, prereflex intrinsic stiffness), just after short latency reflexes(65-100 ms after ramp onset), and in the steady state (350-650 ms after ramp onset). Prior to fatigue, stiffness increased with initial torque or EMG at all time periods. Fatigue reduced muscle gain (as measured by the slope of the torque-EMG relationship) up to 40% in some subjects without affecting the EMG power density spectrum. Pre-reflex intrinsic stiffness had the same dependence on initial torque as it had prior to fatigue. Stiffness at other times was lower after fatigue whether compared at the same torques or the same EMG's. The degree of stiffness reduction was related to the degree of fatigue.

Since stiffness was lower at the same level of EMG, the muscle force increment and hence the force feedback inhibition should have been reduced, leading to an increased EMG response if the gain of force feedback was significant. In contrast, EMG responses superimposed well when compared at the same initial value, suggesting that the response was uniquely related to the initial value of EMG, and was not influenced by feedback from muscle force receptors. Thus, force feedback appears to play a negligible role in the FPL stretch reflex, and stiffness is not preserved in the face of fatigue.

65.3 IDENTIFICATION OF NEUROMUSCULAR DYNAMICS OF THE HUMAN ANKLE DURING TIME-VARYING CONTRACTIONS. R.E. Kearney and I.W. Hunter, Biomedical Engineering Unit, Faculty of Medicine, McGill University, Montréal, Québec, Canada, H3G 1Y6.

It is well known that the mechanical and reflex properties of the neuromuscular control system change dramatically with the level of muscular activity. System identification studies from our laboratory have shown that, under stationary conditions, elastic joint stiffness and reflex gain increase proportionaly with increasing mean tonic activity. However, it is not known how these properties behave under time-varying conditions such as frequently occur in functional situations. The objective of the present work was therefore to identify the time course of changes in neuromuscular dynamics throughout a time-varying isometric contraction of the human ankle muscles.

We have used a technique similar to that of Soechting et al (J.Neurophysiol., 46:1226, 1981). We have, however, extended the method by deconvolving the input waveform from the output so that the system impulse response function may be determined without requiring the input waveform to be white.

Subjects were trained to generate 2s long isometric contractions in response to a computer-generated tracking stimulus at 5s intervals. Simultaneous, stochastic perturbations of ankle position were elicited by applying a computer-generated pseudo-random sequence to the input of our ankle actuator. The actuator input was shifted with respect to the tracking stimulus by one sample for each presentation. The voluntary contraction therefore followed the same time course for each response in the ensemble. The ankle perturbation was different for each response; indeed the perturbation sequence across the ensemble was the same as along a realization. Consequently, system identification could be performed across the ensemble, rather than along a particular realization. The major advantage to this was that mean torque was quasi-stationary across the ensemble but time-varying along each realization. This identification was repeated for each point in the response; the resulting ensemble of impulse responses functions characterizes the time-varying system dynamics.

Using ensembles of 200-300 reponses we have identified the dynamic ankle stiffness at intervals of 5ms throughout the contraction. Stiffness impulse response functions identified for times before the contraction started, or after the target level had been reached, were comparable to those obtained using stationary techniques. However, during the rising phase of the contraction joint stiffness was much larger than expected. This increased stiffness was associated with a decrease in the variance accounted for by the impulse response functions. We are currently attempting to determine whether these changes reflect true changes in joint mechanics or arise from difficulties associated with the identification technique.

65.4 POSITION DEPENDENCE OF STRETCH REFLEX DYNAMICS AT THE HUMAN ANKLE. P.L. Weiss, R.E. Kearney and I.W. Hunter. Biomedical Engineering Unit, McGill University, Montréal, Canada, H3G 1Y6.

Although the ankle joint angle varies substantially during functional activities, little is known about the effect this has on stretch reflexes at the ankle. The purpose of this study was to examine the effect of changes in mean ankle position on the human ankle stretch reflexes during tonically-maintained contractions held over most of the range of motion. The ankle was placed at randomly selected mean positions, target levels of triceps surae (TS) or tibialis anterior (TA) tonic activity were generated, and the ankle was displaced by small amplitude, stochastic perturbations. System identification techniques were used to identify the dynamic relation between positively rectified ankle velocity and TS EMG (TS stretch reflex) and between ankle velocity and TA EMG (TA stretch reflex) at each tonic level/ankle angle combination.

The principal finding was that TS stretch reflexes depended strongly upon the position of the ankle while TA stretch reflexes did not. The TS stretch reflex magnitude increased by as much as a factor of 23 as the ankle was progressively dorsiflexed. In contrast, position-dependent changes in the TA stretch reflex magnitude were relatively small and variable. Such disparate behaviour is consistent with previous results where we demonstrated differences in the shape, linearity, and gain of the TS and TA stretch reflex dynamics (Kearney & Hunter, Experimental Brain Research, 1983; 1984). Moreover, it is not unexpected given the number of physiological, biomechanical, and functional differences between these two agonists.

The question to be answered is what mediates the position-dependent facilitation of the TS stretch reflex? It was not due to changes in the level of skeletal motoneuron excitability since significant variations in the mean EMG were not evident; for a given level of tonic activity, changes in mean agonist EMG were small and not systematically related to either ankle angle or the magnitude of the reflex response. A more probable explanation is that changes in mean ankle position acted by modulating the efficacy of the stochastic ankle perturbation. This could be accomplished in several ways. First, transmission of the afferents mediating the TS stretch reflex could be altered by position-induced discharge of spinal interneurons. Second, the sensitivity of the muscle spindle endings to the dynamic perturbation could be altered by changes in the extent of fusimotor drive. Third, transmission of the dynamic position perturbations to the spindle, and hence the magnitude of the spindle receptor discharge, could be altered by changes in the mechanical properties of either the extrafusal or intrafusal muscle fibers. The relative importance of each of these mechanisms remains to be determined.

65.5 AMPLITUDE MODULATION OF THE SOLEUS H-REFLEX IN THE HUMAN DURING WALKING AND STANDING. C. Capaday* and R.B. Stein. Department of Physiology, University of Alberta, Edmonton, Canada T6G 2H7.

The role of the stretch reflex (or its electrically elicited counterpart with electrical stimulation, the H-reflex) in the control of movement remains controversial. Stretch and H-reflexes are highly modulated during locomotion of a decerebrate cat on a treadmill (Akazawa et al., J. Physiol. 329: 553, 1982), but have yet to be studied in detail in normal human subjects (Morin et al., Neurosci. Lett. 33: 47, 1982). One problem that is encountered with surface electrodes on human subjects is that during each step the position of the electrodes may change relative to the nerve and hence the effective stimulus intensity may vary.

To overcome this problem a range of stimulus voltages were applied to the tibial nerve and the direct effect of stimulating motoneurons (M-wave) was monitored by electrodes over the soleus muscle, as well as the reflex (H-wave). Intervals between stimuli were varied in a random fashion within the limits of 0.4 and 2.0 s. Computer analysis allowed averaging of the waves at 16 different phases of the step cycle (measured with respect to EMG activity in the tibialis anterior muscle). The value of the H-wave was determined using stimulus voltages which produced comparable M-waves during each phase and hence similar, effective stimulus intensities.

In all subjects tested the amplitude of the H-reflex was strongly modulated during the walking cycle and was highest during the stance phase, when the soleus muscle was active. In many subjects the peak reflex occurred close to the peak in soleus EMG activity, but in others it occurred earlier in the cycle. The form of the reflex variation during the step cycle could also be quite different in form than that of the EMG produced during stepping. The H- and M-waves were also determined using similar stimulus intensities when the same subjects were standing and exerting varying amounts of steady force. For equal stimulus strengths and EMG levels, the H-reflex was much larger, up to 3.5 times, during steadily maintained contractions than during walking.

The large reflexes, when subjects were standing, are consistent with the fine control of position in this task. Similarly, the reflexes during walking are greatest during the stance phase, when they will assist in maintaining the upright position of the body against gravity. The reflexes are smallest during the swing phase when they would be counter-productive and would resist the flexion of the ankle. However, since the reflex amplitude is task dependent (greater in standing than walking at the same EMG and stimulus levels), and is not always closely related to the EMG produced during a given task such as walking, the strong modulation of the H-reflex during walking is not simply a passive consequence of the changes in soleus motoneuron excitability, but must depend on central mechanisms in addition to those that modify firing.

65.6 JENDRASSIK MANEUVER INCREASES SOLEUS H REFLEXES WITHOUT CHANGE IN BACKGROUND EMG. R. Dowman and J. R. Wolpaw. Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, NY 12201 and Depts. of Neurology and Anatomy, Albany Medical College, Albany, NY 12208.

In the Jendrassik maneuver (JM) contraction of remote muscles (e.g. wrist extensors) increases H reflex amplitude (e.g. in the soleus). The present study examined whether change in background soleus EMG is responsible for this phenomenon, and whether it can be obtained at different levels of background soleus EMG.

H reflexes, recorded from the soleus (sol), were elicited by stimulation of the posterior tibial nerve (PT) in ten subjects (8 male, 2 female; 25-40 yrs old). The Jendassik maneuver consisted of squeezing a hand grip. Recording electrodes placed over the extensor digitorum (ED) monitored the level of contraction. The experiment was controlled by computer. Subjects initiated each trial by maintaining sol background EMG within a preset range for a randomly determined 1-2 sec interval. The preset range was 0-70 μV for the low background condition and 70 μV-3.0 mV for the high background condition. All subjects maintained sol background EMG within reasonably stable limits (average values were ± 3.2% for the low background condition, and ± 9.6% for the high background condition), eliminating the need for tighter baseline controls. Once the sol background requirement was met, a 2000 Hz tone was given which lasted 1.5 sec. The PT stimulation was given 300 msec following the onset of the tone. During the control condition (C) subjects held the handgrip but did not squeeze. During the Jendrassik condition (J) subjects squeezed the handgrip as hard as possible as soon as the tone came on. The experimental design consisted of presentation of 4 blocks, with 5 stimuli given during each block. One half the subjects received CJJC and the other half JCCJ. Rectified EMG was quantified during the 1200 msec interval preceding the tone as well as during the 300 msec interval following onset of the tone.

The JM increased H reflex amplitude under both the low background (37%) and the high background (43%) conditions ($p<.001$). An increase in ED EMG began 100-200 msec following onset of the tone. There was no change in sol or tibialis anterior background EMG detected before or following onset of the tone. These results suggest that general changes in sol motoneuron excitability are not responsible for the H reflex increase. This increase may be the result of presynaptic modulation of Ia input.

65.7 MUSCLE RESPONSES TO PASSIVE KNEE MOVEMENT AT CONSTANT VELOCITY AND THEIR MODULATION BY VARIOUS MANEUVERS IN NORMAL MAN. S. Desjardins*, C.L. Richards* and M. Filion (SPON: A. Parent). Centre de Recherche en Neurobiologie, Fac. Méd., Université Laval, Québec, CANADA G1K 7P4.

We studied the effects of various facilitatory maneuvers on quadricpes (Q) and hamstrings (H) muscle responses to passive flexion and extension movements of the knee joint. The movements were imposed on the subjects' limbs at a constant velocity of 30 deg/s using a KIN-COM dynamometer. Each trial consisted of 5 repetitions of movement from knee flexion to extension to flexion through an arc of 90°. A one second pause separated each change of direction. Torque of limb resistance and EMG signals were recorded during the movements. Recordings were made in different conditions: the subject being instructed to relax or to engage in different maneuvers: Jendrassik Maneuver (JM), reading aloud, counting backwards, lightly swinging the free leg, and chewing gum. Resistance to passive movement was expressed as the area under the average torque/angle curve for each trial.

EMG responses of Q and H were quantified as the area under the curve of rectified and time averaged signals (time constant 0.2 sec). EMG responses were more common in Q than H and occurred often during Q muscle shortening (as the leg was extended). A single factor ANOVA for repeated measures and post-hoc Tukey tests were used to quantify differences in EMG and resistance across the conditions. The standard JM significantly ($P<0.05$) influenced both torque and EMG responses of the Q muscle. When performed during flexion it increased the stretch reflex; during extension it increased the shortening reaction. Reading aloud and counting backwards did not cause significant facilitation. However, the muscular responses during these activities and those during the JM differed significantly from those observed while swinging the free leg. This maneuver inhibited the muscle responses ($P<0.05$).

The present results confirm and extend those of Sharmann and Norton (1977) and Andrews et al. (1973) in that normal subjects exhibit responses during passive muscle shortening and lengthening and that these responses may be facilitated by different maneuvers. The present results moreover show that although remote muscle activity is often effective in facilitating limb muscle responses to passive movement, some types of remote muscle activity (such as leg swinging here) may cause inhibition of responses to passive movement.

65.8 FREQUENCY FOLLOWING OF THE M2 COMPONENT OF EMG STRETCH RESPONSE. J. S. Thomas. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

Using 10 Hz square wave patterns of torque modulation it is possible to produce profound entrainment of agonist EMG activity by the periodic load signal. Periodic EMG modulation patterns produced in elbow, wrist and finger muscles of human volunteer subjects have been studied in an attempt to evaluate the frequency following capability of the "M2" latency component of the load response seen to a discrete step increase in torque load. As the frequency of torque modulation is increased from ("discrete") 0.3 Hz step increases in torque load to a 2 Hz square wave of periodic torque modulation, M1 and M2 latency peaks of evoked EMG response retain their "discrete" pattern. For periodic load changes between 3 and 8 Hz each load onset occurs during some phase of the response to a previous load change and subjects show an increase in response variance which makes it difficult to judge precise response homologies. Above 9 Hz response variance is minimal and "segmentations" of EMG modulation are seen which are similar to the M1 and M2 phases of the discrete load pattern if compared from the moment of modulated torque load onset in each case. However, above 9 Hz the M2 component to the loading phase of the periodic signal is partially occluded by an M1 latency "off response" to the unloading phase of torque modulation.

If the 10 Hz periodic torque modulation is terminated in the load phase, the masking off response does not occur and both M1 and M2 latency responses are seen to procede from the previous load onset. This effect is seen even if the cycle terminating the periodic torque is unpredictable. Since M2 latencies are homologous with step responses if calculated from the moment of modulated load onset (=maximum of shortening velocity, = onset of the shortening phase of the periodic position excursion) and the movement parameters do not deviate from those of the previous forcing cycle for 1/2 cycle (until the missing unloading phase of the periodic torque signal - i.e., 50 msec at 10 Hz) each phase of load onset must be evoking an M2 latency excitation.

65.9 DEPRESSION OF SHORT LATENCY REFLEXES TO ELECTRICAL STIMULATION AFTER PROLONGED TENDON VIBRATION OF CAT TRICEPS SURAE. L.F. Hayward*, R.P. Nielsen*, C.J. Heckman*, and R.S. Hutton. Department of Kinesiology, University of Washington, Seattle, WA 98195.

Previously, we reported that prolonged vibration of human Achilles tendon produced persistent depression in soleus H-reflexes but had potentiating effects on tendon jerk responses (Heckman et al. Exp. Neurol. 86:576, 1984). However, electrical stimulus intensities set at 1.8 times threshold (XT) elicited post-vibration H-reflex amplitudes comparable to control values suggesting that H-reflex depression at lower multiples of threshold may have been caused by disfacilitation and selective Ib afferent stimulation due to vibration induced elevated Ia electrical thresholds as has been shown in cat (Coppin et al. J. Physiol. 219:18P, 1970). In this study, changes in aggregate triceps surae reflex responses and group I electrical threshold following 20 min tendon vibration (200Hz, $\leq 250\mu$) in cat (N=20) were further examined.

Due to closeness of the afferent and efferent axonal thresholds in the LG and MG muscle nerves, observations of H-reflex EMG recordings, unconfounded by direct M-waves, were rare. Therefore, in most recordings VR_S L_7 and S_1 were sectioned. Following vibration, monosynaptic responses were usually depressed or abolished at 1.2 XT for reflexes (equal to approximately 1.4 XT of Group I volley) but recovered to control amplitudes within 20-35 min. Depression and time to recovery were XT dependent. At >1.5 XT for reflexes, post-vibration potentiated monosynaptic responses were commonly seen, most likely reflecting post-tetanic potentiation of group Ia pathways activated at their new and higher axonal thresholds. Elevated Ia axonal electrical thresholds were observed to recover to pre-vibration values in parallel with post-vibration reflex recovery to control amplitudes at 1.1-1.4 XT for reflexes. Post-vibration Ib axonal electrical thresholds did not change. Findings were in general accord with post-vibration depression seen in human soleus H-reflexes (op. cit.). These findings add further support for proposing that post-vibration depression in human H-reflexes may be caused by disfacilitation and autogenetic inhibition due to increased selectivity of Ib afferent fiber activation.

65.10 STRETCH REFLEX DYNAMICS IN SPASTIC MUSCLE. D.L. Campbell*, R.K. Powers, and W.Z. Rymer (SPON M. Dal Canto). Rehabilitation Institute of Chicago, IL, 60611.

Previous investigators have reported that stretch reflex activity in spastic muscle is prominent during dynamic stretch, but not during maintained stretch. This feature of reflex behavior has been attributed to an enhanced dynamic sensitivity of primary spindle endings under excessive dynamic fusimotor drive (e.g. Herman,R., Brain., 93:273,1970). In contrast, previous work in our laboratory provides little support for the fusimotor theory, and suggests instead that a decrease in stretch reflex threshold is the primary cause of spasticity (Powers, R. et al., Neurosci. Abstr., 10:329,1984).

In the present study, quantitative measures of the relative sensitivity of spastic muscle to dynamic and maintained stretch were based on the torque and EMG output recorded during different portions of ramp and hold extensions of the forearms of spastic hemiparetic subjects. A torque motor configured as a position servo applied 1 radian angular extensions about the elbow at various ramp velocities. A PDP 11/23 computer controlled the presentation of stretch stimuli and the recording of joint angle, torque and surface EMG from elbow flexor and extensor muscles.

Contrary to previous reports, torque and EMG levels recorded during maintained stretch were an appreciable fraction of those recorded near the peak of the ramp portion of the stretch. With the exception of two of the fourteen subjects studied, high levels of dynamic torque were associated with high levels of static torque, so that the ratio of these two variables remains relatively invariant across a wide range of levels of reflex output. Spastic hypertonia is thus not generally associated with a selective increase in the response to dynamic stretch. The presence, however, of the two exceptional cases suggests that such a selective increase can sometimes occur. In order to more thoroughly evaluate the dynamic behavior of the spastic stretch reflex, we plan to re-test a sample of our spastic subjects as well as normal subjects utilizing alternative stimulus waveforms, such as sinusoids or pseudo-random binary pulses.

65.11 INHIBITION IN THE SPINAL CORD OF THE NORMAL AND SPASTIC MUTANT MOUSE IN VITRO. M.R. Duchen* and T.J. Biscoe* (SPON: K.W.T.Caddy). Department of Physiology, University College London, Gower St., London WC1E 6BT.

The mouse mutant, spastic, shows a heritable defect in motor function, manifest as tremor and rigidity. Pharmacological agents, such as the relaxant benzodiazepines and pentobarbitone, which enhance the actions of the inhibitory amino-acid gamma-aminobutyric acid, GABA, ameliorate the symptoms (Biscoe & Fry, (1980), B.J. Pharmacol., 75, 23-35), and an increased number of benzodiazepine binding sites has been demonstrated in the spinal cord of affected animals (Biscoe et al., (1984), J.Physiol. 352, 509-516). In addition, neurochemical studies show a deficit in binding sites for strychnine, thought to represent the receptor for the inhibitory amino-acid, glycine (White & Heller, (1982), Nature, 298, 655-657).

The functional properties of reflex pathways and the synaptic physiology of motoneurones have therefore been examined, using a preparation of the mouse spinal cord in vitro. Dorsal root reflexes (DRRs) and dorsal root potentials (DRPs), indices of GABA-mediated primary afferent depolarisation, and dorsal to ventral root reflexes (D-VRRs) of mutant and normal mice have been compared. In both normal and mutant animals, the DRR and DRP were prominent, without any obvious difference between the animals. The D-VRR in the normal mice consisted predominantly of a monosynaptic response, with little polysynaptic activity. In contrast, the D-VRR in the mutant was characterised by a large polysynaptic wave of activity lasting 50 to 100 msec., following a monosynaptic response that was often relatively small in amplitude.

Intracellular recordings from motoneurones of normal mice with electrodes filled with potassium acetate showed that, although polysynaptic epsps were present, only the monosynaptic epsp was likely to generate an action potential. In the mutant, large polysynaptic epsps were characteristic, often generating multiple action potentials. When recordings were made with electrodes filled with potassium chloride, a prominent late depolarising psp, lasting up to 150 msec, was evoked in normal cells by orthodromic stimulation. Spontaneous depolarising psps were also now prominent. Both spontaneous and evoked chloride dependent psps were rarely seen in mutant cells. These events presumably represent psps mediated by either GABA or glycine. The findings in the mutant are thus consistent with the neurochemical findings of a deficit in glycine receptors.

65.12 ADAPTIVE PLASTICITY IN THE PRIMATE H REFLEX. J. R. Wolpaw, R. Dowman, and E. Vander Schaaf*. Wadsworth Center for Labs and Research, New York State Dept. of Health, Albany, NY 12201; and Depts. of Neurology and Anatomy, Albany Med. Coll., Albany, NY 12208.

The study of memory substrates in higher vertebrates requires a stimulus-response pathway which is defined and accessible, capable of displaying adaptive change, and contains the responsible substrates. Recent studies (J. Neurophysiol. 50:1296-1319, 1983; J. Neurosci. 4:2718-1724, 1984) have shown long-term adaptive plasticity in the simplest, best-defined, and most accessible pathway in the primate CNS, the wholly spinal, largely monosynaptic path underlying the earliest response to sudden muscle stretch, the spinal stretch reflex (SSR). Monkeys can change SSR amplitude when confronted with a task requiring change. Change occurs over months and persists for long periods. Its features strongly suggest the presence of persistent segmental alteration. In an effort to determine whether change in afferent input, i.e. in muscle spindle stretch sensitivity, is responsible for SSR adaptive change, we tried to demonstrate comparable adaptive plasticity in the amplitude of the H reflex (HR), the electrical analog of the SSR.

Monkeys (Macaca nemestrina) with chronic EMG electrodes in calf muscles and nerve cuff electrodes around tibial nerve were trained by computer to maintain a given level of background gastrocnemius EMG activity. At unpredictable times a 1 msec pulse just above M response threshold was given via the cuff. The computer monitored subsequent EMG and calculated the amplitude of the HR, which occurred 12-24 msec after the pulse. Under the control mode, reward followed 200 msec after the pulse. Under the HR↑ or HR↓ mode, reward followed only if HR amplitude was above (HR↑) or below (HR↓) a criterion value. Animals worked 3,000-6,000 trials/day over 3-6 months.

Results from the initial 3 animals indicate animals can change HR amplitude and that HR adaptive plasticity is similar to SSR adaptive plasticity. HR change, increase or decrease, also occurs slowly over weeks and months and is comparable to or greater than SSR change. It appears to persist over gaps in performance.

These results suggest that change in afferent input is probably not the mechanism of SSR adaptive plasticity. The most likely mechanism for SSR and HR adaptive plasticity appears to be change in Ia synaptic function, perhaps due to change in presynaptic inhibition. In addition, the results extend the phenomenon of spinal reflex adaptive plasticity to the lumbar spinal cord. In this location it should be more accessible to acute studies of its neuronal and synaptic substrates in anesthetized animals.
(Supported by NIH NS22189 and by United Cerebral Palsy.)

65.13 POST-TETANIC CHANGES IN THE AFFERENT AND EFFERENT ACTIVITIES IN KITTENS. P. Bawa, Department of Kinesiology, Simon Fraser Univ., Burnaby, B.C. V5A 1S6.

Suprathreshold test stimuli (3-5xTh) were applied to MG + LGS muscle nerves before and after conditioning tetanic stimulation (500/sec, 5-30 sec) of the same nerves in nembutal anaesthetised kittens 1-90 days of age. Resulting compound action potentials of intact L_7DR and monosynaptic reflex in distally cut L_7VR were recorded with bipolar silver electrodes.

Central gain of the reflex was high in newly born kittens and it gradually decreased to zero by 30 days postnatal age. In very young kittens, during tetanic stimulation, afferent peak/peak amplitude decreased and was also depressed post-tetanically. This was possibly due to decreased conduction velocity and greater dispersion in conduction times of different afferents. In older kittens and adult cats, peak/peak amplitude increased during tetanus, possibly due to the increased size of individual spikes of tetanised afferents (Eccles & Krnjevic, J. Physiol. 149: 274, 1959).

Post-tetanic depression and potentiation of monosynaptic reflex were observed in kittens, depression being more dominant in younger kittens and potentiation in older kittens and adult cats. The dynamic balance between depression and potentiation changed gradually with age. Both depression and potentiation decayed with their characteristic time constants. These time constants were long in the newly born kittens and decreased gradually with age. Also, both time constants increased with increased duration of tetanus.

66.1 KYNURENIC ACID ANTAGONIZES SYNAPTIC AND AMINO ACID EXCITATION OF HAMSTER SPINAL DORSAL HORN NEURONS IN VITRO. S.P. Schneider and E.R. Perl. Dept. of Physiology, Univ. of North Carolina Sch. of Medicine, Chapel Hill, NC 27514.

Our previous experiments using an in vitro spinal cord slice preparation (Soc. Neurosci. Abstr., 10: 488, 1984) suggested there is a differential sensitivity of dorsal horn neurons to aspartate (ASP) and glutamate (GLU). Neurons especially sensitive to these compounds are preferentially located within the superficial dorsal horn (laminae I and II) and tend to be excited by volleys in slowly-conducting primary afferent fibers. We have now studied the effects of kynurenic acid (KYN), a putative amino acid antagonist, on synaptic and amino acid excitation of neurons in this in vitro spinal cord slice preparation.

Synaptic excitation of some dorsal horn neurons by dorsal root volleys was found to be reversibly antagonized by bath application of 1 mM KYN. Most of these neurons were depolarized and vigorously excited by addition of GLU to the bathing medium; this effect was reduced or blocked by application of KYN. Neurons reacting in this way were usually in laminae I or II. Synaptic activation by volleys in the unmyelinated (C) and slowly-conducting, myelinated (Aδ) fibers was more susceptible to KYN than was activation by volleys in the rapidly conducting, myelinated (Aαβ) fibers.

Synaptic excitation of other neurons in the same preparation was quite resistant to bath application of KYN. KYN-resistant neurons were located throughout the dorsal horn and tended to be quite unresponsive to GLU (no excitatory effects to concentrations exceeding 3 mM). Most KYN- and GLU-resistant neurons were only excited by Aαβ components of primary afferent volleys.

These results are consistent with the concept that some but not all dorsal horn neurons have excitatory receptors for GLU or ASP and that primary sensory and/or spinal cord neurons terminating within the superficial dorsal horn use ASP or GLU as a neurotransmitter.

66.2 **MODULATION OF SOMATOSENSORY RESPONSES OF DORSAL HORN NEURONS IN THE FELINE LUMBAR SPINAL CORD BY STIMULATION OF THE VESTIBULAR NUCLEI.** **L. L. Cooper and J. O. Dostrovsky, Dept. of Physiology, University of Toronto, Toronto, Ontario, Canada M5S 1A8.**

The somatosensory responses of dorsal horn neurons have been shown to be modulated by stimulation of a number of central sites including components of the motor system such as motor cortex and red nucleus. However, the effect of stimulation of the vestibular nuclei (VN) on dorsal horn (DH) neurons has received little attention, despite the fact that stimulation of the VN has been observed to alter the excitability of primary afferents, in addition to motoneurons. The aim of this investigation was to study the effect of stimulation of the VN on somatosensory responses of DH neurons in the feline lumbar spinal cord.

Experiments were performed on 6 cats anesthetized with either alpha chloralose or sodium pentobarbital and paralyzed with gallamine triethiodide. A tungsten recording microelectrode was introduced into the lumbar enlargement of the spinal cord. Bipolar stimulating electrodes were introduced into the VN ipsilateral and contralateral to the recording site. The effect of stimulating the VN (100 ms trains, 0.1 ms pulse duration, 500 Hz) was assessed on the just suprathreshold response of DH neurons. These responses were evoked by electrical stimulation within the neuron's receptive field 30 ms after the end of the conditioning train. Stimulating sites were verified histologically. Each neuron was categorized on the basis of its response to mechanical and thermal stimulation of its receptive field as a low threshold mechanoreceptive (LTM), a nociceptive specific (NS) or a wide dynamic range (WDR) neuron.

Stimulation of the ipsilateral and/or contralateral VN with currents of 300 μA or less inhibited the evoked responses of 60% of the neurons. The threshold responses of both nociceptive (9/14 WDR and 2/8 NS) and nonnociceptive (10/13 LTM) neurons were inhibited. For those neurons inhibited by stimulation of the ipsilateral and contralateral VN the threshold currents necessary to produce inhibition from each side were approximately equal. Three NS and two LTM neurons were excited by VN stimulation. The excitation occurred during the train and, except for one LTM neuron, was not followed by inhibition. These results show that stimulation of the VN can modulate the somatosensory responses of some DH neurons. The lateral vestibulospinal tract (LVST) is the only descending pathway which originates in the VN and descends to the lumbar spinal cord. As the LVST terminates in lamina VII and some DH neurons have dendrites which extend into lamina VII, the observed effects may have been mediated by the LVST. Alternatively the effects may have been mediated by reticulospinal neurons which are known to be activated from the VN. (Supported by Canadian MRC.)

66.3 SPIKE SHAPE CHARACTERISTICS OF IDENTIFIED CAT DORSAL ROOT GANGLION (DRG) NEURONS. H.R. Koerber, R.D. Rose, M.J. Sedivec & L.M. Mendell. Dept. Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.

We have carried out intracellular recordings from cell bodies in L7 and S1 DRGs to examine whether shape of spikes recorded from the cell body correlated with the receptor type innervated by the peripheral fiber. Previous work in nodose (Belmonte & Gallego, J. Physiol., 342:603-14) and spinal ganglia (Strauss & Duda 1982 Bratisl. led. Litsy 5:513-640) suggests such an association exists. In Strauss & Duda distinctions were made only between high and low threshold cutaneous mechanoreceptors in the cat. In the present work we have recorded from afferents innervating primary (group Ia) and secondary (group II) muscle spindle receptors, Golgi tendon organs (group Ib), cutaneous type I and II slowly adapting receptors (SA I and SA II), G1, G2 and D-hair receptors, and Aβ and Aδ fiber high threshold mechanoreceptors (HTMRs). These experiments were performed in anesthetized (Nembutal) cats using electrodes filled with 4% Lucifer Yellow in 1-2M LiCl (87% of cells) or 3M KCl (13%). A total of 84 cells with spike amplitude >60 mV was analyzed. We measured the duration of the spike at baseline and found that these averaged the least in rapidly conducting muscle afferents (0.7 ms ±0.0 SE in group Ia, 0.6 ms ±0.0 in Ib). Cell bodies of group II muscle afferents, SA Is, SA IIs, G1 and G2 cutaneous afferents exhibited spike widths with means ranging from 0.8 to 1.2 ms. A small sample of cells with Aβ fibers supplying HTMRs was found to exhibit broader spikes (mean duration 1.6 ms ±0.1). D-hair afferents were characterized by much narrower spikes (mean 1.2 ms ±0.1) than Aδ afferents supplying HTMRs (3.9 ms ±0.9). Thus in both Aβ and Aδ conduction velocity groups, cell bodies supplying HTMRs exhibited broader spikes. This broadness was due in large part to an inflection point or hump on the falling phase which was more prominant in the case of cells with low conduction velocities. A single DRG cell with a peripheral C fiber responded only to high threshold input and had a spike width of 7.1 ms. Four additional C fibers whose receptive fields could not be characterized also had very broad spikes (7-10.4 ms) and humps. These data indicate that factors responsible for spike shape differ in a systematic way among cell bodies supplying different receptor types. We have also observed that slowly conducting afferents generally produce broader spikes than fast conducting afferents. That receptor type must play at least as prominent a role as peripheral conduction velocity is evidenced by the finding that spike shape depended on threshold of cutaneous receptor activation within Aβ and Aδ conduction velocity groups of fibers. Supported by NIMH MH08323 (RDR), NS14899 & NS16996 (LMM).

66.4 COMPARISON OF THE DISTRIBUTION OF MET-ENKEPHALIN, DYNORPHIN, AND NEUROTENSIN IMMUNOREACTIVE NEURONS IN THE DORSAL HORN OF THE CAT AND RAT SPINAL CORDS V. Seybold and K.E. Miller, Dept. of Anatomy, University of Minnesota, Minneapolis, MN 55455.

The dorsal horn of both rat and cat is used as a model for investigating sensory processing in the spinal cord. Enkephalin (ENK), dynorphin (DYN) and neurotensin (NRT) have all been implicated in modulating nociception, and neurons containing these peptides are found throughout the dorsal horn. This study compared the distribution of these three peptides in spinal neurons of comparable segements from rat (L4) and cat (L5).

Data were collected from 6 rats and 4 cats. An intrathecal cannula was implanted in each animal, and two doses of colchicine were administered over a 48 hr period. At the end of the colchicine treatment the animals were perfused with Zamboni fixative. Spinal segments were dissected, placed in 5% sucrose overnight, and sectioned transversely at 50 um. Sections were placed alternately into either met-enkephalin (ENK), dynorphin 1-8 (DYN), or neurotensin (NRT) antisera and processed for PAP immunocytochemistry. Immunoreactive (IR) neurons in lamina I and laminae IV-VII were mapped and counted. Total numbers of IR neurons were estimated and cells/volume (mm^3) calculated. The Mann-Whitney and Kruskal-Wallis tests were used to determine statistical differences between species and among laminae within each species.

Lamina I contained numerous ENK-, DYN-, and NRT-IR neurons of both small (5x10 um) and large (35x40μm) size. In both species, ENK-, DYN-, and NRT-IR cells were comparable in number/segment, but rat contained a higher density of cells ($26.6/mm^3$) than cat ($11.3/mm^3$). Immunopositive cells were also found throughout laminae IV-VII; the region of greatest concentration moved from lateral to medial in a ventral progression through these laminae. These neurons were multipolar and ranged from 10x10 to 40x20 um in size. The rat laminae IV-VII contained a larger number of cells/mm^3 than the cat for each of the three peptides [rat: ENK(200)>DYN(170)>NRT(50), cat: ENK(30)>DYN(20)>NRT(2)]. In cat, NRT-IR neurons comprised a smaller percentage of the total-IR cells as compared to the rat.

The results of this study indicate there are distinct differences in numbers of ENK-, DYN-, and NRT-IR neurons both between species and among laminae for each species. These differences need to be taken into consideration in understanding the functional aspects of these peptidergic neurons in the spinal cord. The connections of these cells were not examined in the present study, however neurons in laminae I and IV-VII are known to project to the brainstem. Therefore, these neurons may be involved in ascending pathways related to sensation. Supported by NS17702.

66.5 SPINAL CORD LAMINA X ULTRASTRUCTURE OF THE CAT
K.E. Miller and V. Seybold, Dept. of Anatomy, University of Minnesota, Minneapolis, MN 55455.

During the past several years an interest has developed in the grey matter region surrounding the central canal. Several reports have noted a large distribution of peptidergic terminals within this region, and one report has shown that neurons within this region respond selectively to nociceptive stimuli (Nahin et al., JCN 220:321,1983). Despite the interest in this area very little is known about its ultrastructure. This study examines the ultrastructure of lamina X in the cat lumbar spinal cord.

Animals used for this study were perfused with 2% formaldehyde, 2.5% glutaraldehyde in 0.1M phosphate buffer. Spinal cord segments L4-6 were dissected and sectioned (200 um) on a vibratome. Sections were dehydrated and embedded in Epon 812. Thin sections were cut, stained with lead citrate and uranyl acetate, and examined with a JOEL 100C electron microscope.

The region 200 um lateral to the central canal could be divided into 3 zones. An ependymal zone, comprised of low columnar to cuboidal ependymal cells, lined the central canal. Beneath these cells was a large subependymal zone consisting of microglial cells and many glial fibrous processes which were arranged parallel to the longitudinal axis of the central canal. A few fibrous astrocytes were present within this layer. This zone was approximately 75 um thick at its widest point lateral to the canal. A dendritic zone occurred lateral to the glial fibrous process zone. The components of the dendritic zone were dendrites, lightly myelinated and unmyelinated axons, and cells. The medial portion of the dendritic zone blended with the lateral edge of the glial zone such that fibrous processes were interspersed with lightly myelinated axons and dendrites. The dendrites ranged from 0.5 to 2 microns in diameter and were surrounded by synaptic terminals. Four types of terminals were identified based upon vesicular constituents: a. small round clear vesicles (40 nm); b. small flattened clear vesicles (60x30 nm); c. small round clear vesicles and large dense core vesicles (110 nm); and d. small round clear vesicles and small dense core vesicles (70 nm). Cells in this dendritic region consisted of astrocytes and neurons (10-25 um in diameter).

The results of this study indicate the region 200 um lateral to the central canal includes a glial zone, which may be analagous to the substantia gelatinosa centralis defined by Rexed, and a dendritic zone, which contained a variety of synaptic contacts. Terminal types with large dense core vesicles suggest a peptidergic input, and ultrastructural localization of neuropeptides in this region is in progress.

66.6 IMMUNOCYTOCHEMICAL-IDENTIFICATION OF AXONS CONTAINING CO-EXISTENT SEROTONIN AND SUBSTANCE P IN THE DORSAL HORN AND LAMINA X OF THE CAT LUMBAR SPINAL CORD. T. Tashiro* and M.A. Ruda. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

We have recently directed our attention to identifying axons containing both serotonin (5-HT) and substance P (SP) in the spinal cord. Co-existence of 5-HT and SP in axons of the ventral horn has previously been shown to be very common and to occur in the vast majority of SP axons (Ruda, Soc. Neurosci. Abstr., 1984). The present study examined co-existence of 5-HT and SP in axons of the dorsal horn and lamina X of the cat by an immunologically specific double immunofluorescence method.

5-HT antisera were raised in rabbit and monoclonal SP antiserum was raised in rat. Species non-cross-reacting secondary antisera were tagged with either FITC or TRITC. Double-labeled tissue sections were examined using epifluorescence and filter combinations specific for each fluorochrome. All reagents were tested for crossreactivity and non-specificity.

In the superficial laminae of the dorsal horn, co-existent strands were occasionally detected among the terminal plexi of 5-HT and SP immunoreactive fibers. They were often oriented rostrocaudally. Co-existent strands were more numerous in lamina V where they appeared as short fibers with random orientations. In sagittal sections through lamina V, the double-labeled axons could be seen in the area intervening between the dense periodic patches of SP axons. Co-existent axons were also occasionally found within the dense SP lamina V plexus. In lamina X, the density of co-existent strands was much greater than that in the dorsal horn. In the area immediately adjacent to the central canal, co-existent strands appeared to travel rostrocaudally. The lateral portion of lamina X contained mostly short fibers with random orientations. The co-existent axons appeared as strands of variable length with numerous varicosities. The varicose strands varied in size from very fine axons with thin, elongated varicosities to thicker axons with large bulbous varicosities.

The present study demonstrates that axons containing both 5-HT and SP are found in spinal cord laminae concerned with regulation of somatic and visceral sensory functions in addition to motor function. However, in the dorsal horn, they represent a very minor component of either 5-HT or SP afferent input. Dorsal horn 5-HT afferents likely originate from a subpopulation of brain stem raphe neurons which do not contain SP and thus are distinct from the brain stem neurons which contribute the numerous 5-HT and SP co-existent axons to the ventral horn.

66.7 SOMATOTOPIC ORGANIZATION AND RESPONSE CHARACTERISTICS OF CELLS IN THE CERVICAL SPINAL CORD OF THE CAT. L.S. Sorkin, D.G. Ferrington and W.D. Willis. Marine Biomedical Institute, Univ. Texas Medical Branch, Galveston, TX 77550.

Little information is available concerning the characteristics of sensory interneurons located in the cervical spinal cord. In this study, we examined the receptive field properties and somatotopic arrangement of sensory cells in spinal segments C_6 and C_7 of the chloralose anesthetized cat. Extracellular recordings were made from 191 cells using carbon fiber microelectrodes.

Cells were placed into four categories based on their responses to graded mechanical stimulation of the skin and subcutaneous tissue: Low Threshold (LT) cells responded maximally to innocuous levels of cutaneous stimulation, 34.7%; High Threshold (HT) cells responded exclusively to noxious levels of cutaneous stimulation, 20.6%; Wide Dynamic Range (WDR) cells responded to both innocuous and at a higher frequency to noxious levels of cutaneous stimulation, 22.7%; and Deep (D) cells responded to stimulation of subcutaneous tissue, 22.7%. LT cells were the most superficial in the cord; their average depth below the cord surface was 1.92 mm (lamina IV). WDR cells (av. depth 2.09 mm, laminae IV and V) were located below the LT cells and above the D cells (av. depth 2.58 mm, lamina VI) and HT cells (av. depth 2.60 mm, lamina VI), which were progressively deeper in the gray matter. The difference between all groups except the HT and D cells was significant at the $p < 0.01$ (ANOVA) level.

The somatotopic organization of cells with cutaneous input was similar to that found in lumbar cord. A large ventral paw and toe area in the medial portion of C_6 and C_7, as well as a smaller dorsal paw area lateral to it, were bordered by representations of the medial forearm and elbow in rostral C_6 and the lateral arm in caudal C_7. Glabrous skin receptive fields were observed only for cells recorded in medial C_7; however, only 8.4% of cells in medial C_7 with cutaneous receptive fields had glabrous skin input. Deep cells had no obvious somatotopic organization.

In contrast to lumbar cord, the locations of receptive fields of cells studied in the same electrode track was frequently seen to shift, although they usually showed considerable overlap. Although the pattern of somatotopic organization is similar in cervical and lumbar dorsal horn, the variation of receptive fields within vertical columns suggests a difference in the spread of afferent fiber collaterals.

This work was supported by NIH grants NS09743, NS11255, NS07185; NIH Postdoctoral Fellowship NS07623 to LSS; and a C.J. Martin Fellowship from the NH and MRC of Australia to DGF.

66.8 MORPHOLOGICAL FEATURES OF IDENTIFIED SPINOTHALAMIC TRACT NEURONS IN THE PRIMATE. C.N. Honda, D.J. Surmeier and W.D. Willis. Marine Biomedical Institute, Univ. Texas Medical Branch, Galveston, Texas 77550.

Spinothalamic tract (STT) neurons in the lumbosacral spinal cord of the primate (Macaca fascicularis) were intracellularly stained with horseradish peroxidase (HRP) and examined at the light microscopic level.

A sample of STT neurons projecting to the contralateral ventrobasal thalamus was studied. Each STT neuron was categorized on the basis of responses to graded mechanical cutaneous stimulation into conventional classes: low threshold (LT), high threshold (HT), and wide dynamic range (WDR). Intracellular injections of HRP (10% in Tris/KCL) revealed a population of STT neurons with cell bodies located in laminae IV through VI (mostly lateral V), with perikaryal dimensions ranging from 15x20 µm to 30x50 µm. At the light microscopic level, only a few neurons possessed somatic or dendritic spinous processes.

Proximal dendrites were predominantly oriented in the transverse plane and radiated throughout laminae IV through VI. Distal dendrites were more variable in both their orientation and laminar distribution. Dendritic arbors extended from 500 µm to over 1mm in the rostrocaudal direction. The dendrites of some STT neurons were confined to the lateral regions of the dorsal horn, whereas others distributed over the entire mediolateral extent of the gray matter. Dendrites extended as far dorsally as lamina I and as far ventrally as lamina VII. Most STT neurons possessed dendrites coursing through the reticulated portions of lamina V, and several had dendrites extending into the lateral white matter. In many instances, at least one major dendritic branch extended medially to arborize within the vicinity of the central canal.

Axons of STT neurons consistently crossed the midline within a rostrocaudal distance of 500µm from their cell bodies to travel rostrally in the contralateral ventral funiculus. Local axonal collaterals were not discernable. However, a few STT neurons exhibited one or two axon collaterals that left the vicinity of the cell body without branching, and traveled caudally.

Attempts to determine relationships between morphological features of STT neurons and their functional classification are in progress. Nearly one half of the neurons receiving nociceptive afferent input (WDR and HT cells) have dendritic arbors in the superficial layers of the dorsal horn. The only LT neuron examined possessed dendrites whose dorsal extent was lamina III. Thus, preliminary analyses indicate that the laminar distributions of dendritic arborizations of STT neurons appear to be correlated with conventional functional classification schemes.

66.9 DORSAL HORN CELLS WITH SIMILAR RECEPTIVE FIELDS DISPLAY A WIDE VARIETY OF DENDRITIC FORMS. M.D. Egger, N.C.G. Freeman*, M.F. Jacquin, E. Proshansky* and K. Semba. Department of Anatomy, UMDNJ-Rutgers Medical School, Piscataway, N.J. 08854.

Dorsal horn cells (DHC) in the spinal cord of cats responding to low threshold mechanical stimulation of the plantar cushion (PC) were labelled with intracellular HRP. The 27 DHC recovered had cell bodies in spinal segment L7, in Rexed's laminae III (n = 5), IV (n = 17) and VI (n = 5). Cell bodies of the lamina IV DHC were concentrated at the medial edge of the dorsal horn, but with a few as far lateral as halfway across the dorsal horn. Lamina III cell bodies were in the medial quarter of the dorsal horn, while lamina VI cell bodies were located more laterally, one quarter to one half the distance across the dorsal horn. On sections cut in the transverse plane, cell bodies of lamina III cells appeared oriented with a long dorsoventral (DV) axis and a shorter mediolateral (ML) axis (mean: 28 X 11 μm, n = 4). Cell bodies in lamina IV (mean: 27 X 21 μm, n = 14) and lamina VI (mean: 31 X 29 μm, n = 5) appeared more symmetrical.

Dendritic fields varied greatly, for the most part conforming to patterns corresponding to their location in the dorsal horn (Proshansky & Egger, 1977). The lamina III cells had their greatest dendritic spread in the rostrocaudal (RC) plane. One had RC dendrites extending at least 3360 μm. This cell's dendrites extended 430 μm ML and 490 μm DV. Dorsoventrally, dendrites of the lamina III cells were confined within laminae I-IV. The dendritic spread of the lamina IV cells tended to be more symmetrical (mean: 350 μm (ML); 560 μm (DV); 700 μm (RC) (n = 11)), but there was much variation among these cells, with medially located cells tending to have more narrowly bunched dendrites than those of the more laterally located cells. Dorsoventrally, some lamina IV cells sent dendrites dorsally through lamina I into the white matter, and ventrally to lamina V or VI. Lamina VI cells had long, relatively unbranched dendrites. Dorsoventrally, the dendrites of the lamina VI cells ramified within laminae IV to VII. The dendritic field of one lamina VI cell measured: 850 μm (ML); 1170 μm (DV); 700 μm (RC).

The receptive field (RF) areas of lamina III cells tended to be slightly larger than the surface of the PC, while the mean RF of lamina IV cells was twice that large. Lamina VI cells tended to have the smallest RF, about half that of lamina III cells. In lamina III, ML dendritic spread was positively related to RF area ($r = 0.998$, $p < 0.05$). For lamina IV cells, there was a correlation between ML dendritic spread and ML position of the cell body ($r = 0.79$, $p < 0.01$), but there was no relationship between either of these anatomical variables and RF area. In lamina VI, the ML position of the cell body tended to be related to RF area ($r = 0.82$, $p < 0.10$).

66.10 ANATOMY OF DORSAL HORN CELLS RESPONSIVE TO SLOWLY ADAPTING TYPE I INPUT. P.B. Brown and L.A. Ritz. Physiol. Dept., W. Va. Univ. Med. Center, Morgantown, WV 26505.

Input from slowly adapting type I (SAI) fibers is relayed with high security in the dorsal horn, and ascends in the dorsolateral funiculus (DLF). Spinocervical tract (SCT) cells do not respond to SAI input, but some cells of the postsynaptic dorsal column system do. The morphology of the dorsal horn cells, and of contacts they receive from SAI axons, may help identify the ascending pathway and the mechanism for high synaptic security.

In chloralose-anesthetized cats, two lumbosacral dorsal horn cells which responded to SAI input were iontophoretically injected with horseradish peroxidase. Cell 1's soma was 36 X 48 um, at the lamina III-IV border, in the lateral half of the dorsal horn; its low-threshold excitatory receptive field (LTERF) covered the posterior calf and thigh. The cell had 12 primary dendrites, mostly dorsal and medial, extending from the lamina II-III border into lamina V, 440 um laterally and 280 um medially, 750 um rostrally and 650 um caudally. Dendrites were profusely branched and invested with spines for most of their lengths. Cell 1's axon ascended the DLF, with no collaterals. The soma of cell 2 was 24 X 52 um, in medial lamina V; its LTERF was located on the plantar foot. Cell 2 had 9 primary dendrites radiating in all directions in the transverse plane. The dendrites were less profusely branched than those of cell 1, had no spines, and extended from lamina III to lamina VII, into the dorsal columns and the lateral funiculus, and 350 um rostral and 500 um caudal. The axon of cell 2 gave off fine collaterals as it coursed laterally in the gray matter; these collaterals arborized loosely in laminae V-VII. The axon then projected rostrally in the DLF with no further collaterals.

An SAI axon innervating a Haarscheibe at the proximal end of cell 1's LTERF was injected with HRP: its boutons distributed in a narrow radial sheet which intersected most of the rostrocaudal length of cell 1's dendritic tree. SAI boutons made 9 contacts with 1° through 4° rostrodorsal dendrites, at seven sites.

The two cells studied to date suggest that the ascending path is in the DLF, but not in the SCT, since their dendritic morphologies are different from SCT cells. The basis for high synaptic security may be the multiple contacts between afferent boutons and a cell.

This research was supported by USPHS grant NS12061.

66.11 EXTENT OF THE ROSTRAL PROJECTION OF SMALL DIAMETER (Aδ & C) PRIMARY AFFERENT FIBERS IN LISSAUER'S TRACT. R.J. Traub, M.J. Sedivec, and L.M. Mendell, Dept. of Neurobiology, SUNY, Stony Brook, NY 11794.

The rostral projection of large diameter cutaneous primary afferent fibers (Aβ) projecting in the dorsal columns (DC) of monkeys, cats, and rats has been well documented. On the other hand, the rostral projection of small diameter (myelinated and unmyelinated) cutaneous primary afferents (Aδ & C) is not well established. Recent anatomical studies have shown Aδ and C primary afferents comprise approximately 50% of Lissauer's tract (LT) at the lumbosacral level (Chung et al. JCN 184:587 and ibid, 186:451) and Aδ afferents have been shown anatomically to project in LT 3-4 segments rostral of their root entry zone (Culberson and Brown, J. Neurophysiol. 51:516, but see LaMotte JCN 172:529).

We have developed a method of antidromically stimulating the central projections of small diameter (Aδ & C) primary afferent fibers in LT in the cat lumbosacral spinal cord without stimulating large diameter afferents (Aβ) in the DC. Stimulation sites were intersegmental borders and mid segments from L3/L4 to L7/S1. Recordings were made from the central end of cut dorsal rootlets caudal to the stimulating electrode or from 2 locations on the sural nerve simultaneously. This allowed the most accurate measurement of conduction velocity. Histological procedures verified the position of the stimulating electrode. The results indicate that some Aδ afferents which enter the spinal cord via the S1 dorsal root project rostrally at least as far as rostral L4 (minimum of 4 segments). However, C fibers which arrive over the S1 dorsal root project to the L6/L7 border but not to mid L6.

In order to determine the modality of the Aδ afferents in LT (D-hair or high threshold mechanoreceptors (HTMR)) we made single unit recordings in dorsal rootlets, DRG cells, or LT. Peripheral stimulation was from the sural and tibial nerves. Antidromic stimulation was from LT and the DC at various rostrocaudal levels. All dorsal roots except L7 and S1 were cut acutely. The results show a minimum of 34% of the recorded afferents have a rostral projection of at least 2-3 segments in LT. These afferents could not be activated from the DC at the same rostrocaudal level. None of the afferents that projected in LT responded to low threshold natural stimulation. Rostral projections of D-hair afferents were found only in the DC. Afferents with a rostral projection of at least 2 segments in LT had a faster peripheral conduction velocity (27.7±2.0 m/s; n=23) than those with a shorter rostral projection (21.3±1.4 m/s; n=36) ($p<.01$).

These results show a projection of Aδ HTMRs (but not Aδ D-hairs) and C primary afferents into LT. The Aδ can project rostrally up to 4 segments but the C afferents project rostrally no more than 1 segment. Supported by Program Project PO1 NS14899 and the Helen and Harry Aibinder Scholarship fund to RJT.

66.12 EVIDENCE FOR THE EXISTENCE OF RELATIVELY INEFFECTIVE PROJECTIONS FROM THE SURAL NERVE TO DORSAL HORN NEURONS USING INTRACELLULAR METHODS. L. M. Pubols, H. Hirata, and M. E. Fogelsong*. Neurological Sciences Institute and Department of Neurosurgery, Good Samaritan Hospital and Medical Center, Portland, OR 97209

It was previously reported (L. Pubols, Soc. Neurosci. Abstr. 9:260, 1983) that electrical stimulation of the sural nerve (SN) demonstrates an excitatory input from that nerve to dorsal horn neurons that is not predictable on the basis of receptive field location. Impulses were elicited by nerve stimulation in some cells whose natural receptive fields (RFs) fell outside the region of skin innervated by the sural nerve (SN region). The purpose of the present investigation was to extend those findings by using intracellular methods to reveal any SN projections too weak to elicit impulses during extracellular recording. Micropipettes were used to record the extracellular and intracellular responses of L_6 and L_7 dorsal horn neurons to electrical stimulation of A^{δ} fibers in the SN and to noxious and non-noxious mechanical stimulation of the skin in adult cats anesthetized with sodium pentobarbital. Twenty-eight cells were studied in detail. Nine cells responded extracellularly with impulses to SN stimulation. In 3 of these 9 the RF fell outside the SN region. Of the remaining 19 units, 7 showed one or more of the following signs of subliminal excitatory input from the SN during intracellular recording: 1) EPSP's to SN stimulation, 2) impulses to SN stimulation during depolarization of the cell induced by intracellular current pulses, 3) impulses to SN stimulation when the excitability of the cell had been increased due to the injury caused by impalement. Three of these cells had an RF in the SN region, and 4 had an RF outside it.

Surprisingly, some cells whose RF's overlapped the SN region had no detectable excitatory responses to SN stimulation. Two of the 12 cells that had no excitatory responses to SN stimulation had such fields. This may be attributable to overlap of innervation of the SN region by other nerves. Alternatively, it may indicate that natural stimuli are, under some circumstances, more effective in demonstrating projections than are single electric shocks to nerves.

In conclusion, the present study has shown that subliminal, as well as supraliminal, excitatory effects to SN electrical stimulation are detectable in many, but not all, dorsal horn cells whose natural receptive fields are outside the SN skin region. It has been suggested (P.D. Wall, Phil. Trans. B, 278:361, 1977) that under some conditions, especially following partial denervation, projections detectable in this manner may be capable of mediating responses to natural stimuli, thus altering the modality and/or receptive field properties of dorsal horn neurons. (Support: NIH:NS19523)

66.13 PROJECTIONS OF FIBERS FROM SLOWLY-ADAPTING TYPE I RECEPTORS TO CAT SACROCAUDAL SPINAL CORD. L. A. Ritz and P. B. Brown. Dept. of Physiology, West Virginia Univ. Medical Center, Morgantown, W.V. 26506.

Recently we examined the somatotopic organization of cat spinal cord at caudal and thoracic levels, where the dorsal horns are fused (continuous across the midline). We observed that: 1) dorsal skin is represented laterally in the fused dorsal horns and ventral skin medially; 2) some dorsal horn neuron receptive fields (RFs) span the dorsal or ventral midline (i.e., the RFs are bilateral); 3) dorsal root fibers, as determined by Fink-Heimer degeneration techniques, project to the medial and lateral portions of the contralateral dorsal horn. We wish to determine, using intracellular staining techniques: (a) whether axons with crossed collaterals have uncrossed collaterals as well; and (b) whether the crossed projections are somatotopically appropriate.

In chloralose-anesthetized cats, primary afferent fibers from slowly-adapting type I (SAI) receptors were impaled within the dorsal columns and iontophoretically injected with horseradish peroxidase. Stained neuronal elements were visualized, in serial transverse sections, at the light microscopic level.

We have successfully recovered five individually-stained SAI fibers. Preliminary observations indicate that the five fibers have some or all of the following morphological features: 1) one to three collaterals, branching off the parent axon, within the same section; 2) collaterals which course rostrally as they approach the dorsal horn; 3) collaterals which curve around the medial aspect of the dorsal horn; 4) collaterals within the dorsal horn which give rise to several thick or thin branches; 5) for four units with dorsal RFs, a termination zone in lateral dorsal horn; for the one unit with a ventrolateral RF, a termination zone in medial dorsal horn; 6) for the four units with dorsal RFs, multiple branches of the same collateral which cross the dorsal gray commissure, within the fiber bundle at the lamina IV/V border, and project to the contralateral lateral dorsal horn; 7) crossing fibers, from the same parent axon, at several rostrocaudal levels.

These preliminary findings indicate that (a) an axon projecting to sacrocaudal cord can have both uncrossed and crossed collaterals; and (b) crossed projections appear to be somatotopically appropriate.

This research was supported by USPHS grant NS12061.

66.14 **PROPERTIES OF SPINAL CORD INTERNEURONS WHICH PROCESS INPUTS FROM THE FEMORAL VEIN.** B. J. Yates, F. J. Thompson and J. P. Mickle. Depts. of Neuroscience and Neurosurgery, Univ. of Florida Col. of Med., Gainesville, FL 32610.

Both anatomical and electrophysiological studies have suggested that veins of the feline hindlimb, including the femoral vein, have sensory innervation. Femoral venous afferents (FVA) are activated when intravenous pressures exceed 2-3 mmHg (Thompson et al., 1983); input along these afferents enters the L6 spinal cord (Thompson and Yates, 1985) and activates interneurons found in Rexed's laminae III-V and VII. Many of these interneurons comprise reflex pathways to skeletal muscle motoneurons (Yates and Thompson, 1985). The purpose of the present study was to determine the response properties of spinal interneurons following stimulation of the femoral vein and to show the patterns of convergence of inputs from muscle and skin on the FVA-activated interneurons.

Studies were conducted on decerebrate-spinal cats. Penetrations were made using 15-30 MΩ electrodes filled with 3 M KCl. Responses were recorded from units located 700-1500 μ beneath the L6 cord dorsum. High frequency stimulation was used to show that recordings from primary afferents were not included in the data; an attempt was made to activate most deeper units by antidromic stimulation of the L6 ventral root to determine if they were motoneurons. The responses of interneurons were recorded following electrical activation of FVA, cutaneous and muscle afferents.

65% of the tested interneurons responded to stimulation of the femoral vein with a burst of action potentials; 32% responded with a combination of one or more bursts of action periods and a period during which the firing rate was reduced below the spontaneous rate. The excitability of interneurons was altered for a long duration following vein stimulation ($\bar{X}$ = 58 msec, S = 85).

93% of the tested FVA-activated interneurons could also be driven by stimulation of the tibial nerve; 71% could also be driven by sural nerve stimulation; 67% could be driven by stimulation of both nerves. Effects of inputs from muscle and skin did not simply mirror the effects of inputs from the femoral vein; complex integration of inputs appeared to occur. Inputs along several muscle afferents were shown to affect the excitability of a single FVA-activated interneuron. Such inputs arose from muscles with vastly different locations in the hindlimb. Cutaneous and muscle afferents which carried inputs which affected the interneurons included A-αβ fibers.

Experiments utilizing HRP-filled pipettes are currently underway to determine the locations and morphologies of FVA-activated interneurons.

66.15 THE LATERAL NEUROPIL OF THE MECHANORECEPTORS WITHIN THE SPINAL CORD OF SNAKES. D.M. Schroeder, Medical Sciences Program, Indiana University School of Medicine, Bloomington, Indiana 47405.

Segmentally within the ventrolateral edge of the spinal cord of snakes are large neurons known as marginal cells. They are located primarily within the intravertebral areas and are closely associated with the denticulate ligament which is immediately adjacent to it. The ligament changes in character at that particular point from being filled with collagen to one without collagen. A number of large neurons are aligned along the width of this part of the ligament and their short but branching dendrites extend into the lateral neuropil that is located between their cell bodies and the edge of the spinal cord and ligament. Evidence suggests that this area of the spinal cord has mechanoreceptive functions, responding to bending of the spinal cord. The ultrastructure of this area was examined, concentrating especially on the lateral neuropil. The prominent features of this lateral neuropil are tubular processes oriented parallel to the length of the spinal cord and to the denticulate ligament. They consist of two sizes: a larger one accompanied by a number of smaller ones. The larger tubular processes vary in diameter from 0.75 μm to approximately 1.0 μm; they appear to be at least as long as the main receptor area, approximately 150 μm. Contents of these tubular processes include: microtubules and neurofilaments; small clear vesicles are found in small patches and if located near the edge, are associated with a dense area of the membrane; scattered large, clear vesicles; the few mitochondria are very elongated. The origin of these processes has not been determined; fibrous glial cells, located at the periphery of the mechanoreceptor area, give rise to elongated processes but it is still not clear whether all of these tubular processes are similar and originate from the same cell type. All the small tubular structures have approximately the same diameter, 0.12 um, and appear to contain only neurofilaments. They are found in groups and are always near one of the larger tubules. Most of these small tubules eventually leave the plane of section but some are at least 4 μm long. They originate from the dendrites of the large neurons. These dendritic processes are filled with mitochondria, often very tightly packed; multivesicular bodies, microtubules and neurofilaments are also present. Along the sides of the dendrites are usually synaptic boutons; these boutons as well as others distributed throughout the neuropil contain clear round vesicles. A number of small tubules emerge from the ends of the dendrites in a rostral and caudal direction and join a larger tubular process, passing by the dendrite. Assorted glial processes are distributed throughout the rest of the neuropil and along the edge of the spinal cord.

67.1 PATTERNS OF GENE EXPRESSION IN CHICK RETINA.
J.H. Rogers* and M. Goedert* (SPON: D. Sattelle).
MRC Lab. of Molecular Biology, Cambridge CB2 2QH, England.

We are interested in obtaining molecular markers for individual cell types in the retina. For this purpose, we have constructed a library of cDNA clones from chick retina. In-situ hybridization data will be presented on the distribution of various cloned mRNAs in the retina and in other parts of the nervous system.

67.2 SIALIC ACID-RICH LAYER IN DEVELOPING CHICK RETINA FORMS CENTRAL-PERIPHERAL GRADIENT. S.E. Raiguel* (SPON: R.E. Marc). Dept. of Sensory Sci., Univ. Texas G.S.B.S., Houston, TX. 77030

Recent reports appearing in the literature have indicated that the binding of the sialic-acid sensitive agglutinin from the slug, Limax flavus is specific, stable, and suitable for histologic use when conjugated to an appropriate chromogen (Schulte, et al, 1984). In view of the role which sialation has been proposed to play in the development of the avian visual system (Edelman, 1983), this lectin appeared to be an ideal tool for visualizing the changes in the distribution of sialic acid which have been shown to accompany development (Schlosshauer, et al, 1984). Slug lectin (LFA) was obtained from Calbiochem (San Diego, CA.), conjugated to FITC in our laboratory, and applied to deparaffinized sections of alcohol/acetic acid-fixed chick eyes taken at 8, 12, and 18 days of embryonic development. At eight days of incubation, fluorescence microscopy revealed a crescent of sialic acid-like activity lying in the ganglion cell layer of the inner retina. Initially, this crescent comprised the central one-third of the retina, and was about 20 micrometers thick at the center, becoming gradually thinner peripherally. As development proceeded, this band of fluorescence increased in extent and thickness, until by day 18, the inner plexiform and ganglion ganglion cell layers of the entire circumference of the neural retina were included. In older embryos, sublaminations within this band were evident. Older specimens also displayed bright bands of fluorescence in the photoreceptor outer segments and in the outer limiting membrane. Fluorescence could be completely eliminated by carrying out lectin incubations in the presence of 100 mM N-acetyl neuraminic acid (Sigma type IV), or by pretreatment of the sections with sialidase. LFA staining therefore appears to be specific for sialic acid in this context.

67.3 EXHUBERANCY OF SYNAPTIC RIBBON FORMATION IN THE OUTER PLEXIFORM LAYER OF THE CAT RETINA. David H. Rapaport. School of Anatomy, University of New South Wales, Kensington, NSW 2033 AUSTRALIA.

Several regressive events such as cell death and synapse elimination occur during development of the nervous system. Some of these processes have recently been investigated in the mammalian retina which is a good developmental model due to the limited number of cell types, and their lamination. Since many photoreceptor synapses in the adult are characterized by presynaptic ribbons, study of ribbon formation should reflect photoreceptor synaptogenesis.

Investigation concentrated on central retina, since this is where many developmental events in the cat retina begin. Fetuses of known gestational age, or postnatal kittens were processed for electronmicroscopy. The eyes were removed, and the retina dissected. A wedge of retina was taken from the region of the area centralis, and ultrathin sections (0.09um thick) were cut from the apex. Photomontages of the outer plexifom layer (OPL) were made, and the area of the sample measured with a computer graphics tablet. At E(embryonic)59 the OPL is present over the central 3% of retina. At this age synaptogenesis can be recognized by the presence of ribbons in photoreceptor terminals; often they are associated with two bipolar postsynaptic elements, forming a dyad. At E62, triads with ribbons and vesicles could be observed. The density was 0.33 ribbons/um^3, but this value increased rapidly to a value of 0.63 ribbons/um^3 at P(postnatal)3, and remained at this level over P5, P7, P9, P10, and P11. Sometime after P11 ribbon density begins to decrease: 0.42 ribbons/um^3 at P17, 0.36 ribbons/um^3 at P30 and 0.28 ribbons/um^3 at P42. For almost a year there appears to be a gradual decrease in ribbon density to reach the adult value of 0.13-0.16 ribbons/um^3 (two animals). Repeated measures from different sections of the same retina gave similar densities, indicating that variations in the values obtained between subjects were not due to errors of measurement, but to differences in age, location of the sample, etc. Over the period studied the length of the synaptic ribbons increased slowly from $\bar{X}$=0.22um soon after birth to $\bar{X}$=0.38um at P42 and eventually to $\bar{X}$=0.47um in the adult.

These data demonstrate an exuberancy of synaptic ribbon development in the OPL of the cat retina during the last embryonic and first postnatal weeks of life, with a 3-4 fold reduction in ribbon density during the second week. Several mechanisms could contribute to this decrease: coalescence of ribbons, loss of ribbons through cell death or synapse elimination, and the increase in the volume of the OPL as the animal grows. It is of interest that the rapid decrease in synaptic ribbon density begins shortly after eye opening, suggesting that visual experience may be important in triggering the decrease.

67.4 STRETCH OF THE RETINA CONTRIBUTES TO THE DENDRITIC FIELD AREA OF GANGLION CELLS IN THE BLACK MOOR GOLDFISH. Peter F. Hitchcock. The University of Michigan, Ann Arbor, MI 48109.

As the goldfish ages, its retina grows by the addition of new neurons at the margin, and a balloon-like expansion of the existing retina. With the expansion of the retina, the ganglion cell dendritic fields also expand (Hitchcock and Easter, abstract, Soc. for Neuroscience, 10:465, 1984). It was hypothesized that this increase in the size of the dendritic fields was due to towing of the dendrites by the expanding retina, analogous to the enlargement of a drawing on an expanding balloon.

To test this hypothesis, ganglion cells in a strain of goldfish, commonly known as the black moor, have been studied. This animal has a developmental defect such that the vitreal chamber is grossly enlarged, relative to the normal goldfish, which results in a concomitant gross expansion of the retina. The magnitude of this expansion, however, is highly variable. The prediction is, assuming that the growth of the black moor retina is otherwise normal, that the ganglion cell dendritic fields will be larger in the retinae that have undergone the most expansion.

Ganglion cells were stained by retrogradely transported HRP applied to intraorbital cuts of the optic nerve, and viewed in the wholemount. Dendritic field areas were determined for a subtype of large cells by tracing individual dendrites at 1250X magnification and marking the location of the distal tips on a 150X camera-lucida drawing. The enclosed areas were then measured using a digitizing tablet. Three pairs of retinae were studied. Each consisted of a 'large' and 'small' retina from animals that were matched for lens diameter (2.5, 2.6, and 3.2 mm, respectively), a predictor of retinal area and number of ganglion cells in the normal goldfish.

Within each pair, the dendritic fields of the cells in the central region of the 'large' retina were significantly larger than those in the central region of the 'small' retina with a similar lens diameter (Mann-Whitney, $p<.05$; n=20, 20, and 14, respectively). The average difference in area of the 'large' and 'small' retinae was 35%. The average difference in the dendritic field areas in the 'large' and 'small' retinae was 22%. These data suggest that the towing of the dendrites by the expanding retina is a contributing mechanism for establishing the area of the ganglion cell dendritic field.

67.5 RETINAL CROWDING REDUCES THE SIZE OF DENDRITIC FIELDS OF ALPHA GANGLION CELLS. M. A. Kirby and L. M. Chalupa
Department of Psychology, University of California, Davis 95616.

It has been suggested that the dendritic field size of individual retinal ganglion cells is regulated early in development by interactions among neighboring ganglion cells of the same functional type (Wässle et al., 1981). If this is the case, a manipulation such as in utero uniocular enucleation, which results in a greater than normal density of ganglion cells in the remaining eye (Chalupa, et al., 1984), should produce ganglion cells with smaller than normal dendritic fields.

To assess this possibility, we compared dendritic field diameters of alpha ganglion cells in normal retinae to those of adult animals that had one eye removed either prenatally (on embryonic days 42 and 51) or 6 days after birth. Ganglion cells were labeled by central injections of HRP, retinae were reacted using a modified Hanker-Yates procedure, and then whole-mounted. Cells were sampled from the temporal retina along a corridor established by a line drawn through the optic disk and the area centralis. Alpha cells were differentiated into "ON" or "OFF" types based on their level of stratification within the inner plexiform layer (Peichl and Wässle, 1981), and drawn under oil using a X40 Zeiss, Planapochromat objective. Dendritic field sizes were estimated from these drawings by calculating the mean of the two longest orthagonal diameters.

A plot of dendritic field diameters as a function of retinal eccentricity revealed that the alpha cells of the normal retinae (N=108), as well as those from the postnatally enucleated animal (N=24), were comparable to the Golgi material of Boycott and Wässle (1974). In contrast, in the remaining retina of prenatally enucleated cats (N=144), the diameters of dendritic fields of "ON" and "OFF" alpha cells were significantly less extensive. The magnitude of this effect varied as a function of retinal eccentricity, being most pronounced within 5 mm of area centralis where the differences averaged approximately 100 microns, about 25% of the mean normal size. A similar, but less pronounced difference, was also observed for somal diameters. The most straightforward interpretation of these findings is that increased cell density exacerbates the dendro-dendritic interactions normally present during early development.

67.6 CHANGES IN THE STRUCTURE AND FUNCTION OF RETINAL GANGLION CELLS DURING METAMORPHOSIS IN *RANA PIPIENS*. B. Frank*, and J.G. Hollyfield* (SPON: S.J. Fliesler). Program in Neuroscience, Baylor College of Medicine, Houston, TX 77030.

Developmental changes in the visual system of *R. pipiens* are required to mediate the adaptive behavior to the changing external environment during metamorphosis. Prey catching is not seen in tadpoles; we have determined that this response is first observed at Taylor & Kollros stage 24, indicating the neural substrate for this behavior is present by this time. As a first step, we have followed the neuronal changes in the retina during the metamorphic period. Ganglion cells (GC's) were visualized in tadpoles and adults by backfilling with HRP (5-25%) into either the optic nerve or tectum using pressure or electrophoretic injection. These backfills produced extensive Golgi-like profiles of dendritic arbors; often dendritic spines could be seen. The GC's were classified according to soma size, dendritic branching patterns, and lamina of arborization in the inner plexiform layer (IPL). The origins of the identified cell types were studied by injecting ^{3}H-thymidine into tadpoles at various stages, allowing the tadpoles to mature and survive 2-3 weeks postmetamorphosis, then backfilling the GC's with HRP to visualize cell types in relationship to their neuronal birthdays.

In the mature frogs, there are at least 7 distinct types of GC's based on the above morphological criteria. The structure-function relations for the GC types were shown by making discrete HRP injections into single sublamina of the optic tectum or caudal thalamus and observing the classes of GC's which were backfilled.

Tadpoles also have at least 7 distinct GC types which all broadly correspond to those of the small frog. However, the smallest GC's often have either no dendritic process or only a rudimentary process; this would account for earlier reports of the absence of small cells seen in Golgi preparations of tadpole retina. Another interesting aspect which grossly differs between tadpole and adults, is the presence of a population of displaced ganglion cells (DGC's) in the tadpole; this DGC array is virtually absent in the adult (only 5 DGC's observed out of over 10,000 HRP filled cells examined). To analyze the fate of these DGC's, a stage series of 10 micron sectioned retinas was examined for pyknotic nuclei or migrating cells in the IPL. Migrating cells were seen to peak at stage 24; all of the migrating cell bodies in the IPL could be backfilled with HRP, indicating that the DGC's of the tadpole migrate to the GCL during metamorphic climax.

67.7 Optic Fibre Arrangements on the Retinal Surface of an Animal with an Ordered Optic Nerve and an Animal with a Disorderly Optic Nerve. J.L.James* and S.M.Bunt, (SPON:R.M.Gaze). Department of Anatomy, Medical Sciences Institute, University of Dundee, Dundee DD1 4HN, U K.

All vertebrate classes examined have optic nerves with an orderly arrangement of optic fibres within them. The only exceptions are the mammals where there seems to be considerable variation between species. Man is presumed to have an orderly optic nerve while all other mammalian species examined as adults show varying degrees of disorder in their optic nerve pattern. It has been suggested that the arrangement of fibres as they grow along the optic nerve and tracts may contribute to the formation of the orderly central optic projections in lower vertebrates. Why is it that the mammals do not appear to have orderly optic fibre pathways?

We have investigated the pattern of optic fibre growth across the retina of the goldfish (which has an orderly optic nerve) and the hooded rat (which has a disorderly optic nerve in the adult). 12 Goldfish received partial optic nerve sections at the dorsal or ventral pole of the optic nerve cross section close behind the eye. HRP was applied to the cut in a gelfoam pledget. The procedure was repeated with 12 Long Evans hooded rats. After time for HRP transport the animals were perfused, the retinae dissected out and processed as wholemounts with DAB/Ni/Co. The pattern of backfilled retinal ganglion cells was drawn. Pie slices of the retinae were then selected, dehydrated and processed for electron microscopy.

Examination of the electron micrographs showed that, in the goldfish, if peripheral retinal ganglion cells were filled by a dorsal optic nerve fill, only the superficial fibres of the intraretinal fibre bundles were filled with HRP. When central ganglion cells were filled by a central HRP application only deep fibres were filled in the retinal fibre layer. In contrast, in the rat it was difficult to get a fill of only peripheral or central ganglion cells. Only HRP applications made very close to the back of the eye formed pie slices of filled ganglion cells in the retinal wholemount. The electron microscopy showed filled fibres distributed throughout the retinal ganglion cell fibre layer, filled fibres mixed with unfilled fibres.

One possible explanation of this contrast between the mammals and the lower vertebrates is that they possess numerous ganglion cell types and the growth of the different types occurs at different rates and in varying patterns across the retinal surface. In contrast the growth of lower vertebrate retinae is orderly and circumferential.

67.8 ELIMINATION OF THE TRANSIENT IPSILATERAL RETINOTECTAL PROJECTION IN THE DEVELOPING CHICK. Steven C. McLoon. Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

Previous studies have described a transient ipsilateral retinotectal projection present in the developing chick. Anterograde labeling studies show that the disappearance of this projection coincides with the degeneration of nearly half of the cells in the retinal ganglion cell layer. In order to determine whether cell death selectively eliminates the ipsilateral retinotectal projection, retinal ganglion cells giving rise to the ipsilateral projection were retrogradely labeled early in development, and the retinas were examined after the period of cell death. If cell death eliminated the projection, no labeled ganglion cells should remain. On the ninth day of incubation (E9) chick embryos received an injection of fast blue along the rostral and inferior margins of one tectum. At the peak of the ipsilateral projection, E11, half the embryos were fixed, and their retinas were whole mounted on glass slides. The remaining embryos were processed on E18, well after the disappearance of the ipsilateral projection. Retinas contralateral to the injected tectum were examined by fluorescence microscopy to determine the extent of the injection. Only animals with labeled ganglion cells across the entire extent of the contralateral retina were included in the analysis. The labeled ganglion cells were counted in the retinas ipsilateral to the injected tectum from these animals. Approximately half the number of labeled ganglion cells remained in the ipsilateral retinas of the E18 embryos as compared to the E11 embryos. Examination of sections of the ipsilateral retinas from the E18 embryos showed that the labeled cells were confined to the ganglion cell layer and displaced ganglion cell layer. These results suggest that cell death does not selectively eliminate those ganglion cells which project ipsilaterally during early development since the proportion of those lost is similar to that of all ganglion cells lost during the period of cell death. The remaining ipsilaterally projecting ganglion cells must retract their aberrant axons.

67.9 PROTEIN SYNTHESIS IN THE RETINA AND RAPID PROTEIN TRANSPORT IN THE DEVELOPING HAMSTER VISUAL PATHWAY. K.L. Moya, S. Jhaveri*, G.E. Schneider and L.I. Benowitz. Dept. of Psychology and the Whitaker College, M.I.T., Cambridge, MA 02139 and Dept. of Psychiatry, Harvard Med. Sch., McLean Hosp., Belmont, MA 02178.

The pattern of proteins expressed in the retina has been shown to change during development in higher vertebrates and during regeneration in lower vertebrates. We examined developmental changes of proteins synthesized in the retina and rapidly transported to the lateral geniculate (LGB) and superior colliculus (SC). ^{35}S-methionine was injected into the right eye of hamsters on postnatal days 2 (P2), 6, 17 and in mature animals. After 4 hours to allow retinal proteins to be transported to the SC, the retina, left LGB, left SC (LSC) and right SC (RSC) were analyzed by 2-D gel electrophoresis and visualized by fluorography.

Several major changes occur in the profile of proteins synthesized in the retina during the first 3 weeks of postnatal life. At P2 and P6, α and β tubulin were heavily labelled whereas by P17 α tubulin had disappeared and β tubulin markedly decreased until it was undetectable in the adult retina. A β tubulin associated protein, M.W. 52Kd, pI 5.4, a constituent of SER and RER but not of plasma membrane (Strocchi et al., J. Neurochem. 37: 1295, 1981) did not change markedly. A 28Kd protein present in trace amounts at P2, progressively increased until P17 and in the adult was the most heavily labelled spot on the fluorograms. This latter finding is in accordance with observations by Bock et al. (Neurosci. Abstr. 10: 1030, 1984).

Analysis of proteins in the contralateral LGB and SC showed that the 28Kd protein observed in the retina was rapidly transported and that its presence in the LGD and SC paralleled its synthesis in the retina, being barely detectable at P2 and P6 and becoming prominent at P17 and adulthood. A rapidly transported protein of 50Kd, pI 5.0 was labelled at P2, somewhat diminished at P6 and continued to decrease until it could not be detected in adult animals. Amino acid injected into the eye readily diffused into the circulation and was carried throughout the brain at P2 and P6. Axonally transported proteins were therefore distinguished from those locally labelled by examining the differences between the pattern of labelled proteins in the LSC which received the major projection from the injected eye and the RSC.

Correlated with the changes in retina and in rapidly transported proteins are striking developmental transformations in optic tract axons as they arborize in their target structures, as well as changes in their ability to grow after damage or in response to nearby denervation. (Supported by NIH EY00126, EY02621, EY05504, EY05690.)

67.10 ANALYSIS OF IMMATURE RETINAL GRAFTS MADE TO ADULT HOSTS BY LIGHT AND ELECTRON MICROSCOPY. J. R. Blair* and J. E. Turner (SPON: M. Levitt), Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

A retinal grafting model utilizing neonatal rats as donors and adult rats (225 g male Sprague Dawley) as hosts has been used in our lab to study the development of immature retinal grafts in situ and the ability of these grafts to initiate repair of the lesioned adult retina. Donor tissue is taken from neonatal rats (1-2 days post-partum) of the same strain as hosts. Twenty-three animals received lesions and grafts bilaterally with a graft survival rate of >80%. Eyes were removed for analysis by light, scanning, and transmission electron microscopy 4 weeks after receiving grafts. Analysis at the light level revealed that not only had the vast majority of grafts survived, but that they continued to develop in an organotypical manner reminiscent of intact retinas of littermates. The majority of layers present in the intact retina were present in the grafts including the ganglion cell (GCL), inner plexiform (IPL), inner nuclear (INL), outer plexiform (OPL), and outer nuclear layers (ONL). In addition there was evidence for the presence of an optic fiber layer (OFL), outer limiting membrane (OLM), and developing inner receptor segments. In areas of close apposition of the graft and host retina, the plexiform regions of the two merged. This integrating phenomonon between graft and host was enhanced in areas where the host's ILM had been disrupted such as the host lesion site. The absence of an ILM on the vitreal surface allowed direct observation of the graft GCL by SEM revealing ganglion cells of different size classes as well as smaller cells corresponding to displaced amacrine and glial cells. Open areas in the GCL allowed visualization of the dense meshwork of cellular processes and synaptic terminals of the IPL. Ganglion cell process collected on the graft surface to form large fasicles, which left the graft to course along the dense OFL of the host retina for up to 2 mm. Close examination of a fasicle showed individual fibers leaving the fasicle as it crossed the host retina. These fibers penetrated the OFL and were lost in the deeper layers of the host retina. The presence in the graft of ribbon synapses, conventional synapses, inner segment formation, and ultrastructural characteristics of the major retinal cell types has been confirmed by TEM. This work shows that mammalian neonatal retina grafted to the lesioned adult retina will continue normal development and initiate repair of the lesioned host retina by integration to an as yet undetermined extent. The phenomena noted should be further enhanced by utilizing less mature donor tissue. Supported by grant EY04377 from the National Eye Institute awarded to J.E.T.

67.11 CELL SURFACE CHANGES IN THE DEVELOPING OPTIC NERVE OF MICE. R.D. Lund, V.H. Perry, and C.C. Lagenaur. Department of Anatomy and Cell Biology and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

In previous work (Lagenaur et al., Soc. Neurosci. Abst. 10 759, '84), a monoclonal antibody to a cell surface glycoprotein of mouse CNS neurons, designated M6, was isolated and found to inhibit neurite outgrowth in vitro. We have studied the distribution of this antigen in the developing eye and optic nerve, in part to see whether there would be changes correlated with known maturational processes and partly as a baseline for studies using the mouse neuron marker after transplantation of mouse retina to rat brains (Chang et al., Soc. Neurosci. Abst., 1985).

Anti-M6 staining of retinas and nerves was performed on sections lightly fixed with paraformaldehyde. In adults, while the synaptic and optic fiber layers of the retina are heavily stained, the optic nerve and tract are completely unstained. At birth by contrast, there is heavy staining of all parts of the optic pathway. By 4 days postnatal (PN), individual bundles of fibers lose their staining as they leave the optic fiber layer to enter the optic nerve head. By day 6, there is a pronounced diminution of staining in the proximal part of the optic nerve which persists until between 14 and 18 days PN. At this stage, anti-M6 staining is lost from the rest of the nerve, leaving only the part of the axon in the retinal optic fiber layer stained.

It is suggested that M6 may be an important constituent of the cell membrane involved in maintaining interaxonal adhesion necessary for axonal extension and fasciculation. The loss of staining coincides with the cessation of optic axon growth and with the early stages of myelination when oligodendrocyte processes interpolate between individual axons breaking up the bundles of unmyelinated fibers seen at early postnatal times. The fact that only that part of the optic axon exposed to oligodendrocytes loses its staining with maturation suggests that the loss of M6 from the cell surface is a specific local response to the presence of this glial cell class.

67.12 DEVELOPMENT OF RETINOTECTAL PROJECTIONS FROM RETINAE TRANSPLANTED TO THE CEREBRAL AQUEDUCT (SPON: W. Cameron) M.H. Hankin* and R.D. Lund, Department of Anatomy and Cell Biology, School of Medicine, and the Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

Previous studies suggest that retinal fibers prefer to grow on, or near, surfaces of the brain (Lund et al., 1982; Silver and Rutishauser, 1984). In contrast, cortical fibers seem to have a propensity for growth through a neuropil. We wondered whether the outgrowth of retinal fibers, when presented with a choice of unusual surfaces, would be consistent with these results. To this end, retinae from embryonic day (E) 13.5 mice (C57BL/6J) were transplanted into the cerebral aqueduct of newborn rats (Sprague-Dawley) whose right eye had been removed. We wished to know how soon axons would grow out of the transplants, whether they would follow the aqueduct surface, injection path, or some other cue (e.g. radial glia), and whether they would preferentially innervate the denervated tectum?

Survival times of 2-60 days were used: 80-90% of the transplants survived. Animals were perfusion fixed with 4% paraformaldehyde and the brains placed in 30% sucrose in phosphate buffered saline (PBS) overnight. Frozen sections were processed with (1) silver stain, and (2) immunohistochemically using a monoclonal antibody (anti-M6) directed against a 35 kD mouse neuronal cell surface glycoprotein (courtesy Dr. Carl Lagenaur, University of Pittsburgh).

After short survival (<1wk) silver and anti-M6 staining fail to reveal obvious fibers emanating from transplanted retinae entering either side of the tectum, although fiber bundles are seen within the transplant. By 11d postnatal, axons can be seen with anti-M6 and silver staining leaving the transplants and running in fascicles towards the superior colliculus. With longer survival (>4wks), a substantial terminal field is seen in the superior colliculus on the side contralateral to the missing eye. Axon bundles were never seen coursing along the injection pathway or along the surface of the aqueduct itself.

This study shows that transplanted retinal axons can grow through brain structures, rather than across a surface, to attain a target region. The dynamics of this process and the substrates for the growing axons are presently under investigation.
Supported by NIH grants EY05308 and EY05823.

67.13 MOUSE TRANSPLANTS INTO RAT STUDIED WITH MOUSE SPECIFIC ANTI-M6 IMMUNOCYTOCHEMICAL STAINING. F.-L.F. Chang, R.D. Lund, M.H. Hankin, and C.F. Lagenaur. Dept. of Anatomy and Cell Biology, and Center for Neuroscience, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Neurons taken from embryonic animals survive transplantation to host brain where they frequently become incorporated in host tissue and interconnect with it. However, neither radioactive tracers nor HRP are ideal for studying such transplant - host interactions because of the problem of labeling the entire transplant without tracer leaking to the surrounding host. To overcome this difficulty, we have used an antibody specific to a mouse CNS neuronal surface glycoprotein (M6) to stain transplanted mouse neurons and their projections in host rat brains.

Embryonic day 13 mouse cortical or retinal tissue was transplanted to newborn rat cortex or adjacent to the superior colliculus respectively. After one month of survival, host rats were perfused with 4% paraformaldehyde; frozen cut or vibratome sections were incubated in primary antibody (anti M6) overnight, and reacted with the secondary antibody - the anti-rat IgG conjugated with HRP. Finally, tissue sections were processed with diaminobenzidine (DAB) as the chromogen and intensified with OsO_4. For electron microscopy (EM), vibratome sections were further postfixed in 1% OsO_4 for 1 hour, dehydrated, and embedded in Epon. Thin sections were cut, and examined without lead and uranium double staining.

Mouse cortical and retinal transplants stained darkly over a pale background of non-antigenic rat tissue. The staining of the transplants occurs in a manner identical to the staining in an adult mouse, with reaction product on the membrane surfaces of cell bodies, dendrites and unmyelinated axons. Within host rats, axon plexuses of transplant projections were stained; under the EM, we observed groups of stained unmyelinated fibers in the unstained rat neuropil. Areas of terminal regions of transplant projections were also stained as demonstrated by the labeling in host tectal surface for retinal transplants or local forebrain projections for cortical transplants. Myelinated axons, however, failed to stain, even when in EM sections they were cut open by vibratome sectioning to expose the axonal membrane to antibody.

In summary, our results demonstrate that mouse CNS transplants survive in host rats and send projections into host tissue. The mouse specific antibody permits identification not only of the transplanted cell bodies but also of their terminal axon distribution in the host. This allows the pattern of transplant connectivity to be studied at both the light and electron microscopic levels without the usual invasive tracer techniques. Supported by NIH EY05283.

67.14 Superior Colliculus Transplants: Pharmacological studies in Rats. G.T. Golden, T.N. Ferraro, R.G. Fariello, G.G. Smith*. (Spon: R.N. Harner). Neurology and Research, VAMC Coatesville PA 19320 and Thomas Jeff. Med. College, Phila. PA 19107.

Embryonic presumptive superior colliculus (Tectum) from E15-17 rat embryos was transplanted adjacent to the midbrain of intact 1 day old Long Evans hooded rats. Three to nine months later transplant animals were 1) sacrified by decapitation for HPLC amino acid analysis, or 2) prepared for in vivo microiontophoretic studies, of transplant responsiveness to application of putative amino acid neurotransmitters.

For HPLC analysis, whole brains were dissected on ice and the transplant (TP), host visual cortex (VC), host superior colliculus (SC) and host inferior colliculus (IC) were frozen on ice within 5 minutes. An ultrasensitive HPLC triple-column ion-exchange flurometric amino acid analysis technique, (Ferraro and Hare, Analyt. Biochem. 143, 82-94, 1984) was used to measure over 30 amino acids and related primary amino compounds in transplant and host brain regions. HPLC analysis of normal rat VC, SC and IC demonstrated that these areas have distinctively different amino acid profiles. VC has the highest levels of taurine, glutamate, tryptophan, ethanolamine, ammonia and methyllysine while being lowest in glycine, GABA, B-alanine, lysine, homocarnosine and arginine. IC was highest of the three areas in glycine, lysine, homocarnosine and arginine, while SC was highest in GABA and B-alanine and lowest in methyllysine.

In normal rat superior colliculus tissue, GABA, glutamate, glutamine, glycine, aspartate and taurine were present in μm concentrations and together comprised over 75% of all compounds quantified. Similar to normal superior colliclus, HPLC amino acid analysis revealed that GABA, glutamate, glutamine, glycine, aspartate and taurine were the major components of the superior colliculus transplants, together comprising over 75% of all compounds. Although GABA levels in transplants were higher than any other putative amino acid transmitter, transplant GABA reached only 67% of normal SC levels. Aspartate levels in transplants were 72% of normal SC while transplant levels of glycine, glutamate and taurine were at or above normal SC levels.

Microiontophoretic studies tested responsiveness of transplant neurons to iontophoretic application of GABA/bicuculline, glutamate, and acetylcholine/atropine sulfate. These studies revealed that 57% of all transplant neurons tested responded to application of glutamate while 62% of all transplant neurons responded to GABA, 50% of these GABA units were also responsive to bicuculline, a GABA antagonist.

Transplant units were not responsive to acetylcholine/atropine. The significance of these findings will be discussed. Supported by VA funds.

67.15 TRANSNEURONAL TRANSPORT OF WGA-HRP IN THE XENOPUS VISUAL SYSTEM. S. M. Royer and P. Grant. Department of Biology, University of Oregon, Eugene, Oregon 97403.

Recently, transneuronal transport of wheat germ agglutinin-conjugated horseradish peroxidase (WGA-HRP) has been demonstrated in the visual systems of the developing chick and adult mammals (Itaya and Van Hoesen, 1981, Brain Res. 236:199; Gerfen et al., 1982, Exp. Brain Res. 48:443). These observations suggested that WGA-HRP might be a useful tool for investigating the time course and pattern of innervation of the visual neuropils during development of Xenopus laevis.

Xenopus tadpoles and juveniles were injected intravitreally with 0.7-1.0% WGA-HRP (Sigma). After survival times of 1-14 days, the brains were fixed in phosphate-buffered glutaraldehyde, sectioned at 50 microns with a Lancer Vibratome, and reacted for HRP with TMB, followed by stabilization of the reaction product by post-reaction with DAB and cobalt (Perney et al., 1983, Soc. Neurosci. Abst. 9:300). The sections were mounted on slides and examined under bright and dark field optics.

WGA-HRP was taken up by intact ganglion cells and transported anterogradely in the optic nerve and tract. In stage 54-56 tadpoles, label appeared in the contralateral optic tract, diencephalic neuropils, tectal optic fiber neuropil, and basal optic tract one day after injection. After two days, we found heavier labelling in the primary visual neuropils and also transneuronal labelling of perikarya in the thalamic nuclei and deeper tectal layers, as well as in ependymal cells. Both labelling of the primary visual neuropils and transneuronal labelling increased in extent and intensity with longer survival periods. After five days transneuronal labelling was also observed in the nuclei isthmi bilaterally. The time course of WGA-HRP transport in juveniles both to the primary visual neuropils and transneuronally was somewhat slower than in tadpoles. The pattern of WGA-HRP labelling in juveniles, while generally similar to the tadpole, reflected the more advanced development of the visual system at the later stage. In the juvenile, the ipsilateral retinal projection was labelled, and there was increased development and differentiation of the thalamic neuropils and nuclei. In no case, in either tadpoles or juveniles, was there any evidence of transneuronal transport of WGA-HRP to cells in the ipsilateral optic tectum. In both juveniles and tadpoles, WGA-HRP labelling progressed over time along a rostral-to-caudal gradient in the diencephalon and tectum and along a superficial-to-deep gradient within the tectal layers.

67.16 DEVELOPMENT OF ANTIGEN EXPRESSION IN A POSSIBLE Y-CELL PATHWAY THROUGH THE CAT LATERAL GENICULATE NUCLEUS AND VISUAL CORTEX. M.G. MacAvoy*, S. Hockfield and M. Sur (SPON: M.F. Eckenhoff). Section of Neuroanatomy, Yale Univ. Sch. of Medicine, New Haven, CT and Cold Spring Harbor Labs., Cold Spring Harbor, NY.

The monoclonal antibody CAT-301 recognizes a surface antigen on large cells in laminae A, A1 and the dorsal C-laminae in the cat lateral geniculate nucleus (LGN). Antibody positive cells lie near interlaminar zones, have class I morphology, and project to area 18 (as well as area 17) of visual cortex, suggesting that the antibody specifically recognizes Y-cells in the LGN (Sur et al., Neurosci. Abst., 10:297, 1984). Furthermore, monocular lid suture and dark-rearing, two visual deprivation procedures that lead to a loss of Y-cells recorded physiologically in the LGN, also lead to a reduction of antibody positive cells in the LGN (Hockfield et al., ARVO 287, 1985).

We have examined the postnatal development of antigen expression in the cat LGN, and extended our study to include an analysis of cortical areas 17, 18, 19 and the lateral suprasylvian (LS) cortex. In the LGN, there is little or no antibody staining prior to 8 weeks of age. Antigen expression develops rapidly after 8 weeks, so that by 12 weeks at least half the adult complement of LGN cells are antibody positive.

In the visual cortex of adult cats, CAT-301 stains both pyramidal and non-pyramidal cells. In areas 17 and 18, the most dense label appears in laminae 3 and 4a. Lamina 5, as well as laminae 2 and 6, are moderately labelled. Lamina 4b and lamina 1 are completely free of label. Antibody staining is lighter in area 19 and the LS cortex, but similar in laminar pattern to that in areas 17 and 18 except for lack of label in layer 2.

The development of CAT-301 labelling is essentially similar across the different visual areas, but shows distinct differences in onset and maturation for different cortical laminae. In areas 17 and 18, for example, layers 3 and 4a show antibody labelling earliest, from about 2 weeks of age, to reach nearly adult numbers of labelled cells by 12 weeks. Layers 2, 5 and 6 are almost devoid of label until 8 weeks. Labelled cells in layers 5 and 6 increase rapidly thereafter. Cells in layer 2 are the slowest to develop the adult pattern and intensity of label.

The time course of development of antibody labelling in the LGN is consistent with the time course of development of Y-cell responses in the LGN. The laminar pattern of CAT-301 labelling in area 17 in adult cats shows features consistent with demarcation of a possible Y-cell pathway through the cortex. The laminar differences in development of antigen expression suggest differences in maturation of cells in different laminae of visual cortex, and may imply differences in development of cortical influences over areas and structures receiving input from cortex via the Y-cell pathway. Supported by BNS 8419240 and EY 05241.

68.1 DIFFERENT STRUCTURES IN CAT VISUAL CORTEX REVEALED BY MONOCLONAL ANTIBODIES. Yasuyoshi Arimatsu*, Janice R. Naegele, David Hicks*, and Colin J. Barnstable; Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021

Functionally distinct layers and cell classes have previously been described in the visual cortex with anatomical and physiological techniques. To investigate visual cortical organization at the molecular level, we used area 17 or dorsal lateral geniculate nucleus of the cat to generate monoclonal antibodies which label subsets of layers or subpopulations of neurons within area 17.

Balb/c mice were hyperimmunized with fixed or fresh homogenized tissue injected subcutaneously in Freund's adjuvants. For the final immunization, mice were given an intravenous injection of homogenized tissue in isotonic saline. Four days later, spleen cells were removed and fused with P3-NS1/1-Ag4-1 plasmacytoma cells using 50% polyethylene glycol as the fusing agent. Hybrid cultures were selected in HAT medium and culture supernatants were screened by an immunofluorescence assay on cryostat sections of fixed cat visual cortex. Positive cultures were cloned by plating at limiting dilution and grown in bulk.

Antibodies VC 1.1 and LG 1.1 were classified as IgM's and localized on structures associated with the surfaces of cell bodies and proximal dendrites. Labeled neurons were located primarily in layer 4 but a few were scattered throughout other layers as well. These antibodies exhibited similar cell surface labeling in rat tissue. VC 1.1 stained a primary band of approximately 55-60 KD on immunoblots of rat cortical cell membranes. Preliminary electron microscopic analysis suggests that the determinant resides within presynaptic structures.

Antibodies VC 2.1 and LG 2.1 reacted with layer 1 and layers 4-6 of visual cortex in a manner which suggested the pattern of termination of geniculate afferents. Layers 2+3 were unstained, however the border between layers 3 and 4 was marked by a striking, scalloped pattern of staining. Layers 4 and 5 were labeled continuously and within layer 6, irregular bands of tissue were stained.

Antibody VC 3.1 strongly labeled neuronal cytoplasm in layer 2+3 and weakly labeled some neurons in deeper layers. Layer 2+3 labeling appeared bright against a general labeling of neuropil which was present in all layers.

These antibodies demonstrate some molecular differences between cortical neurons and in addition suggest molecular similarities between some but not all cortical layers.

68.2 MUSCARINIC RECEPTORS IN VISUAL CORTEX OF CAT, MACAQUE AND HUMAN. D. Parkinson and N.W. Daw. Department of Cell Biology and Physiology and McDonnell Center for Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

Pharmacological studies have suggested that there may be two types of muscarinic cholinergic receptors. While antagonists such as atropine, N-methylscopolamine and quinuclidine benzilate show high and similar affinities for both muscarinic receptors, pirenzepine binds with different affinities to the two sites.

Membranes prepared from primary visual cortex of adult cats bind ^{3}H-N-methylscopolamine (^{3}H-NMS) with high affinity. Scatchard plots of ^{3}H-NMS binding were linear with a Kd of 0.15 nM and maximum binding of 717 pmoles/mg protein. A Hill plot of the data gave a slope which was not significantly different from unity. Binding of ^{3}H-NMS (0.2 nM) was progressively inhibited by increasing concentrations of pirenzepine (1 nM-5 μM). Non-linear Scatchard plots were obtained which could be resolved into high (Kd = 12 nm) and low affinity (Kd = 245 nM) components with equal numbers of binding sites in each. These results suggest that there are two types of muscarinic receptors in cat visual cortex.

Receptor autoradiography was used to identify the anatomical location of these two receptors in coronal sections of cat visual cortex. For comparison, sections from visual cortex of macaque and human were also examined. Sections were incubated in the presence of 1 nM ^{3}H-NMS alone, with pirenzepine (1 and 3 μM) to distinguish receptor types or atropine (1 μM) to define nonspecific binding. ^{3}H-NMS binding in cat visual cortex was found in upper and lower cortical layers but essentially absent from middle layers (layer 4). There was no difference in the pattern of labelling in extrastriate visual cortex. The two concentrations of pirenzepine progressively inhibited ^{3}H-NMS binding but with no effect on the relative labelling pattern. In macaque, ^{3}H-NMS binding differed between primary and extrastriate visual cortex. In area 17, labelling was present in upper and lower layers to equal intensities while only part of layer IV was unlabelled. A thin layer of label could also be seen around the layer IV/V boundary. Area 18 was diffusely labelled, more heavily in upper layers. In the presence of pirenzepine, higher labelling was seen in area 17 than area 18. ^{3}H-NMS binding in human visual cortex was different from that seen in macaque. Heaviest labelling was seen in outer layers. Layer IV was unlabelled except for a faint band in the middle and a thin highly labelled band in lower layer IV. The latter was restricted to area 17. Lower layers were less heavily labelled.

These results show that muscarinic receptors in visual cortex of cat, macaque and human show different anatomical localizations. In addition, the two receptor subtypes that can be differentiated with pirenzepine appear to have very similar distributions.

68.3 GABA MARKERS IN DEVELOPING VISUAL CORTEX: IMMUNOCYTOCHEMICAL AND AUTORADIOGRAPHIC STUDIES IN THE PERINATAL CAT. C.A. Stark* and T.P. Hicks, Dept. of Medical Physiology, Faculty of Medicine, The University of Calgary, Calgary, Alberta, Canada T2N 4N1

The traditional view of the development of cortical inhibitory processes has been that these are manifested relatively late in ontogeny, perhaps several weeks postnatally. More recent microiontophretic experiments (Wolf, Hicks and Albus, unpublished) have revealed a surprisingly robust inhibitory role for GABA in animals as young as the second week of age, operating in both spatial and temporal domains. For such synaptic processes to be operative, GABA must be present in cortex, it must be released following appropriate activation of the presynaptic neurones, and there must be a mechanism for its inactivation subsequent to its release. The release criterion has been demonstrated: cortical cup and push-pull cannula experiments have shown that GABA is released into artificial CSF during local electrical stimulation of primary visual cortex (Hicks, 1985). The present communication reports results of experiments addressing the other two criteria: presence (Immunocytochemistry), and re-uptake (autoradiography) of GABA.

Animals ranging in age from 5 days prenatal to 28 days postnatal (the majority being from the first week postnatal) have been used for immunocytochemistry of GABA and autoradiography of ^{3}H-GABA. In general, immunoreactive GABA and ^{3}H-GABA uptake increased with age. Prenatal uptake was observed of ^{3}H-GABA, even in the presence of saturating concentrations of β-alanine and amino-oxyacetic acid. In the autoradiographic studies, between birth and day 1, ^{3}H-GABA uptake rose in layer III and fell in layers I and VI; between days 1 and 4, uptake diminished slightly in layers III and IV and by day 8, uptake in layers I and II had increased to moderate levels. Immunocytochemical studies of GABA have confirmed and extended these results, documenting the ontogeny of GABA-containing neurones in perinatal cortex.

The present results provide supportive evidence for the unexpected finding that GABA mediated synaptic transmission appears to be extensive and operational at a very early stage in development in sensory cortex.

This work was supported by the MRC of Canada and the Alberta Heritage Foundation for Medical Research.

Hicks, T.P. (1985) Some functional and neurochemical determinants of GABA mechanisms in neonatal and adult visual cortex of cats. Invest. Ophthal. Vis. Sci. 26C:266.

68.4 THE EFFECT OF ENVIRONMENTAL COMPLEXITY ON THE NUMERICAL DENSITY OF NEURONS AND ON THE SIZE OF THEIR NUCLEI IN THE VISUAL CORTEX OF CAT. C. Beaulieu and M. Colonnier, Department of Anatomy, Laval University, Quebec.

In a recent study of cat visual cortex, statistically significant differences in the numerical density (Nv) of neurons were found between individual cats. It was suggested that these differences may be due to the relative richness of the (unknown and probably varied) rearing conditions of the animals used in that study. In order to verify this possibility, 2 groups of 6 animals were raised either in isolation (impoveriched condition, IC) or in a colony (enriched condition, EC) from the time of weaning to the age of 8 months. They were paired by litter and by sex. The weight, length and width of the brains were measured, and the number of neurons per mm^3 of striate cortex was estimated using a method of size-frequency distribution.

The weight, length and width of the brains were found to be greater by about 5-7% ($p < 0.05$) in the EC cats. The neuronal Nv is 18% less in EC than in IC cats (47,000 and 57,000 neurons per mm^3; $p < 0.001$). This percentage difference is maintained in most laminae. The average cortical thickness is about 4% greater in EC cats, but this slight difference is not statistically significant. The number of neurons under 1 mm^2 of cortical surface (Nc) is 15% smaller in EC cats (82,000 as compared to 96,600 in IC cats; $p < 0.05$). The area of the nuclei of neurons is 10% larger in the EC cats for the total cortical depth ($p < 0.01$). This was also significant in all layers except layer I.

The lower Nv of neurons in the EC cortex is probably not due to a decrease in the number of neurons but rather to an increase in the mass of the neuropil. The latter would result from an increase in size of the dendritic trees of EC neurons. This is consistent with the demonstrated increase in size of neuronal nuclei (which would somehow reflect the larger mass of the neuronal cytoplasm) and with the larger weight and size of the brain. The increase in thickness does not fully account for the lowered Nv. The surface of the area 17 must also be increased. If this interpretation is correct the number or width of ocular dominance columns should also be increased in area 17 of EC cats. These findings demonstrate that the richness of the environment can lead to interindividual differences of the type seen in our previous study. (MRC grant MT-3735 and FRSQ training grant to C.B.).

68.5 THE DIFFERENTIAL EFFECT OF IMPOVERISHED AND ENRICHED ENVIRONMENTS ON THE NUMBER OF "ROUND ASYMMETRICAL" AND "FLAT SYMMETRICAL" SYNAPSES IN THE VISUAL CORTEX OF CAT. M. Colonnier and C. Beaulieu, Department of Anatomy, Laval University, Quebec.

In a recent study of cat visual cortex, it was shown that there are interindividual differences in the numerical density (Nv) of symmetrical synapses associated with flat vesicles (FS synapses), but not of asymmetrical synapses associated with round vesicles (RA synapses). Since many of the properties of visual cortex neurons which are affected by the environment are GABA-dependent, it was suggested that the selective interindividual differences of FS synapses might be due to environmental factors. In order to verify this possibility we have estimated the Nv of both types of synapses in 2 groups of 6 cats raised either in isolation (impoverished condition, IC) or in a colony (enriched condition, EC) from the time of weaning to the age of 8 months. The animals were paired by litter and by sex.

Paradoxically, the Nv of all synapses is 12% smaller in the enriched condition ($p < 0.001$). This change is almost entirely due to changes in FS synapses. The average number of RA synapses is only 2% less in the EC cats and this difference is not significant ($p > 0.1$). The Nv of FS synapses, on the other hand is 45% smaller in EC cortex ($p < 0.001$). The coefficient of variation of FS synapses which in the previous study (of cats with an unknown rearing history) was on the order of 30% has been reduced to 5% in IC and to 11% in EC cats. The synapse to neuron ratio of both types of synapses shows an inverse trend. There are about 15% more RA synapses and 36% fewer FS synapses per neuron in EC cats.

The differences in the number of synapses in the two groups of animals as well as the reduction in the coefficient of variation in each of the two groups demonstrates that the richness of the environment can lead to interindividual differences of the type seen in our previous study. We suggest that the great difference seen in the Nv of FS synapses may be related to the fact that many of the neuronal properties affected by rearing conditions are GABA-dependent. If this interpretation is correct, we further suggest that during the critical period, these properties would be determined not by the addition but by the pruning of FS synapses. (MRC grant MT-3735 and FRSQ training grant to C.B.).

68.6 THE EFFECTS OF BICUCULLINE ON THE INTRACORTICAL VISUAL EVOKED RESPONSE IN THE MONKEY. M.A. Kraut*, J.C. Arezzo and H.G. Vaughan, Jr. Depts. of Neuroscience and Neurology, Albert Einstein Coll. of Med., Bronx, N.Y. 10461.

The laminar analysis of flash visual evoked potentials (VEP), current source density (CSD) and multiple unit activity (MUA), suggests that inhibition plays a substantial role in intracortical processing of visual information (Kraut et al., Neurosci. Abstr. 9, 1983). Immunocytochemical techniques have demonstrated a high concentration of presumably inhibitory GABAergic neurons in the thalamo-recipient laminae of primate visual cortex. We have utilized bicuculline, a GABA antagonist, to investigate the role of GABA dependent processes in the generation of the VEP.

Data were collected from 20 electrode penetrations in 2 unanesthetized monkeys (M. fascicularis) before and after the intracortical infusion of approximately 1 ul of 1.0 mM bicuculline methiodide at the level of lamina IV. VEP, CSD and MUA were analyzed from only those passes unaccompanied by either seizure discharge or alterations in the epidural VEP waveform recorded at a horizontal distance approximately 0.5 cm from the site of infusion.

Bicuculline had a pronounced effect on the latency and amplitude of all major VEP components. The earliest component affected, N40, is generated in lamina IVCb and partially reflects the initial postsynaptic activation of cortical stellate cells. The onset latency of the MUA and current sink associated with this component was increased by 3 to 5 msecs. A second effect of bicuculline was to extend the laminar distribution of excitatory MUA. Prior to infusion, increases in MUA to binocular stimulation were confined to the parvocellular thalamo-recipient laminae (IVA, IVCb) while after infusion, increases were consistently recorded throughout lamina IV and in the lower portions of lamina III. In contrast, bicuculline did not alter the character or spatial extent of ocular dominance regions. The observed bicuculline effects were fully reversible within 2 hours of infusion.

Our findings illustrate the importance of GABA and thus of inhibition in the genesis of the VEP. The timing of the effects suggest that inhibitory processes may modulate the sensitivity of several cortical neurons, including the initial thalamo-recipient cells. The intra-columnar distribution of flash evoked activity appears mediated by physiological processes, whereas the differentiation of ocular dominance regions is largely determined by the anatomical segregation of afferent terminals within the thalamo-recipient laminae.

Supported in part by NIH NRSAs NS07183, MH15788 and by MH06723 from the USPHS.

68.7 SPECIFIC PATTERNS OF INTERLAMINAR AXONAL PROJECTIONS MADE BY NEURONS WITH SMOOTH OR SPARSELY SPINED DENDRITES IN MONKEY STRIATE VISUAL CORTEX. J.S. Lund. Center for Neuroscience, University of Pittsburgh, School of Medicine, Room 336C Scaife Hall, Pittsburgh, PA 15261.

Interlaminar projections of local circuit (LC) neurons with somata in divisions of lamina 4 have been studied in Golgi preparations of infant and adult macaque monkey striate cortex. In the infant material it is clear that the majority, if not all LC neurons, have both local axon arbors, in the same lamina as their dendrites, and axon trunks that travel vertically between pia and white matter to provide arbors to other layers. The patterns of interlaminar projections appear specific for each neuron variety and also reflect the laminar locus of the LC neuron's cell body and dendritic field. The LC neuron axon arbors do not necessarily mimic the interlaminar relays of spine bearing neurons with the same laminar location. While in the adult the LC neuron axon trunks passing between layers often fail to impregnate in Golgi preparations (due probably to myelination) those neurons successfully impregnated indicate that infant axon arbor patterns are preserved into the mature visual cortex.

From 4Cβ, for example, at least four different LC neuron interlaminar projection patterns have been identified which arise from morphologically distinct LC neurons. These projections target respectively (i) lamina 6, (ii) lamina 3B, (iii) lamina 4A, or (iv) laminae 5A and 4Cα. The spine bearing stellate neurons of the same layer primarily target laminae 4A-3B, but contribute less prominant collaterals to laminae 6, 5A, 4Cα as well as 4Cβ locally. Comparing the LC and spiny neuron projections, it seems that the axons of LC neurons each appear to target only one or two of the laminae served by spiny neuron collaterals.

The presence of these LC neuron interlaminar projections and the knowledge that thalamic axons entering the divisions of lamina 4 terminate on both spine bearing (probably excitatory) neurons and LC neurons (many of which contain the inhibitory neurotransmitter GABA), together suggest that the relay of information from thalamic input layers to efferent neuron groups in striate cortex does not occur in a simple excitatory fashion. Rather, the anatomical evidence indicates that thalamic inputs activate excitatory, inhibitory and modulatory neurons which not only interact within the input laminae, but also they pass on their activity directly to other layers in a pattern unique to each type of neuron. It is therefore proposed that the LC neuron varieties are each specialized to accomplish different roles outside their immediate lamina location. The functional weighting of each of these relays will need to be determined physiologically. Supported by EY05282.

68.8 SOMATOSTATIN-LIKE AND VASOACTIVE INTESTINAL POLYPEPTIDE-LIKE IMMUNOREACTIVITY IN THE VISUAL CORTEX OF THE ECHOLOCATING BAT, MYOTIS LUCIFUGUS. L.K. Laemle and J.R. Cotter. Depts. of Anatomy UMDNJ-New Jersey Med. Schl., Newark, NJ 07103 and SUNY, Buffalo, NY 14214.

An ever increasing number of putative neurotransmitters and neuromodulators is being identified in the mammalian and non-mammalian visual system. Although studies are under way in several laboratories to try to ascertain their roles in vision, their functions for the most part remain unknown. Somatostatin (SRIF) and vasoactive intestinal polypeptide (VIP) are among those neuropeptides which have been identified in cell bodies and fibers in the visual cortex and retina of several species, and whose functional significance remains unclear.

Myotis lucifugus is a species with an all rod retina, in which discrete cycles of visual activity can be isolated. The visual cortex of Myotis is comprised of five layers; a molecular layer, and four layers of cells. The superficial cell layer (layer II/III) is thin and contains densely packed perikarya. The intermediate cell layer (layer IV) is thicker, and cells are less densely packed. Layer V is represented by a discontinuous layer of scattered triangular cells; the deep cell layer (layer VI) is thicker, and cells are closely packed.

We have demonstrated SRIF- and VIP-like immunoreactivity in fibers and perikarya in the visual cortex of three euthermic animals, and compared the distribution of the two peptides. Animals were sacrificed by administration of an overdose of anesthesia; brains were fixed in Bouins solution, embedded in paraffin, and sectioned at 12u in the coronal (2 animals) or saggital (1 animal) plane. SRIF and VIP were localized light microscopically using the appropriate antisera and the PAP method of Sternberger. Staining was judged specific by the absence of DAB reaction product following adsorption of the primary antiserum with synthetic peptide and/or replacement of the primary antiserum with normal preimmune rabbit serum. SRIF-like immunoreactivity was present in all cortical layers. Fine immunoreactive terminals were most numerous in layer II. Larger diameter, branching fibers were observed in layers I and II. Immunoreactive perikarya were morphologically uniform, and were located predominantly in the deep cell layer (layer VI). VIP-immunoreactive fibers, terminals, and perikarya were more numerous than those which were immunoreactive for SRIF. VIP-positive fibers coursed through all cortical layers; terminal plexuses were concentrated in the superficial cell layer. VIP-positive perikarya were observed in both superficial and deep cell layers and were morphologically more diverse than SRIF-positive perikarya. (Supported by NIH grant EY04204 to LKL).

68.9 Segregation of On-center and Off-center Afferents in the Tree Shrew Striate Cortex. D. Raczkowski and D. Fitzpatrick. Dept. of Anatomy, Duke University Medical Center, Durham, N. C. 27710

In the lateral geniculate nucleus of the tree shrew, on-center and off-center neurons are located within different laminae (Conway and Schiller, 1983, J. Neurophysiol. 50: 1330-1342). Neuroanatomical studies and microelectrode recordings have demonstrated that these laminae project to separate layers within the striate cortex (Conley, Fitzpatrick and Diamond, 1984, J. Neurosci., 4: 171-197; Norton, Kretz and Rager, 1983, Invest. Ophthal. Suppl. 24: 265). The aim of the present experiment was to determine how individual on-center and off-center geniculate afferents terminate within the visual cortex. To achieve this aim, we injected horseradish peroxidase into single, physiologically identified axons in the optic radiations.

To date, this study of the tree shrew's visual cortex has revealed that individual on-center and off-center geniculate axons do terminate in separate tiers in layer IV. On-center axons supply a dense arborization to layer IVa and provide only a sparse input to layer IVb. In contrast, off-center axons terminate predominantly in layer IVb. The terminal fields of some axons occupy almost the entire width of layer IVa or IVb, while the terminal fields of others are more restricted. Some of the axons that arborize mainly in either layer IVa or IVb also give rise to collaterals that terminate in layer III; no collaterals were seen in layer VI.

These results provide anatomical evidence for the existence of 'on' and 'off' parallel channels in the tree shrew geniculostriate pathway. The functional significance of preserving the segregation of these pathways into layer IV of the striate cortex is not clear. However, as a consequence of this circuitry, some neurons in the tree shrew striate cortex may be influenced exclusively by either the 'on' or 'off' channel.

68.10 PHYSIOLOGICAL AND MORPHOLOGICAL PROPERTIES OF CORTICOTECTAL CELLS IN THE HOODED RAT. B.R. Schofield, L.E. Hallman* and C.-S. Lin. Dept. Anatomy, Duke Univ. Med. Cntr., Durham, NC 27710

Corticotectal (CT) cells in area 17 of the hooded rat were identified by antidromic activation from the superior colliculus. Quantitative receptive field analysis was conducted using computer-controlled stimuli. Identified CT cells were then impaled and injected with horseradish peroxidase. Our goal was to examine the relationship between the morphology and physiology of CT cells.

Most CT cells respond to visual stimuli at all orientations; however, quantitative analysis reveals that some cells are orientation selective (criteria as in Schiller et al., '76). Similarly, most CT cells are not selective for direction of stimulus movement, although a few directionally-selective CT cells have been found.

The responses of CT cells to stimuli of different velocities suggest that subtypes may exist. Some CT cells respond to a wide range of velocities (e.g. 10-120°/sec); some cells exhibit a high-pass response (e.g. respond to 60-100°/sec, but not to 20°/sec); and others show a low-pass response (e.g. respond to 10-20°/sec, but not to 40-80°/sec).

CT cells labelled with horseradish peroxidase share several morphological traits. All are layer V pyramidal cells. The basal dendrites are distributed throughout the depth of layer V, and often extend into layers IV and VI. The horizontal extent of these dendrites can measure up to 300um in the medial-lateral and anterior-posterior axes.

The apical dendrites of CT cells arborize in layer I in a terminal tuft that can spread over a much wider area than the basal dendritic tree (up to 800um). These processes are thin and spiny and travel in the upper portion of layer I. The apical dendrite also gives rise to several oblique dendrites that extend with little or no branching into layers II/III and IV. The axons of CT cells have numerous intracortical collaterals, most of which arborize within the region occupied by the basal dendrites. Axonal swellings, presumably presynaptic boutons, can be found in layers IV, V and VI. A few collaterals can be traced for longer distances in layer V (200-300um); in one case a collateral could be followed for 700um, extending almost to the lateral border of area 17. In contrast to the local network, the long horizontal collaterals show very little branching.

We conclude that CT cells in the hooded rat are similar to those in other animals. Our current efforts are directed toward: 1) more detailed analyses of velocity tuning of CT cells; 2) comparisons of CT cells with non-CT cells. Supported by NIH EY05490, EY05777, GM07046, and FFS PD84-066.

68.11 TOPOGRAPHY OF AFFERENT PROJECTIONS TO MONKEY STRIATE CORTEX D. J. Perkel*, J. Bullier* and H. Kennedy (SPON: European Neuroscience Association) INSERM U. 94 16, av. Doyen Lépine 69500 Bron FRANCE

It is generally assumed that the projections which link the multitude of retinotopically organized visual structures connect regions representing the same portion of the visual field. One might expect, then, to find a spatial separation in one structure of neurons which project to separate regions of another structure. To test this hypothesis, we have made paired injections of 2 different fluorescent retrograde tracers, fast blue (FB) and diamidino yellow (DY) in separate regions of macaque monkey striate cortex (area 17 or V1), and examined the degree of intermingling of the populations of labelled neurons in the structures afferent to V1.

In 6 animals one injection was made parallel to and 1-2 mm away from the V1/V2 border. In 4 of these, a second injection was made parallel to the first and at a distance of 2-3 mm, and in 2 monkeys the injections were separated by 7 and 17 mm. In all cases, 2 separate populations of labelled neurons were found in the lateral geniculate nucleus (LGN) and in the lateral and inferior pulvinar. Double-labelled (DL) neurons were observed extremely rarely in these structures. In contrast, the claustrum contained almost completely intermingled populations following injections separated by 2-3 mm, and showed diminished overlap for greater injection separations.

Labelled cells were also found in extrastriate cortex. On two-dimensional reconstructions of the cortical surface, 5 patches of labelling could be distinguished for each tracer, including the readily identified areas V2 and MT. Labelled cells in V2 were found in supragranular and infragranular layers, with a greater density and lateral extent in the latter. Following injections separated by 2-3 mm, the 2 populations were partially overlapping, and DL neurons, concentrated in the zones of overlap, made up 5-10% of the labelled cells within these zones. With greater distances between the injections, there was complete separation of the V2 populations, and no DL neurons were found. In area MT, there was essentially complete intermingling of the 2 populations, except in the cases with 7 mm and 17 mm separations. DL cells constituted 5 - 10% of labelled MT neurons in the regions of overlap when the injections were separated by 2-3 mm, but this fraction dropped to nearly 0% with larger injection separations. Intermediate between areas V2 and MT, the 3 patches of labelled cells on the anterior bank of the lunate sulcus and on the prelunate gyrus contained partially overlapping FB- and DY-labelled cell populations after injections separated by 2-3 mm. The intermingling was greatly reduced following the injections separated by 7 mm, and the populations were separate in the 17 mm case. In these areas, as elsewhere, DL cells were confined to the regions of intermingling and formed 5-10% of the labelled neurons in those regions.

The spatial intermingling of neurons in the claustrum and extrastriate cortex which project to separate regions of V1 may be related to the larger receptive field size and scatter found in these structures, in contrast to the separation found in the thalamus, where receptive fields are smaller and less scattered. This suggests that the topography of connections between two visual structures is related to the characteristics of the visual field representation in the afferent and target structures.

68.12 ILLUSORY CONTOURS CAPTURE STEREOPSIS AND APPARENT MOTION V. S. Ramachandran* and P. Cavanagh* (SPON: R. M. Boynton), Dept. of Psychology, UCSD, La Jolla, CA 92093.

We began with a square matrix of four circular 1° wide black discs from which we removed right angle sectors. This created the impression of a white "subjective" square with its four corners occluding the discs ("illusory contours"). The display in the other eye was identical except for a horizontal disparity introduced between the edges of the cut sectors so that an illusory white square floated out in front of the paper. We superimposed a "template" of this stereogram on a vertical square-wave grating (6 cycles/ degree) and found that the illusory square pulled the corresponding lines of grating forward even though the grating was at zero disparity. This illusion ("stereo-capture") was strong enough to overcome the physical continuity of the lines so that apparent breaks appeared on the lines along the upper and lower borders of the subjective square. The illusion could be seen in 160 msec flashes. Since the disparity of the cut sectors was at least 3 times the grating periodicity the observation implies that the disparity signal derived from the subjective surface was strongly influencing the processing of the lines of wallpaper (grating). This is consistent with a novel effect observed recently by Mitchison and McKee. They found that disparity of the end points of horizontal dot rows presented binocularly could influence the matching of repetitive ambiguous elements in the middle.

We also found that capture disappeared if: 1) Disparities were uncrossed instead of crossed (presumably because of conflicting "occlusion" cues); 2) Real black-white line segments were used instead of subjective contours; 3) The template was superimposed on horizontal gratings (the grating remained flush with the background); 4) The disparity of the subjective square was not an exact multiple of the grating spacing; 5) Curved or tilted subjective surfaces were used. These observations imply that capture results not just from attribution but possibly from synergy (e.g. positive feedback gain amplification) between cells in V1 that respond to disparities conveyed by the wallpaper and those in V2 that respond to subjective surfaces.

Analogous effects were observed in apparent motion ("motion capture"). By removing sectors from discs in an appropriately timed sequence we could generate apparent motion of an illusory square. When a template of this display was superimposed on periodic patterns (e.g. grids of dots or gratings) the dots or lines appeared to move vividly with the square even though they were physically stationary. We conclude that segmentation of the visual scene into surfaces and objects can profoundly influence the early visual processing of stereopsis and apparent motion.

68.13 LOSS OF VISUAL SENSATION IN THE MONOCULAR GANZFELD FOLLOWS RULES COMPARABLE TO BINOCULAR RIVALRY. S.J. Bolanowski, Jr., O.S. King* and R.W. Doty. Center for Brain Research, University of Rochester School of Medicine & Dentistry, Rochester, NY 14642.

Monocular presentation of a contourless visual field (Ganzfeld), or stabilized retinal image, produces dramatic vanishings (blankout) and sporadic returns of visual sensation despite continuing stimulation. When equiluminant Ganzfelden are presented binocularly, blankout does not occur, indicating that the locus of the effect must be central and not retinal. These facts and the observations that even during blankout a) the monocular crescent is commonly perceptually visible, b) pupillary dilatation accompanies the blankout, and c) pressure block of the eye in darkness prevents the blankout, all suggest that the phenomenon is related to binocular rivalry (Bolanowski and Doty, Neurosci. Abst., 8:675, 1982). Blankout is thus probably a result of the eye in darkness becoming dominant, suppressing the eye viewing the Ganzfeld. If true, then there should be an elevation of visual threshold in the suppressed eye, comparable to that known to occur in rivalry. To test this, we installed a fiber optic bundle subtending 2.3° on the Ganzfeld surface and measured increment detection thresholds to 10-msec test-probe flashes under three conditions: 1) during binocular viewing of equiluminant Ganzfelden, 2) to the eye viewing the Ganzfeld monocularly prior to blankout, and 3) to that eye during periods of blankout. The test flash was initiated by the observer and its intensity randomly controlled by the experimenter. For a criterion of 50% detection, subjects required a test probe intensity ca 0.4 log units greater for 3) compared to 2); and ca 0.5 log units for 3) versus 1). Such a result is wholly concordant with the supposition that the blankout is a form of binocular rivalry, the eye in darkness suppressing input from the eye viewing the Ganzfeld. Most remarkable was the discovery that this suppression ensued immediately and endured for ca 2-6 sec when the 10-msec flash was presented to the eye in darkness, i.e., blankout in the eye viewing the Ganzfeld was inevitably induced. This ability to control precisely the time of onset of blankout opens up a number of experimental possibilities, including its behavioral and electrophysiological analysis in alert macaques. (Supported by NIH Grant EY04354).

68.14 ESTIMATING THE PROPERTIES OF VISUAL SPATIAL INFORMATION PROCESSORS USING AN EVOKED POTENTIAL INTERACTION PARADIGM. David Ryan-Jones* & M.A. Berkley, (SPON: J. Tunkl), Florida State Univ., Tallahassee, FL 32306.

Current theories of vision suggest that different stimulus features are processed by different neural populations. A variety of psychophysical paradigms have been employed to test this idea and define the characteristics of putative processors. We have applied this strategem in an evoked potential (EP) paradigm to estimate the characteristics of the neural substrate of linear contour and vernier acuity processors. The following assumptions were made: 1) the neural responses (EP) generated by two independent neural populations should show additivity if the responses occur close enough in time; 2) non-independent processors should show little additivity under the same conditions; and 3) spatial overlap of neural populations should show partial additivity.

With these assumptions, evoked potentials were recorded to two briefly presented (100 msec) linear contours (line 2° x .01°) at various onset asynchronies (SOA) where the line targets were: 1) orthogonal to each other; 2) parallel to each other; and 3) when one target was a briefly presented (100 msec) vernier offset and the other was either an 100 msec presentation of an orthogonal line passing through the offset; or a 100 msec presentation of a pair of parallel lines straddling the offset target. The recorded responses were quantitatively compared to the computer-combined sum of the EPs recorded to each stimulus separately.

The results show that for the orthogonal line targets, there was complete summation between the responses elicited by each line target, e.g., recorded EPs and computer-simulated EPs were essentially identical in shape and amplitude at all SOAs. Complete occlusion was observed in the parallel line condition up to SOAs of 100 ms, e.g., recorded amplitude to the parallel line stimulus pair more closely resembled the response elicited by a single line stimulus than the computer-simulated sum. This occlusion effect was seen strongly at spatial separation distances up to 30' and less strongly for separations up to 1°. In the vernier offset-line conditions, the EP recorded to the combined stimuli showed significant summation when an SOA appropriate to compensate for the latency differences between the offset-elicited and line-elicited EPs was employed. Additivity was observed in both vernier offset-line configurations but was greatest when the line passed through the offset.

The results demonstrate that the EP technique can be employed to evaluate the spatial characteristics of neural processors and support the view that: 1) orthogonal contours are processed by separate neural populations; 2) parallel contours are processed by overlapping pools of neural elements, the degree of overlap extending up to at least 1° of separation; and 3) linear contours and vernier offsets appear to be processed by separate neural populations which may share some common elements. 68.15 THE CHARACTERISTICS AND TIME COURSE OF ADAPTATION TO GRATINGS AS ESTIMATED FROM EVOKED POTENTIALS. Alan Ho* & M.A. Berkley, Florida State Univ., Tallahassee, FL 32306.

The threshold contrast for detecting a test grating increases exponentially as a function of the time a moderate contrast adaptation grating is viewed when the spatial frequency and orientation of the adaptation and test grating are similar.[1] The rate at which sensitivity returns to pre-adaptation levels is also exponential. Changes in apparent contrast during prolonged viewing of a suprathreshold grating have similar temporal properties.[2] Psychophysical studies have reported time constants of 10-20 secs for these changes while electrophysiological and behavioral cat studies of adaptation - recovery have reported much shorter values.[3,4] It has been suggested that the longer psychophysical estimates are due to the use of paradigms which have significant response-time delays.[5]

To obtain time-course estimates not limited by response variables, we have recorded visual evoked potentials (EP) in humans during prolonged viewing of counterphase (8 Hz) gratings and during a recovery period in which the grating target was intermittently viewed. Samples (2 sec) of the EPs elicited in response to 0.6 contrast sinusoidal gratings were recorded at 13 intervals during 45 secs of adaptation and at 5 intervals during subsequent 50 secs of recovery. During adaptation, the target was continuously present while during recovery, the grating appeared only during the recording periods, the intervening intervals displaying a zero contrast target of an equal average luminance. A recording session consisted of 16 adaptation-recovery cycles with a 100 sec rest period between each cycle.

Plots of the first two harmonics (16 & 32 Hz) of the EPs against time showed that the amplitude of these components declined exponentially during adaptation and then increased exponentially during recovery. Time constants derived from these data ranged between 2-7 secs, varying with spatial frequency, and were significantly shorter than psychophysical estimates supporting the view that the latter measures may have been limited by procedural constraints. An unexpected finding was that the maximal amplitude EP often occurred 3-6 secs after the beginning of adaptation. Increases in sensitivity after the start of adaptation have not been reported in the psychophysical literature, but delayed peaks have been observed in single cell adaptation studies.[3] The delayed peak response could be eliminated or made to occur earlier by using adaptation contrasts less than 0.1. A multichannel, mutual inhibition model appears to adequately describe the results.

68.16 INDIVIDUAL DIFFERENCES IN SPATIAL FREQUENCY VISUAL PROCESSING. G. Schechter* and E. Callaway. Langley Porter Psychiatric Institute, University of California, San Francisco, California 94143.

Stimulus spatial frequency is a critical variable in visual information processing. Current efforts to explain the role of spatial frequency channels in vision link them to attentional mechanisms. The human visual system can selectively attend to stimuli of specific spatial frequencies contained in a complex visual scene. While studying spatial frequency-attention interactions, we observed wide variability in how individuals responded to low and high spatial frequency components of a complex visual display.

Reaction times (RTs) to stimuli composed of large and small letters, corresponding to low and high spatial frequencies, were compared under separate instructions to attend to designated large letters, small letters, or both. Under instructions to attend equally to both size letters, some subjects had faster RTs to large targets compared to small, whereas others had faster RTs to small targets compared to large. Subjects quantitatively divided into 2 groups on these contrasting response patterns were compared across the 3 attention conditions. There was a significant group by stimulus size by attention interaction. The distinct intersubject differences observed in the equal attention condition also emerged in the selective attention conditions. The largest group difference occurred in response to small targets when attended.

The transient-sustained dichotomy describes visual processing systems differentially sensitive to low and high spatial frequencies, respectively, and has been demonstrated structurally, functionally and behaviorally. If the transient-sustained concept is invoked, intersubject differences might be interpreted as individual variation in the dynamic balance between the two systems. Subjects who naturally responded faster to large targets (i.e., were more sensitive to low spatial frequencies) might have a transient processing system that inhibits the sustained. Other subjects who responded faster or equally to small compared to large targets (i.e., were more sensitive to high spatial frequencies) may have a more active sustained system that inhibits the transient one.

Differences between normal individuals in response to low and high spatial frequency stimuli were demonstrated. Extreme imbalances between transient and sustained processing in pathological states require confirmation.

68.17 CORTICAL DYNAMICS OF DEPTH, BRIGHTNESS, COLOR, AND FORM PERCEPTION. S. Grossberg* and E. Mingolla. Center for Adaptive Systems, Boston Univ., Boston, MA 02215.

A real-time visual processing theory is used to unify the explanation of a wide variety of perceptual phenomena involving depth, brightness, color, and form perception. The theory is also used to analyse and predict phenomena concerning the architecture of striate and prestriate visual cortex. This analysis concerns the processing rules whereby a Boundary Contour System (BCS) and a Feature Contour System (FCS) (Grossberg and Mingolla, Psych. Rev., 1984, 92, 173) differentially react to scenic properties before interacting to generate a percept of color-and-form-in-depth. Predicted BCS properties have been supported by experiments of von der Heydt, Baumgartner, and Peterhans (Science, 1984, 224, 1260) on monkey visual cortex. These properties also provide computer simulations of perceptual grouping and segmentation phenomena, including the grouping of textured images, randomly defined images, and images built up from periodic scenic elements. The BCS provides a unified set of rules for analysis of edges, textures, and surfaces (shape-from-shading). The complex cells of the BCS pool wavelength-sensitive LGN inputs into a broad-band boundary signal (cf. Thorell et al., Vision Res., 1984, 24, 751), whereas the double-opponent cells of the FCS preserve the separation of LGN wavelength-sensitive properties. Multiple spatial scales within these systems are used to parse two-dimensional scenes into a representation of color-and-form-in-depth that is suggested to occur in V4. Binocular disparity-sensitive BCS interactions give rise to signals, called filling-in generators and filling-in barriers, which control the brightness and color signals leading to visible percepts. Computer simulations of brightness data led to this filling-in model (Cohen and Grossberg, Percep. Psychophys., 1984, 36, 428) whose mixed electrotonic and chemical transmitter interactions are formally the same as those reported among the H1 horizontal cells of the turtle retina (Piccolino et al., J. Neurosci., 1984, 4, 2477). The cortical filling-in process may thus be an evolutionary homolog of a retinal process. Applications are made to such additional perceptual phenomena as: tissue contrast, binocular rivalry, transparency, McCullough effect, metacontrast, and hyperacuity.

68.18 SPATIAL CONTRAST SENSITIVITY IN IMPAIRED LEARNING AND RECOGNITION OF FACES. M. Rizzo,* J.J. Corbett,* H.S. Thompson,* A.R. Damasio, (SPON: G.W. Van Hoesen). Div. of Behavioral Neurology and Neuro-ophthalmology Clinic, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

Recent work suggests that the recognition and learning of complex images may rely on spatial filtering characteristics of the human visual system. When high or low spatial frequencies are filtered from pictures of faces, their recognition by normal subjects is impaired. Prosopagnosia, an impairment of the recognition and learning of human faces, might thus result from impaired perception in spatial frequency channels carrying information crucial to these processes. We studied two stable prosopagnosic subjects to investigate the hypothesis that an impairment of spatial contrast sensitivity (SCS) at specific frequencies might be sufficient to explain prosopagnosia.

Both subjects #1 and #2 had sustained bilateral lesions in the occipito-temporal region, shown by computerized tomography and magnetic resonance. Neither subject could learn new faces no matter how lengthy and repeated the exposure. In addition, subject #1 could not recognize the faces of persons she knew before her illness. Both subjects had normal intellect and language, visual acuity of 20/20 OU and no evidence of retinopathy or opacity of the ocular media. Neither had alexia, visual disorientation, ocular apraxia, optic ataxia, or neglect. Electro-oculographic study showed normal scanning of facial features in both; each subject could make subtle discriminations between faces they were not required to learn or recognize.

SCS was tested with the Cadwell CTS-5000 system utilizing the ascending method of limits for presentation of vertical sinusoidal gratings to both eyes. Compared to controls, subject #1 had a relative reduction of SCS at high frequencies but retained adequate SCS in this range to permit accurate processing of high frequency information in room light, for printed materials. Subject #2 had normal SCS at all frequencies.

The findings show that prosopagnosia can be seen with intact SCS, as demonstrated in #2. In addition, SCS at low and intermediate frequencies was entirely normal in #1. The method used here was sensitive enough to detect her relative SCS impairment at high frequencies, but it is unlikely that this defect caused her agnosia since she had sufficient high frequency function to process accurately the high frequency information which composes line drawings. These results are consistent with the notion that recognition and learning of faces depends on the full range of spatial frequencies. The presence of adequate visual sensory ability and normal oculomotor scanning of facial features in these subjects also supports the hypothesis that prosopagnosia is a result of defective visually triggered memory, rather than the consequence of a primary perceptual defect.

68.19 SPATIO-TEMPORAL SEPARATION OF STRIATE FROM EXTRASTRIATE CORTICAL ACTIVITY IN HUMANS. R. Srebro. Depts. Ophthalmology and Physiology, Univ. of Texas, Southwestern Medical School, Dallas,TX 75235

A Laplacian analysis of the visually evoked potential field on the scalp (see Srebro, R.J. Physiol 360, 233, 1985 for details of method) allowed separation of striate from extrastriate cortical activity in both time (following stimulus) and space (cortical mantle). Eight subjects were shown stimuli consisting of 2 degree lower hemifield half-disks filled with 14 minute black and white checks as pattern pulses (16 2/3msecs) against a 12 by 18 degree uniformly illuminated background. In each of 3 recording sessions, 12 scalp electrodes were placed using a regular 2cm tessellation from which were derived 4 Laplacian estimators with 1/2 overlap. A region of scalp from 1cm left to 5cm right of Oz and from 3cm below to 5cm above Oz (approximately 35cm^2 of cortical mantle) was ultimately characterized by 10 Laplacian estimators for each subject. Polarity inversions suggested the existence of at least 2 sources of cortical activity separated in both time and space. The set of 10 Laplacian estimators, $|F_i(t)|$, where i indexes spatial location, was modeled by:

$$F_i(t) = a_i g(t) + b_i g(t+\tau)$$

with, $$g(t) = (n(t/c)^{n-1} - (t/c)^n)\exp(-t/c)$$

i.e. by 2 identical biphasic components which sum linearly to produce all of the 10 Laplacian estimator waveforms. A nonlinear least squares fit established the values of n, c, and τ for each subject. This simple model accounted for the waveforms of the Laplacian estimators very well. The values of τ, the delay between the 2 components, ranged from 10 to 30 msecs for the eight subjects studied. There was always considerable temporal overlap between the 2 components. The set of weighting coefficients, $|a_i, b_i|$, was used to construct maps showing the cortical topographies of the 2 components for each subject. The earlier component was strongest near the midline and spread 2 to 3cm laterally. The later component was strongest 3 or 4cm lateral to the midline. In several subjects there was some spatial overlap between the 2 components, probably reflecting the limit of the spatial resolution of the method. These results suggest sequential activation of striate and extrastriate cortex.

69.1 LOCAL NEURONAL CIRCUITS IN THE LATERAL GENICULATE BODY OF THE ALBINO RAT. S. Reinis and D.S. Weiss*, Department of Psychology, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Multiple unit responses were recorded from spontaneously firing neuronal populations located in the lateral geniculate body of albino rats anaesthetized with Ketamine and Rompun using a single tungsten microelectrode. The positions of the detected spikes in the sweep were stored as well as their amplitudes. During the evaluation of the data, the spikes were divided into eight amplitude classes, from 0 to 7, according to the spike voltage. The lowest, 0 class, represented the noise of the equipment, and was not used for any further calculations. An algorithm was developed to compute the interactions of neuronal groups characterized by a particular amplitude. The algorithm first computed auto- and cross- correlograms between and within the seven classes of spike amplitudes. The most common interspike interval (the peak value of each histogram) was selected from these histograms and was then used for the identification and storage of all the pairs of spikes in the original record which were characterized by that particular interval between them. It is reasonable to expect that the most common interspike interval represents a real, causal interaction between the activities of two neurons. In order to recognize more "real" interneuronal interactions, where firing of one neuron (or group of neurons) is causally related to the firing of another group, and separate them from the "false" interactions which depend on the method of the calculation of correlation histograms, the second spikes related to the most common interspike intervals were then erased from the original record, and the correlation histograms were calculated again. Now, the second most common interspike interval was identified and the relevant spike pairs categorized and stored. In this way, the algorithm proceeded stepwise until the frequencies of the interspike intervals did not differ from data generated randomly. The number of cells involved in the population firing could also be estimated from these calculations. Finally, a model of the sequence of neuronal interactions was constructed, described, and visualized on the screen of the computer. The results show that even in the lateral geniculate body, without any visual stimulation, the nerve cells interact in a complex manner, and form functional systems which may probably be related to a logical analysis of the sensory input. A quantitative expansion of these computer programs may provide a detailed model of the functioning of large neuronal systems.

69.2 DISTINCT METABOLIC SUBDIVISIONS OF THE RAT LATERAL GENICULATE NUCLEUS REVEALED BY CYTOCHROME OXIDASE HISTOCHEMISTRY. P.W. Land. Center for Neuroscience and Dept. of Anatomy and Cell Biology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

The metabolic requirements of individual laminae in the cat and monkey dorsal lateral geniculate nucleus (LGNd) are extremely sensitive to the integrity of retinal input from the appropriate eye. Thus, monocular enucleation, monocular lid suture and tetrodotoxin induced blockage of retinal ganglion cell activity all result in a marked and persistent reduction in activity of the mitochondrial enzyme cytochrome oxidase (CO) in the corresponding geniculate laminae.

CO histochemistry was used in the present study to examine patterns of metabolic activity in the LGNd of Long-Evans black-hooded rats. Sections through the LGNd of normal adult rats and rats that had one eye removed for 60 days beginning either on the day of birth or at 30 days of age were reacted for CO according to the method of Wong-Riley (Brain Res. 171:11, 1979). Some of these animals also received an intraocular injection of horseradish peroxidase (HRP) and in these cases adjacent series of sections were reacted for CO and HRP.

In rats, there are no clear cytoarchitectonic subdivisions of the LGNd corresponding to the segregated retinal input. Nevertheless, in normal animals the CO reaction reveals distinct metabolic subdivisions within the nucleus that coincide with the distribution of crossed and uncrossed retinal ganglion cell axons. Thus, regions of the LGNd receiving a projection from the ipsilateral eye are considerably more reactive than those receiving a contralateral projection. This pattern is enhanced in the LGNd ipsilateral to the intact eye of animals enucleated at 30 days of age and is obscured in the contralateral nucleus. In animals that had one eye removed on the day of birth, and that have abnormal patterns of retinal axon termination, neither geniculate shows this characteristic pattern of CO reactivity.

Taken together, these results indicate a somewhat different contribution of crossed vs. uncrossed retinal input to the overall metabolic activity of the rodent LGNd. They also suggest that there may be functional differences among cells in different portions of the LGNd despite the absence of overt cellular laminae.

69.3 PARABIGEMINOGENICULATE PATHWAYS IN MAMMALS. T. Hashikawa*[1], J.T. Weber[2], D.P. Van Lieshout*[3] and J.K. Harting[3]*. (Spon.: W.T. Welker). Depts. of Anatomy, Iwate Medical University[1], Morioka, Japan, Tulane Medical School[2], New Orleans, 37240, and the University of Wisconsin[3], Madison, WI 53706.

We have used anterograde and retrograde tracing methods to demonstrate the presence and distribution of parabigeminogeniculate pathways in the opossum, rat, grey squirrel, gopher, tree shrew, cat, Galago and Saimiri. While interesting variations occur in the laterality (i.e., in opossum, rat, grey squirrel, gopher and tree shrew the projection is primarily crossed; in the cat it is bilateral, while in Galago and Saimiri the pathway is primarily uncrossed) and distribution of parabigeminogeniculate axons across these eight mammals, a connectional theme revealed by our data is that in all of the species examined, parabigeminal axons distribute most densely to geniculate zones which are targeted by tectogeniculate axons. In those species possessing laminated lateral geniculate nuclei, the overlap of tectal and parabigeminal axons occurs within small-celled layers and interlaminar zones; neurons in such regions project to supragranular layers of area 17 (i.e., layer 3 and interlaminar zones in tree shrew; layers C_3 and C_2 in cat; layers 4 and 5 and interlaminar zones in Galago; "S" layers and interlaminar zones in Saimiri). Since cells within the superficial layers of the superior colliculus provide the primary input to the parabigeminal nucleus, it follows that small-celled geniculate layers and interlaminar zones are heavily influenced by collicular and "collicular-like" information via two subcortical circuits (tectogeniculate and tecto-parabigeminogeniculate). (See Sherk, '78, '79 for review).

In addition to ending quite extensively within tectally innervated regions of the lateral geniculate nucleus, the present data reveal that in most of the species studied, parabigeminal axons also terminate within other layers (magno- and parvocellular). These findings suggest that parabigeminal information not only has access to supragranular layers of area 17 via the small-celled geniculocortical system (as does tectal information), but in addition can reach sublaminae of layer IV and layer VI via channels arising from neurons within the magno- and parvocellular layers. When the total distribution of geniculate afferents arising from the superior colliculus and the parabigeminal nucleus is considered, it seems likely that colliculo-geniculate interactions play a major role in geniculocortical functions(s).

69.4 SUBCORTICAL PROJECTIONS TO THE LATERAL GENICULATE NUCLEUS IN GALAGO AND TREE SHREW. D. Fitzpatrick, G. Luppino*, D. Schmechel*, and I.T. Diamond. Depts. of Anatomy and Psychology, Duke University, Durham, NC 27706.

As a first step in understanding the way in which subcortical inputs may influence the pattern of activity in retino-geniculocortical pathways, we are studying the origin, pattern of termination and neurotransmitter characteristics of subcortical projections to the lateral geniculate nucleus (GL) in the prosimian primate Galago senegalensis and in the tree shrew, Tupaia belangeri.

Injections of HRP into GL in both species produce labeled neurons in the reticular nucleus of the thalamus, the superficial layers of the superior colliculus (SC), the pretectum (PT), the parabigeminal nucleus (PBG), and various subdivisions of the pontine and midbrain reticular formation (locus coeruleus, dorsal raphe, and the region surrounding the brachium conjunctivum). Labeled neurons in most of these structures are located either entirely or predominantly ipsilateral to the injection site in GL except for PBG in the tree shrew that appears to be almost entirely contralateral.

Anterograde transport of WGA-HRP from these subcortical structures reveals different patterns of termination within GL. In Galago, SC projections terminate mainly in layers 4 and 5 (the intercalated layers) and in the interlaminar zones (Fitzpatrick et al., 1980). By contrast, PT terminals are most dense in the parvocellular layers, less dense in the magnocellular layers and sparse within the intercalated layers.

In the tree shrew, SC projections terminate most densely in layers 3 and 6 and in the interlaminar zones surrounding layer 5 (Fitzpatrick et al., 1980). The projection from PT appears to consist of two components: one which originates in the anterior pretectal nucleus and terminates in all geniculate layers and one which originates in more caudal portions of PT and terminates in the same regions as SC. The pattern of projection from PBG is distinct from both tectal and pretectal patterns: labeled terminals are found in layers 1, 3, 5 and 6, and in the interlaminar zones adjacent to layer 5, but not within layers 2 and 4.

Finally, the neurochemical characteristics of some of these subcortical projections have been examined with antisera to neurotransmitter-specific markers. For example, we have found a large number of choline acetyltransferase (ChAT) positive neurons in the region of the brachium conjunctivum and almost every neuron in PBG appears to be ChAT positive. Furthermore, GL in both species is distinguished from other thalamic nuclei by a dense pattern of ChAT positive endings. The exact contribution of these two potential subcortical sources to the pattern of ChAT positive endings within GL remains to be determined. 69.5 DOES THE ASCENDING CHOLINERGIC PROJECTION EXCITE LATERAL GENICULATE NEURONS WHILE INHIBIT THALAMIC RETICULAR NEURONS?

Y. Kayama, M. Takagi* and T. Ogawa*,
Dept. of Physiol., Akita Univ. Sch. of Med., Akita 010, Japan

The ascending reticular activating system has long been supposed to be cholinergic in nature. However, the distribution of cholinergic neurons in the brain has been clarified only recently by means of choline acetyltransferase immunohistochemistry. In the rat cholinergic neurons projecting to the thalamus aggregate largely in the latero-dorsal tegmental nucleus (LDT) of the rostral pons. In the present study the effects of LDT stimulation on single neuronal activities in the dorsal lateral geniculate nucleus (LGd) and in the thalamic reticular nucleus (TR) were studied in rats anesthetized with urethane. The position of stimulating electrode was checked after each experiment on histological sections processed with NADPH-diaphorase histochemistry, which is a reliable method to selectively stain cholinergic neurons in the brainstem.

The firing rate of almost all LGd relay neurons increased upon repetitive stimulation (200 Hz) of LDT, which was weaker than a threshold to desynchronize cortical EEG recorded simultaneously. The effect usually appeared within several hundred msec after the onset of stimulation, and began to fade within a few seconds in spite of ongoing stimulation. The LDT-induced excitation were blocked by scopolamine applied ionophoretically or intravenously. Acetylcholine applied ionophoretically induced a strong increase in discharge, and sometimes led to depolarization block.

Under urethane anesthesia TR neurons usually fired with bursts of several spikes. LDT stimulation stopped the burst activity and induced tonic discharges. The stopping of bursts was brought about by LDT stimulation weak enough to fail to produce desynchronization of cortical EEG. A little stronger LDT stimulation led to EEG desynchronization with tonic discharges of TR cells. Cooling of the cortex blocked the induction of tonic discharges. Ionophoresed acetylcholine also stopped the burst activity and induced tonic discharges of TR neurons.

On the basis of a recent report that, when the resting potential is relatively hyperpolarized, thalamic neurons, in general, generate a burst of spikes superposed on a low-threshold small Ca spike, which is inactivated by depolarization (Jahnsen and Llinás, J. Physiol. 349:205-226,1984), we interprete the present results to indicate that cholinergic stimulation depolarized TR neurons directly and indirectly through neocortical activation. The interpretation challenges the classical concept that the ascending reticular activating system inhibits TR activity, and the inhibition of TR activity disinhibits LGd relay neurons. The ascending cholinergic input from LDT can directly excite LGd relay neurons and also TR neurons.

69.6 EFFECTS OF NICOTINE ON GLUCOSE UTILIZATION IN THE RAT BRAIN VISUAL SYSTEM: M. Dam*, R. Connolly*, G. Wilkerson* and E.D. London (SPON: L. Sharpe).
Neuropharmacology Lab., NIDA Addiction Res. Ctr., Baltimore, MD 21224.

Several lines of evidence have demonstrated that acetylcholine has a neurotransmitter role in the visual system (Fibiger, H.C., Brain Res. Rev., 4:327, 1982). Furthermore, ligand binding and metabolic studies indicate that at least some effects of acetylcholine and cholinomimetics in the visual system are mediated through nicotinic receptors (Dam, M. and London, E.D., Eur. J. Pharmacol., 87:137, 1983; London, E.D. et al., Neurosci. Lett., 53:179, 1985).

We extended these earlier findings by examining the effects of D,L-nicotine on local cerebral glucose utilization (LCGU), as measured by the 2-deoxy-D-[1-^{14}C]glucose ([^{14}C]DG]) method in rat brain regions which are components of, or are related to the visual system (Sokoloff, L. et al., J. Neurochem., 28:897, 1977).

Sixteen 3 month old male Fischer-344 rats were prepared with indwelling femoral arterial and venous catheters. At 3 to 4 hr after the withdrawal of halothane anethesia and 2 min before the intravenous injection of [^{14}C]DG (125 μ Ci/kg), three groups were injected subcutaneously with different dosages of D,L-nicotine bitartrate (0.05, 0.1 or 0.3 mg/kg, free base) in 0.9% NaCl. Control animals received a subcutaneous injection of saline 2 min before [^{14}C]DG.

Nicotine stimulated LCGU, in a dose related fashion, in several regions which are part of the visual system. The greatest effects were observed in the superficial layers of the superior colliculus, dorsal and ventral portions of the medial terminal nucleus of the accessory optic system (AOS), inferior fasciculus of AOS, and nucleus of the optic tract (NOT). Significant increases in LCGU also were observed in the dorsal and lateral terminal nuclei of AOS, anterior pretectal area, olivary pretectal and postpretectal nuclei, parabigeminal nucleus, brachium of the superior colliculus, and the lateral posterior thalamic nucleus. These results support and further extend the concept of a cholinergic nicotinic component of the rat visual system. Previous reports demonstrated that the pretectal nuclei, nuclei of AOS, superior colliculus, and lateral posterior thalamic nucleus are involved in mediating visual attention, oculomotor control, stability of retinal images, and visual discriminative abilities (Sprangue, J.M., Invest. Opthalmol., 11:473, 1972, Hughes H.C., J. Comp. Neurol., 175:311, 1977; Blanks R.H.I., Exp. Brain Res. 48:228, 1982). The present findings show that, nicotine stimulates these visual areas and may influence visual-motor function.

69.7 SEROTONERGIC INHIBITION OF THE DORSAL LATERAL GENICULATE NUCLEUS BY THE DORSAL RAPHE. G.A.Marks, S.G.Speciale, K.Cobbey*, and H.P.Roffwarg. Department of Psychiatry, University of Texas Health Science Center, Dallas, Texas 75235.

Serotonergic innervation of the Lateral Geniculate Nucleus (LGN) by the Dorsal Raphe Nucleus (DR) has been demonstrated through a variety of techniques in many different laboratories. The microiontophoretic application of serotonin (5HT) to dorsal LGN (dLGN) relay cells has a potent inhibitory action on both spontaneous and evoked activity. Although reports have indicated both inhibition and facilitation with DR stimulation, Yoshida et al (Br.Res.290) demonstrated that methysergide antagonizes the inhibitory effect of DR conditioning stimulation on dLGN. We are investigating this problem by means of local neurotoxin injections. Preliminary data support the findings of Yoshida et al insofar as our data supports the inhibitory nature of the serotonergic DR-dLGN projection.

Long-Evans hooded rats are implanted with bipolar stimulating electrodes in the DR and optic tract (OT). Cannula-guidetube assemblies with recording electrodes are implanted in each dLGN. Animals are allowed at least one week recovery from surgery. Under light chloral hydrate anesthesia single square wave pulses to the OT are utilized to elicit pre- and postsynaptic field potentials (FPs) in the dLGN. Conditioning stimulation (three pulse train,300Hz) is delivered to the DR, utilizing various c-t intervals. Twenty alternating trials with and without DR preconditioning (every 10 seconds) are carried out in each c-t interval. Only animals in which DR conditioning produces significant inhibition in the amplitude of postsynaptic FPs are studied further. Subjects are pretreated with desmethylimipramine (25mg/kg) ip. One hour later, the dLGN is injected via the cannula with either 5'7-dihydroxytryptamine (5'7-DHT), ascorbate (0.1%) in n. saline (0.2 ul, 8ug) or an equimolar solution of creatinine sulfate and vehicle (0.2 ul). Six days later, the animal is retested under identical conditions. Following retest, the animal is sacrificed for routine histology. Additionally, 300u sections are taken through the dLGN. By the micropunch technique, tissue surrounding the recording electrode is removed and both 5HT and 5HIAA content are determined by HPLC-ED.

In every animal in which conditioning stimulation produced an inhibition of the postsynaptic dLGN FPs, the conditioning electrode was found to impinge upon the DR. In all cases in which 5'7-DHT injections depleted the dLGN of 5HT and 5HIAA, a disinhibition was demonstrated at retest, whereas vehicle injections did not affect the amplitude of the inhibited FPs. These data support the interpretation that serotonergic innervation of dLGN by the DR is inhibitory.

69.8 PERIGENICULATE INPUT TO THE CAT'S LATERAL GENICULATE NUCLEUS: A LIGHT AND ELECTRON MICROSCOPIC STUDY OF SINGLE, HRP-FILLED CELLS.

J. B. Cucchiaro, D. J. Uhlrich, J. E. Hamos and S. M. Sherman, Dept. Neurobiology and Behavior, S.U.N.Y., Stony Brook, NY 11794.

Cells of the cat's perigeniculate nucleus (PGN) receive excitatory input from axon collaterals of relay cells in the lateral geniculate nucleus (LGN). PGN cells, in turn, provide inhibitory feedback to these relay cells. In order to describe the morphology of PGN inputs to the LGN, we recorded intracellularly from PGN cells with HRP-filled micropipettes, characterized their response properties, iontophoresed HRP into individual cells to fill their somata, dendrites and axon arbors, and then studied their morphology with the light and electron microscopes.

PGN cells have large, ill-defined, usually binocular receptive fields and they respond to optic chiasm stimulation at latencies of 2.2-4.0 msec. The labelled PGN cells have large somata, widespread dendritic arbors that extend >1 mm parallel to the geniculate laminae, and axons that arborize locally in the PGN and also project ventrally into the geniculate A-laminae. One PGN cell has been studied with the electron microscope. This cell has four main axon branches that converge onto a limited portion of lamina A (roughly 0.5 mm^3), and one of these branches extends into lamina A1. The innervation approximately follows a projection line thereby demonstrating a fair degree of retinotopic fidelity. Within laminae A and A1, the PGN axon is fine and beaded. Ultrastructural analysis of part of the arbor in lamina A shows that the labelled axon is myelinated only in the PGN and loses its myelin sheath near the dorsal border of lamina A. Within lamina A the axon makes en passant synaptic contacts at swellings which are 0.3-1.0 μm in diameter (mean = 0.7 μm). These synaptic contacts are symmetric, showing little or no postsynaptic density. The HRP labelling partially obscures the vesicle shape, but based on the small size of these labelled terminals, their symmetric synaptic contacts, and their synaptic relationships (see below), we conclude that these correspond to the F1 profiles described by Guillery (Z.Zellforsch. 96:1-38,1969). The synaptic contacts studied thus far from the PGN cell are made exclusively in interstitial, non-glomerular zones of lamina A onto small caliber dendrites, 0.5-2.0 μm in diameter (mean = 1.25 μm). These and other observations indicate that the synaptic relationships of these PGN axon terminals in the LGN are distinct from those of geniculate local circuit neurons (Hamos et al., Neurosci.Abstr. 10:57,1984), thereby suggesting the the two types of inhibitory innervation serve different functions in visual processing.

69.9 TERMINAL PATTERNS OF THE BRAINSTEM PROJECTION TO THE LATERAL GENICULATE NUCLEUS IN THE CAT: AN ANTEROGRADE TRACER STUDY USING PHASEOLUS VULGARIS LEUCCOAGLUTININ (PHA-L). D.J. Uhlrich, J.B. Cucchiaro and S.M. Sherman. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

Electrical stimulation of the brainstem disinhibits relay cells in the cat's lateral geniculate nucleus (LGN) and thereby improves synaptic transmission to the visual cortex. This indicates that the brainstem may play an important role in the gating of visual information. We have studied the anatomical substrate for this brainstem control. While retrograde tracer studies have demonstrated direct projections from the brainstem to the general area of the LGN and the adjacent perigeniculate nucleus (PGN), the morphology of the axon terminal fields within these regions has not been described. In order to visualize these terminal arbors, we used the newly developed technique of anterograde transport of the lectin, PHA-L (Gerfen and Sawchenko, Brain Res. 290: 219-238, 1984). We made multiple injections of PHA-L deep in the midbrain, dorsal to the brachium conjunctivum, in a series of cats. The target for these injections was an area that we and others find to be rich in retrogradely labelled cells following tracer injections in the LGN/PGN complex. Following an 8-10 day postoperative survival, we processed the ipsilateral LGN to show the distribution of PHA-L labeling. We observe Golgi-like filling of terminal processes in several thalamic nuclei, including all laminae of the LGN, the pulvinar, and the PGN.

The labeled axons have boutons distributed en passant or appended to the axon by short stalks; these boutons are presumed to be synaptic terminals. Some terminal arbors consist of extremely fine axons with boutons only 0.2-0.6 μm in diameter, while others are considerably larger in caliber with boutons 1.0-2.5 μm in diameter. Because we saved every section of the LGN, we could serially reconstruct individual axons. This revealed wide morphological variation. Some parent axons enter the LGN and form localized (400-700μm wide) terminal arbors restricted primarily within a single lamina. Other axons branch in a more diffuse fashion and freely cross laminar borders to innervate all regions of the LGN. We also observe single axons that innervate localized areas in more than one visual thalamic nucleus, such as both lamina A in the LGN and a restricted region in the pulvinar. This work demonstrates that the brainstem projections to the LGN can be quite specific and may serve to coordinate thalamocortical transmission in different visual thalamic nuclei.

69.10 ULTRASTRUCTURE OF AN X-CELL WITH ATYPICAL DENDRITIC MORPHOLOGY. Susan C. Van Horn*, James E. Hamos, and S. Murray Sherman. Dept. Neurobiology and Behavior, SUNY at Stony Brook, NY 11794.

Although Golgi studies of cells in the A-laminae of the cat's dorsal lateral geniculate nucleus have revealed considerable morphological variability at the light microscopic level, only two physiological classes of neuron, X- and Y-cells, exist there. Recent studies relating structure to function via the technique of intracellular labeling with horseradish peroxidase (HRP) indicate that much of this heterogeneity can be ascribed to the X-cells. In order to determine if this heterogeneity has ultrastructural correlates, we have engaged in a long-term electron microscopic study of HRP-labeled X-cells. We previously described ultrastructural features for more common morphological types of relay X-cell (Wilson et al., Proc. Roy. Soc. Lond. B, 221:411, 1984), and we report here on such features for a less common type.

The HRP-labeled cell under study is an on-center relay X-cell located in lamina A with the majority of its dendrites running perpendicular to the laminar borders. Numerous beaded or varicose dendrites, emanating from a 15-μm-diameter soma, characterize this cell. In addition, a few spine-like appendages extend from proximal dendrites. We used the electron microscope to serially reconstruct portions of the labeled neuron and its inputs. The reconstructions suggest a synaptic circuitry similar to that of the more common types of relay X-cell. The cell's retinal inputs were all found within 100μm of the soma in contrast to the presumed cortical inputs that were located on more distal dendrites. The proximally located dendritic appendages were sites of synaptic triadic arrangements involving retinal and inhibitory inputs. Although it has been suggested that beaded dendrites such as those of the HRP-labeled X-cell are presynaptic to dendrites of other geniculate neurons (Famiglietti, Brain Res. 20:181, 1970), we found no evidence of clusters of synaptic vesicles in the beaded dendrites of our cell. The varicosities instead are prominent foci of synaptic inputs. However, we found fine, HRP-labeled processes that occasionally swell into terminals. These terminals are 1.5-2.5μm in diameter, contain round vesicles, and make asymmetrical synaptic contacts. We believe that the processes are collaterals originating from the labeled neuron's axon, which subsequently becomes myelinated and enters the optic radiation.

The labeled X-cell's synaptic circuitry thus seems to be remarkably similar to that of other relay X-cells but differ from that of local circuit neuron's which also have X-cell physiological properties (Hamos et al., Neurosci. Abstr., 10: 57, 1984).

Supported by USPHS grant EY03604.

69.11 PASSIVE ELECTRICAL PROPERTIES OF X- AND Y- CELLS IN THE CAT'S LATERAL GENICULATE NUCLEUS. Stewart A. Bloomfield, James E. Hamos, and S. Murray Sherman. Department of Neurobiology and Behavior, State University of New York, Stony Brook, NY 11794.

We studied the passive electrical parameters of geniculate X- and Y-cells in the cat by modeling them as equivalent cylinders according to Rall's formulation. Intracellular recordings were made from neurons characterized physiologically in vivo. Voltage responses to constant current pulses were analyzed to determine each cell's input resistance (R_N), membrane time constant (τ_m), and electrotonic length (L_N). Some neurons were also injected with horseradish peroxidase to determine their soma-dendritic membrane surface areas (A_N). For those cells in which we measured both A_N and L_N, estimates were made of their specific membrane resistance (R_m) and capacitance (C_m). The resting membrane potentials (V_m) of the neurons studied ranged from -51 to -74 mV and did not differ significantly for X- and Y-cells (mean for both classes, -60 mV). We found no obvious relationship between V_m and R_N for these cells, and their current-voltage relationships were linear within a range of at least ±20 mV of V_m.

We found statistically significant differences between X- and Y-cells for R_N (X=22.6 MΩ, Y=15.5 MΩ, $p<.001$), τ_m (X=10.4 msec, Y=8.3 msec, $p<.001$), and L_N (X=1.09, Y=0.95, $p<0.05$). The difference in τ_m reflects a larger R_m for X- than for Y-cells (X=3565 Ω-cm^2, Y=2900 Ω-cm^2). Moreover, X-cells also displayed a much greater range in R_m values (2708-4406 Ω-cm^2) than did Y-cells (2442-3362 Ω-cm^2). This suggests intrinsic differences in membrane properties between X- and Y-cells, with more variability among the former neuronal class. Interestingly, X-cells also display greater variability of both soma-dendritic morphology and the patterns of synaptic innervation than do Y-cells. Finally, the derived values of L_N indicate that both X- and Y-cells possess remarkable "electrical" compactness. That is, synaptic potentials arising at the most distal dendritic sites would be attenuated by only about 33% when recorded at the soma in Y-cells and by roughly 40% in X-cells. There is thus no reason to expect a dramatic difference in synaptic efficacy between peripherally located excitatory inputs, arising primarily from visual cortex, and the proximally located excitatory innervation from retina.

Supported by USPHS Grant EY03038.

69.12 QUANTITATIVE ANALYSIS OF RETINAL Y-CELL TERMINATIONS IN THE CAT LATERAL GENICULATE NUCLEUS:A COMPARISON WITH X-CELL TERMINATIONS. M. Esguerra*, P.E. Garraghty and M. Sur (SPON: A. Arnsten). Sect. of Neuroanatomy, Yale School of Medicine, New Haven, CT 06510.

We have analyzed the geniculate terminations of single, physiologically characterized retinal Y-cell axons injected intracellularly with horseradish peroxidase. Terminal bouton numbers, volumes and densities, as well as sublaminar bouton distributions, of 11 Y-cell axons were measured. Statistical intra- and inter-group comparisons involved the Mann-Whitney U test and the Cox-Stuart test for trends.

Contralaterally projecting Y-cell axons, terminating in lamina A and the dorsal C laminae, and ipsilaterally projecting Y-cell axons, terminating in lamina A1, had totals ranging from 434 to 2188 boutons (mean=1207). Within the A-laminae, ipsilateral axons in lamina A1 had more boutons but similar terminal volumes compared to the lamina A terminations of contralateral axons. Both contralaterally and ipsilaterally projecting axons had greater numbers of boutons in the ventral half of lamina A or A1, reflecting a progressive increase in boutons from dorsal to ventral in each of the A-laminae.

ON and OFF center axons did not differ in bouton number or sublaminar bouton distribution within laminae A and A1. Axons with receptive fields central in the visual field tended to have higher bouton numbers and higher bouton densities than those located peripherally. Finally, a comparison of conduction velocities indicated that faster Y-cell axons had more boutons and higher densities than slower axons.

Several features stand out when we compare Y-cell terminations with those of X-cells described previously (Kritzer and Sur, Neurosci. Abst. 10:56, 1984). A positive relationship between conduction velocity and bouton number also exists for X-cells, as well as for the pooled X- and Y-cell data, suggesting that bouton number increases with fiber diameter across both cell classes. X-cells terminate in lamina A or A1 with fewer boutons, smaller terminal volumes, but higher bouton densities than do Y-cells. In contrast to Y-cells, X-cell axons have higher numbers of boutons in the dorsal half of lamina A or A1, suggesting that the retinogeniculate projection biases activity toward X-cells dorsally and Y-cells ventrally within lamina A or A1 (cf. Mitzdorf and Singer, J. Neurophysiol. 40:1227, 1977). Further, bouton densities of X-cells located centrally are lower than those of X-cells located peripherally. Since Y-cell terminations show the opposite trend, the retinogeniculate projection must also partially compensate for the imbalance between X- and Y-cells that occurs with eccentricity in the retina.

69.13 SEGREGATION OF 'ON' AND 'OFF' UNITS IN CAT DORSAL LATERAL GENICULATE NUCLEUS. A. Naporn, N. Berman, and B. R. Payne. Dept of Anatomy, Boston University School of Medicine, Boston, MA, 02118 (A.N. & B.R.P.) and Dept of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA, 19129 (N.B.).

Neurons in the cat's dorsal lateral geniculate nucleus (dLGN) respond optimally to either the brightening (ON) or dimming (OFF) of their receptive field centres. In the multilaminated dLGN of some species such as macaque, tree shrew, mink, and ferret, these neurons are segregated into ON or OFF laminae. In the multilaminated dLGN of the cat, however, the ON and OFF neurons are believed to be intermingled within each lamina. We decided to determine if this is the case or if they are segregated into domains other than in the laminar dimension.

Electrode penetrations were made into laminae A and A1 of the dLGN in anaesthetised adult cats. Using retinotopic maps of the dLGN as a guide (1), recordings were made from sequential units located along projection lines (2). The responses of single units to light or dark stimuli presented to their receptive field centres were recorded extracellularly and response histograms generated.

We reasoned that if ON and OFF units are intermingled then for any given unit the following unit along a track has an equal probability of displaying the same or opposite centre response. This model would yield a ratio of close to 1:1, same:opposite. Contrary to this expectation, we obtained a ratio of 10:1 for those units located along projection lines (n=360). These data show that ON and OFF units are segregated into domains which are organised perpendicular to laminar borders.

69.14 FIELD AND MULTIUNIT ANALYSIS OF THE FLASH-EVOKED RESPONSE IN THE MONKEY LATERAL GENICULATE NUCLEUS (LGN). Charles E. Schroeder*, Craig E. Tenke*, Joseph C. Arezzo and Herbert G. Vaughan, Jr. Depts. of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Previous studies in the monkey striate cortex indicate that: 1) The binocular flash VEP is primarily generated in the principal parvocellular thalamorecipient lamina (4cB), with little contribution from 4cA, the principal target of LGN magnocellular afferents; 2) The field potentials generated in 4cB contain oscillations of a characteristic frequency and duration (160 Hz./approx. 50 ms); 3) Regardless of ocular dominance determined for a particular site, contralateral stimulation elicits earlier cortical activation than ipsilateral stimulation. In order to elucidate the role of the subcortical afferent pathway in this pattern of results, the present study examined the laminar profile of flash-evoked activity in the LGN of the unanesthetized monkey (M. fascicularis).

Field potentials and multiunit activity (MUA) were recorded simultaneously in penetrations through the LGN using a 16 channel multicontact electrode with contact impedances of approximately 300 K ohm and spacings of either 75 or 150 microns. This array permitted recording of activity in parvo- and magnocellular laminae concurrently.

Flash stimuli elicited robust field responses and MUA in magno- and parvocellular laminae, which differed along several dimensions. Parvocellular MUA bursts were less than half the duration and one quarter the amplitude of those in magnocellular regions. The parvocellular field and MUA responses displayed oscillations at 160 Hz and approximately 40 ms duration corresponding to features observed in 4cB. Parvocellular oscillations were twice the frequency of those seen in magnocellular laminae. As in striate cortex, contralaterally driven activity preceded ipsilateral by approximately 2-4 ms. Parvocellular responses were more attenuated by decreased stimulus intensity and interstimulus interval than magnocellular responses. In parvocellular laminae, we also observed clear evidence for interocular inhibition, coincident with excitatory activity in adjacent laminae. In magnocellular laminae MUA responses were substantially less robust to binocular as contrasted to monocular stimulation. This effect was enhanced by decreasing ISI.

These results support our conclusion that the waveform of the cortical VEP to binocular flash predominantly reflects activation of parvocellular terminal zones. The failure of binocular flash to activate the magnocellular thalamorecipient zone may stem from the operation of powerful inhibitory processes evident at the LGN.

69.15 MORPHOLOGY OF TECTAL EFFERENTS TO DIENCEPHALON VISUALIZED WITH THE AID OF ANTEROGRADE TRANSPORT OF PHA-L. S. Jhaveri*, D.P.M. Northmore+ and G.E. Schneider. Dept. of Psychology and the Whitaker College, M.I.T., Cambridge, MA 02139. +Inst. for Neuroscience, Univ. of Delaware, Newark, DE 19716.

Anterograde transport of kidney-bean lectin (PHA-L) results in a complete, Golgi-like filling of axons and their terminal arbors (Gerfen & Sawchenko, Brain Res., 290: 219, 1984). We have used this procedure to study the morphology of diencephalic axon terminations originating from cells in the upper layers of the superior colliculus (SC) of adult hamsters.

Injections of PHA-L were made iontophoretically (positive current, 4 μA for 15 minutes, pulsed) into the SC. After 5-7 days, brains were processed according to the immunohistochemical procedure of Gerfen and Sawchenko. Injection sites were usually restricted to less than 1/4 of the SC and confined in depth to the superficial gray and optic layers with some encroachment into the intermediate gray. Diencephalic efferents were traced to the lateral posterior nucleus (LP) bilaterally and to the ipsilateral dorsal (LGd) and ventral (LGv) nuclei of the lateral geniculate body.

In the LP, fine labelled axons form a dense terminal meshwork. Although varicosities of various sizes are scattered along the axons, the larger ones appear to be organized into terminal clusters. Occasionally some clusters overlie a cell soma (counterstained with neutral red), but usually are found in the neuropil or closely adjacent to a cell soma.

In the LGd, two patterns of termination are observed. Near the optic tract (OT), short axon collaterals immediately ramify to form a pericellular plexus bearing numerous small varicosities. Further medially in the nucleus, axons are smooth and only occasionally exhibit large (up to 4μm) boutons, frequently overlying neuronal perikarya. These axons have a morphology distinctly different from that seen nearer the OT.

In the LGv (external lamina), a complex terminal field is formed, by fine caliber axons studded with numerous boutons of a very uniform morphology (<2μm, spherical). The boutons occur all over the neuropil, not being confined to perikaryal domains. Single axon arbors are elongated, extending about 30μm mediolaterally, and up to 100μm in the dorsoventral axis, and are indicative of a highly topographic projection.

Thus, tectal efferents to various diencephalic nuclei have very different morphological characteristics. Whether these efferents arise from the same or different subsets of collicular neurons remains to be elucidated. (Supported by NIH grants EY05504, EY00126, EY02621, EY02697 and Univ. of Delaware Research Foundation.)

69.16 PROJECTIONS FROM THE SUPERIOR COLLICULUS TO THE PULVINAR NUCLEUS IN THE TREE SHREW. R.G. Carey, G. Luppino*, D. Fitzpatrick and I.T. Diamond. Div. Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013 and Depts. Psychology and Anatomy, Duke University, Durham, NC 27706.

We have reinvestigated the tecto-pulvinar pathway in the tree shrew by studying the pattern of labeled terminals in the pulvinar nucleus following small injections of WGA-HRP into the superficial layers of the superior colliculus. Injections into the superior colliculus produce two distinct patterns of labeled terminals within the pulvinar nucleus. In the portion of the pulvinar nucleus adjacent to the lateral geniculate nucleus, labeled terminals are distributed in bands, the locus of which is dependent on the position of the injection site in the superior colliculus. In contrast, the caudal and medial portions of the pulvinar, both ipsilateral and contralateral to the injection, are filled with labeled terminals regardless of the position of the injection site within the tectum. These findings suggest that there are at least two subdivisions within the pulvinar: one which appears to maintain in a precise way, the retinotopic map of the superior colliculus and one which does not. Further support for the presence of these two subdivisions comes from the pattern of labeled terminals found in the pulvinar following intraocular injections of WGA-HRP; labeled terminals (presumed to be the result of transneuronal transport from the superior colliculus) are found only in the non-topographically organized zone. In addition, the non-topographically organized zone is distinguished from the topographically organized zone by the presence of strong acetylcholinesterase staining. Finally, preliminary results suggest that these subdivisions have different targets within the cortex and thus may be part of two separate parallel tecto-pulvinar pathways to extrastriate cortex.

69.17 STIMULUS SIGNIFICANCE AFFECTS PULVINAR VISUAL AND VISUOMOTOR PROPERTIES. D. Burman and L.A. Benevento. Dept. of Anatomy, Univ. of Illinois at Chicago, P.O. Box 6998, Chicago, IL 60680.

Lateral pulvinar single-unit activity was recorded in awake macaques performing a task that tested if a unit would respond differently to a stationary peripheral stimulus according to its significance for intended eye movements. More specifically, would a unit respond one way to a stimulus that served as a saccadic target, and respond another way to a stimulus that signified a later saccade to a stimulus in the opposite direction? In this task, the animal first fixated upon a 1.5^{o} circle (S-0) which appeared at t=0, where "t" is the time elapsed in seconds following S-0 onset. Fixation was maintained upon S-0 until it changed to a 1.5^{o} square, which served as the cue to saccade to a new location. At t=2, the first peripheral stimulus (S-1) appeared at one of eight possible locations, 3.5-10^{o} peripheral to S-0. S-1 was either a 1.5^{o} circle or square. The significance of S-1's shape was as follows. If S-1 was a circle, the animal was cued (by the change in S-0) at t=4 to saccade to S-1 without hesitation. If S-1 was a square, a second peripheral stimulus (S-2, a 1.5^{o} circle) appeared in the opposite direction at t=4, and the monkey had to maintain fixation until t=6, when the animal was cued by the change in S-0 to saccade to S-2. Thus, if S-1 was a circle, the animal had to saccade to it at t=4, but if S-1 was a square, the animal had to saccade in the opposite direction at t=6. Some units responded strongly to the S-1 circle, but gave little or no response to the S-1 square. Since the size and location of S-1 was identical regardless of whether it was a circle or a square, this difference in response must have been due to the significance of S-1. A strong tonic inhibitory response was seen 2000 ms before the saccade, at the onset of S-1 when it was a circle. When S-1 was a square, the tonic inhibitory response occurred only after S-2 onset (again about 2000 ms before the saccade). In either case, there was a strong phasic excitation following the saccade. After saccading to the new target, the animal had to maintain fixation for 2 more seconds before she was rewarded for 1 second. The tonic inhibitory response was seen to reoccur during the reward period, despite the fact that there was no change in visual stimuli at this time. Although not designed for this, the reward could have effectively been a non-visual cue signalling the end of the trial, at which time the stimulus would go off and her eyes moved at will. Since 1) an inhibitory response was seen 500-2000 ms before as saccade regardless of whether the saccade was indicated by S-1, S-2, or the reward, and 2) a phasic excitatory response was seen following a saccade to a new target, we suggest that these neurons may prepare (with inhibition) for a saccade to a target of interest, and signal completion of the saccade (with excitation). (Supported by BRSG 8309 and Sigma Xi.)

69.18 TWO SUBREGIONS WITHIN THE STRIATE-RECIPIENT AREA OF THE CAT'S LATERAL POSTERIOR COMPLEX. Bruce P. Abramson and Leo M. Chalupa Physiology Graduate Group and Department of Psychology, University of California, Davis, CA 95616.

The lateral posterior (LP) complex of the cat's thalamus is thought to contain two visual areas: the principal tectorecipient zone (LPm) and the striate-recipient area (LPl). Here, we report that one of these areas, LPl, can be further subdivided on the basis of its connectivity pattern and functional organization.

Deposits of WGA-HRP into the superficial layers of the superior colliculus revealed anterograde label, not only in LPm, but also in LPl. However, the tectal projection to LPl appeared restricted to the lateral portion of this area, adjacent to the border with the pulvinar. The cells of origin of this projection were studied following electrophoretic deposits of the tracer into this lateral region of LPl. All labeled neurons in the superior colliculus were localized to the superficial layers, primarily SGS 2 and 3. Such deposits also revealed labeled cells in the reticular nucleus of the thalamus, the hypothalamus, the cerebellum, as well as in several cortical visual areas, including areas 17 and 18. By comparison, deposits of WGA-HRP that were confined to the medial portion of the LPl (that is, adjacent to the principal tectorecipient zone) resulted in labeled cells in visual cortex and in the reticular nucleus. These observations suggest that the striate-recipient zone of the cat's LP nucleus is comprised of two subregions: a lateral region receiving tectal as well as hypothalamic and cerebellar projections, and a medial region which appears devoid of these inputs.

The visual response properties of single neurons in the medial LPl also differ from those in the lateral LPl. Most cells in the medial portion of LPl respond securely to specific visual stimuli, possess relatively small receptive fields, and are commonly selective for stimulus orientation and/or direction of movement. In the lateral region of LPl, fewer neurons can be activated reliably by visual stimuli, receptive fields are very large, and cells rarely exhibit response specificity for orientation or direction. At present, however, it is unclear whether or not these two subregions of LPl contain separate representations of the visual field.

69.19 SUBCORTICAL CONNECTIONS OF SUBDIVISIONS OF VISUAL CORTEX IN TREE SHREWS. M. A. Sesma, L. E. Baker, and J. H. Kaas. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Subcortical connections of four subdivisions of visual cortex of tree shrews were determined by placing small injections of WGA-HRP or ^{3}H-proline into area 17 (2 cases), area 18 (3 cases), and two subdivisions of visual cortex previously defined by cortical connection patterns of area 17 and area 18, the temporal dorsal area (TD) (3 cases) and the occipitoparietal area (OP) (2 cases). All cases were sectioned coronally. TMB and standard autoradiographic methods were used to visualize the tracers. Processed sections or adjacent sections were counterstained for nissl, cytochrome oxidase and/or myelin to determine the architectonic borders of thalamic subdivisions.

The connections of area 17 were similar to those demonstrated in other reports. Area 17 had reciprocal connections with the dorsal lateral geniculate (DGL) and the adjacent pulvinar (PUL). Projections were found to the ventral lateral geniculate nucleus (VGL), the reticular nucleus of the thalamus (R), the superficial layers of the superior colliculus (SC), the pretectum (Pt) and the dorsolateral pons. None of the extrastriate areas had connections with the DGL or VGL. Like area 17, area 18, TD, and OP are also interconnected with the PUL, project to R, the pons and the caudate nucleus. Projections to SC from TD and OP are to layer IV, below the stratum opticum, while area 18 projections were to the lower part of the SGS. Injections in area 18, TD and OP also labeled cells and terminals of the lateral nuclear complex including the ventral lateral (VL) and lateral (L) regions. TD and OP also had reciprocal connections with the interlaminar nuclei, received projections from locus coeruleus and had projections to the Pt. Injections in TD and OP resulted in label in the zona incerta and red nucleus. OP had reciprocal connections with the lateral dorsal nucleus and the mediodorsal nucleus. TD had connections with the subthalamic nucleus and the reticular field of Forel in the hypothalamus. Though all three extrastriate subdivisions had some connections in common, the pattern of subcortical connections was distinct for each area. Area 18 had discrete foci of labeled cells and terminals in PUL, VL, and L and projected to the SGS of SC; TD injections resulted in broader foci of label in the PUL; OP injections labeled the lateral thalamus (VL/L) most densely. Thus, subcortical patterns of connections provide further support for the validity of subdivisions of visual cortex suggested by patterns of cortical connections.

70.1 THE OPTIC NERVE OF THE LEAST SHREW, *Cryptotis parva*. L.C. Towns, O.B. Mock* and R.M. Matushin*. Department of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501.

These studies of the least shrew optic nerve were undertaken because both the shrew's small size (4-6 g) and its phylogenetic placement as a common eutherian progenitor make it a useful animal in which to study fundamental organization of the visual system. The optic nerve is 3.3 mm in length with a mean shortest axis diameter of 70 μm. In twelve optic nerves, electronmicroscopic examinations of sections taken 1-2 mm behind the globe indicate that the nerve contains a mean of 2550 myelinated axons. There are approximately one-third as many unmyelinated axons as myelinated. The shortest axis diameter of myelinated axons (including the myelin) ranges from 0.13 μm to 2.17 μm. The frequency distribution of the shortest axis diameters is unimodal and positively skewed with a mode of 0.76 μm. Preliminary data indicate that mean myelin thickness increases with axon diameter up to axon diameters of approximately 0.64 μm. Axons of larger diameter have relatively constant mean myelin thickness. The unmyelinated axons range from 0.13 μm to 1.91 μm and are unimodally distributed with a mode of 0.38 μm. At the level of the optic nerve sampled, the small size of the optic nerve in the least shrew offers an opportunity to view the entire nerve at relatively high magnification. Additionally, the shrew ages rapidly and exhibits a spontaneous maturity onset diabetes. This animal, thus, also offers a model for studies of age-related and diabetes induced changes in the mammalian optic nerve and retina.

70.2 RETINAL GANGLION CELLS LABELED AFTER INJECTION OF HRP INTO THE GROUND SQUIRREL VENTRAL LATERAL GENICULATE. N. Lugo-Garcia and E. Kicliter. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, PR 00901.

In carnivores and primates functional types of retinal ganglion cells are associated with ganglion cells of particular morphological properties. We have been investigating the possibility that this principle may also be applicable to ground squirrels. As part of our studies we are investigating what morphological types of ganglion cells project to several different retinal projection targets. In the present experiments we have determined the sizes of somata of ganglion cells which project to the ventral lateral geniculate nucleus (LGv).

We made iontophoretic injections of horseradish peroxidase (HRP, Sigma type VI, 10% in 0.01 M NaCl) into either the LGv (N=2) or optic tract (N=3) of thirteen-lined ground squirrels. A pressure injection of HRP (50% in 0.9% saline) was also made in the optic nerve of one animal. After three day survival periods the retinas of these animals were reacted according to the Hanker-Yates method (Histochem. J. 9: 789-792, 1977). Profiles of labeled ganglion cells were drawn with a camera lucida and the equivalent circle diameter of each profile was calculated with a Zeiss ZIDAS image analysis system. Histograms illustrating the relation between cell size and frequency were constructed from 200 randomly selected labeled ganglion cells from each retina.

After LGv injections ganglion cells were labeled in only the contralateral retina. These cells ranged from 6-21 um in diameter with a mean of 13.05 um. Most labeled neurons were in the 14-15 um range. After iontophoretic injections of the optic tract (which should have labeled all ganglion cell types) HRP-containing ganglion cell somata in the contralateral retina ranged in diameter from 3-14 um. Their mean diameter was 5.8 um with the highest frequency of labeled neurons in the 5-8 um range. Thus the iontophoretic injections of the optic tract did not label all sizes of ganglion cells. The pressure injection of the optic nerve labeled ganglion cells ranging from 6-18 um in diameter; again, not all of the ganglion cells (particularly the larger cells) were labeled after injections of the optic nerve.

While the present results are preliminary, it appears that not all sizes of ganglion cells project to LGv and those labeled by LGv injections include cells of larger soma sizes. The cells labeled by LGv injections differ from those labeled by dorsal lateral geniculate injections. Ganglion cells labeled by LGd injections are predominantly 8-12 um in diameter (Kicliter and Lugo-Garcia, Neurosci. Abstr. 10: 460, 1984). The present results provide further evidence that different retinal projection targets receive projections from specific classes of retinal ganglion cells. (Supported, in part, by NIH grant NS-07464.)

70.3 SIZES OF RETINAL GANGLION CELLS WHICH PROJECT TO THE GROUND SQUIRREL SUPERIOR COLLICULUS. E. Kicliter and N. Lugo-Garcia. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, PR 00901.

Three functional types of optic nerve fibers have been described in ground squirrels: 1) contrast-sensitive; 2) opponent color; and 3) directionally selective (Michael, J. Neurophysiol. 31: 249-282, 1968; Gur and Purple, Vision Res. 18: 1-14, 1978; Jacobs and Tootell, J. Neurophysiol. 45: 891-902, 1981). The first two types terminate in the dorsal lateral geniculate nucleus while the directionally selective units project to the superior colliculus (SC, Michael, J. Neurophysiol. 35: 815-832, 1972; 36: 536-550, 1973). We wished to determine the soma sizes of ganglion cells projecting to the ground squirrel SC in order to compare their sizes with those of the entire population of ganglion cells. Thus we could resolve whether directionally selective ganglion cells are associated with a particular soma size.

Horseradish peroxidase (Sigma type VI HRP, 10% in 0.01 M NaCl) was iontophoretically injected into either the optic tract (N=3) or the superficial tectal layers (N=3) of thirteen-lined ground squirrels. After three day survival periods the retinas of these animals were reacted according to the Hanker-Yates method (Histochem. J. 9: 789-792, 1977). Profiles of labeled ganglion cells were drawn with a camera lucida and the equivalent circle diameter of each of these cells was calculated with a Zeiss ZIDAS image analysis system. In each retina 200 randomly selected labeled cells were measured and a histogram was constructed to illustrate the relation between cell size and frequency.

After injections of the optic tract (which should have labeled all ganglion cell types) labeled ganglion cell somata in the contralateral retina ranged in diameter from 3-14 μm. Their mean diameter was 5.87 um and most labeled neurons were in the 5-8 um range. After SC injections (which only labeled cells in the contralateral retina) cells containing HRP also ranged in diameter from 3-14 um. However, after SC injections the mean diameter of labeled neurons was 7.35 um and most cells were in the 6-9 um range.

These experiments indicate that a wide range of ganglion cells (by soma size) project to the SC. Thus the directionally selective functional ganglion cell type may be associated with a variety of morphological types.

(Supported, in part, by NIH Grant NS-07464.)

70.4 SOMA SIZE DIFFERENCES BETWEEN TWO PHYSIOLOGICALLY DISTINCT CLASSES OF W-CELLS IN THE CAT'S RETINA. L. R. Stanford. Dept. Struct. Func. Sci. and the Waisman Center for Mental Retardation and Human Development, Univ. of Wisconsin-Madison, Madison, WI 53705.

Retinal ganglion cells in the cat were recorded transclerally and physiologically classified using a battery of response measures. These measures included linearity of spatial and temporal summation, latency to antidromic stimulation of the optic chiasm and optic tract, sustained or transient center response, presence or absence of center/surround organization, and briskness of response to stimulation of the receptive field center. Following physiological classification, the ganglion cells were impaled, retested, and iontophoretically injected with HRP. Thirteen retinal W-cells have thus far been recovered that have dendritic arbors consistent with the gamma cell classification. Physiologically, this sample includes linear and non-linear response types, ON, OFF, and ON/OFF center cells, and phasic and tonic W-cells. Included here are only those neurons that were distinguished as W-cells on the basis of their sluggish responses to stimulation of their receptive field center and/or their long latencies to stimulation of the optic chiasm. Morphologically, all of these W-cells were classified as gamma cells on the basis of their large, sparse dendritic arbors, a feature that readily distinguishes these ganglion cells from retinal alpha cells and beta cells. This sample of gamma cells, however, can be divided into two distinct subpopulations on the basis of soma size. One subpopulation (10 cells) has an average soma size area of 163.9μm^2 (range 112.6μm^2 - 226.7μm^2). The second subpopulation (3 cells) has an average soma size of 387.7μm^2 (range 312μm^2 - 440.5μm^2). No overlap in the soma size distributions has been seen between these two morphological classes at any retinal eccentricity. The two classes can also be distinguished physiologically. Every neuron with a small soma responded phasically to stimulation of its receptive field center while every gamma cell with a larger soma had a tonic response. The tonic W-cells had soma sizes that were in the same size range as cells that have beta morphologies and have been identified as X-cells in these experiments. This group of W-cells probably corresponds to the cat retinal ganglion cells with dendritic morphology typical of a gamma cell, but with beta cell-sized somata, described by Stone and Clark (J. Comp. Neurol. 192:211, 1980). Although it is not possible, from these data, to estimate the relative number of W-cells that have medium-sized somata, it is obvious that they may constitute a significant fraction of the W-cells in the cat. These data emphasize that soma size is not a reliable morphological criterion for distinguishing W-cells from X-cells in the cat retina.

Supported by USPHS Grant EY04977.

70.5 TEMPORAL FLOW OF VISUAL INFORMATION FROM GANGLION THROUCH GENICULATE CELLS. S. Lehmkuhle, A.K. Sestokas, and K.E. Kratz. Dept. of Psychology, Brown Univ., Providence, RI 02912 and Dept. of Anatomy, Louisiana State Univ. Medical School, New Orleans, LA 70112.

We recorded extracellular potentials from retinal ganglion cells (RG) in the optic tract and from dorsal lateral geniculate nucleus cells (LGN) in the A laminae of anesthetized, paralyzed cats. Cells were classified as X or Y by conduction latency to optic chiasm stimulation and linearity of spatial summation. Instantaneous discharge frequency (IF) profiles were analyzed on a trial-by-trial basis to measure response latency and amplitude to 100 msec presentations of sinewave gratings that varied in spatial frequency and contrast. Three measures of response latency were calculated: onset latency, peak latency, and response rise time. Onset latency was defined on each trial as the time at which the IF exceeded the baseline firing rate by 2 standard deviations; peak latency was the time at which the IF reached its peak value on each trial; and rise time was the difference between onset and peak latencies.

The onset latencies for RG Y-cells were about 10 msec shorter than RG X-cells at low spatial frequencies ($\leq$.25 c/deg) but about 10 msec longer at higher spatial frequencies ($\geq$.75 c/deg). Peak latencies of RG Y-cells, however, were similar to RG X-cells for all spatial frequencies and contrasts studied. The rise times of RG Y-cells were longer primarily due to the high IF's elicited from RG Y-cells. The longer rise times of RG Y-cells can explain the similarity between peak latencies of RG X- and Y-cells even though their onset latencies are different.

At lower spatial frequencies, the onset latencies of LGN Y-cells were about 10 msec shorter and the peak latencies of LGN Y-cells were about 20 msec shorter than LGN X-cells. The rise times of LGN Y-cells were shorter than LGN X-cells. The faster rise times of LGN Y-cells occurred despite the higher IF's elicited from LGN Y-cells.

The onset latencies of LGN cells were nearly 20 msec longer than their RG counterparts although the conduction latencies to optic chiasm stimulation were only 1 msec longer. Surprisingly, the peak latencies of LGN Y-cells were nearly identical to RG Y-cells because of the fast rise times of LGN Y-cells. The peak latencies of LGN X-cells remained 10 msec longer than RG X-cells.

These measures of temporal flow of visual information from RG through LGN cells suggest that the transient responses of LGN Y-cells speeds up processing of lower spatial frequencies.

(Supported by PHS grant EY03524-04).

70.6 RESPONSE AMPLITUDE AND VARIABILITY OF GANGLION AND LGN X- AND Y-CELLS IN THE CAT. A.K. Sestokas, S. Lehmkuhle and K.E. Kratz, Dept. of Psychology, Brown Univ., Providence, RI 02912, and Dept. of Anatomy, Louisiana St. Univ. Med. School, New Orleans, LA 70112

We recorded the responses of retinal ganglion (RG) and lateral geniculate nucleus (LGN) neurons to identical visual stimuli in order to compare response amplitudes and variabilities in these closely related structures. X- and Y-cells were tested in anaesthetized, paralyzed cats with repeated, 100-msec presentations of sinewave grating stimuli at spatial frequencies between .17 and 2.0 c/deg, and contrasts between 5% and 40%. Each stimulus was pulsed 24 times at a rate of 1 pulse/sec. Mean discharge rate and peak discharge rate were measured in the 200 msec period that followed stimulus onset in each trial.

In general, Y-cells responded most vigorously at low spatial frequencies and least at high spatial frequencies. X-cells responded most vigorously at intermediate spatial frequencies and less at high and low spatial frequencies. Both X- and Y-cells had larger responses to high contrast gratings than to low. Under optimal stimulus conditions the responses of Y-cells were larger than those of X-cells. RG X- and Y-cells had higher mean discharge rates than LGN X- and Y-cells, respectively, tested under similar stimulus conditions. This may be due in part to the higher spontaneous discharge rates of RG cells. However, the results for peak discharge rates did not follow the same pattern. Peak discharges of LGN X-cells were similar to those of RG X-cells. Peak discharges of LGN Y-cells were slightly smaller than those of RG Y-cells for optimal stimuli, and slightly larger for non-optimal stimuli.

Absolute response variability, measured by response standard deviation across repeated trials, tended to increase with increases in mean response amplitude for both RG and LGN neurons. However, relative response variability, measured by coefficients of variation (standard deviation/mean response across trials), decreased with increases in response amplitude, which suggests that relative noise levels in the neural signals may decrease with increasing signal strength. Coefficients of variation were generally larger for peak discharge rate than for mean discharge rate, indicating that the latter is a more reliable measure of response amplitude. Coefficients of variation were significantly larger for LGN cells than RG cells in all stimulus conditions. The larger relative variability of LGN cells may be a direct consequence of their lower discharge rates.

(Supported by NIH grant EY03524-04)

70.7 SELECTIVE DEGENERATION OF P-BETA RETINAL GANGLION CELLS IN THE MACAQUE. T. A. Eskin* and W. H. Merigan (SPON: T. Pasternak). Univ. of Rochester Med. Ctr., Rochester, NY 14642.

Chronic acrylamide intoxication in the macaque induces retinal ganglion cell degeneration which the following evidence indicates is confined to the medium-sized (P-beta) cells. Such cells subserve high visual acuity and color opponency in the macaque. Intravitreal horseradish peroxidase injection demonstrates markedly reduced anterograde axonal transport to parvocellular layers of the lateral geniculate nucleus, (which receives P-beta cell input), but normal transport to magnocellular layers, (which receives P-alpha cell input). Cytochrome oxidase histochemistry in the lateral geniculate nucleus shows little activity in parvocellular but normal activity in magnocellular layers. Selective reduction of the cytochrome oxidase staining in parvocellular layers suggests that the parvocellular neurons have undergone deafferentation and transsynaptic atrophy.

Cytochrome oxidase histochemistry in striate cortex in these animals reveals virtually no cytochrome oxidase activity in layer 4A and greatly reduced activity in the lower two-thirds of layer 4C-beta. These layers receive direct input from parvocellular layers of the lateral geniculate nucleus. In contrast, cytochrome oxidase activity appears normal in layer 4C-alpha (which receives input from magnocellular layers of the lateral geniculate nucleus) and the upper third of layer 4C-beta. Many neuronal perikarya are still present in the affected layers. Of particular interest is the preservation of cytochrome oxidase "blobs" or "puffs" in layers 2 and 3, which have been reported to be involved in the color opponent visual pathway.

Supported by NIH grants ESO 1885 and ESO 1247.

70.8 HISTOCHEMICAL LOCALIZATION OF CYTOCHROME OXIDASE IN THE NORMAL AND DENERVATED GOLDFISH OPTIC TECTUM: A COMBINED GOLGI-CYTOCHROME OXIDASE STUDY. G.H. Kageyama* and R.L. Meyer , Dev. Biol. Center, University of California, Irvine, CA 92717.

The histochemical localization of cytochrome oxidase (C.O.) was examined in the optic tectum and retina of normal and monocularly enucleated (or optic nerve crushed) goldfish. In the optic tectum several distinct C.O.-reactive bands were observed. The most intense staining was localized within two narrow (10-16 μm) darkly reactive bands at the top and bottom of the stratum fibrosum et griseum superficialis (SFGS). Monocular enucleation or optic nerve crush resulted in a notable decrease in the overall staining intensity of the contralateral SFGS. Normally the deeper of the two SFGS sublaminae contained a plexus of intensely reactive large diameter (2-3 μm) puncta (presumed axon terminals). These terminals disappeared following either enucleation or nerve crush, indicating that they were of retinal origin. A class of large, darkly reactive retinal ganglion cell was observed in the retina. Based on a correspondence in relative size, C.O.-reactivity and response to enucleation or nerve crush it is likely that the large reactive puncta in the deep SFGS represent the terminal arborizations of the large darkly reactive ganglion cells. Stratum superficialis (SS) was darkly stained, while stratum opticum (SO) was only lightly stained. The C.O. reaction product within stratum marginalis (SM) appeared to be localized predominantly within the dendrites of type I cells, based on their oblique, rather than horizontal orientation. The C.O. staining within stratum griseum centrale (SGC) and stratum album centralis (SAC) consisted of four to six moderately reactive bands. These bands often appeared to be more distinctly segregated within the dorsomedial tectum than in the lateroventral tectum. The perikarya in stratum periventriculare (SPV) were predominantly moderately to lightly reactive. Neurons with darkly reactive perikarya were sparsely distributed throughout the different layers of the tectum. In combined Golgi-C.O. stained sections, Golgi impregnated neurons had dendrites that arborized preferentially within the C.O.-rich bands of the SS, SGC, and SAC as well as the SFGS. These observations suggest the presence of a laminar and sublaminar histochemical organization in the goldfish optic tectum that correlates with the stratified distribution of tectal neuron dendrites and presumed sites of synaptic input. The presence of two C.O.-reactive laminae and a specific class of large diameter C.O.-reactive retinal axon terminals in the deeper portion of the SFGS suggests that there is functional segregation of retinal input to distinct sublaminae within this layer.

This work was supported by NIH Grant No. 15381 and a Monsanto Postdoctoral Training Fund.

70.9 FURTHER EVIDENCE INDICATING THE EXISTENCE OF VARIOUS POPULATIONS OF PEPTIDE-CONTAINING RETINAL GANGLION CELLS IN RANA PIPIENS. Rodrigo O. Kuljis and Harvey J. Karten. Departments of Neurology, Psychiatry and Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, New York, 11794, U.S.A.

Previous studies have indicated that various populations of putative peptidergic retinal ganglion cells (RGCs) terminate at different depths of the frog's retino-recipient tectal neuropil (RRTN). To date, the evidence was based on the visualization of peptide-like immunoreactivity (PLI) in the RRTN (Kuljis & Karten, JCN '82), the modifications of the latter PLI after retinal deafferentation (Kuljis & Karten, JCN '83), the visualization of PLI in optic nerve axons under conditions of axoplasmic flow blockade (Kuljis et al., JCN '84), and the observation of PLI in regenerating retinofugal axons (Kuljis & Karten, JCN '85). All of these observations relied on the visualization of PLI in portions of the protoplasm of the RGCs other than the soma, and more importantly, often under conditions allowing the possibility of expression of new peptide phenotypes in response to trauma from the experimental manipulations. The present study eliminates these difficulties, by directly demonstrating PLI in RGC somata, and avoiding the need for experimental traumatic manipulations.

Fifteen Rana pipiens tadpole eyes, optic nerves and brains were processed for substance P (SP) and leucine enkephalin (LENK) PLI by the fluorescent, peroxidase-antiperoxidase and avidin-biotin methods. Stages analyzed span from stage 25 of Shumway ('40) to stage XXV of Taylor and Kollros ('46). Some of the specimens were generously provided by Dr. M. Constantine-Paton.

Between stages 25 of Shumway to V of Taylor and Kollros, first the RGCs somata and then the optic nerve exhibit SP and LENK PLI. Subsequently, the RGCs and optic nerve gradually loose PLI, progressively resembling adult animals in which PLI is normally not demonstrable at this level by our methods (Kuljis, et al., '84). By stage VII-XII of Taylor and Kollros the basic pattern of PLI has been established in the RRTN, and subsequently continues to approach that of the adult. Experiments are still in progress to establish further details on the sequence of events.

These results provide the first direct evidence of PLI in the somata of RGCs, inferred in all previous experiments. Thus, our observations support the previous contention that different populations of RGCs contain different transmitters/modulators, and end at different depths of the RRTN, presumably subserving different functional roles in the processing of visual information. Supported by EY 04796 to HJK.

70.10 FUNCTIONAL AND MORPHOLOGICAL CORRELATION OF FROG RETINA GANGLION CELLS : U. Grüsser-Cornehls* and G. Kahle* : (SPON : European Neuroscience Association), Department of Physiology, Freie Universität Berlin, Arnimallee 22, D - 1000 Berlin 33 (Germany)

The categorization of frog (Rana esculenta) retina ganglion cells recorded intracellularly into classes 0 to 5 on the basis of their neurophysiological properties (Grüsser,O.-J. and Grüsser-Cornehls,U., Frog Neurobiology, R. Llinas and W. Precht, eds., 297, Springer-Verlag Berlin 1976) was followed by iontophoretic staining with Lucifer yellow. In this way a correlation could be made for the first time between some morphological and electrophysiological ganglion cell types in the frog's retina. A close affiliation between rapid Golgi stained cells and those with the Lucifer yellow (flat-mount) method was discovered.

By incompletely stained neurons, only the soma size was defined for each neurophysiological cell class. As a correlation between soma size and diameter of the dendritic tree has been determined through extensive morphometric studies (Kalinina, A.V., Vision Res. 14:1305, 1974), the latter was calculated for our neuron sample and subsequently the presumable diameter of the respective receptive field. A good correlation was established between field sizes determined morphometrically and those electrophysiologically. With some reservation one can say that in the frog retina the extension of the dendritic branches of a ganglion cell probably determines the diameter of the excitatory receptive field of that neuron.

Electrophysiologically determined retinal ganglion cell class	mean Soma-diameter (μ)	Diameter of dendritic tree (μ)	Calculated ERF (40 μ in dia on the retina ≈1° of visual field) ***	Electrophysiologically determined ERF ****
0	8	200 – 250	5° – 6.25°	4° – 15°

70.11 Quantitative Relationships between Morphology and Receptive Field Characteristics of Frog "Off" Centre Ganglion Cells Stained with Horseradish Peroxidase (HRP). R. V. Stirling* and E. G. Merrill* (SPON: S. Judge). NIMR, Mill Hill, London NW7 1AA and University Laboratory of Physiology, Oxford OX1 3PT, U. K.

We have recorded intracellularly from the axons of frog retinal ganglion cells in the optic nerve, characterized their receptive fields (RFs) and then injected them with HRP. Both the cell in the retina and the central projections were subsequently stained with a modification of the cobalt/nickel intensification of the diaminobenzidine method (Adams, J. C., J. Histochem. Cytochem.., 29: 775, 1981). Stained axons in the optic nerve were examined with electron microscopy. RFs were tested with dark and light spots, annuli and square wave reversal gratings. Although most of the ganglion cell classes previously recognized (Maturana, Lettvin, McCulloch & Pitts, J. Gen. Physiol., 43:129-175, 1960) have been filled, we discuss here only our results for the "off" centre ("dimming detector") cell class.

The typical dimming detector RF center size was about 15°, with a range of less than 8° to more than 35°. A third of these cells had isolated excitatory "on" regions in their surrounds (Keating, M. J. & Gaze, R. M., Q. J. Exp. Physiol., 55: 129-142, 1970), about half had inhibitory surrounds, and about a third were non-linear (ie. they responded with frequency doubling at all positions of reversal gratings in their RF centers) (Gordon, J. & Shapley, R. M., Visual Psychophysics and Physiology, ed. Krauskopf, J. & Wooten, B. R., New York: Academic Press, 1978).

In spite of this heterogeneity, dimming detectors all had: (a) a large ganglion cell (mean diameter, 21.9 um.), with a large dendritic arbor (400-1000 um. diameter) confined to a single stratum in the outer third of the inner plexiform layer, (b) a medium-sized myelinated axon (2.4 um., mean diameter), (c) a small contralateral pretectal arbor, and (d) a contralateral tectal arbor near layer 8. Cells with "on" regions in their surrounds had compact tectal arbors (120-150 um.) above layer 8; the others had large (300-550 um.) terminal zones in and below layer 8.

In this presentation we will examine the relationships between RF size, dendritic spread and tectal arbor size for these cells. We will also describe their RF center properties and surround features quantitively.

70.12 OPTIC AXONS IN THE DIENCHEPHALON OF CHANNEL CATFISH. RETINAL ORIGINS AND DISTRIBUTION PATTERNS. S.M. Fraley and S.C. Sharma. Dept. of Ophthalmology, NY Medical College, Valhalla, NY 10595.

The retina of many siluroid fishes possesses multiple optic papillae, each containing axons from a restricted portion of the retina. In channel catfish, papillar axons are topographically ordered in the optic nerve (Dunn-Meynell, A. and Sharma, S.C., Soc. Neurosci., 10:466, 1984) and the diencephalon of these fish receives optic axon innervation (Rao, P.D. and Sharma, S.C., J. Comp. Neurol., 210:37, 1982). Since several nuclei in the diencephalon of goldfish were observed to contain ordered maps of the retina (Fraley, S.M. and Sharma, S.C., Cell Tiss. Res., 238:529, 1984), and we were interested in determining whether corresponding diencephalic maps existed in channel catfish. We therefore investigated retinal topography in the diencephalon of pigmented Ictalurus (Ameiurus) punctatus by applying the horseradish peroxidase (HRP) to isolated optic papillae. Wholemounts of the retina and sections of the brain were reacted with chromagen to visualize HRP-labeled ganglion cells and axons.

The optic tracts of catfish consist of numerous medial fascicles formed by dorsal retinal axons traveling deep in the diencephalon and of a lateral optic tract formed by ventral and dorsal retinal axons traveling along the outer margin of the diencephalon. The nucleus of the dorsolateral thalamus (NDL) is served by the dorsomedial fascicle of the optic tract and this fascicle is formed by axons departing from the medial fascicles and lateral optic tract. The axons are topographically arranged in the NDL such that dorsal retinal axons project to its ventral aspect and ventral retinal axons project to its dorsal aspect. Axons from both dorsal and ventral retina also project to other diencephalic nuclei, including lateral geniculate and pretectum. The suprachiasmatic nucleus (SCN) receives projections primarily from dorsal retina. These axons project densely along the caudal aspects of SCN whereas ventral retinal axons project only sparsely at its rostral pole. The retinal maps in the SCN of catfish and goldfish do not correspond because, in the latter species, the nucleus is innervated primarily by axons from ventral retina. However, the retinal maps correspond closely in other nuclei, including NDL. There are also between-species similarities with respect to the pathways by which retinal axons reach diencephalic targets. We have determined that the medial fascicle in goldfish diencephalon, the fasciculus medialis tractus opticus, is composed of dorsal retinal axons from the center (oldest) retina. The multiple medial fascicles of catfish are also composed of dorsal retinal axons, and we are presently studying whether the alignment of these fascicles in the diencephalon represents an age-related ordering.

70.13 HUMAN RETINO-HYPOTHALAMIC PATHWAYS. Betty M. Johnson and Alfredo A. Sadun, Dept. of Ophthalmology, USC School of Medicine, Los Angeles, CA 90033.

Retinofugal projections to certain hypothalamic nuclei have been suggested in the cat, rat and monkey (R.Y. Moore, Brain Res., 1973). Until recently, a reliable method for tracing retinofugal pathways in man has not existed. However, the paraphenylene-diamine staining technique (PPD) permits tracing of degenerated axons in the human visual system, even after extensive survival periods (Sadun et al, J. Neuropath. Exp. Neurol., 1983).

The PPD method was applied to brain specimens from five human cases in which there have been documented unilateral damage to the optic nerve. Degenerated axons, found only in the optic nerve ipsilateral to the lesion, were traced to the optic chiasm. At the level of the optic chiasm, one column of degenerated axons were noted to ascend dorsally and terminate in the suprachiasmic nucleus (SCN) of the hypothalamus. A second column of degenerated axons seemed to proceed more posteriorly and laterally and these were seen to terminate in both the anterior and posterior lobes of the supraoptic nucleus (SON) of the hypothalamus. A third column of degenerated profiles were seen to ascend dorsally alongside the third ventricle. These degenerated axons appeared to terminate in the rostral and medial portions of the paraventricular nucleus (PVN) of the hypothalamus.

The SCN, SON, and PVN of the hypothalamus contribute fiber bundles which course through the infundibulum to the posterior lobe of the hypophysis. In addition, several pathways from these nuclei are thought to project to brain stem and spinal cord nuclei. Oxytocin and vasopressin are among the neurotransmitters known to be synthesized by these nuclei. The SCN and PVN have been implicated in the control of circadian rhythms in several mammals. The demonstration of a visual input to these hypothalamic nuclei in humans suggest that this may be a means by which visual information entrains the diurnal cycle in man. In fact, disruption of water, carbohydrate, and insulin balance has been described in the blinded (Hollwich, Ann. N.Y. Acad. Sci., 1964). Thus, these three hypothalamic nuclei shown to receive a direct retinofugal input, may play an integral role in the diurnal regulation of certain autonomic functions in man.

RETINA I

71.1 THE TRANSITION TEMPERATURE IN ARRHENIUS PLOTS OF ATP-DEPENDENT CALCIUM ION UPTAKE IN RAT RETINA IS INCREASED BY TAURINE. J.B. Lombardini, Depts. of Pharmacology and Ophthalmology & Visual Sciences, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

The rat retina contains high concentrations of taurine (50 mM). However, there is little information as to the role for taurine in the retina at a physiologic level and the mechanism of action at a molecular level. Taurine appears to be participating in at least two different functions: 1) as a modifier of calcium fluxes, and 2) as a membrane stabilizer. Here we show that taurine raised in a dose dependent fashion the transition temperature of the discontinuity observed for ATP-dependent calcium ion uptake in rat retinal membrane preparations. (Calcium ion concentration was 10 μM.) In the absence of taurine the transition temperature was 17.9 ± 4.9°C while the addition of 20 mM taurine to the incubation system increased the transition temperature to 25.4 ± 0.8°C. The apparent activation energies obtained from the Arrhenius plots were 5.96 ± 0.76 and 3.41 ± 0.68 kcal/mole for above the transition temperatures in the ATP dependent and taurine-stimulated ATP dependent calcium ion uptake systems ($P < 0.05$). No significant differences were observed for the activation energies below the transition temperatures when taurine was added to the system (22.5 ± 3.6 vs. 16.2 ± 1.2 kcal/mol). Arrhenius plots of the maximum velocities for calcium ion uptake over a range of calcium ion concentrations (5 - 300 μM) also demonstrated a taurine effect. The transition temperatures for the ATP-dependent calcium ion uptake was 13.5°C while a value of 25.5°C was observed in the presence of taurine (20 mM). These data suggest that taurine is inducing a conformational change in the transport proteins associated with calcium ion uptake. (Supported by NIH grant EY04780).

71.2 PIGMENT EPITHELIAL INVOLVEMENT IN LOW INTENSITY CYCLIC LIGHT TOXICITY. S.L. Semple-Rowland* and W.W. Dawson, Departments of Ophthalmology and Neuroscience, University of Florida, Gainesville, FL 32610

The results of many studies on light damage suggest that the primary site of retinal damage is the photoreceptor outer segment and that light damage is a rhodopsin-mediated phenomenon. In the present study we have investigated the morphological and physiological effects of long term exposure to 20, 10, and 5 FtL cyclic light (12:12 L:D) on the retinas of albino rats raised from birth under 0.5 FtL cyclic light. Animals were exposed to these intensities for various durations of time (1-83 days) beginning at 15-17 weeks of age. We found that 20 FtL light causes severe retinal damage in these animals, and that 10 and 5 FtL light levels appear to approach threshold for producing irreversible damage. The primary morphological change in the damaged retinas was a rapid and significant loss of photoreceptor nuclei accompanied by a loss of the outer segment layer. Changes in the electroretinogram (ERG) included a decrease in the amplitude of the b-wave and an increase in its peak-latency relative to the 0.5 FtL controls. Examination of the d.c. ERGs from our animals reared under 0.5 FtL cyclic light showed that the c-wave, a prominent signal of pigment epithelial (PE) origin, was absent or greatly attenuated. This finding was especially interesting since the retina and PE histology appeared normal in these animals. To investigate the effects of cyclic light on PE function, we recorded the c-wave and changes in the d.c. potential in response to a low dose bolus of intravenous sodium azide in our control animals and in animals raised in constant darkness. Sodium azide was used as a second measure of the integrity of the PE. The azide induced potential is specific, direct and independent of a stimulus light. This potential arises from interference with ionic exchange processes across the PE cells' membrane (Noell, W.K., Air Univ. Sch. of Aviation Med., Proj. #21-1201-0004, Report 1, 1953). In this experiment, the c-waves were recorded under two light adaptation conditions followed by azide (40mM, 0.1 cc/kg) injection through a chronically implanted jugular catheter. The amplitudes of the c-waves and the azide responses from the animals raised under 0.5 FtL cyclic light were significantly smaller ($p<.05$) than those recorded from animals raised in constant darkness. From these results, we conclude that very low levels of cyclic light may disrupt the electrical properties of the pigment epithelium of the albino rat in the absence of histopathology (LM) of the retina or PE. These results suggest that the toxic effect of light on the PE may be primary and that visual cells may become secondarily involved due to (a) abnormal PE function , or (b) a synergy of PE and photoreceptor, functional unit, toxic responses. Supported by a grant from Sigma Xi and NIH grant R24 RR01635.

71.3 ROD SELECTIVE DEFICIT PRODUCED BY DEVELOPMENTAL LEAD EXPOSURE: REGIONAL RETINAL DIFFERENCES. D.A. Fox and L.W.-F. Chu*. College of Optometry, University of Houston, Houston, TX 77004.

Our previous ERG and cyclic nucleotide metabolism studies have established that low-level developmental lead exposure (0-21 days postnatal;0.2% lead acetate to dam) produces a longterm rod selective deficit in Long-Evans hooded rats (Neurosci. Abs. 9: 89, 1983; IOVS Suppl. 25: 287, 1984). To determine the morphological correlates of this rod-mediated deficit we quantified the no. of rod and cone photoreceptor cells (nuclei) in the posterior or central (POST) and peripheral (PERI) quadrants of the temporal retina of 90 day old control and developmentallylead-exposed rats (n=6-12 retinas/group). Nuclei were identified by light microscopy on the basis of nuclear heterochromatin pattern and staining (LaVail, IOVS 15: 64, 1976). We also measured the length of rod outer segments (ROS) and the thickness of the outer and inner nuclear layers (ONL and INL), inner plexiform layer (IPL), pigment epithelium (RPE) and total neural retina (TNR) in superior (S) and inferior (I) retina. Utilizing EM, ultrastructural alterations produced by lead were examined. In controls, the no. of rod and cone nuclei/100μm of POST retina is 140 and 2.6, respectively, while in PERI retina it is 81 and 1.5, respectively. In controls no differences in the no. of nuclei are observed between S and I retinal quadrants. In contrast, in the lead rats the no. of rod nuclei are decreased 17% and 28% in the POST S and I retina, respectively, and 13% and 22% in the PERI S and I retina, respectively. No change in the no. of cone nuclei is observed in leaded rats. In controls the ROS in S retina are 20-25% longer than in I retina (30 vs 24μm), as previously reported (Battelle and LaVail, 1978). In lead rats there is a 9% and 12% decrease in ROS length in S and I retina, respectively. Similarly there is a 14-16% and 22-29% decrease in thickness of ONL, INL, IPL and TNR in S and I retina, respectively. No between group differences in RPE thickness are observed. Thus the effects of lead are greater in (1) POST than PERI and (2) I than S retina. The two most prominent ultrastructural alterations are random patches of swollen and necrotic ROS (especially in proximal one-half) and the presence of numerous glycogen granules within the mitochondria of rod inner segments. There is also morphological evidence of an increased permeability of the blood-retinal barrier. These quantitative histological results confirm our ERG and cyclic nucleotide studies demonstrating that developmental lead exposure produces a longterm rod selective deficit. They also extend these findings by showing regional differences in photoreceptor and inner retinal degeneration and produce evidence of some general retinal damage---glycogen and blood-borne macrophages. It remains to be established that these findings have relevance to human pediatric lead exposure or retinal degenerations such as retinitis pigmentosa.

Supported by NIH Grant ES 03183 to DAF.

71.4 **TELODENDRITE NETWORK OF HRP INJECTED CONES: ANATOMICAL AND FUNCTIONAL PROPERTIES IN THE WALLEYE RETINA.** Timothy W. Kraft[1], and Dwight A. Burkhardt[2]. Departments of Physiology[1] and Psychology[2], Univ. of Minnesota, Minneapolis, MN 55455.

Intracellular recordings from walleye cones were obtained using an isolated, superfused retina-pigment epithelium cell preparation, and triangular glass pipets filled with 10% HRP, 5% Lucifer Yellow in 0.5M LiCl (170-250MΩ). Iontophoretic injection of HRP into physiologically identified cones resulted in cells filled with a dense reaction product. Twenty-five of 46 injected cells were recovered; 16 cones showed several basal processes, or telodendrites projecting radially from the cone pedicle. Serial sections through the pedicle region (0.7-1.2μm) were photographed with phase contrast to reconstruct the telodendrite pattern and neighboring unstained pedicles.

Three to five fine telodendrites (0.3-1.0μm dia.) extend laterally into the outer plexiform layer for distances up to 35μm. En passant and terminal swellings were frequently noted. The diameter and length of the telodendrites increased as the diameter of the inner segment increased. Therefore each cone was able to make direct contacts only with neighbors within a distance of 2-3 cone diameters. Over 65% of the telodendrites were seen to end in close apposition with neighboring pedicles. Previous works suggest that electrical coupling may occur between walleye cones via gap junctions between telodendrites and neighboring pedicles.

Compartment models of individual and electrically coupled cones were used to measure the attenuation of signals passively spreading within and between photoreceptors via gap juntions. Results suggest that the signal generated in the photoreceptor inner segment spreads with little loss to the distal tips of the telodendrites. However, because of the cell geometry, membrane potential changes introduced in the telodendrites are attenuated considerably in the pedicle, and dramatically by the time they reach the inner segment.

Modeling electrical synapses as 2500MΩ junctions accurately predicts summation in the near surround which has been measured physiologically. However, this type of a network of interconnections should only produce weak spectral interactions.

71.5 RECEPTOR ORGANIZATION IN THE GRAY SQUIRREL RETINA. H.M. Petry, Dept. of Psychology, SUNY at Stony Brook, NY 11794.

The eastern gray squirrel (Sciurus carolinensis) is a diurnal mammal with a cone-dominated retina. Its photoreceptors are organized into two tiers: an inner, more vitreal tier and an outer, more scleral tier. Because the receptors appear uniformly cone-like when viewed under the light microscope, the gray squirrel retina was long thought to be "all-cone". But, electrophysiological (Green & Dowling, 1975) and electron microscopic (Cohen, 1964; West & Dowling, 1975) analyses have indicated the presence of a substantial population of rods. Furthermore, the EM analysis showed that cone and rod receptors appear to be spatially segregated. Cones appear to be located in the outer tier of receptors and rods in the inner tier. However, data previously presented at these meetings (Petry, 1982) suggested that this segregation may not be complete. Intravitreally-injected Procion yellow dye, which selectively stains short-wavelength-sensitive (SWS) cones in the monkey retina (DeMonasterio et al., 1981), was shown to be taken up by receptors in the gray squirrel's "rod" tier. The present study was undertaken as an alternative means of identifying SWS cones in the gray squirrel retina using repeated exposures of moderately intense short-wavelength light. In monkeys, such a procedure has been shown to produce selective damage to SWS cones, but not to other cone types or rods (Sperling et al., 1980).

Anesthetized gray squirrels were given daily 40 min exposures of one eye to moderately-intense (1.5 J/cm^2, daily) blue light over a 7 or 10 day period. The blue light (451nm, ±3nm) was presented in Maxwellian view and subtended a visual angle of 65 deg. centered on the retina. Post-exposure survival time ranged from 14-21 days. Light microscopic examination of the exposed retinas showed that light-induced cellular damage, (e.g., gaps in the receptor mosaic), was restricted to that area of the retina that had been exposed to the blue light. Furthermore, this damage was observed only in the inner tier of receptors and never in the outer tier.

These results confirm the Procion yellow findings and indicate that the gray squirrel's SWS cones are located, with its rods, in the inner tier. Such a receptor arrangement would be adaptive to the species for two reasons. First, by the layering of the dichromatic gray squirrel's other cone type, the long-wavelength-sensitive (LWS) cones, in the outer tier and the SWS cones in the inner tier, the effects of chromatic aberation on the retinal image would be minimized. Second, because a portion of the inner tier receptors are SWS cones and not rods, then West & Dowling's estimate of a total of 40% rod receptors would be reduced proportionately. Thus, fewer rods and more cones must compose the gray squirrel's retina, allowing for more of its receptors to function under the photopic light levels in which this diurnal squirrel is usually active.

71.6 **INHIBITION OF THE ELECTROGENIC SODIUM PUMP IN ROD PHOTORECEPTORS DURING MAINTAINED ILLUMINATION.** H. Shimazaki and B. Oakley II. Depts. of Electrical and Computer Engineering & Biophysics, & the Bioengineering Program, Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801.

In our earlier work involving measurement of the light-evoked decrease in extracellular potassium ion concentration, $[K^+]_o$, in the subretinal space (J. Gen. Physiol. 84:475-504, 1984), we hypothesized that the Na^+/K^+ pump in the membrane of the rod inner segment becomes inhibited progressively during maintained illumination. In order to test this hypothesis directly, we recorded light-evoked changes in membrane voltage from rod photoreceptors in the isolated retina preparation of the toad, **Bufo marinus**. During our standard test conditions, the retina was superfused with pharmacological agents that blocked voltage-dependent conductances (and, in some experiments, calcium-dependent conductances, as well). Under these test conditions, the amplitude of the hyperpolarizing photoresponse became much greater than under control conditions. Results of several experiments support the conclusion that this increase in photoresponse amplitude was due primarily to current from the rods' electrogenic Na^+/K^+ pump, flowing across a high membrane resistance (which, in these experiments, resulted from a combination of the pharmacological agents and light). A similar conclusion was reached earlier by V. Torre (**J. Physiol. 333**:315-341, 1982).

Having established that, under our standard test conditions, a major component of the rods' photoresponse is produced by the rods' electrogenic Na^+/K^+ pump, we next recorded rod responses to continuous illumination under these test conditions. At the onset of a period of continuous illumination, the rod membrane first hyperpolarized by approximately 50 mV, and then began to repolarize, and after 180 seconds of illumination, the membrane voltage had recovered by as much as 77% of its initial hyperpolarization. Both the enhanced hyperpolarization at light onset and the slow depolarization during maintained illumination were blocked by superfusion with 10 micromolar strophanthidin. These results support the hypothesis that the rods' electrogenic Na^+/K^+ pump becomes inhibited progressively during maintained illumination. Moreover, the time course of the rod membrane repolarization during maintained illumination had a time course that was slightly more rapid than that of the recovery of the light-evoked decrease in $[K^+]_o$. This latter observation provides additional evidence in support of the hypothesis that inhibition of the rods' Na^+/K^+ pump produces the significant recovery of $[K^+]_o$ in the subretinal space observed during maintained illumination.

This work was supported by NIH grant EY04364, and by a grant from the Chicago Community Trust/Searle Scholars Program.

71.7 DIFFUSIONAL RESTRICTION AND DYE COUPLING IN INSECT BRAIN SLICES. M. Järvilehto*, I.A.Meinertzhagen and S.R. Shaw (SPON: D. Mitchell) Department of Psychology, Dalhousie University, Halifax, N.S., Canada, and Department of Zoology, University of Oulu, Finland.

Neurons in the peripheral visual system of certain insects are uniquely anatomically identifiable, and in the neuronal ensembles (cartridges) of the lamina in Diptera, all the connections have been documented. Exploitation of these resources for physiological purposes has been hindered, however, because recovery of dye-injected cells is time consuming. We have therefore developed a perfused dipteran brain slice preparation that includes the eye, in which dye injections can be watched directly by epifluorescence. Visual stimulation so far has been crude, but sufficient to confirm that cells in the slice can remain viable for >3h. We report here two findings made with this slice preparation.

First, we frequently observed unexpected and almost immediate dye-coupling between cells in the optic lobe, always radiating from the position of the microelectrode tip. These occurrences were neither consistent from site to site, nor expected from the known ultrastructure. For example, the photoreceptor terminals are known not to be coupled via gap junctions either to postsynaptic monopolar neurons or to epithelial glial cells (EGCs), yet sometimes one or other type stained along with a terminal, when sites in the lamina were injected with Lucifer Yellow or other dyes. We suspect that such anomalous cases of dye-coupling are artefactual, perhaps due to genesis of relatively low impedance pathways through cells with surface membranes damaged by the micropipette tip.

Second, local dye ejection revealed a major restriction upon extracellular diffusion in the lamina synaptic zone, compared to other parts of the brain examined. In the medulla, chiasm and retina, a current pulse produced a halo of dye fluorescence around the pipette tip, that dissipated a few seconds after current-off, indicating a relative lack of constraint upon local extracellular diffusion. In the lamina, currents of 1 - 20nA applied for many minutes produced no lateral diffusion, only intense local columnar staining, which usually spread no further laterally than 1 - 2 cartridge widths, then persisted indefinitely. Subsequent histology disclosed one or more stained EGCs at the site. The EGCs in some cases appeared to form a dye-coupled network. This direct demonstration of compartmentalization in the lamina complements predictions made on other grounds (review: Shaw, S.R., J. Exp. Biol. 112: 225, 1985). Since the extracellular route is blocked, the laterally spreading photocurrents that can be observed in the lamina must be travelling in part intracellularly. The glial network is indicated as the probable conduit for these currents, which have been implicated in light adaptational and lateral inhibitory control. Supported by NSERC, Canada (I.A.M., S.R.S.), and NSERC International Exchange Award, and Finnish Academy (M.J.).

71.8 GABA (γ aminobutyric acid) ANTAGONISTS STIMULATE RELEASE OF DOPAMINE FROM INTERPLEXIFORM CELL PROCESSES IN THE CARP OUTER PLEXIFORM LAYER. Patricia O'Connor*, Charles L. Zucker and John E. Dowling, Dept. of Cellular and Developmental Biology, Harvard University, Cambridge, MA 02138.

In the outer plexiform layer (OPL) of teleost fish retina, the spatial properties of horizontal and bipolar cells are modified by dopaminergic interplexiform cell (DA-IPC) input. It has been shown in several species including carp (Cyprinius carpio), that dopamine, as well as the GABA antagonists picrotoxin and bicuculline (pic/bic), decrease electrical and dye-coupling between horizontal cells. The effects of GABA antagonists are blocked by the dopamine antagonist haloperidol suggesting that these agents disinhibit the DA-IPC causing dopamine release. In this study, the ability of pic/bic to release endogenous dopamine and activate the dopamine sensitive adenylate cyclase in isolated intact carp retina was investigated. Additionally, the cellular localization of this release has been determined autoradiographically.

HPLC analysis showed that pic/bic (100 μM) stimulated a 4-fold increase in endogenous dopamine release over a basal efflux of 1.25 pmole/mg protein. The release evoked by these agents was calcium dependent. Pic/bic, at concentrations which evoked dopamine release, stimulated an increase of 300 pmole/mg protein of cAMP above control levels. This activation of adenylate cyclase was blocked by preincubation with 100 μM haloperidol.

Retinas were preloaded with 0.2 μM ^{3}[H]dopamine, incubated with or without pic/bic and processed for light microscopical autoradiography. 1.5 μm plastic sections of control and antagonist treated retinas were processed on the same slides to prevent the variability common to autoradiographical techniques. Picrotoxin (100 μM) caused a reduction in grain density over the outer plexiform and horizontal cell layers by about 40% compared to control retinas. Bicuculline caused a similar reduction but to a lesser degree (20%).

It thus appears that the regulation of horizontal cell receptive field size by the DA-IPC is subject to GABAergic inhibition provided by amacrine cells in the inner plexiform layer. This inhibition influences the release of dopamine transmitter from DA-IPC synaptic terminals onto horizontal cell bodies in the OPL.

71.9 MORPHOLOGICAL EFFECTS OF DOPAMINE ON GOLDFISH HORIZONTAL CELL GAP JUNCTIONS. R.G. Miller and W.H. Baldridge, Dept. of Anatomy, The University of Calgary, Calgary Alberta, Canada.

Horizontal cells are second order neurons in the inner plexiform layer of vertebrate retina. Horizontal cells have been associated with both color vision and contrast regulation, as suggested by extensive gap junction coupling of both their cell bodies and also their axon terminals. Coupling of horizontal cells at gap junctions can be regulated by dopamine (Teranishi et al. J. Neurosci,. 4:1271, 1984) either by direct applications in situ or by light induced release of dopamine from interplexiform cells (Kramer, Inv. Ophthal. 10:438, 1971). Electrophysiologic evidence suggests that dopamine uncouples horizontal cells. The role of gap junctions in horizontal cell coupling has been studied extensively through dye coupling but relatively few studies have characterized morphological changes associated with horizontal gap junction coupling.

In this study, we have investigated the morphology of gap junctions on both horizontal cell bodies and their axon terminals in the goldfish using freeze-fracture electron microscopy. Light or dark (>1 hr.) adapted retinae and retinae from eyes intraocularly injected with various drugs were fixed in glutaraldehyde and prepared for freeze-fracture by standard procedures. We find significant changes in gap junction particle density associated with cell body coupling. No changes in axon terminal junctions were observed. Under conditions of coupling (darkness and no dopamine) gap junctions exhibit a particle density of 3,680 μm ± 280 μm^{-2} (mean ± SEM) compared to gap junctions which are uncoupled (treated with dopamine (in the dark) or exposed to light) which exhibit a density of 2,600 μm^{-2} ± 225 μm^{-2}. The action of dopamine can be blocked in all cases with haloperidol which results in "coupled-like" gap junction particle densities on the order of 3,600 μm^{-2} ± 200 μm^{-2}. Interestingly, gap junctions located at axon terminals appeared as coupled and did not significantly alter particle density under experimental manipulations.

van Buskirk and Dowling (PNAS, 78:7825, 1984) have implicated cyclic AMP as a second messenger of dopamine action in horizontal cells. Preliminary results suggest that vasoactive intestinal peptide (VIP), an adenylate cyclase stimulator, acts to uncouple horizontal cells as indicated by a less dense organization of gap junction particles. Further studies are underway to investigate the role of cyclic AMP on gap junction morphology. Electrophysiologic determination of coupling state prior to fixation is underway to verify presumed coupling states.

71.10 THE USE OF VECTOR PROCESSING SUPERCOMPUTERS FOR THE DISCRETE TIME SIMULATION OF LARGE NEURAL NETWORKS...A CASE STUDY USING A MODEL OF THE FROG RETINA. J.L. Teeters* and Y. Lee* (SPON: M.A. Arbib). Dept. of Computer and Information Science, University of Massachusetts, Amherst, MA 01003.

Discrete time computer simulation at the neuron level is important for the testing of neural network models, but is so computationally expensive that it is often impractical, especially for large networks. On a conventional computer the major bottleneck is that all the neurons must be simulated sequentially in the simulation of each time step before advancing to the next time step. Supercomputers (such as the Cray or Cyber-200 machines) have the capability to greatly reduce this bottleneck by using vector instructions to (in effect) simultaneously simulate many neurons within each time step. However, to take full advantage of this capability the simulation program must be structured so that nearly all of the computations are done by vector instructions. While this is not possible for most typical computer programs, the simultaneous operation of neurons in a network makes programs to simulate them good candidates for vector processing computers.

In the retina model the potentials of individual neurons are modeled by variations of a leaky-capacitor model. The density of each type of neuron and the existence and size of connections are based on anatomical data. A population of neurons is modeled to provide a spatio-temporal pattern of activities for every cell involved in the cone-pathways for a patch of frog's retina. Parameters for each type of model neuron are set so that their temporal activities approximate the typical intracellular recording for the corresponding neurons given the known visual/electrical stimulus patterns.

Simulating a small area (16 visual degrees) of the retina on a VAX 11/780 takes about one hour of computer time for each second of real time. Expanding the area simulated (which is necessary to test some aspects of the model) is impractical if the VAX is used because several weeks of computer time would be required to complete a single run. By carefully restructuring the program to make use of the vector capabilities of the Cyber 205, simulation time for the 16 degree patch was reduced to under thirty seconds for each second of real time. Using the 205, test requiring the simulation of a large visual area are feasible as the time required is under an hour. (This research was supported in part by NIH under grant No. NS14971-06A2.)

71.11 *THE EFFECTS OF DESTROYING THE INDOLEAMINE-CONTAINING RETINAL NEURONS ON THE ELECTRORETINOGRAM OF THE CARP.* *J. L. Cohen and S. Hensley*. Dept. of Anatomy, Wright State University, School Medicine and School of Science and Engineering, Dayton, OH 45435.*

The action of intravitreal injection of 5,7 dihyroxytryptamine is to destroy the indoleamine-accumulating neurons of the retina. In the teleost fish these neurons have been identified as amacrine cells. The electroretinogram is the algebraic sum of the electrical potentials of retinal neurons. We therefore wanted to determine what effects the destruction of the indoleaminergic-amacrine cells would have on the electroretinogram.

Twenty microliters of a solution containing 2 mg of 5,7 dihydroxytrptamine dissolved in 1 ml 0.9% NaCl with 1 mg ascorbic acid added as an antioxidant was injected into the vitreous of the right eyes of carp, 4-6 inches in length on two consecutive days. The left eyes acted as the control. One week after injection, the eyes were removed and the cornea, lens and vitreous cut away. The remaining eyecup was placed in a chamber with moist 100% oxygen blowing on it. A silver-silver chloride electrode was inserted into the vitreous and connected to a Grass P16 AC preamplifier and displayed on an oscilloscope. To determine if the serotonergic cells were indeed destroyed, 20 ul of a solution containing 3.5 mg of 5,6 dihydroxytryptamine dissolved in 0.5 ml of 0.9% NaCl was added to the eyecup at the end of each experiment. The preparation was allowed to incubate for 30 minutes in the dark. The retina was removed and then fixed in a solution containing 4% paraformaldehyde, 0.5 gluteraldehyde, 35% sucrose and 0.1M phosphate buffer. The retina remained in the solution overnight and was then air dryed for 24 hours and examined under a fluorescence microscope.

The b-wave of the electroretinogram was found to be significantly smaller in the treated eyes. Intensity-response curves obtained with 460nm, 520nm and 620nm light stimuli revealed curves with approximately the same slope, but with differences in the maximum amplitude. The amplitudes recorded from control retinas were twice that of treated retinas. The duration of the b-wave was longer than that from control eyes. The a-wave was not affected. Double flash experiments showed that the suppression of the second flash was greater for control retinas than for treated retinas. Fluorescence microscopy revealed the absence of indoleamine-containing cell bodies in the treated retina, thus demonstrating the destruction of the indoleaminergic neurons.

71.12 **THE ROLE OF INDOLEAMINES IN VISUAL PROCESSING IN THE RABBIT RETINA.** **William J. Brunken and Nigel W. Daw, Department of Cell Biology and Physiology, Washington University Medical School, St. Louis, Missouri 63110.**

We have reported previously that the serotonergic antagonists ketanserin and methysergide, both 5-HT2 antagonists, altered the center-surround balance of off-center rabbit ganglion cells in favor of the central (off) mechanism (Brunken et al. '84). Furthermore, 5-methoxy N, N, dimethyltryptamine (5-MDT), a potent agonist at autoreceptors, a subclass of 5-HT1 receptors, produced similar results. Thus, these data provided physiological evidence for the existence of both 5-HT1 and 5-HT2 receptors in rabbit retina. This conclusion has recently been confirmed by binding studies (Redburn et al. '85).

We are now pursuing the question of what is the functional significance of these two serotonin receptor classes. The attempts to elucidate the role of 5-HT1 receptors are limited by the lack of a specific antagonist at this site. We have employed methiothepin, an antagonist potent at 5-HT1 subtypes, including the autoreceptor, and less potent at 5-HT2 receptors. Methiothepin, like both methysergide and ketanserin, reduced spontanteous activity and abolished the on-component of the response to both diffuse or annular stimulation for off-center cells. However, unlike either of these other drugs, methiothepin reduced the sensitivity and responsivity of the central component of the response as well. In some cases, it eliminated the response to small spots centered on the receptive field altogether. We suggest that this latter action is the result of specific antagonism at 5-HT1 receptors.

In order to assess whether or not the blockade of the on-component of off-center cells produced by 5-HT2 antagonism represents a shift specifically in the center-surround balance or rather an interruption of the on-pathways in rabbit retina, we have turned to monitoring the effect of 5-HT2 antagonists on the properties of on-off directional selective ganglion cells. LY-53857, a 5-HT2 antagonist, which has effects on off-center cells similar to ketanserin and methysergide, but unlike these other drugs lacks any histamine or alpha-adrenergic effects, reduced the spontaneous activity and both the leading and trailing edge responses of on/off directional selective cells. Thus, it appears that at least in these cells the endogenous indoleamine modulates (increases) both the on and off inputs. Furthermore, these results are distinctly different from those obtained with the D1 dopamine antagonist Sch 23390, which selectively reduces the leading edge response of on/off directionally selective cells. Thus, we conclude that there is a functional role for an as yet unidentified indoleamine in the mammalian retina.

71.13 EFFECTS OF MORPHINE ON LIGHT RESPONSES OF GANGLION CELLS IN THE LARVAL TIGER SALAMANDER RETINA. S.E. Feingold*,C.B. Watt*, D.M.K. Lam, and S.M. Wu. Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030.

Previously, using immunocytochemical techniques, we have demonstrated the presence of enkephalin-like immunoreactivity in two populations of amacrine cells in the larval tiger salamander retina (Watt et al., Neuroscience Abstract 248.16, 1984). Light microscopy showed heavily stained processes in sublamina 5 and punctate deposits in sublamina 1 of the inner plexiform layer. At the ultrastructural level, enk-immunoreactive processes make synaptic contacts with other amacrine cells, bipolar cells, and possibly ganglion cell processes.

To study the function of these enkephalinergic cells, single-unit ganglion cell light responses were monitored in the superfused salamander eyecup before, during, and after applications of morphine sulfate. In about 1/3 of the on-off cells tested, 1 mM morphine caused a reversible reduction in firing frequency at the onset of broad-field illumination. Little change was observed at the cessation of light stimuli. Approximately 80% of the on-center and off-center cells encountered responded to morphine application. In the on-center cells, a transient on-response to surround illumination appeared in the presence of morphine. In the off-center cells, administration of 1 mM morphine resulted in an increase in firing frequency at the onset of surround illumination and caused no change in the responses to center illumination.

Physiological observations described above suggest that the primary action of morphine is to alter selectively the electrical responses to onsets of broad-field illumination in retinal ganglion cells. This is consistent with the immunocytochemical results since amacrine cells mediate the broad-field inputs to ganglion cells, and cells which send processes to sublamina 5 are thought to be involved in the on-pathway of the inner retina.

71.14 RETINAL GANGLION CELL MORPHOLOGY IN CATFISH. A.A. Dunn-Meynell* and S.C. Sharma (SPON A.B. Drakontides). Dept. Ophthalmol., New York Med. Coll., Valhalla, New York 10595.

Retinal ganglion cell morphology was examined in the catfish Ictalurus punctatus using horseradish peroxidase (HRP) techniques which permit fine details of the structure of these cells to be discerned. HRP was applied to small lesions in the optic papillae at the point at which they left the retina in 3-5 inch catfish. After 3-5 days the neural retina was isolated, flat mounted and reacted to reveal HRP using diamino benzidine as chromagen.

Ganglion cells could be broadly divided into giant (soma diameter about 15-30 μm, dendritic field area roughly 15 X 10^4 μm^2) and small (soma diameter approximately 7-15 μm, area of dendritic arbor in the order of 3 X 10^4 μm^2). We subdivided the inner plexiform layer (ipl) into 4 laminae (from most chorad - a, to most vitrad - d) to describe the depth of dendritic arbor.

The following general characteristics distinguished the 12 classes of ganglion cells which we delineated: GIANT CELLS; G1 - The axon arises from the soma, thick dendrites ascend to ipl lamina a. In the dorsal retina the dendritic fields of these cells have a marked naso-temporal elongation and the cells have a roughly regular distribution. G2 - The axon arises from a dendrite, the soma has an irregular shape, the dendrites arborize in ipl lamina b. G3 - Typified by their medium diameter dendrites which arborize in ipl lamina d. These cells tend to be smaller than other giant cells. G4 - Found almost solely in a band running nasotemporally along the center of the retina. In this position the dendritic field is elongated dorsoventrally. The main dendrites arborize in lamina c, fine dendrites ascend to arborize in laminae a or b. G5 - The soma is displaced into the inner nuclear layer (inl), the dendrites arborize in ipl lamina a. SMALL CELLS; S1 The axon arises from a round or oval soma, the dendrites (which are fine and are often seen to have an intricate arbor) ascend to ipl lamina b. S2 - These cells have a roughly round soma from which the axon departs. The dendrites are fine and their arbor is unstratified. S3 - The cells are oval with about 3 dendrites which arborize in laminae a and c. S4 - The axon arises from an oval soma, the dendrites form a small arbor in lamina b. S5 - The cells have a round soma with dendrites in lamina d. S6 - The soma is displaced into the inl. The dendrites arborize in lamina a. These cells form a clearly distinct population from the giant displaced ganglion cells (G5). S7 - The axon arises from a dendrite, the dendrites arborize in lamina c.

These results show the ganglion cell population in catfish to be diverse and complex. Further subdivision of cell types may be possible.

71.15 ELECTRICAL PROPERTIES OF TIGER SALAMANDER RETINAL GANGLION CELLS. Peter. D. Lukasiewicz* and Frank S. Werblin*
(Spon: G. Westheimer) Neurobiology Group, University of California, Berkeley, Ca 94720

The membrane properties of salamander retinal ganglion cells were studied using "gigaseal" whole cell patch recording techniques. Recordings were made from retinal slices and cells were identified by their locations in the slice. The membrane currents were composed of five components; a fast transient sodium current, a slow transient sodium current, a voltage-dependent potassium current, a calcium-dependent potassium current, and a sustained calcium current.

The fast and slow sodium currents were both activated at potentials more positive than -40 mV and were maximal at -10 mV. Both types of sodium currents were blocked by tetrodotoxin or by substituting choline for external sodium. The voltage-dependent potassium current was activated at potentials more positive than -20 mV and was blocked when the cell was internally perfused with cesium. The calcium-dependent potassium current was activated at potentials more positive than -20 mV and was suppressed by 20 mM TEA, 4 mM cobalt or 1 mM cadmium. The sustained calcium current was activated at potentials more positive than -25 mV and was maximal at +10 mV. The sustained calcium current was blocked by 4 mM cobalt or 1 mM cadmium.

The input resistance of these cells was greater than 2 gigaohms and the resting potential was near -70 mV. We have measured excitatory synaptic currents greater than 50 pA which could bring these cells within the range of activation for all currents described above. Gated currents may thus significantly alter the form of response following synaptic input from amacrine and bipolar cells.

71.16 THE DELTA GANGLION CELL OF THE CAT RETINA. H. Kolb and R. Nelson, Physiology, Univ. Utah Sch. Med., Utah, and Neurophysiology, NINCDS, National Institutes of Health, Bethesda, MD.

A ganglion cell type belonging to the ill-defined W cell class in the cat retina has been studied by intracellular recording, iontophoresis of HRP and electron microscopy. The ganglion cell has a dendritic branching pattern typical of the delta cell described originally by Boycott and Wassle (1974) and further defined by Kolb, Nelson and Mariani (1981). The 20 um cell body gives rise to long curved dendrites that are narrowly stratified in s2, on the sublamina a/b border of the inner plexiform layer. The overall dendritic tree size is 660 um and the dendrites are essentially smooth bearing only a few small spines. Electron microscopy of the delta ganglion cell indicates that it receives cone bipolar synapses primarily from type cb1, and various amacrine synapses. The delta cell dendrite usually shares the cone bipolar ribbon synapse with an A19 amacrine cell dendrite. The A19 characteristically makes a reciprocal synapse back upon the cone bipolar terminal and occasionally also upon the delta ganglion cell dendrite.

The intracellular responses of this ganglion cell are characterized by a complex interplay of inhibitory and excitatory post synaptic potentials. With diffuse stimulation there is a rapid on-hyperpolarization which is modulated by a delayed sustained repolarization punctuated by large, rapid fluctuations in membrane potential, both hyperpolarizing and depolarizing. The larger depolarizations trigger action potentials. The initial hyperpolarizing event reveals a large receptive field with a half width of about 650 um. The edges of the receptive field are characterized by depolarizing events. The cell is not directional along the axis of the receptive field measurement, and appears concentric, with a central region of inhibition being overlapped and flanked by more peripheral excitation. Some differences in the cells behaviour under light and dark adaptation have been noted. Thus, although concentrically organized, the physiology of the delta ganglion cell appears to be more complex than that of the alpha or beta ganglion cells of the cat retina.

71.17 REGULATION OF GABA AND SOMATOSTATIN RELEASE IN RETINA AND OLFACTORY BULB BY VASOACTIVE INTESTINAL PEPTIDE (VIP) AND DOPAMINE. D. Smith*, S.L. Horowitz*, J.F. Cubells and M.H. Makman*. (SPON: E.B. Gardner). Departments of Biochemistry, Molecular Pharmacology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

We have previously reported that VIP stimulates several fold the release of ^{3}H-GABA from retinal synaptosomes that had been prelabeled either with ^{3}H-GABA or with ^{3}H-glutamate in order to assess the release of newly formed ^{3}H-GABA (Soc. Neurosci. Abstr. 10:837, 1984). PHI, secretin and glucagon also stimulated GABA release, with relative potencies resembling those for stimulation of adenylate cyclase (AC) activity. In further studies the VIP-stimulated release of newly formed GABA was not blocked by tetrodotoxin or by substitution of Co^{++} for Ca^{++} in the medium. Glutamate at 500 uM markedly stimulated GABA release. Glutamate at 50 uM only slightly increased GABA release but greatly enhanced the amount of GABA released due to VIP; percent increase by VIP was unchanged. In the presence but not in the absence of glutamate, dopamine (DA) also stimulated GABA release; however, DA was less effective than was VIP. In preliminary studies the selective D_1 receptor antagonist, SCH23390, blocked the effect of DA. Comparable studies have been carried out with synaptosomes prepared from rat olfactory bulb (OB). VIP caused a marked stimulation of GABA release from OB synaptosomes. The relative order of potency of related peptides was similar to retina, except that at high concentration (10 uM) PHI was more potent than VIP in OB, while VIP was more potent in retina. AC may not be involved in the effects of VIP in OB or retina since forskolin was inactive and cyclic AMP analogues had little effect.

Release of somatostatin from bovine retinal and rat OB synaptosomes has also been studied. VIP and also DA stimulated immunoreactive somatostatin release from both retinal and OB synaptosomes. The receptors involved in these effects are under investigation. It remains to be established if GABA and somatostatin are colocalized in neurons containing VIP receptors. Somatostatin itself did not influence basal or VIP-stimulated GABA release. While VIP and DA acting at D_1 receptors may have common effects, differences are also expected on the basis of studies of additivity of VIP-AC and DA-AC. It is of interest that in two sensory systems, retina and OB, VIP exerts similar effects on other transmitters. (Supported by USPHS grants EY-04633 and 5T32-GM-07260.)

71.18 IS RETINAL GANGLION CELL RESPONSE TO MOTION PREDICTABLE FROM THE CELL RESPONSES TO STATIONARY FLASHING STIMULI? M.F. Sarna* (SPON: P. Sterling) Dept. Neurophysiology, Nencki Institute, Warsaw, Poland and Dept. Physiology, University of Pennsylvania, Philadelphia, PA 19104.

Assuming linear spatiotemporal summation within receptive field of a visual cell one should be able to predict the cell response to movement from the cell responses to stationary stimulus flashing on and off with properly adjusted timing in consecutive positions along trajectory of a movement. These experiments were carried out to examine this principle.

Responses of retinal ganglion cells of the pretrigeminal cat to small bar flashing on and off in randomly ordered positions along a line within the cell receptive field were recorded. Peri-stimulus time histogram (PST) was collected for each bar position. The 'predicted' PST to moving stimulus was then constructed from stationary data by summing up PSTs related to succeeding stationary bar positions each PST shifted by the appropriate time. Such a 'predicted' PST was compared with 'actual' PST recorded during stimulus motion along the same line with properly adjusted velocity.

A comparison showed near-perfect matching of both 'predicted' and 'actual' histograms in the case of X-cells, both ON- and OFF-center. In the case of Y-cells matching was much worse, ranging from good for relatively sustained ON-center cells, through poor for transient ON-center cells, to lack of any matching in majority of OFF-center cells. In general, excitatory peaks matched much better than inhibitory valleys, which frequently were hardly seen in 'predicted' PST of Y-cells.

These findings are consistent with the assumption that spatiotemporal summation within X-cell receptive field is nearly linear, whereas within Y-cell is strongly nonlinear. But these results can also be explained, at least roughly, without assuming nonlinearities. Since resting firing level of Y-cells is small, then both strong and weak inhibition produce the same image in stationary PSTs, i.e. a zero line, whereas stronger excitation produces higher peaks than weaker excitation. This leads to underrepresentation of inhibition in stationary responses and consequently in 'predicted' PST.

71.19 COMPUTER IMAGE ANALYSIS OF LASER INDUCED PUNCTATE LESIONS. H. Zwick*, L. Sherman*, and D. O. Robbins Letterman Army Institute of Research, San Francisco, CA 94925 and Ohio Wesleyan University, Delaware, OH 43015.

In previous experiments we have evaluated the immediate and long term effects of single and multiple laser exposures on spatial vision of rhesus monkeys. For exposure energies ranging from near the morphological damage level to energies several log units below this level, brief (100 msec) foveal exposures of various retinal diameters, produced immediate and transient changes in both visual acuity and contrast sensitivity. The magnitude and duration of these changes in visual sensitivity were related to the energy, duration, and placement of the exposure on the retina but extended beyond what might be expected solely on the basis of local adaptation of foveal receptors. Repeated exposures over days or weeks at energy densities below ED 50 for the single exposure condition ultimately produced long term changes in acuity characteristic of those produced by single exposures of higher energy above the ED 50 level. Exposure of the fovea to a minimal diameter ($\leq 50\,\mu$) single Q-switched pulse of extremely short (15 nsec) duration but high energy density (50 - 100 μJ), on the other hand, produced rather small and extremely variable changes in immediate postexposure acuity despite the fact that these energies densities were significantly above the ED 50 level. Long term shifts in acuity to these high energy, Q-switched pulses were observed only after repeated exposures over several days or weeks. Postexposure sensitivity was, however, marked by increased response variability not evident in pre-exposure testing.

In this paper we have correlated these behavioral findings with funduscopic changes through the use of digital image analysis techniques. Punctate foveal lesions from exposed animals were differentiated from normal retina on the basis of grey scale distributions measured in local foveal regions and referenced to unexposed regions from the same retina. Such relative grey scale distributions are capable of characterizing the degree of focal and non-focal disturbance induced by punctate damage. A second technique involving the use of two dimensional fast fourier transformations over local regions such as the fovea enhanced the contrast of relatively large but low contrast aspects of foveal-macular detail. This latter procedure has demonstrated the full extent of lesions in the fovea that otherwise would be nearly impossible to detect by conventional funduscopy. Correlation of these enhanced morphology disruptions with behavioral changes will be presented.

71.20 COMPARISON OF PATTERN-EVOKED RETINAL RESPONSES AND VISUAL-EVOKED POTENTIALS IN RHESUS MONKEY. R.D. Glickman, F.H. Previc and R.M. Cartledge*+. Life Sciences Div., Technology Inc., San Antonio, TX 78216, and +Radiation Sciences Div., Brooks AFB, TX.

We have recorded the pattern-evoked retinal response (PERR) and the visual-evoked potential (VEP) under identical stimulus conditions from the rhesus monkey. The monkey was anesthetized with barbiturates, paralyzed with gallamine, and mechanically ventilated. Focal VEP's were recorded with bipolar, stainless-steel electrodes implanted in the foveal projection region of both visual cortices. These electrodes measured the potential generated between the cortical surface and a depth of 3 mm. Monocular PERR's were recorded with an ERG-jet electrode (Life-Tech, Inc.). A conductive thread electrode ("D-T-L") on the occluded eye served as a reference. Stimuli subtended 6 or 12 degrees of visual angle and consisted of green and black square-wave, luminance-modulated gratings presented on a CRT monitor. These gratings ranged in spatial frequency from 0.5-8 cpd and were counterphased at 1-20 Hz. Maximum luminance of the gratings was 14 cd/m^2 and the contrast was varied between 30-85%.

Several consistent differences were noted between the rhesus VEP and PERR. With a 1 Hz counterphased grating, the implicit time of the prominent negative wave of the PERR (84 $\pm$ 3.5 msec) was always greater than that of the VEP (72 $\pm$ 7 msec). The VEP peaked in amplitude in response to stimuli of 4 cpd, while the optimal spatial frequency for the PERR was about 1 cpd. Both the VEP and PERR showed the largest amplitude responses to stimuli counterphased at or below 5 Hz. The PERR, however, was detectable at counterphase rates up to 20 Hz (the highest rate tested), whereas the VEP became unreliable above 10 Hz. Signal amplitude was highly dependent on stimulus size and contrast, e.g., the PERR amplitude increased from 1.6 to 6.5 uV as stimulus contrast was varied from 30 to 85% while the VEP amplitude (86 uV) saturated at about 50% contrast. We examined the contribution of the central visual field to the PERR by selectively stimulating parts of the retina. The PERR appeared to be derived uniformly from the central 12^o of visual field that was tested. The PERR has characteristics distinct from those of the VEP, especially with respect to temporal modulation.

AUDITORY SENSORY ORGANS AND TRANSDUCTION

72.1 THE TEMPORAL ACTIVATION OF AUDITORY NEURONS AS A FUNCTION OF ACOUSTIC FREQUENCY IN THE HATCHLING CHICK. T.A. Jones, H. Brown,*R. Czeranko* and M.M. Beck, Depts. of Oral Biology, University of Nebraska Medical Center, and Animal Science, University of Nebraska, Lincoln Ne. 68583.

A vibration of the basilar papilla (basilar membrane) travels from the base to the apex of the cochlea at a velocity which decreases as a function of distance (Bekesy 1960). The time of its arrival at any particular position will depend on the traveling wave velocities encountered and the distance traversed during travel. Amplitudes of the vibration also change as a function of cochlear position and for a given frequency will be maximum at a particular location. At low intensities, narrow band stimuli may be used to preferentially activate neurons innervating this corresponding region of maximum amplitude. The latency of activation for such neurons will reflect the cochlear travel times for the acoustic stimulus. Tonotopic maps presenting the position of maximum amplitude as a function of frequency have been described for birds and many species of mammals. The corresponding temporal data relating the latency of neural activation as a function of frequency are not available for birds. In the present study, low intensity narrow band stimuli (pure tones:15 msec duration) were employed to estimate the delay in neural activation for various frequencies (approx. 5k, 3k, 1650, 990, 490, 290, 220, and 180 Hz). Tones were presented at a repetition rate of 10/sec. Hy-line chicks (one to three days after hatch) were used in the present study. Auditory responses were recorded using subcutaneous electrodes (vertex=G1; exoccipital=G2;abdominal ground) where electrical signals were led to an amplifier (10,000X; Lf=100; Hf=10,000) and in turn to a computer averager (8.3 microsec/point; 1024 points). Neural and cochlear microphonic (CM) potentials were resolved out of the background electrical noise using computer averaging (n=512). Threshold stimulus levels were determined for each frequency to generate audibility functions. Wide band maskers were also applied to verify neural components and the resulting non-neural waveforms (CM & electrical artifact) were subtracted from the unmasked responses to stimuli of the same frequency and intensity. Latencies of neural response components were then plotted against frequency. Neural response thresholds were below 88dbSPL for all frequencies and were lowest for frequencies between 400 and 5k Hz (range: 30-60dbSPL). The slopes of the latency/frequency curves were nonlinear over the range of frequencies studied. Latency/ frequency slopes were least at frequencies below 290 and above 3kHz presumably reflecting properties of the apex and base of the cochlea respectively in these young birds. (Bekesy, G. v. Experiments in Hearing, New York:McGraw-Hill, 1960)

72.2 A SURVEY OF SPONTANEOUS OTOACOUSTIC EMISSIONS IN THE NONHUMAN PRIMATE. B.L.Lonsbury-Martin, G.K.Martin, R.Probst,* and A.C.Coats. Dept. of Otorhinolaryngology & Communicative Sciences, Baylor Col. of Med., Houston, TX 77030.

A number of reports have described a relatively high (40%) incidence of continuous, low-level, narrowband signals known as spontaneous otoacoustic emissions (SOAEs) in recordings made from the sealed human ear canal. The subsequent finding of significant differences in incidence and some basic characteristics between SOAEs of humans and those of common laboratory animals raises important concerns regarding the differences in micromechanics between human and animal ears. The present study of nonhuman primate ears was conducted to determine the incidence of SOAEs in an animal ear that is phylogenetically closer to the human than previously studied animals. Both ears of 61 seemingly normal-hearing primates representing four species of Old World macaque and one species each of ape (baboon) and New World monkey (squirrel) were examined. Multiple emissions were discovered in three ears of three different macaques, two Macaca mulatta and one M. nemestrina. Overall, 2.5% of nonhuman primate ears and 5% of the monkeys demonstrated SOAEs. In contrast to what has been typically documented in other laboratory species, the ranges describing frequency, amplitude, and bandwidth characteristics of the monkey emissions were identical to those that have been reported for humans. To further characterize the psychoacoustic properties of monkey SOAEs and to relate the SOAEs to other classes of emissions (evoked, stimulus-frequency, distortion-product), detailed testing of one emitting rhesus monkey was performed. Results from these tests showed additional features highly similar to those that have been described for human ears. The appreciably lower incidence of spontaneous emissions in nonhuman primates, although notably greater than that shown for other laboratory species, suggests that despite similar features, subtle differences in the micromechanical generating mechanism(s) must exist between monkey and human ears. Work in progress is aimed at determining if monkey SOAEs are associated with cochlear pathology.

72.3 SCANNING ELECTRON MICROSCOPY OF THE COCHLEA IN RATS EXPOSED TO VARYING DURATIONS OF HIGH-INTENSITY, BROAD-BAND NOISE.
M.S. Wallace*, J.E. Penny, C.M. Henley*, K.A. Purdy* and R.D. Brown, Departments of Anatomy and Pharmacology, L.S.U. Sch. of Med., Shreveport, LA. 71130

The organs of Corti (OC) of Sprague-Dawley rats exposed to varying durations of high-intensity, broad-band noise (2 school bells ringing at 124 dB SPL) were examined by scanning electron microscopy (SEM). The rats were divided into eight groups (G) of noise exposure (1/5 the noise given daily for 5 consecutive days): G-1 (7.5 min); G-2 (10 min); G-3 (15 min); G-4 (25 min); G-5 (50 min); G-6 (75 min); G-7 (120 min); G-8 (0 min).

Cochleas from each group were examined 21 or 28 days post noise exposure. Each rat was perfused through the heart with 3% buffered glutaraldehyde and the cochleas removed and stored in the perfusate over night. After rinsing with water, the temporal bones were post-fixed for one hour in osmium tetroxide, decalcified in EDTA, then dehydrated to 70% ethyl alcohol for microdissection. After microdissection, the entire organ of Corti (OC) was prepared for SEM.

The OC contained damage in proportion to the length of noise exposure. Animals exposed to short noise durations (the 7.5, 10, and 15 minute groups) had minor damage while animals exposed to long durations of noise (the 25, 50, 75 and 120 minute groups) had more extensive damage. Hair cell loss and stereocilia loss, elongation, clumping and/or fusion was most extensive in the long duration groups. Inner hair cells were affected first and sustained more damage than outer hair cells. For this particular noise stimulus, the basal turn contained more damage than the hook, middle turn, and apex at similar durations of noise exposure. Headplate (HP) damage in the short duration groups was slight with the HPs being curved in different areas; however, in the long duration groups, up to 100% of the HPs were sloughed off and replaced by supporting cells. A smaller, yet progressive increase in damage was seen in the short duration groups.

Animals studied at 28 days post noise exposure (dpe) in the 25 and 120 minute groups exhibited more damage than the 21 dpe animals of the same groups. It seems likely that cells which appeared to be only damaged in the 21 dpe group were actually dying, because by 28 dpe, more damage was apparent. However, there was little difference in the damage sustained in the 21 vs. 28 dpe animals in the 7.5 and 10 minute groups. It seems likely that cells in the 21 dpe groups were insufficiently damaged to cause cell death great enough to manifest itself in the 28 dpe animals, or that healing had occured.

These data show morphologically demonstratable damage to the OC with increased durations of exposure to high intensity, broad-band noise. Furthermore, the extent of cochlear damage in long exposure times is not complete until at least 28 days after noise exposure. (Supported in part by The Deafness Research Foundation)

72.4 DOSE-EFFECTS OF GENTAMICIN IN NOISE EXPOSED RATS.
C.M. Henley†, R.D. Brown†, J.E. Penny¶ and M.S. Wallace*¶. Depts. of Pharmacology† and Anatomy¶, LSU School of Medicine, Shreveport, LA 71130.

Ototoxic interaction between aminoglycoside antibiotics and noise has been studied in the guinea pig. Studies of this interaction are lacking in the rat. The purpose of this study was to investigate the dose effects of gentamicin (GM) and noise on cochlear function in the rat. The experiments employed the following 8 groups (G). In each group (n=10): GIa - GM 50 mg/kg/d; GIb - GM 100 mg/kg/d; GIc - GM 150 mg/kg/d; GId - Saline only; GIIa - Noise then GM (N/GM) 50 mg/kg/d; GIIb - N/GM 100 mg/kg/d; GIIc - N/GM 150 mg/kg/d; GIId - N/Saline. The indicated doses were divided into 3 equal doses and administered i.m. every 8 hours for 10 days. Rats in GII were exposed to broad band noise (124 dB SPL peak intensity) 90 seconds/day for 5 days prior to GM or Saline treatment. Cochlear round window membrane recordings were assessed 28 days post noise exposure and 18 days post drug treatment. All recordings were made on day 29 of the experiment.

Depressions of auditory nerve action potentials (N_1) and the a.c. cochlear potentials (ACCP's) produced by gentamicin alone bore a direct relationship to dose of the drug, with larger depressions being produced as the dose of gentamicin was increased. Noise/Saline treatment significantly depressed N_1 potentials (compared to Saline alone); with no effect on the ACCP's at 4, 12 and 20 kHz. The combined effects of noise and low dose gentamicin on N_1 and on the ACCP's at 4 kHz were significantly greater than those due to noise or gentamicin alone, demonstrating a classical noise-drug ototoxic interaction. The lack of interaction of noise and low dose gentamicin on the higher frequencies (12 and 20 kHz) was due to the noise used; noise of this duration and intensity has little effect on the areas of the cochlea corresponding to the higher frequencies. There was no detectable interaction between noise and the two higher doses of gentamicin; this was due to these doses producing an overwhelming cochlear toxicity by themselves. The effect that noise had on this dose-effect relationship is relatively straightforward, if one recalls two facts: 1) N_1 is the most susceptible indicator of noise trauma and 2) the 4 kHz region of the cochlea appears to be most susceptible to noise-induced damage. Thus, in these experiments, it is probable that noise trauma to a frequency-selective area of the cochlea facilitated entry of gentamicin into that area of the cochlea.

72.5 SALICYLATE-RELATED CHANGES IN INTRACOCHLEAR CALCIUM AS A CAUSE OF AUDITORY DYSFUNCTION.
P.J. Jastreboff*, M.M. Jastreboff*, R. Hansen*, and C.T. Sasaki. Depts. of Surgery and Pharmacology, Yale Univ. School of Medicine, New Haven, CT 06510.

Both the coupling of stereocilia to the tectorial membrane and the rigidity of ciliary anchoring to hair cells are crucial to normal cochlear micromechanics. According to previous theories, partial de-coupling and/or loss of ciliary stiffness may result in tinnitus, recruitment, or disorders in speech perception. We hypothesize that salicylate-related auditory dysfunction, particularly tinnitus of cochlear origin, may result from salicylate-induced changes in calcium concentration within perilymphatic fluids. Our hypothesis is based upon observations that: i) salicylates, which are known to cause tinnitus, evoke their activity on the auditory system at the level of the cochlea; ii) administration of salicylates decreases serum calcium; and iii) decrease of calcium concentration in perilymph results in de-coupling of stereocilia from the tectorial membrane as well as decreased stiffness of ciliary anchoring.

To test our hypothesis, we performed the following set of experiments. Guinea pigs and rats were anesthetized with pentobarbital (50 mg/kg). Samples of blood, cerebrospinal fluid and perilymph were taken at different times after i.p. injection of sodium salicylate (464 mg/kg) and evaluated for total calcium by means of the Atomic Absorption Method, or for free calcium by a calcium selective electrode. After salicylate administration, the level of total and free calcium in serum, cerebrospinal fluid and perilymph decreased to about 80% of control values, although with different time courses. Characteristics of cochlear microphonics and whole nerve action potential were measured before and two hours after salicylate administration. Before salicylate, the characteristics were linear for low levels of stimuli and showed saturation for high levels. After salicylate, microphonic characteristics showed recruitment-type nonlinearities for low levels of stimuli. In identical experimental situations, recordings of spontaneous activity of single cells residing in the inferior colliculus and lobulus V of the cerebellar vermis revealed increased spontaneous activity in the inferior colliculus as contrasted with no change in the cerebellum.

Our data support the hypothesis that salicylate may influence the auditory system by decreasing calcium concentration in cochlear fluids, resulting in de-coupling of cilia from the tectorial membrane and/or decreasing the stiffness of ciliary anchoring to hair cells, thereby affecting the mechano-electrical transduction properties of the cochlea. (Supported by NIH Grant #NS22024)

72.6 ACTION OF SALICYLATE ON THE ACTIVITY OF AFFERENT FIBERS IN THE XENOPUS LAEVIS LATERAL LINE.
R.P. Bobbin, S. Bledsoe, Jr., and G. Ceasar*. LSU Medical School, Dept. of Otorhinolaryngology and Biocommunication, Kresge Hearing Research Lab. of the South, New Orleans, LA 70119 and Kresge Hearing Research Institute, Univ. of Michigan Medical School, Ann Arbor, MI 48109.

The mechanism for the reversible hearing loss induced by aspirin is unknown. Salicylate suppresses the compound action potential and single fiber activity of the auditory nerve with no effect on cochlear microphonics (Bobbin and Thompson, Ann. Otol. Rhinol. Lar. 87:185-190, 1978; Evans et al., In: Tinnitus, Ciba Foundation Symposium 85, pp. 108-138, 1981). We examined the action of salicylate on the isolated lateral line of Xenopus laevis to explore further the mechanism of action of salicylate at the hair cell-afferent nerve fiber junction.

The compounds were dissolved in a frog Ringer solution and then applied to the serosal surface of an isolated frog lateral-line stitch utilizing techniques previously described (Bledsoe and Bobbin, Neurosci. Lett., 32:315-320, 1982).

Sodium salicylate (0.3-2.5 mM) reversibly suppressed the spontaneous activity of the lateral line nerve and the increase in spontaneous activity evoked by kainate (10-20 μM) and glutamate (1-2 mM). Salicylate had little (10%) effect on the magnitude of the difference between spontaneous activity and the excitation induced by water motion. After washing out the salicylate the excitation to kainate, glutamate and water motion were greater than their responses before salicylate.

In previous studies it was found that glutamate and kainate induce excitation in the presence of low calcium/high magnesium, demonstrating an action postsynaptically on the nerve. Together these results indicate that salicylate acts on the nerve to suppress spontaneous activity and the responses to kainate and glutamate, but not water motion. Future experiments will test salicylate against NMDA, quisqualate and other agonists.

72.7 POTASSIUM GRADIENTS IN SCALA TYMPANI OF THE GUINEA PIG IN THE ABSENCE OF SOUND STIMULATION. P. Dulguerov*, M. Zidanic*, W.E. Brownell and G.A. Spirou*. Dept. of Otolaryngology-HNS, Neurosciences and Biomedical Engineering, John Hopkins Medical School, Baltimore, MD 21205.

Potassium-sensitive electrodes and current density analysis techniques were used to assess potassium activity gradients in scala tympani of the guinea pig cochlea.

The presence of a high extracellular potassium concentration in endolymph (150mM) coupled with the positive endocochlear potential (+80mV) constitute chemical and electrical gradients that drive potassium out of scala media and into the surrounding perilymphatic and intracellular spaces. Ionic outflow is restricted by tight junctional complexes located at the apexes of all cells bordering scala media. Tracer flux experiments (Konishi & Salt, Exp. Brain Res. 40:457) suggest that the receptor cells of the organ of Corti are one of the major pathways of potassium efflux from scala media. This hypothesis would be supported by the existence of potassium gradients in scala tympani with the maximum potassium activity near the organ of Corti.

Double-barrelled potassium-sensitive microelectrodes of the liquid membrane type, using potassium-tetra-p-cholorophenylborate as an ion-exchanger, were made according to the method developed by Coles and Tsacopoulos (J. Physiol. 270:12-14P, 1977). The micropipettes were introduced through a 50-150µ fenestration in the bony otic capsule into scala tympani of the third turn of the guinea pig cochlea. DC potentials and changes in K+ activity were measured along a radial track parallel to the basilar membrane. The potassium activity was obtained by subtracting the DC potential recorded by the reference barrel from the signal of the potassium barrel. Potassium activity gradients were computed using the first derivative of the potassium activity profiles (Brownell et al., J. Acoust. Soc. AM. 74:792).

Preliminary results have confirmed the radial standing currents described in our laboratory (Zidanic et al. ARO abstract #114,1984) and have shown an increase in potassium activity in the perilymphatic spaces beneath the organ of Corti. A biological origin of these potassium gradients is indicated by their disappearance postmortem.

72.8 POSTNATAL DEVELOPMENT OF THE CORTI-ORGAN IN GERBILS. V. Bruns*, S. Anton, Ch. Wied, B. Gottschalk and W. Plassmann. Zool. Dept. Univ. Frankfurt, D-6000 Frankfurt/M. (* Sponsor: G. Neuweiler)

In mammalian cochlear ontogeny, both the structure-function relation and the differentiation of the developmental pattern in baso-apical direction were unclear. This study attempts to shed some light on these aspects. Gerbils were chosen for two reasons: (1) hearing begins late after birth, which makes the animal suitable for postnatal analysis; (2) the cochlea is morphologically specialized, which provides ample opportunity to study the development of these specializations during ontogeny. The structure of the Corti-organ was studied in 7 postnatal stages during 4th-28th day after birth (DAB) as well as in adult animals, by analyzing semi-thin sections of 10 equidistant locations in the cochlea of each animal. The daily changes in the hearing thresholds were recorded by means of cochlear microphonics during 16th-25th DAB and compared with those of adult.

Hearing begins in gerbils on the 16th DAB and the auditory threshold curve at that age shows maximum sensitivity in the frequency range of 10 kHz and an upper frequency limit of 20 kHz. Development towards the adult stage reveals an expansion of the high-frequency range from 20 kHz to 40 kHz and an extraordinary sensitivity increase at about 2 kHz. Both length and width of the basilar membrane reach their final values as early as on the 12th DAB. After the 16th DAB, changes occur only in the fine structure of the Corti-organ. The filaments of the basilar membrane, for instance, are predominantly formed between the16th and 24th DAB, which strengthens the membrane`s stiffness and makes a shift towards higher frequencies likely.

As early as on the 4th DAB, the stereocilia of the outer hair cells have the same length throughout the cochlea. Starting with the 8th DAB, they grow in length towards the apex and reduce in length towards the basis. These factors can be assumed to shift local mechanical resonance on the basilar membrane. During their postnatal development, the special cochlear structures of adult gerbils- e.g. the conspicuous thickness of the basilar membrane and the mass of the tectorial membrane- grow disproportionately in the upper middle region of the cochlea. Since the final forms of these structures can be correlated with the 2 kHz frequency range on the basilar membrane, it is suggested that their functioning as resonators may explain the remarkable sensitivity of adult gerbils with respect to low frequencies.

72.9 DEVELOPMENT OF HAIR CELLS: LOCATION-SPECIFIC PATTERNS OF CILIA NUMBER, CILIA LENGTH, AND BUNDLE ORIENTATION DIFFERENTIATE AFTER DENERVATION AND TRANSPLANTATION OF EMBRYONIC COCHLEAE. J. T. Corwin and D. A. Cotanche. Dept. of Zoology and Bekesy Lab., Univ. of Hawaii, Honolulu, HI 96822 and Dept. of Otolaryngology, Med. Univ. of South Carolina, Charleston, SC 29425.

Work in several laboratories, in particular work by Tilney and colleagues, has demonstrated that hair cells develop ultrastructural phenotypes that are specific for each hair cell location in the basilar papilla of the chick cochlea. Hair cells express these individual phenotypes in the form of sensory cilia bundles that differentiate by embryonic day 9-10, simultaneously with the first extensive formation of afferent synapses in this epithelium.

The dependence of hair cell differentiation on synatogenesis was tested by transplanting 43 surgically denervated otocysts from donor chick embryos onto the chorioallantoic membranes of host embryos. Transplants were then grown for twelve days before they were fixed. The basilar papillae from the experimental ears and from control ears transplanted with innervation intact were examined by scanning electron microscopy. Denervated cochleae that were transplanted on embryonic day 5 contained thousands of hair cells with cilia bundles that were indistinguishable from those in normal embryos at equivalent chronological stages. The transplanted papillae were much shorter and wider than those from normal embryos, but at each level in the base-to-apex axis of the cochlea the cilia bundle characteristics were appropriate for the hair cells at that relative position in a normal cochlea. The hair cell cilia bundles were uniformly oriented as in normal cochleae. They also developed the normal gradients of cilia length and number. Hair cells at the bases of the denervated cochleae possessed short cilia bundles with more than 200 stereocilia on each cell surface; those at the apexes possessed longer cilia bundles with as few as 40 cilia on each cell; and cells in intermediate positions had intermediate cilia lengths and numbers that graded between those extremes just as in normal cochleae.

The massive formation of synapses that occurs on embryonic days 9 & 10 is not necessary to trigger or to instruct hair cells that participate in the location-specific differentiation of cilia bundles that occurs on days 9 & 10. However, it is possible that the presence of the nerve before denervation at stage 25 (Embryonic Day 5) has influences that last until days 9 & 10. It is also possible that the factors that control the development of these location-specific features may relate to location themselves, this hypothesis is suggested because the ultrastructural gradients in transplanted basilar papillae develop normally for each relative location in the base-to-apex axis of the cochlea even though the dimensions of those papillae were shorter and wider than those of normal papillae. (Supported by grants from NINCDS and the Deafness Research Foundation to JTC and a NRSA Fellowship to DAC.)

72.10 MORPHOLOGY OF GERBIL COCHLEAE AND SOUND LOCALIZATION IN MERIONES UNGUICULATUS. W. Plassmann, M. Kausch, R. Kuhn, W. Peetz and B. Gottschalk. Zoological Institute, University of Frankfurt, 6000 Frankfurt, West Germany.

The auditory system of Gerbils is particularly sensitive in the range of medium and low frequencies. Comparative study of serial sections through the cochleae of Meriones unguiculatus, Meriones tristrami, Psammomys obesus, Pachyuromys duprasi and Tatera spec. reveals - among other things - that the basilar membranes of these Gerbils are by far longer, wider and thicker than those of rats, whereas the number of acoustic neurons in the nerve VIII is inferior to that of rats. Comparison of the above Gerbil species with each other also shows morphological differences in cochlea structure which are partly reflected by the different 1 uV CM-isopotential curves.

Localization of sound might be problematic in Gerbils because their small heads are of limited value for the measuring of intensity and time differences. Behavioral studies of sound localization showed, that Meriones unguiculatus is well able to localize sound sources both in low and high frequency ranges, exept for frequencies between 4 and 5 kHz. Experiments involving delivery of stimuli of different shapes indicate that the animals may evaluate phase differences in the frequency range below 4 kHz. CM-potential recordings under the condition of stimulus presentation from different directions yield the following two results: (1) A sound shadow exceeding 6 dB occurs only in the frequency range above 4 kHz; (2) phase differences smaller than 180 , which are necessary for correct evaluation of sound directions, can only be obtained in the frequency range below 3 kHz. The maximum interaural time differences calculated from the phase differences for individual frequencies reach values of 120-160 usec. The difficulty of sound localization in the range of 4-5 kHz may be explained by the following physiological findings: the phase differences above 3 kHz exceed 180 and therefore prevent directional hearing based on evaluation of phase differences; it is only above 4 kHz that the intensity difference due to sound shadow effects is large enough to permit directional hearing. Thus, the frequency range around 4 kHz appears to constitute the transitional zone between the two types of evaluations.

Supported by the Deutsche Forschungsgemeinschaft/SFB 45.

72.11 HAIR-CELL INNERVATION BY SPIRAL GANGLION CELLS IN ADULT MICE. A.M. Berglund* and D.K. Ryugo. Dept. of Anatomy & Cellular Biology, Harvard Med. School, Boston, MA 02115, and Eaton-Peabody Lab, Mass. Eye & Ear Infirmary, Boston, MA 02114.

The mammalian cochlea contains two types of acoustic receptors: inner (IHCs) and outer (OHCs) hair cells. HRP methods have shown that in adult cats, type I spiral ganglion cells innervate IHCs, while type II ganglion cells innervate OHCs (Kiang, N.Y.S. et al., Science 217:175, 1982). In contrast, Golgi descriptions in neonatal rodents have suggested that a single ganglion cell can innervate both receptor types (e.g., Lorente de No, Laryngoscope 47:373, 1937). The present study sought to determine whether the innervation of both receptor types by a single neuron reflected maturational or species differences.

Individual spiral ganglion cells (n=34) in adult mice were labelled using HRP-DAB methods and reconstructed through serial sections from their cell bodies to their peripheral terminations. All ganglion cell somata are bipolar in shape and roughly similar in size. Type I neurons (n=21) emit peripheral processes that are very thin (~0.5 um) in the vicinity of their somata. Within 25 um of the cell body, each process abruptly thickens and maintains a relatively constant diameter (1-1.4 um) as it travels radially and unbranched through the osseous spiral lamina. After passing through a habenular opening, the fiber becomes thinner. Most (19) contact a single IHC via one terminal swelling. Two fibers branch: one forms two terminals against the same IHC, while the other sends a terminal to each of two adjacent IHCs. In contrast, type II neurons (n=13) emit peripheral processes that exhibit a maximum diameter in the vicinity of the cell body. These processes gradually become thinner as they project radially through the osseous spiral lamina, but reach a relatively constant diameter (~0.4 um) as they pass through the IHC region. They cross the tunnel of Corti at low levels before entering the OHC region; then they turn basally and spiral for up to 500 um before emitting short collaterals with bouton-like endings to 3-10 OHCs.

In conclusion, no ganglion cell innervates both types of acoustic receptors in the adult mouse. Previous observations of IHCs and OHCs innervated by the same neuron in neonatal rodents is presumed to represent a transient developmental characteristic. The segregated innervation of IHCs and OHCs by type I and type II ganglion cells has now been shown for several species, and may therefore reflect a generalized plan of afferent organization for the mammalian cochlea.

SENSORY SYSTEMS: AUDITORY PATHWAYS II

73.1 **COMPARISONS OF SYNAPTIC INPUTS TO THE CENTRAL NUCLEUS OF THE INFERIOR COLLICULUS FROM THE ANTEROVENTRAL AND DORSAL COCHLEAR NUCLEUS.** D. L. Oliver and C. Krevolin*, Dept. of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

Neurons in the central nucleus of the inferior colliculus (ICC) integrate acoustic ionformation from the cochlear nucleus, the superior olivary complex, and the lateral lemniscal nuclei. The response of a neuron in the ICC to sound depends, in part, upon which sources provide the most numerous inputs. Since the subdivisions of the ICC may receive different combinations of ascending inputs, it is important to determine the relative contribution of axonal endings from afferents which synapse in that subdivision. In the present study, we used EM autoradiography to visualize axonal endings in the ICC after small injections of 3H-leucine and/or 3H-proline in the anteroventral (AVCN) and dorsal (DCN) cochlear nucleus of the cat. Samples were from regions of the ICC in which heavily labeled bands of afferents were identified in adjacent LM autoradiography sections. The hypothetical grain procedure was used to verify significant labeling and identify radioactive sources.

Axonal endings in the ICC from both the AVCN and DCN contained round synaptic vesicles and are probably excitatory. After injections, labeled endings in both contralateral and ipsilateral pars lateralis of the ICC were densely packed with small-to-medium sized, round synaptic vesicles and made one or two asymmetric synaptic contacts on dendritic shafts. Less often, synapses with labeled endings occurred on smaller dendritic processes or on cell bodies and primary dendrites. Endings in these samples were labeled with 1.9-2.9 grains/um^2 and contained 29-40% of the radioactivity. Unmyelinated axons also were labeled routinely. Injections in the DCN produced comparable labeling of axonal endings in the contralateral pars medialis and centralis of the ICC. Synaptic vesicles in these endings averaged 47 nm or less.

Although axonal endings with round synaptic vesicles represent 60% of all endings in the ICC, they may originate from different sources in each subdivision. For example, pars lateralis receives bilateral projections from the AVCN but lacks projections from the DCN. The AVCN projections may account for a third of all round-vesicled endings with nearly equal numbers from both sides. These endings could contribute to bilateral excitation in time-sensitive units found in pars lateralis. In contrast, pars centralis and medialis receive direct projections from the contralateral AVCN and DCN which account for about 25% of the round-vesicled endings. These projections could contribute to contralateral excitation in the central and medial ICC.

73.2 DISCRETE BILATERAL GABAERGIC NEURON POOLS AT THE COMMISSURES OF SUPERIOR AND INFERIOR COLLICULI IN THE RAT. D. E. Vetter and E. Mugnaini, Lab. of Neuromorphology, Univ. of Conn., Storrs, CT 06268

Immunocytochemical stains provide useful vistas of brain organization by highlighting special neuronal pools and pathways that lack distinctness in standard histological sections. Using a serum against glutamic acid decarboxylase (GAD), the synthetic enzyme for the inhibitory neurotransmitter GABA, we have observed discrete and sizeable assemblies of GABAergic neurons situated at the commissures of the superior (SC) and inferior (IC) colluculi in rat. Sprague-Dawley rats were perfused with a zinc-aldehyde fixative. Frozen serial sections of the brain stem cut in the three standard planes were immunoreacted with a double PAP procedure using the sheep antiserum to rat brain GAD obtained by Oertel et al., (1981). In the paramedian region where the ICs are joined at the midline two bilateral cell groups made up of small neurons appeared immunostained. One of these cell groups is situated rostrally and laterally in the commissure of the IC and occupies a triangular region bordered dorsally by the pia, and laterally by the external cortex of the IC. The other cell group is more extensive and appears prominent at all levels of the IC. The cells show orientation of their dendritic arbors, which are flattened in the sagittal plane where they are traversed by bundles of commissural fibers. Ventrally and caudally this group is contiguous, if not continuous, with the dorsal portion of the periaqueductal grey matter (PAG) which also contains numerous GABAergic small neurons. The paramedian region of the superior colliculus is also populated by numerous neurons. GAD-immunostaining of the superficial grey layer, including the stratum zonale is strikingly dense and this helps distinguish the laminated parts of the superior colliculus. A bilateral subcortical assembly of closely packed small GABAneurons is present at the medial edges of the intermediate and deep grey layers of SC. Sagittal sections suggest that the median GABAergic cell groups of SC and IC may form a continuous cell column. Numerous GABAergic terminals are present in the neuropil pertaining to these cell groups, but the source of this inhibitory input is not known.

A battery of traditional and immunocytochemical methods will be necessary to characterize further these discrete assemblies of GABAergic neurons and to determine whether they constitute definite nuclear subdivisions deserving separate names.

73.3 COMMISSURAL CELLS OF THE EXTERNAL NUCLEUS OF THE RAT INFERIOR COLLICULUS: NEURONAL ARCHITECTURE AND CELLS OF ORIGIN. K.D. Games, M.C. Townsley*, and J.A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

The external nucleus (ICX) of the inferior colliculus (IC) has somatic sensory as well as auditory functions, receiving axons from dorsal column and pontine nuclei, and projecting to the superior colliculus and thalamus. We characterized ICX cells participating in the intercollicular commissural system of the inferior colliculus.

Neurons in the rat ICX were studied in Golgi preparations and in Nissl stained material. The ICX formed the lateral rind of the inferior colliculus and was bordered dorsally by the dorsal cortex and medially by the central nucleus. The ICX was distinguished from the dorsal cortex, whose cells often had smaller somata and dendritic fields, and from central nucleus cells, which had disc-shaped dendritic fields and formed fibrodendritic laminae. We subdivided the ICX into dorsal and ventral parts. In Nissl preparations, the ventral part had significantly larger somata (mean: 113 sq. μm, s.d.: 52) than the dorsal part (mean: 72 sq. μm, s.d.: 32; $p<0.01$). The dorsal part had more cells per unit area.

We made pressure injections of 15-30% horseradish peroxidase in the contralateral IC. TMB-labeled somatodendritic profiles in the ICX were correlated with the cells identified in Golgi preparations. Multipolar cells had three or more dendrites radiating from the cell body. Bipolar cells had two primary dendrites emerging from the somatic poles. Projection cells included small, medium-sized, and large bipolar cells and medium-sized and large multipolar cells. The small multipolar cells were not identified in our TMB-reacted material. Most commissural cells were medium-sized (72%; 81-201 sq. μm) or large (23%; >201 sq. μm). Small cells (<81 sq. μm) constituted only 5% of labeled cells. The mean somatic area of commissural cells was 148 sq. μm (s.d.: 68). We found no significant difference in somatic size or in the form of labeled cells between the dorsal and ventral parts of ICX; however, the dorsal part contained more labeled cells.

In summary, bipolar and multipolar cells are the principal commissural neurons of the ICX. Besides their commissural projections, many of these cells could project to the thalamus, auditory brain stem, and participate in the intrinsic organization of the IC. This suggests that, whatever the functional role of the external nucleus in the commissural system, it may differ from the commissural pathways of the dorsal cortex and central nucleus.

73.4 EFFECTS OF GABA ON INFERIOR COLLICULUS NEURONAL RESPONSES TO ACOUSTIC STIMULI. C.L. Faingold, G. Gehlbach* and D.M. Caspary (SPON: H.R. Konrad). Dept. Pharmacology Southern Illinois University, School of Medicine, Springfield, IL 62708

The responses of inferior colliculus (IC) neurons to acoustic stimuli in many cases exhibit periods of suppressed firing. Recent evidence indicates that IC neurons exhibit processing of acoustic input beyond that seen in more caudal auditory nuclei. Intracellular studies have reported that inhibitory postsynaptic potentials are involved (Nelson and Erulkar, J. Neurophysiol. 26:908-923, 1963). Neurotransmitter mechanisms which may subserve inhibition in the IC are not well established. High levels of GABA as well as the enzymes which synthesize and metabolize GABA are present in IC, and GAD-immunoreactive terminals on IC neurons are observed which may arise, in part, from projections of the dorsal nucleus of the lateral lemniscus (Adams and Mugnaini, Brain Res. Bul. 13:585-590, 1984). Release of GABA from IC has been demonstrated in vitro. This study was initiated to examine the criteria of mimicry and pharmacological identity for establishing GABA as an inhibitory neurotransmitter in the IC. Sprague-Dawley rats were initially anesthetized with ketamine and subsequently paralyzed with gallamine treithiodide and respired. The animal's comfort was maintained using a semichronic adapter with local anesthetic infiltration. Response patterns at characteristic frequency were evaluated using poststimulus time histogram analysis. Iontophoretic application of GABA inhibited the firing of most IC neurons. The effect was rapid in onset, occurred in a large majority (over 90%) of neurons in the central nucleus of IC and showed a rapid offset. Of the other putative inhibitory neurotransmitters reported to be present in IC (Guth and Melamed, Ann. Rev. Pharmacol. Tox. 22; 383-412, 1982) glycine also produced inhibition with a rapid onset and offset but was less potent than GABA. Norepinephrine and 5-hydroxytryptamine were much less effective at producing inhibition and usually displayed a much longer time of onset. The benzodiazepine, flurazepam, which is postulated to act at the GABA receptor complex inhibited IC neuronal firing and enhanced the action of GABA. The inhibitory action of iontophoretically applied GABA was enhanced by simultaneous application of the GABA uptake inhibitor, nipecotic acid. Nipecotic acid also directly enhanced stimulus-induced inhibition in certain cases. The action of exogenously applied GABA was blocked by the GABA receptor antagonist, bicuculline. Binaural ihibition could also be blocked by the application of bicuculline in doses which did not affect the monaural response. These data taken with the neurochemical and release data support a role for GABA as an important inhibitory neurotransmitter in the inferior colliculus.

73.5 RESPONSES OF INFERIOR COLLICULUS NEURONS TO HIGH- AND LOW- FREQUENCY NOISE BANDS IN C57BL/6 MICE WITH AGE-RELATED HEARING LOSS. J.F. Willott and K.P. Hunter*. Dept. of Psychology, Northern Illinois University, DeKalb, IL 60115.

During the first year of life, C57BL/6 mice undergo progressive peripheral hearing loss, predominantly for high frequencies. Extracellular single-unit responses were obtained from the central nucleus of the inferior colliculus (ICC) of anesthetized mice of 3 age groups: 1-mo.-old (optimal sensitivity), 7-mo.-old (moderate hearing loss), and 12-mo.-old (severe hearing loss). Recordings were obtained at approximate 200μm dorsoventral intervals, sampling the low- to high-frequency tonotopic axis. Two noise bands, 12kHz low pass (LP) and 12kHz high pass (HP) were used as stimuli (duration 200ms, 2.5Hz rate). Post-stimulus time histograms were obtained at 10 dB intensity steps from a maximum of 80 dB SPL to below unit threshold.

Response properties of ICC neurons changed across age, but the changes depended on the stimulus employed (HP vs. LP) and the dorsoventral depth of the neurons.

(1) In 1-mo.-olds, the shortest latencies were evoked by HP stimuli. Latencies tended to be shorter ventrally than dorsally. With aging, there was little change in the latencies of responses to LP stimuli, but latencies to HP stimuli tended to increase. The increase in HP latencies was more pronounced in the ventral ICC.

(2) The incidence of neurons with nonmonotonic intensity functions (presumably an indication of inhibition) decreased with aging. In 1-mo.-olds, there were more neurons with nonmonotonic intensity functions dorsally than ventrally, so the age-related decrease in nonmonotonic functions was most pronounced in the dorsal ICC. The stimulus also influenced the effects of aging on nonmonotonicity: In 1-mo.-olds, more nonmonotonic functions were associated with HP stimuli than with LP stimuli; in 7-mo.-olds, HP and LP stimuli were about equally capable of producing nonmonotonic functions; by 12 months, more nonmonotonic intensity functions were produced by LP stimuli than by HP stimuli.

(3) In 1-mo.-olds, the incidence of spontaneously active neurons was greatest in the ventral ICC. With aging, the incidence of spontaneously active neurons increased in the dorsal ICC, but not in the ventral ICC.

In summary, the effects of aging and/or hearing loss on the responses of ICC neurons are different in high frequency regions (ventral) and low frequency regions (dorsal) and depend on whether high or low frequency stimuli are used. A full understanding of the effects of peripheral hearing loss on central neuronal responses must take both factors into account.

73.6 BINAURAL RESPONSES OF SINGLE NEURONS IN THE INFERIOR COLLICULUS OF THE UNANESTHETIZED RABBIT. T.R. Stanford*, R. Batra and S.Kuwada (SPON:G.Maxwell). Department of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

Most electrophysiological studies of the auditory system have used an anesthetized preparation. Since anesthetics have a powerful effect on synaptic transmission, we felt it essential to examine the responses of auditory neurons in an unanesthetized animal. Of the few studies that used an unanesthetized preparation, most employed free-field stimuli. Free-field stimuli are useful for determining functional features of neuronal responses, but, they do not provide the stimulus control necessary to study neuronal mechanisms, especially those involved in binaural interactions. We chose the rabbit because of its willingness to remain still with minimal restraint. To achieve stimulus control we used earmolds which allowed acoustic stimuli to be presented to each ear independently. We report preliminary results on the responses of single neurons in the inferior colliculus (IC) of the unanesthetized rabbit.

Under general anesthesia the skull was exposed and a steel rod cemented to the bone. A hole was drilled for electrode entry and capped with Silastic. Prior to recording, the rabbit was placed in a stocking and its head immobilized by clamping the steel rod. The Silastic was removed, dura swabbed with lidocaine, and an electrode placed using approximate stereotaxic coordinates.

Although studies have found changes in spontaneous rate and tuning characteristics, little is known of the effects of anesthesia on binaural interactions. We examined the responses of binaural neurons to changes in interaural phase, interaural time and interaural intensity differences. Some low frequency neurons showed interaural phase sensitivity. This was demonstrated by a discharge rate that varied cyclically as a function of interaural delay with a period corresponding to the stimulating frequency and also by a cyclic response to sinusoidal changes in interaural phase created by delivering slightly different frequencies to each ear. Some high frequency neurons were sensitive to changes in interaural intensity. These cells were contralaterally excited and ipsilaterally inhibited, and their discharge was dependent upon the relative intensities of the stimuli at each ear.

Our preliminary findings indicate that IC neurons in this preparation show a sensitivity to interaural phase and intensity similar to that seen in anesthetized mammals. However, our sample is too small to draw definitive conclusions. The unanesthetized rabbit avoids potential confounding effects of anesthesia. It also permits repeated sampling of neuronal responses within a nucleus as well as comparison of the responses of neurons at different stages of sensory processing within the same animal.

73.7 RESPONSE LATENCIES IN THE INFERIOR COLLICULUS OF THE CAT: ANOTHER EVIDENCE FOR AN AUDITORY PERIODICITY MECHANISMS. G. Langner and C. Schreiner*.
Zoological Institut, Technical University, 61 Darmstadt, FRG and Coleman Lab., University of California, San Francisco, CA 94143

Neurons in the auditory midbrain nucleus MLD of the Guinea fowl are involved in periodicity analysis (Langner, G.,Exp.Brain Res. 44:450, 1981, and 52: 333, 1983). Using sinusoidal amplitude modulations as simple models of complex periodic signals, many units in the MLD were found to be tuned to certain best modulation frequencies (BMF < 1000Hz), related to neuronal oscillations triggered by the AM cycles, and influenced to a certain degree by the carriers (in the range of phase coupling below 5kHz). These observations resulted in a temporal model for periodicity processing suitable also for the explanation of certain pitch effects in human subjects. The model is supported by additional results obtained in the IC of the cat (Schreiner, C. and Langner G., Soc. Neurosci. Abstr. Vol. 10, Part 1, p. 395, 1984). Further evidence for central periodicity analysis in vertebrates now comes from the observation of AM tuning of units in the midbrain of frogs (Rose, G. and Capranica, R.R. Science 219: 1087, 1983).

According to the periodicity model AM tuning of units in the midbrain may be explained by coincidence mechanisms involved in a cross correlation analysis between envelope and fine structure of periodic signals, resp. in an auto correlation of the envelope for carrier frequencies above 5kHz. As demonstrated for the central nucleus of the IC of the cat such AM tuned units are arranged on each isofrequency lamina in a concentric BMF map.

Additional evidence for temporal processing of periodicity comes from the measurement of response latencies together with CF and BMF in 637 recordings. Latencies were measured using tone bursts with frequencies at CF, 2ms rise time, and 60dB above the thresholds of the units. Temporal mechanisms are connected with delays and were consequently expected to have some influence on the neuronal latencies. In the present investigation latencies varied typically between 4 and 25ms. When BMF as a neuronal parameter was neglected the averaged latency appeared to depend strongly on CF. This is explained by the fact, that BMF averaged over all units with the same CF increased with CF. On the other hand using the periods $\tau_{CF} = 1 / CF$ and $\tau_{BMF} = 1 / BMF$ as variables a multiple lineal regression analysis resulted in a significant approximation ($r = 0.46$, $p = 0.05$, $n = 637$):

Latency $= (7.1+0.9)ms + (1.2+0.2) * \tau_{CF} + (0.16+0.03) * \tau_{BMF}$.

The contribution of BMF was much greater than that of CF, because on the average τ_{BMF} was 60 times greater than τ_{CF}. The contribution of CF may be a good approximation of the delay introduced by the cochlear mechanics. (Supported by the Heisenberg program of the DFG, NIH Grant NS-10414, the Coleman Fund and HRI.)

73.8 EFFECTS OF FRICATIVE AMPLITUDE ON CAT MEDIAL GENICULATE BODY (MGB) NEURON RESPONSES TO PLOSIVES IN FRICATIVE-PLOSIVE SEQUENCES. J.V.Urbas* and H.Spenner* (SPON: K.Albus). Dept. Neurobiology, Max-Planck-Inst. for Biophysical Chemistry, 3400 Göttingen, FRG.

Perception of stop consonants (plosives) depends on a preceding silent interval corresponding to articulatory closure (Dorman et al., J.Acoust.Soc.Am. 65:1518, 1979). If the silent interval between sibilant (fricative) and following plosive is removed, the plosive is no longer heard (e.g. spin is heard as sin). This has been interpreted as evidence for a phonetic stage in speech perception correlated with articulatory processes (Dorman et al., 1979). We previously reported that cat medial geniculate body (MGB) neuron responses to plosives in fricative-plosive (FP) sequences depend on the silent interval length (SIL) in a way similar to plosive perception by humans (Spenner and Urbas, J. Physiol. 328:39P, 1982).

The present report is based on 34 MGB neurons recorded from sodium pentobarbital anesthetized cats. All cells were located in either the laminated lateral ventral part or its dorsal cap. The signals were naturally spoken, digitally stored German words with FP sequences. The stored words were modified to have various SILs following the sibilant and also various sibilant sound pressure levels (SPLs). Thus, we copied two important parameter variations used in the paradigm of psychoacoustical forward masking.

The results show that for changes in preceding SIL and sibilant SPL, the neuron responses to plosives: 1) correspond well with results measured using simple tonal signals; 2) show good analogy to psychoacoustical results using the same word stimuli; 3) can be interpreted as evidence for involvement of subcortical auditory mechanisms in speech perception phenomena.

We conclude that special phonetic processes in speech perception are not necessary to account for plosive suppression by a preceding sibilant. Instead, evidence for the role of subcortical auditory mechanisms, analogous to those responsible for the perceptual phenomenon of forward masking, has been strengthened by our data.

73.9 TIME DOMAIN ANALYSIS OF COMPLEX SOUNDS IN THE THALAMUS OF THE NORTHERN LEOPARD FROG (Rana pipiens pipiens). J. C. Hall* and A. S. Feng. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

The mating calls of anurans show species differences in both the frequency and time domain. Females utilize these differences in their selection of conspecific males as mates. The neural correlates of this behavior apparently reside within the auditory pathway and the neural analysis of spectral and temporal acoustic cues provided by the mating calls.

The neural analysis of spectral information has been examined in detail throughout the auditory pathway. A recent study of R. p. pipiens (Fuzessery and Feng, J.Comp.Physiol., 150:333, 1983) implicated the posterior nucleus of the thalamus as an important center for call recognition in the frequency domain. On the other hand, the neural analysis of temporal information has been examined only up to the level of the auditory midbrain (Wilczynski and Capranica, Prog. in Neurobiol. 22:1, 1984). In this study, we have utilized single unit recordings and horseradish peroxidase (HRP) transport techniques to examine the physiological and anatomical substrates of temporal processing in the anuran thalamus.

The results of our study show neurons in the thalamus which respond selectively to two temporal parameters of complex sounds: the pulse repetition rate and the pulse duration. The latter is of particular interest as short duration pulses (< 10msec), approximating those of the mating call, may elicit a sustained discharge of 1-2sec from some neurons. This phenomenon represents a divergence from the classical concepts of duration coding in the central nervous system and indicates the need for their reevaluation. In addition,it also suggests that pulse duration, like pulse repetition rate, may be a critical feature for recognition. Histological verification of the recording site indicated that all of the neurons were located within the central nucleus. This is in contrast with findings (see above) demonstrating the presence of spectrally selective neurons in the posterior nucleus. Thus, temporal and spectral information may be processed in parallel by different subsets of neurons within the thalamus. This hypothesis is supported by anatomical data showing that the two nuclei have distinct afferent and efferent innervation patterns. (Supported by NSF grant BNS 82-04160 to A.S.F.).

73.10 NEONATAL DEAFENING ALTERS THE BRANCHING STRUCTURE OF NONPYRAMIDAL NEURONS IN RABBIT AUDITORY CORTEX. N.T. McMullen, B. Goldberger*, C. Suter* and E.M. Glaser. Dept. of Physiology, Univ. of Maryland School of Medicine and Dept. of Surgery, Univ. of Maryland Hospital, Baltimore, MD. 21201

The large spine-free nonpyramidal neuron is the major interneuron in lamina III/IV of the primary auditory cortex of the rabbit (McMullen, et. al., 1984). Computer microscope analyses of these cells have revealed a prominent vertical orientation of dendrites along the pia-white matter axis. In the present study, we investigated the effects of neonatal deafening on the branching pattern of these neurons in the auditory cortex. NZW rabbits (n=11), anesthetized with ether, were unilaterally deafened at postnatal day 1 (birth = day 0) by surgical removal of the incus and stapes ossicles and Kanamycin injection (330mg/ml) into the oval window. Litter mate control pups (N=5) received a sham-operation. All pups were allowed to mature until 60 days of age at which time auditory brain stem response tests (ABER) were conducted. All experimental animals exhibited the complete absence of an ABER on the side which received the neonatal surgery. Following ABER tests, the brains of both experimental and control rabbits were removed following exsanguination and processed according to Golgi Cox procedures. Alternate thick (300-400 um) and thin (75-100 um) sections through the auditory cortex contralateral to the deafened ear were processed and Nissl counterstained. Lamina III/IV spine free non-pyramidal neurons in the auditory cortex of the deafened and control rabbits were digitized at a magnification of 800x using oil immersion optics with our Image Combining Computer Microscope. Results from the deafened rabbits were compared to data from litter mate controls and normal adult rabbits. Early deafening affected the dendritic system of auditory cortical spine-free NP cells in two major ways : (1) their dendrites systems are larger and (2) there are a greater number of dendritic branches oriented parallel to the pial surface. Total dendritic length/cell in deaf animals ($\bar{X}$=4653 um) is elevated 42-50% in comparison to litter mate controls (3275 um) and normal adult rabbits (3087 um). A "fan-in" (Glaser & McMullen, 1984) analysis revealed a significant increase in the number of dendrites oriented parallel to the pial surface resulting in a 70% increase in dendritic length oriented within 30 degrees of the tangential (parallel to the pia) plane. Thus, early cochlear damage results in reorganization of the auditory pathway which extends to the cerebral cortex. (Supported by a grant from the Deafness Research Foundation and NIH Grant NS17861)

73.11 PATTERNS OF INHIBITION IN AUDITORY CORTICAL CELLS OF AWAKE SQUIRREL MONKEYS. D.Symmes and S.Shamma*.Lab.of Comparative Ethology, NICHD, Bethesda, MD 20205

We have studied inhibition in primary auditory cortical cells of awake squirrel monkeys, employing the method of single cell recording. Single tone bursts, simultaneous double tone bursts, and broad-band noise stimuli were presented under program control in a design which sampled low rate cells adequately and minimized the effect of short term response fluctuations. Inhibition was inferred from reductions in rate of extracellular spikes below background level, below excitatory response level, or both. Type A units(29%) exhibited low background activity, sharply tuned non-monotonic excitatory responses to tones, and weak responses to noise. Profound lateral or two-tone inhibition was demonstrable, which could appear both above and below BF, or asymmetrically. Type B units (26%) had high background rates and inhibitory responses to single tones. Two-tone testing was not attempted, but noise evoked excitatory activity was observed. We classified cells which had excitatory responses to single tones but no demonstrable lateral inhibition (i.e., summated excitatory responses to double tones up to saturation) as Type C (18%). A final class in this scheme includes cells with phasic single tone responses which produced temporal inhibition to any subsequent stimulus (Type D, 22%).

We propose that in the general sense inhibition in cortical cells has received insufficient attention experimentally, and may offer if understood some insights into the complex behavior of proposed feature detecting cells. We propose specifically in light of these data a network model which would generate similar response patterns.

73.12 THREE-TONE SEQUENCE SELECTIVITY IN CAT'S PRIMARY AUDITORY CORTEX (AI) IS SHOWN BY CROSSCORRELATION AMONG ITS SPIKE TRAINS. I.E.Espinosa* and G.L.Gerstein, (SPON: M.J.Bloom) University of Pennsylvania, Dept. of Physiology/G4, Philadelphia, PA 19104.

We report continued cross-correlation analysis of our separable multi-neuron recording data from cat's primary auditory cortex (AI) in response to three-tone sequences (1,2).

Crosscorrelation of spike trains from neuron pairs showed the usual signatures of direct and/or shared input. These appeared individually or in combination and for most pairs were present in spontaneous conditions. However, in stimulated conditions these spontaneous interactions were strongly enhanced. The analysis detected differences in neuronal interaction during presentation of different tones. Similar differences in neuronal interaction occurred during the presentation of any single particular stimulus if there was a history of different immediately previous tones. Controlled modifications in the auditory stimulation modified the crosscorrelations. When data from individual neuron pairs were put together to form a functional connectivity diagram among all recorded neurons, they turned out as different diagrams for different stimulus conditions. If the crosscorrelations are compared according to the class of stimuli, they show a statistically significant selectivity for some specific sequence of three-tones which is independent of the corresponding increase in the neurons' firing rate, that is, due only to neural interactions and not to stimulus coordination (3).

Variations in the connectivity diagram due to detection of previous tone-burst history and to three-tone sequence selectivity may represent different mechanisms. The former seems to depend on the interplay of excitatory-inhibitory influences due to poststimulus effects and could be responsible for a short-memory system. The latter, possibly using that system, differentiates sequences according to the correlated firing they evoke. Of 35 neuron pairs analyzed in detail, all presented the short-memory effect by increasing or decreasing their correlated firing rates and 16 pairs showed three-tone sequence selectivity. These mechanisms do not seem to depend on the geometry of the bundle microlectrode, nor on the type of interaction, nor on the recorded neurons localization in AI.

73.13 COMMISSURAL TERMINAL FIELDS IN CAT PRIMARY AUDITORY CORTEX (AI): LAMINAR DISTRIBUTION AND AFFERENT-EFFERENT RECIPROCITY. R.A. Code and J.A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

We studied the commissural cells of origin and terminal fields in cat primary auditory cortex (AI) with combined injections of horseradish peroxidase (HRP) and tritiated proline in the middle ectosylvian gyrus. Unilateral pressure injections of 0.3-2.0 µl of HRP (20-30%) and 30-200 µCi of tritiated proline (50-100 µCi/µl) were made with a Hamilton syringe. After a 24-72 hour survival, the contralateral AI and ipsilateral medial geniculate body were frozen sectioned in the frontal plane in two adjacent series: 60 µm thick for tetramethylbenzidine (TMB) histochemistry and 30 µm thick for autoradiography. The pattern of anterograde-retrograde labeling in the ipsilateral medial geniculate body was a control for the locus of injection; only experiments in which the ventral nucleus was the primary target are included here. The densest concentration of silver grains was in the contralateral layer III, followed by layers V, VI, and I. The labeling in layer I was heaviest in its deeper portion, layer Ib. Why layer Ib should receive such a heavy commissural innervation is curious, since it has no commissural cells of origin (Code, R.A., Winer, J.A., Proc. Soc. Neurosci., 1983, 9:953; Code, R.A., Winer, J.A., J. Comp. Neurol., 1985, submitted) and thus represents a striking exception to the principle of afferent-efferent reciprocity. Layer IV had the least labeling, followed by layer II. The labeling was always greatest over the neuropil and lightest over neuronal perikarya in all layers. Commissural terminal fields formed radial patches oriented perpendicularly to the pia, averaging about 500 µm wide (range: 330-1280 µm). The number of silver grains in a patch was consistently three times greater than that in an inter-patch area. However, the number of silver grains in an inter-patch area was always significantly above background, suggesting a commissural projection to those areas as well. Complete reciprocity between the commissural cells of origin and terminal fields was not found, although the correspondence was usually high. Often, patches of terminal fields were free of retrogradely labeled cells, and there were patches of labeled cells without an overlying commissural terminal field. The commissural terminal fields form bands oriented in a caudoventral-to-rostrodorsal direction across AI, similar to the orientation of EE (excitatory-excitatory) and EI (excitatory-inhibitory) binaural bands (Middlebrooks, J.C., Dykes, R.W., Merzenich, M.M., Brain Res., 1980, 181:31-48). Commissural terminal fields connect homotopic regions of the contralateral AI, and no region of AI lacks commissural innervation. These data suggest that commissural afferents might connect corresponding tonotopic and homotopic binaural portions of AI. This research was supported by USPHS grant R01 NS16832.

73.14 MINIMUM AUDIBLE ANGLES FOR MIDLINE AND LATERAL FIELD SOUND LOCALIZATION IN THE ALBINO RAT: IMPLICATIONS FOR STUDIES OF CORTICAL FUNCTION. G. L. Kavanagh* and J. B. Kelly. Dept. of Psychology, Carleton Univ., Ottawa, Canada K1S 5B6.

The ability to localize sounds in space has been shown in a number of mammalian species to depend upon the auditory cortex. Monkeys, cats, dogs, and ferrets, all suffer severe impairments in sound localization following bilateral auditory cortical ablations. Also, more recently it has been shown that the effects of cortical lesions are especially evident in the lateral fields of auditory space. The effects of unilateral lesions, not seen in tests of midline localization, are readily manifested in tests of sound localization within the contralateral field. Even with relatively small lesions restricted to the primary auditory cortex, impairments are found primarily in the quadrant of space opposite the side of the lesion. Also, in the ferret small bilateral lesions result in impairments in both left and right lateral fields, but have only limited effects on left vs. right localization around midline.

Studies of the effects of auditory cortical lesions in the rat have failed to show severe impairments in midline sound localization. Tests of lateral field localization were introduced, with the intention of revealing deficits which might have escaped our notice in previous studies. Animals were trained in a semicircular apparatus to localize clicks presented from loudspeakers around the perimeter of the apparatus. Three tests were given: a) left hemifield, with speakers at -90° and -30°, b) midline, with speakers at -30° and +30°, and c) right hemifield, with speakers at +30° and +90° azimuth. The animals had no difficulty localizing a single click in the midline test and were subsequently shown to have small minimum audible angles. Performance in both the left and right lateral fields, however, was very low and did not exceed the level expected by chance in most cases. Additional studies have shown that lateral field performance is also poor with white noise bursts provided that the stimulus duration is brief. These results preclude further study of the effects of cortical ablation on lateral field localization. We suggest that the albino rat is normally lacking an ability which is dependent on the integrity of the auditory cortex in a number of other mammals.

This study was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

73.15 EFFECT OF AUDITORY CORTEX LESIONS ON ABSOLUTE THRESHOLDS IN MACAQUES. H. E. Heffner, R. S. Heffner, and W. E. Porter*. Lab. of Comparative Hearing, Bureau of Child Research, Univ. of Kansas, Parsons, KS 67357.

Hearing thresholds of five Japanese macaques (Macaca fuscata) were assessed following two-stage bilateral lesions of auditory cortex including most or all of the superior temporal gyrus. The thresholds of two additional macaques were assessed before and after unilateral ablation of auditory cortex. Thresholds were determined for tones ranging from 63 Hz to 32 kHz using a conditioned avoidance procedure.

Bilateral ablation initially resulted in a complete inability to respond to sound with the first signs of hearing coming 2 to 11 weeks after surgery. Hearing sensitivity improved gradually with maximal recovery reached 24 to 35 weeks after surgery. Recovery was most pronounced for low frequencies which generally returned to normal or near-normal levels. However, the monkeys appear to have suffered a permanent hearing loss of up to 50 dB in their mid-frequency range around 8 kHz.

Unilateral ablation resulted in a hearing loss in the contralateral ear while thresholds in the ipsilateral ear remained normal. Hearing losses varied with frequency and initially ranged up to 66 dB with the largest losses generally occurring from 8 kHz to 25 kHz. The animals showed gradual recovery, particularly at the lower frequencies, but still had losses of 46 dB or more in the midfrequency range 6 weeks after surgery.

Though the possibility of a cortical hearing loss in monkeys was raised some time ago (Ferrier, Philos. Trans. Roy. Soc., 165:433, 1876), it is widely believed that such a deficit does not exist. The failure of others to note a hearing loss is probably due to the partial recovery of hearing, especially at low frequencies, as well as to the fact that few studies have ever determined thresholds. However, a review of the literature reveals reports of "postoperative amnesia" and "loss of learned habit" following bilateral auditory cortex lesions which may well have been due to initial deafness followed by partial recovery.

73.16 PITCH PERCEPTION IN NON-HUMAN PRIMATES R.W.W Tomlinson*, D.W.F Schwarz*, Otoneurology Lab, Acute Care Unit FF-153, University of British Columbia, Vancouver, B.C. Canada, V6T 2B5.

The psychoacoustics of the pitch of pure and complex tones has been well studied in humans. It is known that the pitch of a harmonic series is identical with that of the fundamental (lowest component), even though the fundamental may not be physically present. Some workers believe that the pitch of the missing fundamental may be perceived only by humans as an epiphenomenon of speech processing. The purpose of this study was to examine if non-human primates can also perceive the pitch of the lacking fundamental. Monkeys were trained to push a button when two tones presented in sequence had the same fundamental frequency. The intensities were randomly varied over 25 dB to eliminate frequency dependent intensity cues. The complex waveform was constructed digitally at a rate of 32 kHz, then converted to analogue, allowing complete control of frequency and intensity of each component. The monkey received sound from an overhead speaker in a sound attenuating room. The pitch of an unknown tone was found by changing the fundamental of a second complete harmonic series until a match was made by the monkey. Rich, 5-component harmonic complexes were used to match 5-component complex tones missing one, two or three of the lowest harmonics. Fundamentals of 200 to 600 Hz were used for the unknown tones. Under these conditions the monkeys consistently made matches to the pitch of the missing fundamental, though the error rate increased as the timbres became more different. It was concluded that non-human primates can perceive pitch in the synthetic mode (Terhardt, J. Acoustical. Soc. Am 71:679-688, 1982).

73.17 AFFERENT INPUT TO AUDITORY ASSOCIATION CORTEX OF THE CAT. C. Shipley (SPON: M. Chase). Mental Retardation Research Center, UCLA School of Medicine. Los Angeles, CA 90024.

Auditory responses can be recorded in a number of polysensory association areas of the cortex in awake or chloralose anesthetized cats. Several of these areas respond similarly after auditory stimulation and may share a common thalamic input. In the present study, afferents to three polysensory cortical areas in which auditory responses are present, peri-cruciate cortex, anterior lateral gyrus, and suprasylvian gyrus, were studied through the use of retrograde axonal transport of cortically injected markers. Double-labelling techniques were used in order to visualize the topographic relationship of thalamic fields projecting to different cortical areas and to determine if individual neurons projected to more than one of these areas.

Animals were anesthetized with alpha-chloralose and click evoked potential maps were made in two of the three cortical association areas. On the basis of these maps, an injection of wheatgerm lectin-bound horseradish peroxidase (HRP) was placed in a site responsive to auditory stimulation in one of the areas and nuclear yellow (NY) was placed in a responsive site in the second. In some cats evoked potential waveforms and latencies were nearly identical at the two injection sites while in others they differed greatly. Cats were terminated with pentobarbital 22-48 hours after the injections, perfused transcardially with paraformaldehyde and processed with tetramethylbenzidine for HRP.

Thalamic labelling was present in a number of nuclei including ventralis anterior (VA), ventralis lateralis (VL), centralis lateralis (CL), centromedian, the ventrobasal complex, lateralis dorsalis, and the lateralis posterior-pulvinar complex (LP-PUL). Dense labelling of both HRP and NY in adjacent or overlapping fields was found in all animals and these fields generally ran for a few millimeters rostro-caudally, crossing one or more borders of the traditionally defined thalamic nuclei. Depending on the injection sites, dense labelling of both HRP and NY was seen in VA, VL, CL, and LP-PUL. These results suggest that a major portion of the input to the polysensory areas studied originates in topographically related fields of the thalamus that may comprise a functional column extending across boundaries of several thalamic nuclei. Double-labeled cells were present but they represented far less than one percent of the labeled neurons.

73.18 HUMAN AUDITORY EVOKED POTENTIAL INDICES OF TEMPORAL PROCESSING. E. O'Malley[1]*, C. Ollo[2]*, N.K. Squires[1]*, and A. Cutler[1]* (SPON: T. Baker[2]). Dept. of Psychology[1], SUNY Stony Brook, Dept. of Psychiatry[2], Sch. Med., Stony Brook, NY 11794.

Rapid temporal processing of auditory stimuli was evaluated using ERPs in a passive task in which a 600 msec noise burst was interrupted by a brief "gap", or silent interval. In the first experiment, binaural trains of noise bursts were presented to seven normal hearing subjects (18-22 yrs); the subjects ignored the stimuli and read a book during the experiment. Gap duration was varied across runs using gaps of 10 msec, 5 msec, 3.5 msec, 2.5 msec, or 1 msec duration. ERPs were recorded from Fz and Cz and referenced to the neck (band pass .1 to 100 Hz) and averaged on-line. The latency of the N100 component of the auditory evoked response was measured to stimulus onset and remained stable across gap size. Also, a well-defined component was identified that indexed the occurrence of the gap. The latency of this gap component increased with decreasing gap size ($p < .009$).

In experiment II, ear advantage was examined using monaural and binaural noise bursts with a gap interval of 10 msec. The latency of the onset N100 and the latency of the gap component were significantly faster in the binaural than in either monaural condition ($p < .009$ and $p < .014$, respectively). This finding cannot be attributed to an intensity increase due to binaural stimulation as N100 latency is relatively invariant for intensity increases of 10-20 dB at presentation levels above 60 dB SPL. Post-hoc analysis of the onset N100 latency revealed that left ear stimulation produced significantly faster responses than with right ear presentation. No significant ear effect was noted for the gap component.

Experiment III was conducted to clarify these findings. In this experiment only monaural presentations were used to determine if the previous relationship between gap component latency and gap size were due to the binaural stimulation. The results verified the findings of Exp. I showing that the latency of the onset N100 is constant while the gap component varies inversely with gap size ($p < .0001$). Analysis of ear of presentation data indicated that the gap component latency for left ear presentations was faster than for right ear stimulation($p < .03$). These data taken together suggest that the gap component may have a different physiological basis than the onset N100 and as such is a unique electrophysiological measure of rapid temporal processing of auditory stimuli. Behavioral correlates of this phenomena are being studied.

74.1 INCREASED NEURONAL SURVIVAL AND REGENERATION FOLLOWING POLYAMINE TREATMENT. M. Dornay*, V.H. Gilad* and G.M. Gilad. The Center for Neurosciences and Behavioural Research and The Isotope Department, The Weizmann Institute of Science, 76100 Rehovot, Israel.

After injury of their axon damaged neurons shift their metabolic activity into a reparative mode aimed at survival and recovery by axonal regeneration or, alternatively they undergo degenerative changes and die. We have recently demonstrated that at the initial stages of the response to axonal injury polyamines (PA) are essential for neuronal survival. When increased demand for PA arises, not only does PA biosynthesis increase, but also the capacity to take up extracellular PA is greatly enhanced. In the present study, therefore, we sought to establish if treatment of rats with PA can enhance survival and regeneration of neurons. Regeneration of crushed pre- or postganglionic sympathetic nerves of the superior cervical ganglion (SCG) was accelerated by daily intraperitoneal injections of spermine (10 mg/kg) or of a combination of putrescine, spermidine and spermine (10 mg/kg each) for 7d starting at the time of operation. This was adjudged by accelerated reappearance of choline acetyltransferase activity in the SCG, and return of [^{3}H]norepinephrine uptake in the pineal and iris, respectively. The functional recovery from ptosis of the eyelid was also accelerated after PA treatment. In newborn rats, injection of PA (10 mg/kg) subcutaneously from 2d to 9d after birth, resulted, at 35d of age, in a 40 to 50% increase in both nerve cell number and tyrosine hydroxylase activity in the SCG. PA had no effect on the diameters of neuronal cell bodies (22.6±0.3 μm) or nuclei (12.5±0.3 μm). The number of satellite glia cells surrounding each neuron (5.3±0.6) were also unaffected. We conclude: a) treatment with exogenous PA accelerates regeneration of crushed sympathetic nerves, and b) treatment of newborn rats with PA leads to an increased number of neurons in the adult SCG. The data imply that the beneficial effect of PA may be through enhancement of neuron survival during development and after axon injury. - Supported by grants from the Muscular Dystrophy Association and the American Paralysis Association.

74.2 VITAMIN A TREATMENT ALTERS PATTERN FORMATION IN REGENERATING EMBRYONIC RETINA OF XENOPUS LAEVIS. C.H. Holder* and C.F. Ide (SPON: F.E. Dudek) Dept. of Biology, Tulane Univ., New Orleans, LA 70118.

Vitamin A treatment has been shown to alter pattern formation during regeneration in vertebrate limbs. It causes clumping of cells near the wound edge as well as the production of serial and mirror pattern duplication of limb structures during subsequent regeneration. To test if vitamin A affects pattern formation during embryonic retinal regeneration, we removed 1/3 of the embryonic eyebud of stage 32 embryos. The resulting 2/3 size fragments not treated with vitamin A showed low incidence of external clumping of cells in the region of the ablation outside of the main fragment body (8/182 embryos, 4.3%). In preliminary studies they also formed relatively normal retinal ganglion cell projections to the midbrain optic tectum (assayed electrophysiologically). Fragments treated with retinal palmitate (1.5 IU/ml) for 24 hours after surgery and assayed at 24, 48, and 72 hours after surgery showed an increased incidence of clumping of cells in the region of the ablation (68/200, 25.3%); treated fragments also formed some retino-tectal projections with duplicated visual field points.

In both control and retinoid treatment fragments, clumped cells found in the region of the ablation were apparently derived from cell movements into the vacant area. In control embryos, these external cells organized into retinal layers and fused with the main fragment within 48 hours post-surgery. In retinoid treated embryos, the external cells remained rounded and undifferentiated as late as 72 hours post-surgery. Thus, vitamin A treatment may interfere with normal cell-cell recognition by altering cellular adhesion and/or other properties involved in the determination of normal retinal geometry and the formation of an orderly single projection to the midbrain optic tectum. Supported by NSF Grant PCM-8316142.

74.3 GANGLIOSIDE ADMINISTRATION REDUCES BEHAVIORIAL DEFICITS AFTER BILATERAL ENTORHINAL CORTEX LESIONS IN RATS. J. J. Ramirez*, S. Karpiak, T. Kilfoil*, B. Henschel*, & W. Grones* (Spon: G-Y. Wen). Dept. of Psychology, College of St. Benedict/St. John's University, Collegeville, Minn., and Div. Neurosience, NYSPI, Dept. of Psychiatry, Columbia U. Medical Center, NY, NY.

Administration of gangliosides facilitates recovery of learned spatial alternation behavior after unilateral entorhinal cortex (EC) lesions in rats [1]. This enhacement of recovery had been postulated to result from facilitated lesion-induced sprouting of the crossed-temporodentate projection to the denate gyrus. However the behavioral recovery occured well before lesion-induced sprouting takes place. Further studies showed that lesion-induced sprouting in the dentate gyrus was decreased after unilateral EC lesions in rats treated with gangliosides [2]. We have now examined the effects of ganglioside treatment in a paradigm where recovery is believed to occur independent of sprouting. We studied the behavioral recovery of rats subjected to bilateral EC lesions. This recovery is reported not to be associated with hippocampal afferent sprouting [3]. Sprague-Dawley male rats were randomly assigned to one of three experimental conditions and were trained in a Y maze to criterion. Two groups were subjected to bilateral EC lesions and the remaining group was sham-operated. One of the EC damaged groups and the sham controls were injected with total ganglioside peparation (i.m. 50mg/kg). The remaining group was injected with saline. Injections began one day preoperatively and were continued for five consecutive days, and every other day thereafter. The rats were tested to a maximum of 32 days post-EC lesions. Preliminary results indicate that the two lesioned groups were indistinguishable with respect to the number of errors committed or the number of days required to attain criterion. However the lesioned rats injected with ganglioside committed significantly fewer perseverative responses than saline controls (N=15, $p<0.01$). Although gangliosides did not reduce the lesion-induced memory deficit as indicated by the total number of errors committed, the ganglisoide treatments did reduce the disruption of response inhibition as measured by perseverative errors. The impairment of response inhibition is frequently associated with hippocampal afferent formation damage. It has been reported that ganglioside treatment reduces CNS edema, therefore limiting the extent of cell damage [4]. Therefore, the decrease in perseverative responses after ganglioside treatment may reflect a "protection" of neuronal plasma membranes (e.g. decreased dendritic degeneration).

74.4 ENHANCEMENT OF HINDLIMB REFLEXES IN ADULT RAT WITH TRANSPLANTS OF EMBRYONIC CNS TISSUE. J. T. Buchanan*, H. O. Nornes (Sponsor J. E. Rash). Department of Anatomy, Colorado State Univ., Fort Collins, CO 80523

Transplants of embryonic CNS tissue into the adult brain of rodents may restore functional deficits due to chemical lesions, congenital abnormalities or aging. The purpose of this study was to determine if transplants of embryonic CNS neurons have an effect on spinal cord function in the adult spinal cord of rat.

Cell suspensions of catecholamine (CA) neurons were injected into the lumbar level (Sprague-Dawley, 180-200 gm. females). The anlagen of locus coeruleus was dissected from 8.5-11.0 mm (crown-rump) rat embryos and the tissue pieces were mechanically dissociated in glucose-saline solution (0.9% NaCl, 0.6% glucose). Five μls of suspension were injected into 3 different sites from L_3-S_1 in rats whose descending catecholamine fibers had been eliminated with intracisternal injections of 6-hydroxydopamine. Up to 1000 CA containing cells were found two and four months post-implantation. Reinnervation of CA-containing fibers was observable in animals with more than 100 CA-containing neurons.

The force of the hind leg reflex (which is enhanced by catecholamines) was used as a functional assay to determine whether the embryonic CA-containing neurons formed functional connections. After spinal transections, animals with suspensions had significantly stronger reflexes (about 150 percent) than those in the control animals. The reflexes were significantly reduced after i.p. injections of the alpha-adrenergic blocker, phenoxybenzamine, indicating that some of the enhancement was due to the release of CA from the transplanted CA neurons. Further, animals with 300 or more CA containing neurons had a mean reflex force of 25 percent stronger than those with less than 300 CA containing neurons.

Suspensions of CA neurons survived, formed a normal appearing fiber plexus in the grey matter of the cord, and enhanced hind leg reflexes. This study raises the possibility of restoring deficits in the spinal cord with intraspinal injections of cell suspensions of embryonic neurons.

74.5 REINNERVATION OF FOREIGN TISSUE TRANSPLANTS IN BABOONS UNDER CYCLOSPORIN A IMMUNOSUPPRESSION. D.D. Samulack, R.W. Dykes, R.K. Daniel*, E.P. Egerszegi* and S.E. Skanes*. Microsurgical Research Laboratories, McGill University, Montreal, Canada. H3A 1A1

Immunosuppression by Cyclosporin A (CyA; Sandoz Ltd) interferes with the production of antibodies against foreign tissues and has provided unique opportunities to study allogeneic (intra-species) tissue transplantation. In this study, neurovascular free flaps were allografted between unrelated individual baboons to investigate the degree to which allogeneically-transplanted tissues would re-innervate in a primate species (Papio anubis), in the presence of CyA immunosuppression.

Two surgical models were used. The first, an index finger model, involved the isolation and transplantation of the soft tissue coverage of the second digit, complete with its neurovascular pedicle. The second model involved the transplantation of a whole hand, at a level 4 cm proximal to the wrist. Transplantation success was achieved in five index finger free flaps and two hand transplants, with viable longterm survival ranging from 5 to 10 months, at which time their state of reinnervation was assessed.

Electrophysiological recordings from a sample of more than 300 single afferent fibers in median and radial nerves showed that sensory axons had reinnervated the transplanted skin. Well-defined, low threshold receptive fields were observed. Both slowly (SA) and rapidly adapting (RA) responses could be identified. In those cases which had undergone a period of rejection, the thresholds tended to be elevated with an excess of RA fibers observed. In contrast, in a flap that had not undergone any rejection, the ratio of SA to RA was reversed to favor the SA responses. The most striking abnormality was a reduced conduction velocity for those axons ensheathed by foreign Schwann cells. Reinnervation of donor muscle was also demonstrated through motor unit recruitment in step-wise fashion, following electrical stimulation of the recipient's median and ulnar nerves. Afferent fibers serving the donor's joints and muscle spindles were also observed.

Comparisons of the results from transplants that underwent a serious rejection episode with those experiencing only minor, or no episodes of rejection, suggest that (except for conduction velocities) the quality of neural function may be related to this variable, rather than to some intrinsic inability of the recipient axons to reinnervate foreign skin receptors.

74.6 PRESYNAPTIC ELEMENTS ON IMPLANTED POLYLYSINE COATED BEADS. Richard W. Burry and Diane M. Hayes*, Department of Anatomy and the Neuroscience Research Laboratory, The Ohio State University, Columbus, Ohio 43210

Previous studies with cell cultures of neonatal rat cerebellum have shown that neurites in contact with a polylysine coated bead can form a presynaptic element with the bead in the position of a postsynaptic element. Results reported here show that neonatal rats with implanted polylysine coated beads can also form presynaptic elements on beads.

Presynaptic elements on coated beads were identified in the electron microscope as neuronal swellings that contain both clusters of small diameter vesicles at the site of contact with the bead and a slight thickening of the plasma membrane at the site of contact (Burry, Brain Res., 1980, 184:85-98; 1982, 247:1-16). In addition, the small diameter vesicles in the swelling have been shown to stain with antibodies to synaptic vesicle antigens Synapsin I and SV48 (Burry, Neurosci. Abst., 1984, 10:578). The number of presynaptic elements on beads reaches a maximum at 7 days incubation and then shows a dramatic decline. Results from experiments in culture with antimitotic drugs that stop glial cell proliferation, have shown that the resulting decrease in number of glial cells correlates with an increase in the number of presynaptic elements on beads (Burry, Neurosci. Abst., 1983, 9:690). These studies have indicated that formation and loss of presynaptic elements on polylysine coated beads may serve as a model for regeneration and formation of synapses after lesion.

Experiments reported here show that axons of neonatal rat cerebellar neurons can also grow and form presynaptic elements on polylysine coated implanted beads. The number of beads with presynaptic elements was highest at 3 and 7 days after implantation and dropped to almost zero at 14 and 21 days after implantation. Measurements of the size of the presynaptic element and the number of vesicles at 3 and 7 days after implantation showed an increase, while these parameters decreased at 14 and 21 days after implantation. Additional data showed axons that formed presynaptic elements grew into the implant to a distance of several hundred micrometers.

These results show that presynaptic elements can form on implanted beads in neonatal cerebellum, and that the presynaptic elements show a decline in number after 7 days similar to that seen in culture. It is possible that the loss of presynaptic elements after 7 days may be related to the glial cells.

74.7 IMPLANTATION OF DISSOCIATED FETAL SPINAL CORD CELLS INTO ADULT RAT SPINAL CORD. U. Vaidya and M.R. Wells., Neurochemistry Research Laboratory, V.A. Hospital, Washington, D.C. 20422.

Pieces of whole fetal rat spinal cord can be introduced into the injured or uninjured spinal cord of adult hosts using a variety of implantation techniques. The use of tissue of appropriate age can result in the growth and development of the implant within the host (Patel, U. and Wells, M.R., Soc. Neurosci. Abstr. 10:1023, 1984). The injection of dissociated fetal spinal cord as cells offers a relatively atraumatic and accurate means of introducing fetal tissues into host animals. Timed pregnant female rats were injected with 5 µCi./g. body weight of [^{3}H]thymidine 24 hours prior to use. E13 fetal spinal cords were collected from embryos, dissected free of meninges and adhering tissue and dissociated by trituration in culture media (3 spinal cords/ml media). Viability of dissociated cells and small aggregates were assessed by trypan blue exclusion. The dissociated spinal tissue (1 µl) was injected into the uninjured spinal cord of anesthesized adult hosts with a 10 µl syringe. At time periods of 1-6 weeks, anesthesized host animals were perfused with 4% parformaldehyde, the spinal cords embedded in paraffin, sectioned at 6 u, and processed for autoradiography with NTB-3 emulsion. After a 4 week exposure, slides were developed and stained. Over all time periods examined, cells with [^{3}H]thymidine labeled nuclei could be identified in the host. Many appeared as differentiated neuronal cells. Most labeled cells were located near the site of injection, but some cells were found on the surface of the host spinal cord in aggregates. The data demonstrate that dissociated fetal spinal cord can survive and develop after injection into adult host spinal cord similar to whole tissue implants. The close contact of dissociated cells with the host tissue after injection appears to be an advantage to the viability of the implant. Survival and development of similar implants in injured host spinal cord is presently under investigation.

Supported by the Veterans Administration.

74.8 SCIATIC NERVE AUTOGRAFTS (SNAs) INTO THE RAT HYPOTHALAMUS: NEUROPHYSIN IMMUNOHISTOCHEMISTRY AND FINE STRUCTURE. H.-D. Dellmann*, L.-F. Lue*, S. I. Bellin* and A. J. Cosimini* (SPON: C. Jacobson). Department of Veterinary Anatomy, Iowa State University, Ames, IA 50011.

As part of an ongoing investigation of the capability of peripheral and central nervous tissues to induce regeneration of transected neurosecretory axons in the hypothalamus, several small pieces (0.25 mm^2) of intact or degenerated (14-40 days) sciatic nerve were autografted stereotactically into the region situated between the supraoptic and paraventricular nuclei. Animals were sacrificed 5, 10 and 20 days post operationem. Alternate 50 µm vibratome-cut horizontal sections were processed for neurophysin immunohistochemistry and conventional electron microscopy, respectively.

There is an increased degree of innervation of SNAs by neurophysin-positive axons with time: A few short axons penetrate the graft periphery at 5 days, more and longer axons with numerous varicosities are present at 10 days and abundant axons permeate the graft at 20 days. There are differential patterns and magnitudes of neurophysin-positive axon innervation between intact and degenerated SNAs. Areas of intact SNAs that contain numerous macrophages have no or only sparse innervation while degenerated SNAs and areas of intact SNAs without macrophages contain a dense plexus of beaded axons. In degenerated SNAs, the innervation appears to be more orderly with axons often coursing in parallel. Axons are more numerous in degenerated than in intact SNAs. Furthermore, within and in the vicinity of SNAs, blood vessels (arterioles, venules) are surrounded by a light plexus of neurophysin-positive axons at 10 days and by a heavy one at 20 days. These findings are confirmed at the fine structural level. SNAs are composed of varying proportions of fibroblasts, collagen fibers, neurolemmocytes, macrophages and axons; typical peptidergic neurosecretory axons as well as non-neurosecretory axons are partially or totally invested by neurolemmocyte processes. Blood vessels are surrounded by axon profiles located within the perivascular connective tissue space. Many of these axons are in direct contact with the basal lamina and have characteristics of typical neurosecretory axon terminals, i.e., neurosecretory granulated vesicles, vacuoles and microvesicles clustered frequently at the membrane facing the basal lamina.

SNAs obviously promote neurosecretory (and other) axonal regeneration or sprouting, not only into the graft but also into adjacent hypothalamic perivascular connective tissue spaces, an interesting phenomenon which is currently under further investigation. Supported by NSF grant BNS-84-04183 and by Basic Research Grant No. 1-900 from the March of Dimes Birth Defects Foundation.

74.9 DELAYED TRANSPLANTATION OF EMBRYONIC SPINAL CORD INTO THE INJURED SPINAL CORD OF THE ADULT RAT. J. D. Houle and P. J. Reier. Depts. of Neurological Surgery and Neuroscience, Univ.of Florida College of Medicine, Gainesville, FL. 32610.

We and others have recently demonstrated that embryonic CNS tissues can be successfully grafted into acute lesions of the neonatal and adult rat spinal cord. While some anatomical continuity could be restored in most cases, the degree of host and donor tissue approximation was nonetheless variable due to the presence of small cysts and focal infiltrations of connective tissue. In the present study, we investigated whether better fusion of host and donor tissue could be obtained by using a delayed grafting approach. This strategy was suggested by previous studies showing that delayed intraspinal grafts of peripheral nerve tissue yielded better host-graft appositions than when implants were made immediately after injury.

Subtotal lesions of the lumbar spinal cord were made in adult rats by aspirating tissue to form a 2-3 mm long cavity. E14 spinal cord (FSC) tissue was subsequently implanted against vascular-rich surfaces either immediately after the lesion or 6-14 days post-lesion. Animals were perfused 30 days after transplantation, and tissue was prepared for either conventional light microscopy, electron microscopy or immunocytochemical visualization of astrocytes using antibody to GFAP (Glial Fibrillary Acidic Protein).

The survival (i.e., ~80%) and differentiation of FSC tissue were equivalent under both acute and delayed conditions; however, delayed grafts exhibited a better apposition with the host spinal cord such that fewer cystic cavities and mesenchymal infiltrations were present at host-graft interfaces. Comparable GFAP-like immunoreactivity was also observed in both conditions within the transplant proper as well as at the interfaces between the adjacent tissues. On the other hand, an extensive astroglial reaction was observed in lesioned spinal cords which did not receive grafts. These observations demonstrate that embryonic CNS tissue can be grafted into the injured spinal cord following a post-injury delay of at least two weeks. Under this condition, extensive apposition of host and donor tissue can be achieved, and the delayed grafts can fuse with the host spinal cord without formation of any appreciable glial interfaces. Therefore, the delayed grafting approach may offer some practical advantages to embryonic neural tissue transplantation and spinal cord repair. Studies are in progress to determine whether similar grafting results can be obtained in chronic spinal cord lesions (≥1 month) and to determine whether axonal interactions between donor and host can be achieved under these conditions. (Supported by NIH grant NS-22316)

74.10 TRANSPLANTS OF SEPTAL EXPLANT CULTURES PROVIDE A CHOLINERGIC REINNERVATION TO ADULT RAT HIPPOCAMPUS. Elizabeth B. Ezerman and Lawrence F. Kromer. Dept. of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

In vitro explant preparations provide a convenient method for exposing developing CNS tissue to various trophic, neurotoxic, or labeling agents. Thus, this procedure was combined with the tissue transplantation technique in order to determine whether culturing embryonic septal-basal forebrain cells prior to transplantation altered their ability to provide a cholinergic reinnervation to denervated host hippocampi. For these studies E15-16 septal-basal forebrain tissue was maintained in explant culture for 1 to 4 days prior to transplantation into the hippocampus of adult rats with fornix-fimbria transections. The morphology of the transplants, survival of cholinergic neurons, and reinnervation of the host hippocampus by cholinergic fibers from the explant-transplant after one and three weeks survival in cerebro were assessed with AChE histochemistry, ChAT immunocytochemistry, and cresyl violet (CV) staining. Comparable explants were studied at 1, 4, and 8 days postexplantation.

At 1 day in vitro, the explants contain circumferential germinal zones containing small mitotic cells. By 4 days some cell bodies and short processes demonstrated light staining for AChE comparable to that observed at an equivalent in vivo stage (E19-20). Eight day explants also show AChE reactive cell bodies and processes which extend for considerable distances within the explant. In addition, the explants containa variety of AChE-negative neurons of various sizes. After 1 week in cerebro, the 1 day explant-transplants exhibit robust growth, contain clusters of AChE+ cells and fibers,and possess a similar degree of intrinsic organization to the 8 day explants. In addition, a dense plexus of AChE+ fibers is present at the transplant-host hippocampal interface, with some axonal growth into the host hippocampal formation. Septal explants in culture for 4 days prior to transplantation also have AChE+ cell bodies and some fibers penetrating the host hippocampus at a 1 week survival. By three weeks posttransplantation specimens of both 1 and 4 day explant-transplants contain ChAT+ neurons and possess an extensive intrinsic plexus of AChE+ fibers. In cases with a good host-transplant interface, there also is an extensive cholinergic reinnervation of the host hippocampus. This study demonstrates that short-term explants of embryonic septal-basal forebrain tissue survive transplantation and provide cholinergic reinnervation to denervated adult hippocampi. The combined explant-transplant experimental approach thus is a potentially valuable method to assess factors important for cholinergic cell survival and growth. (Supported by PHS Grants #NS-18126 and NS-07289.)

74.11 **EFFECTS OF NEURAL TUBE IMPLANTS OBTAINED FROM DIFFERENT STAGES UPON THE RESPONSES OF THE HOST NERVOUS SYSTEM.** **B.E. Sisken, J. Fowler and E. Bell.** Wenner Gren Res.Lab. and Dept. of Anatomy, Univ. of Kentucky, Lexington, KY 40506.

The right wing buds of stage 24 chick embryos were amputated at the future elbow region. Experimental embryos had a segment of stage 15, 24, 28 or 34 neural tube implanted longitudinally into the limb stump to induce regeneration (Fowler and Sisken, JEZ, 221, 1982). Stumps of control limbs were implanted with stage 30 heart, or were not implanted. To analyze effects of the neural implant upon the relations of the peripheral load to the host neural components, quantitative determinations were made of the peripheral load, lateral motor column of the spinal cord (LMC) and dorsal root ganglia (DRG) of one brachial spinal cord segment.

The peripheral load was estimated by determining the area of the skeletal elements of the amputated and unamputated limb of each embryo. The LMC was determined by counting the number of neurons on both operated and unoperated sides of a single spinal cord segment, the DRG by making area measurements of the ganglia in the same spinal cord segment.

The peripheral load was significantly greater in amputated limbs that received a neural tube implant, indicating a stimulation of growth even in limbs in which epimorphic regeneration did not occur. The area of the dorsal root ganglia showed a direct relationship to the size of the peripheral load indicating that cell death of sensory neurons was correlated with reduction of sensory targets by limb amputation. The number of neurons in the LMC was significantly greater in embryos with a neural implant than was expected based upon the peripheral load. This suggests that the neural implant may produce a neuronal survival factor that protects motor neurons from amputation-induced cell death but, affords no protection for sensory neurons. Supported by NIH NS197898-02.

74.12 REJECTION OF RETRANSPLANTED NERVE ALLOGRAFTS. A. A. Zalewski, A. K. Gulati*, Y. Kadota*, and N. A. Azzam. Lab. of Neurobiology, NINCDS, NIH, Bethesda, MD 20205 and Dept. of Anat., Georgetown Univ. Sch. of Med., Washington, D. C. 20007.

Nerve grafts, 5 cm long, were taken from adult male rats and transplanted into the thighs of immunologically deficient nude rats. After postoperative periods of one to five months, the ACI nerves were retransplanted into allogeneic Fischer (FR) rats. The purpose of this study was to determine whether the ACI allogeneic cells responsible for initiating nerve allograft rejection would die or become altered in an intermediate host rendering these ACI grafts non-antigenic. As a control procedure, some ACI nerves from nude rats were regrafted into isogeneic ACI hosts. All ACI nerves survived after transplantation into nude rats. The one month grafts were in the process of Wallerian degeneration whereas the five month grafts contained regenerated nude rat axons that were remyelinated throughout the entire graft length by ACI Schwann cells. In addition, all one and five month ACI grafts had a patent vasculature, a perineurium and no detectable cellular immune reaction. After retransplantation into FR hosts, all the nude rat passed ACI nerves were rejected. At five months all that remained of the ACI grafts was a short 5 mm nerve segment that contained a few regenerated and remyelinated axons. On the other hand, retransplanted ACI nerves survived in ACI hosts. These grafts retained their length, and they bore many remyelinated nerve fibers. They also contained a patent vasculature, a perineurium, and were free of any immune reaction. In another study, a similar rejection occurred in FR rats that received ACI nerves that were first passed through FR rats treated with the immunosuppressive agent cyclosporin-A. These results indicate that the antigenic cell type(s) responsible for nerve allograft rejection are long-lived and not readily eliminated by physiological cell turnover of one to five months. Accordingly, it is now important to identify the antigenic cell in a nerve allograft, alter or eliminate it, and determine what effect this has on the capacity of the nerve graft to support host axonal regeneration through it.

74.13 VIABILITY AND MORPHOLOGY OF TRANSPLANTED SUPERIOR CERVICAL GANGLIA IN PERIPHERAL NERVE OF ADULT RAT. D. W. Hoovler. Dept. of Physiol., George Washington Univ. Sch. of Med., Washington, D.C. 20037 and the Veterans Administration Med. Ctr., Washington, D.C.

Spinal cord injury causes the loss of functional connection and trophic influence to peripherally innervated structures below the site of injury leading to paralysis and atrophy of muscle tissue. Successful transplantation of viable central or ganglionic neurons into peripheral nerve and the subsequent afferent and efferent connection of the transplanted neurons with viable host tissue has the potential of maintaining the integrity of, or possibly restoring function to, functionally denervated tissues. The first step of this procedure involves the identification of tissues capable of surviving transplantation, being innervated by host fibers and elaborating axons that have the ability to innervate target tissue. Mature rat superior cervical ganglion (SCG) was chosen as the transplant tissue because it survived in other transplant studies, it is a relatively simple neural tissue that has the ability to change its neurotransmitter substance in vitro, it has the potential of being innervated by regenerating cholinergic peripheral axons or other types of fibers and its fiber outgrowth can be evaluated by fluorescence microscopy of catecholamines. SCG were removed from anesthetized adult male Sprague-Dawley rats and placed in ice cold Tyrode Ringer solution, desheathed and divided into 0.5 mm cubes. These were inserted into the nerve to the biceps femoris muscle of 60 adult male Sprague-Dawley rats through a small slit in the epineurium of the nerve at a site where the nerve had been crushed. In half the animals, the sciatic nerve proximal to the branching of the biceps femoris nerve was transected, creating 2 types of transplants; those in degenerating nerve and those in regenerating nerve. At 14, 30, 60, 90 or 120 days postoperative (DPO) host rats were anesthetized and the transplant site exposed and stimulated with a bipolar electrode. Tissue was processed for light and electron microscopy and for glyoxylic acid induced fluorescence of catecholamines. The allografts of mature rat SCG survived up to 120 days following transplantation. The transplants contained the constituents of normal mature SCG including postganglionic sympathetic neurons, Schwann cells, satellite cells, small intensely fluorescent (SIF) cells, blood vessels and catecholaminergic containing fibers. Morphological changes were present in the transplanted SCG neurons and signs of cellular necrosis were more prevalent in specimens by 90 or 120 DPO. There were indications of catecholaminergic fiber outgrowth from the transplants, however, no muscle response could be elicited by electrical stimulation of the implanted nerve where the transplanted mature SCG neurons were the only source of nerve fibers. (Supported by the American Paralysis Association).

74.14 ELONGATION OF AXONS FROM ADULT RAT MOTOR CORTEX INTO PNS GRAFTS. J.C. Horvat and A.J. Aguayo. Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Quebec, H3G 1A4 Canada. In 24 Sprague-Dawley female rats (200-250 gms) a 1.5-2 cm of autologous sciatic nerve (PNS) was excised from the leg and used to test the regenerative response of motor cortex neurons injured near their somata. One end of the PNS segment was implanted 0.5 to 2 mm deep into the cortex, in the region known to contain the cells of origin of the corticospinal tract (Sanderson K.J. et al., Brain Res, 292:251-260, 1984) while the free outer end of the graft was sutured to the temporalis muscle. From 41 to 71 days later the peripheral tip of the PNS graft was transected and a 20% solution of HRP was applied to its cut end. Rats were perfused with fixative 48 hrs later and their brains processed by light microscopic histochemistry. In 17 animals we found a total of 393 HRP labeled neurons . The laminar distribution of the majority of these cells could be determined with considerable accuracy, as follows: layer II=3, layer III=13, layer IV=72, layer V= 251, layer VI= 17; 37 other cells could not be as accurately localized. The shape and size of many of the neurons in layer V indicate that the largest pyramidal cells (Betz) also extended their axons into the grafts. Thus, although PNS grafts inserted into the mid-thoracic spinal cord of rats have not been proven to be invaded by axons of the corticospinal tract (Richardson et al, Brain Res. 237:147-162, 1982), the cells of origin of this tract nevertheless regenerate processes into PNS grafts inserted near their somata. These findings and those reported for other descending and ascending spinal axons (Richardson et al, J.Neurocytol. 13:165-182, 1984), as well as for retinal (So and Aguayo, Brain Res. 328:349-354, 1985) and olfactory (Friedman and Aguayo, J.Neurosci. in press, 1985) projections indicate that the regenerative response of these central neurons is strongly influenced by the proximity of the lesion and graft to the cell body.

74.15 AXONAL REGENERATION FROM THE RAT RETINA AFTER TOTAL REPLACEMENT OF THE OPTIC NERVE BY A PNS GRAFT. M. Vidal-Sanz*, M. Villegas-Pérez*, P. Cochard* and A.J. Aguayo (SPON: M. Rasminsky). Neurosciences Unit, The Montreal General Hospital and McGill University. Montreal. Quebec. Canada H3G 1A4.

Retinal ganglion cells regenerate cut axons along peripheral nerve (PN) grafts inserted directly into discrete portions of the retina (So & Aguayo, Brain Res. 328: 349,1985). Here we describe in adult rats an extensive axonal regeneration from retinal ganglion cells after complete substitution of the optic nerve (ON) by a peripheral nerve graft.

In female Sprague-Dawley rats, weighing between 200 and 250 gms, a 3.5 cm segment of sciatic nerve was dissected and removed from the leg. By a superior temporal approach the left ON was exposed within the orbit and transected at its origin from the retina. The proximal stump of the autologous PN graft was attached to the optic disk and secured to the sclera with 10-0 sutures while the rest of the peripheral nerve segment was either laid subcutaneously over the skull or connected to the superior colliculus. Axonal regeneration from the retina into the PN grafts was examined from 6-8 weeks after ON nerve substitution by the application of HRP (40%) to the distal end of the PN segment. 48 hours later, the animals were perfused through the heart with saline, followed by a 4% solution of paraformaldehyde. Grafted eyes were dissected, placed in phosphate buffer and the retinae prepared as flat wholemounts, rinsed in phosphate buffer and reacted according to a modified Hanker-Yates method. Some of the retinae were also examined by fluorescence microscopy after incubation with antibodies to neurofilaments.

Grafted eyes did not show obvious intraocular residual damage. It was documented that ganglion cells of different sizes, located throughout the entire retina, had regenerated axons along the length of the PN grafts for distances equivalent to those of the normal retino-tectal projection.

74.16 RESPONSES TO VISUAL STIMULI OF RAT RETINAL GANGLION CELLS REGENERATING AXONS INTO PERIPHERAL NERVE GRAFTS. S.A. Keirstead, M. Vidal-Sanz*, M. Rasminsky, A.J. Aguayo, M. Levesque* and K.-F. So. Neurosciences Unit, Montreal General Hospital, Montreal, Quebec, Canada H3G 1A4.

As is the case for neurons in several parts of the adult mammalian central nervous system, axotomized retinal ganglion cells regenerate axons into peripheral nerve (PN) grafts inserted into the retina (So & Aguayo, Brain Res. 328:349,1985). We have now recorded electrical activity in single axons teased from such grafts 1 to 2 cm from the retina 9 to 48 weeks after the insertion of one tip of a 3-4 cm long autologous PN segment into the superior temporal retina, close to the optic disc. The other end of the graft was tied off and left unconnected under the scalp overlying the occiput.

In 47 of the 626 units recorded in 14 rats, the discharge frequency was influenced by changes in illumination. 28 cells were "on" units, responding to the onset of light with increased firing; 12 cells were "off" units that responded to the onset of the light stimulus with decreased firing and to the cessation of the light stimulus with increased activity; 7 cells were "on-off" units with enhanced firing both at the onset and cessation of light stimulation. 22 units had circular receptive fields <1 to 8° in diameter. These fields were invariably located in the inferior visual field consistent with the placement of the PN grafts in the superior portion of the retina. An antagonistic surround was found in 6 units. These responses by ganglion cells with regenerated axons are similar to those of normal rat retinal ganglion cells (Brown & Rojas, J. Neurophysiol. 28:1073,1965).

The number of light-responsive units appeared to decline with time after implantation of the blind-ended grafts. We recorded 32 responsive units in 3 rats with 9-11 week grafts, 13 responsive units in 5 rats with 25-28 week grafts and only 2 responsive units in 6 rats with 44-48 week grafts. The many units that did not respond to light could represent either retinal ganglion cells with altered membrane properties and/or altered afferent connectivity, or non-retinal neurons which extended axons into the grafts.

These experiments indicate that axotomized retinal ganglion cells regenerating axons into PN grafts can retain or regain a complement of synaptic input adequate to permit normal responses to light stimuli but that this responsiveness does not persist indefinitely. It is possible that the conditions in the PN grafts which promote the regeneration of retinal ganglion cell axons cannot assure the long term functional viability of cells lacking synaptic connections with appropriate targets.

74.17 HOW DOES PERIPHERAL NERVE INJURY TRIGGER ENHANCED CENTRAL REGENERATION OF PRIMARY SENSORY NEURONS? P.M.Richardson, and V.M.K.Verge*. Division of Neurosurgery, McGill University and Montreal General Hospital, Montreal, Canada H3G1A4.

In earlier studies, injury of the peripheral processes of bipolar sensory neurons was shown to enhance the regeneration of corresponding axons in the dorsal columns (Nature 309:791,1984). Axons ascending from the fourth and fifth dorsal root ganglia (L4 & L5 DRG) are one hundredfold more likely to regenerate into a peripheral nerve graft to the dorsal spinal cord if the sciatic nerve is cut rather than uninjured. This preparation has now been used to study the nature of the signal from injured peripheral axons that triggers an enhanced propensity to regenerate in sensory neurons.

Crushing of the sciatic nerve or single intraneural injection of colchicine (5ul, 25mM) each caused severe Wallerian degeneration yet was only one tenth as effective as nerve section in evoking central regeneration. However, four injections of colchicine to block retrograde axonal transport for two weeks mimicked more closely (42%) the inductive effects of nerve transection. A working hypothesis compatible with these observations is that sensory neurons are activated to regenerate when their cell bodies are deprived of a neurotrophic molecule normally supplied by peripheral glial cells along distal nerve segments.

Preliminary results of experiments with continuous infusion of nerve growth factor (NGF) to the proximal stump of the cut sciatic nerve indicate that NGF can mitigate this inductive phenomenon and thus may be implicated in the regeneration of sensory neurons.

74.18 REGENERATION OF MEDIAL FOREBRAIN BUNDLE (MFB) AXONS INTO RAT PERIPHERAL NERVE GRAFTS. R.P. Dum and C.G. Salame*, Dept. Neurosurgery, SUNY at Upstate Med. Ctr., Syracuse, New York 13210.

Many different types of CNS neurons regrow axons into implanted nerve grafts (Benfry et al, Nature 296: 150, 1982), but the neuronal population is usually heterogeneous and located quite close to the implant site. In this study, we attempted to induce a more specific population of neurons to grow into a peripheral nerve graft located remotely from the cell bodies.

Under aseptic conditions, autologous sciatic nerve grafts (25mm long) were implanted vertically through the cortex to intercept the MFB in anesthetized female rats (200gm). The distal end of the graft was implanted in muscle. Up to 1 year later, the cut end of the graft was dipped for 1 hour in a fluorescent dye, granular blue (GB) or Evans blue (EB). After perfusion with 10% formalin, the brains of GB rats were cut frozen at 30um. EB rats were pretreated with Nialamide (400mg/kg). Their brains were removed whole and frozen. Cryostat sections cut at 8um were reacted by the glyoxylic acid method to produce catecholamine (CA) histofluorescence.

In each case, the nerve graft interrupted the MFB at the posterior hypothalamus. The dense accumulation of CA histofluorescence on the experimental versus the control side was consistent with the interruption and blockage of CA fibers within the MFB.

In those rats with healthy grafts, large numbers of labeled neurons (mean 750±311; range 272-1084) were found in brainstem nuclei, but not in the cortex or thalamus. The location of labeled neurons always followed a consistent pattern, labeling brainstem nuclei which project rostrally in the MFB (Takagi et al, Brain Res. 193: 315, 1980). The heaviest labeling was found in the dorsal raphe nucleus which contained at least 50% of the total labeled cells. Both locus coeruleus and medial raphe nuclei were densely labeled while the raphe pontis and caudal linear nuclei were sparsely labeled. Infrequent labeling occurred in the following nuclei: A2, A4, parabrachial, lateral and ventral tegmental, interpositus, pontine gray, hypothalamus and the reticular formation.

CA containing neurons grew into the graft as revealed by the large numbers of CA fluorescent fibers within the graft and the high percentage of EB labeled neurons in locus coeruleus which also showed CA fluorescence.

The pattern of labeling was not due to spillage of dye directly on the cortex since many neurons were found in the cortex and thalamus following direct application of dye to the cortex in control rats.

Our results show that monoaminergic containing nuclei which project in the MFB have a high capability to grow into peripheral nerve grafts. Since the nerve graft is located remotely from the cell bodies, the physiological function of these MFB nuclei is more likely to be normal. Additionally, the epineurium provides a potent barrier which limits axonal access to the graft's cut end.

74.19 THE USE OF BASAL LAMINA TUBES FROM EVACUATED MUSCLE AS A PERIPHERAL NERVE GRAFT. J.W.Fawcett* and R.J.Keynes* (SPON: C.Asanuma). Salk Institute, La Jolla, CA 92037, and Dept. Anatomy, Cambridge University, England.

Severed peripheral nerves often cannot be rejoined without the use of a graft to bridge the gap between their proximal and distal stumps. Current clinical practice is to use sural nerve autografts for this purpose, although these have a number of disadvantages. We have investigated the use of basal lamina (BL) grafts derived from muscle as a substitute for these nerve autografts.

To prepare the grafts, either rat soleus or rabbit adductor magnus muscles were removed from recently killed animals. Myoplasm was evacuated from strips of muscle either by repeated freezing and thawing in liquid N_2 and buffer, followed by osmotic and mechanical evacuation, or by the technique of Wallis et. al (Biochim. Biophys. Acta 599, 505). This procedure leaves the BL essentially intact, but effectively eliminates most of the muscle components. The grafts were stored at -70°C until use.

The sciatic nerves of a series of rats were exposed and divided proximal to their bifurcation. A 0.5 cm BL graft was then stitched into the gap. We saw signs of nervous function returning to the leg about 1 month after surgery, and in cases with successful grafts, good functional recovery within about 2 months. Histological examination showed that many axons had regenerated through the grafts and into the distal stump within 10 days of operation. After 3 months the distal part of the nerve was almost as large as the proximal one, and there were large numbers of thick, myelinated axons in both the graft and the distal stump of the nerve. Although we have not yet stained specifically for Schwann cells, it looks as if these migrate into the graft with the front of ingrowing axons. Control sciatic nerve autografts were as successful as basal lamina grafts, but frozen sciatic nerve grafts were less satisfactory.

In our rabbit experiments a 4cm graft derived from rabbit adductor magnus was sutured into the divided nerve. In animals killed 3 weeks after surgery there were many axons that had grown through the graft, and into the distal stump; this corresponds to a growth rate of more than 2mm/day. After 3 months the animals showed significant but incomplete functional recovery, and had thick and healthy nerves distal to the repair.

In order to see if grafts from one species could be used in animals of a different species, we grafted rabbit derived BL grafts into rat sciatic nerves. These nerve repairs seem to be as satisfactory as those done with rat derived grafts.

Muscle BL grafts are a potential source of nerve grafts which have the advantages that they can be made in almost any size or shape, can be stored indefinitely, and do not have to be surgically removed from elsewhere in the body.

74.20 CHANGES IN GLIAL REACTIVITY TO IMPANTATION OF NITROCELLULOSE BRIDGES INTO ACALLOSAL ANIMALS AT VARIOUS AGES AND THE EFFECT ON REGENERATING CALLOSAL AXONS. G.M. Smith*, R.H. Miller*, and J. Silver (SPON: M. Singer). Dept. of Developmental Genetics and Anatomy., Case Western Res. Univ., Cleve., OH 44106.

When the "sling-like" glial structure that guides developing callosal axons is surgically severed in normal mice the commissural axons form large neuromas lateral to the midline, producing an acallosal animal (Silver et al. J.C.N. 210,1982). If a specially designed piece of Millipore filter is implanted into the would-be callosal pathway of acallosal neonates, axons can be induced to extend out of the neuromas and across the midline along astrocytes that, in essence, recreate the embryonic enviornment as they attach to the filter's surface (Silver and Ogawa, Science 220, 1983). Since callosal neuromas persist into adulthood, we asked whether a critical period does exist, and we have documented a variety of changes in the reactive gliosis that, in part, may lead to the axon growth refractory state. In acallosal postnates given untreated implants prior to day 10, GFAP + stellate shaped astrocytes rapidly attached to the filter by inserting foot processes into the filter's pores. This form of gliotic response established an axon growth promoting substratum within 48 hours after implantation. During this pre-critical stage there was no evidence of typical CNS scar formation or necrosis at or around the implant surface. However, when acallosal mice were implanted later than P 10, extensive tissue degeneration occured, and 5 to 7 days later a mixed population of astrocytes and fibroblasts invaded the surface of the implant producing a dense, basal lamina that permeated the scar. Reactive astrocytes within the scar had a flattened rather than stellate morphology, and did not promote axonal outgrowth.

It is important to determine which of the various changes in reactive gliosis contribute to an inhibition of axon growth during the post-critical period. In order to determine if the physical change in the shape of the astrocyte, from stellate to flat, influences axon outgrowth, untreated implants were partially crushed midsagittally prior to implantation into P 2 (pre-critical period) acallosal animals. Crushing, reduces the size of the filter's pores and forces the astrocytes to flatten along that portion of the surface. In such animals axons were observed growing among the stellate astrocytes (uncrushed region) but, turn abruptly at the crush/noncrush interface and did not extend on flat astrocytes.

In conclusion, our studies suggest that when controlled, gliosis during pre-critical stages can be a benefical process that can promote the reconstruction of malformed axon pathways. In older animals a variety of changes in the reactive glia may work together to hinder axon regeneration during the post-critical period. Supported by NSF (BNS8218700)

75.1 **LIPID PEROXIDATION-INDUCED CALCIUM UPTAKE BY BRAIN SYNAPTOSOMES AND CULTURED SPINAL CORD NEURONS.** J.M.Braughler, L.A.Duncan* and R.L.Chase*, CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

Ischemic or traumatic injury to the CNS is associated with accumulation of intracellular Ca^{++} that is hypothesized to play a role in the development of irreversible cell damage (Siesjo, J. Neurosurg. 60:883, 1984). Lipid peroxidation (LP) also has been postulated to cause cellular damage following trauma or ischemia (ibid). Previously we have examined the interactive membrane-damaging effects of LP and Ca^{++} in CNS and found them to be synergistic (submitted) in agreement with studies by Barsacchi et al. (BBA, 762:241, 1983) in heart. In the present study, the ability of LP to induce a large and rapid movement of Ca^{++} ions across CNS membranes is reported.

Brain synaptosomes (BS) were isolated from male Sprague-Dawley rats (Braughler, J. Neurochem. 44:1282, 1985) and cultures of murine spinal cord neurons (SCN) were prepared (Ransom et al., J. Neurophys. 40:1132, 1977). Ca^{++} uptake into BS was measured by incubating BS at 37°C in Hepes-Krebs buffer, pH 7.4 (KB) containing 1.5mM 45-$CaCl_2$. Uptake was terminated by rapidly diluting, filtering, and washing incubated BS in ice cold Ca^{++}-free KB containing 1mM $LaCl_3$. Filters were transferred to scintillation vials. Ca^{++} uptake by SCN was determined similarly, except that SCN were washed with La^{+++}-KB, then solubilized with 1% SDS for counting. LP of BS was initiated with 500μM ADP, 100μM H_2O_2, and 200μM $FeCl_2$, and followed continuously using a Clarke-style O_2 electrode. Malonyldialdehyde (MDA) was determined by TBA reaction, and conjugated dienes (CD) were monitored in Lubrol-dispersed BS by Abs, 232nm. Loss of arachidonic acid (AA) from SCN was followed by measuring release of 14-C-AA from SCN preloaded with 14-C-AA.

Within 30 sec after Fe^{++} initiation of LP in BS, Ca^{++} uptake had risen 10-20 fold, and by 6 min had increased 30-40 fold. The initial 30 sec burst of Ca^{++} uptake was coincident with a sharp increase in O_2 consumption and CD formation; MDA formation was minimal at this early time. In the absence of Fe^{++} a 3-5-fold increase in Ca^{++} uptake occurred that apparently corresponded to breakdown of pre-existing lipid hydroperoxides in BS membranes. Fe^{++}-induced Ca^{++} uptake and LP were partially blocked by methylprednisolone sodium succinate (100μM) and completely by desferrioxamine (500μM). The Ca^{++} channel blockers verapamil, nifedipine, and cinnarizine partially inhibited Ca^{++} uptake by BS in the absence of Fe^{++} but did not prevent Fe^{++}-induced Ca^{++} uptake or LP. LP of SCN caused a 3-9-fold increase in Ca^{++} uptake that was associated with AA release. The rate of AA release was half that seen with Ca^{++} ionophore, A23187 (10μM).

These findings suggest that perturbation of neuronal membranes by LP can result in the rapid influx of Ca^{++} which may mediate further membrane damage, perhaps via phospholipase activation. Observations such as these suggest an interactive role between LP and membrane permeability to Ca^{++} that may be important in the pathophysiology of CNS trauma and ischemia.

75.2 NEURONAL CELL DEATH AFTER DENDRITE AMPUTATION. J. H. Lucas*, G. W. Gross, C. R. Gardner* and J. B. Kirkpatrick††
Department of Biology, The Texas Woman's University, Denton, TX 76204 and ††Department of Pathology, Baylor College of Medicine, Houston, TX 76030.

Little is known about the reactions of neurons to dendritic disruption. Dendrites may ramify as far as 1000 μm from somata (Shepherd, G. M., The Synaptic Organization of the Brain, p. 83, 1976) and dendritic damage undoubtedly is an important part of both diffuse and localized CNS injury. Using UV laser microbeam techniques (Gross et al., J. Neurosci., 3: 1979, 1983), we have amputated dendrites of mouse spinal neurons in culture (3-5 wks post seeding). Dendritic processes (2-5 μm in diameter) were amputated at distances of 50, 100 or 150 μm from the perikarya. A total of 60 cells was operated at each distance. Cell survival values at 24 hrs were 31 ± 3 %, 53 ± 6 % and 71 ± 5 % respectively at the three lesion distances. No further cell death was observed at 48 and 72 hrs.

Previous investigations have demonstrated that percent loss of resting potential 20 min following neurite amputation is an exponential function of lesion distance (Lucas et al., Neurosci. Abst. 10: 1178, 1984). However, injury potentials are surprisingly persistent. Complete recovery of resting potentials has not been observed in a one hr period. Preliminary data indicate that even at 24 hrs potentials are still slightly below unoperated control cell resting potential values.

Measurements of physical parameters of the operated cells at a fixed lesion distance (100 μm) reveal a definite inverse correlation between percent cell survival and diameter of the transected neurite at the lesion. A direct correlation between the combined membrane areas of the soma and the proximal segment with cell survival is also indicated. These parameters probably reflect the magnitude of the injury current through the lesion and the compensating effects of ionic pumps in the membrane. Cell survival may ultimately depend upon the ability of the cell to buffer these ionic influxes especially the calcium component. The effect of low calcium on cell survival is presently under investigation.

75.3 VERY EARLY CHANGES IN CHICK DORSAL ROOT GANGLIA FOLLOWING PARTIAL ABLATION OF THE NEURAL CREST. V.McM. Carr. Dept. Biochem., Molec. and Cell Biol., Northwestern Univ., Evanston, IL 60201.

Responses of dorsal root ganglia (DRG) to partial ablation of the brachial neural crest were examined in chick embryos. Ablation was carried out at the level of DRG 15-17 as described previously (Carr, J.Neurosci.4:2434,1984). In those previous studies embryos were examined at H. and H. stage 35, near the end of the period of naturally occurring neuronal cell death in the brachial DRG (Hamburger, et al., J.Neurosci.1:60,1981). Significant changes were found in the size of the ganglia examined as well as in neuronal nuclear size, neuronal numbers, and degenerative activity. A most surprising observation was that compensatory hypertrophies were not confined to brachial DRG (DRG 13-17) but were found in cervical ganglia several segments anterior to the site of lesion.

The current experiments examine responses of the DRG during early stages of neuronal cell death. Studies at stage 27, the time of onset of naturally occurring cell death (Hamburger, et al. op. cit.), show that ganglionic volume was reduced at the site of lesion as expected. However, compensatory enlargements of cervical DRG occurred as far anterior as DRG 10, the rostral limit of the investigation. These hypertrophies were highly significant in all cases (p .005) and thus agree with the cervical DRG hypertrophies seen at stage 35. To date changes in cell numbers have been tabulated in DRG 13. These changes correlate with the ganglionic hypertrophy: cellular hyperplasias of 42 to 45% were found in whole ganglia (p .005) as well as in lateroventral and mediodorsal regions of the ganglia. However, no changes in degenerative activities were found. These observations would suggest that the ganglia may in some way be able to respond to reduction in brachial ganglionic material several segments away prior to the onset of neuronal cell death. Further investigations are being carried out.

75.4 ACCELERATED MOTONEURON CELL DEATH IN THE BRACHIAL LATERAL MOTOR COLUMN (LMC) OF WINGLESS (WI) MUTANT CHICK EMBRYOS. M.E. Lanser*, C.J. Flanary* and J.F. Fallon* (SPON: A.W. Clark). Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

Cell death is an integral part of the development of the nervous system. While there are many theories to account for this phenomenon, little is known about its true nature. In the chick embryo spinal cord, the LMC undergoes a predictable degeneration. Cell loss occurs after cellular proliferation and migration, begins on embryonic day 6 (D.6) when contact with the target limb musculature is established, and eliminates about half of the initial population of motoneurons. Because of the temporal relation between cell death and target innervation, it has been proposed that the dying motoneurons are those that fail to acquire some kind of trophic support from the target. Since limiting the amount of available target results in proportionately fewer motoneurons surviving the cell death period, it has been proposed that motoneurons normally compete with each other for a limited amount of trophic support. However, these experimental data can only be taken to indicate the normal occurrence of simple competition if the time course of cell loss is the same in each case. In previous work on limbless chick embryos, we demonstrated that cell death was accelerated in the brachial LMC in the absence of a periphery (J. Neurosci. 4(8):2043-50). In order to confirm this observation, we examined the pattern of cell death in the wi brachial LMC. Wi is an autosomal recessive mutation that results in no wing development and variable leg development in homozygotes. We counted the number of living motoneurons in the brachial LMC of wi embryos and their normal sibs on D.6 through D.12. The results are:

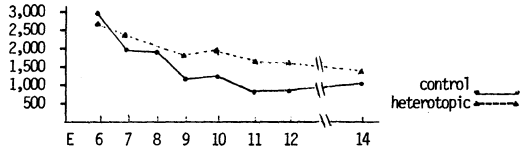
	D.6	D.8	D.10	D.12
Normal:	14,774 (5) +/- 2,292	13,150 (2) +/- 704	10,396 (5) +/- 750	8,462 (5) +/- 1,649
Wingless:	10,830 (2) +/- 1,974	3,942 (2) +/- 79	2,264 (5) +/- 968	2,879 (5) +/- 1,195

This shows that: (1) there are already fewer motoneurons in the wi brachial LMC on D.6 when target contact is normally first established; and (2) cell death is accelerated in the wi brachial LMC compared to normal. Because of this altered time course, these results do not necessarily indicate or support a role for simple competition in regulating naturally occurring neuronal death. These results do suggest that embryonic motoneurons require an interaction with the developing limb to stabilize them through an early critical period in their development. The failure to establish this interaction results in rapid destabilization and death. These data do not address the question of whether the required interaction is chemical, mechanical or functional in nature. (Supported by NIH-T32AM07389 and NSF-PCM8406338)

75.5 GROWTH AND DIFFERENTIATION OF THORACIC NEURAL TUBE TRANSPLANTED TO THE LUMBAR REGION IN THE CHICK EMBRYO. M. O'Brien*, R. W. Oppenheim and D. Prevette*. Dept. of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103.

In order to study the growth, differentiation and survival of neurons located in a foreign environment, heterotopic transplantation of several (2-6) segments of thoracic neural tube to the lumbar region (T-L) was carried out on embryonic day (E)2, shortly after neural tube closure. Control operations included homotopic T-T and L-L transplants. Embryos were sacrificed at different stages between E5 and E14, processed histologically and examined in the light microscope. Prior to sacrifice the movements and reflexes of hindlimbs were recorded. Hindlimbs innervated wholly or partially by thoracic spinal cord exhibited normal appearing movements and reflexes up to the oldest stages examined so far (E12-E14). Embryos retained for detailed histological examination exhibited normal differentiation of the heterotopic thoracic cord and in most cases the transplanted tissue had merged with host cord so that there was apparent anatomical continuity. Ongoing studies of the retrograde transport of HRP between donor and host cord will be able to substantiate this apparent anatomical continuity. The sympathetic preganglionic neurons (nucleus of Terni) that are characteristic of normal thoracic spinal cord were present in the heterotopically located thoracic tissue. Motoneurons (MNS) in the transplanted segments also appeared to differentiate normally. In fact, MN size (nuclear diameter) on E10 was larger in the transplanted vs control thoracic spinal cord (5.6 vs 5.9 μm, $p<0.01$). Cell counts between E6-E14 indicate that there are significantly more MNS in heterotopic vs control thoracic spinal cord (Fig. 1). Furthermore, in cases where 3-4 segments of transplanted thoracic cord were located in the central or rostral segments of the lumbar region the number of MNS in the lumbar lateral motor column caudal to the transplanted tissue was increased when compared to segment-matched control regions (L4-8) of the lumbar LMC (cont. = 1,800/seg., n=3; exp. = 2,400/seg., n=3). This suggests that the presence of fewer MNS in adjacent thoracic segments may have resulted in less cell death of contiguous lumbar MNS due to reduced competition for target-related survival factors. Studies are presently in progress on: (1) the hindlimb projection patterns of heterotopic thoracic MNS; (2) the projections of sympathetic preganglionic neurons from transplanted tissue; and (3) the development and differentiation of various properties of hindlimb muscles innervated by foreign MNS.

[Fig. 1]



75.6 LOSS OF ACETYLCHOLINE ESTERASE POSITIVE CELLS AND CHOLINE ACETYLTRANSFERASE ACTIVITY IN THE SEPTAL AREA AND DIAGONAL BAND OF BROCA FOLLOWING FIMBRIA FORNIX TRANSECTION. Klas Wictorin*, Walter Fischer*, Lawrence R. Williams, Silvio Varon, Anders Björklund, and Fred H. Gage, Dept. of Histology, University of Lund, Dept. of Biology, UCSD, Dept. of Neurosciences, UCSD.

A variety of retrograde changes occur in central and peripheral nerve cell bodies following axotomy. In instances of minimal collateralization proximal to the axotomy, cells have been reported to die. In order to investigate the mechanisms involved in this cell death, and to develop potential therapies that may prevent the cell death, a model system is required. We, and others (Grady et al., SN, 1984), have chosen the septo-hippocampal system as a model system to investigate cell death in the CNS because of its well defined anatomical, and biochemical characteristics.

In the present study unilateral fimbria-fornix (FF) aspiration lesions were performed, which destroy a major cholinergic pathway, prior to extensive collateralization in the hippocampus. At 1 day and 1,2,4 and 6 weeks following aspiration, we measured the number and size of acetylcholine esterase(AChE)-positive cell bodies in the medial septum and vertical and horizontal limbs of the diagonal band of Broca. Animals were pretreated with diisopropylfluorophosphate (DFP), to facilitate the quantification of cell size and number. In a parallel set of animals we measured choline acetyltransferase (ChAT) activity in the septo-diagonal band region ipsilateral to the FF lesion and compared those values to the values obtained from the contralateral septo-diagonal band region.

A significant 31% loss of AChE-positive cells was observed in the medial septum already at 1 day following the FF lesion. The loss reached 64% by 1 week, but did not significantly change between 1 week and 6 weeks post-lesion. At all time points there was a greater decrease in cell number in the medial septum as compared to the vertical limb, and a greater decrease in cell number in the vertical limb relative to the horizontal limb. No significant difference in cell size (major axis of the measured AChE positive cells) was observed until a decrease in cell size was measured at 4 weeks post-lesion. This difference was also apparent at 6 weeks. No change in ChAT activity was observed between tissue taken contralateral to the lesion and tissue from unoperated controls. A significant decrease in ChAT was observed ipsilaterally 1 day following lesions, but this difference gradually returned to normal control levels over 6 weeks. A marked sprouting of AChE positive fibers in the dorsal lateral septum was observed in rats not treated with DFP, which could account for the gradual return of ChAT activity to normal levels. These results suggest that a cascade of events occur in the cholinergic septo-diagonal band region following axotomy, which include a dramatic loss of cell bodies, a decrease in cell size as well as a possible sprouting response of the remaining cholinergic neurons.

75.7 AN AUTORADIOGRAPHIC ANALYSIS OF ALTERATIONS IN CELL DEATH CONSEQUENT TO MONOCULAR ENUCLEATION IN THE HAMSTER RETINAL GANGLION CELL LAYER. J. I. Raabe and B. L. Finlay. Department of Psychology, Cornell University, Ithaca, NY 14853.

Monocular enucleation results in decreased cell death in the temporal retina of the remaining eye (Sengelaub and Finlay, Science, 213, 1981) and an enhanced ipsilateral projection. In normal development of the retinal ganglion cell layer, the rate of cell loss is highest for the first generated cohorts (those cells generated on embryonic days 10 and 11), and lower for later cohorts (E12-15) (Finlay, Sengelaub and Dolan, Neurosci. Abs., 10, 1984), and it is possible that the earliest generated cells might serve as pioneers in the early establishment of projection laterality. In addition, cells of different embryonic cohorts may be of different types, such as x-, y- or w-like cells, or "displaced" amacrine cells (Drager, Neurosci. Abs., 10, 1984; Finlay, et al., Neurosci. Abs., 10, 1984). To determine if the increased cell survival seen in the temporal retina following monocular enucleation results from a specific saving of the early generated cohorts, and if enucleation differentially alters survival of particular cell types, we examined the relative loss of cells in particular embryonic cohorts in enucleated and normal animals using tritiated thymidine.

Pregnant hamsters were injected with ^{3}H thymidine (5μCi/gm body weight; specific activity 20Ci/mM) on one of embryonic days 10, 12, or 14 (E15 = day of birth). On the day of birth, half of the pups in each litter were monocularly enucleated. Pups were killed on either postnatal day 4 or 5, the days of maximal reduction in cell loss in the enucleate relative to normal. After autoradiographic processing, counts of labeled normal and degenerating cells in the retinal ganglion cell layer were made from horizontal retinal sections.

In all the unoperated controls, almost all of the labeled degenerating cells observed were generated on E10 and E12, 5 times the number observed from E14. This pattern remained the same after enucleation, and is further evidence that the E14 cohort consists primarily of "displaced" amacrine cells. Rates of neuronal loss (number of labeled degenerating cells per 1000 labeled normal cells) for the E10 (early) and E12 (later) cohort were reduced in the enucleates with respect to normal, but equal to each other. The effect was greatest in the temporal retina, where cell death rates were reduced by half. Since enucleation reduced cell death in both the early and later generated retinal ganglion cell cohorts equally, it is unlikely that the earliest generated cohort serves as pioneer neurons and competitive processes must affect both cohorts equally.

75.8 SPATIAL GRADIENTS IN BOTH NEURONAL GENERATION AND DEGENERATION PRODUCE THE RETINOTOPIC AND LAMINAR ORGANIZATION OF THE HAMSTER SUPERIOR COLLICULUS. K. C. Wikler, D. R. Sengelaub, M. H. Kane*, and B. L. Finlay. Department of Psychology, Cornell University, Ithaca, NY 14853.

Neuronal degeneration in the early development of the hamster superior colliculus has two striking spatial inhomogeneities (Finlay, et al., J. Comp. Neurol., 204, 1982). First, neuronal death is elevated in the intermediate and deep gray laminae relative to the superficial laminae, and second, neuronal death is elevated in the peripheral margins of the superficial laminae relative to the center. In order to assess the relative contributions of neuronal proliferation and neuronal death to the final composition of the adult superior colliculus in terms of its laminar and retinotopic organization, we traced the spatial distribution and pattern of degeneration of those cells produced on the peak day of neurogenesis in hamster (Crossland and Uchwat, Devel. Brain Res., 5, 1982), through the period of peak neuronal death to adulthood.

Pregnant hamsters were injected with ^{3}H thymidine (5μCi/g. body weight, specific activity 20 Ci/mM) on embryonic day 11, with the 24 hours following mating designated as E0. Pups were killed on postnatal day 4 (prior to the peak of degeneration), P6 (after the degeneration peak), or at adulthood. After processing for autoradiography, 3 equally-spaced coronal sections of the superior colliculus were charted for labeled and unlabeled degenerating and normal cell profiles.

Rates of degeneration for all cells (degenerating cells per 1000 normal cells) on both P4 and P6 replicated the spatial differences found in the previous study. For the E11 cohort alone, however, unlike the pattern for all cells in the superficial laminae, cell death rates were uniform throughout (center = 14.3 ± 6.6, periphery = 13.2 ± 9.6). Therefore, earlier cohorts must produce the center/periphery disparity in cell death rates, a pattern which we have observed previously in the creation of center/periphery disparity in cell density in the hamster retinal ganglion cell layer.

As was the case for all cells, degeneration rates for the E11 cohort were elevated in the deeper laminae (P6, superficial mean rate = 13.5 ± 8.1; deep = 34.0 ± 12.7). Prior to cell death, the number of cell labeled in the intermediate and deep gray laminae was twice (ratio = 2.18) that of the superficial laminae. However, by adulthood the proportion of labeled cells was nearly equal (r = 1.1), indicating that the number of cells in the lower laminae was differentially reduced, consistent with the cell degeneration pattern. Throughout development and to adulthood, the proportion of all cells in the superior colliculus from the E11 cohort remained constant, indicating that all cohorts must be subject to the same differential generation and loss of the deeper laminae. Initial spatial gradients or uniformity in patterns of cell generation observed early in development can thus be reversed or abolished by later differential cell loss.

75.9 A REDUCTION IN MOTONEURON DEATH IN THE CHICK LATERAL MOTOR COLUMN IN VIVO BY EXTRACTS OF EMBRYONIC SKELETAL MUSCLE.
GUY J. PETRUZZELLI*and W. F. HUGHES* (SPON: S.K. JACOB).
Dept. of Anatomy, Rush Medical College, Chicago, IL.

Factors present in the soluble fractions of muscle cell homogenates have been shown to enhance neuron survival, neurite outgrowth, and choline-acetyl transferase activity in vitro (Nurcombe,V., Brain Res., 291:19, 1984; Smith, G., Science,219: 1079,1983). The present study attempted to determine if crude extracts applied to the vascularized chorioallantoic membrane (CAM) could modify the in vivo developmental program in the lumbar lateral motor column (LMC). In our experiments, skeletal muscle extracts were prepared according to previously reported methods. The total protein concentration of our extract was determined to be 3.266 mg/ml using the dye binding assay of Bradford. Extracts (0.5 mls.) were applied to the CAM of embryonic chicks on alternate days between embryonic days 5 to 12 (E 5,7,9,11). During this period of normal development, a 40 % loss of somatic motor neurons is observed in the LMC. In day 12 extract treated embryos, counts of neurons in the lumbar LMC were increased 11.4 % over values for aged-matched normal embryos. The mean of the untreated LMC populations was consistant with values in the literature. re: 12,636 neurons ($\pm$ 238.70, n=8) Embryos receiving extracts had a mean LMC population of 14,077 neurons ($\pm$ 272.09, n=9). The student's t-test indicated significance at a $P < 0.002$ level. Control embryos receiving heat inactivated extract showed intermediate increases at the 12 day period. The results suggest a possible role for a diffusible muscle derived motoneuron growth factor in the regulation of the normal pattern of neuron survival in the lumbat LMC. A reduction in naturally occurring cell death has similarly been demonstrated in the pre-ganglionic sympathetic motor column using purified beta-nerve growth factor applied to the chorioallantoic membrane. Our results also suggest the utility of this model as an in vivo assay system in which purified muscle fractions or other motoneuron survival modulating factors can be tested.

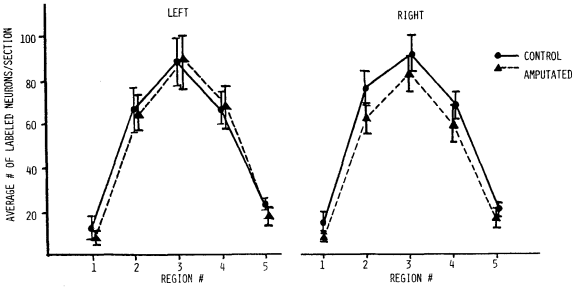
75.10 THE EFFECTS OF AMPUTATION ON MOTOR NEURON POOLS.
E.R. Feringa and H.L. Vahlsing*.Univ. Calif. and VAMC, San Diego, Ca. 92161, and Medical College of Ga. and VAMC, Augusta, Ga. 30910.

It has been suggested that the loss of corticospinal neurons (CSNs) in amyotrophic lateral sclerosis may be a secondary phenomenon following loss of lower motor neurons (LMNs). Such trans-synaptic degeneration of neurons has been demonstrated in the visual system of man and other mammals. Degeneration of geniculate cells after loss of an eye occurs in adult or young animals. Retrograde trans-synaptic degeneration in the retina and optic nerve after occipital cortex lesions is established in young animals and some evidence suggests it may also occur in adults. In this experiment the number of LMNs in the L-5 gray matter and the number and distribution of CSN somata remaining 25 weeks after amputation of the right hind limb of the rat were compared with unoperated controls.

Twenty five weeks after right hind limb amputation, the number of large neurons in the area of L-5 spinal gray which contains those cells projecting to the hind limbs is dramatically decreased on both sides when compared to exactly matched isogeneic controls. In control rats $2.92 \pm .22$ large neurons were identified per 7µm section on the left side and $3.14 \pm .20$ on the right side. Twenty five weeks after right hind limb amputation $1.60 \pm .21$ such cells were found on the left and $1.72 \pm .21$ on the right. The decrease in large neurons was significant on both sides ($p<0.001$).

The same experimental rats showed 5726 ± 652 CSNs on the right and 6169 ± 778 CSNs on the left. Controls showed 6862 ± 673 CSNs on the right and 6441 ± 831 CSNs on the left. The number and distribution of demonstrated CSNs 25 weeks after right hind limb amputation is not significantly different from that found in controls.



HRP Labeled Neurons Found In Sensory Motor Cortex After T_3/T_4 Insertion Of HRP 25 Weeks After Right Hind Limb Amputation

75.11 MOTOR NEURON SURVIVAL FOLLOWING REDUCTION IN THE SIZE OF NEURON POOL.
G. S. Sohal and T. Yamashita*. Dept. of Anat., Med. Coll. of Georgia, Augusta, GA 30912; *Dept. of Anat., Sch. of Med., Kanazawa Univ., Kanazawa 920, Japan.

Loss of large numbers of motor neurons during the course of embryonic development appears to be an integral part of ontogeny of some neural centers. It is commonly supposed that motor neurons compete for some aspect of the periphery. The competition at the periphery is thought to be for postsynaptic sites and/or trophic substances essential for neuron survival. The motor neurons which die during normal development are thought to be those which have failed in this competition. In the present study an attempt was made to test the competition hypothesis by reducing the size of the initial neuronal pool, before motor neurons extend their axons into the periphery.

The trochlear nucleus of duck embryos attains a maximum of about 2400 neurons and after the period of cell death about 1300 neurons. The maximum number of neurons in the trochlear nucleus of Japanese quail embryos is about 1250 and after the period of neuron drop out only 750 survive. The midbrain vesicle of quail was transplanted in place of the midbrain of duck embryo on day 3 of incubation by established microsurgical procedures. The grafted neurons were verified by taking advantage of the structural difference in the interphase nucleus of these embryos. Only the quail nuclei exhibit a large heterochromatic mass associated with the nucleolar RNA. The peripheral connections of the grafted motor neurons were confirmed by retrograde transport of HRP injected into the superior oblique muscle, the sole target of innervation of the trochlear motor neurons.

Our preliminary counts on motor neuron survival indicate an average of about 700 neurons in the trochlear nucleus of the experimental embryos. In other words cell death of normal magnitude occurred despite increased periphery or reduced peripheral competition. According to the competition hypothesis none of the neurons should have degenerated. That is, the experimental embryos should have had about 1250 neurons in the nucleus. These observations suggest that the trochlear motor neurons die for reasons other than competition at the periphery.

Supported by NIH grants HD 17800 & HD 18280.

75.12 LIMB REGULATION OF MOTOR NEURON NUMBER DURING THE PERIOD OF PROFOUND CELL LOSS.
E.D. POLLACK, N.A. KETT* and C.A. BIALY* . Inst. Study Develop. Disabil., Dept. Biol. Sci., Comm. Neurosci., Univ. Illinois at Chicago, Chicago, IL 60680.

The presence of the limb during development has been long recognized as a necessity for the ongoing survival of lateral motor column (LMC) neurons. As the target for the spinal motor axons, limb absence invariably results in the eventual depletion of LMC neurons. Less obvious is the requirement for an intact limb in order that the natural occurrence of motor neuron loss can proceed according to a developmental timetable. We have been examining the influence that the limb exerts on the number of retained motor neurons during the period when cell loss is normally at its maximum in the lumbosacral LMC of the frog tadpole (stages IX through XIII). When the developing hindlimb was amputated at the usual time of onset of profound neuronal loss in the LMC, the process of reduction in cell number was inhibited so that the LMC retained throughout this period nearly all the neurons that were initially present. Some neuronal retention also occurred in the contralateral LMC. A series of control experiments that included the traumatization of the limb without its removal, but with accompanying axotomy, demonstrated that intact motor neuron-limb communication is required for the initiation of maximal cell loss. Absence of the limb or axonal transection presumably prevents this interaction, and thus interferes with the flow of information that is required for the selective events of neuronal loss and survival.

Developmental limb asynchrony produced by unilateral, partial limb amputation at an early larval stage (stage V), followed by regeneration, resulted in a paradoxical LMC cell count during the profound cell loss phase. This was manifested by equal numbers of neurons on both sides of the spinal cord, even though one limb was morphologically younger than the other. Once again, an effect appeared in the LMC contralateral to the manipulated limb in which case the neuronal count was representative of a stage younger than that indicated by the unoperated limb. Analysis of neuronal distributions in the LMC reflected the differentiated configuration of the regenerate in which its proximal portion was appropriate to the stage of the animal, and the distal region was appropriate to the delayed development of a regenerating limb.

It is clear that the extent of LMC cell reduction is strongly dependent on the developmental events related to the limb target. The data from each of these limb manipulations can be explained in terms of the availability of a putative motor neuron survival factor originating from the "least differentiated" or "dedifferentiated" tissue of the limb.

75.13 THE EFFECT OF T3 AND METHIMAZOLE ADMINISTRATION ON MOTONEURON CELL DEATH IN THE SPINAL CORD OF THE CHICK EMBRYO. C. Williams*, C. Wohlenberg* and M.J. O'Donovan. (Spon: M. Dekin) Dept. of Physiology and Biophysics, Univ. of Iowa, Iowa City, IA 52242

Thyrotropin releasing hormone has recently been shown to influence motoneuron cell death in the lumbosacral spinal cord of the chick embryo (Weill, Neurosci. Abstr. 10:641,1983) an effect that could be mediated by altered levels of thyroid hormone. The purpose of the present study was to investigate this hypothesis by determining the effects of thyroid status on motoneuron cell death in the lumbosacral spinal cord of the chick embryo. Chick embryos received daily injections of triiodo-L-thyronine (L-T3) or methimazole (NMI) in concentrations previously reported to induce hyper- or hypothyroidism (L-T3: 1-3 µg/100 g body wt; NMI: 5mgm/100 body wt). Control embryos received daily injections of either saline or a biologically inactive isomer of T3, triiodo-D-thyronine (D-T3). T3 injections were begun after motoneuron proliferation and encompassed the cell death period (day 6-13). Methimazole injections spanned day 2-13 and were started earlier to ensure low T3 levels during motoneuron cell death. The embryos were sacrificed at the end of the cell death period (day 13 or later), processed histologically and the total number of surviving lumbosacral motoneurons determined. All counts with the exception of the methimazole series were performed "blind" so that the individual counting the sections was unaware whether they were from experimental or control embryos. The results are summarized in Table 1.

L-T3	D-T3	MMI	CONTROL
11,582±1484	12,082±1408	12,753±2081	12,469±1408
(N=9)	(N=13)	(N=8)	(N=19)

TABLE 1. Uncorrected motoneuron counts (mean±sd) in control and experimental embryos.

The results show that neither T3 nor methimazole injections lead to significant changes in the extent of motoneuron cell death, indicating that thyroid hormone probably does not regulate this aspect of motoneuron development. Therefore, the effect of TRH on motoneuron cell numbers is presumably mediated through a mechanism other than altered levels of T3. (Supported by MDA).

75.14 THE ENHANCEMENT OF NATURAL MOTONEURON CELL DEATH BY GLUCOCORTICOIDS. C.L. Weill. Depts. of Neurology and Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

Binding of (^{3}H)corticosterone has been localized to spinal cord motoneurons (Duncan and Stumpf, Brain Res. 307:321,1984). Our unpublished studies demonstrate the presence of glucocorticoid receptors in motoneurons on embryonic day 6. This study was undertaken to determine the effect of exogenously added glucocorticoids on natural motoneuron cell death.

Steroids dissolved in sesame seed oil were administered to chick embryos (Harco X Partmer red) by injecting 25 ul into the yolk sac on embryonic days 5-9. Embryos were sacrificed on day 10, staged, and weighed. The lumbar cord was dissected, fixed, stained, embedded in paraffin, and serially sectioned at 10 um. For every 10th section all large, dark-staining cells of the lateral motor column (LMC) containing at least one nucleolus were counted at 400x.

During normal development a peak of 22,838 +/- 731 (mean +/- S.E.M., n=6, uncorrected) motoneurons per LMC is observed on embryonic day 6. The number of cells declines by 33% to 15,260 +/- 403 (n=4) on day 10 in oil-injected control embryos. Injections of 0.197 ug of dexamethasone (Dex) per embryo resulted in a 28% decrease in survival yielding 10,913 +/- 813 (n=4) motoneurons per LMC. Reducing the dose 2-fold resulted in the survival of 11,263 +/- 1370 (n=3) cells, an increased loss of 26%. Equal molar injections of the glucocorticoid antagonist, methyl-hydroxyprogesterone (MHP), resulted in a statistically significant increase (29%) in motoneuron survival yielding 17,420 +/- 115 (n=4) cells. Treatment with the mineralocorticoid, aldosterone (Ald), yielded 16,757 +/- 652 cells (n=3), a value statistically indistinguishable from controls.

Body weight for controls was 2.545 +/- 0.108 g (n=8). Treatment with 0.197 ug Dex reduced mean body weight by 27% ($P<<0.01$) to 1.865 +/- 0.074 g (n=4). Treatment with MHP increased body weight by 16% ($P=0.001$) to 2.966 +/- 0.157 g (n=11). Serial reconstruction indicates that the LMC's of both controls and treated embryos traverse the same number of spinal segments. Qualitative examination of the cross sectional areas of the LMC's does not indicate significant differences between control and treated embryos.

These data demonstrate that the exogenous addition of glucocorticoids to developing chick embryos during the period of natural neuronal death enhances the loss of motoneurons from the spinal cord LMC. Addition of a glucocorticoid antagonist prevents motoneuron loss, while a mineralocorticoid had no effect. Thus these data support the suggestion that glucocorticoids may regulate natural neuronal death (Cowan et al., Sci. 225:1258,1984), but do not permit a distinction between a direct effect on motoneurons via an intraneuronal steroid-receptor system and an indirect effect via altered muscle trophic factor or synaptic site availability. Supported by NIH grant NS18642.

75.15 MINIMAL EFFECT OF INTRAOCULAR TETRODOTOXIN ON THE POSTNATAL REDUCTION IN THE NUMBER OF OPTIC NERVE AXONS IN THE ALBINO RAT. D.Crespo, D.D.M.O'Leary, J.W.Fawcett* and W.M.Cowan The Salk Institute, P.O. Box 85800, San Diego, CA. 92138

We have previously determined that about two-thirds of the axons found in the optic nerve at E20 are eliminated by about P10. About 90% of this loss occurs postnatally and reflects a comparable decline in the number of retinal ganglion cells. We have now examined the effect of blocking retinal ganglion cell (RGC) activity with the sodium channel blocker tetrodotoxin(TTX) on the postnatal reduction of the number of optic axons. The left eyes of albino rats were injected with 0.03 ul-0.06 ul (dose increased with age) of 0.1% TTX on alternate days, beginning with P0. The rats were perfused on P3, P7, P12 or P14 with saline followed by 1.5% paraformaldehyde, 3% glutaraldehyde, 0.6% acrolein and 0.6% DMSO in a 0.1% cacodylate buffer(pH 7.3). The left and right optic nerves were removed, postfixed, rinsed, osmicated, and embedded in Spurr's resin. Semithin and ultrathin sections were cut from the midpoint of each nerve. The ultrathin sections were photographed on a Zeiss 109 EM. From montages (2000X) the cross-sectional area of each nerve (excluding the area occupied by large glial processes, cell bodies and blood vessels) was determined. Micrographs were taken at 12000X from areas relatively free of large glial processes, and enlarged 3X. From these the mean density of nerve fibers was determined, and the total number of axons in each nerve was calculated. Three pairs of nerves were examined at each age. The means ± S.D. for both normal (from Crespo, O'Leary & Cowan, Dev. Brain Res., in press) and experimental rats are given below.

AGE	NORMAL	TTX TREATED(left)	CONTROL(right)
P0	273,740 ± 20,970	---	---
P3	216,600 ± 18690	238,360 ± 13,500	234,690 ± 9540
P7	167,760 ± 5900	161,250 ± 6370	160,120 ± 5960
P10	118,540 ± 15,410	124,600 ± 4890(P12)	136,250 ± 4240(P12)
P14	105,810 ± 5230	111,220 ± 15,000	129,300 ± 10,840

Our results indicate that both the magnitude and time course of the reduction in the number of axons in the TTX treated and control nerves are similar to that seen normally, and thus a near normal amount of RGC death occurs in both the TTX treated and control retinas. Preliminary results suggest that the slightly greater number of optic axons found in the P12 TTX treated rats can also be brought about by large systemic injections of TTX. We have previously shown (Fawcett, O'Leary & Cowan, PNAS 81:6131; Fawcett & O'Leary, TINS, Apr.'85) that intraocular injections of TTX prevents the preferential elimination of both ipsilaterally projecting and topographically incorrectly projecting RGCs. The present findings confirm that the overall magnitude of RGC death is affected little by TTX, although there may be a small systemic effect. Supported by NIH grants EY-03653 and FO5-TW3540.

73.16 SYNAPSE FORMATION AND DENDRITIC DEVELOPMENT OF SPINAL MOTONEURONS IN THE CHICK EMBRYO FOLLOWING CHRONIC CURARE TREATMENT. A. Okada*[1], S. Furber*[2], R. W. Oppenheim[2] and N. Okado[3] (SPON: K. O'Steen) [1]Dept. Anat., Nihon Univ. Sch. of Med., Tokyo 173, Japan, [2]Wake Forest Univ., Bowman Gray Sch. Med., Winston-Salem, NC 27103, USA and [3]Univ. Tsukuba, Inst. Basic Med. Sci., Ibaraki 305, Japan.

During normal development of chick spinal cord, there is a major loss of motoneurons in the lateral motor column (LMC) between embryonic day (E)5 and E12. Previous experiments in which neuromuscular activity was chronically blocked with curare during the cell death period have shown that motoneuronal death can be reduced or prevented. This result raises two questions: (1) whether motoneurons which are rescued from natural cell death by curare treatment can receive afferents; and (2) whether afferent inputs can form synaptic contacts on motoneurons which have lost functional interactions with their target.

Four embryos that received daily injections of curare (2 mg curare/0.2 ml saline) between E6 and E9 and four saline injected controls were used for electron microscopic analysis. The packing densities of synapses in the lumbar LMC (Seg. 26) were examined on E10 and E16. The number of synapses per unit area of the motor neuropil (packing density) was used for estimating axodendritic synapses; the ratio between the amount of somal membrane which is covered with active zones (synapses), vs the entire somal circumference (synaptic covering ratio) was used for estimating axosomatic synapses. On E16 packing densities of axosomatic (6.08 ± 2.75%; M ± SD) and axodendritic (0.0810 ± 0.0174 synapses/µm^2) synapses in the curare embryos were significantly lower than axosomatic (9.22 ± 4.09%) and axodendritic (0.1389 ± 0.0214) synapses of controls. By contrast, no significant differences were found for either type of synapse between E10 curare and saline groups. Because the total number of motoneurons in the LMC of curare embryos was approximately 1.5 times greater than controls, and because there were no significant differences in motoneuron size or total volume of LMC, the total number of axosomatic synapses probably does not differ between curare and controls on E16. By contrast, the decrease in axodendritic synapses in the curare embyros on E16 is probably considerably greater than the 40% reported above since the size of the motor neuropil in the curare group is reduced to an extent proportionate with the increment in motoneuron numbers. The reduction in axodendritic synapses does not appear to be due to abnormal dendritic development. Therefore, the number of afferent terminals may be directly affected by the curare treatment. Measures of dendrite length and branching from Golgi-impregnated motor neurons in curare embryos on E10-11 and E15-16 were similar to those found in control embryos on E10-11 and E15-16.

75.17 CHRONIC MORPHINE ADMINISTRATION DELAYS NORMAL CELL DEATH IN THE AVIAN CILIARY GANGLION. S.D. Meriney and G. Pilar. The Department of Physiology and Neurobiology, The University of Connecticut, Storrs, CT 06268.

Natural cell death in the ciliary ganglion occurs during the period of synapse formation with the target and results in an approximate 50% reduction in cell number (6260 ± 339 at E 8 to 3704 ± 241 at E 14). Previously, enkephalin-like immunoreactivity has been demonstrated in preganglionic terminals in vivo, and ciliary ganglion cells themselves in vitro (Crean,G. et al. Soc. Neuro. Abst. 10, 429, 1984). We have examined the possibility that opiates may play some role in regulating normal cell death in the ciliary ganglion. Drugs were administered daily to the chorioallantoic membrane on embryonic days 7 through 14. Experimental and control embryos were sacrificed on E 14 and the ciliary ganglia were fixed in Bouins, paraffin sectioned at 8 u, stained with hematoxylin/eosin orange, and counted at 400x. Daily treatment with an increasing dose of morphine (20-200ug/day) rescued most of the cells that would have died (5948 ± 345 at E 14), and this effect was reversed by naloxone. Daily treatment of naloxone alone did not significantly affect cell survival when administered during the normal cell death period. When morphine treatment was discontinued at E 14 and the animal was sacrificed at E 16, cell death increased toward control levels (4302 ± 509 at E 16). When morphine treatment was continued through hatching to 7 days-post-hatch (DPH) a slight increase in cell survival was still present. When the treatment was discontinued at 7 DPH and the animal was sacrificed a 14 DPH, cell death reached control values. Therefore, morphine treatment in increasing doses appears to delay cell death only until the treatment is discontinued. To determine if these effects are restricted to the ciliary ganglion, morphine's effect on cell death in the lumbosacral LMC of the spinal cord was examined. There was no significant effect of morphine on spinal motoneuron survival. Therefore, morphine's influence on cell survival does not seem to be a general effect on motoneurons, and may be restricted to cells with endogenous opiates.

The mechanism by which morphine influences cell survival in the ciliary ganglion is not known. Morphine's effect on iris contractions is not significant (measured pupilomorphically following electrical stimulation of the ciliary ganglion), but morphine can partially block synaptic transmission through the ganglion. Morphine's effect in the ciliary ganglion may be do to its influence on activity in this system, or a direct effect of the opiate on the ciliary ganglion cells themselves. Supported by BSN 8410581 and the U. CT Research Fdn.

75.18 HYPOGLYCEMIA-INDUCED NEURONAL NECROSIS IN THE RAT STRIATUM IS PREVENTED BY A N-METHYL-D-ASPARTATE-RECEPTOR ANTAGONIST. T. Wieloch* (SPON: W.H. Oldendorf), Laboratory for Experimental Brain Research, University of Lund, S-22185 Lund, Sweden

Hypoglycemia if severe enough to cause cessation of brain electrical activity (isoelectricity) lead to neuronal necrosis in discrete brain areas (1). Following 30 minutes of isoelectricity 50-70% of the neurons in the striatum are irreversibly damaged. Recent evidence have shown that excitatory amino acids may be important factors in the development of hypoglycemia-induced brain damage (2). Unilateral ablation of the frontal neocortex in rats subjected to 30 minutes of hypoglycemia-induced isoelectricity, protected the subjacent striatum against neuronal necrosis. Concomitantly, a 10% decrease in the striatal levels glutamate was observed in the lesioned hemisphere (3).

The present investigation was performed to establish whether glutamate receptors of the N-methyl-d-aspartate (NMDA) type are involved in the pathogenesis of neuronal necrosis due to hypoglycemia.

Hypoglycemia was induced by 8 IU insulin i.p. (1). Thirty to forty minutes prior to the onset of isoelectricity, the rats were injected either with 2 ul saline (n=4) or 40 ug 2-amino-7-phosphonoheptanoic acid (APH) (n=5) in 2 ul saline pH 7.0 , into the striatum over a period of 10 minutes. Following a hypoglycemic insult of 30 minutes and one week recovery, the rats were perfusion fixed with formalin, sectioned and stained with acid fuchsin and celestine blue. Neuronal necrosis in the striatum was assesed in an area (600x400 um) surrounding the injections site.

		number of neurons	
treatment	hemisphere	necrotic (%)	total
saline	injected	61 ±8 (57)	106 ±9
saline	contralateral	74 ±10 (61)	121 ±11
APH	injected	6 ±8 (5) p 0.01	110 ±10
APH	contralateral	81 ±7 (68)	118 ±9

The data demonstrate that APH prevents hypoglycemia-induced neuronal necrosis in the striatum. Furthermore the results indicate that activation of the NMDA receptors by aspartate or glutamate may be important factors in the pathogenesis of hypoglycemic neuronal damage.

75.19 RAPID DOWN REGULATION OF HIPPOCAMPAL ADENOSINE RECEPTORS FOLLOWING BRIEF ANOXIA. K.S. Lee and W. Tetzlaff. Dept. of Neuromorphology, Max Planck Institute, 8033 Planegg-Martinsried, West Germany.

The selective vulnerability of certain CNS neurons to brief periods of anoxia has been known for over a century. Rather than causing a uniform type of cellular damage, the interruption or reduction of the normal oxygen supply to the brain results in a variety of cellular responses which can vary from region to region or even within subregions of the same structure. Pyramidal cells in the CA1 region of the hippocampus are perhaps the most sensitive cells in the brain to transient periods of anoxia. Following a 5-15 minute period of global anoxia, these cells exhibit a relatively slow series of changes which ultimately result in their death after 1- 2 days. This "maturation" process is of particular clinical interest inasmuch as the elapsed time between the anoxic trauma and the resultant cell death is presumably long enough to allow for therapeutic intervention. In the present study we sought to examine whether a change in the strength of the inhibitory, neuromodulatory action of adenosine might contribute to the hyperexcitability and epileptiform activity which precedes cell death in the hippocampus. The regional density of high-affinity, A1 type of adenosine receptors is known to be one of the factors which control the strength of the inhibitory action of adenosine. Thus quantitative autoradiographic studies of 3H-CHA (which binds to A1 type adenosine receptors) binding were undertaken to examine whether changes in the number of adenosine receptors occur subsequent to a brief period (12 min) of global anoxia. In the neocortex and striatum, a transient but nonsignificant decrease in 3H-CHA binding was observed. These changes were small, less than 5%, and tended to recover within 4-22 hours post-clamping. In contrast, the stratum radiatum of CA1 in the hippocampus exhibited a rapid and significant reduction in 3H-CHA binding following anoxia. Within one hour, CA1 showed a reduction of 10-15% and by 2 hours post-clamping the amount of 3H-CHA binding was reduced ca. 20% from control levels. This loss of 3H-CHA binding persisted for at least 22 hours, the longest time period tested and a time at which CA1 pyramidal cells have begun to irreversibly cease firing. This effect was not due to some form of selective swelling as the width of the stratum radiatum was not changed. A Scatchard analysis of 3H-CHA binding to crude membrane preparations from the CA1 region showed that the reduction in binding was due to a loss of binding sites, with their apparent affinity being unchanged. In summary, the region of the brain most sensitive to transient anoxia, i.e. CA1 of the hippocampus, showed a rapid and selective loss of 3H-CHA binding sites following brief anoxia. This reflects a reduction in the number of A1 type adenosine receptors and may be responsible for the hyperexcitability and epileptiform activity seen in CA1 pyramidal cells following tranisient global anoxia.

75.20 EVIDENCE OF INCREASED CELL DEATH IN RAT CEREBRAL CORTEX FOLLOWING IN UTERO EXPOSURE TO HYPOXIA. Mang C. Yu. Dept. of Anatomy, New Jersey Medical School, Newark, N.J. 07103.

The vulnerability of the central nervous system to hypoxia during development was studied in rats. Dams (Sprague-Dawley strain) on the 12th day of pregnancy were exposed to hypoxia (10% 02; 90% N_2) for 7 consecutive days. After hypoxic exposure, the dams were returned to breathe normal air until they littered. At birth, the neonates were removed from their dams and cross-fostered by healthy lactating dams until weaning. For control, neonates from dams which were exposed to normal ambient air during pregnancy were used. The hypoxic rats and the control were killed at postnatal days 5, 12 and 22, respectively. Biochemical measurements of DNA of the entire cerebral cortex, as an index of cell number, and electron microscopic examination of morphological alteration in the parietal cerebral cortex revealed the following findings. The total DNA contents of the hypoxic rats were significantly less than the control, being 70, 85 and 65% of the control at days 5, 12 and 22, respectively. Morphologically, the number of developing nerve cells showing degenerative changes in the cortical plates, particularly at postnatal days 5 and 12 in the hypoxic rats, was much greater than the control group. This study suggests that the reduction in cell number in rats exposed to hypoxia in utero was due, in part, to increased cell death.

75.21 IN VITRO ANOXIA SELECTIVELY DAMAGES STRIATAL AND HIPPOCAMPAL ACETYLCHOLINE AND CARBON DIOXIDE PRODUCTION. V. Mykytyn* and G.E. Gibson. Cornell Univ. Med. College, Burke Rehabilitation Center, White Plains, NY 10605.

An in vitro model of brain ischemia may facilitate an understanding of the molecular basis of selective vulnerability. Our previous studies with tissue slices (0.3 x 0.3 mm) from whole brain demonstrate that anoxic incubations in depolarizing concentrations of K^+ (treatment incubation) cause lasting metabolic changes in a subsequent incubation in the presence of 100% oxygen and depolarizing concentrations of K^+ (test incubation). Decreases are apparent in CO_2 production from glucose (-67%; a general measure of oxidative metabolism) and ACh synthesis (-63%; a marker of coupling of metabolism to function). Omission of calcium from the treatment incubation ameliorates these deficits, as determined in the test incubation. Since in vivo pathological studies of others suggest that ischemic damage may be post-synaptic or in the cell body, the consequences of this "in vitro ischemia" were examined with hippocampal slices, which contain cholinergic nerve terminals but not cell bodies, and with striatal slices which contain cholinergic cell bodies and cholinergic nerve terminals. An anoxic treatment incubation reduced the subsequent test incubation production of CO_2 similarly in hippocampus (-41%) and striatum (-36%). However, ACh synthesis was altered differently in the two regions; the prior ischemia reduced production by 48% in the striatum, whereas hippocampal ACh formation was unaffected. Addition of EGTA to the treatment incubation did not alter test incubation ACh synthesis by hippocampus, whereas it increased striatal synthesis by 80% (i.e. diminished damage of the treatment incubation). These results suggest that cell bodies are more damaged by anoxic insults than nerve terminals and that calcium is important in the production of these changes. To further test this possibility, synaptosomes were made anoxic in a treatment incubation; this did not alter test-incubation ACh synthesis or CO_2 production. Together, these results suggest that cell bodies (in this model, cholinergic ones) may be more sensitive to anoxic-induced damage than nerve endings. (Supported by grants NSO3346, AGO4171, and the Burke Relief Foundation.)

75.22 GOLGI STUDIES OF THE MATURATION OF CELL DAMAGE FOLLOWING REVERSIBLE FOREBRAIN ISCHEMIA. L.A. Paul*, J. Deshpande*, T. Wieloch* (SPON: S. Zornetzer). Laboratory for Experimental Brain Research, Lund University, S-22185 Lund, Sweden.

Neuronal necrosis in the hippocampus following cerebral ischemia takes time to develop, and maximal cell loss occurs many hours or even days after the ischemic insult. Rodent models allow the induction of reversible ischemia followed by recovery to full consciousness, both for varying amounts of time. The nature and distribution of cell death as seen with Nissl stains after ischemia followed by one week recovery have been described (Smith et al., 1984). This study details cell damage as seen with the Golgi stain in animals subjected to ischemia for 10 minutes and allowed to recover for several days.

Wistar-SPF rats (Møllegaards Avslab., Copenhagen) were anesthetized with halothane. Catheters were inserted in the jugular vein for subsequent withdrawal of blood, and in the tail artery for monitoring blood gases. Both common carotid arteries were exposed and loose sutures placed around them. Needle electrodes were placed into the temporalis muscle to monitor EEG. The rats were immobilized, artificially ventilated on N_2O:O_2, and the halothane discontinued. Ischemia was induced by the infusion of trimetaphan (Arfonad^R) and the withdrawal of blood until MABP reached 50mm Hg. Vascular clamps were then applied to both carotid arteries. Isoelectricity was observed within fifteen seconds in all cases. Ischemia lasted 10 minutes from the time the EEG became isoelectric. To end the ischemia, blood was reinfused, vascular clamps removed, and $NaHCO_3$ was given. Animals were extubated at 45-60 minutes, when they resumed spontaneous ventilation. They were placed in their cages with access to water and food, and allowed to recover varying times.

Following formalin perfusion, brains were removed and stained with a variant of the rapid Golgi technique and 90-micron coronal sections taken. Qualitative study in cortical regions of this material revealed no gross pathology such as denuded dendrites or distorted dendritic trees. However, in CA_1-subiculum of ischemic rats, an apparently spine-free cell with soma in s. pyramidale and large, regular swellings on its dendrites was seen. These swellings were more marked in the longer-recovered animals. It is likely from this cell's shape and location that it is a basket cell, supposed to play an inhibitory role in hippocampus.

Smith, M.-L., R.N. Auer, B.K.Siesjö. Acta Neuropath. (Berl.) 64:319-332, 1984.

75.23 INVESTIGATION OF A RAT MODEL FOR STUDYING THE EFFECTS OF DRUGS ON SURVIVAL DURING CEREBRAL ISCHEMIA. K. Viik* and B.R. Cooper, Dept. of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Certain barbiturates and related substances are known to have a protective effect on the brain during cerebral ischemia. One of these agents, phenobarbital, has occasionally been used clinically as an adjunct to brain surgery, or as a treatment of ischemia due to stroke or trauma. The CNS sedative effects of the barbiturates, however, are a major limitation in the use of barbiturates for stroke and certain other hypoxic conditions. Development of easily quantitated animal models of cerebral ischemia sensitive to the protective actions of standard drugs such as phenobarbital would facilitate research into CNS protective non-sedative antihypoxic agents. A number of "stroke" models using gerbils and middle cerebral artery ligation have been described in the literature (Levine, L. and H. Payan, Exp. Neurol. 16:255-262, 1966; Robinson, R. and F. Bloom, Biol. Psychiatry, 12:669-680, 1977). We will report in this abstract that measurement of survival time of 500+ gm male Long Evans rats after bilateral carotid artery occlusion provides another model sensitive to protective effects of phenobarbital and suitable for limited pharmacological screening. Male 500+ gm Long Evans rats were briefly anesthetized with fluothane and the carotid arteries occluded by cauterization. The wound was closed and phenobarbital, saline, or other drugs were injected i.p. five minutes after termination of fluothane anesthesia. Survival time of control animals was 101 ± 22 min., and 10 out of 11 died in the 5 hr observation period. Phenobarbital (30 mg/kg i.p.) doubled survival time in the 3/7 animals that died within the 5 hr observation to 205 ± 33 min., and 4/7 lived longer than 24 hrs. The effects of phenobarbital were less dramatic at higher doses that also had overt sedative and muscle relaxant effects. In addition to phenobarbital, pretreatment with intracisternal injection of 400 µg of the GABA-T inhibitor, BW 357U, naloxone (10 mg/kg i.p.), dilantin (30 mg/kg i.p.), diazepam (5 mg/kg i.p.), haloperidol (5 mg/kg i.p.), amitryptyline (10 mg/kg i.p.), muscimol (1 mg/kg i.p.), baclofen (5 mg/kg i.p.) and other drugs did not prolong survival time when given in this model. In conclusion, the bilateral carotid occlusion model of cerebral ischemia is sensitive to the protective effects of phenobarbital against brain ischemia, and suggests that elevation of GABA levels in brain may protect the brain from the lethality of cerebral ischemia as well.

75.24 LOCAL PROLIFERATION OF CAPILLARIES ASSOCIATED WITH GLIAL CELL ACTIVATION IN IBOTENIC ACID LESIONS OF THE PRIMARY SENSORY CORTEX IN RAT. D.J. Reis, C. Iadecola, S.P. Arneric, L.W. Tucker and H. Baker. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

The excitotoxin ibotenic acid (IBO), when locally microinjected into brain, destroys neuronal perikarya sparing fibers and is associated with glial proliferation (Schwarcz et al., 1979). It is not known, however, whether the neuronal loss and the concomitant glial growth is associated with changes in local capillary surface-area (CSA) and/or metabolic demands resulting in altered local cerebral blood flow (lCBF). In this study, local IBO lesions were produced in order to assess: (a) the time-course of the glial proliferation, (b) whether glial proliferation is associated with growth of capillaries and, if so (c) whether lCBF is modified with the lesion. IBO (10 ug in 1 ul) was microinjected unilaterally into the primary sensory cortex (SmI) of rats under halothane anesthesia. One, 3,5,7,15,30 days later, animals were were sacrificed and the brain sectioned and processed. Glial cells were counted on thionine-stained sections (20 um). Brain capillaries were visualized on adjacent sections by staining for alkaline phosphatase; CSA was determined using a vidicon-based image analysis system (Eyecom, PDP 11/45). lCBF was measured autoradiographically in anesthetized (chloralose), paralyzed rat, by the 14C-iodoantipyrine technique.

No perikarya were detectable in the lesioned SmI by 24h. By day 1, the number of glial cells within the lesion increased 2.8-fold (with respect to unlesioned controls), continued to rise up to 11.5-fold at day 7, and then fell to reach a steady 5.4-fold increase by 15 and 30 days ($p < 0.05$; analysis of variance; n=3-4 per group). In the lesioned SmI, CSA was unchanged at day 1, increased linearly from day 5, reaching a maximum of 3.2-fold at day 7 ($p < 0.05$) and stabilizing at a 2.7-fold increase at 15 and 30 days ($p < 0.05$). In the contralateral SmI and in the underlying caudate n., CSA did not change. Five to 7 days after IBO treatment, when the glial-capillary proliferation was maximal, lCBF in the lesion was dys-homogeneous with high-flow zones corresponding to areas of maximal glial proliferation and with low-flow zones corresponding to areas of hypocellularity. However the average lCBF in the lesion (117+36 ml/100 gr x min) did not differ from that of the contralateral SmI (123 + 8; $p > 0.05$; paired t-test; n=5). We conclude that IBO lesions of the SmI induce a massive glial proliferation paralleled by an increase in CSA. The increased CSA, most likely reflecting increased number of capillaries, it not associated with a proportional increase in local tissue perfusion, suggesting that not all the neoformed capillaries are patent and/or available for exchange. Elimination of local neurons in cortex does not result in reduced lCBF, most likely because the increased local metabolic activity resulting either from the concomitant glial growth or activity of innervating processes keeps lCBF in the normal range. Glial cells may be an important factor contributing to control local cerebral microcirculation.

76.1 AUTORADIOGRAPHY OF [3H]-TRYPTAMINE RECEPTORS IN BRAIN. L. L. Martin*, A. M. Wasley*, M. R. Marien and C. A. Altar (SPON: R. Gerber). Neuroscience Res., Pharm. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

[3H]-Tryptamine binds to brain homogenates with a high affinity and pharmacological selectivity indicative of functional receptors for the putative neurotransmitter tryptamine (C. Cascio and K. Kellar, Eur. J. Pharmacol. 95: 31, 1983). The present studies determined the capacity, affinity, pharmacology and distribution of [3H]-tryptamine binding sites in coronal and horizontal sections of rat brain.

[3H]-Tryptamine binding to brain sections was 45-58% displaced by 10 uM tryptamine, of high affinity (Kd values of 3.6-7.4 nM), and showed a 10-fold quantitative variation between brain regions. The concentration of sites was highest in the n. accumbens (Bmax values of 701-760 fmol/mg protein). Specific binding was also high in the claustrum, hippocampus, septum, olfactory tubercle, frontal cortex, cingulate cortex and caudate-putamen (Bmax values of 440 to 660 fmol/mg protein). [3H]-Tryptamine binding was displaced with high affinity (IC50 < 30 nM) by 5-methyltryptamine, harmaline and p-methoxyphenylpropylamine (PMPPA). Hill coefficients obtained with harmaline and PMPPA were less than one in most brain regions suggesting the presence of pharmacologically different populations of tryptamine sites. NE, 5-HT and spiperone occupied these sites with very low (≥ uM) affinity. Thus, [3H]-tryptamine binds to site(s) recognized by phenylalkylamines, B-carbolines, and tryptamine analogues but not to alpha- or beta-adrenergic, D_2 dopaminergic, or S_1 or S_2 serotonergic sites.

Our findings with autoradiography agree closely with studies with brain homogenates. Since the distribution of [3H]-tryptamine receptors in brain is similar to that of dopamine nerve terminals and correlates highly with the autoradiographic localization of [3H]-N-methyl-4-phenylpiperidine ([3H]-MPP+) binding (M. R. Marien et al., this volume), it is possible that tryptamine may modulate dopaminergic transmission in the brain.

76.2 A STUDY OF THE UNDERLYING MECHANISMS FOR ACUTE METHAMPHETAMINE DEPRESSION OF STRIATAL TRYPTOPHAN HYDROXYLASE. P.K. Sonsalla*, J.W. Gibb and G.R. Hanson, Dept. of Biochem. Pharmacol. and Toxicol., Univ. of Utah, Salt Lake City, UT 84112

The administration of a single dose of methamphetamine (METH) to rats produces a very rapid, but transient depression of tryptophan hydroxylase (TPH) activity, the rate-limiting enzyme in the synthesis of 5-hydroxytryptamine (5HT) without altering tyrosine hydroxylase (TH) activity, the rate-limiting enzyme in dopamine (DA) synthesis (Knapp et al., 1974; Bakhit and Gibb, 1981). In contrast, multiple doses of METH produce long-lasting decreases in neurochemical parameters of both the 5HT and DA systems which can be prevented or attenuated by DA receptor blockade (Hotchkiss and Gibb, 1980; Schmidt et al., 1984; Sonsalla et al., 1985). These findings suggest 1) the 5HT system responds more rapidly and is more sensitive than the DA system to METH treatment, 2) DA receptor activation contributes to the actions of METH on both the DA and 5HT systems with multiple dose treatment, and 3) different mechanisms may be involved in the response of the 5HT system to acute vs repeated treatment with METH.

The present studies were undertaken to investigate possible mechanism(s) involved in the acute actions of METH on TPH activity. To determine if the METH-induced depression of TPH activity was mediated by either DA or 5HT receptors, the D1 antagonist, SCH 23390 (0.5 mg/kg/i.p.), the D2 antagonist, sulpiride (80 mg/kg/i.p.) or the 5HT2 antagonist, ritanserin (1 mg/kg/i.p.) were coadministered with METH (15 mg/kg/s.c.). The rats were killed 4 h after treatment. In addition, in vitro experiments were conducted to determine if this acute action of METH was mediated locally at the 5HT terminal sites. Striatal slices were incubated in a Kreb's buffer solution containing METH (10^{-3}M) for 1 or 3 h. The slices were then homogenized and TPH activities measured.

In the in vivo experiments, METH alone decreased TPH activity in the neostriatum to approximately 50% of control; none of the antagonists tested modified this response to METH. In the in vitro studies, incubation of striatal slices with METH did not depress TPH activity. These findings suggest the acute effect of METH on TPH activity 1) is not related to D1, D2, or 5HT2 receptor-mediated actions and 2) is not mediated locally within the neostriatum, but rather, appears to require an intact neuronal circuitry.

76.3 CHARACTERIZATION OF HIGH- AND LOW-AFFINITY [^{3}H]IMIPRAMINE BINDING SITES IN RAT BRAIN HOMOGENATES. J.R. Ieni, K. Saidara, S.R. Zukin and H.M. van Praag. Depts. of Psychiatry and Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Analysis of [^{3}H]imipramine binding in rodent brain (Reith et al., 1983; Conway & Brunswick, 1983; Ieni et al., 1985), human brain (Cash et al., 1984) and human platelet membranes (Ieni et al., 1984) gives curvilinear Scatchard plots consistent with the existence of more than one class of binding sites. In our laboratory, computer-assisted analysis of [^{3}H]imipramine binding to whole rat brain homogenates yielded an apparent high-affinity component (K_d = 8 nM, B_{max} = 505 fmol/mg pr.) and an apparent low-affinity component (K_d = 805 nM, B_{max} = 10.9 pmol/mg pr.). Characterization of the high-affinity binding site suggests a relationship with the neuronal reuptake system for serotonin. The high-affinity component has been implicated as a possible biological marker for depressive illness, since some laboratories have demonstrated reduced densities of these sites on platelet membranes of depressed patients compared to controls. Determination of the pharmacological and physiological significance of the low-affinity binding component was the goal of the present study.

The binding of [^{3}H]imipramine to rat brain homogenates is influenced by Na^+ and K^+ ions. Removal of these ions from the incubation medium resulted in decreases in the number of high-affinity binding sites and increases in the number of low-affinity sites without altering the two K_d's. Incubation of the rat brain homogenates with 50 nM nonlabeled imipramine resulted in a linear Scatchard plot consistent with the low-affinity component of [^{3}H]imipramine binding under control conditions. Displacement of drugs from the low-affinity site labeled with 300 nM [^{3}H]imipramine yielded IC_{50}'s in the 1-10 uM range for tricyclic antidepressants (trimipramine, 2.6 uM; cyanoimipramine, 2.7 uM; chlorimipramine; 2.7 uM; protriptyline, 3.4 uM; imipramine, 4.1 uM; desipramine, 4.4 uM and amitriptyline, 4.9 uM. Zimelidine-Z gave an IC_{50} of 23.5 uM at the low-affinity site. Serotonin was unable to displace low-affinity [^{3}H]imipramine binding. These data suggest that the ratio of high- to low-affinity [^{3}H]imipramine binding sites may be regulated by Na^+ and K^+ ions. However, based on the displacement experiments, since the tricyclics all show similar potencies, the low-affinity site does not appear related to serotonin uptake. Further research is needed to identify and characterize this low-affinity site, its relationship to antidepressant drug action as well as affective disorders.

76.4 β-PHENYLETHYLAMINE AND DOPAMINE: CONCURRENT DEPLETION FOLLOWING 6-OHDA OR ELECTROLYTIC LESIONS OF THE SUBSTANTIA NIGRA. A.J. Greenshaw* and A.V. Juorio* (SPON: A.A. Boulton). Psychiat. Res. Div., Sask. Health, Univ, Sask., Saskatoon, Sask., Canada.

β-Phenylethylamine (PE) is a behaviourally active compound which occurs naturally in mammalian central nervous system (CNS) and which forms the basic carbon structure of a range of sympathomimetic amines. The status of PE as an amine associated with the intraneuronal compartment of CNS remains to be elucidated. To address this problem, the relationship between striatal PE levels and the depletion of striatal dopamine (DA) and 5-hydroxytryptamine (5-HT) has been investigated. Striatal DA depletion was accomplished with unilateral 6-OHDA (8 µg) or electrolytic lesions of the substantia nigra (SN). Striatal 5-HT depletion was accomplished with electrolytic lesions of the dorsal and median raphé nuclei. Concurrent depletion of PE (to 55% of controls) DA, DOPAC and of HVA (to 30%, 48% and 45% of controls) was observed 7 days after SN lesioning. These effects were evident with pretreatment with a monoamine oxidase inhibitor (l-deprenyl 2 mg/kg^{-1} 2 hr prior to assay).

In contrast to these results no striatal PE depletion was observed 7 days after electrolytic raphé lesions at which time striatal levels of 5-HT and 5-HIAA were reduced to 50% and 38% of their respective control values. The results demonstrate clearly an intraneuronal localisation of PE in the striatum. These observations indicate the possible existence of PE-containing cells in the nigro-striatal pathway or PE-containing neurons whose axons pass through the region in or around the SN. Although PE is possibly associated with catecholamine neurones rather than monoamine-containing neurones per se (in view of the lack of effect of 5-HT depletion), the previously reported lack of effect on PE levels of reserpine indicates the possible independence of PE and DA in this context.

Supported by Sask Health and a Saskatchewan Health Research Board Fellowship).

76.5 SIMILARITIES IN DORSAL RAPHE NEURONS IN BALB/c AND CBA MOUSE STRAINS. L.A. Mattiace, S.G. Speciale and D.C. German. Depts. of Physiol. and Psychiat., Univ. of Texas Health Sci. Cntr., Dallas, TX. 75235.

The BALB/c mouse has significantly more midbrain dopaminergic (DA) neurons than the CBA mouse but no difference in the number of locus coeruleus (LC) noradrenergic neurons (Ross et al., Nature, 264:654-656, 1976). The BALB/c mouse also exhibits more DA-related behaviors than the CBA (i.e. spontaneous locomotion, exploration and stimulant-induced locomotion). Although these behavioral differences may be related to DA system differences, raphe serotonin (5-HT) neurons can also influence the DA system and DA-related behaviors (Lucki & Harvey, Neuropharmacol., 18:243-249, 1979).

The purpose of the present experiment was to compare, in these two mouse strains; (1) dorsal raphe (DR) cell numbers using a tyrosine hydroxylase (TH) antibody, which recently has been reported to cross-react with DR serotonergic neurons (Towle et al., Neurosci. Abstr., 9:1056, 1983), and (2) 5-HT levels bilaterally in the caudate nuclei, a projection site of the DR. For the neuroanatomical studies, three male mice of each strain (20-30 gms) were perfused sequentially with: 0.1 M phosphate buffered saline (pH 7.4; 32°C) and 10% buffered formalin (pH 7.4; 32°C). Adjacent fifty micron sections from the midbrain at the level of the occulomotor complex, through the rostral hindbrain to a level immediately anterior to the appearance of the LC (1.5-1.7 mm) were stained with a TH-antibody using the PAP immunocytochemical procedure. For the biochemical studies six mice of each strain were sacrificed, the brains rapidly removed and micropunches (1.0 mm diameter) of the left and right caudate nuclei were removed and analyzed using HPLC-EC. The round/oval DR cells measured 10-14 μm in diameter and the CBA mice had an estimated 2600 DR cells. The CBA mice had 13% more cells than the BALB/c, however, this difference was not statistically significant. The CBA also had 12% more 5-HT in the caudate nucleus than did the BALB/c (5.39 ± 0.58 vs. 4.83 ± 0.43 ng/mg protein), and this difference was also not statistically significant. There was no left/right caudate differences in 5-HT levels in either strain. In conclusion, the BALB/c and CBA mice differ predominantly in DA neuronal numbers and not in serotonergic or noradrenergic cell numbers. Research supported by grant MH-30546.

76.6 DISTRIBUTION OF TYROSINE HYDROXYLASE POSITIVE NEURONS IN THE BRAIN OF THE GOLDFISH. S. C. Sharma*, Dept. of Ophthalmology, New York Medical College, Valhalla, N. Y.

The regional distribution of tyrosine hydroxylase (TH) positive cells and axonal branches was assessed in the goldfish brain using sheep anti TH antibodies and peroxidase anti peroxidase methods for light microscopy.

A large cell group in the area dorsalis telencephali pars centralis bordering the area dorsalis ventralis pars centralis was observed. Labelled cells were usually small in diameter (5-7μ) with finer branches extending laterally. Fine caliber axons were also labelled in the anterior commissure and in the pars medialis. Further caudally and ventrally, numerous cells in the preoptic recess were labelled. These cells apparently sent axons which innervated the paraventricular area of the hypothalamus. In the diencephalon, cells in the nucleus dorsalis lateralis and medialis showed a very high sensitivity to TH. The axons of these cells were also labelled and were traced to at least three distinct laminae in the ipsilateral optic tectum, e. g. stratum opticum, stratum fibrosum et griseum superficiale (SFGS) and stratum album centralae. These are the same areas in which optic axons terminate.

Axonal branching and fine varicosities were easily recognizable in the SFGS, which has the highest number of labelled axons. Optic axons were not labelled.

Dorsolateral to the medial longitudinalis fascicle, in the isthmal area of the tegmentum, were 10-12 large labelled cells which sent axons both rostrally and caudally. In addition, the mesencephalic and medial reticular formation contained large-size neurons which showed positive TH reaction.

Based upon the distribution pattern of TH labelled cells and comparing this pattern of labelling to that of serotonin in the goldfish brain, it is quite likely that TH labelled cells represent dopaminergic neurons. Supported by N.E.I. 01426.

76.7 INTERACTION OF tele-METHYLIMIDAZOLEACETIC ACID WITH BENZODIAZEPINE BINDING SITES IN RAT BRAIN MEMBRANES. P.Blandina*,S.Maayani and J.P.Green.Dept. of Pharmacology, Mt. Sinai School of Medicine, City University of New York,New York,NY 10029.

All evidence supports the hypothesis that histamine (HA) is a neurotransmitter in brain (Prell and Green,1986,Ann.Rev.Neurosci.,in press).The final product of HA turnover in brain is tele-methyl -imidazoleacetic acid (t-MIAA).Since imidazoleacetic acid (IAA),the peripheral metabolite of HA,acts like GABA on GABA sites,including those associated with benzodiazepine (BZ) binding sites,we examined the effect of t-MIAA on the binding of [3H] flunitrazepam ([3H]FLU) to washed membranes from different brain regions.The experiments were given further impetus by suggestive evidence that the GABAergic and histaminergic systems may be colocalized (Takeda et al.,Proc.Nat.Acad.Sci.USA,1984,81:7647-7650).

t-MIAA (10-100 μM) depressed the affinity of [3H]FLU for its binding sites,both in the presence (10 μM) and absence of GABA. Scatchard analysis showed that the effect of t-MIAA is due entirely to a shift in the affinity of the drug for its binding sites with no change in the number of binding sites.The effect of t-MIAA was observed in hypothalamic,cerebral cortical and cerebellar membranes. HA (100 μM), its immediate metabolite, tele-methyl- histamine (100 μM),IAA (100 μM) and pros-methylimidazoleacetic acid (100 μM) all failed to affect the binding of [3H]FLU.As had been observed by others IAA (100 μM) antagonized the effect of GABA (10 μM) on [3H]FLU binding.Bicuculline (10μM),the GABA antagonist, completely antagonized the effect of 10 μM GABA but failed to affect the action of t-MIAA on [3H]FLU binding.The GABA receptors are part of complex containing receptor sites for GABA,BZ and picrotoxin/barbiturates. Experiments showed that t-MIAA does not interact with picrotoxin sites. The effect of t-MIAA on [3H]FLU binding occurs at a site different from sites affected by bicuculline and picrotoxin.This work also implies that metabolites of transmitters may have functions, functions different from the transmitters.

76.8 PHARMACOLOGICAL AND NEUROCHEMICAL ACTIONS OF ALPHA-FLUOROMETHYL-HISTAMINE. G.D.Prell, P.Blandina*, S.Maayani and J.P.Green. Department of Pharmacology, Mount Sinai School of Medicine of the City University of New York, New York, N.Y. 10029.

In mammalian brain, histamine (HA) functions as a neurotransmitter. Its functions in the brain are obscure , although evidence suggests that it is likely to have direct (e.g. prolactin release) as well as modulatory (e.g. ACTH release) effects (Prell and Green, Ann. Rev. Neurosci. [in press]). The use of highly selective inhibitors (Kollonitsch et al., Nature 274: 906, 1978) of the HA synthesizing enzyme, histidine decarboxylase, could be important tools in exploring the functions of histamine. Alpha-fluoromethylhistidine (α-FMHis), an irreversible inhibitor, has been extensively used to deplete the brain and peripheral tissues of HA. Alpha-fluoromethylhistamine (α-FMHA), another selective irreversible inhibitor, may not penetrate the blood-brain barrier in vivo in analogy with HA. α-FMHis and α-FMHA could be useful tools to distinguish the central from the peripheral effects of endogenously synthesized (and released) HA. For these purposes, α-FMHA must be devoid of significant effects other than histidine decarboxylase inhibition.

We examined the effects of α-FMHA on brain HA receptors, whole brain HA levels and on HA methylation by histamine N-methyltransferase. α-FMHA was a partial agonist at the H_2 receptor linked to stimulation of adenylate cyclase in guinea pig hippocampal homogenates. Its intrinsic activity was approximately 0.3 relative to HA with a K_B about 100 μM . Administration of α-FMHis (400 μmol/kg,i.p.) to rats markedly reduced brain HA levels after five hours but the same dose of α-FMHA failed to cause significant changes. α-FMHis (up to 1 mM) had no effect on HA methylation by histamine N-methyltransferase, but α-FMHA was a substrate for this enzyme in vitro.

Although these results suggest that α-FMHA has actions in addition to histidine decarboxylase inhibition, the use of α-FMHA in parallel with α-FMHis to distinguish between central and peripheral actions of HA may remain a valid tool if α-FMHA is used at low concentrations. In addition, since histidine may be decarboxylated in vivo by an enzyme(s) other than histidine decarboxylase when given in large amounts (Prell et al., Fed. Proc. 44: 1246,1985), it is feasible that some α-FMHis may be converted to α-FMHA. Additional studies of the actions of α-FMHA and its possible formation from α-FMHis are warranted before these agents can be accepted as specific probes of the histaminergic system.

76.9 HISTAMINE-IMMUNOREACTIVE SMALL CELLS IN SYMPATHETIC GANGLIA OF THE RAT. H. PÄIVÄRINTA, O. HÄPPÖLÄ, S. SOINILA AND P. PANULA. Department of Anatomy, University of Helsinki, Siltavuorenpenger 20 A, SF-00170 Helsinki, Finland.

Biochemical, physiological and pharmacological studies have provided evidence that histamine may function as a neurotransmitter in the mammalian central nervous system. Immunohistochemical studies have demonstrated the presence of neuronal cell bodies showing histamine-immunoreactivity in the hypothalamic and premamillary areas of the rat brain. Biochemical studies also suggest that histamine is present in the preipheral nervous system, where it has been proposed to have a dual localization: in a mast cell pool and in a non-mast cell pool. Histamine has been shown to affect nervous transmission through sympathetic ganglia. The aim of the present study was to investigate the presence of histamine in the rat sympathetic ganglia by immunohistochemistry.

Adult rats were perfusion fixed with 4 % paraformaldehyde. Cryostat sections were cut and incubated with specific histamine antiserum. The indirect immunofluorescence method was employed.

Histamine-immunoreactive small cells were observed in the superior cervical ganglion and in the coeliac- superior mesenteric ganglion complex. Mast cells were also often detected in the ganglia but they were clearly distinguished from the small immunoreactive cells due to their large diameter and granular cytoplasmic immunoreaction. The small immunoreactive cells, 10-20 μm in diameter, were either solitary or, more often formed clusters. The immunoreactive cell clusters were often around, or in close contact with blood vessels. The principal nerve cells were distinguished as large cells, 30-60 μm in diameter, with no detectable immunoreaction. No histamine-immunoreactive nerve fibres were observed. The specific immunoreaction of the small cells and the mast cells was completely abolished by absorption with 50 μM histamine.

Due to close morphological similarities, small size and high nucleus/cytoplasm diameter ratio, it is concluded that the small histamine-immunoreactive cells represent small intensely fluorescent (SIF) cells first detected by formaldehyde-induced fluorescence method.

76.10 THE CENTRAL CARDIOVASCULAR ACTIONS AND BLOCKING EFFECTS OF TWO NEW H2 ANTAGONISTS: BMY-25405 and BMY-25368 IN THE CONSCIOUS FREELY MOVING RAT. J.J. Poulakos*, E.N. Gerges* and S.B. Gertner* (SPON: R.D. Howland).Dept.of Pharmacology, N.J. Medical School, UMDNJ, Newark, N.J. 07103

Histamine and cimetidine produce a dose dependent pressor response and bradycardia when administered intracerebroventricularly (ICV) to conscious freely moving rats. The experiments reported here were undertaken to study the cardiovascular actions of other H2 antagonists as well as their ability to block H2 receptors in the CNS. Two new H2 antagonists: BMY-25405 and BMY-25368 which are selective and long acting when tested on atrial muscle and gastric acid secretion, were administered ICV to conscious freely moving Sprague-Dawley rats. Graded doses of BMY-25405 and BMY-25368 were given ICV and challenged 15' later with 25ug ICV of the selective H2 agonist impromidine (IMP), to determine the cardiovascular H2 blocking activity of these compounds. Since centrally administered IMP causes desensitization of the pressor response upon repeated injection, (Poulakos & Gertner, Frontiers in Histamine Research Symposium, Jouy-en-Josas, France, 1984 P.67), control responses of IMP were obtained 24 hours after the first injection, when there is full recovery of the response. BMY-25405 produced dose dependent pressor responses with 50ug, 100ug and 200ug doses (11.2±4.7, 13.6±2.5 and 20.8±2.1 mmHg rise in mean arterial pressure (MAP)), which recovered in 10 minutes. The bradycardia induced by ICV BMY-25405 was also dose related but reached a plateau at the 100ug and 200ug doses (25.2±10.3, 61.5± 8.0 and 47.2±12.6 beats per minute (BPM)). More importantly, BMY-25405 totally blocked a challenge dose of 25ug IMP 15' after ICV administration of the 200ug dose. Unlike BMY25405, graded doses of BMY-25368 (10ug, 25ug and 50ug) did not produce graded pressor responses (34.6±2.5, 42.1±2.5 and 30.1±2.8 mmHg increases in MAP). Heart rate decreases were also equivalent (67.3±7.2, 77.6±9.6 and 73.0±7.0 BPM). These three doses of BMY-25368 failed to block a challenge dose of 25ug IMP given 15' later. These cardiovascular effects are of central origin since the intravenous administraion of 25ug, 100ug and 500ug doses of BMY-25405 or BMY-25368 produced a tachycardia and had no effect on MAP. The aforementioned results illustrate that BMY-25405 and BMY-25368, like the H2 antagonist cimetidine, cause a pressor response and bradycardia upon ICV administration. However, only BMY-25405 shows the ability to block the centrally elicited pressor response of the H2 agonist IMP and is therefore working by blocking the central cardiovascular H2 receptor.

STRUCTURE AND FUNCTION OF IDENTIFIED CELLS I

77.1 EFFECTS OF AN ORGANIC SOLVENT ON NERVE CELLS IN VITRO AND IN VIVO. S. Jacobson, R. Auerbach*, D. Albertini*, Departments of Anatomy and Cellular Biology, Tufts University School of Medicine, Boston, MA. 02111.

Organic solvents are one of the most common sources of pollutants in our environment and exposure to these compounds produce physiological and behavioral dysfunction. In order to determine the effects from exposure to these agents on the organelles and cytoskeleton of neurons we have exposed mammalian nerve cells to an organic solvent trichloroethylene (TCE).

Adult albino rats were exposed to TCE in an environmental chamber for 1-2 hrs for 5-10 days. Pregnant albino rats were also exposed to the TCE in the chamber. The levels of TCE in the chamber were 280-670 ppm.

The brains from the non-pregnant animals were removed after perfusion fixation and prepared with Nissl, H&E, Myelin, Acetylcholinesterase and Golgi Neuronal stains. The brains from the exposed fetuses (E14-17) were mechanically dissociated and placed in tissue cultures. The media consisted of DMEM supplemented with amino acids, vitamins, L-Glutamine, PS, Ara C, Sodium Pyruvate, and Fetal Calf Serum.

Brain cells from normal pregnant animals were isolated from fetuses (E14-18) and newborn pups and mechanically separated and exposed to TCE dissolved in DMSO at 100-500 or 1000 ppm. The tissue cultures were fixed and stained with monoclonal antibodies to identify neurons, glia and fibroblasts.

The exposure to TCE in the chamber produced a light to moderate anesthetic affect. All the animals that were exposed to TCE developed increased respiration and hypersensitivity. The neurons from pups exposed to TCE on E14-15 and their controls were placed in tissue culture. The cells from the exposed pups demonstrated more neuritic processes and did not aggregate. In order to more accurately document the formation of processes we are undertaking scanning electron micrographic analysis (SEM) of the cells in tissue culture. The brains from the adult animals exposed to TCE in the chamber are currently being examined.

The major affect we have noted on cells has been an increase in neuritic processes as a consequence of exposure to TCE in utero. The SEM in conjunction with the monoclonal antibody technique should permit determination of the cell types producing the neurites and other cell to cell interactions which are affected by TCE exposure. We are currently analyzing neurons with the other neurohistological methods to determine if there are other changes in the cell surface or in the organelles. (Supported by funds from The Center for Environmental Management Tufts University).

77.2 VESICULAR PROFILES IN RAPID-FROZEN, FREEZE-SUBSTITUTED FROG PERINEURIAL CELLS. C.H. Latker*, K.J. Lynch*, N.L. Shinowara and S.I. Rapoport (Spon: R. Burke) Lab. of Neurosciences, National Institutes on Aging, NIH. Bethesda, Maryland 20205.

The perineurial cells in the sciatic nerve of the frog contain numerous vesicular profiles throughout their cytoplasm. In order to determine if these vesicles are influenced by chemical fixation, we examined rapid-frozen, freeze-substituted, as well as glutaraldehyde-fixed frog perineurium. We also compared nerves that were rapid-frozen or fixed immediately after they were removed from the animal, with nerves kept in Ringers for several hours prior to fixing or freezing.

The frogs were divided into two groups. In group I, the nerves were rapid-frozen on a Polaron quick freeze unit either immediately after removal or after five hours of incubation. In group II, the nerves were chemically fixed either immediately after removal or after five hours of incubation. All tissues were processed for electron microscopy.

Vesicular profiles were present in the perineurial cells in all experimental groups. Some of the vesicles opened to the surface while others appeared to be isolated profiles within the cytoplasm. No difference was observed in the morphology of the individual vesicles in nerves frozen after incubation and in nerves frozen immediately. However, there was a characteristic rosette-like configuration of fused or linked vesicles observed in the incubated, rapid-frozen cells. These were not as frequently seen in the immediately frozen cells. In the chemically fixed tissues vesicles were always present, but rosettes were rare. Vesicular profiles were spherical, but more variable in shape than in rapid-frozen cells, and caveolae usually were connected to the surface membrane by longer neck regions than in the frozen perineurium.

Aldehyde fixation is slow and does not stabilized all membrane constituents at the same time. The ultrastructure of tissues that have been well frozen and freeze-substituted is presumed to be more representative of the in vivo configuration than is the ultrastructure of fixed tissues. The present study shows that vesicular profiles are prominent in frog perineurial cells in rapid-frozen as well as in chemically fixed tissues. It can be concluded, therefore, that vesicular profiles are a normal constituent of perineural cells and do not result from chemical fixation. However glutaraldehyde fixation may modify their size, shape and number.

This research is supported by LNS, NIA, NIH; USUHS EM Facility.

77.3 COMPARISON OF CYTOSKELETAL ELEMENTS IN RAT PHEOCHROMOCYTOMA CELLS (PC12) AND A VARIANT PC12 SUBLINE IN CULTURE. K.J. Daniels*, I. Kim*, N.J. Pantazis, and A. Sandra*. (SPON: A.K. Afifi) Dept. of Anatomy, Univ. of Iowa Medical College, Iowa City, IA 52242.

In comparison with primary cells in culture, transformed cells characteristically exhibit a less ordered cytoskeleton with fewer stress fibers, microfilaments, microtubules, and loss of adhesion plaques. Typically, therefore transformed cells are anchorage independent and grow quite well in suspension. Changes in the rates of synthesis of the major cytoskeletal proteins have also been reported for many cell lines compared to primary cells. Since substrate attachment may play a key role in the expression of cytoskeletal elements, the present study explores possible differences in cytoskeletal organization and/or protein composition in substrate-attached versus non-attached transformed cells.

The PC12 cell line, cloned from a rat pheochromocytoma (Greene, L.A. and Tischler, A.S., Proc. Natl. Sci. USA, 73:2424, 1976) grows well in suspension. In response to nerve growth factor, NGF, the PC12 cells will attach to a substratum. In addition, NGF will induce changes in various cytoskeletal elements including actin organization and neurite outgrowth. Recently, Kim and Pantazis (see abstract this meeting) observed that with time in culture, a substantial number of PC12 cells attached to the flask. The PC12 cells were therefore divided into two sublines PC12A which readily grew attached to the flask; and PC12F which, more typical of PC12 cells, did not attach and grew in suspension. Other variants of PC12 cells which also attach have been reported (Bothwell et al., Cell 21:857) but cytoskeletal changes have not been examined in any of these PC12 variants.

Homogenates of PC12A and PC12F cells were examined on two dimensional polyacrylamide gel electrophoresis using Coomassie blue staining. In the PC12A cells there was a qualitative increase in the amounts of α and β tubulin and isoactins compared to PC12F cells. Vimentin, an intermediate filament protein, was lacking in both cell types, a result which has been previously observed.

In conclusion, preliminary gel analysis indicates that there are significant cytoskeletal differences between the two PC12 cell sublines. Whether or not these cytoskeletal differences are involved in or a result of substrate attachment is unknown. Future work will examine the organization of the cytoskeleton using indirect immunofluorescence against the major cytoskeletal proteins: actin, tubulin and intermediate filament proteins. Rates of synthesis of cytoskeletal proteins will be determined by ^{35}S-methionine incorporation followed by two dimensional electrophoresis, autoradiography and scintillation spectrometry. (Supported by NIH grant GM28644 to N.J.P.).

77.4 A RAPID GOLGI METHOD FOR STAINING EXPLANT OR DISSOCIATED CELL CULTURES OF CEREBELLUM. A.P. Oliver and U. Vaidya. Neuropsychiatry Branch, NIMH, Intramural Research Program, Saint Elizabeths Hospital, Washington, D.C. 20032.

Morphological characterization of cells as they differentiate in culture is an important aspect of development and intercellular relationships. The Golgi technique is an excellent means for demonstrating the morphology of neurons, but usually involves extended times for impregnation. We have developed a rapid Golgi method requiring approximately 2.5 hours suitable for explant or dissociated cell cultures of cerebellum based on a standard Golgi technique (Gabbott and Somogyi, J. Neurosci. Meth. 11:221-230, 1984). Rat E20 cerebellum explants (100 μm thick) or dissociated cells were cultured on collagen coated dishes using culture techiques and media described by D.L. Gruol in 1983. At various times after culturing, up to 1 month, cultures were fixed in 4% gluteraldehyde and 2% paraformaldehyde mixture in 0.1 M phosphate buffer pH 7.3 followed by phosphate buffer rinse (15 min.). Cultures were then post fixed in 1% osmium in phosphate buffer for 5 min. and rinsed. Cultures were immersed in 2% potassium dichromate for 35-45 min., rinsed with distilled water and placed in 0.5% silver nitrate for 1-1.5 hours. Cultures were gold toned in 0.2% gold chloride (rinsed 5-10 sec.) and placed in phosphate buffer. Differentiated bipolar, multipolar and Purkinje like cells seemed to selectively stain although some neuroglia were also impregnated. Cell bodies, axons and dendrites with primary, secondary and tertiary processes could be clearly distinguished. The speed, convenience and simplicity of this techique make it an excellent method for examining the development of neurons in culture.

Supported by NIMH.

77.5 SELECTIVE UPTAKE BY PURKINJE NEURONS OF ANTIBODIES TO S-100 PROTEIN. S.E. Karpiak, M.M. Rapport & S.P. Mahadik. Div. of Neuroscience, NYS Psychiatric Inst., Depts. of Psychiatry, Biochemistry & Molecular Biophysics, College of Physicians & Surgeons, Columbia U., 722 W 168th St., NY, NY. 10032.

A recent study describes the selective extraction of both large and small molecules by cerebellar Purkinje cells [1], and this process may account for the susceptibility of these neurons to various pathological agents [2]. In connection with our studies of the effects on CNS function of antibodies directed against neural antigens, we studied the localization of several rabbit antibodies in vivo. We found that affinity purified antibodies to S-100 protein localized in Purkinje cells whereas affinity-purified antibodies to goat-immunoglobulin G or to bovine serum albumin did not. Male Sprague-Dawley rats, anesthetized with ether, were injected (intaventricularly) unilaterally into the lateral ventricle with 5µg (in 20µl) of purified antibodies labled with [125]I (0.22µCi/ug protein). Forty-eight hours later, the rats were perfused with fixative transcardially. Brains were embedded in paraffin and coronal sections of 10um were cut selectively throughout the brain. Slides were examined by exposure to photographic nuclear emulsion for 3-4 mos.

In rats injected with antibody to S-100, intense localization was seen in Purkinje cells of the cerebellar vermis. The localization was primarily in the cell body, with further localization extending for a distance of 25-30µm into the axon. No localization was seen with antibodies either to BSA or goat immunoglobulin. No other (intracellular) localization was seen in other brain regions with any of the antibodies. Our study suggests that with antibodies Purkinje cell uptake is selective and probably antigen dependent. While the uptake by Purkinje neurons of molecules like propidium iodide [1] results in motor disturbances (tremor, ataxia & nystagmus), the uptake of antibodies directed against specific antigens may result either in less generalized or more subtle deficits. Although animals used in the localization studies were not studied for behavioral effects, we have shown that the intraventricular injection of antibodies to S-100 interferes with learning [3].

77.6 PRODUCTION AND CHARACTERIZATION OF A MONOCLONAL ANTIBODY THAT SELECTIVELY LABELS MOSSY FIBER BOUTONS. B.D. Boss. The Salk Institute, P.O. Box 85800, San Diego, CA 92138.

I recently reported success in generating a panel of mouse IgM monoclonal antibodies against cultured rat dentate granule cells using a simplified in vitro immunization procedure [Boss, B.D. (1984) Brain Res. 291:193-196]. Among this panel of monoclonal antibodies, one termed G2 has been found to selectively label mossy fiber terminal boutons both in vivo and in vitro. Immunoperoxidase localization of G2 reactivity in vivo closely resembles the reactivity of hippocampal tissue to Timm's silver sulfide stain. Interestingly, intracisternal injection of 48 µg colchicine 48 hours prior to tissue fixation appears to enhance the terminal bouton immunoreactivity of G2 (as compared to saline controls). In addition, G2 immunoreactivity is preserved by perfusion with Carnoy's solution, a fixative commonly used in conjunction with Timm's silver sulfide stain.

Since this monoclonal antibody reacts equally well with monkey and rat tissue, the G2 antigen appears to be highly conserved. Ideal fixation conditions for the rat antigen appear to be 3.5% paraformaldehyde pH 7.4 for 30 minutes with no postfixation or detergent treatment. While frozen sections of monkey brain react well with G2, freezing rat tissue greatly diminishes G2 immunoreactivity. Electron microscopic visualization of the reaction product indicates the G2 antigen surrounds the numerous synaptic vesicles found in mossy fiber terminals.

In culture, G2 immunoreactivity is confined to bouton-like structures located along nerve fibers and neuronal cell bodies, most probably reflecting the rearrangement of synapses known to occur in vivo when the normal target cells of granule neurons are removed. Growth of granule neurons in chemically-defined N2 medium [Bottenstein, J.E. and Sato, G.H. (1979) Proc. Natl. Acad. Sci. U.S.A. 76:514-517] enhances G2 immunoreactivity. It is not known whether this enhancement is an indirect consequence of the increased neuronal clustering seen in N2 medium. Electron microscopic localization of the immunoreactivity in vitro shows it to be identical to the in vivo reactivity (i.e., surrounding synaptic vesicles).

When rat hippocampal homogenates are separated by SDS-PAGE and blotted onto nitrocellulose, one band of G2 immunoreactivity stains heavily at approximately 70,000 Mr. Homogenates of rat cerebral cortex, olfactory bulb and cerebellum contain relatively smaller amounts of this protein, verifying the sparse to undetectable nature of G2 reactivity found immunohistochemically in these other areas of the brain.

The time course for appearance of G2 immunoreactivity in vivo appears to parallel the development of mossy fiber terminals, being present by postnatal day 6 (earliest tested) and increasing with age over the next few months.

77.7 A MONOCLONAL ANTIBODY THAT STAINS THE PERIMETER AND GOLGI APPARATUS OF SUBPOPULATIONS OF NEOCORTICAL AND CEREBELLAR NEURONS. P.E. Marshall*, L.M. Hemmendinger, A.M. Boyer*, M. Yamamoto & V.S. Caviness, Jr. Dept. of Neurol., Mass. Gen. Hosp., Boston, & E.K. Shriver Ctr., Waltham, Mass.

Monoclonal antibody 4F4 was prepared against whole cells from E15-17 rat cortex in Balb/c mice. The distribution of antibody staining in the cortex and cerebellum of adult mice was mapped on paraformaldehyde-fixed sections using direct and indirect labeling methods. Two patterns of intracellular staining can be distinguished. Some neurons demonstrate intense staining concentrated at the perimeter of the perikarya and dendrites, with punctate intracellular staining. Other cells show only diffuse or punctate intracellular staining.

At the electron microscopic level, the two patterns of cellular staining described above can be related to the intracellular distribution of the 4F4 antigen. In cells with intense staining around the perikaryon and dendrites, deposition of reaction product occurs just inside the plasma membrane as well as in the Golgi apparatus. Cells with diffuse or punctate staining have smaller amounts of reaction product associated with the Golgi apparatus only.

The majority of neurons in all neocortical regions contain the diffuse pattern of intracellular 4F4 staining. Neurons with intensely stained perimeters constitute subpopulations which vary in their distribution within the different cortical areas. In parietal fields these neurons are concentrated in two zones corresponding to layers III-IV and lower V-VIa. In contrast, the intensely stained neurons have a wider distribution in cingulate cortex and are found throughout layers II-VIa. In motor cortex and other frontal fields, intensely stained neurons are found primarily in lower V-VIa. This distribution continues throughout occipital and temporal fields, but fewer intensely stained neurons are found.

In the cerebellum, intense staining is seen in Golgi II neurons and in the deep cerebellar nuclei. All Purkinje cells and some stellate cells demonstrate diffuse staining only. Basket and granule cells are not stained.

The 4F4 antigens have been identified by thin layer chromatographic and Western blotting techniques as a glycolipid and glycoprotein in the embryonic brain (Schwarting et al., unpublished) and as a 150-250 kD glycoprotein in adult cortex. The structure of the carbohydrate epitope has been identified by comparison with a standard glycolipid isolated from human sciatic nerve (Chou et al. Biochem. Biophys. Res. Comm. 128, 383-388, 1985).

77.8 MONOCLONAL ANTIBODIES TO NEURAL ANTIGENS IN ASCARIS GENERATED AFTER SPECIFIC IMMUNOSUPPRESSION. Paisarn Sithigorngul*, Carl D. Johnson*& Antony O.W. Stretton
Department of Zoology, University of Wisconsin
Madison, WI 53706

We have used the immunosuppression technique pioneered by Matthew and Patterson (1983, CSHSQB XLVIII,635) to increase the yield of monoclonal antibodies against neural antigens. Pure neural tissue from Ascaris is hard to obtain because of the close association of the nervous system with other tissues, especially hypodermis and muscle. We therefore immunized mice with homogenates of dissected muscle and/or hypodermis and after two days injected 0.8 mg cyclophosphamide to suppress the cells stimulated by the primary injection. The mice were then immunized with dissected nerve cords (which included about 80% muscle, 10% nerve cord, and 10% hypodermis) or with nerve cord obtained after removal of muscle with collagenase (50% nerve cord and 50% hypodermis). After boosting with the same antigen hybridomas were generated and screened using ELISA, frozen sections and whole mount preparations from collagenase-treated worms. Compared with our previous experiments in which nerve cords dissected from collagenased worms were used as immunogens (Soc. Neuroscience Abstr. 9, 302) the number of clones producing antibodies that bound to hypodermis was much reduced; furthermore the antibodies that bound to neurons show much lower background binding than those we described earlier.

We obtained a number of antibodies which label all neuronal cell bodies and have virtually no reactivity toward hypodermal antigens. Other antibodies react with the surfaces of all neurons. These antibodies have been used to locate and identify all of the neurons in adult female Ascaris. They have been particularly useful for analyzing the anatomy of neurons located in the tail (30 cells in the female) and for neurons whose cell bodies are in the lateral lines in the body (7 bilaterally symmetrical pairs of cells distributed over a distance of 20-30cm).

Other interesting antibodies isolated from these fusions react with subsets of neurons. These include one which labels only a single bilaterally symmetrical pair of neurons in the anterior lateral ganglion and several antibodies which label the nuclei of subsets of neurons.

77.9 ULTRASTRUCTURAL DISTRIBUTION OF CALCIUM WITHIN NEURONS: AN OXALATE PYROANTIMONATE STUDY. M. Mata, J. Staple*and D.J. Fink. Neurology Research Laboratory, University of Michigan and VA Medical Center, Ann Arbor, MI 48105

Calcium appears to play a critical role in a number of normal neuronal cell functions as well as in pathologic studies. In order to define the role of calcium, we undertook to determine the ultrastructural distribution of calcium within neurons of the rat sciatic nerve using the oxalate-pyroantimonate technique. In this method oxalate is used to chelate the calcium while other cations are rinsed out prior to precipitation with pyroantimonate. Both stained and unstained grid sections were examined in a JEOL 100S electron microscope.

We used 2 controls to determine that the precipitates represent calcium pyroantimonate. In the absence of pyroantimonate treatment no precipitates occurred, and washing the grids with 10mM EGTA for 1 hour removed precipitates. X-ray microanalysis using a KEVEX energy dispersive spectrometer with deconvolution of the spectrum obtained showed a calcium peak. Analysis by electron spectroscopy imaging with a Zeiss 902 EM confirmed the calcium distribution.

In cell bodies of the dorsal root ganglia, calcium precipitate was found in the nucleus but not in the nucleolus, in the golgi, mitochondria and large vesicles but not lysosomes, and prominently absent from regions of rough endoplasmic reticulum and ribosomes. A similar distribution was found in non-neuronal cells.

At the neuromuscular synapse in the gastrocnemius muscle calcium was also seen in mitochondria, and a dense precipitate was found in every synaptic vesicle. While the synaptic cleft itself appeared free of calcium, there was prominent precipitate in the muscle just underneath the post-junctional folds.

Within the axon itself precipitate was also found sequestered in mitochondria and smooth endoplasmic reticulum. In addition to precipitate sequestered in organelles, precipitate appeared diffusely through the axoplasm with a gradient of distribution. Precipitate appeared uniform in unmyelinated fibers but in myelinated fibers the amount of precipitate decreased predictably in the axoplasm beneath the Schmidt-Lantermann clefts and in the paranodal regions at the nodes of Ranvier. This correlated with the presence of dense precipitate in the Schmidt-Lanterman clefts themselves and in the paranodal loops of myelin.

Intracytoplasmic ionic calcium is maintained at 10^{-7} M by balanced processes of influx, sequestration and extrusion of calcium. The irregular distribution of calcium precipitate in the axoplasm of myelinated fibers suggests that there may be specific regions of preferential efflux across the axolemma. The relationship of these results to previous results using methods that measure calcium binding sites or calcium sequestration will be discussed.

77.10 X-RAY MICROANALYSIS OF INTRACELLULAR CALCIUM IN RAT PERITONEAL MAST CELLS. A. Angel*, R.M. Kriebel, and J.F. Fiekers (SPON: S. Robison). Dept. of Anatomy and Neurobiology, Univ. of Vermont Col. of Med., Burlington, VT, 05405.

It is well known that calcium has a major role in the initiation, regulation and control of numerous cell functions. However, the ultrastructural localization of intracellular stores of calcium and their involvement in cell function is not well understood. X-ray microanalysis has been used in these studies to examine intracellular calcium location within mast cells. Peritoneal rat mast cells were obtained by abdominal lavage with Locke's solution and purified by density gradient centrifugation through 24% metrizamide. After washing, the pellets containing >90% mast cells were fixed in 2.5% phosphate buffered glutaraldehyde. The cells were washed in buffer, postfixed in 2% osmium tetroxide, rapidly dehydrated and embedded in epon. Thin sections were mounted on copper or aluminum grids and studied in a JEOL 100CXII STEM equipped with a Tracor Northern energy dispersive spectrometer. Energy spectra were collected by either spot analysis or rastering the beam over defined regions of cells. In control preparations, microanalysis of intracellular granules within mast cells yielded energy spectra demonstrating prominent peaks for calcium. In addition, peaks of sulfur corresponding to mucopolysaccharides within granules were also shown. Compound elemental mapping for calcium and sulfur verified their association with granules. Analyzed areas of mast cell nuclei as well as eosinophils generated spectra with insignificant or reduced peak intensity for calcium. Pretreatment of purified cells with EGTA in zero calcium Locke solution was used to produce "chelated mast cells". Significant decreases in calcium peak intensity were observed following this perturbation. To explore the potential role of calcium in receptor-mediated events, cell suspensions similarily prepared were exposed to either 48/80 or substance P prior to fixation. It has been shown that chemical fixation is problematic in the maintenance of intracellular elemental content and interpretation of such studies needs to be made with caution. Physical fixation procedures have been used to optimize conditions for minimal extraction and translocation of substances. The chemical and microanalytical methodologies applied in these studies, without the expense of cryo-preparative equipment, have provided a successful preliminary assessment of intracellular calcium distribution and provide the basis for future comparison with results obtained under similar conditions on quick frozen preparations. 77.11 ULTRASTRUCTURAL LOCALIZATION OF A CALCIUM-ACTIVATED PROTEASE (CALPAIN) IN RAT CNS: ASSOCIATION WITH MICROTUBULES, MITOCHONDRIA, AND SYNAPTIC ELEMENTS. L.S. Perlmutter, C. Gall, R. Siman and G. Lynch. Depts of Psychobiology and Anatomy, Univ. of Calif., Irvine, CA 92717.

The importance of calcium-dependent proteases as modulators of both normal and pathological cellular metabolism has recently received much attention (Trends in Biochem. Sci., 8:167, 1983). Calpain (the family of proteases) has been implicated in such diverse phenomena as the degradation of neurofilament, myelin and myofibrillar proteins, the aggregation of platelets, and shape changes in erythrocytes and dendritic spines. Research on the enzyme has thus far been principally biochemical; little work has been done on its actual anatomical distribution and subcellular localization. To maximize our understanding of its ultrastructural localization, both monoclonal and polyclonal anti-calpain I, as well as pre-embed and post-embed immuno-electron microscopic techniques, were employed. Regions of the spinal cord, olfactory bulb, and the hippocampal formation were chosen for study.

Young adult rats were perfused with 2-4% paraformaldehyde, 0.1-0.4% glutaraldehyde (pre-embed) or 1-2% paraformaldehyde, 0.2-2.5% glutaraldehyde (post-embed). For pre-embed, sections were prepared on a freezing microtome or vibratome and incubated in either monoclonal or polyclonal anti-calpain I. For post-embed, tissue was first embedded in LR White Resin and the immunocytochemistry carried out directly on the thin sections. The biotin-avidin-peroxidase system (Vectastain) was used throughout. Both types of antibody and both methods yielded virtually identical results, which were seen across brain regions. Reaction product was found to decorate both axonal and dendritic microtubules, the outer surface of mitochondria, many postsynaptic densities, and, occasionally, synaptic vesicles and presynaptic terminals. The apparent association of calpain with the microtubules suggests a role for this enzyme in intracellular transport; it also suggests that the protease may be involved in the cytoskeletal disarray seen in degenerative diseases such as Alzheimer's. The sporadic occurrence of immunoreactive presynaptic terminals and postsynaptic densities may reflect either the vagaries of the technique (although this possibility is lessened due to the use of both pre- and post-embed methodologies), the very specific localization of this antigen to these regions, or, more plausibly, the blocking of antigenic sites due to interactions with other molecules (Neurosci, 10:449, 1983). Thus, calpain immunoreactivity may be a reflection of activational state. If this is correct, it suggests a role for calpain in neurotransmission and perhaps in the synaptic plasticity known to occur in some of these regions. 77.12 CO-LOCALIZATION OF A CALCIUM ACTIVATED PROTEASE (CALPAIN) AND ONE OF ITS SUBSTRATES (FODRIN) IN THE RAT CENTRAL NERVOUS SYSTEM. M.B. Passani*, C. Gall, R. Siman, L. Pearlmutter and G. Lynch. Depts. of Psychobiology and Anatomy, Univ. of Calif., Irvine, Ca., 92717.

Recent studies have shown that fodrin or brain spectrin, a high molecular weight protein that cross-links cytoskeletal elements, is an excellent substrate for calcium activated proteases (calpains) (Proc.Nat.Acad.Sci.,1984,81). This provides a mechanism through which transient changes in intracellular calcium levels could produce structural modifications of neurons as well as of the organization of membrane surface proteins (Science,1984,224). In support of this, evidence has been reported that degradation of fodrin by calpain in synaptic membrane fractions results in an increase in the number of binding sites for a putative neurotransmitter (Nature,1985,313). Given the evidence that both calpain (J. Neurochem.,1983,41) and fodrin(Siman et al,unpublished) exist in multiple pools,it seems likely that their interaction is involved in a number of cellular processes. In considering this question it will be useful to have information on the extent to which the enzyme and substrate covary in concentration across cell types and brain regions. The present experiments were directed at this question.

Young adult rats were intracardially perfused with 4% paraformaldehyde and 30 um brain sections were incubated for 48 h at 4^0 C in both monoclonal anti-calpain I and polyclonal anti-fodrin. FITC-conjugated and rhodamin-conjugated secondary antibodies were used. Immunoreactivity of both antibodies was visualized on the same section.

Calpain-like and fodrin-like immunoreactivity were co-localized in cell bodies and dendrites of neurons in many brain regions including cerebellar Purkinje cells, deep cortical pyramidal cells, substantia nigra pars compacta, subiculum and spinal motor neurons. Certain cell groups including the granule cells of the cerebellar cortex exhibited only very weak staining to either antibody. Finally, some cell groups contained intense fodrin-like but little calpain-like immunoreactivity (i.e. hippocampal and certain cortical pyramidal cells.)

Biochemical experiments have demonstrated the existence of both soluble and membrane-associated calpain in the brain (J.Neurochem. 1983, 41); it is possible that the surprising discrepancy in calpain versus fodrin concentration found in some cell types is due to the absence of one of these pools. It has been suggested that the soluble (and larger) fraction of neuronal calpain is involved in the turnover of cytoskeletal elements; if this idea were correct, then the present results might indicate that significant differences exist between neurons in the rate at which skeletal elements are broken down and replaced.

NEUROETHOLOGY I

78.1 A QUANTITATIVE STUDY OF THE VARIANTS OF CRAWLING IN THE LEECH. W. Stern-Tomlinson, M.P. Nusbaum, L.E. Perez* and W.B. Kristan, Jr. Dept. of Biology, Univ. of Ca. San Diego, La Jolla, Ca. 92093.

We have done a parametric study of crawling in leeches, as a prelude to an investigation of the neural basis for this behavior, including the neural mechanisms underlying behavioral modifiability. By using this data as a control, we will then be able to specify the behavioral abnormalities induced by tethering, reduction, and dissection in the neurophysiological preparation.

The leech, Hirudo medicinalis, is an amphibious, segmented worm which can crawl in two related ways: vermiform crawling and inchworm crawling (looping). The active components of either variant are rostrocaudal body extension and fixation of the anterior sucker, followed by rostrocaudal body shortening and fixation of the posterior sucker. There are also two quiescent components: a post-extension pause and a post-shortening pause. These four components comprise a cycle. The qualitative difference between the two variants is the final position of the posterior sucker; in inchworm crawling, the sucker is fixed at a position close to the head, resulting in arching of the body, whereas in vermiform crawling, this sucker is placed at some distance from the head, and the body remains parallel to the substrate.

From videotaped behavior, we measured at intervals the absolute position of the head and tail, and the lengths of five body sections delineated by small beads sewn along the lateral aspects of the body. Subsequent analyses were done from this data. The results of comparison between the two crawl variants show some differences:

1. The duration of a cycle (the period) and the distance traveled per cycle are greater for inchworm crawl than for vermiform crawl. (The velocity along the substrate is the same for both.)
2. For both variants, the durations of the crawl components usually co-vary with the period, the exception common to both being the duration of the post-extension pause in the two most posterior body sections. The difference between the crawl types is that the duration of extension in the most posterior body section is independent of period for inchworm crawl, and not for vermiform crawl.
3. The onsets of post-extension pause, shortening, and post-shortening pause occur earlier in the cycle for inchworm crawl in the most posterior body section. Post-shortening pause occurs earlier for inchworm crawl in the two most anterior body sections as well.

We are now testing the influence of sensory input on crawling by doing similar analyses on data from animals in which part of the peripheral innervation has been eliminated.

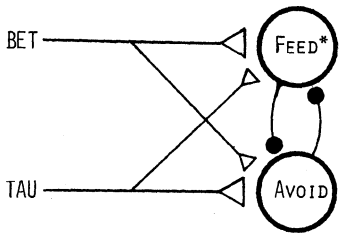
78.2 MIXED SIGNALS IN CHEMOSENSORY REGULATION OF FEEDING BEHAVIOR: MOTIVATION TIPS THE BALANCE IN PLEUROBRANCHAEA. R.-C.Huang and R.Gillette. (SPON: F. Delcomyn). Department of Physiology and Biophysics, University of Illinois, Urbana, Illinois 61801

We found that betaine (trimethylglycine; BET) was the most effective amino acid stimulant of feeding behavior in P. californica (10^{-6}-10^{-3}M) followed by cysteine, then glycine. Surprisingly, taurine (TAU: 10^{-5}-10^{-3}M) elicited strong aversive behavior. Both amino acids are present in high concentrations (>10 mM) in many animals acceptable as prey. In their behavioral responses to TAU, animals fell in two groups. One group showed aversive responses alone and was associated with high feeding thresholds to BET; the second showed initial transient feeding responses to TAU followed by avoidance, and had low BET thresholds. When animals were tested with mixtures of various dilutions of BET + 1 mM TAU, feeding thresholds for BET were raised significantly. In these experiments BET did not suppress the aversive response to TAU unless active and overt feeding was elicited; in this situation, avoidance always followed the cessation of feeding. That is, feeding behavior appears to suppress avoidance and vice versa. Satiation was found to raise the feeding threshold to BET, but did not effect the TAU threshold for aversion. BET alone can elicit avoidance in some satiated animals. These findings suggest a neural model for the organization of feeding behavior in which sensory pathways for BET strongly excite a central pattern generator (CPG) for feeding and also excite the CPG for avoidance. TAU pathways may weakly excite the feeding CPG and strongly excite that for avoidance. Feeding and avoidance CPGs are mutually inhibitory, and the normal expression of the two is governed by a motivational factor setting the arousal level in the feeding CPG. Our findings depict a type of structural organization of behavior likely to be widespread among animals.



*Arousal

78.3 DESCRIPTION OF A NEWLY-DISCOVERED SPONTANEOUS BEHAVIOR, "RESPIRATORY PUMPING SEIZURE", IN APLYSIA. J. E. KANZ, W. D. QUAST*. Marine Biology Department, Texas A&M University at Galveston, Galveston, TX. 77553.

We report the discovery of a previously unreported stereotyped neuronal/behavioral event in the Gastropod Mollusc, Aplysia californica, termed "respiratory pumping seizure" (RPS). Each RPS consists of a long series of single respiratory pumping (RP) responses (totally 20-60) with an initially very short inter-response interval ranging from 10-15 seconds (measured onset-to-onset) that increases, in a regular fashion, to 5-10 minutes as the seizure progresses. The seizure's duration, number of RP responses and progression of inter-response intervals were reasonably stereotyped for a given animal.

RP seizures occur infrequently (0-3 per 24 hrs.) under ambient normoxia, and are usually initiated while the animal is quiescent. Long-term videotape and in vivo extracellular electrophysiological monitoring of intact freely-behaving Aplysia also revealed other forms of spontaneously occurrring RP activity including 1) RP doublets and triplets (i.e., 2 and 3 RP responses, respectively, with inter-response intervals of $\leq$ 10 seconds) 2) abbreviated RP seizures (i.e., a temporal sequence of RP responses identical to that of an RPS but shorter in duration and with $\leq$ 10 individual RP responses), and 3) a double RPS (i.e., 2 full RP seizures, one after the other).

Long-term ambient hypoxia (1.2 - 2.7 ppm O_2) depressed all forms of RP except for an increase in the rate of single RP responses as hypoxia was first developing; the rate of single RP responses decreased following this initial elevated rate. Therefore, there was no correlation between the degree of respiratory stress (dissolved O_2 level) and a hierarchial display of RP activity (i.e., from single RP responses to RP doublets/triplets, to abbreviated seizures to single and double RP seizures).

In one in vitro experiment involving an isolated abdominal ganglion, an RPS was recorded. Thus, under certain circumstances, the RP cellular network(s) appears sufficient to generate RP seizures without peripheral initiation. Two potential triggering and maintenance mechanisms for RPS's are : 1) a stimulus(i) extrinsic to the RP cellular networks elicits a series of RP bursts from the network(s) in a stimulus-concentration dependent fashion or 2) an extrinsic stimulus(i) elicits a series of RP bursts from the network(s), however, the number of bursts in the series is independent of the initiating stimulus, but dependent on the synaptic efficacy between cells within and across each RP network.

Clearly, the Asplysia behavior known as respiratory pumping is more complicated than previously supposed. And any behavioral/physiological adaptation ascribed to it must account for the selective occurrence of all forms of RP activity.

78.4 INFLUENCE OF ABDOMINAL NERVE CORD LESIONS ON THE DIRECTION AND AMPLITUDE OF WIND ELICITED ESCAPE TURNING MOVEMENTS IN THE COCKROACH. J. P. DOWD* and C. COMER. Dept. Biological Sciences, Univ. of Illinois at Chicago, Chicago, IL 60680.

Cockroaches (P. americana) usually respond to abrupt wind puffs by turning away from the source of wind. This turn is truly directional in that turn amplitude (angle) is related to stimulus position, i.e. puffs from the rear elicit small angle contraversive turns, while those which originate more frontally elicit larger angle contraversive turns. Previous work has suggested that turn direction, at least, might be related to a bilateral comparison of wind information at the level of sensory input since covering one of the cerci (paired abdominal appendages containing sensory hairs) frequently causes turns to be incorrectly directed toward wind on the side of the covered cercus (Camhi & Tom, J. Comp. Physiol. 128:193, 1978).

Cercal receptors primarily activate wind sensory giant interneurons on the ipsilateral side of the abdominal nerve cord. We have therefore tested the possibility that a bilateral comparison of wind information at the interneuronal level determines the orientation of turns. Transmission was blocked on one side of the nerve cord by cutting all the axons in one abdominal connective. The behavior of these hemisected animals was compared with the behavior of surgical controls and animals with one cercus removed. Nine adult male cockroaches have so far been studied. Their responses to standard puffs of wind were recorded with a high-speed video system.

Both hemisection and unilateral cercal removal caused animals to respond less often to standard wind stimuli, but the pattern of turning behavior was different in the two groups. Unilateral cercal removal increased the number of misdirected turns as compared with prelesion levels. The increase in incorrect turns was specific to frontal winds on the side of the missing cercus (3% before versus 47% after removal). Hemisection of the cord also increased the number of incorrect turns made in response to winds from the side of the lesion, but in this case 100% of turns to both frontal and rear winds were incorrect. Analysis of turn amplitude as a function of wind stimulus angle along the side of the lesion showed that the incorrect turns were not directional. For the correct turns made in response to winds from the unlesioned side, however, turns were directional as in normal animals and controls (amplitude was correlated with wind stimulus angle).

These results are consistent with the idea that a bilateral comparison of wind information in the CNS is necessary for the proper specification of turn direction, but wind information within one connective is sufficient for the determination of turn amplitude, at least for ipsilateral stimuli.

(Supported by NSF grant #BNS 83-11980 to C.C.)

78.5 PROCESSING BEYOND THE RETINAL MAP IN THE VISUAL SYSTEM OF A JUMPING SPIDER (SALTICIDAE: PHIDIPPUS JOHNSONII). D. W. Sivertsen* (SPON: J. Allman), Division of Biology, Caltech, Pasadena, CA 91125.

Jumping spiders have a highly specialized visual system for the detection and analysis of prey. The retina of each of the anterior medial eyes has a compact, high resolution, three dimensional array of receptors that can scan, saccade, and engage in slow tracking. Computer controlled data collection and randomized stimulus presentation were used in an electrophysiological study of high order visual neurons.

Receptive field mapping revealed neurons with well defined, stable receptive fields. Some of these receptive fields had an angular extent greater than that of the static retinal array. The stability with respect to the cephalothorax and the angular subtense of these receptive fields suggest integration of retinal information and eye position. Most neurons had receptive fields of constant angular subtense as the distance to the tangent screen varied. I found some neurons with fields which remain relatively constant in absolute physical size (changing in angular subtense) as screen distance varied. Such size constant cells are useful in assessing prey suitability. These characteristics require integration of depth information. These cells are driven monocularly, ruling out disparity cues. Jumping spiders do not use muscular accommodation. Instead, the retina has a layered, tiered structure. Depth of focus cues are probably the source of this information, as hypothesized previously (Land, M.F., J. Exp. Biol. 51: 443, 1969).

This work was supported by the Lawrence A. Hanson Fund at Caltech.

78.6 STARTLE RESPONSES OF BURROWED LAMPREY LARVAE. Scott Currie, Dept. Human Physiology, U.C. Davis, Davis, Ca. 95616.

When initially at rest in a pan of water, intact larval lampreys exhibit a robust, vibration-evoked startle response in which both sides of the body contract simultaneously (Currie 1984, Neurosci. Abstr. 10). EMG's recorded from mid-body reveal a response latency and duration of 15-30 ms and 10-20 ms respectively. The movement animals make during the response varies with their resting posture. Areas of inward curvature contract more forcefully than areas of outward curvature. Simultaneous spikes in both Mauthner axons are both appropriate and sufficient for this response (Currie 1984, Biol. Bull. 167).

Larval lampreys normally live burrowed in the sand or silt of fresh water streams. Therefore, it seemed prudent to study the startle response in the context of the animal's normal, burrowed posture. To observe burrowed animals, a thin-section aquarium (similar to an ant farm) was constructed of clear plexiglass. Fine glass beads (0.18 mm) were used as a burrowing substrate. Burrowed animals are visable in silhouette when shining light through the aquarium from behind. Their usual position is to have their mouthparts near or just above the surface of the "sand" while their bodies slant deeper into the burrow at a shallow angle. They are almost always dorsal side-up and curved along their backs so that their heads approach the surface nearly vertical. There are usually small lateral body bends visable in the trunk and tail.

A light hammer tap on top of the aquarium served as the stimulus and was recorded with a calibrated phono-stylus in contact with the aquarium wall. Tapping evokes a jerked withdrawal of the larva's head, 3-6 mm deeper into the burrow. To record head movement during this response, a light beam was shone through the aquarium toward a photoresistor on the other side. The light and photoresistor were positioned so that the animal's head was in between, and partially obstructed the light. Head withdrawal thus translated to increased light intensity and was recorded as a change in voltage across the photoresistor.

One of the larvae studied had a fine, monopolar electrode threaded into its spinal canal, making it possible to record both the extracellular Mauthner spike and trunk EMG. The aquarium water was replaced with Ringers and recordings made relative to an indifferent bath electrode. The animal was allowed to burrow and simultaneous recordings were made of trunk EMG and head withdrawal. Taps which elicited a time-locked EMG spike were always followed by withdrawal. Withdrawal never occurred in the absence of the EMG response. The latency from the start of the EMG response to the start of withdrawal was 19.0 ms ± 1.6 (mean ± s.d., N = 11). The stimulus-EMG latency was 18 ms.

78.7 HABITUATION TO ELECTROSENSORY STIMULI IN THE WEAKLY ELECTRIC FISH HYPOPOMUS OCCIDENTALIS. R. Zelick and W. Heiligenberg. Neurobiology Unit, Scripps Inst. of Oceanography, University of California, San Diego La Jolla, CA 92093.

During periods of inactivity, H. occidentalis produce 1-msec electric organ discharges (EODs) at stable rates of 20 to 40 Hz. An electronically generated electric pulse train of a slightly different frequency than that of the fish mimicks a neighboring conspecific. To such a stimulus the fish responds with a transient increase in EOD rate as each instance of pulse coincidence approaches. This jamming avoidance response (JAR) is asymmetric in that foreign pulse rates lower than the EOD rate typically produce larger responses than do higher rate foreign pulse trains. A short, connecting two parts of the body surface previously at unequal potential, also elicits a momentary acceleration in EOD rate. The first in a series of experimental stimuli (shorts or foreign pulses) typically produced the largest acceleration (a novelty response). Subsequent accelerations revealed a gradual habituation. In most cases the response to shorts habituated more quickly than that to foreign pulses. Identical behaviors were observed in curarized preparations in which an artificial signal (S1) is accepted by the fish as a substitute for its silenced EOD. (In this case the response is detected as the spinal nerve command signal to the tail electric organ.) Step amplitude modulation (1-5%) of the S1 yielded responses which, although initially of the same magnitude as those to a short or foreign pulses, showed little or no habituation. Recordings were made from axons of the anterior lateral line nerve while presenting S1 modulations and shorts (shorts directed to a small region of the body surface including the receptive field for the axon being tested). In no case was there evidence of habituation of the receptor response, even when such was obvious from the simultaneous measurement of the behavioral response. This implies a central mechanism for the habituation to such electrosensory input. Surprisingly, when similar experiments were performed on fish in which the telencephalon and optic tectum were removed, the asymmetric JAR, habituation to foreign pulses and to shorts all remained intact. Thus only the electrosensory hindbrain and midbrain structures play a role in these behaviors.

78.8 THE MULTIMODAL REPRESENTATION OF SPATIAL INFORMATION IN THE OPTIC TECTUM OF THE ELECTRIC FISH EIGENMANNIA. W.Heiligenberg and G.Rose. Neurobiology Unit, Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093

Intracellular labelling of physiologically identified neurons has revealed classes of tectal neurons that are characterized by their laminar location, general morphology and functional properties Most types of neurons respond to moving objects and are sensitive to either visual, electrical, mechanical or auditory cues, or particular combinations of these modalities. The sensory modality of these neurons is closely correlated with the laminar location of their dendrites.

Electroreceptive neurons may respond to electric signals interfering with the animal's own electric organ discharges and may even discriminate the sign of the frequency difference, Df, between the interfering signals. This particular property suggests that these neurons participate in the Jamming Avoidance Response, a Df-sign-specific frequency shift of the medullary pacemaker. These same neurons may also respond to the electric images of moving objects, and their ability of detecting moving objects may be hampered by signal interference.

Large neurons in the deeper layers of the tectum are often multimodal, respond to moving objects with directional specificity and project to premotor areas in the reticular formation. The Df-sign-specific electrosensory neurons are of similar morphology although they send additional collaterals to a diencephalic region apparently not contacted by neurons that only respond to moving objects. This suggests that the Jamming Avoidance Response shares neuronal mechanisms with regular physical responses to moving objects and that it probably represents an evolutionary modification of more general motor responses.

78.9 MODULATION AND CONTROL OF THE PACEMAKER NUCLEUS OF WEAKLY ELECTRIC FISH. J. Dye and W. Heiligenberg. Dept. of Neurosciences and Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093.

The mesencephalic pacemaker nucleus of wave-type, weakly electric fish is the most precisely regular neural oscillator known. This nucleus, which commands the electric organ discharge of the animal, is quite simple as regards intrinsic cell types and sources of afferent input. The high degree of precision in its firing offers opportunities to monitor, reproducibly and quantitatively, subtle physiological effects through alterations in pacemaker frequency. Most interesting from the behavioral standpoint are those changes in frequency employed by the organism to effect various functions subserving electrolocation and intraspecific communication. Heretofore, attempts to identify the proximal mechanism by which the pacemaker frequency is modulated in such behaviors have yielded only negative results.

We report here studies on isolated pacemakers in a brain slice preparation which show a strong effect of the excitatory amino acid transmitters, aspartate and glutamate, on pacemaker firing frequency. Application in micromolar concentrations causes immediate acceleration of the rhythm. This short-term effect is transient due to rapid desensitization. Such exposures, however, prolong the activity of the nucleus in vitro from the usual period of 8 to 12 hours to several days. Millimolar concentrations of these amino acids result in the normally tightly-coupled and synchronously-active cells of the nucleus to fire incoherently for these extended periods.

The pacemaker frequency of these fish has long been known to be extremely temperature-sensitive. In order to accurately separate the effects due to a putative transmitter from unavoidable temperature variations accompanying rapid solution changes, we undertook to characterize the temperature dependence of pacemaker activity. We have found the frequency to change linearly across the physiological temperature range, and the regression coefficient to itself increase monotonically with the fish's individual frequency. Our hope is that an understanding of the temperature dependence may indicate the source of individual variation in baseline frequency and, hence, the mechanism of hormonal control of the pacemaker frequency.

78.10 PYRAMIDAL CELLS IN THE MULTIPLE ELECTROSENSORY MAPS OF THE ELECTROSENSORY LATERAL LINE LOBE (ELLL) HAVE A CENTER-SURROUND RECEPTIVE FIELD. C.A. Shumway, Scripps Inst. of Oceanography UCSD, La Jolla, CA 92093

The weakly electric fish Eigenmannia virescens has 3 tuberous electrosensory maps in the first-order nucleus, the electrosensory lateral line lobe (ELLL). Studies are actively underway to determine the anatomical and physiological differences among the maps in hopes of understanding their functional significance. I recently discovered that the maps differ anatomically by the presence or absence of a local axonal collateral on the amplitude-coding pyramidal cells in the ELLL. I am currently examining the receptive field properties of single pyramidal cells in the different maps. Whether or not the pyramidal cells have a center-surround receptive field has been in dispute for some years (see Maler et al.,J. of Comp. Neurol. 195:87-139,1981 and Bastian,J. of Comp. Physiol. 144:481-494,1981). The cells are first characterized as E or I units (E units are excited by a rise in amplitude, I units are excited by a fall in amplitude) by whole body stimulation with a positive amplitude modulated (AM) signal. To localize the receptive field, the whole body stimulation is turned off, and a small local AM signal is applied with an electrode positioned directly on the skin. The pyramidal cell is subsequently filled with Lucifer Yellow to determine its map origin.

Using electrodes positioned directly on the skin, these results convincingly demonstrate that pyramidal cells have a center-surround receptive field which should enhance the spatial contrast of an electric image. E units were excited by the AM in the center of their receptive field and inhibited in the periphery. An electrode placed in the center of the receptive field with an additional electrode in the periphery either inhibited or reduced the excitation of the E unit. I units were inhibited by the AM in the center of their receptive field and excited by the AM in the periphery. These physiological results correlate with the predictions made by Maler et al. on the basis of Golgi light and electron microscopic studies. Maler and coworkers found that E units receive direct excitatory input from the primary P-type afferents in the center of their receptive field and inhibitory input via granule cells in the periphery. An I unit receives inhibitory input in its receptive field center from granule cells and excitatory gap junction input in the periphery of its receptive fields from granule cells.

It is possible that the pyramidal cells in the maps differ in receptive field size,in response to objects with a given size, shape, or velocity, or in direction selectivity. One I unit from the C-M map was direction selective, responding more to movement of the electrode ventrodorsally than dorsoventrally.

78.11 **ELECTRORECEPTOR TUNING PREDICTS TEMPORAL ENCODING OF SPECIES SPECIFIC SIGNALS IN ELECTRIC FISH.**

S.I. Arnesen* and C. D. Hopkins. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

Mormyrid electric fish communicate with pulse-like electric organ discharges (EODs) which are species-specific and often sexually different. EODs are coded as a unique time-domain pattern of spikes by peripheral electroreceptors (Knollenorgans) in mormyrids. Single units with differing frequency tuning characteristics produce different temporal codes. Our goal was to model the effect of frequency tuning on the pattern of spikes in the time domain.

Receptor potentials from single Knollenorgans were recorded non-invasively from the mormyrid, *Brienomyrus brachyistius*, while artificial stimuli were delivered to the unit via a bridge circuit. Frequency tuning curves (FTCs) and compound post-stimulus time histograms (PSTHs) were collected from each cell in response to sine waves, EODs, delta functions, step functions, and other stimuli.

Since Knollenorgans behave as linear bandpass filters for low amplitude stimuli, we used linear filter theory to describe the transfer characteristics of the electroreceptor. Tuning curves were matched by eye to the gain curves of known electronic bandpass filters. The matching was based on four parameters: the low and high frequency cutoff slopes, the damping coefficient, and the best frequency. Once the transfer function had been determined, we then could predict the response to any arbitrary test stimulus, by performing the convolution between the original stimulus, and the impulse response of the filter. The results are compared to the compound PSTH (fig. 1). [Since the receptors rectify electrical stimuli, compound PSTHs are assembled from PSTHs to a stimulus presented in one polarity, and then its inverse.]

For low amplitude stimuli, the compound histogram matches the predicted filtered stimlus. Knollenorgans respond to positive-going transitions in the stimulus waveform only, and are inhibited by negative-going transitions. The waveform of the compound PSTH and the relative amplitude of the peaks matches the predicted filter response. For high amplitude stimuli, non-linearities distort the PSTH.

Brienomyrus brachyistius has two classes of Knollenorgans tuned respectively to 800 Hz, and to 1.0-2.0 kHz. Each class fires spikes with a characteristic PSTH. Our modeled responses can account for the differences observed for the two classes of units.

A fish may require two types of Knollenorgans in order to encode its own species' EOD in a unique way.

78.12 BRAINSTEM CENTERS GENERATING MOTOR BEHAVIOR FOR ELECTRO-LOCATION IN THE ELECTRIC FISH Eigenmannia. K.Behrend Zool. Inst. Universität Mainz 65 Mainz,FRG

The electric fish Eigenmannia investigates objects in it's "electrosensory world" by a motor behavior termed "probing"(1).The fish bends it's tapering caudal end towards the object of interest thereby enhancing its electrosensory resolution.Since cerebellar activity is involved in this motor act(1) to further clarify it's role in motor co-ordination the sites where cerebellar output acts on had to be determined.Fish were anesthetized by perfusion of aerated MS 222 solution(1:15ooo) through the mouth,placed in a head holder and the brainstem was stimulated (5o Hz train,6o μsec square pulses for 55oms) in 2oo μ steps along its longitudinal extent.The trunk musculature which in this fish does not serve locomotion could be activated along a strip comprising the medial reticular nucleus.Two sites are of special interest: at the level of entrance of the VIII nerve stimulation elicits synchronous forward flapping of the pectoral fins followed after about 1oo ms by contralateral body bending.This corresponds to "backwards probing" as analyzed in free moving fish(1).The second site is in the midbrain tegmentum at its rostral border lateral to the nucleus of the f.l.m..Here,the pectorals move alternating and the body bends ipsilaterally which equals "forward probing"(1).The two sites comprise distinct groups of large(2o-5oμ)neurons projecting directly down the spinal chord,which has been shown by retrograde staining with HRP deposited at various spinal levels.The midbrain site seems to be a good candidate for the still much debated red nucleus in teleosts.

78.13 **ACOUSTIC SONG IN AN ELECTRIC FISH**

J.D.Crawford*, M.M.Hagedorn* and C.D.Hopkins (SPON:H. Howland). Section of Neurobiology and Behavior. Cornell University, Ithaca, New York 14853.
(Order of authors determined by coin toss)

Although African electric fish (*Mormyridae*) are known to have a highly- specialized auditory system based on a tiny inner-ear air bladder which contacts the saccular otolith, the function of this auditory system has been a mystery. We now describe a rich repertoire of underwater acoustic signals which accompany courtship and agression in one electric fish, ***Pollimyrus isidori***.

1. Two males and one female *Pollimyrus* were induced to spawn in a community aquarium by gradually decreasing the water conductivity over a period of several months. For weeks prior to each spawning, the males went through a phase of nest building and territorial defense while producing frequent underwater sounds [**"grunts"**, **"moans"** and **"growls"** (sound spectrogram in Fig.)]. Calling accompanied *hovering* and active *patroling* by males. It was most frequent at night, especially at dusk, and at dawn. Calling rate increased more than three fold when a gravid female entered a male's territory, but was unaffected by the presence of juvenile (non-breeding) females. Males and females were silent during time of actual spawning.

2. During agonistic encounters between males, between breeding and non-breeding females, or between male and female, we also recorded **"hoots"** and **"pops"**(not illustrated).

3. **Grunts** are a highly stereotyped bursts of about 15 clicks in 300 msec(c.v.-3%). Our two males produced grunts differing consistently by 10 Hz. **Moans** and **growls** are more variable; the two males overlap in characteristics of these calls. Males call from preferred sites which may signal future spawning spots to females.

4. *Pollimyrus* continues to discharge its electric organ during bouts of acoustic calling but is usually *electrically silent* during the the "grunt-moan" sequence.

5. The sonic organ has not yet been identified.

The diversity of acoustic signals suggests that acoustic communication is an important function for audition in mormyrids. Although mormyrids also communicate with electric signals, sound may be more useful for attracting mates from a longer distance.

78.14 HAIR CELLS IN THE LATERAL LINE ARE TROPHICALLY DEPENDENT ON INNERVATION BOTH FOR MAINTENANCE AND FOR REGENERATION. P. C. Borden* and J. T. Corwin. Dept. of Zoology and Bekesy Lab., Univ. of Hawaii, Honolulu, HI 96822 (SPON: H. Gillary).

Trophic interactions between nerves and hair cells in lateral line neuromast organs were investigated in the aquatic salamander Ambystoma mexicanum. In one series of experiments unilateral transection and removal of a 2 mm segment of the lateral line nerve in the abdominal region of anesthetized salamanders resulted in dramatic reductions in the number of lateral line neuromasts on the ipsilateral side of the tail. The difference in the number of neuromasts between denervated and control sides of the tail was statistically significant ($P<0.05$, two-tailed) in specimens that survived for 110 to 140 days postoperatively.

In other experiments unilateral abdominal transection of the lateral line nerve was combined with amputation of the tip of the tail in anesthetized salamanders. These experiments provided evidence suggesting that the regenerative replacement of hair cells and neuromasts in this species is dependent on the local presence of a lateral line nerve. When the regenerating lateral line nerve grew into deep tissues so that it was not near the surface of the regenerated tail no neuromasts regenerated and persisted. In several specimens in both experimental series, foreign nerves invaded previously denervated regions, in these specimens neuromasts did not regenerate or persist in the denervated regions but they did appear to regenerate and persist in the regions that were innervated by the foreign nerve.

Our findings are essentially opposed to conclusions reported by Jorgensen and Flock (J. Neurocytol. 1976, 5:33) based on similar manipulations in the same species. However, we made comparisons between a control and an experimental side in each animal, recorded quantitative results, and noted the positions of neuromasts before and after the manipulations. We also operated on salamanders that were older and larger (47-68 days old, 38-52 mm) than those used by Jorgensen and Flock (14 days old, 24-27 mm) and we allowed longer postoperative survival times. Jorgensen and Flock reported on noninnervated neuromasts that they identified as newly regenerated neuromasts in salamanders where bilateral nerve transections and amputation of the tail were combined. The results of our study indicate that the lateral line neuromasts are strongly dependent on intact innervation. If the conclusions reported by Jorgensen and Flock are also correct, then this suggests that the postoperative survival period of sixty days used in their study was too short to allow an effect to develop or that there may be a critical period in the development of the lateral line system when hair cells and neuromasts are not yet dependent on a neurotrophic interaction that later becomes required.

78.15 INDIVIDUAL VARIATION IN VOCALIZATIONS AND AUDITORY SENSITIVITY OF THE GREEN TREEFROG, HYLA CINEREA. M. Penna*, R.R. Capranica and J. Somers*(Sponsor: P.M. Narins). Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

Spectral characteristics of anuran mating calls vary individually according to the male's body size. Large males produce lower-pitched calls than smaller males. Variation in tuning of auditory sensitivity related to sex and age is also correlated with individual size differences. Female green treefrogs rely on spectral features for mating call recognition and subsequent orientation towards males. This species therefore provides an opportune model for estimating the importance of individual variations in vocal and auditory tuning for sound communication during the breeding season.

The experimental group consisted of 32 males and 21 females which were induced to call after subcutaneous implants of testosterone pellets and injections of arginine-vasotocin. Vocal responses of the animals to a ten-minute presentation of conspecific calls were tape recorded and analyzed with a Mini-Ubiquitous Spectrum Analyzer (Nicolet 444). Multiunit auditory responses to pure tones were recorded in the torus semicircularis of the midbrain with gross tungsten electrodes (75 μm width) in these same frogs all at the same temperature (21± 1°C).

The calls of males have a low-frequency peak centered at 1030 Hz (range 817-1300 Hz) and a high-frequency peak at 2742 Hz (range 2242-3211 Hz). A mid-frequency peak at 1897 Hz (range 1617-2180 Hz) is also present in the calls of some individuals. The audiograms for both sexes have three dips of improved sensitivity which in males are centered at 550, 990 and 2690 Hz. In females the region of optimal high-frequency sensitivity is at 2530 Hz. A significant negative regression with body size exists for the low frequency peak of the males' calls ($F=9.96$, $p<0.01$) and for the region of high-frequency sensitivity in their audiograms ($F=12.34$, $p<0.05$).

The lack of correlation between the low-frequency region of auditory sensitivity and size is in agreement with behavioral data which have shown that body size in H. cinerea females is not correlated with a preference for lower-frequency components in the cells of males as tested in discrimination experiments (Gerhardt, H.C., Am. Zool. 22:581-595, 1982). The significance of size-dependent variation in the region of high-frequency sensitivity is unclear and deserves further behavioral study.

78.16 DETECTION OF COMPLEX SOUNDS BY THE GREEN TREEFROG. A. Megela-Simmons and C.F. Moss. Dept. Psych., Brown Univ., Providence, RI 02912

Green treefrogs (Hyla cinerea) can detect harmonically-structured complex sounds that mimick essential features of their conspecific mating calls with greater sensitivity than non-harmonic complex sounds or pure tones. Using the technique of reflex modification, we measured detection thresholds for pure tones and complex acoustic signals against a background of broadband noise. The frog detects pure tones at communication frequencies of 900 Hz and of 3000 Hz with power signal-to-noise ratios of about 20 dB, detects non-harmonic complexes with frequencies near 900 and 3000 Hz with power signal-to-noise ratios of about 18 dB, and detects harmonically-structured complex sounds near 900 and 3000 Hz with signal-to-noise ratios as low as 11 dB. The superior ability to resist noise masking of harmonic complexes may be due to perception of coherence, or phase-locking, of the harmonics, possibly through detection of the first-harmonic periodicity. Coherence detection alone provides the frog with about 7 dB of noise rejection for complex sounds beyond what occurs as a consequence of conventional critical-band rejection of noise. Because reception of the 900 Hz and 3000 Hz components occurs in anatomically separate sense organs in the treefrog's inner ear, the coherent comparison of these components must take place centrally. The very strong frequency selectivity (narrow critical ratio-bands) implied by low signal-to-noise ratios for detection of harmonic complexes may be achieved by temporal processing in the frog's central auditory system.

78.17 ALLIGATOR BAEPS: EFFECTS OF TEMPERATURE AND HYPOXIA. G.M. Strain and T.A. Tucker*. Louisiana State Univ., Sch. of Vet. Med., Baton Rouge, LA 70803.

Brainstem auditory evoked potentials (BAEPs) were recorded from 10 young alligators (Alligator mississippiensis), and the effects of hypothermia, hyperthermia and hypoxia on the waveforms was determined. Average weight and length were 406 gm and 54 cm, corresponding to an age range of 1-3 years. Recordings were made with needle electrodes placed subdermally at vertex and just below the left external ear flap, with ground on the tail. Click stimuli (21/S, 100 μsec) were presented through an insert earphone 1 cm from the ear flap. Body temperature was controlled by submersion in a water bath with a temperature-regulating circulator. Body temperature was monitored with a cloacal thermistor. The waveform shape was similar to the human BAEP, although extra waves were occasionally seen. The responses were highly repeatable, and varied in a predictable manner as a function of stimulus frequency, polarity, intensity, and body temperature. Rarefaction clicks produced waveform latencies longer than those from condensation clicks. BAEPs were present over the entire temperature range studied (0-36°C). In contrast, mammalian BAEPs disappear over the temperature range of 20-27°C, and seizures occur at 20-21°C. At temperatures below 20°C, the alligator BAEP peak amplitudes decreased with decreased temperature, but latencies did not greatly decrease. At temperatures above 20°C the peak amplitudes increased, and the latencies decreased with temperature. Transient brain hypoxia, achieved by inverting the alligator, produced a progressive decrease in BAEP waves to an isoelectric amplitude without greatly altered latencies. The reverse sequence of changes was seen during recovery. Metabolic differences between mammals and the alligator likely account for the alligator's resistance to hypothermia, hyperthermia and hypoxia.

78.18 THEORETICAL ANALYSIS OF VELOCITY DEPENDENCE IN THE RESPONSE OF TECTAL CELL T5(2).[1] F. Cervantes-Pérez* and M. A. Arbib (SPON: A. Barto). Centro de Inv. en Fis. Celular, UNAM, México 04510 and Center for Systems Neuroscience, Univ. of Mass., Amherst, MA 01003

Electrophysiological studies have identified different types of cells within the anuran's optic tectum. Some of the properties exhibited by specific tectal cell responses are still a matter of debate. In toad (Ewert, 1976) and in frog (Schuerg-Pfeiffer & Ewert, 1981), Ewert and coworkers identified a tectal cell they classified as T5(2) that responded to different moving configurational visual stimuli with firing levels that resembled the overt behavior of the animal. These authors also found that a T5(2) cell preferred "worm-like" to "square" or "antiworm-like" stimuli independently of the stimulus direction of motion (Ewert et al., 1979) and velocity function (Ewert, 1980, 1984).

Roth and collaborators have also recorded cells of this type in toads (Roth & Jordan, 1982) and in salamanders (Himstedt & Roth, 1980). However, they found that a subgroup of this type of cell changed their preference as the stimulus velocity was varied. Roth and Jordan reported that 16 out of 41 cells, which behaved as T5(2), preferred worm-like to square stimuli at low velocities while at high velocities squares were more effective.

In Cervantes-Perez, Lara and Arbib (1985) we developed a family of neural models of the anuran's optic tectum and its interactions with the pretectum. Following Ewert's original hypothesis, the aim was to analyze how an inhibitory effect from a pretectal cell he classified as TH3 to tectum enables T5(2) cell to discriminate between prey and non-prey stimuli. Ewert (1980) and Ingle (1981) showed that such inhibition is modulated by the motivational state of the animal. Additionally, Himstedt (1982) suggested that the "inversion phenomenon" reported by Roth's group could depend on the animal's experience with certain type of prey. Based on these observations, we hypothesize that the mechanisms responsible for the difference between the results obtained by the Ewert and Roth laboratories might be related to parameters that produce changes in the level of pretectal inhibition upon tectum.

Computer experiments simulating variations in TH3 neuron parameters were conducted to study the ways in which T5(2) responses might be velocity dependent. Results from these simulations suggest that if pretectal inhibition over tectum is delayed or reduced then retinal axons impinging upon tectum build up a strong effect that causes a switch in T5(2) preference between worm-like and square stimuli as stimulus velocity is increased. We want to stress that the interplay of theoretical and empirical studies is necessary and will clarify the real nature of these processes.

79.1 BENZODIAZEPINE RECEPTOR INVOLVEMENT IN THE POSTICTAL REFRACTORY PERIOD OF THE SPONTANEOUS SEIZURE PRONE HAMSTER. J. E. Fisher, Jr.* and W. B. Iturrian. Pharmacology Dept., Univ. of Georgia, Athens, Ga. 30602 (SPON. J. M. Bowen).

Several lines of evidence indicate that the postictal period following electroconvulsive seizure is characterized by a neural hypometabolic state and that maximal electroshock (MES) has anticonvulsant properties. Animal and human research has shown that MES results in an elevation in threshold for pharmacological as well as electrical induction of seizures. Post et al. (1984) showed that electroconvulsive seizures inhibit amygdala kindling. While the mechanism of this anticonvulsant effect of MES is unknown, post seizure changes in ligand binding properties in a variety of seizure models have reinforced the involvement of the BDZ receptor in the regulation of seizure activity. A transient, time dependent increase in number of Diazepam binding sites has been found after experimentally induced (MES, Metrazol, amygdala kindling) seizures. We demonstrated an inherent difference in the nature of BDZ receptors during spontaneous seizures in genetically epileptic hamsters (sz, BIO 89.93).

We used paired MES to measure the time course of hyperexcitability and depression during the postictal period. The hyperexcitability phase in which a second flexor-extensor seizure occurs was extended to over 80 sec. in sz hamsters in contrast to only 10 sec. in controls. The optimal depression inter-test interval for control animals occurs at 32 sec. with 31% (N=52) having a second seizure. Insertion of the sz trait onto the LVK background increased the incidence to 83% (N=78), suggesting a hereditary deficit in the inhibitory system producing the depression phase. Breeding experiments demonstrate a linkage between the sz trait and the prolonged hyperexcitability phase. CGS 9896 (20 mg/kg), a partial agonist at the BDZ receptor, reduced the incidence of second seizures by 50% in sz hamsters without altering the initial seizure. The prolongation of the hyperexcitability phase does not develop until the sz hamster outgrows its susceptibility to spontaneous seizure, which occurs at about 60 days of age. MES increases the number of available BDZ binding sites and we find that it reverses sz seizures with a temporal course resembling the receptor effect. CGS 8216, a BDZ receptor antagonist, blocks this protective effect of MES, suggesting that the sz trait may be the result of a BDZ receptor or endogenous ligand alteration.

79.2 ANTICONVULSANT ACTIVITY OF A BENZODIAZEPINE INJECTED INTO SUBSTANTIA NIGRA PARS RETICULATA. H.C. Rosenberg, E.I. Tietz and T.H. Chiu. Medical College of Ohio, Toledo, OH 43699.

Several studies have suggested that the pars reticulata of the substantia nigra (SNpr) is part of a system that regulates seizure spread. Activating nigral GABA systems, and thereby suppressing SNpr neuronal activity, appears to be an important mechanism for regulating seizure susceptibility. Benzodiazepines potentiate GABA activity, and can suppress the discharge of SNpr neurons. Injection of clonazepam into SNpr suppressed kindled seizures (King and McNamara, Soc. Neurosic. Abst. 10:343), and rats made tolerant to benzodiazepines show down-regulation of benzodiazepine receptors which is especially prominent in SNpr (Tietz et al., Soc. Neurosci. Abst. 10:644). This suggests that SNpr may be an important site for the anticonvulsant action of benzodiazepines, and that tolerance to benzodiazepines may occur within SNpr. Experiments were begun to evaluate acute and chronic benzodiazepine actions in SNpr.

Male, Sprague-Dawley rats (250-300 gm) were deeply anesthetized with pentobarbital. Using stereotaxic technique, bilateral stainless steel guide cannulas with close-fitting obturators were implanted, aimed at the SNpr. A week was allowed for recovery from the surgery before testing. The water soluble benzodiazepine, midazolam, was infused bilaterally over 1 min, 5 µg per side in 1 µl. The injectors were steel hypodermic tubing that extended 1 mm past the end of the guide cannulas. Injectors were left in place another minute, then withdrawn slowly and replaced with obturators. 5 min after midazolam, pentylenetetrazol (PTZ), 100 mg/kg was given IP. Rats were observed for another 12 min and any seizure activity recorded. Appearance of a tonic-clonic, or severe clonic seizure with loss of posture was considered a negative midazolam response, and 40 mg/kg Na pentobarbital was immediately given to prevent death. If less intense, or no seizures were seen for 12 min, animals were considered protected from PTZ, and were given Na pentobarbital to preclude later appearance of lethal seizures. After 5-7 days, rats were anesthetized, and brain tissue was taken for histological verification of injection sites.

In previously untreated rats, 100 mg/kg PTZ produced tonic-clonic seizures within 3 min in virtually all cases. After intranigral midazolam injection, all rats had some response, ranging from mild jerks to tonic-clonic seizures. Results are shown grouped according to sites of midazolam injection:

Midazolam Injection Sites	#Protected/# Tested
Both sides in SNpr	5/5
One or both sides < .2 mm out of SNpr	4/5
One or both sides > .2 mm out of SNpr	0/5

These data show that injection of a benzodiazepine into SNpr produced a clear anticonvulsant action. SNpr may prove useful for studying mechanisms of tolerance to benzodiazepines.

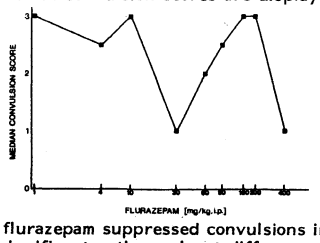
Supported by DHHS grants RO1-DA02194, RO1-NS16595, F32-DA05265.

79.3 ANTICONVULSANT AND CONVULSANT PROPERTIES OF FLURAZEPAM. M.W.Kalichman. V.A. Med. Ctr. & Univ. of Calif., San Diego, Dept. of Anesthesiology, V-151, La Jolla, CA 92093.

The benzodiazepine drug flurazepam is one of the most widely-prescribed sleeping pills. Although benzodiazepines are typically effective anticonvulsants, several investigators (Randall & Kappell, The Benzodiazepines, Garattini et al., eds., Raven Press, New York, 1973, pp. 27-51; Rosenberg, Pharmacol. Biochem. Behav. 13: 415, 1980; Barr & Lithgow, Nature 302: 431, 1983) have provided evidence that flurazepam may be convulsant in rats, cats, and mice.

The significance of flurazepam's convulsant property may be related to the demonstration by MacDonald & Barker (Brain Res. 246: 257, 1982) that low concentrations (500 picomolar) of flurazepam could effectively antagonize the paroxysmal depolarizing events produced by picrotoxin in cultured mouse spinal neurons, but higher doses (10 nanomolar) produced minimal antagonism of the picrotoxin-induced activity. In light of the evidence of a convulsant property of flurazepam as well as a dose-dependence for antagonizing an effect of the convulsant drug picrotoxin, 30 male Sprague-Dawley rats were tested two to three times each with different doses of flurazepam hydrochloride against convulsions produced by picrotoxin (4 mg/kg, i.p.).

Median picrotoxin convulsion scores are displayed in figure 1.



No dose of flurazepam suppressed convulsions in all subjects tested, but a significant anticonvulsant difference was present for a dose of 30 mg/kg when compared to doses of greater than 150 mg/kg ($P<0.05$). At a dose of 400 mg/kg, all subjects died (with or without convulsions). These observations are consistent with the reports of direct convulsant properties of flurazepam in other animal models and are a clear behavioral demonstration of a dose-dependent anticonvulsant property similar to that described for cultured mouse spinal neurons. At this point it is not clear whether flurazepam epileptogenicity may simply be a pharmacokinetic interaction; however, the study of MacDonald & Barker demonstrates the possibility that the mechanism may be found at flurazepam's site of action in the central nervous system.

79.4 INTRANIGRAL MUSCIMOL ATTENUATES ELECTROGRAPHIC SEIZURES INDUCED BY INTRAVENOUS BICUCULLINE IN RATS. D.S. Garant* and K. Gale (SPON: S.J. Potolicchio). Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

Previous work in our laboratory demonstrated that muscimol infused bilaterally into the substantia nigra (SN) reduces the severity of behavioral seizures induced by chemoconvulsants (Science 218:1237, 1982). We now report that bilateral infusion of muscimol into the SN attenuates electroencephalographic epileptic activity induced by i.v. bicuculline.

Bilateral guide cannulae directed to the SN were implanted along with epidural and depth electrodes in 350 g male rats. Records were made using a Grass Model 6 electroencephalograph (EEG). After at least a 24 hr recovery from surgery, rats were tested on alternate days with either i.v. bicuculline 30-60 min following intranigral muscimol (25-50 ng), or with the identical dose of bicuculline alone as a control, with order of treatment randomized. EEG recordings and drug injections were performed without restraint or anesthesia. Doses of bicuculline (0.15-0.23 mg/kg) were selected which were just subthreshold for inducing clonic activity and which produced marked bilateral epileptic activity in the EEG. Following intranigral muscimol, the duration of electrographic seizure activity was reduced by more than 75% in the majority of animals. The animals had control seizures with recurrent epileptic EEG activity lasting 3 min or more; after muscimol, they usually experienced only a single brief episode averaging 15 sec.

These results indicate that GABAergic inhibition of nigral output neurons can attenuate not only motor seizures, but electrographic seizure activity as well. Thus, SN efferents must normally facilitate seizures, either by maintaining or promoting propagation of epileptic activity. This further supports our findings that inhibition of SN outflow produces a shift in the dose-response for chemoconvulsants, rather than a selective blockade of any specific motor component of the seizures (Brain Research 273:156, 1983).

79.5 ANXIOLYTIC AND ANXIOGENIC DRUG EFFECTS IN A NEW ANIMAL TEST OF ANXIETY. Sharon Pellow and Sandra E. File. MRC Neuropharmacology Research Group, The School of Pharmacy University of London, London, U.K.

We have recently carried out an extensive behavioural physiological and pharmacological validation of a novel test for the identification of anxiolytic and anxiogenic drug effects in the rat (Pellow, Chopin, File & Briley, J. Neurosci. Meths. submitted 1985). The apparatus consisted of a +-maze elevated to a height of 50 cm, with 2 open arms opposite to each other, and 2 closed arms with an open roof. Rats were placed in the centre of the maze and their behaviour noted for 5 min. The percentage of the total time that rats spent on the open arms, and the percentage of open arm entries, provided a measure of fear-induced inhibition of exploratory activity. The total number of arm entries provided a measure of overall activity. Clinically effective anxiolytics (benzodiazepines) significantly elevated, and drugs that are anxiogenic in man (yohimbine, caffeine and pentylenetetrazole) significantly attenuated, the percentage of time spent on the open arms. Antidepressants and neuroleptics non-specifically reduced overall activity.

In the present investigation we examined the effects of several novel putative anxiolytic and anxiogenic agents that are believed to produce their effects by interactions with the GABA-benzodiazepine receptor complex. The following compounds had anxiogenic activity - FG 7142 (1-5 mg/kg); CGS 8216 (3-10 mg/kg); Ro 5-4864 (1-5 mg/kg). The benzodiazepine receptor antagonists Ro 15-1788 (10-20 mg/kg) and ZK 93426 (5-10 mg/kg) that can have anxiogenic activity in certain tests, were ineffective. The following compounds had anxiolytic activity: CGS 9896 (10-20 mg/kg); tracazolate (5 mg/kg); CL 218,872 (10-20 mg/kg). Ineffective compounds included the 3,4-benzodiazepine tofisopam (25 mg/kg), PK 8165 (10-25 mg/kg) and buspirone (0.5-20 mg/kg), consistent with their lack of efficacy in other animal tests of anxiety.

Thus, it appears that the present procedure provides a valid and reliable test for the detection in the rat of anxiolytic and anxiogenic drug effects. The test is simple and rapid, and its advantages over other tests include the lack of necessity for food or water deprivation, or for the use of electric shock.

79.6 CAN ANIMAL TESTS OF ANXIETY DETECT ANTI-PANIC COMPOUNDS? Sandra E. File, Sharon Pellow and Philippe Chopin* MRC Neuropharmacology Research Group, The School of Pharmacy University of London U.K. &*Centre de Recherches Pierre Fabre, 81100 Castres, France.

Several lines of clinical evidence suggest that the neural mechanisms underlying generalised anxiety states and panic disorders are distinct. For example, the benzodiazepines (BDZs), that are clinically effective in generalised anxiety, are generally ineffective in the prevention of panic attacks; whereas for tricyclic antidepressants (ADs) the reverse is true. The discovery of the triazolobenzodiazepines has for the first time provided a group of compounds that are effective in both types of disorder. It has also been suggested (though the evidence is controversial) that the α_2-adrenoceptor agonist clonidine may be effective in both disorders.

The purpose of the present investigations was to compare the effects of these different classes of compound in two extensively validated animal tests of anxiety: the social interaction (SI) test (File, J. Neurosci. Meths. 2:219-238, 1980) and the elevated plus-maze (Pellow, Chopin, File & Briley, J. Neurosci. Meths. submitted; see also Pellow & File, this meeting). Classical 1,4-BDZs have an anxiolytic profile in both tests, although chronic pretreatment is necessary in the social interaction test. After acute treatment, the triazolobenzodiazepines alprazolam, adinazolam and U-43,465 had strongly anxiolytic effects in the +-maze, but only U-43,465 was effective in the social interaction test. Several antidepressants, after both acute and chronic treatment, have been found to be inactive in the social interaction test. These include imipramine, clomipramine and 5-HT uptake inhibitors. In the +-maze, neither imipramine nor mianserin (after acute treatment) had an anxiolytic-like effect; in fact, mianserin was weakly anxiogenic. Results after chronic treatment will be presented. Clonidine did not have anxiolytic activity in either test; its effects also were mildly anxiogenic, but sedation was a confounding factor.

In conclusion, it is apparent that current animal tests that have been extensively validated to indicate the specificity of their measurement of anxiety-related behaviours, are sensitive to the effects of compounds that are effective in the treatment of generalised anxiety states, but not to those effective in the prevention of panic attacks.

79.7 TRIAZOLOPYRIDAZINES WITH ANTAGONISTIC PROPERTIES OF BENZODIAZEPINE ACTIONS IN RODENTS. J.P. Chambon (1), S. Tebib (2), J.J. Bourguignon (2), A. Perio (1), M. Heaulme (1), K. Bizière (1) and C.G. Wermuth (2). (1)Sanofi Recherche, rue du Prof. J. Blayac, 34082 Montpellier Cedex, France ; (2)Laboratoire de Pharmacochimie Moléculaire, UA 501, Centre de Neurochimie du CNRS, Université Louis Pasteur, 67084 Strasbourg Cedex, France.

The benzodiazepine-like activity of the triazolopyridazine CL 218872 and its specific action at the BZD-1 central receptor site has been extensively established since the original work of Lippa et al. (Pharmacol. Biochem. Behav. 11 : 96-106, 1979).

In order to investigate the structural requirements which are needed in this chemical series for the interaction with the BZD central receptor sites, we synthesized triazolopyridazines substituted in the 5-position of the pyridazine ring. These compounds exhibited lower affinity for the BZD central receptor sites than CL 218872 with IC50 values ranging from 1 to 10 µM. When administered orally to mice these derivatives did not elicit the classical sedative pattern of activity of BZD. These derivatives did not induce myorelaxant effects in mice (traction test) but administered orally (12.5 to 100 mg/kg) 30 min before diazepam 3.5 mg/kg i.p., they dose-dependently suppress the BZD-induced myorelaxation in this test. These compounds were found inactive in antagonizing pentylenetetrazole-elicited seizures in mice but prevented the anticonvulsant effect of diazepam against pentylenetetrazole-induced clonic seizures. Finally, in the conflict test in rats performed according to the Geller and Seifter procedure these compounds (0.7 to 25 mg/kg i.p.) antagonized the desinhibitory effect of diazepam 4 mg/kg i.p..

In conclusion, the data strongly suggest that triazolopyridazines substituted in the 5-position of the pyridazine ring have potent antagonistic properties of BZD actions in rodents.

79.8 CENTRAL CARDIOVASCULAR EFFECTS OF BACLOFEN AND ITS INTERACTION WITH BARORECEPTOR REFLEXES IN SPONTANEOUSLY HYPERTENSIVE RATS. R. Singh* and M.K. Ticku (SPON: A. Modak). Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284.

Our previous studies have demonstrated that specific [^{3}H]-baclofen binding to $GABA_B$ receptors in brain is significantly different between spontaneously hypertensive (SHR) and normotensive Wistar-Kyoto (WKY) rats (Neurosci. Abstracts 10:387, 1984). Here we report the effects of intracerebroventricular (icv) administration of baclofen on mean arterial pressure (MAP) and heart rate (HR) in conscious SHR and WKY. In 12 week old SHR (n = 8) and WKY (n = 8), steel cannula (21-gauge) were implanted into the lateral cerebral ventricle. One week after cannulation, catheters were placed in femoral artery and vein for recording of MAP and intravenous (iv) injection, respectively. MAP and HR were monitored on a Beckman R-611 polygraph with an Ailtech pressure transducer (MS-20). ICV injections were made with 30-gauge injector connected to 10 µl syringe with PE20. Administration of (±)baclofen (0.5 - 1.5 µg/kg) icv elicited a dose-dependent increase in MAP and HR in both SHR and WKY. The peak increases after 60 min of icv baclofen (1.0 µg/kg) was 13 ± 3 mmHg in SHR vs 27 ± 5 mmHg in WKY. Changes in HR were variable and not different between the two strains. Baclofen (1.0 µg/kg) icv significantly suppressed the reflex bradycardia to phenylephrine (3.0 µg/kg, i.v.) in conscious SHR (-49 ± 3 vs -24 ± 2 beats per minute [bpm], n = 7) but not in WKY (-33 ± 5 vs -33 ± 4 bpm, n = 7). Similarly, reflex increases in HR to nitroprusside (10 µg/kg, i.v.) was significantly lowered after baclofen in SHR (99 ± 8 vs 58 ± 8 bpm) than in WKY (87 ± 10 vs 89 ± 8 bpm). However, treatment with sympathetic ganglionic blocker hexamethonium (HX; 25 mg/kg, iv) produced an equivalent fall in MAP between SHR (n = 6) and WKY (n = 6) rats injected icv with either baclofen or 0.9% saline alone. These findings indicate that baclofen effect on baroreceptor reflexes in SHR may not be completely dependent on the total functional contribution of the sympathetic nervous system.

79.9 EFFECTS OF METHYL ß-CARBOLINE-3-CARBOXYLATE, RO 15-1788 AND CGS 8216 ON THE MUSCLE TONE IN GENETICALLY SPASTIC RATS. M. Schwarz *, C. Ikonomidou *, L. Turski *, T. Klockgether * and K.-H. Sontag * (SPON:U. Kuhnt), Max-Planck-Institute for Exp. Medicine, Hermann-Rein-Str. 3, D-3400 Göttingen, F.R.G.

Benzodiazepines (BDZs) are supposed to exert their anticonvulsant, anxiolytic and muscle relaxant action by interacting with specific BDZ receptors. Substances which antagonize the action of BDZs have been classified as either 'neutral antagonists' due to their lack of intrinsic activity or as 'inverse agonists' due to their ability to exert actions opposite to those of benzodiazepines. In the present study the effect on the muscle tone of ß-carboline-3-carboxylic acid methylester (ß-CCM), an inverse benzodiazepine (BDZ) agonist, and that of Ro 15-1788 and CGS 8216, both putative neutral BDZ antagonists were studied in genetically spastic rats. These animals exhibit pathologically increased muscle tone, which can be recorded and quantified in the electromyogram (EMG) of the gastrocnemius (GS) muscle. ß-CCM, 2.5 and 3.0 mg/kg i.p., augmented the tonic activity in the EMG of GS muscle in spastic rats, while did not modify the muscle tone at doses of 1.0 and 2.0 mg/kg. Diazepam, 0.4 mg/kg i.p. and Ro 15-1788, 5 mg/kg i.p., but not CGS 8216, 5 mg/kg i.p., antagonised the effect of the ß-carboline on the muscle tone. Ro 15-1788, at doses of 0.1-5 mg/kg i.p., did not affect the muscle tone in genetically spastic rats, whilst at doses of 25-200 mg/kg the imidazodiazepine dose-dependently increased the tonic activity in the EMG. The action of Ro 15-1788, 50 mg/kg i.p., was reversed by diazepam, 0.4 mg/kg i.p., and ß-CCM, 2 mg/kg i.p., while CGS 8216, 5 mg/kg i.p., facilitated the effect of Ro 15-1788 on the muscle tone. CGS 8216 at doses of 5 and 25 mg/kg i.p. was devoid of any effect on the muscle tone, whilst at doses of 50 and 200 mg/kg the pyrazoloquinoline increased the tonic activity recorded in the EMG from the GS muscle of spastic rats. The effect of CGS 8216, 50 mg/kg i.p., on the muscle tone was blocked by diazepam, 0.4 mg/kg i.p., while Ro 15-1788, 5 mg/kg i.p., and ß-CCM, 2 mg/kg i.p., augmented the action of CGS 8216. Diazepam, 0.4 mg/kg and ß-CCM, 2.0 mg/kg, both did not influence the activity in the EMG of genetically spastic rats by themselves. This study demonstrates that increase in the muscle tone may be achieved via inverse agonist action at BDZ receptors. The results indicate that BDZ receptors are involved in the effect ß-CCM and Ro 15-1788 displayed on the muscle tone and suggest that at a critical dose range Ro 15-1788 possesses inverse agonist activity at BDZ receptors in vivo. The failure of both ß-CCM and Ro 15-1788 to prevent the augmenting effect of CGS 8216 on the muscle tone might indicate a different mechanism of interaction of the pyrazoloquinoline at the BDZ receptor.

79.10 CAFFEINE ANTAGONIZES BENZODIAZEPINE EFFECTS ON SACCADIC EYE VELOCITIES, SEDATION, AND VIGILANCE. V. Matsuo, D.W. Hommer, O. Walkowitz*, G.A. Chrousos* and H. Weingartner*. NEI, Clinical Branch, and NIMH, NSB, NIH, Bethesda, MD 20205.

Previous studies have established that intravenous benzodiazepine (BZ) reduces the peak velocity of horizontal saccades and impairs cognitive functions in a dose dependent manner. The purpose of this series of experiments was to determine whether pretreatment with caffeine, a methylxanthine with recognized diazepam antagonist properties, had any effect on BZ effects on eye velocity and cognitive processes.

Five healthy normal volunteers were used. They gave informed consent. Caffeine or placebo pretreatments were administered double blind on three occasions at least one week apart. Each subject received 3 mg/kg caffeine, 10 mg/kg caffeine or quinine placebo orally 50-60 min before BZ. Diazepam was given in serial doses of 25, 25, 50 and 100 µg/kg i.v., at 15 min intervals. Subjects performed a saccadic tracking task within 2-5 minutes of receiving each dose. They viewed a horizontal array of 5 LED's placed centrally, and 7.5° and 15° to the right and left. The LED's were activated in a quasi-random order and the subject was instructed to move his eyes to the target as quickly and accurately as possible. Eye position was monitored using IR reflection, and differentiated to give eye velocity. The effects of diazepam were also evaluated on self-rated sedation, on vigilance, recent episodic memory, and semantic memory.

The slowing of saccadic velocities following placebo pretreatment was consistent with earlier results. After the highest dose of BZ the velocity of 15-30° saccades was reduced by as much as 200-300°/s. Smaller saccades were slowed to a lesser degree. In contrast, after 10 mg/kg caffeine, 15-30°saccades were slowed by approximately 50°/s. Other BZ-induced changes in saccadic following were also blocked, viz., instability of fixation and increased variability in the amplitude-velocity curve. Pretreatment with 3 mg/kg caffeine did not appear to have a consistent effect on saccadic velocities.

Following placebo pretreatment, diazepam increased sedation and reduced vigilance and recent memory. Retrieval of information from long-term memory was unaffected. Pretreatment with 3 mg/kg of caffeine had no consistent effect on any of these measures. Pretreatment with 10 mg/kg of caffeine reduced the self-rated sedation produced by diazepam and blocked the vigilance deficit produced by diazepam ($p=0.05$). Caffeine pretreatment had no effect on diazepam induced impairment of recent memory.

We conclude that 10 mg/kg of caffeine pharmacologically antagonizes several of the effects of BZ. This antagonism appears to be selective for less complex cognitive and motor tasks.

79.11 GABA UPTAKE INHIBITORS PRODUCE A GREATER ANTINOCICEPTIVE RESPONSE THAN OTHER TYPES OF GABAERGIC DRUGS. S.H. ZORN AND S.J. ENNA. Depts. Pharmacology and of Neurobiology and Anatomy, University of Texas Medical School, Houston, Texas 77025.

GABAergic drugs produce antinociception in laboratory animals and man. It has been reported that the ethyl ester of nipecotic acid (NAEE), a GABA uptake inhibitor, is a more efficacious antinociceptive agent than direct-acting GABA receptor agonists or GABA transaminase inhibitors. However, it is difficult to determine whether this greater activity was due solely to an ability to enhance GABAergic transmission or whether the cholinomimetic properties of NAEE were primarily responsible for the observed response. This issue was addressed in the present study by comparing the antinociceptive responses to some new GABA uptake inhibitors, SKF-89976A and SKF-100330A with NAEE, direct-acting $GABA_A$ and $GABA_B$ receptor agonists (THIP and baclofen, respectively) and the GABA transaminase inhibitor γ-acetylenic GABA (GAG).

Unlike NAEE, the SKF compounds have no appreciable affinity for cholinergic muscarinic receptor binding sites in rat brain, suggesting that they are devoid of cholinomimetic activity. Uptake experiments with rat brain synaptosomes revealed that the SKF compounds are selective inhibitors of GABA transport, having no effect on the accumulation of aspartate, glutamate, ß-alanine or glycine. Using a mouse tail-immersion assay it was found that, as with uptake inhibition, the antinociceptive response to SKF-89976A was stereoselective, with the d-isomer possessing most of the activity. A comparison at maximally effective doses revealed that the SKF compounds were substantially more efficacious than the GABA transaminase inhibitor and the direct-acting receptor agonists, even when the latter drugs were given in combination with one another. The results suggest that GABA uptake inhibitors are more efficacious antinociceptive agents than other types of GABAergic compounds, suggesting that they may be facilitating GABAergic transmission in a system that is less affected by THIP, baclofen, or GAG. (Supported in part by grants from the National Science Foundation, the National Institute of Mental Health and Bristol-Myers, Inc.).

79.12 REVERSIBLE CONFORMATIONAL CHANGES ACCOUNT FOR CONVULSANT/BARBITURATE RECEPTOR ACTIVITIES ON THE GABA/BENZODIAZEPINE RECEPTOR/IONOPHORE COMPLEX. Ronnie G. King, Greg B. Stauber* and Richard W. Olsen. Department of Biochemistry, University of California, Riverside, and Department of Pharmacology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Convulsant/Barbiturate activities of the GABA/benzodiazepine (BZ) receptor complex, abolished by membrane exposure to or solubilization in Triton X-100, can be recovered by removal of Triton and exchanging into CHAPS detergent, suggesting that changes in conformational states account for the presence or absence of this activity. Receptor sites for BZ, barbiturates, and a variety of convulsant drugs are intimately related to the GABA receptor-Cl^- channel complex which mediates the central inhibitory synaptic action of this neurotransmitter. The cage convulsant [^{35}S]t-butyl bicyclophosphorothionate (TBPS) labels the picrotoxin/convulsant receptor site on the GABA/BZ receptor-ionophore complex. [^{35}S]TBPS binding activity has been solubilized with the zwitterionic detergent 3-[(3-cholamidopropyl)-dimethylammonio] propanesulfonate (CHAPS) and co-purifies with the GABA/BZ receptor protein (King and Olsen, Biochem. Biophys. Res. Comm. 119, 530-536 (1984); Sigel and Barnard, J. Biol. Chem. 259, 7219-7223 (1984); Olsen et al., Neuropharmacology 23, 853-854 (1984). [^{35}S]TBPS binding activity and barbiturate enhancement of GABA and BZ binding were not detected in extracts solubilized and purified in Triton X-100 or deoxylcholate (DOC) and appeared to be irrversibly lost, while BZ binding was unaffected and GABA binding was improved. This could be due to one or more of four possible explanations: selective denaturation of part of the complex, loss of peptide subunits or other essential membrane molecules, different aggregation states of a protein complex of constant subunit composition, or different conformational states of a single protein complex of constant size and subunit composition.

Convulsant/barbiturate activities present in 1.0% CHAPS extracts were lost rapidly upon addition of 0.5% Triton X-100. However, the activity could be recovered upon removal of Triton by gel filtration column chromatography in 0.5% CHAPS, with no change in apparent molecular weight. Similarly, maximal yield of GABA and BZ binding activity is obtained in 0.5% DOC, but negligible TBPS/barbiturate activity is observed. [^{35}S]TBPS binding and barbiturate modulation of GABA/BZ binding are found after exchanging DOC for CHAPS on a Trisacryl column. Finally, a CHAPS extract, spiked with 0.5% Triton, showing no convulsant/barbiturate activity before or after purification on a BZ affinity column, recovered those activities upon exchange of Triton for CHAPS. These results suggest that conformational states (4th hypothesis above) account for convulsant/barbiturate activity, the active state being associated with low affinity GABA agonist binding.

79.13 INHERENT DIFFERENCES IN CONVULSANT SENSITIVITY TO RO 5-4864, PICROTOXININ AND PENTYLENETETRAZOLE AMONG INBRED STRAINS OF MICE. T.W. Seale, G.T. Bolger* and P. Skolnick. Lab. of BioOrganic Chemistry,NIADDKD, National Institutes of Health,Bethesda,MD 20205.

The neurophysiological significance of specific,high affinity binding sites in the brain for peripheral type benzodiazepines (PTB) has remained unknown. Until recently these binding sites were thought to be associated primarily with non-neuronal elements and no function could be assigned to them. The discovery that the PTB Ro 5-4864 possessed potent convulsant activity suggested that these binding sites are receptors with important biological functions in the CNS. However, because Ro 5-4864 and its analogs are potent competitors for displacement of ^{35}S t-butylbicyclophosphorothionate(TBPS) from the picrotoxinin binding site, there remained the possibility that the convulsant action of Ro 5-4864 resulted from its interaction with the picrotoxinin binding site, rather than being mediated by the PTB binding site. We have used genetic techniques to resolve the site of action of Ro 5-4864. Variants with altered dose dependent responses to Ro 5-4864 were identified by scoring the occurrence of clonic and tonic seizures in a 30 minute time period following i.p. administration of the convulsant (0.1ml/mouse in a vehicle composed of 70% saline,30% of a 1:1 mix of Emulphor and dimethylsulfoxide). Male mice 10 weeks old were used. Strain BALB/cBy was found to be hyporesponsive to both the clonic- and tonic- seizure inducing action of Ro 5-4864 compared to 8 other inbred strains of mice (e.g. in DBA/2 the EC_{50} for clonic seizure induction is 17mg/kg, in BALB/cBy it is 34 mg/kg). This difference in sensitivity to Ro 5-4864 is specific because no difference between DBA/2 and BALB/cBy exists for the dose dependent induction of seizures by strychnine or bicuculline. However,BALB/c By mice are markedly hyporesponsive to the convulsant action of picrtoxinin and pentylenetetrazole compared to DBA/2 mice. Entry of Ro 5-4864 into the brains of the two mouse strains did not differ significantly. Binding of 3H Ro 5-4864 to cerebrum membrane preparations showed a reduction of 15-20% in the number of Ro 5-4864 binding sites in BALB/cBy compared to DBA/2 but no change in their affinity (B_{max}=1005 fmol/mg, K_d=0.8 nM for DBA/2). The number of PTB binding sites in kidney of the two strains did not differ in this way. No difference in the number of TBPS binding sites or their affinity was found when the brains of these two strains were compared. We conclude that hyporesponsiveness to the convulsant action of Ro 5-4864 in BALB/cBy mice results from a genetically determined,brain-specific decrease in PTB sites and that these sites are functional receptors. A second qualitative change in the picrotoxinin binding site probably accounts for the alteration in response to picrotoxinin and pentylenetetrazole.

79.14 PICROTOXIN REVERSAL OF BARBITURATE-STIMULATED CHLORIDE EFFLUX FROM SYNAPTONEUROSOMES PARALLELS DIFFERENCES IN IN VIVO CONVULSANT SENSITIVITY BETWEEN TWO INBRED STRAINS OF MICE. Rochelle D. Schwartz Thomas W. Seale , Phil Skolnick* and Steven M. Paul*. Clinical Neuroscience Branch, NIMH and Lab. Bioorganic Chem. NIADDKD, NIH, Bethesda, MD 20205.

Differential seizure sensitivity to convulsants active at the GABA receptor complex has been recently identified in 2 inbred mouse strains (Seale et al., this vol.). The Balb C/By (BC) strain is hypo-responsive to convulsants such as picrotoxinin and pentylene tetrazole while the DBA/2 (DB) strain is hyper-responsive to these agents. In the present study, we have investigated the interaction of pentobarbital (PB) with picrotoxinin-induced convulsions in these 2 strains of mice. The ED_{50}s for picrotoxinin-induced clonic seizures in the BC and DB mice were 3.2 and 18 mg/kg, i.p., respectively. When varying concentrations of PB were given 10 min prior to the administration of picrotoxinin (5 mg/kg, ED_{100}), the IC_{50} for PB protection from picrotoxnin-induced tonic seizures was less in the BC strain (5.5 mg/kg) than in the DB strain (18 mg/kg). We have also investigated possible neurochemical correlates to the behavioral differences observed in these 2 mouse strains using ^{36}chloride (Cl^-) efflux and receptor binding assays. Recently we reported the use of a novel subcellular brain preparation ("synaptoneurosome") to study $^{36}Cl^-$ efflux associated with the GABA/picrotoxin/ barbiturate receptor complex (Schwartz et al., FEBS Lett., 175, 193-196, 1984; Schwartz et al., J. Neurosci., in press). In this study, the effects of PB and picrotoxin on $^{36}Cl^-$ efflux from mouse forebrain synaptoneurosomes were determined. PB (500 uM) stimulated $^{36}Cl^-$ efflux to the same degree in both strains of mice. Picrotoxin (1 mM) had no significant effect on basal $^{36}Cl^-$ efflux. However, a significant difference in the ability of picrotoxin to reverse the PB-induced $^{36}Cl^-$ efflux was observed in the BC and DB strains (38.3 ± 6.5 vs 74.8 ± 7.4% inhibition, resp.). In binding studies there was no difference between the 2 strains in either the EC_{50} for PB-enhancement of ^{3}H-muscimol binding, nor the picrotoxin reversal of PB-enhanced ^{3}H-muscimol binding (low or high affinity sites). However, the ability of PB to decrease ^{35}S-TBPS (which putatively binds to a picrotoxin-like site on the Cl^- ionophore) binding was greater in the BC strain than in the DB strain (IC_{50} = 74 uM and 130 uM, resp.) These behavioral and biochemical studies suggest that the altered sensitivity of the binding sites on the Cl^- ionophore associated with the GABA receptor complex and the subsequent functional alterations in Cl^- transport may account for the genetic differences in convulsant sensitivity in these 2 strains of mice.

79.15 CHLORIDE TRANSPORT STUDIES IN BRAIN SYNAPTONEUROSOMES: EFFECTS OF GABA AGONISTS AND ANTAGONISTS, PENTOBARBITAL, FLURAZEPAM AND THE ROLE OF PHOSPHOLIPASE A_2. Steven M. Paul*, Rochelle D. Schwartz, Phil Skolnick, and Jane Jackson*, (SPON: C.R. Mantione), Clinical Neuroscience Branch, NIMH, Bethesda, MD 20205.

Recently, we have reported the use of a novel subcellular brain preparation ("synaptoneurosome") to study chloride (Cl^-) transport associated with the GABA/barbiturate/picrotoxin receptor complex (Schwartz et al., FEBS Lett. 175, 193-196, 1984; Schwartz et al., J. Neurosci., in press). In the present study we have investigated the effect of the GABA receptor agonist muscimol, GABA and the water soluble benzodiazepine, flurazepam on $^{36}Cl^-$ transport from rat cerebral cortical synaptoneurosomes. Muscimol and GABA caused a dose-dependent increase in $^{36}Cl^-$ efflux ($EC_{50} \simeq 2\mu M$ and 500 μM, resp.). These effects were reversed by bicuculline (500 μM) which also decreased $^{36}Cl^-$ efflux ($EC_{50} \simeq 150$ μM). However, in experiments where bicuculline had no effect on basal $^{36}Cl^-$ efflux, it significantly decreased muscimol-stimulated $^{36}Cl^-$ efflux. Flurazepam was inactive at low concentrations (< 100 μM) but stimulated $^{36}Cl^-$ efflux at concentrations greater than 300 μM (8-20%). This effect was not reversed by the benzodiazepine antagonist, Ro15-3505, indicating a probable action of flurazepam directly with the Cl^- channel. In separate studies $^{36}Cl^-$ uptake was also measured. Muscimol stimulated $^{36}Cl^-$ uptake in a multiphasic manner ($EC_{50} \simeq 10$ μM). the effect of muscimol was reversed by bicuculline (100 μM). The advantages and disadvantages of measuring $^{36}Cl^-$ uptake vs. $^{36}Cl^-$ efflux will be discussed. The effects of phospholipase A_2 (PLA_2) on $^{36}Cl^-$ efflux were also investigated. Pretreatment of synaptoneurosomes with PLA_2 (naja naja venom, 0.05 units/ml) decreased the stimulation of $^{36}Cl^-$ efflux by muscimol and pentobarbital (30-70%) and decreased the inhibition of $^{36}Cl^-$ efflux by bicuculline and picrotoxin (30-92%). The effects of PLA_2 were reversed by mepacrine (100 μM) and EGTA (2.5 mM). Pretreatment of synaptoneurosomes with mepacrine had the opposite effect; the stimulation of $^{36}Cl^-$ efflux by muscimol and pentobarbital and the inhibition of $^{36}Cl^-$ efflux by bicuculline and picrotoxin were enhanced by 116-120% amd 50-80%, respectively. These data indicate that the functional properties of the GABA/barbiturate/picrotoxin receptor complex may be regulated by alterations in phospholipids closely associated with the membrane-bound receptor complex.

79.16 FUNCTIONAL RESPONSES OF THE γ-AMINOBUTYRIC ACID RECEPTOR FROM BRAIN. K. Subbarao* and D.J. Cash. Neurochemistry Unit, Missouri Institute of Psychiatry and Department of Biochemistry, University of Missouri-Columbia, School of Medicine, St. Louis, MO 63139.

A combination of two new tools is being used to investigate the functional response of the γ-aminobutyric acid (GABA) receptor from rat brain. Harris has recently observed a GABA mediated uptake of radioactive chloride ion using a "microsac preparation" from whole mouse brain (Allan, A.M. et al., abstracts FASEB meeting, Anaheim, CA, 1985). Based on this observation we have developed a preparation from rat brain regions suitable for use with quench flow technique. Quench flow technique has been used to measure acetylcholine mediated cation transmembrane ion flux in vesicle preparations from electric fish, and on this basis a minimal kinetic scheme for the functional response of acetylcholine receptor was proposed (Cash, D.J. and Hess, G.P. (1980) Proc. Natl. Acad. Sci. USA 77, 842-846; Hess, G.P. et al., (1983) Ann. Rev. Biophys. Bioeng. 12, 443-473).

A homogenate of rat cerebral cortex was centrifuged at 300 g, 5 min. The supernatant was pelleted, resuspended in physiological saline and centrifuged on a 4-12% Ficoll-400 gradient at 100,000 g, 1 hr. A middle band containing the functionally active vesicles was separated from a lighter "myelin" fraction and a heavier "mitochondrial" fraction. The transmembrane ion flux was initiated on addition of GABA and terminated by addition of bicuculline or N-methyl bicuculline. The ^{36}Cl content of the vesicles was determined by a filter disc assay. This vesicle preparation had a specific internal volume (accessed via GABA mediated transmembrane chloride flux) of 5 x 10^{-2} μl/mg protein. Transmembrane equilibration of chloride was completed in two phases of ion flux at saturating concentrations of GABA ($\geq$100 μM). The first phase was complete in less than 100 ms and the second in about 4 s. Experiments in which the membrane vesicle preparation was preincubated before the addition of chloride tracer ion showed that this behavior involves a single population of membrane vesicles with GABA receptors which are desensitized in two processes, one with a halftime of $\leq$ 50 ms and the second with a halftime of about 1 s. With decreased GABA concentrations both phases are decreased in amplitude. The ligand dissociation constants corresponding to the measured responses are in the region of 30 μM and desensitization and ion flux have a different dependence on GABA concentration.

These results, complementary to measurements of ligand binding and electrophysiology, indicate that the GABA dissociation constant of the active state of the receptor is higher than previously reported and that the receptor is rapidly converted to desensitized states in the presence of GABA.

79.17 CONTRASTING EFFECTS OF PHENOBARBITAL AND PICROTOXIN IN THE MEDIAL AND LATERAL SEPTUM ON HIGH AFFINITY CHOLINE UPTAKE IN THE HIPPOCAMPUS. J.A. Richter and J.M. Gormley*. Depts. Pharmacology and Psychiatry, Indiana Univ. Sch. Med., Indianapolis, IN 46223.

Systemic in vivo administration of phenobarbital and picrotoxin cause an inhibition and stimulation respectively of septal-hippocampal cholinergic neurons as measured by changes in high affinity choline uptake in hippocampal synaptosomes in vitro. In order to determine where within the brain these drugs act to cause these effects, we have administered these drugs to selected brain sites in the awake rat via permanently implanted cannulae.

Phenobarbital injected into the medial septum caused a decrease in choline uptake in the hippocampus. Similar effects were obtained with barbital and with muscimol. When tested in the lateral septum phenobarbital was much less effective. In contrast, picrotoxin had no effect when injected in the medial septum but it stimulated hippocampal choline uptake when it was injected in the lateral septum. Picrotoxin coadministered with phenobarbital in the medial septum inhibited the effect of phenobarbital alone.

These data are consistent with the results of Brunello and Cheney (JPET 219: 489, 1981) on the effects of muscimol and bicuculline in the medial septum on hippocampal ACh turnover. In addition we have demonstrated that phenobarbital and barbital have inhibitory effects in the medial septum on septal-hippocampal cholinergic neurons. Together the results suggest that GABAergic receptor complexes exist in the medial septum but they are not tonically active since the antagonists alone have no effect there.

Our data further suggest that there are other GABAergic receptor complexes in the lateral septum. These complexes are tonically active and influence the medial septal cholinergic neurons, since picrotoxin in the lateral septum stimulates hippocampal choline uptake. Costa et al. (Life Sci. 32: 165, 1983) have shown GAD-positive cell bodies in both the medial and lateral septum and have suggested that both have terminals in the medial septum. Our data are consistent with this possibility, and our data also indicate there are other GABAergic receptor complexes in the lateral septum which are tonically active and which influence the medial septal cholinergic neurons by an unknown pathway. (Supported by PHS grant DA 00796).

79.18 PIPECOLIC ACID: A NEW NEUROMODULATOR? E. Giacobini (SPON: D. Hoffman). Department of Pharmacology, Southern Illinois University School of Medicine, Springfield, IL 62708 USA

Pipecolic acid (PA), one of the three cyclic secondary amino acids or imino acids present in the brain, along with proline and hydroxyproline, represents the major metabolite of lysine in the CNS. Its presence in the rodent brain has been unambiguously demonstrated with TLC-MS (Schmidt-Glenewinkel et al., 1977) and its regional distribution described with a new HPLC-EC method (Kim and Giacobini, 1984). Pipecolic acid levels and transport in brain are particularly high during the perinatal period (Kim and Giacobini, 1984). A high affinity, Na^+-dependent, uptake of PA in brain synaptosomes and a Ca^{++}-dependent release from brain slices have been demonstrated in our laboratory. In addition, a saturable transport across the blood-brain-barrier and high affinity specific binding of ^{3}H-PA have been described (Nishio et al., 1981, 1982; Gutierrez and Giacobini, 1983). The specific binding of ^{3}H-PA shows a regional distribution. This evidence strongly suggests that PA containing neurons and terminals may exist in the brain. Evidence for a reciprocal modulatory effect of PA and GABA has been made recently available (Giacobini and Gutierrez, 1983). These results, taken together with the evidence for localization, distribution, metabolism and action of PA in brain neurons, strongly support the role of PA as an endogenous and physiological modulatory substance in the mammalian brain. (Supported by U.S. Public Health Service Grants NS 11430 and NN 14086 and by SIU Cent. Res. grant 2-40202 to E.G.)

GABA AND BENZODIAZEPINES: RECEPTOR CHARACTERIZATION AND LOCALIZATION I

80.1 ASSOCIATION WITH REGULATORY PROTEINS: AN ALTERNATIVE TO MULTIPLE BENZODIAZEPINE RECEPTORS, W. F. Herblin, Central Research and Development Department, E. I. du Pont de Nemours & Company, Experimental Station, Wilmington, Delaware 19898

A mathematical model is presented which describes the association of a ligand-receptor complex with a regulatory subunit. This is meant to simulate the situation in which a receptor is coupled to a regulatory protein or subunit which serves as a tranducer between the ligand binding event and the subsequent second messenger changes, as has been found in the case of theβ -adrenergic receptor.

We have used experimental data obtained with the benzodiazepine receptor to evaluate the parameters of this model and to compare its performance to that of the alternative multiple-site hypothesis. Results obtained from experiments using equilibrium binding, competition by the same or different ligands, or time-dependent kinetics can be individually accommodated by either model, but the association model more easily encompasses their combination.

The major advantage of the association model is that it is based on a biochemical process that has been experimentally demonstrated to exist. Therefore, many of the assumptions that were required in the development of the model as well as many of the derived predictions from the model are subject to direct test and experimental verification.

80.2 PHOTOAFFINITY LABELLING OF THE BENZODIAZEPINE RECEPTOR OF THE GABA RECEPTOR COMPLEX IN LOCUST CNS. G.G.Lunt*, D.MacAllan*, and T.Robinson* (SPON: R.W.Olsen). Dept. of Biochemistry, University of Bath, Bath, England, BA2 7AY.

We have previously shown that membranes from the supraoesophageal ganglion of the locust (Schistocerca gregaria) have GABA receptors that interact with benzodiazepine binding sites in a manner similar to that seen in mammalian brain (Robinson et al., Neurochem. Int. in press 1985; Biochem. Soc. Trans. in press, 1985). We have now extended these studies and have used [^{3}H]flunitrazepam to specifically photoaffinity label the locust receptor complex.

Membranes were prepared as described previously (Robinson et al., Neurochem. Int. in press, 1985) and resuspended in 10mM Tris HCl, 4mM $CaCl_2$, 4mM $MgCl_2$, 0.15M choline chloride, pH 7.4 and preincubated in the presence or absence of 10^{-4}M diazepam at 0°C for 30 min. Following the addition of [^{3}H]flunitrazepam (74 Ci/mmol) at a final concentration of 20nM the membrane suspension was incubated at 0°C for 90 min and then irradiated for 3 min at 350nm.

Membranes were extensively washed and the membrane proteins separated by SDS-PAGE. Gels were either sliced at 2mm intervals and counted or subjected to autoradiography. Specific labelling was observed in a band at 50K. This specific labelling was enhanced when membranes were incubated in the presence of 10^{-8}M GABA. In other studies we have found that the equilibrium binding of [^{3}H] flunitrazepam to the membranes is enhanced maximally by 10^{-8}M GABA.

Our results show that locust GABA receptor complex has a benzodiazepine binding component of a similar size to that seen in mammalian brain. The pharmacology of the locust benzodiazepine site is however different from that seen in mammalian brain (Robinson et al., Biochem. Soc. Trans. in press, 1985).

We are grateful to the SERC (T.R.) and the AFRC (D.M.) for support.

80.3 REEVALUATION OF SATURATION BINDING TO BENZODIAZEPINE RECEPTORS. E.I. Tietz, M. Ito*, T.H. Chiu and H.C. Rosenberg, Medical College of Ohio, Toledo, OH 43699.

Overwhelming evidence favors benzodiazepine receptor heterogeneity despite a few incongruent pieces of evidence. The most widely noted, is the linearity of Scatchard plots reported by our laboratory and most others. Recently, we noticed a consistent curvilinearity in plots generated from [^{3}H]flunitrazepam ([^{3}H]FNP) assays in which we used higher than usual concentrations of [^{3}H]FNP to compete for residual drug following chronic treatment. Experiments in untreated rats were done to verify this observation.

Centrifugation assays provide the most accurate estimation of bound and free ligand concentrations. The cerebral cortex (CTX), hippocampus (HIP), or cerebellum (CEB) was dissected from male rats (200-250 gm, .7 - 1 gm tissue). The P_2 pellet was triple washed in Tris-HCl (pH 7.4 at 0°C). Protein (.6 - .75 mg/ml) was incubated in duplicate with 16 concentrations of [^{3}H]FNP (.25 - 32 nM) or [^{3}H]Ro15-1788 ([^{3}H]RO) (.125 - 24 nM) for 1 hr at 0°C. Nonspecific binding was in the presence of 10^{-6} M clonazepam. The reaction was terminated by centrifugation (20,000g X 20 min at 4°C). The supernatant was removed by suction and the bound pellet was gently washed 2X with ice-cold Tris buffer, was solubilized (Protosol) with mixing, and counted. Each experiment was repeated 2 or 3 times.

Results were analyzed with the LIGAND program. [^{3}H]FNP binding to CTX and HIP revealed two high affinity binding sites of different proportions. Binding to CEB tissue was less conclusive but suggested one site. [^{3}H]RO labelled only one site in the three areas and the number of sites was less than that labelled by FNP.

Nonspecific binding was linear across all concentrations for both ligands. These findings do not reflect binding to "peripheral type" sites since [^{3}H]FNP binding in the presence of Ro5-4864 was still curvilinear.

		Kd1 (nM)	Kd2 (nM)	Bmax1	%	Bmax2	%	BmaxT
[^{3}H]FNP	CTX	.24±.08	3.86±.12	.64±.19	(20)	2.44±.10	(80)	3.08±.28
	HIP	.55±.01	10.2±.78	1.54±.04	(49)	1.62±.06	(51)	3.16±.09
	CEB	1.48±.46		2.43±.22	(100)			
[^{3}H]RO	CTX	.77±.02		2.65±.04	(100)	pmol/mg protein		
	HIP	.70±.01		2.16±.20	(100)			
	CEB	.81±.04		2.66±.00	(100)			

The curvilinear Scatchard plots are compatible with either two binding sites or negative cooperativity. 2 nM [^{3}H]FNP was dissociated by 100-fold dilution, with or without addition of excess cold FNP. With the addition of FNP, dissociation after 60 min was only increased 3-4%. Thus negative cooperativity is unlikely.

The results suggest that the benzodiazepines bind to two classes of high affinity sites in CTX and HIP. The proportion of sites is similar to that reported using other methods.

Supported by DHHS grants RO1-DA02194, RO1-NS16595, F32-DA05265.

80.4 ENHANCEMENT OF ^{3}H-GABA BINDING BY COMPOUNDS THAT BIND TO THE BENZODIAZEPINE RECEPTOR BUT DIFFER IN EFFICACY. B. A. Meiners* and A. I. Salama (SPON: R. D. Krell). Biomedical Research Department, Stuart Pharmaceuticals, Division of ICI Americas Inc., Wilmington, DE 19897.

Compounds known to interact at the benzodiazepine binding site have been shown to either mimic the actions of benzodiazepines (diazepam, CL218872), antagonize the actions of benzodiazepines (RO15-1788, CGS8216) or share in some but not all the actions of the benzodiazepines (CGS9896, CGS9895). This categorization has largely been obtained through behavioral studies. The effect of these compounds on the binding of ^{3}H-GABA to rat brain membranes was measured to determine whether it could be possible to distinguish between these classes. The assay was performed at 37°C in the presence of EGTA and the bound ^{3}H-GABA separated from the free by centrifugation. Diazepam and CL218872 caused a 20% to 45% increase in the binding. In contrast, RO15-1788 and CGS8216 caused a marginal enhancement of GABA binding (8% to 10%). In addition, these agents were capable of antagonizing the diazepam enhancement of GABA binding. On the other hand, CGS9896 (partial agonist) caused an intermediate level of enhancement (15% to 20%). The effect of CGS9896 was statistically distinguishable from that of both a full agonist and a full antagonist. These data suggest that enhancement of ^{3}H-GABA binding by compounds that interact with the benzodiazepine receptor may reflect the efficacy (agonist, antagonist, mixed type) of the compounds. CGS9895 caused an increase in GABA binding that was equal to that of diazepam but unlike diazepam, the effect was not reversible by either RO15-1788 or by beta-carboline ethylester suggesting that this enhancement of GABA binding was not mediated at the benzodiazepine binding site.

80.5 **KINETICS OF [^{3}H]FLUNITRAZEPAM BINDING TO BRAIN CELL CULTURES IN SITU** G. D. Schiller* and D. H. Farb (SPON: W. Riss). Dept. of Anatomy & Cell Biology, SUNY Downstate Med. Ctr., Bklyn., NY 11203.

The enhancement of [^{3}H]flunitrazepam (FNZM) binding by GABA decreases during chronic exposure to flurazepam (Farb et al., Ann. N.Y. Acad. Sci. 1984, 435, 1). As a first step to examine the interactions between the benzodiazepine (BZD)- and GABA-binding sites in situ, we have investigated the kinetics of [^{3}H]FNZM binding to living primary brain cell cultures, (derived from 7d old embryonic chick, maintained in culture for 6 to 7d). Association of [^{3}H]FNZM (1,2.5,5,10nM) was determined from 0.5 to 90min at 0°C. Nonspecific binding was defined as [^{3}H]FNZM bound in the presence of 0.1mM FNZM. The kinetics for association were biphasic with fast and slow exponential components. The k_{obs} increased for both components as ligand concentration was increased. A plot of k_{obs} for the fast and slow components versus ligand concentration yielded 2 straight lines ($r^2 > 0.9$). The pseudo-first-order association rate constants (k_1) were 0.286×10^9 and 0.042×10^9 $M^{-1}min^{-1}$; the dissociation rate constants (k_{-1}) were 0.64 and $0.042min^{-1}$ for the fast and slow components respectively. The resulting affinities were 2.2 and 4.2nM in proportions of 36±5% and 64±5% for the fast and slow components, respectively. Analysis of equilibrium binding to intact cells (0°C) yielded a single high affinity binding site of 4nM (n=5 experiments). Biphasic dissociation was confirmed independently (2 experiments): Cells were equilibrated with 5nM [^{3}H]FNZM at 0°C and dissociation was initiated either by dilution (k_{-1}, 0.52 and $0.035min^{-1}$) or by addition of 0.1mM (final conc.) FNZM (k_{-1}, 0.78 and $0.055min^{-1}$). This shows that high-affinity BZD binding to neurons in situ does not follow simple one-site Michaelis Menten kinetics. We cannot yet say whether the BZD-binding sites exist as interconvertible conformers or as distinct receptors. It remains to be determined whether or not both of the sites reported here are coupled to a GABA-receptor and if binding of [^{3}H]FNZM to both of these sites is subject to enhancement by GABA. It will be important to examine the potential role of these two sites in the functional regulation by BZDs of GABA-receptor action.

80.6 **CHLORDIAZEPOXIDE STIMULATES DESENSITIZATION OF THE GABA RESPONSE** D. Mierlak* and D. H. Farb. Dept.of Anatomy & Cell Biology, SUNY Downstate Med. Ctr. Brooklyn, NY 11203.

GABA receptor (GABA-R) modulation by benzodiazepines (BZDs) has been previously described. Electrophysiological studies have established that (1) GABA induces an increase in chloride conductance, (2) BZDs potentiate GABA-mediated conductance increases and (3) GABA responses desensitize during prolonged application of GABA. Studies demonstrating GABA enhancement of BZD binding utilize long incubation times with respect to the time course of GABA-R desensitization, presumably reflecting enhanced BZD binding to the desensitized GABA-R. This predicts that BZDs have a greater affinity for the desensitized GABA-R and should promote GABA-R desensitization. We have begun to investigate these paradoxical observations by determining the apparent rate constants of desensitization of the GABA response in the presence and absence of a saturating concentration (300uM) of chlordiazepoxide (CDPX).

Intracellular recordings were made from spinal cord cultures under standard current-clamp conditions with 3M KCl electrodes. Drug solutions were delivered by pressure ejection from multi-barrel pipets. Application of GABA in the absence or presence of CDPX caused a conductance increase (gGABA), which faded with time to a steady-state (gSS). CDPX alone caused small or no changes in potential or conductance. gGABA values were corrected by subtracting gSS and plotted semi-logarithmically against time. The best straight line was used to determine the apparent rate constant of desensitization for GABA alone (kapp) or in the presence of CDPX (kapp'). Extent of desensitization (%D) was determined as follows:[(peak gGABA - gSS) / peak gGABA] X 100%.

In three neurons, kapp for 10uM GABA was 0.041 ± 0.006 s^{-1}. In the presence of 300uM CDPX, this increased to kapp' = 0.146 ± 0.032 s^{-1}, representing a 3.5 ± 0.5 fold stimulation of kapp. In addition, the presence of CDPX increased %D by 18% ± 5%. In two initial experiments where multiple GABA concentrations were applied to the same neuron, kapp and %D increased with increasing peak gGABA. The range of GABA concentrations used produced gGABA values above and below the CDPX potentiated 10uM GABA response. In both cells, kapp' and %D determined for the CDPX potentiated 10uM GABA response was greater than the predicted kapp and %D for an equivalent gGABA produced by GABA alone: kapp' was enhanced 2.4 & 2.0 fold; %D was enhanced 18% & 8%. This result suggests that the stimulation of kapp and %D seen in the presence of CDPX cannot be accounted for solely by the increase in gGABA produced in the presence of CDPX. The stimulation of GABA desensitization by CDPX is consistent with a model in which CDPX has a greater affinity for a GABA-bound desensitized GABA-R while displaying low affinity for the unoccupied desensitized GABA-R.

80.7 EFFECT OF BENZODIAZEPINE BINDING SITE LIGANDS ON t-BUTYLBICYCLO-PHOSPHOROTHIONATE([^{35}S]TBPS) BINDING TO RAT BRAIN. A. Concas[1]*, D. Gehlert[2]*, J.K. Wamsley[2] and H.I. Yamamura[1](SPON: S.P. Duckles). Dept. of Pharmacology, Univ. of Arizona,AZ 85724[1] and Dept. of Psychiatry, Univ. of Utah, UT 84132[2].

[^{35}S]t-Butylbicyclophosphorothionate binds with high affinity to brain specific sites within the γ-aminobutyric acid (GABA) receptor-ionophore complex. TBPS binding in rat membranes is inhited potently by GABA and a number of GABAmimetics, and is also modulated by many sedatives-hypnotics and anxiolytics. Studies of benzodiazepine (BZ) interactions with[^{35}S]TBPS binding have in general yielded inconsistent results showing inhibition, no effect and stimulation of[^{35}S]TBPS binding by BZ. We now report tissue mounted slide binding and autoradiographic data that low concentrations of BZ allosterically modulate TBPS binding sites.

Slide mounted 20 μ sections of rat brain were labeled by immersion for 90 min in Na/K phosphate buffer (pH 7.4) containing 0.2 M NaCl and 2 nM[^{35}S]TBPS (initial spec. act. 109.8 Ci/mmol, NEN) in the presence or absence of 1 μM of unlabeled TBPS, followed by 2 rinses of 5 min each in the same buffer and a dip in distilled water. The sections were dried, stored overnight and apposed to a sheet of LKB Ultrofilm and the autoradiograms generated were analyzed by DADS Model 560 computer interfaced with an MPV compact microphotometry system attached to a Leitz Orthoplan microscope. For tissue mounted biochemical experiments, tissue sections were wiped off the slides using Whatman GF/B filters after the incubation and the final rinse, and placed in scintillation fluid and counted 24 h later. To prevent the inhibitory effect of GABA on [^{35}S]TBPS binding, tissue sections were preincubated for 30 min at 25°C in buffer alone. This procedure stimulated[^{35}S]TBPS binding to tissue sections, presumably by depleting the endogenous GABA from the tissue.

[^{35}S]TBPS slide mounted tissue binding was inhibited by 1 μM clonazepam when the tissue sections were not preincubated most likely GABA was not present in the tissue. In preincubated sections clonazepam did not alter [^{35}S]TBPS binding. Moreover, when 5 μM GABA was added in slide mounted tissue sections previously preincubated, the effect of clonazepam was similar to that seen in the sections without preincubation. Interestingly, the BZ inverse agonist, methyl β-carboline-3-carboxilate (MCC) enhanced [^{35}S]TBPS binding under non-preincubated conditions as would be predicted from its pharmacological profile.

These results suggest that the presence of GABA is an absolute requirement for the modulation by BZ receptor ligands of [^{35}S]TBPS binding and that the low affinity GABA receptor is involved in BZ anticonvulsant and anxiolytic actions.

Supported by NIMH Grants.

80.8 PERIPHERAL BENZODIAZEPINE BINDING SITES IN HUMAN BRAIN. J. Bénavidès*, N. Vaucher*, M. Daniel*, C. Malgouris*, A. Doble*, A. Özan, C. Guérémy* and G. Le Fur. PHARMUKA Lab., Groupe RHONE POULENC SANTE, 92231 Gennevilliers, France.

The pharmacological properties of peripheral-type benzodiazepine binding sites (PBBS) and their subcellular and anatomical distributions, have been examined in human brain using the radioligand [^{3}H]PK 11195.

In cortex, this ligand binds reversibly to a homogeneous population of high-affinity binding sites with an affinity of 3.6 ± 1.18 nM and a capacity of 400.7 ± 43.6 pmol/g protein. The affinities of a variety of compounds for this site are consistent with the pharmacological properties of the PBBS characterized elsewhere, although it should be noted that, as in the cow, cat and dog, the affinity of the benzodiazepine RO5-4864 for this site is 200-fold lower than it is in rat brain. The association and dissociation of [^{3}H]PK 11195 to and from its binding sites are monoexponential with kinetic constants of k_1 = 3.5 ± 0.5 x 10^{9} sec^{-1} M^{-1}, k_{-1} = 3.8 ± 1.3 x 10^{-4} sec^{-1} and k_{-1}/k_1 = 1.10 x 10^{-9} M. The binding was not temperature-dependent.

The subcellular distribution of this binding site in cortex parallels that of the binding of [^{3}H]flunitrazepam and of particulate lactate dehydrogenase. This indicates that these sites are likely to be localized to synaptic structures in human brain. This conclusion is supported further by autoradiographic studies of the distribution of these sites, which is very heterogeneous and localized predominantly to grey matter.

The binding of [^{3}H]PK 11195 to slide-mounted tissue sections has identical characteristics to that to tissue homogenates. In spinal cord, binding is found mainly in the outer laminae of the dorsal horn ; in medulla, there is an intense labelling in the inferior olive. Several pontine nuclei are also labelled strongly, as are the cerebellar cortex and deep cerebellar nuclei. Labelling is also found in the hippocampus, caudate nucleus and cerebral cortex.

This distribution is completely different from that of the brain-type benzodiazepine receptor, and resembles that described previously in cat, but not rat, brain.

These studies suggest a role, as yet unknown, for the PBBS in neuronal function in man, and encourage further studies to elucidate this role. Furthermore, the cat may prove a more relevant subject that the rat for such studies.

80.9 BENZODIAZEPINE RECEPTOR CHANGES IN DISCRETE AREAS OF RAT BRAIN FOLLOWING ADRENALECTOMY. N.E. Goeders, M.J. Kuhar and E.B. De Souza. Laboratory of Neuroscience, NIDA Addiction Research Center and Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

A variety of clinical and experimental data suggest that glucocorticoids can enhance anxiety while benzodiazepines are effective anxiolytic agents. However, a more direct relationship may exist between glucocorticoids and benzodiazepines. For example, benzodiazepine administration inhibits stress-induced increases in plasma glucocorticoids and glucocorticoid administration can alter the anxiolytic effects of benzodiazepines in conflict procedures. This investigation was designed to determine the effects of bilateral adrenalectomy on benzodiazepine receptors in discrete regions of the rat brain.

Saturation studies were carried out with [^{3}H]-flunitrazepam to characterize changes in benzodiazepine receptors (ie., K_d and B_{max} values) resulting from the treatment conditions. The concentration (B_{max}; mean fmol/mg protein ± SEM) of benzodiazepine receptors was significantly increased in the hypothalamus (1046 ± 49 vs. 1699 ± 180, $p < 0.01$, sham-operated vs. adrenalectomized) and the striatum (559 ± 89 vs. 844 ± 36, $p < 0.01$) at two weeks after adrenalectomy. Adrenalectomy resulted in variable effects on the concentration of benzodiazepine receptors in the hippocampus although a slight increase was observed. In contrast, the adrenalectomy did not significantly affect the concentration of benzodiazepine receptors in the cerebral cortex, olfactory bulb or cerebellum. No significant differences in K_d values were seen in any brain region examined. The adrenalectomy-induced increase in benzodiazepine receptors in the hypothalamus and striatum was completely reversed by glucocorticoid replacement with dexamethasone.

In summary, the results of this investigation demonstrate that endogenous glucocorticoids are capable of selectively modulating benzodiazepine receptors in discrete regions of the rat brain that may be involved in glucocorticoid negative feedback. These data further suggest a mechanism whereby glucocorticoids can be anxiogenic. (Supported by USPHS Grants DA 00266, MH 00053, NS 15080 and MH 09111 and the McKnight Foundation).

80.10 **EVIDENCE FOR CELL SURFACE AND SEQUESTERED BENZODIAZEPINE RECEPTORS IN CHICK BRAIN CULTURES** C. Czajkowski* and D. H. Farb (SPON: J. Jakway). Department of Anatomy & Cell Biology, SUNY Downstate Med. Ctr., Brooklyn, NY 11203.

Recent experiments from our laboratory have shown that it is possible to measure the turnover of the benzodiazepine receptor (BZD-R) in monolayer brain cell culture, using flunitrazepam (FNZM) as a specific irreversible label (Science 226:857,1984). To explore the mechanisms involved in receptor degradation the subcellular distribution of BZD-Rs in living cells was examined. Intact and saponin-treated brain cells were treated with trypsin and specific reversible and irreversible binding of (^{3}H)FNZM measured. After cells were treated with trypsin (0.5mg/ml, 37°C, 90'), soybean trypsin inhibitor (0.5 mg/ml) was added, and cultures were scraped, homogenized, centrifuged (30,000xg,20'), resuspended in PBSS and specific reversible and irreversible binding of 5nM (^{3}H)FNZM measured by filtration. Following trypsin treatment, specific reversible binding was reduced to 43% ± 2% (n=11) and irreversible binding to 41% ± 8% (n=4) of control. No further reduction in binding was observed when trypsin treatment was extended to 3 hours. When cultures were permeabilized with 0.5% saponin prior to trypsin treatment, 7% ± 1% (n=7) of the reversible binding and 11% ± 5% (n=3) of the irreversible binding remained. Saponin treatment alone did not affect binding. Binding affinity for FNZM (K_d = 5.8nM by competition binding) was unaltered by trypsin treatment. SDS-PAGE revealed a decrease in labeling of both 51K and 48K receptor subunits normally seen (approx. 20% remaining) and the appearance of a smaller receptor fragment that retains its recognition site for FNZM and is photolabeled subsequent to trypsin treatment (approx. 20% of control labeling). Thus, the reversible and irreversible binding measured by filtration following trypsinization of intact cells (approx. 40% of control) represents both intact BZD-Rs and a membrane associated trypsin-generated fragment of the receptor that retains the ligand binding site. We conclude that approximately 80% of BZD-Rs are susceptible to trypsin attack and may represent surface receptors while 20% are trypsin resistant and may represent membrane sequestered or intracellular receptors. The small fragment generated after trypsin treatment retains its recognition site for FNZM, as measured by both reversible and irreversible binding, and remains associated with the membrane. After saponin treatment of photolabeled cells, trypsin degrades the fragment, indicating that it has a cytoplasmic domain as well as an extracellular domain, as expected for a transmembrane protein. It appears that *in situ* trypsinization of the BZD-R may provide a way of probing the structural features of the receptor involved in the processes of receptor binding and receptor turnover.

80.11 PREGNENOLONE AND CORTICOSTERONE: POSSIBLE MODULATORS OF THE GABA/BENZODIAZEPINE RECEPTOR COMPLEX. M.D. Majewska*, P. Skolnick, S.M. Paul* (SPON: F.K. Goodwin). Clinical Neuroscience Branch, NIMH, Bethesda, MD 20205.

We have previously reported that adrenal steroids potentiate [^{3}H] muscimol binding to CNS GABA receptors (Majewska et al., Brain Res., in press; Soc. Neurosci. Abstr. 1984). To further clarify the physiological significance of this phenomenon we investigated the effect of various steroids on benzodiazepine receptor binding carried out under a number of different incubation conditions. A number of naturally-occurring steroids potentiated [^{3}H]flunitrazepam binding to crude synaptosomes when the binding was carried out at 37°C. Two endogenous brain steroids, pregnenolone and its sulfate derivative were the most potent (EC_{50} = 0.4 nM) enhancers of [^{3}H]flunitrazepam binding with a maximal effect (25 - 48%) observed at concentrations from 1 to 10 nM. Other steroids such as cholesterol, testosterone, β-estradiol, dihydroepiandrosterone and dexamethasone enhanced specific binding at concentrations greater than 50-100 nM with maximal effects achieved at near micromolar concentrations.

The effect of corticosterone on [^{3}H]flunitrazepam binding was examined in control and adrenalectomized rats. In sham operated rats corticosterone only slightly potentiated (about 10%) [^{3}H] flunitrazepam binding (EC_{50} = 60-100 nM). In adrenalectomized animals (2 weeks post surgery) the dose response curve of corticosterone was shifted to the left (EC_{50} = 15 nM). The effect of corticosterone in enhancing [^{3}H]flunitrazepam binding was potentiated in the presence of depolarizing concentrations (50 mM) of KCl in a Ca^{2+} dependent manner while that of other steroids was not significantly affected by depolarizing conditions. Scatchard analysis of the effects of both pregnenolone and corticosterone on [^{3}H] flunitrazepam binding revealed that the effects of both steroids were due to an increase in the affinity of the benzodiazepine receptor for [^{3}H]flunitrazepam. Since the effects of both steroids in enhancing [^{3}H]flunitrazepam binding were abolished by picrotoxin, our data suggest that steroids interact with the GABA-benzodiazepine-chloride ionophore receptor complex, most probably in the domain of the Cl^- ionophore. Studies are in progress to determine whether the effects of these naturally-occurring steroids on [^{3}H] flunitrazepam binding occur under physiological conditions.

80.12 EFFECTS OF PENTYLENETETRAZOLE ON GABA/BENZODIAZEPINE/PICROTOXIN RECEPTOR COMPLEXES IN RAT BRAIN REGIONS. M. Ito*, T.H. Chiu and H.C. Rosenberg (Spon: H.J. Waller). Medical College of Ohio, Toledo, Ohio 43699

Evidence suggests that pentylenetetrazole (PTZ) causes convulsions by interacting with the GABA/benzodiazepine/chloride ionophore receptor complexes. The present study examined the effects of acute convulsive doses of PTZ on these complexes in various regions of rat brain.

Male rats (200-250 g) received subcutaneous PTZ (1 ml/kg, 90 or 100 mg/kg). Control rats were given the same volume of saline. Tonic-clonic convulsions were usually observed twice at 2-5 min and 13-17 min after PTZ injection. The mortality rate was 43-46%. Rats that survived were sacrificed 30 min after the injection. Brains were rapidly removed, dissected into 7 regions (cerebral cortex, hippocampus, midbrain, striatum, hypothalamus, medulla oblongata, and cerebellum), and stored at -70°C.

Brain regions were thawed and homogenized in 20 vol of ice cold 50 mM Tris-citrate buffer (pH 7.1) with a Polytron (PT 10, setting 6, 20 sec). The homogenate was centrifuged at 48,000 x g for 20 min, and the pellet was resuspended in ice-cold distilled water and recentrifuged. The pellet was washed 3 times with buffer and stored at -20°C for 16 hrs. After thawing, the pellet was washed once with Tris-citrate buffer and the final pellet was suspended in buffer for assay (protein concentration: 0.2-0.45 mg/ml). [^{3}H] Muscimol (2 and 80 nM) and [^{3}H]flunitrazepam ([^{3}H]FNP, 1 and 20 nM) binding were by filtration after incubation on ice for 30 min and 1 hr respectively. [^{3}H]GABA (4 and 100 nM) binding was by centrifugation after 1 hr incubation at 4°C. [^{35}S]t-Butyl bicyclophosphorothionate ([^{35}S] TBPS, 2 and 20 nM) binding was in buffer + 200 mM KBr for 2 hrs at room temperature followed by filtration.

PTZ caused a significant increase in striatal [^{35}S]TBPS binding; no change was found in other brain regions. Binding of the low concentration of [^{3}H]muscimol was decreased in cerebellum. No other changes in [^{3}H]muscimol, or in [^{3}H]FNP or [^{3}H]GABA binding were found.

	[^{35}S]TBPS binding		[^{3}H]Muscimol binding	
	2 nM	20 nM	2 nM	80 nM
Striatum (n=6-9)				
Control	27 ± 4	157 ± 20	254 ± 21	1486 ± 142
PTZ-treated	44 ± 5*	224 ± 24*	279 ± 23	1667 ± 174
Cerebellum (n=5-9)				
Control	90 ± 6	488 ± 31	1476 ± 52	6665 ± 340
PTZ-treated	71 ± 19	357 ± 92	1296 ± 75*	6827 ± 156

Values are mean+SEM (fmol/mg protein); *$p < 0.05$, two-tailed t-test

These results suggest that PTZ seizure selectively affects GABA/benzodiazepine/picrotoxin receptor complexes in certain brain regions. TBPS binding sites in striatum may be an important site of action of PTZ. Supported by RO1 NS16595 and RO1 DA02194.

80.13 INVERSE AGONISTS OF CENTRAL BENZODIAZEPINE RECEPTORS: "IN VIVO" VERSUS "IN VITRO" STUDIES IN THE RABBIT. L. Mele*, D. Lucantoni*, M.G. Caporali*, F.Gatta* and M. Massotti (SPON: R. del Carmine) Laboratori di Farmacologia and Chimica del Farmaco, Istituto Superiore di Sanità, 00161, Roma, Italy.

Inverse benzodiazepine agonists (IBA) induce effects opposite to those of the benzodiazepine (BDZ) agonists through an inhibition of GABA synaptic activity. Present work is aimed to assess whether a possible correlation can be found in the rabbit between the electroencephalographic (EEG) changes induced "in vivo" by IBA and their negative interaction with GABA receptor activity "in vitro".

The administration of IBA in the rabbit elicits EEG changes, characteristic enough to be chassified in three dose-related stages, similar to those observed after bicuculline,picrotoxin pentetrazol and Ro 5-3663: slow waves in the optic cortex, spike-and-wave complexes in the sensorimotor cortex, and grand-mal generalized seizures. These changes are antagonized by the administration of the BDZ antagonist Ro 15-1788 (0.4 mg/kg iv). No change of the electrical activity can be recorded in the spinal cord. The convulsant β-CCM (0.25-5 mg/kg iv) and DMCM (0.4-5 mg/kg iv) elicit all the three stages of EEG changes. The proconvulsant β-CCE (0.2-2 mg/kg iv) and FG 7142 (2-20 mg/kg iv) produce only the first two, while CGS 8216 (2-20 mg/kg iv) elicits only the first stage.

"In vitro" binding studies were aimed to show the ability of the various IBA to compete with ^{3}H-diazepam at BDZ receptors in presence and in absence of GABA. Membrane preparations from rabbit brain cortex frozen-thawed and incubated at 37°C for 30 min were used. The binding parameters of ^{3}H-diazepam were the following: K_D 32 nM; B_{max} 1.28 pmol/mg of prot. The various IBA inhibit ^{3}H-diazepam binding (1.5 nM) giving rise to the following values of IC_{50} (nM): DMCM, 21.2; β-CCM, 5.8; β-CCE, 24.2, FG 7142, 163.3; CGS 8216, 3.32. In the presence of GABA (10^{-5} M), the values of IC_{50} increased. The ratio between the values found in absence over those found in presence of GABA (GABA shift) was calculated for each IBA. The convulsant DMCM and -CCM show values of 0.20 and 0.14, respectively. The proconvulsant -CCE and FG 7142 show the values of 0.80 and 0.77, respectively, while CGS 8216 show the value of 0.94.

These data suggest that, in the rabbit, the extent of the GABA shift found with the various IBA parallels their ability to progress through the three stages of EEG changes characteristic of drugs which down regulate GABA synaptic activity by interfering with the function of GABA-BDZ-picrotoxin receptors oligomeric complex.

80.14 INESCAPABLE TAILSHOCK STRESS DECREASES "PERIPHERAL-TYPE" BENZODIAZEPINE BINDING IN RAT KIDNEY. Robert C. Drugan, Anthony S. Basile, Jacqueline N. Crawley, Steven M. Paul, and Phil Skolnick. Clinical Neuroscience Branch, NIMH and Laboratory of Bioorganic Chemistry, NIADDK, NIH, Bethesda, MD 20205

Pharmacological and biochemical evidence suggests that central benzodiazepine receptors mediate the antianxiety actions of benzodiazepines and related compounds. Rats exposed to stressful or "anxiety"-producing situations show decreased numbers of benzodiazepine receptors (Lane et al., Eur. J. Pharmacol., 83:183-190, 1982; Braestrup et al., Psychopharm., 65:273-277, 1979; Lippa et al., Pharm. Biochem. and Behav., 9:853-856, 1978). Another pharmacologically distinct class of recognition sites for benzodiazepines can be characterized using the ligand [^{3}H]Ro5-4864 (4'-chlorodiazepam). These sites, in contrast to brain benzodiazepine receptors are found in both peripheral tissues (e.g. heart, lung, kidney) and the central nervous system. The physiological significance of these sites is unknown, although they appear to be under both neural and hormonal control.

We have investigated the effects of short and long sessions of inescapable tailshock stress on these "peripheral-type" benzodiazepine receptors and now report rapid changes in [^{3}H]Ro5-4864 binding sites following both short and long sessions of inescapable shock. Male Sprague-Dawley rats (250-350 gms) received either no shock, 20 5-second (1 mA) inescapable tailshocks or 80 5-second (incremented from 1-2 mA) inescapable tailshocks at a rate of approximately 1 per minute. Two hours after the end of the shock session, subjects were sacrificed for assay of [^{3}H]Ro5-4864 binding in whole kidney homogenates according to the methods of Weissman et al., J. Neurochem., 42:969-975, 1984). A significant decrease in the Bmax of [^{3}H]Ro5-4864 binding was observed following both short and long sessions of inescapable tailshock stress. Twenty shocks resulted in a 22% reduction in binding sites, while eighty shocks resulted in a 28% decrease in comparison to home cage controls. These results suggest that the "peripheral-type" benzodiazepine binding site may be important in the modulation of physiological responses to stressful stimuli.

80.15 [^{3}H]-FLUNITRAZEPAM BINDING IN BRAIN AND KIDNEY IS DISPLACED BY THIAZIDE AND THIAZIDE-LIKE DIURETICS. B.J. Ciliax, J.B. Penney, and A.B. Young. Depts. of Pharmacology and Neurology, University of Michigan, Ann Arbor, MI 48109.

[^{3}H]-Flunitrazepam ([^{3}H]-FLU) binds with high affinity to central/neuronal receptors (CNR) and to a peripheral binding site (PBS) located in a number of peripheral tissues (especially kidney). We tested the effects of a wide variety of diuretics on [^{3}H]-FLU binding to tissue sections from both brain and kidney.

Brains and kidneys were quickly removed from decapitated adult male Sprague-Dawley rats and frozen in dry ice. Frozen tissue sections 20 microns thick were cut and thaw mounted on microscope slides. The tissue sections were pre-washed in 50 mM Tris-HCl buffer pH 7.4 at 4°C for 3x5 minutes and then air-dried. The sections were incubated for 60 minutes in same buffer containing 5 nM [^{3}H]-FLU (74 Ci/mmol) in the absence and presence of increasing concentrations of the diuretics listed below. The drug vehicle was 1:1 dimethyl sulfoxide: ethanol present in the assay at a concentration of 0.1%. Sections were then rinsed for 5 min in ice cold buffer and quickly air-dried. LKB Ultrofilm-^{3}H™ was exposed to these sections for quantitative autoradiography. We tested prototype drugs from the following classes of diuretics: (a) thiazide/thiazide-like, (b) high-ceiling, (c) potassium-sparing, and (d) carbonic anhydrase-inhibitors. All drugs tested except those listed below displaced less than 30% of specific binding at concentrations as high as 1 mM. The inhibition constants (K_I) for the effective displacers were as follows:

Diuretics/Displacers	Inhibition Constants (K_I)	
	Brain	Kidney
1 Ethacrynic Acid	> 1mM	285uM
2 Hydrochlorothiazide	> 1mM	31uM
3 Trichlormethiazide	> 1mM	44uM
4 Metolazone	18uM	0.6uM
5 Quinethazone	295uM	> 1mM
6 Amiloride	340uM	> 1mM

The most effective drugs in displacing [^{3}H]-FLU from kidney (drugs 2-4) belong to the thiazide/thiazide-like class, which suggests that the PBS might be a site of action for this class of diuretics, whose mechanism of action remains unclear. The results suggest that the PBS may have, or be coupled to, an endogenous/pharmacological function, such as ion transport.

Interestingly these results may have clinical significance since metolazone displaces [^{3}H]-FLU from the CNR completely and this drug has been reported to aggravate convulsions (Br.Med. J. 1:1381-2, 1976).

80.16 LIGAND-INDUCED CHANGES IN GABA RECEPTOR BINDING KINETICS AND MODULATION BY BARBITURATES. Jane Yang and Richard W. Olsen. Department of Pharmacology and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Both dissociation and association rates of [^{3}H]muscimol binding to GABA receptors were altered by agonist concentration in a manner suggesting negative cooperativity. This could be eliminated by pentobarbital, an effect consistent with enhancement of GABA-mediated inhibition as a mechanism of barbiturate action.

[^{3}H]Muscimol binding in freshly prepared mouse brain membrane homogenates has demonstrated the heterogeneity of γ-aminobutyric acid (GABA) receptor binding sites. The heterogeneity could be due to distinct receptor sub-types or to multiple conformational states of a single receptor. The explanation for binding heterogeneity and its possible functional relevance was investigated using both binding kinetics and tracer radioactive chloride flux assays with cortical slices. The kinetics of [^{3}H]muscimol binding showed a heterogeneity of rate constants. The overall dissociation rate was greatly increased as the concentration of [^{3}H]muscimol increased. Two measurable rate constants on the seconds to minutes scale adequately described the data at 5 nM ligand but three were required at ≥ 30 nM, with one portion too fast to measure (< 1 sec). The association rate (22°C) was decreased by increasing [^{3}H]muscimol concentration, with some very slowly associating sites evident. The changes in on-rate were greater than expected from differential occupancy of multiple populations by varying concentration and, together with the effects on off-rate, suggest ligand-induced interconversion.

Pentobarbital (0.3 μM), which synergistically enhanced muscimol (1 μM)-stimulated $^{36}Cl^-$ flux in brain slices, greatly enhanced the initial apparent association, and decreased dissociation rate. This eliminated the slowly associating binding seen at high muscimol concentrations.

We conclude that the GABA receptor exists in a resting, activatable state (fast on-rate, slow off-rate, Kd = 0.2-1μM). The binding of muscimol to the receptor induces a conformational change, probably involved in agonist activation of chloride channels, accompanied by negative cooperativity that results in the acceleration of muscimol dissociation. Pentobarbital enhances muscimol physiological activity by preventing the occurrence of negative cooperativity, thus prolonging the lifetime of the active state. These observations apparently do not relate to the phenomenon of desensitization which presumably occurs at higher ligand concentrations with even slower kinetics, or can be seen at 0°C corresponding to very high affinity sites (Kd = 1-50 nM).

Supported by NIH grant NS20704 and NSF grant BNS 83-18001.

80.17 PURIFICATION OF ENDOGENOUS BENZODIAZEPINE-LIKE MOLECULES FROM THE MAMMALIAN BRAIN. L. Sangameswaran* and A.L. De Blas. Dept. of Neurobiology & Behavior, State University of New York at Stony Brook, New York, 11794.

We have previously reported[1] the presence of endogenous benzodiazepine-like (BZD-like) antigenic determinants in the rat brain by using the anti-benzodiazepine monoclonal antibody (mAb) 21-7F9. This mAb is now used for the purification of an endogenous BZD-like substance from the soluble fractions of rat and bovine brains by immunoaffinity chromatography.

The immunoaffinity purified substance blocked the binding of the agonists [^{3}H] flunitrazepam and [^{3}H] diazepam, the inverse agonist [^{3}H] β carboline carboxylate ethyl ester, and the antagonist [^{3}H] Ro15-1788 to the neuronal-type benzodiazepine receptor (BZDR). However, it did not inhibit the binding of [^{3}H] Ro5-4864 to the peripheral-type BZDR. The inhibition of [^{3}H] Ro15-1788 binding to the BZDR by the endogenous substance was potentiated by 10^{-4}M GABA suggesting that the BZD-like substance is a receptor agonist. These binding properties were different from those of nicotinamide, adenosine, inosine, guanosine and hypoxanthine which have been proposed to be putative endogenous ligands for the BZDR. The endogenous molecules did not block the binding of the ligands for other transmitter receptors (adrenergic, GABA and adenosine receptors).

The endogenous BZD-like substance from bovine brain has been purified to homogeneity by the following sequential steps: i) immunoaffinity chromatography with mAb 21-7F9 coupled to Affigel G-10, ii) gel filtration on Sephadex G-25 and iii) two different HPLC steps. The purified substance appears between cyanocobalamin and bromophenol blue after gel filtration on Sephadex G-25 suggesting a M_w between 1355 and 670. The activity of the purified BZD-like substance is heat-stable and resistant to proteases.

80.18 EVIDENCE FOR A LINK BETWEEN CALCIUM CHANNELS AND PERIPHERAL BENZODIAZEPINE RECEPTORS IN A CULTURED PITUITARY CELL LINE. A. Doble*, M.L. Perrier*, M.C. Burgevin*, I. Pisseau*, J. Bénavidès*, A. Uzan, C. Guérémy* and G. Le Fur. PHARMUKA Lab., Groupe RHONE POULENC SANTE, 92231 Gennevilliers, France.

Radioligand binding to peripheral-type benzodiazepine binding sites (PBBS) and the effects of ligands specific for this site on various second messenger systems have been studied using the rat pituitary transformed cell line, GH3.

[^{3}H]PK 11195, a specific non-benzodiazepine ligand for the PBBS, binds with high affinity to a single saturable population of binding sites on intact GH3 cells. Their affinity and capacity are 3.3 nM and 243 fmol/10^6 cells respectively. The pharmacological characteristics of these sites are identical to those characterized previously in rat heart, brain or kidney. The binding is unaffected by chloroquine or cell lysis, consistent with binding to the outer surface of the cell membrane.

GH3 cells accumulate $^{45}Ca^{++}$ in response to depolarizing concentrations of potassium. This uptake can be blocked by dihydropyridines implicating voltage-sensitive calcium channels (VSCC) in this phenomenon. In fact, the VSCCs can be observed directly by the binding of [^{3}H]verapamil. The $^{45}Ca^{++}$ flux can be blocked by RO5-4864, a benzodiazepine selective for the PBBS. This effect is reversed by PK 11195, which will also reverse the stimulation of $^{45}Ca^{++}$ flux by the dihydropyridine BAY K-8644. These interactions of ligands acting at the PBBS with the VSCC are similar to previous findings in cardiac muscle. No interaction, however, could be demonstrated between the binding sites for [^{3}H]PK 11195 and [^{3}H]verapamil.

In contrast, the turnover of phosphoinositides (PI), which is thought to be related in some way to mobilization of intracellular calcium, was modified neither by RO5-4864 nor PK 11195. This was true both for basal PI turnover and for PI turnover stimulated by TRH. Neither have preliminary experiments demonstrated any effect of PBBS ligands on the pattern of protein phosphorylation in GH3 cells.

These results, obtained from a secretory cell, provide further support for the hypothesis, proposed on the basis of data obtained from cardiac cells, that the PBBS can regulate selectively the VSCC.

81.1 GAMMA-AMINOBUTYRIC ACID (GABA) ACTIVATES A PICROTOXIN-RESISTANT CHLORIDE CONDUCTANCE ON SPINY LOBSTER FOREGUT AND OPENER MUSCLE. J. Albert*, C.J. Lingle, E. Marder and M. O'Neil*. (Spon: J. Elam). Dept. Biol. Sci., Florida State University, Tallahassee, FL 32306 and Dept. Biology, Brandeis U. Waltham, MA 02254 .

GABA-activated chloride conductance increases in both invertebrate and vertebrate systems are known to be exquisitely sensitive to the convulsant alkaloid, picrotoxin (PTX). At the opener muscle of the walking leg of Homarus vulgaris, 50% block of a 40 micromolar dose of GABA occurs at less than 200 nM PTX (Constanti, 1978, Neuropharm. 17:159). In marked contrast, we have encountered a GABA-activated conductance change on the opener and GM6 muscles of the spiny lobsters, Panulirus interruptus and Panulirus argus, which is about 3 orders of magnitude less sensitive to PTX than are muscles of previously studied crustacean species. The experiments described here examine the properties of this PTX-resistant GABA response.

Most experiments were done on the GM6 muscle using standard two electrode current-clamp procedures. The threshold for the GABA-activated conductance increase is about 10-20 uM and the reversal potential of the response was close to the cell resting potential. The chloride-dependent nature of the response was verified by several experiments. Saline with 50% sodium or 0 calcium produced no change of the GABA-activated conductance change or reversal potential of the response. In contrast, shortly following perfusion of the muscle with a 50% chloride saline (proprionate substitution), a 12 mV depolarizing shift in the reversal potential for the response was observed. The threshold for PTX action on this GABA conductance was about 10 uM. 50% blockade of responses to 200 uM GABA required at least 500 uM PTX. The GM6 GABA response is mimicked by muscimol, but not baclofen. Bicuculline is a weak blocker, while beta-guanidino-proprionic acid produces weak agonist and blocking actions. Except for the relative insensitivity to PTX, in all respects the Panulirus GM6 and opener muscle GABA response appears similar to other crustacean GABA responses. In addition, we find that the GABA response of the GM6 muscle of Homarus is almost totally blocked by 1 uM picrotoxin.

Our results show that in Panulirus the classical neuromuscular GABA response has a reduced sensitivity to picrotoxin perhaps analagous to TTX-resistant sodium channels. Minimally, the results indicate that the binding site for picrotoxin can be altered without changing other functional properties of the GABA-activated conductance. (Supported by NIH NS-19139 to CL).

81.2 INTRACELLULAR STUDIES IN VITRO OF INHIBITORY SYNAPTIC EVENTS AND THE ACTIONS OF GABA AGONISTS IN THE DORSOLATERAL SEPTAL NUCLEUS (DLSN) OF THE RAT. D. R. Stevens, J. P. Gallagher, and P. Shinnick-Gallagher. Dept. Pharmacology, Univ. of Texas Medical Branch, Galveston, Texas, 77550.

The septal area has been proposed to function in the expression of anxiety and in learning of avoidance responses. γ-aminobutyric acid (GABA) has been suggested as an inhibitory neurotransmitter in this area. We have previously described the actions of GABA and the GABA-b agonist, (-) baclofen on principal neurons of the DLSN in a rat brain slice preparation (Gallagher, et al. Neuropharm. 23;825,1984) Here we report the results of further studies of the action of GABA and studies of inhibitory synaptic events in the DLSN.

The action potential of DLSN neurons is followed by an afterhyperpolarization (AHP) which is blocked by manganese (1 mM). The early phase of the AHP is depressed by low calcium-high magnesium treatment and by bicuculline methiodide (10 μM). This result indicates the presence of a synaptic contribution to the AHP which is mediated by GABA.

Local stimulation occasionally elicits an inhibitory postsynaptic potential (IPSP) with a latency of 2-3 milliseconds. The IPSP is depressed by picrotoxin (10 μM) and by low calcium treatment. The reversal potential of the IPSP is near -70 mV, a value similar to that of hyperpolarizing GABA potentials in these neurons.

Increasing the stimulus intensity results in the appearance of a late hyperpolarizing potential (LHP). This potential is of long duration (500 msec) and is associated with an increase in conductance. The LHP is insensitive to picrotoxin (10 μM) and has a reversal potential approximately 25 mV more negative than that of the IPSP. This value is comparable to the reversal potential of the baclofen hyperpolarization seen in these neurons.

Since baclofen is thought to act at a subtype of GABA receptor, we examined further the action of GABA on DLSN neurons. GABA produces a biphasic potential when applied by iontophoresis to these neurons. A hyperpolarizing response to gaba persists in the presence of picrotoxin (10 μM) or bicuculline methiodide (50 μM) when relatively large ejection currents are used. This hyperpolarization is the result of a conductance increase. The reversal potential of the picrotoxin-resistant GABA response is more negative than that of the ipsp and is comparable to the reversal potential of the baclofen response.

These results support the proposal that GABA is an inhibitory neurotransmitter in the DLSN. In addition, GABA activates a conductance which is comparable to that activated by baclofen. Finally, the ionic mechanisms of the hyperpolarizing baclofen response and that of the picrotoxin-resistant GABA response are similar to that of the LHP. It is possible that the the LHP is mediated by synaptically released GABA acting at a GABA-b receptor.

81.3 STEROID MODULATION AND MIMICKRY OF GABA-ACTIVATED CHLORIDE CONDUCTANCE IN CULTURED MAMMALIAN CENTRAL NEURONS. N.L. Harrison*, S. Vicini*, D.G. Owen* and J.L. Barker. Laboratory of Neurophysiology NINCDS, NIH, Bethesda, MD. 20205

The steriodal anesthetic alphaxalone (3 α-hydroxy 5α-pregnane 11,20-dione) enhances GABA-evoked Cl^--dependent responses in rat cuneate slices and stimulates [^{3}H]-muscimol binding to rat brain membranes (N.L. Harrison and M.A. Simmonds, Brain Res., 323:287-292). We have begun to study this interaction at the single cell level using conventional intracellular recording and whole-cell patch clamp techniques. Cl^--loaded hippocampal and spinal neurons depolarized from rest by pressure applications of GABA (20μM) were invariably potentiated by application of low (≤ 1μM) concentrations of alphaxalone. Higher steroid concentrations produced direct depolarizations that were accompanied by a fall in R_m and, like GABA-evoked responses, reversed at membrane potentials between -20 and -30mV. In neurons recorded with 3MKAc-filled electrodes GABA-evoked Cl^- currents were markedly potentiated by ≤ 1μM alphaxalone. Higher steroid concentrations (≥ 1μM) produced Cl^- currents in the absence of applied GABA. As is the case for pentobarbital, the peak current evoked by GABA could be increased 2-3-fold and the decay time for the current substantially prolonged (Fig. 1). The potentiating effect of the steroid following brief (2-5s) application was far more rapidly reversed than was the case for similar applications of diazepam. All steroid actions were insensitive to the benzodiazepine antagonist Ro15-1788. In view of the structural similarity between the steroid anesthetic and certain steroid metabolites, it is possible that endogenous steroid hormones modulate GABA-activated Cl^- conductance in the mammalian CNS.

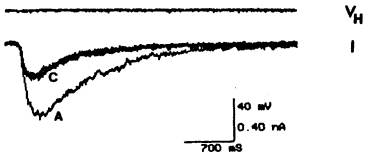

Fig. 1. Whole-cell patch clamp recording from a cultured rat hippocampal neuron voltage-clamped at -50mV (V_H) with a patch pipette containing 145mM KCl. 20μM GABA was applied by pressure (<2psi) to the cell body for 150 msec at a rate of 0.08Hz. Five control (C) current (I) responses are shown superimposed together with the first current response obtained after a brief (2s.) application of 1μM alphaxalone (A).

81.4 GABA-ACTIVATED CHLORIDE CHANNELS ANTAGONIZED BY PICROTOXIN SHARE KINETIC PROPERTIES WITH ONE FORM OF THE NATURALLY-GATED CHANNEL. M.G. Weddle and R.L. Macdonald. University of Michigan, Ann Arbor, Michigan, 48104-1687.

We have studied the actions of the γ-aminobutyric acid (GABA)-antagonist picrotoxin (PICRO) on GABA-activated single channel chloride currents, and have found similarities between channels in the presence of antagonist and one kinetic variation of the channel gated in its absence. Fetal mouse spinal cord neurons were maintained in dissociated cell culture for 2-6 weeks. For experiments, cells were transferred to a Hepes-buffered saline solution containing the glycine antagonist strychnine (100-500 nM.). Using the patch clamp technique, outside-out patches were obtained (intra-pipette solution contained the impermeable cation TRIS, a [Cl^-] similar to that of the bath and an EGTA-Ca^{++} buffer). Patches were clamped at positive-inside potentials (+50 to +80 mV.), and broken-tipped micropipettes were used to approach the patches and apply GABA and PICRO-containing solutions by diffusion. Some spontaneous currents were present in all of the patches used in this study, and GABA was frequently applied to increase the occurrence of this activity. The currents reversed at a membrane potential of 0 mV., and this reversal was shifted with a partial substitution of isethionate anions for bath chloride, indicating that Cl^- was the principal charge carrier producing these currents. Recorded activity was almost exclusively in the form of channel 'bursting': the channels tended to frequently, though briefly, close while in the open state. Less frequently, groups of discrete (non-bursting) openings were observed. First, the time distributions of channel openings and closures within channel bursts were analyzed. In the absence of PICRO, both distributions contained at least two populations of exponentially-distributed events. With increasing concentrations, the initial action of PICRO was the elimination of long open-time population(s), reducing the intraburst open-time distribution to a single exponential. The loss of one or more populations of long open-states in the presence of PICRO was not accompanied by a similar loss of closed-states. Higher concentrations of PICRO disrupted patterns of bursting, and further reduced the remaining open-times. Next, the time distributions of channel open- and closed-states during groups of nonbursting openings were analyzed. The longer intervals between these discrete events were represented in a shift of the closed-time distributions, and open-time distributions were of the form of single exponentials. These were quite similar to the intraburst open-state durations in the presence of low concentration PICRO. The data suggest that one action of PICRO may be to reduce the complexity of open-state kinetics in a way which can occur within the naturally-gating channel. Supported by Grant #NS 19613-01.

81.5 ETOMIDATE PROLONGS THE RECURRENT GABA-MEDIATED IPSP IN RAT HIPPOCAMPAL CA1 PYRAMIDAL NEURONS IN VITRO. W.R. Proctor, M. Mynlieff and T.V. Dunwiddie. Dept. Pharmacol., Univ. Colorado Health Sciences Ctr. & VA Medical Research Serv., Denver, CO 80252

Etomidate is a sedative/hypnotic drug that has barbiturate-like anesthetic properties. Biochemical studies have shown that the (+) isomer of etomidate interacts with the GABA receptor-chloride ionophore complex (GABA/barbiturate/benzodiazepine receptors coupled to a chloride channel) in a barbiturate-like fashion, i.e., it enhances both benzodiazepine and GABA binding. The (-) isomer of etomidate is much weaker in this regard, but unlike many other stereoisomeric barbiturates, it does not appear to have excitatory properties. The present electrophysiological investigations were designed to examine the effects of the isomers of etomidate, and to compare their actions to those of barbiturates such as pentobarbital.

The effects of etomidate and pentobarbital were examined in the well-characterized recurrent GABAergic inhibitory pathway in the CA1 region of the in vitro hippocampal slice. Electrical stimulation of the alveus produces a hyperpolarizing Cl^--mediated IPSP in CA1 pyramidal cells, which is usually followed by a second inhibitory potential (late hyperpolarizing potential or LHP) of much longer duration that does not involve a chloride conductance. To examine the effects of etomidate and pentobarbital on each of these IPSP's independently, we recorded intracellular responses using bath superfusion with bicuculline methiodide (10 uM) to block the initial GABAergic IPSP, or with Cs^+-acetate filled electrodes to block the slower, presumably K^+-mediated IPSP.

Both pentobarbital (100 uM) and (+) etomidate (10 uM) markedly potentiated the duration of the initial GABA-mediated IPSP, increasing the duration from the usual 75-125 msec to as much as 400 msec in the presence of drug. In addition, there was occasionally a modest (10-20%) increase in the amplitude of this potential. However, no significant effects of either of these drugs were observed on the LHP. These responses showed a high degree of stereospecificity, in that (+)-etomidate was at least 10 times more potent than the (-) isomer, and approximately 10 times more potent than pentobarbital. These results correspond well with the relative as well as absolute potencies of these drugs in modulating the binding of GABA and benzodiazepines in in vitro binding assays. Although etomidate does not have the characteristic barbiturate structure as does pentobarbital, the similarity between the biochemical and functional effects of these drugs suggest that they act at a common stereoselective receptor site that is intimately associated with the GABA receptor and Cl^- ion channel.

81.6 BLOCKERS OF GABA UPTAKE DIMINISH SPONTANEOUS IPSP SIZE IN MAMMALIAN DISSOCIATED CELL CULTURE. J.R. Buchhalter* and M.A. Dichter. Children's Hospital Medical Center, Boston, MA 02115.

Uptake of GABA into neurons and/or glia has been postulated to be a major mechanism of GABA inactivation. Thus, blockers of uptake would be expected to potentiate inhibitory postsynaptic potentials (IPSPs) as well as enhance the effects of exogenously applied GABA. We have examined these issues in rat cortical neurons which exhibited spontaneous GABA mediated IPSPs.

Rat cortical dissociated cell cultures were prepared as described previously (Dichter, MA. Br.Res. 149:279, 1978). Intracellular recordings were performed with potassium acetate filled electrodes utilizing standard methods. When an impaled neuron exhibited spontaneous IPSPs, it was pneumatically perfused with either a neuronal, glial or mixed blocker of GABA uptake in the indicated concentrations: diaminobutyric acid (DABA, 1mM; neuronal), beta-alanine (ALA, 1mM & 100uM; glial) or racemic nipecotic acid (NIP, 1mM; both glial and neuronal). DABA, ALA and NIP produced a decrease in the amplitude of spontaneous IPSPs in 17 of 20 neurons.

Experiments were performed to test the effect of the blockers on the postsynaptic hyperpolarization produced by exogenously applied GABA (5uM). Co-perfusion of DABA with GABA was compared with GABA and each blocker applied alone. NIP and DABA enhanced the effect of GABA in 9 of 21 and 2 of 7 cells, respectively. The effect of ALA was not interpretable as it produced significant hyperpolarization when perfused alone.

Our results are not consistent with the hypothesis that either neuronal or glial GABA uptake plays a role in limiting the size of IPSPs, at least for inhibitory synapses in culture. The mechanism by which the uptake inhibitors diminish IPSPs is likely to be presynaptic. They might block inhibitory interneuron action potentials, act on presynaptic receptors to decrease GABA release, or get taken up into axon terminals and released as "false transmitters." Some of these hypotheses should be testable by recording from pairs of neurons where both the pre and postsynaptic elements of the inhibitory synapse can be monitored.

81.7 HYPERPOLARIZING RESPONSES TO GABA AND ANALOGS ON PRIMARY AFFERENT FIBRES. G.M. Mitsoglou* and A.L. Padjen, Dept. of Pharmacology and Therapeutics, McGill University, Montreal, Quebec, Canada H3G 1Y6.

Our previous studies indicated that GABA and analogs (baclofen; kojic amine; taurine) have dual effects on primary afferent fibres: a bicuculline/picrotoxin sensitive depolarization, and a hyperpolarizing response insensitive to the blockers (Bourne & Padjen, Abs. Neurosci. 1980; Padjen & Hashiguchi, Abs. Neurosci., 1982). In this study we have examined some properties of the hyperpolarizing response. Experiments were done at 11-12°C on isolated hemisected spinal cords of frog (R. pipiens) superfused with a Ringer's solution containing tetrodotoxin (.2 μM) to block indirect drug responses. Drug-evoked responses were recorded from the intramedullary part of dorsal roots (9th and 10th segment) using the sucrose gap technique. L-baclofen (0.005-0.5 mM) caused a long-lasting conc-dependent hyperpolarization of primary afferent fibres (2 mV at 0.5 mM, for up to 90 min in duration). D-baclofen was at least three times less potent in causing hyperpolarization. Kojic amine, GABA and taurine in low conc (<0.1 mM) were also able to hyperpolarize primary afferent fibres but this type of response was best seen in the presence of blockers (bicuculline, picrotoxin for GABA, kojic amine, taurine and 6-aminomethyl-3-methyl-4H-1,2,4-benzothiadizine in the case of kojic amine and taurine). Hyperpolarizing responses were $[K]_o$-dependent: in 0.1 mM K^+, the amplitude of L-baclofen (0.1 mM) response was increased by 150-200%, and in 4 mM K^+ decreased by 80%. At the same time, depolarizing responses to GABA (0.5 mM) and taurine (1 mM) were affected in the opposite sense: in 0.1 mM K^+, depolarization was decreased and often a hyperpolarizing component of the responses appeared. Addition of Ba^{2+} (0.5 to 5 mM) blocked hyperpolarizing responses to L-baclofen by up to 100%, while responses to other neutral as well as acidic amino acids were only depressed. On the other hand Mn^{2+}, Co^{2+} (both 2 mM) and Cd^{2+} (0.5 mM) were without effect on hyperpolarizing responses. Alleged antagonists of $GABA_B$ receptors (1 mM of delta-aminovaleric acid or delta-aminolaevulinic acid) had little effect on hyperpolarizing responses.

These results suggest that the hyperpolarizing responses to GABA and analogs, which appear to result from activation of $GABA_B$ receptors, are mediated by a "K^+ mechanism" and do not seem to be dependent on Ca^{2+} entry.

81.8 EFFECTS OF BENZODIAZEPINES ON SINGLE UNIT ACTIVITY OF DOPAMINERGIC AND NON-DOPAMINERGIC NEURONS IN THE VENTRAL TEGMENTAL AREA. D.P.O'Brien and F.J.White. Depts. of Veterinary Biosciences and Psychology, Univ. Illinois, Urbana, IL 61801

GABAergic pathways descend from the corpus striatum to the substantia nigra (SN) and from the nucleus accumbens to the ventral tegmental area (VTA). It has been suggested that these pathways form inhibitory feedback circuits,and that drugs which enhance this inhibition may be useful in disorders where excessive dopaminergic (DA) function is suspected, such as schizophrenia. Intrinsic GABAergic neurons are, however, present in both the VTA and SN. In SN, evidence suggests that the descending, GABAergic pathway inhibits other GABAergic neurons in the SN pars reticulata (SNR) which in turn inhibit DA cells in the SN pars compacta (SNC). Further, drugs which enhance GABA activity, such as the benzodiazepines, are more potent at the SNR than the SNC and thus consistently inhibit the non-DA SNR neurons while having variable effects, including excitation, on DA neurons in the SNC (Ross et al Life Sci 31:1025-1035, 1982; Grace and Bunney Eur J Pharm 59:211-218, 1979). The interactions of DA and non-DA neurons in the VTA are not as well understood. Since the VTA DA neurons are thought to be involved in the affective components of behavior as well as the pathogenisis of schizophrenia, the relationship between GABAergic and DA neurons in this area is of considerable practical importance. Therefore, we initiated experiments to determine the effects of benzodiazepines on DA and non-DA neurons in the VTA.

Extracellular single unit activity was recorded in chloral hydrate anesthetized rats. DA and non-DA neurons were distinguished by their waveforms, firing rates, and firing patterns.

Diazepam (DZ) administered iv exerted a potent inhibitory effect (usually >75%) on non-DA, SNR-like cells in the VTA at doses as low as 50μ_g/kg. The effects of DZ on DA cells was variable. Although most cells showed potent excitation (75% increase over basal rates) some showed moderate inhibition while others no effect. All the changes seen could be reversed by the benzodiazepine antagonist RO15-1788. Often the firing rate would rebound past the basal rate when the DZ effect was reversed by RO15-1788, although the latter had no effect when administered alone.

Preliminary microiontophoretic studies have shown that direct application of chlordiazepoxide also produces potent inhibition of non-DA cells in the VTA and moderate inhibition of some DA cells (but no excitation). Thus the inhibitory effects of benzodiazepines on these cells are probably mediated directly by benzodiazepine receptors on the cells. The extent to which the increase in firing in DA cells following iv DZ administration is dependent upon indirect mediation via SNR-like,non-DA neurons is presently under investigation.

82.1 THE RELATIONSHIP BETWEEN THE AVAILABILITY OF GLUTAMINE AND THE RELEASE OF GLUTAMATE AND GABA FROM HIPPOCAMPAL SLICES. J.C.Szerb and P.A.O'Regan*. Dept. of Physiology and Biophysics, Dalhousie Univ. Halifax, N.S. B3H 4H7, Canada.

Glutamine (GLN) is present in the CSF in a high concentration of 0.5-0.6mM. It has been shown previously (Szerb and O'Regan, J.Neurochem. in press) that GLN added to the superfusion fluid in this concentration enhances the evoked release of glutamate much more than that of GABA. The smaller effect of GLN on GABA release could be the result of a greater contribution to release of GABA taken up by the terminals than of GABA freshly synthesized. Therefore, the effect of 0.5 mM GLN on GABA release was measured when GABA uptake was inhibited by 1 mM nipecotic acid. Nipecotic acid caused an increase both in the spontaneous and high K^+evoked release of GABA but GLN still had very little effect on GABA release while greatly enhancing both the spontaneous and evoked release of glutamate. Alternatively, GLN fails to increase GABA release because its synthesis is saturated at a lower concetration of GLN than that of glutamate. Therefore, rats were pretreated with methionine sulfoximine (MSO), a GLN synthetase inhibitor. This resulted in a 50% reduction in GLN efflux and a more rapid decline in glutamate release with prolonged depolarization. GABA release also declined in slices from MSO treated rats but much less than that of glutamate. Added 0.5 mM GLN fully reversed the effect of MSO pretreatment by increasing glutamate release twentyfold and doubling that of GABA. Since it is well established that labelled GLN is as readily incorporated into releasable GABA as is labelled glucose, lack of an effect of GLN on total GABA release suggests that releasable GABA synthesis is controlled by the enzyme GAD which can utilize glutamate derived from GLN or glucose interchangeably. In contrast, the rate of glutamate synthesis, which does not involve such a regulatory enzyme, depends more on substrate concentration.

82.2 THE CALCIUM DEPENDENCY OF [3H]-GABA RELEASE EVOKED BY ELECTRICAL OR POTASSIUM STIMULATION. J. Peris*, R. A. Harris and N. R. Zahniser. Dept. Pharmacology, Univ. Colorado Health Sci. Ctr., Denver, Co 80262.

The stimulated release of cholinergic and adrenergic neurotransmitters from in vitro neuronal preparations is absolutely dependent on the presence of calcium ions (Ca); this is compatible with the Ca-dependent vesicular release hypothesis. However, the Ca dependency of the release of gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in cortex, remains equivocal. Usually, either potassium (K) at high concentrations or electrical field stimulation (E) of high frequencies has been used to evoke GABA release. Although in some studies, K-stimulated GABA release was Ca independent, most reports conclude that a substantial proportion of this release is Ca dependent; in contrast, E-stimulated GABA release is mostly Ca-independent. In addition, Ca-dependent GABA release is occasionally only demonstrable when Mg levels are increased simultaneously with Ca removal. In order to determine the Ca-dependency of GABA release from rat cerebral cortex, we examined both E- and K-stimulated [3H]-GABA release from superfused cortical slices in the presence and absence of Ca (1.3mM) and elevated Mg (2.5 mM). We also measured the effects of a Ca-channel blocker (ruthenium red) on GABA release when Ca and Mg concentrations remained unchanged from normal Krebs' buffer. We found that K-stimulation and higher Mg concentrations led to a greater proportion of Ca-dependent release (50±0.6% of total stimulated release; X±SEM) compared to that found when slices were E-stimulated in the absence of excess Mg (20±19%). Intermediate proportions of Ca-dependent release were found when only one of these conditions (i.e., K-stimulation or excess Mg) was present. For example, Ca-dependent K-stimulated release was 40±8% of total stimulated release in the absence of excess Mg while Ca-dependent E-stimulated release was 30±5% when Mg was increased. Ruthenium red caused a dose-dependent decrease in E-stimulated GABA release with a maximum inhibition of 40% at 100 µM. Under all of these conditions, at least 50% of GABA release was not mediated by Ca-dependent mechanisms even under conditions favorable for Ca-dependent GABA release. It is possible that E- and K-stimulated GABA release are evoked from different neuronal pools, one of which is Ca dependent and the other Ca independent. The Ca-dependent component has traditionally been thought to be vesicular release while the Ca-independent component has been postulated to be a reversal of the Na-coupled transport system for GABA uptake. It is of interest that dopamine has been recently found to inhibit only Ca-independent GABA release from the retina (Kato, et al., J. Neurochem., 44, 893-899, 1985). We will determine whether drugs selectively alter the Ca-dependent and -independent release of GABA. This work was supported by grants NS 09199 (NRZ) and DA 07043 (JP).

82.3 GABAERGIC PRESYNAPTIC RECEPTORS IN TERMINALS IN SUBSTANCIA NIGRA COMPACTA BUT NOT IN NIGRA RETICULATA. B. Floran* and J. Aceves* (SPON: E. Stefani). Dept. of Physiology and Neuroscience. Centro de Investigación del IPN. 07000 México, D.F.

Arbilla et al.[1] suggested the presence of GABAergic presynaptic receptors in striatonigral terminals. However the GABAergic terminals going to the pars compacta seem to be different from those going to the reticulata: the first receives terminals mainly from globus pallidus (and from the reticulata itself through recurrent collaterals from neurons in the reticulata that project to thalamus, superior colliculus and reticular formation), while the latter receives most of the terminals coming from the neostriatum (globus pallidus also receives a large proportion of GABAergic terminals from neostriatum). We are studying the distribution of the GABAergic autoreceptors in the terminals of these GABAergic pathways, and here we report the results so far obtained.

Eventhough the natural ligand to activate the receptors is GABA itself, the exchange diffusion for GABA precludes the use of GABA to see the consequence of activation of the receptors on evoked release of tritiated GABA. Therefore muscimol was used instead of GABA. The experiments were done in slices of rat substantia nigra (either compacta or reticulata), globus pallidus and superior colliculus. The tissue samples were loaded with tritiated GABA in the presence of ß-alanine (1 µM) and the perfusion solution contained nipecotic acid (10 µM). Release was evoked by high potassium (15 mM), which was maintained elevated throughout the experiment. The release was Ca-dependent and TTX-sensitive. Muscimol (1 µM) totally inhibited evoked release from nigra compacta, but not from reticulata. Bicuculine (10 µM), which had not effect by itself, blocked the muscimol inhibition. Muscimol also inhibited evoked release from superior colliculus but not from globus pallidus slices. These results suggest that not all GABAergic terminals have presynaptic autoreceptors, but that there is a preferential location of the receptors on the terminals of certain GABAergic pathways. The physiological significance of this preferential location of the presynaptic GABAergic autoreceptors is difficult to assess. (Supported by PBBCCNA-020884 grant from CONACyT of México).

82.4 THE EFFECT OF ETHOSUXIMIDE ON BRAIN GABA CONTENT AND THE IN VIVO INTERACTION BETWEEN ETHOSUXIMIDE AND $GABA_a$ RECEPTOR AGONIST (THIP) IN MICE. E. Lin-Michell*, A.Y. Chweh, and E.A. Swinyard*. Dept. of Biochemical Pharmacology and Toxicology, Univ. of Utah, Salt Lake City, UT 84112.

The effect of ethosuximide (an antiepileptic drug) on the GABA content in mouse brain was investigated. In addition, the effect of a $GABA_a$ receptor ligand, THIP, on the anticonvulsant activity and minimal neurotoxicity of ethosuximide was determined. Brain GABA content was estimated by a radioreceptor assay. Anticonvulsant activity and minimal neurotoxicity were measured by the pentylenetetrazol (PTZ, 85 mg/kg, s.c.) and rotorod tests, respectively. Administration of the anticonvulsant ED50 of ethosuximide (150 mg/kg, i.p.) did not increase brain GABA content (1.49 ± 0.07 vs 1.50 ± 0.06 µmol/g wet tissue). However, administration of the median minimal neurotoxic dose of ethosuximide (400 mg/kg) significantly increased brain GABA content (1.23 ± 0.02 vs 1.92 ± 0.14 µmol/g wet tissue, $p < 0.01$). Mice treated ten days with 500 mg/kg of ethosuximide exhibited no neurotoxicity; moreover, such treatment had no significant effect on brain GABA content (1.40 ± 0.05 vs 1.33 ± 0.03 µmol/g wet tissue). Administration of THIP with ethosuximide had no effect on either the anticonvulsant activity or the minimal neurotoxicity of ethosuximide. These observations suggest that GABA receptors are not directly involved in either the anticonvulsant or minimal neurotoxicity of ethosuximide; however, the increase in brain GABA content induced by toxic doses of ethosuximide contributes to its neurotoxicity. (Supported by NIH Contract No. NO1-NS-4-2361)

82.5 REGIONAL VARIATIONS IN THE IN VIVO EFFECTS OF GAMMA ACETYLENIC GABA ON GABA TRANSAMINASE AND GLUTAMATE DECARBOXYLASE ACTIVITIES IN RAT CNS: RETINA vs BRAIN. J.F. Cubells, J.S. Blanchard*, D.M. Smith*, and M.H. Makman*. Depts. of Neuroscience, Biochemistry, and Molecular Pharmacology. Albert Einstein College of Medicine, Bronx, NY 10461

4-amino, 5-hexynoic acid (gamma-acetylenic GABA; γ-AG) is a mechanism-based, irreversible inhibitor of several pyridoxal phosphate-linked enzymes, including GABA-transaminase (GABA-T), ornithine decarboxylase, and glutamic acid decarboxylase (GAD). We have shown previously that retinal GAD activity is more completely inactivated than striatal or nigral GAD activities in rats which have received 50 or 100 mg/kg γ-AG s.c. 4 hours prior to decapitation. We now report that decreases in both GAD and GABA-T activities which result from s.c. γ-AG administration vary according to the region of CNS in which they occur.

Male Long-Evans rats were given 2 ml/kg water or 1,5,10,25, or 50 mg/kg γ-AG s.c., and decapitated 4 hours later. The brains and eyes were removed rapidly. Retinae, substantiae nigrae, striata, olfactory bulbs and frontal cortices were dissected. One of each of these was frozen under nitrogen for GAD assay. The other samples were homogenized in ice-cold 0.32 M sucrose for immediate GABA-T assay.

At every dose, both GAD and GABA-T activities were markedly more diminished in the retinal samples. Frontal cortical GABA-T activity was more diminished than olfactory bulb, striatal or nigral GABA-T activities at 10,25, and 50 mg/kg. GAD activities in striatum and frontal cortex were more diminished at 25 and 50 mg/kg than those from olfactory bulb or substantia nigra. ID 50s for each enzyme were estimated from the dose response curves for each CNS region. They were as follows:

CNS Region:	Retina	F.Cortex	Striatum	O.Bulb	S.Nigra
Enzyme GAD:	8	43	52	>>50	>>50
GABA-T:	<1	28	60	60	>>50

In summary, GAD and GABA-T activities in retina are much more sensitive to γ-AG administered peripherally, in vivo, than they are in 4 other CNS regions. Regional variations in γ-AG induced loss of GAD and GABA-T activities also occur in the brain itself, but to a lesser degree than those observed between retina and brain. These regional differences may be due to differences in regional delivery of γ-AG within the CNS. The marked retinal sensitivity to γ-AG permits the in vivo study of this drug, and possibly other similar drugs, at low, nontoxic doses in an easily accessible region of the CNS.

γ-AG was a gift from Merrell Dow Research Institute. Supported by USPHS grants EY 04633, NS 09649, and T32GM7288.

82.6 IMMUNOCYTOCHEMICAL DEMONSTRATION OF GABA- AND SEROTONINERGIC ENDINGS AT THE LEVEL OF THE SECOND ORDER NEURONS OF THE ELECTROSENSORY PATHWAY IN MORMYRID FISH (TELEOSTEI, PISCES). J.P. Denizot°, S.Clausse°, K.Elekes°, K.Grant°, T.Szabo, M.Véron°. C.N.R.S., Lab. Physiologie Nerveuse, Dept. Neurophysiologie Sensorielle, 91190 Gif sur Yvette, France.

Several electrophysiological reports have demonstrated a strong inhibition in the fast electrosensory pathway of mormyrid fish at the level of the lateral line lobe nucleus (nLLL) (Steinbach & Bennett, 1971; Zipser & Bennett, 1976; Szabo et al., 1979; Bell, 1982). This inhibition appears as a result of the corollary discharge controled by the electric organ discharge (EOD) command system (Bell et al., 1983) and represents a gate at the level of the nLLL for the sensory impulses set up by the fish's own EOD. The nLLL is composed of several hundred, adendritic, 20um cells with a complex synaptology (Szabo & Ravaille, 1976): a small number of club endings with mixed synapses, originating from primary afferent electrosensory fibers (Szabo et al., 1983; Bell & Russell, 1978) contact the somatic membrane of each cell, while a very large number of synaptic boutons cover the rest of the somatic membrane as well as the initial segment. Ultrastructurally, two types of boutons can be distinguished.

Immunocytochemical treatment of 50um thick transverse sections with antisera dilutions of 1:2000 to 1:10000, developed using the PAP, IgG or Biotin/Avidin complex techniques, revealed the presence of the biosynthetic enzyme glutamic acid decarboxylase (GAD) and the inhibitory transmitter gamma aminobutyric acid (GABA) in a large number of bouton-like endings on the soma and on the initial segment of nLLL neurons. Labeled terminals in plastic embedded semi-thin (1um) sections showed that GABA containing boutons made synaptic contacts with nLLL neurons. This suggests that GABA is the inhibitory transmitter at this level of the fast electrosensory pathway.

Antiserotoninergic (5HT) (dilutions used 1:400 to 1:2000) immunoreactivity was demonstrated in numerous preterminal axons branching within the nLLL and in a small number of terminals within the neuropil contacting the soma of nLLL neurons.

(The authors are indebted to Drs. H.Bras, J.Hamori, J.Somogyi and M.Tappaz for providing the 5HT, GABA and GAD antisera).

82.7 IMMUNOHISTOCHEMICAL LOCALIZATION OF GAD IN RAT SUPERIOR CERVICAL GANGLION. S.L. Kenny* and M.A. Ariano (SPON: W.G. Bradley). Department of Anatomy and Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

The superfusion of GABA in rat superior cervical ganglion (SCG) in vitro has been shown to produce depolarization of the resting membrane potential and an increased conductance to chloride ions in the principal, postganglionic neuron (Bowery & Brown, 1974; Adams & Brown, 1975). In an attempt to find the morphological substrate containing GABA in the SCG, we performed imunohistochemical localization for its synthetic enzyme, γ-amino butyrate decarboxylase (EC 4.1.1.15, GAD). Specific polyclonal sheep anti-GAD was a generous gift of I.J. Kopin (NIMH) and has been characterized previously (Oertel, et al, 1981).

Pairs of SCG were isolated from male Sprague-Dawley rats (200-250 gm), and frozen at -25°C in a cryostat. 8 μm sections were thaw-mounted onto chrom-alum coated glass slides. GAD antiserum was used at 1:1000 dilution in phosphate-buffered saline (PBS), incubated overnight at 4°C in a moisture box. PBS washes were used to remove unbound primary antisera. Secondary, fluorescein-conjugated antisera (Cappel Labs, West Chester, PA) was applied at 1:100 dilution in PBS for 1 hour at 4°C. Following a final PBS wash, sections were covered with 5% n-propyl gallate PBS-glycerine (1:9, Giloh & Sedat, 1982) and examined using ultraviolet optics (485 nm/520 nm; primary/secondary filter combination) on a Zeiss Photomicroscope. Alternatively, sections were incubated using the Sternberger-PAP technique (1979). Control experiments included omission of primary antisera or omission of secondary antisera. Sections were not reactive under these conditions.

The immunohistochemical localization of GAD was found to be present in intensely reactive, irregular annular structures of approximately 20 μm diameter. Safaranin-O counterstain showed these structures were not postganglionic neurons, capillary endothelia, or glial-satellite cells. Glyoxylic acid histofluorescence (De la Torre, 1981) staining of serial sections demonstrated that the GAD immunoreactive elements were not dopaminergic SIF cell neurons of the SCG. This preliminary data suggests that the GAD-immunoreactive cells may be a separate population of small-diameter neurons in the rat SCG.

82.8 GAD^+ NEURONS FOR GABA-MEDIATED INHIBITION IN KAINATE-HIPPOCAMPAL EPILEPSY. C.J. Davenport[1]* and T.L. Babb[2]. Division of Neuropathology[1] and Department of Neurology[2], Brain Research Institute and Reed Neurological Research Center, University of California at Los Angeles, Los Angeles, CA 90024.

Previous in vivo and in vitro electrophysiological studies have suggested that kainic acid (KA) induced hyperexcitability in regions "remote" (ie, CA_1) from areas of cell loss (ie., CA_3 & CA_4) is due to a loss of GABA-mediated recurrent inhibition (Lancaster, B. and H.V. Wheal, Brain Res., 295:317, 1984; Wheal et al., Electrophysiology of Epilepsy, Academic Press, 1984). The present study quantitates KA toxicity on hippocampal principal cells and inhibitory interneurons proximal and remote to the KA injection.

0.5 - 1.5 μg KA/0.2 μl volumes were injected ipsilaterally into the posterior hippocampus of rats (n=15), with survival periods varying from 1-28 days. The control animals (n=10) received either a 0.2 μl saline injection or no injection ($saline^{\pm}$ = normal). Volumetric cell densities of anterior & posterior hippocampal subregions in Nissl stained preparations included FD upper & lower, CA_4, CA_3, CA_2, CA_1, prosubiculum, subiculum, parasubiculum, and medial & lateral entorhinal cortex. Glutamic acid decarboxylase (GAD) immunocytochemistry using sheep anti-GAD and the ABC technique was used to assess KA toxicity on hippocampal inhibitory interneurons in the hilar polymorph (superior hilus, hilar taper), CA_3 radiatum, CA_3 oriens, CA_1 radiatum and CA_1 oriens.

There was no significant (α=0.05) change in pyramidal or granule cell density in both the anterior & posterior hippocampus on the side contralateral (KA^-) to the KA injection when compared to controls. In the ipsilateral anterior ("remote" KA^+) hippocampus, only CA_3 and CA_4 subregions demonstrated significant cell loss when compared to the KA^- side and to controls. Ipsilateral posterior (injection site) cell densities were significantly reduced in all subregions examined. KA ($\geq$ 0.5 μg/0.2 μl) caused no significant change in hippocampal interneuron density in all the anterior ($KA^{\pm}$) or contralateral (KA^-) posterior hippocampal subregions examined when compared to controls. The effect of KA on principal cell and inhibitory interneuron density was not concentration or time dependent within the KA concentration range or survival times examined.

GAD^+ interneuron density remained unaffected in regions remote from the site of KA injection regardless of whether there was a significant (ie., CA_3 & CA_4) or nonsignificant (ie., CA_1) change of principal neuron density. Thus KA is not selectively neurotoxic for GAD^+ interneurons. These results suggest that CA_1 hyperexcitability is not due specifically to a loss or reduction of GABA-mediated inhibition.

83.1 EFFECT OF ANTI-CHOLECYSTOKININ ANTIBODY (AB) ON MORPHINE (MOR) INDUCED SUPPRESSION OF SPINAL NOCICEPTIVE TRANSMISSION. S.N. Suberg, E.S. Culhane*, G. Rosenquist*, E. Carstens & L.R. Watkins. Dept. Animal Physiol., Univ. of Calif., Davis, CA 95616.

Proglumide, the putative cholecystokinin (CCK) antagonist, has been shown to potentiate MOR induced suppression of spinal nociceptive transmission (Suberg et al., Soc. Neurosci. Abs. 10:106, '84). Our results indicated that endogenous CCK may modulate the pain suppressive effects of opiates. Because proglumide has not been shown to bind to CCK receptors the aim of our present study was to determine if CCK is indeed acting as an endogenous opiate antagonist and if the potentiation seen previously with proglumide is due to antagonism of CCK. To accomplish this we used a more specific antagonist, an anti CCK-antibody (capacity of AB to bind S-CCK-8 is 5 fm/ml).

An agar pool was constructed around the lumbosacral enlargement to allow drugs to be placed directly on the spinal cord. Tungsten microelectrodes recorded responses of single dorsal horn cells to noxious heating (48°-54°C, 10 sec/2 min) of the hind footpad of rats receiving continuous infusion of sodium pentobarbital to maintain constant anesthesia. The femoral vein was cannulated for administration of naloxone. Recordings of heat responsive neurons were made over time, to the application of MOR (.1 µg), AB and MOR+AB. MOR remained on the cord until heat evoked responses were 50% of baseline or for 30 min if no suppression occurred. AB remained on the cord for 40 min. MOR+AB remained on the cord between 30-60 min dependent upon the cell's prior response to MOR. Between application of MOR & AB the cord was rinsed with saline and recording was continued until responses returned to baseline. Between applications of AB and AB+MOR, 2 paradigms were tested: 1) AB was removed, the cord rinsed and recording was continued until responses returned to baseline or 2) AB was removed but the cord was not rinsed off.

AB alone did not effect baseline responsivity more than ±10%. In paradigm 1 (n=5), there was no potentiation of MOR inhibition when AB+MOR was applied (n=4). In one cell there was a slight potentiation of inhibition (~30%). In the 2nd paradigm, in 2 of 4 cells studied there was a potentiation of morphine induced inhibition with application of AB+MOR. In these cells inhibition was naloxone reversible (10 mg/kg, i.v.). In the remaining cells there was no difference between MOR inhibition and AB+MOR inhibition. Though the evidence as yet is inconclusive, these initial positive results indicate that CCK could be acting as an endogenous opiate antagonist and that the potentiation seen with proglumide may be due to antagonism of CCK. The results where AB+MOR did not potentiate MOR inhibition may be due to incomplete diffusion of AB (150,000 M.W.) to recording site. Supported by UCD grant DG #512 to S.N.S.

83.2 ANTINOCICEPTIVE AND MOTOR EFFECTS OF INTRATHECAL (IT) VASOPRESSIN (VAS). C.L. Thurston*, S.N. Suberg, E.S. Culhane*, E. Carstens, & L.R. Watkins (SPON: D.J. Mayer). Dept. of Animal Physiol., Univ. of Calif., Davis, CA 95616 USA

VAS has been suggested to have a role in pain modulation based on anatomical and behavioral evidence. VAS is located in the spinal cord dorsal horn as well as in brain regions thought to have a role in analgesia. Paralleling these anatomical findings, systemic, intracerebroventricular, and IT injections of VAS have been shown to produce non-naloxone reversible analgesia suggesting that VAS can inhibit pain at multiple levels.

The effects of IT VAS were characterized in 102 rats using 5 pain tests and analyzing motor function. Baseline values on tail flick (TF), tail shock vocalization (TSV), hot plate (HP), hind paw pinch (PP), and tail pinch (TP) tests were measured prior to drug injection. VAS was injected IT in doses of 0, .25, 2.5, and 25 ng dissolved in .5 µl saline. Rats were tested for responsiveness to pain using a blind procedure 5, 20, or 40 minutes post injection. Motor functions were tested 5 min post injection, 5 min prior to pain testing, and upon completion of the pain tests.

IT VAS showed dose-related effects on pain responsiveness and motor function. A prolonged dose-dependent decrease in response to pain was observed in the TF test with 25 ng and 2.5 ng VAS. A transient dose-related decrease in response to pain on the HP test was seen with 25 ng and 2.5 ng VAS. Transient suppression of the pain responses to TSV, PP, and TP was seen with 25 ng VAS while 2.5 ng had no effect. Dose-related transient effects on motor function including flaccidity of the hind quarters, splaying of the hind limbs, and to a lesser degree, a lack of grasping and righting reflexes were seen with 25 ng and 2.5 ng VAS. The lowest dose, .25 ng VAS, had no significant effect on any of the pain tests nor on motor function.

Although IT VAS can produce motor deficits, the deficits appear to be separable from the effects on responses to pain. First, for the TSV and HP tests, hind quarter motor suppression would not prevent the rat from responding. Second, the effects on pain responsiveness generally outlasted any observable motor deficits. Third, observations made during pain testing showed that rats responding least to pain showed no signs of pain perception (i.e., no orientation to pain, vocalization, or forebody movement to escape the pain). Thus, it appears that IT VAS can exert both motor and pain suppressive effects in a dose-dependent manner. Whether these antinociceptive effects are secondary to IT VAS induced hypertension is currently under investigation. Preliminary studies show that IT VAS does increase blood pressure and possible correlations with tail flick latency are being examined.

83.3 EVIDENCE FOR A MODULATORY ROLE FOR SUBSTANCE P IN NOCICEPTION USING DESENSITIZATION TO SUBSTANCE P FOLLOWING REPEATED INTRATHECAL ADMINISTRATION. J. Sawynok and G.S. Robertson*, Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4H7

There is considerable evidence that Substance P (SP) is a primary afferent transmitter for nociceptive sensory stimulation. However, there are a variety of situations in which there is a mismatch between alterations in SP function and sensory responses, and an alternative regulatory or trophic function has been proposed (SP in the Nervous System, Ciba Fdn. Symp. 91, 1982, p. 249). Recently, we demonstrated that the intrathecal injection of SP produced hyperalgesia in the rat tail flick test (control latencies 6-9 sec) and that this response desensitized progressively following repeated injection (Br. J. Pharmacol., 1984, 82:381). In the present study, we examined the effect of desensitization to SP on the antinociceptive effect of intrathecal morphine and baclofen to provide behavioural evidence for a role for SP in the spinal antinociceptive mechanism of action of these agents. Effects of desensitization on baseline values also were monitored because if SP is a transmitter for noxious thermal stimulation, desensitization should alter these values. All drugs were injected intrathecally.

Repeated injection of SP (7.5 or 15 µg) or pretreatment with two injections of these doses of SP produced desensitization to the hyperalgesic response to SP. Desensitization was dose-related with respect to degree and duration, and was relatively specific in that the hyperalgesic responses to methysergide, a serotonin receptor antagonist, and phentolamine, an adrenergic receptor antagonist, were much less affected than SP. Pretreatment with a desensitizing regimen of SP potentiated the antinociceptive effect of morphine and baclofen when these agents were injected immediately after the regimen. However, if a 30 minute delay was permitted before the injection of morphine and baclofen, an inhibition of their effects was observed. These results support the notion that the spinal antinociceptive effect of morphine and baclofen are due to interactions with SP mechanisms in the spinal cord, but the nature of such interactions may be more complex than is presently understood. Desensitization did not produce changes in baseline responsiveness in the tail flick test. This suggests either that the hyperalgesic response to SP is due to an action at a site other than the primary afferent synapse, or if the response is at this site (a) unspecified compensatory mechanisms occur or (b) SP is not the primary determinant of tail flick latency but may play a modulatory role. (Supported by MRC Canada).

83.4 EFFECTS OF HIGH DOSE INTRATHECAL OPIATES. Harty, G.J.* and Yaksh, T.L.* (SPON: Peter J. Dyck). Laboratory of Neurosurgical Research, Mayo Clinic, Rochester, MN 55905.

Intrathecal (IT) administration of morphine produces a powerful analgesia characterized by an action at an opioid receptor, e.g. characterized by a predictable structure-activity relationship, reversed by naloxone and cross tolerance to systemically administered opiates. At higher doses non-opiate receptor mediated phenomenon have been reported (Woolf, Brain Res. 209:491, 1981). We sought to examine these effects. Rats implanted with IT catheters were divided into groups and received drugs administered in 3 µl of saline. After a 1-2 min latency IT morphine (150 µg) resulted in a striking behavioral syndrome which consisted of: 1) spontaneous agitation (SA) characterized by intense biting and scratching of the body innervated by the portions of the cord segments proximal to the catheter tip, and 2) clear hyperesthesia where light stroking of the fur over the lower abdomen and flanks (but not the face or ears) would produce violent, coordinated effects to escape and/or attack of the probe, i.e. touch evoked (TE) agitation. Quantifying the SA behavior at 1-min intervals using a 3-point rating scale and the TE behavior at 5-min intervals using a 3-point scale, revealed a peak effect at 10-15 min and near absence at 50-60 min. The animals were examined on the hot plate (HP) and tail flick (TF) at 60 min.

IT Drug	SA score (Σ60 min)	TE score (Σ60 min)	HP (sec)	TF (sec)
Saline	0	0	18	2
Morphine (150 µg)	42	5	60	60
Morphine (30 µg)	0	0	60	60
Morphine (150 µg) + Naltrexone (30 mg/kg IP)	62	6	23*	2*
Morphine (150 µg) + Morphine pellets (150 mg/5 days)	49	5	33*	2*
Sufentanil (100 µg)	0	0	60	60
Methadone (150 µg)	0	0	60	60
Naltrexone (90 µg)	0	0	15	15
Morphine-3 glucuronide (3 µg)	40	4	19	2

*$p < 0.05$ as compared to morphine dose; n = 4 each group.

These results emphasize the observation that high dose morphine produces a phenomena which has a pharmacology totally unlike that observed with lower doses. Though the mechanisms are not clear, we note: 1) that the glucuronide produces the same syndrome at 0.02 x the dose, and 2) high dose of opiates may have an antiglycinergic action. (Funds from DA-02110 and the Mayo Foundation.)

83.5 INTRATHECAL BICUCULLINE IN RATS EVOKES HYPERALGESIA AND EXAGGERATES AVOIDANCE OF CONTACT BY OTHER RATS. S. Schwartz-Giblin and D.W. Pfaff. Rockefeller University. New York, N.Y., 10021.

Chronic catheterization of the spinal subarachnoid space was performed on 14 ovariectomized female rats (220-350 g) which had subcutaneous 5 mm silastic implants of estradiol. Gross inspection and dye studies showed the catheter tips to be between the lower thoracic and lumbar spinal segments. In 7/8 rats intrathecal injections of the GABA antagonist bicuculline methiodide in doses ranging from 1nM-4nM (0.5-2μg in 1μl-7μl) produced a syndrome of hyperalgesia and stereotyped behavior which was dose dependent in individual animals. The latency to onset was 1.5-3 min; the effect was maximal by 10 min and was usually over by 20-30 min. The onset was characterized by biting and scratching the flank. Subsequently, the animals avoided light touch or a weak air jet to the proximal hindlimbs and trunk by turning, rolling or jumping. These same stimuli were innocuous in the control period or following injection of saline. The rats vocalized to tactile stimulaton and displayed aggressive pawing and biting of the instruments of stimulation. At the higher doses, rats elicited spontaneous hyperkinetic behaviors such as persistent pushing of bedding material across the test cage, and intermittent jumping and kicking often related to scratching of the flank. Intrathecal picrotoxin at a threshold dose of 3.3nM elicited the same syndrome in 3/4 rats tested. Similar responses to intrathecal strychnine sulfate (5μg) have been reported (Beyer et al. Soc.Neurosci Abstr. 310.6, 1983).

The mating behavior of 4 females during 10 min tests with stud males was compared before and from 0-10 min after intrathecal bicuculline (1nM-4nM in 5μl), with or without subcutaneous progesterone. Females often vocalized and avoided male mounts by getting into the corner, turning over(T), kicking(K) and rearing(R). An avoidance index was calculated: T+K+R/Mounts+Attempted Mounts. From 0-10 min after drug, all females had a higher avoidance index compared to the control period. By contrast, at the same time, the Lordosis Quotient (lordoses/mounts with thrusting) was not reliably reduced by bicuculline.

Our data suggest: GABA modulates spinal mechanisms related to cutaneous signalling and pain, and may thus affect responses to rat-rat contact. But in mating tests, if the male can mount well, lordosis behavior may be prepotent even during bicuculline-induced hyperalgesia. (Supported by PHS HD 13795.)

MOTOR SYSTEMS: MOTOR AND SENSORY INTEGRATION

84.1 PRETERM HUMAN INFANTS: HEART RATE AND MOVEMENT CHANGES IN RESPONSE TO TACTILE STIMULATION. C. R. Almli and S. Lofsness*, Dept. Preventive Medicine, Program in Occupational Therapy and Neural Science, Washington University School of Medicine, St. Louis, MO, 63110.

Knowledge of the premature human infant's responses to sensory stimulation is important for an understanding of the relation between development of the nervous system and behavioral ontogeny, and for an understanding of the effects of early neuropathology on behavioral development. The present study investigated the preterm infant's motor movements and heart rate changes in response to 3 modes of tactile stimulation.

Preterm infants, born at 26 to 32 weeks estimated gestational age (EGA) were tested at 1 and 3 weeks postnatal age. Heart rate and respiration were recorded (polygraph and FM tape recorder) and movements were simultaneously videotaped. While supine in their beds, punctate, brush and pressure tactile stimuli (10 grams) were applied to the left and right perioral and abdominal regions (3 trials each, 5 sec stimulation, 20 sec interstimulus internal). Heart rate and movement data were averaged over trials into 5 second bins.

Analysis of heart rate revealed that preterm infants responded with cardiac acceleration to punctate or brush modes of stimulation, and with cardiac deceleration to pressure stimulation. The motor movement data paralleled the heart rate data with increased movement to punctate or brush stimulation and decreased movement in response to pressure stimulation. These responses were obtained on tests at 1 and 3 weeks postnatal. The major difference between tests was a large increase in movement for the test at 3 weeks of age. Infants with diagnosed neuropathology (e.g., intraventricular hemorrhage) displayed complex reactions to the tactile stimulation.

These results indicate that preterm infants: (1) can discriminate punctate, brush and pressure modes of tactile stimulation; (2) may display an "orienting-like" response to certain modes of sensory stimulation (e.g., pressure); and (3) show integrated autonomic and skeletal nervous system response to sensory stimulation (in contrast to previous reports). The results also indicate that pre-term infants with and without intraventricular hemorrhage may be discriminated on the basis of movement and heart rate changes in response to sensory stimulation. (Supported by Grant USHRSA-51998)

84.2 MALDEVELOPMENTS OF VISUAL MOTION PROCESSING IN HUMANS WHO HAD STRABISMUS DURING INFANCY. L. Tychsen* and S.G. Lisberger. (SPON: J.L. Bixby) Div. Neurobiol., Dept. Physiol., U.C.S.F., San Francisco, CA.

Strabismus during the critical period is known to cause deficits in information processing in the visual cortex. We have used pursuit eye movements, and psychophysical judgements of target velocity, as probes to determine if these deficits include motion processing in humans.

The initiation of pursuit was studied in 7 adult subjects who had strabismus in infancy (concomitant esotropia, "latent" fixation nystagmus, and dissociated vertical deviation). Subjects were non-amblyopic, i.e. optotype acuity was normal in both eyes. Small targets were presented in individual trials of ramp motion. Eye position was recorded using a scleral coil. Eye acceleration, averaged over the first 100 msec of smooth eye velocity, was used to estimate the open-loop response of the pursuit system.

Strabismics had a naso-temporal asymmetry in the initiation of pursuit. Viewing monocularly, strabismics initiated pursuit weakly for temporally-directed target motion, and normally for nasally-directed target motion. The movements of the two eyes were always conjugate, and the asymmetry flipped direction when viewing changed from right to left eye. Maximum temporally-directed eye acceleration was 2-8X lower than maximum nasally-directed acceleration. Strabismics often initiated pursuit in the wrong direction. When the target moved temporally, they accelerated nasally. By starting the target at different locations in the visual field, we were able to map the topography of this defect; wrong-way pursuit was most pronounced for targets 12 deg or more eccentric in the nasal visual field. Strabismics also had up-down asymmetries of pursuit initiation. For targets in the lower visual field, downward pursuit acceleration was 2-6X lower than upward pursuit acceleration.

To determine if these defects were due to abnormal visual processing, we used the method of S.P. McKee and L. Welch (J Opt Soc Amer 2:243, 1985) to test foveal velocity discrimination in 2 strabismics. Targets appeared in individual trials of horizontal ramp motion, at one of five unpredictable velocities (range 9-19°/sec). The subject judged whether each trial was faster or slower than the perceived mean of the range. Strabismics, like normals, were able to divide the velocities into slow or fast categories, but viewing monocularly, they judged temporally-directed targets to be moving 15-35% slower than nasally-directed targets that were actually moving at the same velocity. The psychophysical error, and the pursuit defect, correlated with the magnitude of the strabismus.

We conclude that maldevelopments of visual motion processing are closely related to strabismus. The lack of binocularity during the critical period, however, makes it difficult to assign cause and effect. (Supported by Fight for Sight Inc. of NYC, Nat. Children's Eye Care Foundation of Wash DC, and NEI grant EY05431).

84.3 **SENSORY GATING DURING STEREOTYPED BEHAVIOR IN THE RAT.** R.T. KNIGHT and S. BRAILOWSKY. Dept. of Neurology, Univ. of Calif., Davis, VAMC, 150 Muir Rd., Martinez, Calif., 94553

The effects of stereotyped behavior on sensory transmission were investigated with auditory evoked potential and EEG power spectra techniques. Chronically implanted, free-moving F344 rats (n=8) were recorded while alert and immobile and during grooming episodes. In each behavioral state, brainstem auditory potentials (BAEP, 100-3,000 Hz bandpass, 11/sec stimulation rate) and longer latency auditory potentials (AEPs, 1-300 Hz bandpass, 0.5/sec stimulation rate) were recorded from a vertex electrode to free field clicks (0.1 msec, 55 dB above BAEP threshold). EEG power spectra (0-32 Hz) was simultaneously recorded from the same electrode. Behavioral state had no effect on the amplitude or latency of BAEP waves I,II-III, IV or the following negativity (4.6 msec). In the alert and immobile animal a myogenic N7-P12 potential was recorded which was associated with a startle response at higher intensities. Following the myogenic response, prominent (25 - 90 uV) neurogenic N17, P23, N38 and N50 AEPs were recorded in all animals. In contrast to the BAEP, the myogenic P12 and all neurogenic AEPs had significant amplitude reductions during grooming periods (P12 , $p < 0.01$; N17 , $p < 0.05$; P23 , $p < 0.001$; N38 , $p < 0.002$; and N50 , $p < 0.001$). These attenuations were accompanied by a theta peak in the power spectra (7.17 +/- 0.33 Hz) which was absent in the alert, immobile animal. The unaltered BAEP during grooming indicates intact lemniscal conduction up to the level of the inferior colliculus. The suppression of the startle associated N7-P12 potentials may be mediated at sub-collicular levels. Further data on the intracranial sources of the behavior dependent neurogenic AEPs is necessary to determine the locus of their inhibition. The association with a prominent theta rhythm, however, supports involvement of hippocampal structures.

84.4 SINGLE UNIT RESPONSES IN THE MEDULLARY ELECTROSENSORY NUCLEUS IN THE LITTLE SKATE. J.G. NEW .Dept. of Biology, Wesleyan University Middletown, CT 06457

Single unit responses to localized electric fields were recorded in the dorsal octavolateralis nucleus (DON) to determine the response characteristics of different cell classes. Little skates, Raja erinacea, were anesthetized during surgery, then decerebrated, and immobilized with tubocurarine chloride (1mg/kg). A concentric bipolar stimulating electrode was placed in the lateral mesencephalic nucleus (LMN); the principal midbrain target of ascending DON efferents. E fields were presented as DC step uniform fields or small localized fields from a dipole surface.

Several different classes of cells could be distinguished by responses to E field presentation and antidromic responses to LMN shock; afferent fibers of the anterior lateral line nerve (ALLN), DON efferent cells ascending to the LMN, and local DON interneurons. ALLN fibers possessed very small excitatory receptive fields (RFs) at threshold stimulus intensities which could usually be isolated to the area of a single ampullary pore. These responded to cathodal stimuli with increased tonic activity, increasing in frequency with increasing stimulus intensity. Ascending efferent cells, identified by antidromic responses to LMN shocks, possessed larger ipsilateral RFs encompassing several pores with no evidence of an inhibitory surround. Efferents responded to cathodal fields with an initial burst of spikes followed by an elevated rate of firing. The frequency of the burst spikes increased with increasing stimulus intensity as the response latency decreased. Three classes of interneuron response could be discerned: 1) Cells that exhibited activity indistinguishable from the efferent cells but that were not activated by LMN stimulation. A minority (<3%) possessed only RFs contralateral to the DON. 2) Cells that possessed larger and more diffuse RFs and responded to increasing stimulus intensity with tonic activity of increasing duration and spike frequency. 3) Cells with very large and very diffuse RFs that responded to cathodal stimuli with an elevated bu irregular firing rate with variable latency and temporal pattern.

All of the cells recorded within the DON were excited by presentation of a cathode and inhibited by presentation of an anodal field. The small RFs of the DON efferents reflect limited convergence of ALLN fibers in ascending pathways, and the uniform cathodal excitability of these cells and other DON neurons differs from previous studies in different fish species.
(Supported by a Sigma Xi Grant-in Aid of Research.)

84.5 DIFFERENTIAL PROJECTION OF THALAMIC NEURONS UPON THE NUCLEUS OF THE BASAL OPTIC ROOT AND PRETECTAL NUCLEUS LENTIFORMIS MESENCEPHALI. K. V. Fite, L. Bengston* and N. Montgomery. Division of Neuroscience & Behavior, University of Massachusetts, Amherst, MA.

Utilizing both anterograde and retrograde transport of HRP, we have shown that neurons which are postsynaptic to the retinorecipient thalamic neuropil of Bellonci project to a region of the ventral mesencephalon which includes the nucleus of the basal optic root (nBOR). In addition to the primary projection from the contralateral retina, nBOR thus appears to receive second-order optic input from the ipsilateral anterior thalamus (Montgomery, et al, J. comp. Neurol., 203: 595-612).

Recently, we have further observed a second population of thalamic neurons which project to the pretectal nucleus lentiformis mesencephali (nLM). Following microinjections of crystalline HRP into nLM, retrogradely HRP-filled neurons were seen in the ventrolateral nucleus and in the most caudal portion of the "lgn" and "nucleus rotundus" cell groups (terminology of Frontera, 1952). Many of these neurons extend long dendrites laterally into the second major thalamic optic neuropil, corpus geniculatum. A differential retinal distribution of ganglion cells also exists which distinguishes the first-order optic projection to nBOR vs that to nLM. The peripheral retina appears to be more substantially represented in the retinofugal projection to nBOR, while the central retina predominates in the retinal projection to nLM. These neuroanatomical relationships suggest that major differences exist in the organization of both first and second-order visual projections to these extratectal, mesencephalic optic nuclei which may be related to central vs peripheral regions of the visual field and, functionally, to the initiation and/or modulation of compensatory oculomotor behaviors. (Supported by NSF BNS 8209026)

84.6 TECTO-RETICULO-SPINAL NEURONS HAVE PHASIC DISCHARGE RELATED TO HIGH BUT NOT LOW VELOCITY SACCADIC GAZE SHIFTS. D.Munoz and D.Guitton. Montreal Neurological Institute, Dept. Neurology and Neurosurgery, McGill Univ. Montréal, Québec, H3A 3B4, Canada

Tecto-reticulo-spinal neurons (TRSNs) are normally silent in the alert cat looking spontaneously about the laboratory. However, when the hungry cat is presented with a food target, TRSNs can show gaze related discharges that are both sustained and phasic. We believe that the sustained discharge maintains cells, at a particular collicular site, active until the saccade associated with that site is finally triggered. (Brain Res 1985 in press). The phasic discharge is discussed below. Methods: 22 TRSNs were recorded in the superior colliculus (SC) of 4 alert cats whose heads were either fixed or free. Cells were antidromically identified by stimulation of either the spinal cord at C1 or the predorsal bundle rostral to the abducens nucleus. Eye and head movements were recorded with the magnetic search coil technique. EMG activity of dorsal neck muscles was monitored. Results: When observed, the movement-related phasic bursts were well correlated to the amplitude and direction of the gaze shift and the accompanying bursts of neck EMG activity. A characteristic feature of the phasic bursts was their inconsistent presence even if the amplitude and direction of the gaze shift was optimal for that cell. This was particularly evident in a paradigm where the cat oriented to either a visible or an imagined food target. In this task, the target, visible to one side of a rectangular opaque barrier, was fixated by the cat. The target then disappeared behind the barrier and either reappeared on the other side, in the TRSN's visual receptive field, or remained hidden behind the barrier. The cat predicted the reappearance of the target and oriented irrespective of whether the target reappeared (visible target) or not (imagined target). Gaze shifts to both the visible and the imagined targets were preceded by a sustained discharge. When the target was visible, the cell also discharged a high frequency burst of spikes whose onset was tightly correlated to that of the gaze shift. This phasic component was usually absent when the cat oriented to the imagined target. In this condition, the gaze shifts were generally slower than those to the visible target. However, in those few trials where high velocity gaze shifts were directed at the imagined target, TRSNs had a phasic burst. Conclusions: The phasic bursts preceded a population of saccadic gaze shifts whose directions and amplitudes (vectors) defined a movement field. But the cat was capable of generating saccadic gaze shifts along the optimal vector (head-fixed or head-free) without these bursts in the TRSN pathway. Bursts in the TRSN pathway were observed when the target was a very "arousing" stimulus and coincided with an increase in the velocity of the orienting movement. (Supported by MRC, Canada.)

84.7 HOW ARE SONG SYLLABLES REPRESENTED IN THE BRAINS OF AWAKE SONGBIRDS? D. S. Vicario and F. Nottebohm. The Rockefeller University, New York, NY 10021

We studied the functional organization of a nucleus in the vocal control system of songbirds: the hyperstriatum ventralis, pars caudale (HVc). HVc projects to nuclei in the motor pathway for song and lesion experiments have shown that it is essential for normal song production. Recordings made in awake songbirds have shown that some HVc neurons have song-related activity, and this activity can be specific to the syllable produced (McCasland, 1983). Interestingly, HVc's volume is correlated with the size of the individual bird's learned song repertoire. Could this mean that particular syllables are associated with sub-regions of HVc? HVc has also been shown to receive auditory input and birdsong appears to be an especially effective stimulus (Margoliash, 1984). How is the auditory input from particular syllables distributed to neurons with specific motor associations?

To address these questions, recordings were made in both anaesthetized and awake, freely-moving zebra finches and canaries. In order to carry out a spatial analysis of sensory and motor activity, 4-7 fine wire electrodes were chronically implanted in the left and/or right HVc. Signals were led off through a flexible cable and multichannel commutator. These enabled directly comparable recordings to be made simultaneously at multiple sites.

Auditory responses to artificial (tone and noise bursts) and natural (song and song fragments) stimuli were studied in both awake and anaesthetized birds. Auditory evoked potentials with a short, stable latency, often accompanied by multi-unit activity, were seen at all HVc locations. The pattern of response depended on the stimulus, the recording site, and the bird's state. For instance, when song or syllable pairs extracted from song were presented to an anaesthetized bird, responses to the second and later syllables were weak or absent; however, in the awake bird, there was a response to each syllable. Single units had either irregular bursting or very low spontaneous activity and variable auditory responses, as others have reported. We are attempting to define factors contributing to this variability, which seems greater in the awake preparation.

We also recorded in awake birds during active song with the same electrode arrays. "Silent" units with no spontaneous or auditory activity were often recruited during song. Some features of single and multi-unit activity were similar to those noted by McCasland (1983), such as burst patterns related to the pattern of song syllables being produced. Most interestingly, simultaneous recordings from electrodes in different sites showed differences in timing and patterns of song-related activity. This may be evidence that subregions of HVc contribute particular influences to the motor pathway. (Supported by NS17991, MH39319, MH15125)

84.8 ACOUSTIC RESPONSE PROPERTIES OF MOTONEURONS INNERVATING THE STAPEDIUS MUSCLE OF THE CAT. J.B. Kobler, S.R. Vacher*, and J.J. Guinan. Dept. of Elec. Eng. & Comp. Sci., M.I.T., and Eaton-Peabody Lab., Mass. Eye & Ear Infirmary, Boston, MA 02114.

Retrograde transport studies have shown that a large number of motoneurons (>1100) innervate each cat stapedius muscle, and that they are located in a number of different perifacial and periolivary areas (Shaw, M.D. and Baker, R., J. Comp. Neur. 216:10, 1983; Joseph, M.P. et al., J. Comp. Neur. 232:43, 1985). Stapedius EMG responses following partial lesions of the stapedius motoneuron pool suggest that stapedius neurons in different locations might have different inputs and response properties (McCue, M.P. and Guinan, J.J. Soc. Neurosci. Abst. 9:1085, 1983). We have now recorded the responses of stapedius motoneurons to acoustic stimuli; the results show that the stapedius motoneuron pool does have functional subdivisions.

Cats were anesthetized with ketamine or decerebrated (both preparations produced similar results), and were paralyzed with gallamine to prevent muscle movement. The dorsolateral surface of the stapedius muscle and adjacent facial nerve were exposed surgically. Single fibers in the facial nerve fascicles which innervate the stapedius were impaled with glass micropipets.

Stapedius units exhibited high thresholds (>75 dB SPL) to acoustic stimuli and responded with regular discharge patterns characteristic of motoneurons. Units were divided into four groups based on their responses to sound: 1) "Binaural-Or" units (47% of 116 units) responded when sound stimulated either the left or the right ear and often showed summation when both ears were stimulated simultaneously; 2) "Binaural-And" units (12%) responded only when both ears were stimulated; 3) "Ipsilateral" units (17%) responded selectively to ipsilateral stimuli (showing little or no responses to contralateral stimuli); and 4) "Contralateral" units (24%) responded selectively to contralateral sounds. Ipsilateral and contralateral units frequently showed lowered thresholds and higher discharge rates in response to binaural stimuli.

Frequency tuning curves show that most stapedius motoneurons are maximally sensitive to frequencies between 1 and 2 kHz. All were broadly tuned, and, for levels of 105 dB SPL, many responded throughout the frequency range from less than 1 to greater than 30 kHz. Spontaneous activity was found in 10% of the units; 75% of those with spontaneous activity were of the "binaural-or" response type and had relatively low thresholds.

We conclude that the recruitment order of stapedius motoneurons will be strongly influenced by the spatial position and spectral characteristics of sounds eliciting the acoustic reflex. Thus, in this motoneuron pool, recruitment order is not solely a function of intrinsic motoneuron properties such as size or surface area.

84.9 SOMATOSENSORY MODULATION OF JUVENILE PLAY IN THE RAT. S.M. Siviy and J. Panksepp. Dept. Psychology, Bowling Green State University, Bowling Green, OH 43403.

Rough-and-tumble social play in the juvenile rat is best characterized as an energized level of social activity, including chasing, jumping, rough grooming and wrestling. Therefore, this activity involves the processing of a multitude of sensory information. In the following work, we evaluated the involvement of somatosensory input in the play of juvenile rats at various levels of neural integration. A social deprivation paradigm was used, with pups housed individually and observed for 5 minute periods on test days (see Panksepp & Beatty, Behav. Neural Biol., 1980, 30, 197).

Anesthetization of the dorsal body surface of juvenile rats with xylocaine resulted in a concentration-dependent reduction in the frequency of pinning, an indicator variable of play, with a 2.0% concentration reducing pinnning by 36%. Play motivation was not impaired by this concentration of xylocaine. We next sought to analyze the central modulation of somatosensory involvement in play by examining involvement at several points along the neural hierarchy. Electrolytic lesions placed within the ventrolateral aspects of the brain stem resulted in a 51% reduction in the frequency of pinning, while having no reliable effect on play motivation. Electrolytic lesions of either the parafascicular area of thalamus or posterior thalamus reduced pinning by 64% and 62%, respectively. Lesions of similar size placed within the ventrobasal complex of the thalamus had minimal effects on pinning. While lesions of the parietal cortex resulted in a 65% reduction in frequency of pinning, generalized activity was also increased among these animals by 123%, suggesting that any play deficits may have been due to a generalized enhancement of activity and/or impaired attentional abilities.

It is concluded that somatosensory information, traveling via ventral brain stem pathways and terminating in parafascicular and perhaps posterior thalamus is involved in mediating the elaboration of juvenile play in the rat. Although not yet conclusive, the data do not suggest a role for parietal cortex in the modulation of play, supporting past work (Soc. Neurosci. Abst., 1984, 10, 612).

84.10 ORGANIZATION OF THE FIFTH SOMATIC SENSORY CORTEX(SV) IN THE CAT. A Mori*, N Matsuura*, K Kagaya*, T Seki*, H Hiraba* and R Sumino*. (SPON:Y Shinoda) Dept. of Physiol., Sch. of Dent., Nihon Univ., Chiyoda-ku, Tokyo 101, Japan.

We examined the physiological properties of the neuron in the anterior suprasylvian sulcus (ASSS) and suprasylvian gyrus of the cat's cortex. Under ketamine anesthesia a chamber was installed over the skull surrounding the SI, SII and SIII. A single tungsten in glass microelectrode was inserted into the SI, SII, SIII and ASSS, and was used for intra-cortical microstimulation (ICMS), and also for recording unitary spikes from the cortex. The motor effects were examined either by recording EMG or observing movements. The receptive fields of neurons were examined by using natural somesthetic stimulation.

A new somatic sensory area of the body surface in the cat was found in the rostro-caudal part of the medial bank of the ASSS by recording unit activites responding to tactile stimulation. This area was isolated from SI-SIV.This region was located in area 5. We have designated this area as the Fifth Somatic Sensory Cortex (SV). Cells with receptive fields on the face formed the rostral aspects of the ASSS. The tail and hindlimb areas are situated in the caudal aspect of the medial ASSS. The trunk area was located in the medial bank of the ASSS between the fore- and hindlimb regions. The majority (68%) of somatic cells studied in this region responded to a light touch of the skin. The other somatic cells responded to movement of the hair by a gentle stream of air (32%). In addition, a few neurons responded to a light touch of the skin and visual stimuli. However, neurons of the SV did not receive input from receptors in the deep structure of the face and the body. Neurons in the SV have large receptive fields from the contralateral side of the body and face. The receptive field of neurons in the trunk area was larger than in the other areas of the SV.

ICMS of the face region in the medial bank of the ASSS produced eye blinking or whisker movement on the contralateral side of the face using 10μA or less. The minimum threshold current for movement of eye blinking was 2μA. The threshold current that produced eye blinking was lower than that which produced whisker movement. However, ICMS of the limbs or trunk regions in the SV did not show any movement using 20μA or less. The latencies of the EMG responses in the face muscles, measured from the start of ICMS, ranged from 13-17ms (average:15ms). Neurons in the motor effective area received afferent input from receptors in the skin structures in the region of the face which was related to that movement. However, ICMS of the first somatic sensory area (SI) did not show any movement using 20μA or less.

84.11 THE ORGANIZATION OF TECTAL PROJECTIONS TO THE VENTRAL MIDBRAIN IN RANA PIPIENS. T. Masino and P. Grobstein. Dept. of Anatomy., Univ. of Chicago, Chicago, ILL. 60637

The role of direct descending projections from the optic tectum has been the focus of much previous work on the neuronal basis of orienting behavior in the frog. Recent studies from this lab suggest that indirect descending tectal projections, involving relays in ventral midbrain tegmental nuclei, may also be important in orienting behavior. Cells in the nucleus of the medial longitudinal fasiculus (nMLF), the anterodorsal tegmental nucleus (AD), and the nucleus profundus lateralis (LP) all have descending axons in a ventral white tract which when lesioned unilaterally abolishes orienting turns in one direction (Kostyk and Grobstein, submitted). That each of these nuclei themselves receive tectal input is suggested by several general studies of tectal efferent organization, but there has been no specific description of the organization of tectal projections to the ventral mesencephalon. To provide such a description, we have studied patterns of anterograde labelling following horseradish peroxidase injections into the optic tectum.

Following multiple HRP injections distributed widely across one tectal lobe, prominent collateral branching from the tectal efferent bundles was evident throughout their midbrain trajectory, both contralateral and ipsilateral. Dorsally, collateral branches and associated finer fibers with bouton-like swellings defined a rostro-caudally oriented columnar terminal zone lateral to the compact tegmental grey matter. Ipsilaterally, this zone extended from the rostral to the caudal end of the midbrain; contralaterally, it was less extensive caudally. Rostrally, this dorsal terminal zone overlies the LP on both sides of the brain, confirming earlier reports of a bilateral tectal projection to this structure. More caudally, it overlies cells identified by some workers as a continuation of the LP and by others as the magnocellular nucleus of the torus. Medial to the dorsal columnar terminal zone, branched fibers bearing swellings reached the anterodorsal nucleus on both sides of the brain. Ventrally, prominent collaterals were associated with the nMLF, more dramatically ipsilaterally, but also contralaterally. These findings confirm earlier reports of tectal projections to these nuclei and indicate that these projections too are bilateral. Collaterals were also apparent bilaterally in the area of the isthmic reticular nucleus. Prominent collaterals into the vicinity of the oculomotor and trochlear nuclei were also evident, as noted by some but not by all previous workers. We were unable to confirm the suggested existence of a projection into the ventrally located interpeduncular nucleus. In addition to the more prominent projections, our material also suggested the existence of a more diffuse terminal zone, occupying much of the ventrolateral tegmentum, adjacent to the anteroventral, posterodorsal, and posteroventral nuclei. Labelling patterns following single HRP injections placed either rostrally or caudally were quite similar to each other and, in the distribution of labelling, to the described patterns following multiple injections.

In general, our findings indicate the existence of quite substantial projections from the tectum into more ventral midbrain structures. These projections could certainly provide a basis for indirect descending tectal outflow paths, and may indicate that a significant amount of the post-tectal information processing involved in orienting occurs in the ventral midbrain, rather than in more caudal structures. Our findings also provide further evidence that the efferent projections of different tectal regions are quite similarly distributed.

84.12 SHORT AND LONG TERM EFFECTS OF UNILATERAL VESTIBULAR LESIONS ON POSTURE AND ORIENTING MOVEMENTS IN THE FROG. C. Comer, J. Schotland* and P. Grobstein. Dept. Biol. Sciences, Univ. of Illinois at Chicago, Chicago, Il. 60680.

Frogs (Rana pipiens) capture prey with orienting movements of the head and body and a rapid flick of the tongue. Previous research (Comer and Grobstein, J. Comp. Physiol., 142:141, 1981) has suggested that once these movements are triggered by a sensory stimulus, they can proceed to completion without the use of sensory feedback concerning the position of the stimulus. We have been interested in determining if proprioceptive feedback participates in the control of these orienting movements.

To characterize the extent of vestibular involvement in orienting behavior, we have analyzed the visually and tactually elicited movements of frogs with selective unilateral lesions of the VIIIth nerve. In a group of eight adults we cut either the anterior or posterior branch of the left VIIIth nerve and then measured their orienting behavior using standard perimetric techniques. Lesions of the posterior branch of VIII (innervating the post. vertical canal, auditory papillae and lagena) produced a slight postural asymmetry, but had little or no effect on vestibular reflexes and orienting movements. Abnormalities in posture disappeared with 1 week.

Lesions of the anterior branch of VIII (innervating the ant. vertical and horizontal canals, sacculus and utriculus) produced marked postural asymmetry, disrupted vestibular reflexes and caused a clear abnormality in visual and tactile orienting behavior. These frogs responded readily to prey items but their orienting and snapping responses (to both visual and tactile stimuli) usually overshot their target. Though the metrics of movement were thus abnormal, the amplitude of orienting turns still varied systematically with target position. In addition, the degree of overshooting was much greater for movement toward the side of the lesion than for movements away from it. Within 2-4 weeks, the animals compensated for the postural and reflex deficits. However, the abnormality in orienting movements persisted for as long as the animals were tested (5 months).

These results indicate (1) unilateral loss of vestibular afference can produce abnormalities in orienting movements which are not directly dependent on changes in posture or vestibular reflex function. (2) Circuitry related to the control of orienting movements possesses a much different potential for vestibular compensation than that related to posture and reflex control. (3) The results suggest that movements of the head and body of the sort used in orientation may not be entirely centrally generated and that proprioceptive signals may play a role in specifying the final position of the response.

84.PO COMPARISON OF HUMAN AND PRIMATE PERFORMANCE IN A SUSTAINED ATTENTION TASK

G. Güçer, L. Viernstein*, and R. Szymanski*
Department of Neurosugery, Francis Scott Key Medical Center, a Johns Hopkins Institution, Baltimore, MD 21224

The performance of 3 humans and 4 monkeys were compared in two tasks, one using tactile and the other using auditory stimuli. Both tasks were designed to avoid responses to predictable stimuli while requiring sustained attention of the subject for maximum performance. The subjects were cued that the tactile task could be performed by the presence of a green light which was turned on at the beginning of the task and remained on throughout the task. Random vibratory stimuli of variable amplitude and duration were then delivered to the glabrous skin of the right hand. The left hand was used to press a lever for response which was allowed to occur up to 1 sec after the start of the stimuli. Humans were instructed that detection of a 10 Hz stimulus would result in a high score which was the object of the task, and the monkeys were rewarded with a few drops of fruit juice for correct responses.

The performance (% score) of humans and primates were charted as a function of stimulus durations at various stimulus amplitudes. Both humans and monkeys only need 100 msec duration threshold vibratory stimulus (10 Hz) to perform at 80%. Below 100 msecs the performance dropped severely. Both humans and monkeys were then required to not only detect but to discriminate between frequencies of randomly occurring vibratory stimuli (10 Hz vs 100 Hz).

Again the results show that both humans and monkeys need only 100 msecs of threshold stimulus to detect and discriminate among stimuli. However the reaction times were prolonged by 250 msecs as compared to the case when only detection was needed for a correct score. A similar task using auditory stimuli demonstrated a similar detection and discrimination response.

We conclude that human and primate performance is very similar in the task of our paradigm. Humans and primates require 100 msecs of threshold stimulus to detect and discriminate randomly occurring auditory and vibratory stimuli. However, the reaction time increased by 250 msecs when they were required to discriminate. We argue since humans report that they must decide whether the stimulus is 100 Hz or 10 Hz after detection that discrimination must occur in the period beginning at 100 and ending at 350 msecs after the onset of the random stimuli in this paradigm.

84.PO NEURAL ACTIVITY IN THE PERIARCUATE REGION DURING VARIOUS EPOCHS OF MONKEY BEHAVIOR IN A GO NO-GO PARADIGM

L.Viernstein*, G.Gucer, R.SZYMANSKI* (Spon: M.Greenberg)
Department of Neurosurgery, Francis Scott Key Medical Center, a Johns Hopkins Institution, Baltimore, MD 21224

The object of this report is to describe our exploration of the functional properties of neurons in the periacuate region of the monkey cortex. The monkeys were trained in a paradigm as described in the previous paper to make decisions about arriving stimuli and to respond only to contingent stimuli. Previous studies by us and others have shown that ablation of the periarcuate region causes severe deficits in paradigms such as we are using. Thus in monkey this region plays some crucial role in this type of paradigm. As shown in the previous paper the performance scores and timing of humans and monkeys were found to be very similar. Verbal reports of humans suggests that there is a temporal order to the behavorial events in the paradigm. The sequence can be characterized by: 1) a state of attentiveness in awaiting the stimulus arrival, 2) a detection of stimulus presence, 3) a discrimination phase to determine whether the stimulus is contingent, 4) a decision period of whether or not to act, and finally, 5) the action if the stimulus is contingent.

While the monkeys were performing these tasks the single unit activity of neurons in the periarcuate region of the cortex was observed. Neurons were found in this region that were excited or inhibited for short periods after the time that the stimulus was presented. The various periods during which these neurons were active could be associated with various epochs of the information processing steps. In particular some neurons were found that had activity related to the detection of the stimulus onset. These neurons were active for both the rewarding and the non-rewarding stimuli. Other neurons were found that were active during the time period in which discrimination must occur. These neurons were active only when the rewarding stimulus occurred. Other neurons were found that were active about 200 msecs before the onset of movement. The verification of these associations were made by shifting the time during which the named epoch can occur while noting the corresponding shift in timing of the neural activity.

The results show that neurons can be identified in the periarcuate that play an important role in go no-go tasks with regard to the decision making required.

85.1 SEX DIFFERENCES IN ETHANOL SENSITIVITY AND METABOLISM IN THE SYRIAN HAMSTER. H.B. Moss*, R.J. Salin-Pascual*, P.R. Giri*, D. Goldman*, and L. Tamarkin*, (SPON: G. Merriam). Laboratory of Clinical Studies, DICBR, NIAAA and Clinical Psychobiology Branch, NIMH, Bethesda, MD 20205.

Syrian hamsters preferentially select ethanol over water in a free-choice situation, with female hamsters showing a lower ethanol preference than males. We have evaluated sex differences in both ethanol sensitivity and liver alcohol dehydrogenase activity to determine how these correlate with preference patterns. Adult male and female Syrian hamsters (n=6/group) were administered by IP injection one of four different doses of ethanol (10% w/v). Duration of loss of righting reflex (LRR) was measured. Recovery of righting reflex (RRR) was defined as the time at which the hamster was able to right itself twice in one minute. At RRR a blood sample was obtained by cardiac puncture for measurement of blood ethanol concentration (BEC). Determination of liver alcohol dehydrogenase activty was performed on samples from alcohol-naive male and female hamsters using an established assay. At the three highest dosages, males had a significantly longer duration of LRR. Although BEC upon recovery was higher in females at each dosage level, significance was achieved only at the 3.5 gm/kg dose.

Dose: (gm/kg)	Sex:	%LRR:	DURATION LRR: (MIN.)	BEC AT RRR: (MG./100 ML.)
4.0	F	100	60.43±19.0*	223.8
	M	100	145.2±74.0	196.6
3.5	F	66.6	45.45±12.4**	301.1 #
	M	83.3	151.38±75.5	285.5
3.0	F	66.6	23.1±9.0***	240.1
	M	100	70.76±10.0	221.5
2.7	F	33.3	12.2±4.2	265.1
	M	50	23.1±4.0	237.0

*p<.05, **p<.006, ***p<.0001 #p<.005

Liver alcohol dehydrogenase activity of female hamsters was approximately twice that of males and about three times that of the male Fisher rat. The results indicate that female Syrian hamsters are more resistant to the ataxia-producing effects of ethanol probably on the basis of more rapid metabolism. The BEC data upon recovery suggests that there may also be a differential CNS sensitivity between male and female hamsters. It appears that in this animal model, sex specific preference for ethanol correlates with greater sensitivity and less rapid metabolism.

85.2 CEREBRAL NEUROTRANSMITTER RECEPTORS IN RAT LINES SELECTED FOR ALCOHOL-RELATED BEHAVIORS. E.R. Korpi* (SPON: L. Sellin). Research Laboratories of the Finnish State Alcohol Company (Alko Ltd), SF-00101 Helsinki, Finland.

As a part of ongoing research on the neurochemical differences in the central nervous system between rat lines selectively bred for low and high voluntary alcohol consumption or sensitivity to ethanol-induced motor-impairment, the dopamine and opiate receptors of these lines have been studied. Naive male rats of about 250 g were used. After decapitations, the brains were quickly excised, striatae and olfactory tubercles dissected for dopamine D-2 receptor assay and forebrain hemispheres for delta-opiate receptor assay. The tissue pieces were stored at -70°C in plastic containers. The D-2 receptor numbers and affinities were determined with [^{3}H]spiperone as a ligand (20 to 800 pM), (-)-sulpiride (3 μM) defining the specific binding in the presence of physiological extracellular sodium concentration. The delta opiate receptors were assayed using [^{3}H]-D-Ala^2-D-Leu^5-enkephalin as a ligand (0.1 to 20 nM), unlabelled D-Ala^2-D-Leu^5-enkephalin (1 μM) defining the specific binding in the presence of morphiceptin (3 μM) to block mu-receptors in the absence of ions. The brain membranes were incubated with ligands for 15 min at 37°C, then filtered on glass fiber discs under vacuum, and washed three times with ice-cold incubation fluid. The spiperone binding displayed a single binding site in striatum and olfactory tubercle as deduced from straight Scatchard plots and Hill coefficients close to 1. No differences in D-2 receptor numbers or affinities were observed between the rat lines. In vitro, ethanol was also a poor inhibitor of D-2 receptor binding, causing only 20 % decrease of [^{3}H]spiperone (50 pM) binding at the concentration of 1000 mM. Analysis of delta-receptor binding revealed a single binding site in cerebral hemispheres with a K_D of about 4 nM and B_{max} of about 5 pmol/g original tissue weight. Our preliminary experiments on alcohol drinking (AA) and non-drinking (ANA) rat lines suggest that in the alcohol drinking rat line there are fewer delta-opiate binding sites with higher affinity towards the ligand than in the non-drinking line. Recently, ethanol has been shown to inhibit opiate binding in vitro, especially that by delta receptors, thus warranting further studies on the possible line difference in these receptors.

85.3 REGIONAL BRAIN SEROTONIN CONTENT IN ALCOHOL-PREFERRING AND -NON-PREFERRING RATS FROM THE N/Nih HETEROGENEOUS STOCK. J.M. Murphy, W.J. McBride, L. Lumeng* and T.-K. Li*, Dept. Psychiatry, Biochemistry and Medicine, Inst. Psychiatric Research, Indiana Univ. Sch. Medicine, Indianapolis, IN 46223.

Many studies have attempted to establish a relationship between brain serotonin (5-HT) and alcohol-drinking behavior, but findings have been equivocal. We have shown previously that rats of the selectively-bred alcohol-preferring P line exhibit lower levels of 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) in the cerebral cortex, hippocampus, thalamus and hypothalamus when compared with the alcohol-nonpreferring NP line (Murphy et al., Pharmacol. Biochem. Behav. 16: 145, 1982). Moreover, 5-HT uptake inhibitors have been found to reliably decrease alcohol consumption in the P rats (Murphy et al., Alcohol, in press). The present investigation was designed to test the generality of this relationship by examining brain monoamine contents of rats from the N/Nih heterogeneous stock which differ in alcohol preference. The N/Nih rats exhibit a wide range of individual differences in alcohol-drinking behavior when tested with food, water and a 10% (v/v) ethanol solution freely available. After testing, ethanol was withdrawn from those selected for study for at least three weeks. Animals with high preference (HP; N=13; 6.8 ± 0.2 g ethanol/kg body wt/day) and low preference (LP; N=15; 0.2 ± 0.1 g/kg/day) were killed by near-freezing in liquid nitrogen. The brains were dissected at -20°C into the cerebral cortex, corpus striatum, hippocampus, thalamus, hypothalamus and midbrain. The brain regions were stored at -70°C until assayed for monoamine contents by HPLC with electrochemical detection. Compared with the LP rats, the HP animals had significantly lower contents of 5-HT in the thalamus (5.88 ± 0.17 vs. 6.39 ± 0.17 nmoles/g) and hypothalamus (7.20 ± 0.26 vs. 7.87 ± 0.18 nmoles/g). The HP rats also had significantly lower levels of 5-HIAA in the thalamus and hypothalamus, and had lower contents of dopamine (DA) and norepinephrine (NE) in the thalamus. No other regional brain differences between the HP and LP groups were observed for 5-HT, 5-HIAA, NE, DA, and the DA metabolites 3,4-dihydroxyphenylacetic acid and homovanillic acid. Taken together with the previously observed differences between the NP and P lines in the regional brain contents of 5-HT and 5-HIAA, the present findings with the N/Nih rats suggest a possible role for 5-HT neuronal systems of the hypothalamus and thalamus in the mediation of preference for alcohol. (Supported by AA 03243).

85.4 HUMAN CEREBROSPINAL FLUID CONTAINS Protein III, A SYNAPTIC VESICLE-ASSOCIATED PHOSPHOPROTEIN. M.D. Browning, E. Perdahl*, G. Sedvall*, and P. Greengard. Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University. New York, N.Y. 10021.

Protein IIIa and Protein IIIb are two homologous phosphoproteins (collectively referred to as Protein III) that, together with synapsin Ia and synapsin Ib, constitute a family of synaptic vesicle-associated phosphoproteins. Protein III has been shown to be phosphorylated in response to electrical stimulation, potassium depolarization, or exogenous cAMP in intact nerve cell preparations. These and a variety of other data have led us to hypothesize that Protein III may play some role in modulating synaptic vesicle function.

In rat brain, Protein IIIa migrates as a 74,000 M_r band on SDS-gels while Protein IIIb migrates as a 55,000 M_r band. In a recent study, we demonstrated that Protein III was present in human brain. In this material, which was obtained at autopsy, three M_r variants in both Protein IIIa and Protein IIIb were detected in some of the autopsy samples examined. While one of the variants of Protein IIIa and Protein IIIb in human brain comigrated with the rat forms of these proteins, the two other variants of Protein IIIa and Protein IIIb migrated more slowly than the rat forms of Protein IIIa and Protein IIIb. Interestingly, although the more slowly migrating variants were rarely seen in control material (only 2 of 17 individuals), in material obtained at autopsy from alcoholic individuals who died sober (no detectable blood alcohol levels) 12 of 12 samples examined exhibited the more slowly migrating variant forms of Protein III. Moreover, in material obtained at autopsy from alcoholic individuals who died while intoxicated (blood alcohol levels >50mg/100 ml), the more slowly migrating variant forms of Protein III were seen in only 4 of 17 cases. A high incidence of the more slowly migrating Protein III variants was also detected in a number of individuals who had suffered from a variety of neuropathological conditions (e.g. Alzheimer's disease).

In an attempt to follow up on these observations in material that can be obtained from living subjects, we have examined human cerebrospinal fluid (CSF) for the presence of Protein III. We have determined by immunochemical and peptide mapping studies that both Protein IIIa and Protein IIIb are present in human CSF. A quantitative radioimmunochemical assay has been used to determine the amount of Protein III in the CSF of alcoholics. These studies have provided preliminary evidence that there is an increase in Protein III in the CSF of abstinent alcoholics compared to non-alcoholic controls. Work is currently under way to determine whether this increase in Protein III represents an increase in one or in more of the variant forms of this protein.

85.5 Differential Enhancement of Benzodiazepine Binding, by GABA, in Mice Selectively Bred for Sensitivity to Ethanol. R.J. Marley* and J.M. Wehner* (Spon: J.R. Sheppard). Inst. for Behav. Genetics and School of Pharm., Univ. of Colo., Boulder, CO. 80309.

Previous observations have indicated that CNS effects of ethanol may result from an interaction with the GABA-benzodiazepine (BZ) system. The exact nature of this interaction has not been determined, but it has been suggested that ethanol potentiates GABAergic functions at a site other than the GABA-BZ receptor complex (Greenberg, D.A., et al., J. Neurochem, 42:1062, 1984). We investigated both the binding of ^{3}H-flunitrazepam (FNZ) and the allosteric enhancement of FNZ binding by GABA among females from two lines of mice, short-sleep (SS) and long-sleep (LS), selectively bred for sensitivity to ethanol. Each experiment represents from three to five assays conducted at 37°C. The allosteric enhancement of ^{3}H-FNZ binding (1_3 - 3 nM), by increasing concentrations of GABA (10^{-7}M - 10^{-3}M), was investigated initially in extensively washed membrane preparations from whole brain. Significant differences in GABA's enhancement of FNZ binding were observed between LS and SS mice at all concentrations of GABA employed in the study. The binding of ^{3}H-FNZ was enhanced to a greater degree in SS mice than in LS mice. Similar differences in GABA enhancement were also observed in crude membrane preparations of whole brain from these two lines of mice, however, the effect was much more robust in well-washed preparations. To further investigate this phenomenon, brains were dissected into seven major regions (cortex, midbrain, hindbrain, cerebellum, hippocampus, hypothalamus, and striatum) and the specific binding of ^{3}H-FNZ in the presence and absence of 10^{-5}M GABA determined following extensive washing of the membrane preparations. FNZ binding was enhanced, by GABA, to a greater degree in SS mice, than in LS mice, in cerebellum, hypothalamus, and striatum. No difference was observed in the other four regions, with the possible exception of cortex where a small difference was observed. No differences were observed in either ^{3}H-FNZ binding affinity (11.3 nM for SS and 10.5 nM for LS) or binding capacity (1.08 and 1.25 pmol/mg protein for SS and LS, respectively) when saturation assays were conducted on membranes prepared from whole brain. There were no differences observed when single-point binding assays were conducted on the various brain regions using a concentration of approximately 1.5 nM ^{3}H-FNZ. In these binding assays, the various membrane preparations were washed in the same manner as in the enhancement studies. These results suggest that the differences in ethanol sensitivity observed for these two lines of mice may be related to differences in some factor responsible for modulation of the GABA-BZ receptor complex. (Supported, by AA-03527 and an NSF Graduate Fellowship).

85.6 NEUROCHEMICAL EVIDENCE FOR THE DEVELOPMENT OF NEURONAL TOLERANCE IN THE ALCOHOL-PREFERRING P LINE OF RATS. W.J. McBride, J.M. Murphy, M.B. Waller, L. Lumeng* and T.-K. Li*, Depts. Psych. & Med., Inst. Psychiatric Res. and Regenstrief Institute, Indiana Univ. Sch. Med., Indianapolis, IN 46223.

The objective of the present study was to provide neurochemical evidence for the development of neuronal tolerance after chronic alcohol treatment. Adult, male rats of the alcohol-preferring P line were divided into 4 groups (N=6 each). Groups A and B were maintained on H_2O and normal rat chow ad lib. Group C was given a liquid diet containing 5% ethanol and group D received a control liquid diet without ethanol. As measured by a jumping-platform test (Waller et al., Pharmacol. Biochem. Behavior 19: 683, 1983), P rats in group C demonstrated behavioral tolerance to an i.p. injection of 2.5 g ethanol/kg after 8 days of chronic ethanol consumption (10 ± 1 g ethanol/kg/day). Rats in group D, which were given the liquid diet without ethanol, did not show this behavioral tolerance to i.p. ethanol. Groups A and B were not tested and hence remained ethanol naive until the day of killing. One week after the observed development of behavioral tolerance by group C, all 4 groups were killed by the near-freezing technique. Prior to killing, group A received i.p. saline while groups B, C and D received 2.5 g ethanol/kg. One hour after the injection of either saline or ethanol, the rats were killed and the frontal cortex (FCTX) and nucleus accumbens (ACC) were dissected at -20°C. These two limbic regions were assayed by HPLC for dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), serotonin (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA). There were no differences in the levels of DA, DOPAC and HVA in the FCTX and of DA in the ACC of the ethanol injected groups (B, C and D) in comparison to the values for the saline injected group (A). However, in the ACC, the contents of the DA metabolites were higher in groups B (6.6 ± 0.2 nmol/g for DOPAC; 3.0 ± 0.1 for HVA) and D (6.6 ± 0.3 for DOPAC; 2.9 ± 0.1 for HVA) than were found in the saline-injected group (5.6 ± 0.4 for DOPAC; 2.1 ± 0.2 for HVA). Similarly, the levels of 5-HIAA in the ACC were greater in groups B (4.36 ± 0.05 nmol/g) and D (4.36 ± 0.12) than in A (3.65 ± 0.07). Higher levels of 5-HIAA were also observed in the FCTX of groups B (2.60 ± 0.09) and D (2.90 ± 0.11) than in A (2.36 ± 0.06). On the other hand, the ethanol-tolerant rats (group C) did not demonstrate increased levels of DOPAC (5.6 ± 0.4), HVA (2.2 ± 0.1) and 5-HIAA (3.55 ± 0.13) in the ACC or of 5-HIAA (2.50 ± 0.12) in the FCTX following i.p. ethanol. The results suggest that ethanol-tolerant P rats do not respond to an i.p. dose of ethanol with increased release and/or metabolism of DA and 5-HT in the ACC and of 5-HT in the FCTX as do the nontolerant groups. These specific regional DA and 5-HT systems may represent neuronal substrates for the demonstrated behavioral tolerance to ethanol in the P rats. (AA-03243)

85.7 Synaptosomal Phospholipid Acyl Composition of Mouse Strains Differing in Ethanol Sensitivities. L. Lee and T. L. Smith. Veterans Administration Medical Center, Tucson, AZ 85723 and the Dept. of Pharmacology, University of Arizona Medical Center, Tucson, AZ 85724.

Through studies with inbred rodents, it is evident that initial neurosensitivity to ethanol is under strong genetic influence. Yet, the neurochemical basis for differential neurosensitivity to ethanol among various mouse strains is poorly understood. For example, synaptic cholesterol/phospholipid ratios observed in different mouse strains are not correlated with behavioral sensitivity to ethanol (Smith, J. Pharmacol. Exp. Ther. 232:702, 1985). It is known, however, that an increase in fatty acyl saturation results in an increase in membrane microviscosity which, in turn, has been related to alterations in tissue sensitivity to ethanol. Thus, it was of interest to determine and compare fatty acid composition of synaptosomes from cerebral cortex and cerebellar tissues of RIIIS and AKR/J mouse strains which differ in their initial behavioral sensitivity to ethanol. Mice from both strains were injected with ethanol (I.P., 4.0g/kg body wt.) and blood alcohol conc. (B.A.C.) upon awakening was determined. In a separate group of animals which were not previously treated with ethanol, synaptosomes were prepared and the fatty acyl composition determined. RIIIS and AKR/J mice had B.A.C.'s (mg %) of 306±20 and 197±35, respectively. Fatty acyl compositions of RIIIS and AKR/J cerebral cortical synaptosomes were essentially identical. Similarly, synaptosomes from cerebellum which is more directly associated with ethanol-induced ataxia were also analyzed. The fatty acid compositions of cerebellar tissues from these two mouse strains were also identical. Interestingly, in both mouse strains significant differences in the % composition of 16:1 were observed when comparing fatty acid profiles of cortex with that of cerebellum. It is concluded that the synaptosomal fatty acyl composition is not a determinant for differences in initial neurosensitivity to ethanol observed in RIIIS and AKR/J mice. Supported by a medical research grant from the Veterans Administration.

85.8 GENE FREQUENCY FOR A BRAIN POLYPEPTIDE VARIANT DIFFERS BETWEEN SELECTIVELY-BRED MOUSE LINES PRONE (WSP) AND RESISTANT (WSR) TO ETHANOL WITHDRAWAL SEIZURES. D. Goldman* and J.C. Crabbe. (M. Meikle, Spon.) Lab. Clin. Stud., NIAAA, Bethesda, MD 20205 and Ore. Hlth. Sci. Univ. and VA Med. Ctr., Portland, OR 97201.

A substantial proportion of individual differences in ethanol withdrawal severity are genetically determined in mice. For example, inbred strains of mice differ widely in the severity of ethanol withdrawal after a standard chronic treatment regimen. One of us (JCC) has selectively bred two mouse lines prone (withdrawal seizure prone: WSP) to withdrawal seizures following cessation of chronic ethanol inhalation. Two lines have been bred for ethanol withdrawal seizure resistance (WSR) and two non-selected control lines (WSC) are maintained. The WSP lines exhibit 10-20 fold more severe withdrawal seizures than the WSR lines after identical chronic ethanol exposure. Little inbreeding irrelevant to the selected characters has occurred in these lines, so any fixed genetic differences should be markers or determinants of the selected trait.

Whole brain homogenates from eight mice from each line were typed by two dimensional gel electrophoresis at Generation S_{13} for eight brain polypeptides which show genetic variation between inbred strains of mice. One variant, a highly abundant, 71 kilodalton pI 5.4 polypeptide, was genetically fixed in both WSR lines (0/16 individuals exhibited the basic allele). Allelic frequencies in the two WSP lines were .125 and .21, and in the WSC lines .08 and .06. The differences in allele frequency among the lines were significant ($p < .05$) by chi square and probability analysis.

This variant brain polypeptide may be a genetic marker for ethanol withdrawal severity, and/or may be a functional determinant of withdrawal.

85.9 NEONATAL MSG LESIONS REDUCE NEUROSENSITIVITY TO ETHANOL-INDUCED HYPOTHERMIA IN MICE. J.C. Crabbe, A. Kosobud*, B.R. Tam*, E.R. Young*, L.D. Keith*, J.D. McSwigan*, and D.M. Dorsa. Ore. Hlth. Sci. Univ. and VA Med. Ctr., Portland, OR 97201, and Univ. Wash. and GRECC, VA Med. Ctr., Seattle, WA 98108 (DMD).

A number of studies have indicated a relationship between brain peptide activity and sensitivity to the behavioral effects of ethanol. Specifically, it has been suggested that ethanol effects are mediated by changes in the endogenous opioid peptides derived from the proopiomelanocortin (POMC) precursor. Most cell bodies containing brain POMC-derived peptides are found in the arcuate nucleus of the hypothalamus. Neonatal administration of monosodium glutamate (MSG) has been reported to destroy cell bodies of the arcuate nucleus. We treated WSC strain mice on postnatal Day 4 with a single sc injection of 4 mg/g MSG or saline. When adult, mice were challenged with 3.5 g/kg ip ethanol and reduction in body temperature was assessed 45 min later. Blood ethanol concentration (BEC) was measured and the hypothalamic content of ß-endorphin like immunoreactivity (ß-EP) was determined by radioimmunoassay.

ß-EP was reduced 79 percent in females and 50 percent in males by MSG treatment. MSG-treated animals of both sexes showed significantly less ethanol-induced hypothermia than controls. BEC was higher in MSG-treated animals of both sexes than in controls, so the differences were not due to ethanol pharmacokinetics. ß-EP was generally lower in males.

These data suggest that ß-EP cell bodies in the arcuate nucleus of the hypothalamus mediate neurosensitivity to ethanol-induced hypothermia in mice.

Support for this work was obtained from the Veterans Administration, the Medical Research Foundation of Oregon, and PHS Grants AA05828, AA06243, and NS20311.

85.10 REPRODUCTIVE BEHAVIOR OF FEMALE RATS TREATED POSTNATAL DAYS 1-8 OR 8-14 WITH ETHANOL. T.B. Sonderegger, B. Mesloh,* A. J. Ritchie,* A. Tharp,* and M. Spencer,* Dept. of Psychol., Univ. of Nebraska-Lincoln, Lincoln, NE 68588-0308.

The studies reported here examine the effects of known quantities of ethanol administered during postnatal weeks 1 or 2 upon the reproductive behavior of female rats. In study one, ethanol in a 30% Sustagen (Mead Johnson) vehicle was administered twice daily on postnatal days 1-7 (early) or 8-14 (late) using an intragastric intubation procedure designed to counteract the effects of underfeeding (Sonderegger et al., Neurobehavior. Tox. and Teratol. 4:477, 1982). Doses were tapered to reach a maximum of 4 g/kg on treatment day 4. In study one, 25 litters of Charles Rivers CD albino rats (10 pups per litter) were used in a split-litter design. On day 1 after birth pups were assigned to a treatment group: ethanol (E), Sustagen (S), pair-underfed (P), or handled (H). S pups received comparable volumes of isocaloric (sucrose) vehicle. Unhandled (U) animals were obtained from additional litters.

Body weights of all animals were comparable on day 21 and thereafter. Animals were weaned and housed in same-sex pairs with ad libitum food and water.

On day 90, females were bred in groups of 3 (E, S, and P littermates) with one proven sire; 42 females from early and late groups. If pregnancy did not occur within two weeks, subsequent two week trials with other proven sires were given. Ratios of animals that became pregnant for early and late groups, respectively, were E = 3/8, S = 5/6, P = 2/6; E = 3/10, S = 5/6, P = 5/6. Estrous cycles of all animals appeared to be typical. However, the nonfertile females when in estrous, did not exhibit lordosis in a standard mating test. Litter sizes and sex ratios of pups of females that became pregnant did not differ among treatment groups.

In study two, the procedure was repeated using animals from 14 litters. All treatment groups had comparable body weights on day 21. Findings from this study will also be described.

Univ. NE-Lin Research Council, Biomedical Support Grant RR 07055.

85.11 PRENATAL PHENOBARBITAL EXPOSURE ALTERS THE DEVELOPMENT OF BEHAVIORAL TOLERANCE IN ADULT RATS. C. Stamper, D. Braget* and J. Diaz. Dept. of Psychology, University of Washington, Seattle, WA 98195.

Prenatal exposure to phenobarbital has been shown to have long-term effects on hormonal systems, CNS morphology, drug metabolism and behavior. The purpose of the present study was to investigate the effect of prenatal exposure to phenobarbital on the development of behavioral tolerance to barbiturates in adulthood. Behavioral tolerance has been described as a decrease of the behavioral effects of a drug after it has been administered for a number of times.

Phenobarbital was administered to pregnant dams in the drinking water from days 9-18 of gestation. The mean serum phenobarbital level on the last day of drug administration was 101.6+26 ug/ml. Beginning on postnatal day 180, the offspring were trained on an automatic treadmill device which assessed the animal's motor performance. Following the training period, the animals were tested for performance on the treadmill after the administration of pentobarbital (10 mg/kg) for a period of five days.

There were no significant differences in the preweanling growth of the offspring. On day 90, the control group offspring were significantly heavier than the drug group offspring ($T=2.23, p<.05$). There were no significant differences between the groups in the learning of the treadmill motor task. There was a significant group effect ($F(1,4)=5.9$, $p<.05$) and a significant time effect ($F(1,4)=21.7$, $p<.001$) for the development of tolerance segment of the study. The following table summarizes the results:

	Seconds of Error on the Treadmill				
	day 1	day 2	day 3	day 4	day 5
Control	53.2	39.4	39.2	34.7	17.1
Barb	48.4	36.6	21.0	7.8	3.4

These data indicate that there were significant differences in the development of behavioral tolerance to pentobarbital between animals exposed to phenobarbital in utero and control group animals. There is a great deal of variation in the response of individuals to various drugs, which is not explained by gender, size or age. Perhaps early (even prenatal) exposure to certain drugs is responsible, in part, for determining the response to a variety of drugs throughout life.

85.12 THE EFFECTS OF THE IN UTERO ADMINISTRATION OF ALCOHOL ON GAMMA GLUTAMYL TRANSPEPTIDASE FROM RAT HIPPOCAMPUS. E. Reyes, D. Sandoval*, K. Garcia* and J. Wolfe*. Department of Pharmacology School of Medicine The University of New Mexico, Albuquerque, NM 87131.

The membrane bound enzyme, gamma glutamyl transpeptidase (GGTP), has been shown to be elevated by alcohol treatment in brains of adult rats. Several different brain areas have been shown to be significantly higher in GGTP activity following alcohol treatment (Reyes, 1978,85). Recently we have shown that the in utero administration of alcohol produces an elevation of GGTP in specific brain areas. It was the intent of the present study to determine if the increase in GGTP activity observed in Fetal Alcohol Syndrome (FAS) rats is due to an alteration in the isoenzyme distribution or to alterations in their kinetic properties. Animals from alcohol treated mothers and from pair-fed control mothers were sacrificed by decapitation at 30 days of age. The brains were immediately excised and dissected according to the method described by Glowinski & Iverson (1966) and homogenized in 0.01M Tris buffered saline to yield a 20%(w/v) suspension. GGTP from the hippocampus was purified according to the method described by Reyes & Barela (1980). In the hippocampal area the total GGTP activity for the FAS group was found to be 1.66 units and that for the control group was 0.866 units. The 30-70% ammonium sulfate enzyme preparations were applied to a DEAE cellulose column and eluted with a linear NaCl gradient. Two distinct peaks of GGTP activity (I,II) were produced from the FAS enzyme preparation while only one peak (I) was found for the control. Fractionation of peak I from the FAS and control groups on a concanavalin A-sephrose 4B affinity column showed that the peak I was composed of the same 3 isoenzyme groups. Peak II from the FAS group was also fractionated into isoenzymes with varying affinities for concanavalin A. Approximately 7 times more enzyme was recovered from the FAS preparation than from the control preparation. The isoenzymes were characterized with respect to molecular weights and Michaelis constants for the substrate γ-glutamyl-p-nitroanilide. This work was supported by MBRS program grant #081-39 and New Mexico Child Health Care 73/665.45.32/022.

85.13 BEHAVIORAL EFFECTS OF PRENATAL ETHANOL IN RAT PUPS. C.S. Sebastian*, M. Herkert* and S.I. Dworkin (SPON: G. Trapp). Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Sebastian, et al (Federation Proceedings, 43:286, 1984) found no differences in performance between prenatally ethanol or dextrose exposed rat pups in a radial arm maze. This was attributed to factors including a low dose (5 mg/kg), pups' age when tested (70 days), an insensitive test and the direct effect of intubation. However, an additional study using a higher dose (7 mg/kg) and younger pups (25 days) also failed to show differences. Therefore, a behavioral procedure that was more sensitive to the effects of prenatal-drug exposure was evaluated. An interresponse time schedule of liquid food presentation was used to study the effects of prenatal ethanol administration. This schedule requires the animals to pause a specified period of time between each response and has been used to assess the effects of many pharmacological agents. Three groups of pregnant rats were studied. One group (N=3) received ethanol (7 mg/kg) and the second group was given (N=3) isocaloric dextrose by gavage during third week of gestation. The third group (N=2) was untreated.

The offspring of ethanol-treated (N=16) and untreated (N=11) rats were studied. Sessions were run Monday-Friday and were terminated after 15 minutes. A nose-poke response was used and the reinforcer consisted of liquid milk. Response-independent food presentations were presented an average of every 3 min. Furthermore, each response that was spaced one sec after the previous response resulted in additional food presentations. The response-indpendent schedule was first eliminated and then the IRT value was raised to 5 sec during additional sessions. The pups exposed to ethanol had higher response rates and received fewer food deliveries during all sessions.

These pups were tested at a younger age and a behavioral baseline that was more sensitive than in prior experiments. They showed constant behavioral differences from untreated pups. While the effect of stress from intubations to these findings could not be assessed in this study, it is noteworthy that the rats were dosed with ethanol only during the third week of gestation instead of the entire gestation as in previous experiments, thus reducing the stress considerably.

85.14 PRENATAL ALCOHOL EXPOSURE DOES NOT INFLUENCE SEXUAL DIMORPHISM OF SACCHARIN PREFERENCE IN C57 MICE. H.C. Becker, C.L. Randall and R.F. Anton. VA Medical Center and Medical University of SC, Charleston, SC 29403.

Maternal alcohol consumption during pregnancy has been shown to produce a number of physical and behavioral anomalies in human and animal offspring (e.g., Abel, 1984; Randall et al., 1982). Most recently, McGivern et al. (1984) reported that prenatal exposure to alcohol in rats eliminated the expression of gender differences in behaviors that are typically sexually dimorphic in nature (e.g., saccharin preference, maze learning). The purpose of this study was to investigate whether prenatal alcohol exposure influences the sexual dimorphic nature of saccharin preference in the mouse. We have previously found C57 mice to be susceptible to both the morphological as well as behavioral teratogenic properties of ethanol (Randall and Taylor, 1979; Middaugh and Randall, 1985).

Pregnant C57 mice were fed liquid diets containing either 25% or 0% ethanol-derived calories (EDC) from Gestation Day 6-18. The 0% EDC group was pair-fed to the 25% EDC animals. A third control group received lab chow ad libitum throughout gestation. Parturition was noted and litters were culled to six of equal sex, when possible. Offspring were weaned at 25 days and then left undisturbed.

At 50 days of age, one male and one female offspring from each of the three prenatal treatment groups was given two bottles containing either water or 0.1% saccharin. After four days, the saccharin concentration was increased to 0.2% for four additional days. Food was freely available for the duration of the preference test. Mice were weighed every other day and the bottles were read daily, at which time position of the tubes was alternated.

Results indicated that relative saccharin intake (ml per 100 g body weight) was reliably greater for females than males for both concentrations of saccharin ($F(1,74)=22.35$, $p< 0.01$). This main effect of sex, however, was not influenced by prenatal treatment (sex x treatment interaction, $p< 0.1$). Thus, contrary to findings in the rat, prenatal exposure to alcohol does not appear to influence the sexual dimorphism of saccharin preference in C57 mice. Whether this discrepancy is related to differences in species or some other methodological issue remains to be determined.

(Supported by the Veterans Administration and the National Institute on Alcohol Abuse and Alcoholism.)

85.15 PRENATAL ALCOHOL EXPOSURE FACILITATES FEMININE SEXUAL RESPONSIVITY WITHOUT DISRUPTING MASCULINE SEXUAL BEHAVIOR IN MALE RATS, A. Lumia[1]*, P. Kleber*, S. Vanderwoude*, J. Flynn*, and J. Broida* (SPON: B.Sachs). Psychology Department, Skidmore College, Saratoga Springs, NY 12866.

Perinatal exposure to testosterone is important for display of male sexual behavior. its absence increases the potential for the display of feminine behavior. Prenatal exposure to alcohol, which inhibits release of testosterone, should have a deleterious effect upon the organization of masculine copulatory behavior. We examined the effects of prenatal exposure to alcohol on expression of both male and female sexual responsivity in adulthood.

Pregnant female rats were given a liquid diet containing 36, 18 or 0 percent alcohol derived calories on days 5 through 20 of gestation. Additional females received standard laboratory chow. Litters were culled to 8 pups and cross-fostered to a separate group of non-alcohol exposed dams on the day of birth, and male offspring were castrated 3 days later.

At 60-80 days of age, males were screened for mounting in response to sexually receptive females prior to testosterone replacement therapy. These males were then given daily injections of 500ug testosterone proprionate and paired with sexually receptive females every other day until they mounted.

Additional males were given two injections of estrogen (6ug), 48 and 24 hours prior to exposure to a sexually vigorous male. These animals also received a single injection of progesterone (500ug), 4 hours prior to pairing, when their lordotic behavior was assessed. Lordosis was assessed twice, the second test one week after the first.

Prenatal exposure to alcohol did not alter on latency to mount, However, animals whose mothers received 36% ethanol during pregnancy had higher LQs (75) than did those whose mothers received 18% or 0% ethanol or lab chow controls (39, 20, and 12, respectively), Differences in body weight did not account for this differential sensitivity to estrogen and progesterone. Thus prenatal exposure to alcohol was found to disrupt defeminization without affecting masculinization.

86.1 EXCITATORY EFFECT OF ETHANOL ON MOTOR ACTIVITY AND ROTATION MEASURES IN MICE. P.B. Silverman and H.L. Altshuler. Neuropsychopharmacology Section, Texas Research Institute of Mental Sciences and Neuroscience Program, University of Texas Graduate School of Biomedical Sciences, Houston, Texas 77030 USA

The long term objective of the work begun here is to gain understanding of the mechanisms involved in the excitatory effect of ethanol. The euphoriant, excitatory effect of a drug is generally considered an important indication of abuse liability. The excitatory effect of ethanol, especially after repeated administration, is a relatively unexamined phenomenon despite its probable role in alcohol abuse. The work presented here was intended to examine the excitatory effect of ethanol as a function of the schedule and context of administration and to assess the effects of acute and chronic ethanol in a behavioral model of dopamine function.

The specific aims were to determine if tolerance or sensitization to the locomotor stimulant effect of ethanol in mice develops upon repeated administration, to determine the contribution of intertreatment interval and context (setting) on any such changes in the locomotor stimulation induced by successive ethanol treatments, to determine if changes in ethanol-induced stimulation can be attributed to changes in blood and brain levels of ethanol in a well established whole animal model of central dopamine function, i.e, the unilaterally 6-hydroxydopamine-lesioned mouse rotation model.

Results to date show a dose dependent increment in locomotor activity in DBA and Swiss-Webster mice in response to 1 to 3 g/kg ethanol. No striking change in locomotor response to repeated ethanol treatments in this dose range has been found in either strain of mice despite testing with a number of different intertreatment intervals. This lack of demonstrable tolerance or sensitization may be the result of only a limited number of treatments (5 or 6) having been given. More treatments than were initially anticipated may be required to demonstrate a change in locomotor response.

In the rotation experiments, mice lesioned by intrastriatal administration of 6-hydroxydopamine were screened for rotation in response to the dopamine agonists, apomorphine and (+)-amphetamine, which resulted in contralateral and ipsilateral rotation, respectively. They were then tested for rotational response to ethanol. Surprisingly, ethanol induced contralaterally directed rotation in a dose responsive manner up to 3 g/kg. In our initial studies, this effect of ethanol was significantly antagonized by 10 mg/kg naloxone in Swiss-Webster mice.

(Supported by NIAAA Grant # 5 R23 AA06279-03 to P.B.S.)

86.2 FACTORS INFLUENCING DEPRESSANT-INDUCED NARCOSIS IN THE SHORT-SLEEP AND LONG-SLEEP MICE. T.D. McIntyre and H.P. Alpern. Behavioral Neuroscience Program, Dept. of Psychology, University of Colorado, Boulder, CO 80309.

We have argued that mechanisms responsible for sleep time differences in mice selectively-bred for short and long ethanol-induced sleep times (SS/LS) are not alcohol specific. Evidence indicates that differences between these lines are due to differences in more general CNS mechanisms (McIntyre and Alpern, 1985), because, LS are more sensitive to soporific effects of ethanol, t-butanol, methanol, enflurance, isoflurance, paraldehyde, chloral hydrate, trichloroethanol, gamma-butyrolactone, chlordiazepoxide, adenosine, pentobarbital, barbital, phenobarbital and thiopental. Under certain conditions, however, SS appear to be more sensitive to pentobarbital. To explain this discrepancy we examined the experimental designs of reports dealing with pentobarbital-induced narcosis, and believe that factors such as dose, sex, age, and periodicity may have significantly impacted the results. In only one of the five reports which fail to find LS more sensitive to pentobarbital is more than one dose employed. Further, all mixed both sexes, used animals at different ages and tested at different times. Thus, our experiments examined the effects of each of these variables on depressant-induced narcosis.

In the first study several doses of pentobarbital were given to both sexes of LS and SS at three different times. The results are complex in that there were interactions among all variables. In general, LS were affected by time of day and SS were not, and at 2400h line differences disappeared. Further, females tended to sleep longer than males, although female scores fluctuated over time of day. To show that these variables are important for other depressants, thiopental was given to both sexes of the lines at three ages. Again, there were interactions among all variables. Males of both lines gave stable results at all ages, but females displayed variability over the age factor. In Experiment 3 chlordiazepoxide was given to both sexes of the lines at three ages. LS animals regardless of sex or age had longer sleep times than SS. An age effect was not apparent for SS, but young SS had significantly lower sleep times than older SS.

Clearly, interpretation differences may arise when experimental variables are not adequately controlled.

86.3 ROLE OF PAVLOVIAN CONDITIONING IN THE DEVELOPMENT OF TOLERANCE AND CROSS-TOLERANCE TO THE HYPOTHERMIC EFFECT OF ETHANOL AND HYDRALAZINE. A.D. Lê*, J.M. Khanna and H. Kalant*. Dept. of Pharmacology, University of Toronto, and Addiction Research Foundation of Ontario, Toronto, Canada M5S 2S1.

The development of tolerance to the hypothermic effect of ethanol and of cross-tolerance to hydralazine, was investigated. In the first study, the influence of Pavlovian conditioning on tolerance was examined. Two groups of rats (n = 12) were treated on alternate days with 2 or 4 g/kg of ethanol (i.p.) in a room made distinctive (DR) by dim light and static noise from the radio. On the non-alcohol days, they were injected with saline in their home room (HR). A control group (n = 12) received saline in both environments. Tolerance to the hypothermic effect of ethanol (2 g/kg i.p.) was demonstrable in the DR in both the 2 and 4 g/kg treatment groups. Tolerance, however, was observed in the HR only in the 4 g/kg treated group. Cross-tolerance to the hypothermic effect of hydralazine (5 mg/kg i.p.) was observed for both ethanol treated groups in the DR but not in HR. In the second study, ethanol treatment was carried out by daily intubation with 6 g/kg of ethanol in the home cage. Tolerance to ethanol-induced hypothermia was demonstrated either in the home cage or in a novel environment. This treatment, however, failed to confer cross-tolerance to the hypothermic effect of hydralazine.

The results suggest that when high ethanol treatment dosage was employed, tolerance could be manifested in the absence of classical conditioning. Conditioning, however, plays a predominant role in the tolerance produced by low ethanol treatment dosage. The data also suggest that conditioning might be a separate component in tolerance development, which is of special importance for "effect-specific" rather than "drug-specific" tolerance.

86.4 SEASONAL VARIATION OF THE EFFECTS OF ALCOHOL ON AGGRESSIVE BEHAVIOR AND GONADAL HORMONES IN HIGH-STATUS SQUIRREL MONKEYS. J.T. Winslow*, K.A. Miczek, and J. Ellingboe. Dept. of Psychology, Tufts U., Medford, Ma 02155 and Alcohol and Drug Abuse Research Ctr., McClean Hosp.-Harvard Med.Sch., Belmont, Ma 02178.

Gonadal hormones such as testosterone (T) and luteinizing hormone (LH) may mediate the effects of alcohol on primate social behavior. We invesigated the relationship between endocrine processes, sensitivity to alcohol, social behavior within groups of squirrel monkeys. Consistent behavioral differences between dominant and subordinate monkeys were quantitatively measured using computer assisted, continuous measurement techniques. Dominant monkeys exhibited higher frequencies of aggressive behavior than subordinate monkeys, but the amount of time allocated to social behavior accounted for less than 10% of an individuals behavior. In contrast, social behavior was a significant determinant of general behavioral comportment and endocrine activity. Blood samples collected during breeding season revealed 267 ng/ml of T in dominant monkeys and 57.9 ng/ml T in subordinate monkeys. We previously determined that alcohol produced biphasic changes in the aggressive behavior of dominant but not subordinate monkeys, with low doses (0.1, 0.3, 0.6 g/kg) increasing the the frequency of threats, grasps and displacements and a higher dose (1.0 g/kg) decreasing these behaviors in dominant monkeys. Subordinate monkeys were not affected at any dose. We have studied the effects of alcohol on blood levels of T, LH and concurrent behavioral changes. Preliminary data suggest that changes in aggressive behavior produced by alcohol may be related to corresponding changes in T, however both of these effects are dependent on seasonal variations of endocrine activity. We are studying seasonal changes in T and LH, and sensitivity to alcohol in an effort to clarify how status-dependent drug effects are related to blood levels of gonadal hormones.

86.5 RENTENTION OF LEARNED ALCOHOL AVERSIONS FOLLOWING GUSTATORY NEOCORTEX AND OLFACTORY BULB ABLATIONS. C. W. Metzler*, S. W. Kiefer and G. J. Lawrence. Dept. of Psychology, Kansas State Univ., Manhattan, KS 66506.

Ablation of the gustatory neocortex (GN) in rats disrupts retention of learned aversions utilizing basic tastes (E.g., sucrose) but does not disrupt the retention of learned alcohol aversions. It was suggested that alcohol is a complex stimulus and that olfactory cues may mediate the normal aversion retention in GN rats. The present experiment tested the effect of gustatory neocortex ablations as well as olfactory bulbectomies on the retention of learned alcohol aversions.

Fifty one naive rats were placed on a schedule of restricted fluid access. All rats were trained to avoid both a 5% alcohol solution and a 0.1 M sucrose solution using LiCl illness (3% bw of 0.15 M LiCl). Following training, animals were divided into four surgery groups: normal controls (NC, N=15), GN ablations GN, N=15), olfactory bulbectomy (OB, N=10), and a combination GN and OB ablation (GNOB, N=11). As much as possible, rats were grouped according to training scores (amount consumed) and order of aversion training. Three weeks of post-operative recovery were followed by a return to the restricted fluid schedule. Tests for aversion retention were then done; sucrose and alcohol were presented in alternate test trials, each separated by two days of water access.

All animals acquired aversions to both sucrose and alcohol solutions in one or two trials. Postoperatively, the animals with GN lesions and GNOB lesions consumed more sucrose solution than animals with NC or OB lesions ($p<.01$). The means (and SEMs) for the sucrose solution consumption (ml) were: GN=13.8 ($\pm$1.7), GNOB=15.3 ($\pm$2.1), OB=2.6 ($\pm$1.5), NC=0.1 ($\pm$.1). These data indicate that the GN ablations were complete and included the critical gustatory area. Although rats lacking GN failed to retain the sucrose aversion, these rats displayed normal retention of the alcohol aversion. In contrast, the olfactory bulbectomies disrupted alcohol aversion retention. Groups OB and GNOB consumed significantly more alcohol solution than the NC and GN groups ($p<.01$: GNOB=9.3 ($\pm$1.5), OB=8.8 ($\pm$2.3), GN1.4 ($\pm$.6), NC=0.0 ($\pm$0.0).

The results indicate that alcohol aversion retention is not disrupted by GN lesion but is disrupted by olfactory bulbectomy. This suggests that odor is a potent cue in learned alcohol aversions and that the odor can mediate the aversion when the salience of the taste is degraded by GN ablation.

86.6 **STUDIES OF STRESS-INDUCED FREE CHOICE CONSUMPTION OF ETHANOL BY RATS. I. A POSSIBLE ROLE FOR THE HYPOTHALAMUS-PITUITARY-ADRENOCORTICAL AXIS.** **J. F. Nash, Jr.# and R. P. Maickel. Dept. of Pharmacology and Toxicology, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.**

Previous experiments from this laboratory (Nash and Maickel, Fed. Proc. 43: 782, 1984) have demonstrated the induction of ethanol consuming behavior in adult, male Sprague-Dawley rats exposed to stressful stimuli (immobilization or isolation) on an unpredictable/irregular schedule for two weeks. The animals had continuous access, in a choice situation to two consummatory fluids: 0.1% aqueous (w/v) saccharin and 10% (v/v) ethanol in 0.1% aqueous (w/v) saccharin. Twenty-four hour consummatory volumes were recorded. In an attempt to assess the role of the hypothalamus-pituitary-adrenocortical axis in this consummatory behavior, two sets of experiments have been performed. In one set, repetitive doses of crystalline ACTH were administered intravenously over a two week period at irregular intervals corresponding to the times of immobilization or isolation stress previously used. The dosages used were 20-80 mU/rat; these provided plasma corticosterone response patterns similar to those seen with 1-4 hours of stressful stimuli (Smith, et al., J. Pharmacol. Exptl. Therap. 139: 140, 1963). The effects of this treatment were reflected in alterations in the consummatory behavior of the rats during and following the treatment with ACTH. In a second set of experiments, sustained release pellets containing dexamethasone (15 mg, release rate 0.71 mg/24 hours; 5 mg, release rate 0.24 mg/24 hours) were implanted, subcutaneously in the dorsal neck region, 7 days prior to the start of the two week period of immobilization or isolation on the irregular/unpredictable schedule. Animals implanted with the high dose of dexamethasone were sensitive to the stress; virtually all died in 7-10 days, with increased consumption of saccharin and markedly decreased body weight. The consumption of ethanol by these animals was minimal. The results suggest that adrenocoortical function may play a role in stress-induced consumption of ethanol (Supported in part by USPHS grant GM-07095 and by a grant from Innovative Research of America).

86.7 ACUTE TOXICITY OF COMBINATIONS OF ETHANOL AND FLURAZEPAM. R.J. Reiffenstein and W.Y. Hu* (SPON: G.B. Baker), Department of Pharmacology, Faculty of Medicine, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Concurrent consumption of ethanol is said to greatly increase the effects of benzodiazepines and vice versa, but the severity of this interaction in humans or animals is really unknown. We assessed the acute interaction between flurazepam and ethanol in male ICR (outbred) albino mice.

The drugs were given i.p. either alone, or in combination, to groups of 6-24 mice per dose combination. Endpoints observed were death (at 18 h), and acute anesthesia, loss of righting reflex (motor coordination), heavy sedation (hypnosis) and light sedation. Probit analysis was used to determine ED_{50}'s for each of these endpoints for each drug alone and in combination with constant doses of the other drug, and these and their 95% confidence limits were plotted as 50%-response isobolograms (Gessner, P.K. & Cabana, B.E., J. Pharmac. exp. Ther., 174: 247, 1970).

Lethality of either compound was not significantly affected by the other (except near the LD_{50} of the other). The drugs were also less than additive for anesthesia. Loss of righting reflex was additive for ethanol up to 1.5 g/Kg, however there was mutual potentiation at higher doses of ethanol. The drugs were also synergistic for heavy sedation above 0.8 g/Kg of ethanol, and for light sedation at and above 0.5 g/Kg of ethanol.

For comparison purposes one can equate the mouse LD_{50} for ethanol (4 g/Kg) to the average human lethal blood level (400 mg/dl). Likewise, the human hypnotic dose of flurazepam (30 mg) is about equivalent in effect to 100 mg/Kg in the mouse. On this basis one could predict that one hypnotic dose of flurazepam, taken while blood ethanol is above 150 mg/dl, is likely to produce total incapacitation or coma. Likewise, 80-150 mg/dl of ethanol, combined with the residual flurazepam 24 h after a single hypnotic dose, is likely to produce extreme drowsiness or sleep. Even low levels of flurazepam and very low ethanol levels are likely to produce unexpectedly severe sedation and loss of alertness. On the other hand, it is apparent from the lethality data that the combination does not greatly increase the likelihood of death due to overdose.

Supported by the Scientific Advisory Council of the Distilled Spirits Council of the United States, Inc. W.Y. Hu held a Summer Studentship of the Alberta Heritage Foundation for Medical Research. Flurazepam was kindly supplied by Hofmann-LaRoche Canada.

86.8 TEMPERATURE DEPENDENCE OF ETHANOL DEPRESSION MEASURED BY ROTAROD PERFORMANCE IN MICE. R.L. Alkana, M. Bejanian, B. Jamieson*, B. Jones*, G.G. Galleisky, P.J. Syapin and D.A. Finn*. Alcohol and Brain Research Laboratory, Institute for Toxicology, School of Pharmacy, University of Southern California, Los Angeles, CA 90033

Previous findings in our laboratory indicate that ambient temperature during intoxication influences body temperature and ethanol sensitivity as measured by sleep-time, wake-up blood and brain ethanol concentrations and lethality in mice and rats. The current study extended this investigation to sub-hypnotic ethanol doses. Rotarod-trained, adult, male, drug-naive C57BL/6J mice were injected i.p. with 1.5 or 2.5 g/kg ethanol or an equivalent volume of normal saline and exposed to ambient temperatures of 15, 22 or 36°C. Ethanol induced a significant, dose and ambient temperature related effect on body temperature. Rotarod performance decreased with increased ambient and resultant body temperatures in the intoxicated mice. The time course for the return of rotarod fucntion was significantly faster in the intoxicated mice exposed to 15°C than in mice exposed to 36°C. The enhanced performance in the cold versus warm exposed groups could not be attributed to temperature related changes in the elimination of ethanol, since blood ethanol concentrations did not differ between ambient temperature groups at 60, 90 and 120 minutes post-ethanol injection, or to the effects of temperature on sober performance. The results indicate that temperature dependence of ethanol sensitivity occurs following sub-hypnotic ethanol doses and can be measured using the rotarod task. Further, these results support the hypothesis that brain sensitivity to ethanol depression varies with body temperature in accordance with membrane perturbation theories of anesthetic drug action. (Supported by RO1 AA05234, National Institute on Alcohol Abuse and Alcoholism, ADAMHA).

86.9 HYPERBARIC EXPOSURE ANTAGONIZES THE DEPRESSANT EFFECT OF ETHANOL ON LOCOMOTOR ACTIVITY IN MICE. P.J. Syapin (1), J. Chen*, D.A. Finn* and R.L. Alkana. Alcohol and Brain Research Laboratory, Insitute for Toxicology, Univ. South. Calif. School of Pharmacy, and (1) Department of Neurology, Univ. South. Calif. School of Medicine, Los Angeles, CA 90033.

Previous studies have shown that hyperbaric exposure antagonizes the acute behaviorally depressant effect of hypnotic ethanol doses in rodents, precipitates and exacerbates withdrawal in ethanol-dependent mice, and reduces ethanol-induced inhibition of in vitro ATPase activity. The present study extends these investigations to include the sub-hypnotic dose range. C57BL/6J, adult, male, drug-naive mice were given two treatments, 2.5 g/kg ethanol and 0.9% saline, spaced one week apart according to a balanced cross-over design. Following injection, animals were individually exposed to 1 atmosphere absolute (ATA) air or to 1 ATA or 12 ATA helium-oxygen (HeOx) inside 18 liter hyperbaric chambers. Locomotor activity was measured continuously, beginning 10 minutes after injection, and was recorded at prescribed intervals for 60 minutes. Chamber temperatures were adjusted to offset ethanol-induced hypothermia and the cooling effect of helium, when applicable.

Exposure to 12 ATA HeOx significantly reduced locomotor activity in saline-injected mice compared to 1 ATA saline-injected controls ($p < 0.001$). Consequently, within subjects comparisons between saline and ethanol performance were used to evaluate the effect of hyperbaric exposure on ethanol intoxication. These comparisons indicated that 2.5 g/kg ethanol induced a significant reduction in locomotor activity for the first 30 minutes post-injection in the 1 ATA exposed mice ($p < 0.01$), with no significant differences occurring in the second 30 minute period. In contrast, the activity of ethanol-injected mice exposed to 12 ATA HeOx did not change significantly with respect to their activities following saline injection for the first 30 minutes after injection. Over the next 30 minutes, locomotor activity after ethanol injection was significantly increased in the 12 ATA exposed mice ($p < 0.01$). These results indicate that hyperbaric exposure antagonized the acute depressant effect of ethanol on locomotor activity. Blood ethanol concentrations were not significantly different 70 minutes post-injection in mice treated with 2.5 g/kg ethanol and exposed to either 1 ATA air, 1 ATA HeOx, or 12 ATA HeOx, thus making a pharmacokinetic explanation of these results unlikely. These results are consistent with, and extend, previous evidence suggesting that hyperbaric exposure antagonizes ethanol's action at the membrane level. (Supported by PHS grant RO1-AA03972, National Institute on Alcohol Abuse and Alcoholism, ADAMHA).

86.10 CHRONIC LITHIUM TREATMENT INCREASES BOTH WATER AND ALCOHOL DRINKING IN THE RAT. E.C. Critcher* and R.B. Mailman (SPON: H.Tilson). Biological Sciences Research Center, University of North Carolina School of Medicine, Chapel Hill, NC 27514.

Enhanced water intake is a common side effect of chronic lithium treatment and an effect which can be reliably produced in the laboratory animal. We have recently reported that lithium increases the voluntary consumption of alcohol in the rat in a dose-dependent manner when water and a 5% solution of alcohol are offered concurrently (Critcher,E.C. and Mailman,R.B., Alcohol, in press, 1985). Alcohol intake increased significantly during treatment with 2 mmol/kg of LiCl, when compared with the control treatment of 2 mmol/kg of NaCl. A dose of 1 mmol/kg of LiCl produced an intermediate level of alcohol intake which was not significantly different from the other two treatment groups. The daily dose of lithium (2 mmol/kg) which is effective in increasing alcohol and water drinking produces plasma levels comparable to therapeutic levels in humans (i.e., 0.6-1.2 mmol/kg). During the course of treatment, animals follow a normal growth pattern and exhibit no overt signs of toxicity. Although both water and alcohol intake increase with chronic lithium, the time course for their development differs substantially. Water intake is maximal within 6 to 10 days of treatment, whereas an increase in alcohol intake appears only after 18 to 30 days.

It has been shown that water polydipsia induced by lithium requires an intact nigrostriatal dopaminergic system (Mailman,R.B., Psychopharmacol.80:143-149, 1983). In regard to this finding, we now report that haloperidol (0.5mg/kg i.p.) attenuates water, but not alcohol, drinking. In addition, naloxone and atropine, each in a dose of 1 mg/kg, fail to alter either water or alcohol intake. When increasing concentrations of alcohol (7-15%) were offered, the g/kg intake of alcohol and total fluid intake remained unchanged, whereas water intake increased. This finding suggests that under these experimental conditions alcohol may be consumed for its pharmacological action(s). Work is continuing to characterize the neurochemical basis of these observations. However, these data do suggest that the neuronal substrates of lithium-induced increases in water consumption are different than those for the increased consumption of alcohol. (Supported in part by NIAAA Grant #AA-05192).

86.11 THE ROLE OF CENTRAL ACETALDEHYDE IN THE MEDIATION OF ETHANOL-INDUCED NARCOSIS. C.M.G. Aragon*, K. Spivak* and Z. Amit (SPON: L. Switzman). Center for Studies in Behavioural Neurobiology, Department of Psychology, Concordia University 1455 de Maisonneuve Blvd. W., Montreal, Quebec, Canada H3G 1M8.

This investigation presents evidence for the oxidation of ethanol in the brain via the peroxidatic activity of catalase and the oxidation of acetaldehyde via brain aldehyde dehydrogenase. In addition, it provides evidence for the role of central acetaldehyde in the narcotic effect produced by ethanol administration in rats. Pretreatment with the catalase inhibitor, 3-amino-1,2,4-triazole shows an attenuation in the length of sleep after an ethanol dose of 3 g/kg as compared with control animals pretreated with saline. Simultaneous pretreatment with 4-methylpyrasole (alcohol dehydrogenase inhibitor) and sodium cyanamide (aldehyde dehydrogenase inhibitor)significantly increased the time to regain the righting reflex as compared with the two previous groups. Peripheral blood and acetaldehyde levels were similar in animals regardless of pretreatment in the course of the experiment. Correlations between the enzymatic activity of brain catalase and aldehyde dehydrogenase and the observed behavior were performed. The results suggest a role for central acetaldehyde in the mediation of ethanol-induced sleep time. In addition these data increase the support for the notion that acetaldehyde is produced and degradated directly in the brain.

86.12 ETHANOL AND 1,4 BUTANEDIOL IN LIVER : INTERACTIONS AND IMPLICATIONS. Flavio Poldrugo, O. Carter Snead, III, Steven Barker, F. Mallardi, M. Basa. Department of Pediatrics, Pharmacology, Chemistry, and The Neurosciences Program. The University of Alabama at Birmingham School of Medicine, Birmingham, Alabama and Department of Anatomy, The University of Trieste School of Medicine, Trieste, Italy.

1,4 butanediol (BD) is a hepatotoxic aliphatic diol which occurs naturally in mammalian brain and liver and which has been shown to potentiate the behavioral effects of ethanol (ETOH). The object of these experiments was to pursue this BD-ETOH interaction in terms of toxicology, pathology, and biochemistry. These were two groups of experiments. For the first, rats were administered large doses of BD and ETOH either alone or in combination. The animals were observed behaviorally for sedation, catalepsy, ataxia, and loss of righting reflex. Blood ETOH and liver BD levels were measured. Mortality was assessed at 24 hours and histopathologic studies of liver and kidney performed. The second group of experiments were designed to ascertain the effect of acute and chronic ETOH administration on endogenous concentrations of BD in liver. These studies were prompted by the observations of Rutstein et al that other aliphatic diol compounds are elevated in the serum of chronic alcoholics (Lancet 2:534, 1983). Rats were treated acutely or chronically (5 days) with ETOH, sacrificed and liver concentrations of BD determined.

The combined administration of ETOH and BD resulted in a significantly increased mortality over either alone. ETOH also potentiated the hepatotoxic effects of BD. Marked fatty infiltration and necrosis of hepatic parenchyma were seen in the livers of animals treated with both BD and ETOH.

Acute ETOH administration had no effect of liver BD; however, chronic ETOH treatment resulted in a two-fold increase in endogenous liver BD concentrations.

These data showing potentiation of the hepatotoxic effect of BD by ETOH and elevation of liver BD by chronic ETOH, presumably by competition for alcohol dehydrogenase (Poldrugo and Snead, Neuropharmacology 23: 109, 1984), raise the possibility that BD may play a role in the pathogenesis of liver disease in chronic alcoholics.

86.PO THE EFFECTS OF ALCOHOL, A MINOR TRANQUILIZER, AND AN ANTI-HYPERTENSIVE AGENT ON THE CONDITIONED SUPPRESSION OF BEHAVIOR. M.A. Caplan, Dept. of Psychol., Adelphi Univ., Garden City, NY 11530

Subjecting an animal to various kinds of aversive stimulation can result in an increase in the voluntary consumption of an alcohol solution by animals that initially show an aversion to it. This increased alcohol intake has been attributed to the reinforcing pharmacological properties of alcohol, that it reduces tension induced by stressful stimulation. The definition of tension however, has never been verified independently of the increased alcohol intake following the application of some form of aversive stimulation. One way to accomplish this would be to compare the anti-suppressant properties of an anti-anxiety agent and an anti-hypertensive drug with the behavioral disinhibiting properties of alcohol.

The conditioned emotional response paradigm has been standardized as a prototypical behavioral analogue of conditioned anxiety, or tension, and is used as a standardized baseline for the study of anti-anxiety drugs. According to this procedure, a neutral stimulus is paired with shock while the organism is responding for positive reinforcement on a free-operant schedule. Following a limited number of such stimulus-shock pairings, the stimulus acquires conditioned aversive properties and results in suppression of the free-operant behavior when it is presented.

This procedure was used in the present experiment to compare the possible anti-suppressant effects of propanolol (Inderal), a clinically effective anti-hypertensive agent, and alcohol on this conditioned suppression of behavior. Albino rats received tone and uncontrollable footshock pairings in an aversive conditioning chamber, and were then transferred to an operant test chamber where they had been conditioned to press a lever for sweetened condensed milk. The tone was randomly presented during the session and resulted in an average of 50% response suppression. Two doses each of propanolol and alcohol were administered over a 2-3 week period; since none of the injections resulted in a reinstatement of the appetitive behavior when the tone was presented, two doses of chlordiazepoxide (Librium) were administered. This drug did restore appetitive responding during the tone presentations. Alcohol thus cannot be said to have the kind of tension relieving properties that are characteristic of anxiolytic drugs. The respective drug effects must be appropriately distinguished, and "tension" must be more precisely defined in order to delineate the psychological and behavioral effects of alcohol.

NEURAL BASIS OF BEHAVIOR: ALCOHOL III

87.1 CHRONIC ALCOHOL FAILS TO ALTER BRAIN GANGLIOSIDES. W. R. Klemm and D. M. Foster*, Dept. Vet. Anat., Texas A&M Univ., College Station, TX 77843 and Lab Svc., Olin E. Teague Veterans' Center & Dept. Med. Path. (Texas A&M Univ.), Temple, TX 76501.

We recently reported (Fed. Proc. 44 (4): 1089, 1985) that a single dose of alcohol (3 gm/kg), given to alcohol-naive rats, markedly decreased all species of brain gangliosides to less than 1/2 of normal at 4 hours post injection. Here, we evaluated the effect of chronic alcohol, given via liquid diet for 35 days, beginning at 30 days of age. The same analytical methods were used as in our previous acute study; namely, brains were extracted with chloroform-methanol and purified through sequential steps of DEAE chromatography, saponification, reverse-phase chromatography, and silicic acid chromatography; data were quantified with TLC densitometry and integrating recorder.

Daily alcohol consumption ranged from 13.8 to 15.8 gm/kg for each rat, and mean blood alcohol at sacrifice (0900 hrs) was 49.1 mM/l. Brain weights of alcohol rats were 7.8% less than the pair-fed controls, but that was accounted for by smaller total body weight. No significant differences were noted between alcohol-treated and control rats in any of the ganglioside bands (GT_{1b}, GD_{1b}, GD_{1a}, GM_1, GM_3). The total ganglioside levels in controls averaged 97.25% that of their alcohol-treated pair mates. The lack of effect is attributed to the relative neurological maturity of the rats when first exposed to alcohol and to a "protection" afforded by tolerance development (alcohol in the diet was increased gradually during the first week). Three prior reports that chronic alcohol decreases sialic acid are explained by methodological differences and by the fact that the effects were small and could have been largely due to a glycoprotein origin of the sialic acid.

Because acute alcohol reduces gangliosides, it suggests a transition period during chronic exposure in which brain cells develop a capacity to resist damage; the time course could parallel the resistance to membrane "fluidization" that develops during chronic exposure to alcohol. Thus the issue is raised: are ganglioside levels merely an expression of tolerance, or does ganglioside metabolism help to create membrane-level tolerance?

87.2 SYSTEMIC INDOMETHACIN OR ARACHIDONATE DO NOT AFFECT ETHANOL STIMULATED CORTICOSTERONE PRODUCTION. R.F. Anton, C.J. Wallis, H.C. Becker and C.L. Randall. VA Medical Center and Medical University of SC, Charleston, SC 29403.

Acute ethanol exposure stimulates adrenal corticosteroid production in rodents and man. Some of ethanol's neurobehavioral effects in mice can be inhibited by pretreatment with prostaglandin synthesis inhibitors, such as indomethacin, suggesting a role for eicosanoids as mediators in this process. Additionally, eicosanoids are involved in the regulation of corticotropin releasing factor (CRF) and ACTH release. We wished to examine the effect of the in vivo pharmacologic manipulation of eicosanoid production on ethanol-induced corticosterone release in mice.

C3H/He male adult mice were group housed (N=5) with free access to water and lab chow on a 12 hr light cycle with lights on at 0600. Between 0800 and 1000 hrs daily for seven days, the animals were handled and on four of those days given i.p. injections of saline to acclimate them to the stress of the procedure. On day eight in three separate experiments, animals (at least 5/group) received injections of study drugs or controls in a balanced design at defined times prior to an i.p. injection of ethanol (1.6 g/kg) or control saline. Animals were decapitated 30 min after ethanol or control injection and trunk blood was obtained for plasma corticosterone and blood alcohol level determination. Corticosterone was measured by a competitive protein binding assay and ethanol by a spectrophotometric assay. In Experiment 1, indomethacin (I) (5 mg/kg) or buffer control (B) was given i.p. 30 min prior to ethanol (E) or saline control (S). Corticosterone (ug%) levels (X±S.E.M.) for B-S, I-S, B-E, and I-E were 5.8±3.0, 5.1±1.4, 54.7±13.0, and 53.6±8.4, respectively. There was a main effect of E on plasma corticosterone ($p < 0.01$) but no main effect of I or interaction between I and E. In Experiments 2 and 3, the eicosanoid precursor arachidonate (A) as the sodium salt (50 mg/kg) or buffer (B) control was given s.c. at either 1 hr (Exp. 2) or 24 hr (Exp. 3) prior to injection with ethanol (E) or saline (S) control. The corticosterone levels for B-S, A-S, B-E, and A-E in Exp. 2 were 8.4±3.3, 7.8±1.8, 23.0±1.9, and 28.6±4.1 and in Exp. 3 were 3.5±1.4, 1.2±0.6, 20.2±2.9, and 17.9±2.3, respectively. In both experiments there was a main effect of E ($p < 0.01$) but no main effect of A or interaction between A and E. The blood ethanol concentration (X±S.D.) achieved across all experiments was 150±13.3 with no difference between treatment groups.

These data support previous findings that acute i.p. ethanol increases plasma corticosterone in mice. There was no effect of systemic pharmacologic manipulation of the prostaglandin system on either basal or ethanol stimulated corticosterone production. (Supported by the Veterans Administration.)

87.3 ACUTE ETHANOL ALTERS FIRING PATTERN AND SYNAPTIC INPUT OF PURKINJE NEURONS IN CULTURE. C.L. Franklin* and D.L. Gruol (SPON: S. Henriksen). Div. of Preclin. Neurosci. and Endocrin., and The Alcohol Research Center, Research Institute of Scripps Clinic, 10666 North Torrey Pines Road, La Jolla, CA 92037.

The Purkinje neuron (PN) of the cerebellum is a target of ethanol (EtOH) action when EtOH is administered systemically to rats. In this experimental paradigm, alterations in PN activity may result from direct actions of EtOH on the PN or via changes in afferent input from sensitive cerebellar interneurons or extracerebellar targets that regulate cerebellar activity. To identify actions of EtOH that are intrinsic to the cerebellum and direct to the PN we have developed a cerebellar culture system that is limited to only the five neuronal types present in the cortical region. We have previously shown that interneuronal associations and synaptic events reflective of the known circuitry in vivo are established in culture and that the cultured cerebellar neurons display many of the physiological and pharmacological characteristics typical of cerebellar neurons in vivo (Gruol, Brain Res. 263, 1983). In the present studies, the effect of acute EtOH (20-50 mM) on the spontaneous activity of cultured PNs was examined using extracellular and intracellular recording techniques and computer analysis of data. The majority of PNs studied (N=25) displayed a regular (10-20 Hz) simple spike (SS) firing pattern similar to that characteristic of PNs in vivo. The remainder exhibited mixed or bursting patterns. Intracellular recordings from the PNs revealed that the regular SS firing pattern is endogenously generated by ionic mechanisms intrinsic to the PN. In PNs exhibiting the regular SS firing pattern, acute EtOH, added to the recording medium (final concentration of 20 to 50 mM), increased the firing rate (1-5 Hz) and regularity of the SS pattern in a dose-dependent manner. In neurons exhibiting bursting patterns, acute EtOH (20-50 mM) changed the bursting pattern to a simple spike pattern. This change in pattern was usually accompanied by a small decrease in firing rate (1-3 Hz). In preliminary experiments intracellular recordings were used to examine the effect of acute EtOH on firing rate and spontaneous synaptic activity. EtOH (20-50 mM) increased the SS firing rate and frequency of synaptic input in these experiments. These data suggest EtOH can alter the activity of PNs by two mechanisms: 1) an action on the voltage-sensitive conductances generating the endogenous activity and 2) an action at cerebellar interneurons providing the synaptic input. Studies using intracellular recordings will examine the postsynaptic sites of EtOH action in more detail and extracellular recordings will be used to identify the sensitive presynaptic neurons. (Supported by NIAAA grant AA 06420)

87.4 POSTSYNAPTIC EFFECTS OF ETHANOL AT A CRAYFISH NEUROMUSCULAR JUNCTION. R.N. Friedman* and G.D. Bittner. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Intracellular recordings of potential changes in the membranes of single, opener muscle fibers in the propodites of crayfish (Procambarus simulans and clarkii) first walking limbs were used to assess the postsynaptic effects of ethanol (EtOH). Earlier studies showed that EtOH at concentrations that depressed excitatory junctional potentials (EJPs) had no presynaptic effect on nerve terminal potentials (R.N. Friedman and G.D. Bittner, Subst. Alc. Act. Misuse, in press).

As in the previous studies, EJPs were evoked by inducing short-term facilitation with superthreshold pulse trains of 15 to 40 Hz. Single, surface muscle fibers were impaled with two microelectrodes spaced less than 100 um apart to pass constant current pulses and to record resulting changes in membrane potential. Current-voltage relationships were plotted and effective membrane resistances (R_{eff}) in control and 500mM EtOH solutions were compared. Following each R_{eff} determination, EJPs were evoked and measured after 10s of stimulus application.

The results show a 24% decrease in R_{eff} of the muscle fiber membrane accompanying a 40% depression of EJP amplitude. Following the observation of the effects of 500mM EtOH, the preparation was again bathed in control (van Harreveld's) solution. EJP amplitude was increased to a level greater than that of the pre-treatment control. There was a concommitant increase (35%) in R_{eff}. The resting potential (-77mV) remained stable for the duration of the experiment. The membrane time constant varied with the changes in R_{eff}.

The results indicate that EtOH-induced EJP depressions that occur without change in nerve terminal potential, as previously observed, are most likely due to conductance increases in the muscle fiber membrane. The EJP enhancement on returning the preparation to the control bathing medium may be due to residual EtOH which has been shown to increase EJP amptitudes in this preparation at a 50mM concentration in our previous studies (R.N. Friedman and G.D. Bittner, Soc. Neurosci. Abstr. 10:195, 1984).

87.5 **DECREASES IN MEDIO-BASAL HYPOTHALAMIC SEROTONIN IN RATS CONSUMING ETHANOL IN A LIQUID DIET**. Felten, S.Y. and D.L. Felten. Dept. of Anat., Univ of Rochester, Sch. of Med., Rochester, NY. 14642

Numerous attempts to correlate chronic ethanol exposure with changes in brain catecholamine and serotonin levels have led to contradictory findings, depending on dose of ethanol, route of administration, nutritional state, length of exposure, sex of the animal, and area of the brain examined. In an attempt to resolve some of these contradictions, age and weight matched female Wistar rats were pair-fed isq-caloric liquid diets (AIN 76) for 20 weeks. The alcohol diet contained the same levels of vitamins, minerals, protein, and fat as the control diet, but 36% of the calories were derived from ethanol. The control diet had the same number of carbohydrate calories, but in the form of maltose dextrin. Animals receiving the alcohol diet were allowed to consume as much as they wanted in a 24 hr period. This amount was recorded and given to the control animal of the pair the next day. This type of pair-feeding is designed to control for nutritional differences between ethanol treated and control animals, and in addition, minimizes the amount of animal handling necessary. At sacrifice there was no difference in weight between groups. The dose of ethanol averaged 11.26 g/kg body weight.

After 20 weeks of ethanol consumption animals were sacrificed by decapitation, brains were rapidly removed, and discrete areas were microdissected. Each sample was placed in 0.1M perchloric acid sonicated for 10 sec, and centrifuged at 11,000 g for 10 min. The supernatant was removed and injected onto a C18 reverse phase HPLC column for separation of the monoamines which were subsequently detected with electrochemical detection (Brain Res Bull 13:437). Monoamines were measured in 9 areas: paraventricular nucleus, dorsal raphe, medio-basal hypothalamus, 3 regions of hippocampus (CA 1, CA 2 + CA3, CA 4), striatum, parietal cortex, and cerebellar cortex. Serotonin and its metabolite 5-hydroxyindoleacetic acid were reduced in the medio-basal hypothalamus and dorsal raphe in animals consuming ethanol. Norepinephrine was increased in the CA 1 region of the hippocampus but decreased in the CA 2 - CA 3 region.

The reduced serotonergic input to medio-basal hypothalamus may be related to the altered endocrine state of animals consuming alcohol, particularly in the hypothalamo-pituitary axis related to gonadotropins and ACTH. In the hippocampus, rather than decreased serotonin levels, such as those found in the genetic strain of alcohol preferring rats (Pharm Biochem Behav 16:145), these alcohol fed rats showed alterations in NE. The difference in levels among different regions of the hippocampus suggests that alcohol consumption results in a redistribution of noradrenergic fibers within the hippocampus. Whether this is a primary effect or the result of neuronal alterations in the target neurons of the hippocampus is being explored with other techniques.

87.6 CHOLECYSTOKININ OCTAPEPTIDE: EFFECT ON THE ETHOGRAM OF ETHANOL CONSUMPTION AND BLOOD ETHANOL LEVELS. P. J. Kulkosky*, M. R. Sanchez* and G. W. Glazner* (SPON: P. Schnur). Dept. of Psychology, Univ. of Southern Colorado, Pueblo, CO 81001.

Recent experiments show that peripheral injection of sulfated cholecystokinin octapeptide (CCK-8) specifically inhibits consumption of ethanol solutions in the rat. This effect of CCK-8 was characterized by constructing an ethogram of ethanol consumption and measuring blood ethanol levels. Ten naive, male Wistar rats were deprived of water for 23 hours. Rats were injected with i.p. saline and allowed access to 5% w/v ethanol for 45 minutes daily, followed by 15 min access to water. During daily ethanol access, behavioral observations were made with the technique of Gibbs et al. (Soc. Neurosci. Abstr., 6: 530, 1980). Observations of behavior were made at tone-cued 1 min intervals and classified into categories which included ethanol drinking, feeding, standing, grooming, resting, and a category for all other behaviors. After an initial adaptation period of 6 days, rats were randomly assigned to receive injections of either saline or CCK-8 (4 µg/kg). Injection of CCK-8 significantly reduced ethanol consumption, $F(1, 9)=20.17$, $p < 0.05$. Examination of the observational data revealed a significant difference only in total observed feeding behavior after CCK-8. Analysis of these data in 5-min blocks showed a significant decrease in feeding 15 min after ethanol presentation. No other differences were found in any other category of behavior. These rats were then adapted to a schedule of 30 min access to 5% ethanol followed by 30 min access to water. Rats received i.p. injections of CCK-8 (4 µg/kg) or saline 10 min prior to ethanol presentation. At the conclusion of ethanol access, a blood sample was taken from the tail of each rat and assayed for ethanol content as described by Cornell and Veech (Anal. Biochem., 132:418, 1983). CCK-8 significantly reduced both ethanol consumption, $F(1, 8)=24.05$, $p < 0.05$, and blood ethanol level, $F(1, 8)=9.18$, $p < 0.05$. Mean ethanol consumption and blood ethanol level were 14.2 ml and 46.3 mg/dl after saline, and 5.6 ml and 19.1 mg/dl after CCK-8. Blood ethanol level was significantly correlated with ethanol consumption, $r(8)=0.88$, $p < 0.05$. These experiments indicate that CCK-8 reduces ethanol consumption and blood ethanol levels. The accompanying behavioral display differs from control only in feeding behaviors. These results are consistent with the possibility that CCK-8 may act endogenously as a factor in ethanol satiation. (Supported by NIH Grant No. RR-08197).

87.7 ETHANOL INHIBITION OF NOREPINEPHRINE, GLUTAMATE, AND POTASSIUM BUT NOT CARBACHOL STIMULATED INOSITIDE HYDROLYSIS IN BRAIN. F.T. Crews, C. Theiss* and R.A. Gonzales. Dept. of Pharmacology, University of Florida Medical School, Gainesville, FL 32610.

A variety of neurotransmitters have been shown to stimulate the breakdown of inositides in rat brain slices. Evidence suggests that this biochemical event represents the initial step in a receptor activated cascade-amplifier mechanism used in the process of neurotransmission. We have investigated the effects of ethanol in vitro on stimulated inositide hydrolysis in brain. Cortical slices were prepared from male Fisher 344 rats and incubated with [^{3}H]inositol to label membrane inositides. The accumulation of [^{3}H]inositol phosphates stimulated by various agonists ± ethanol was determined in the presence of 8 mM lithium as measured by Dowex-1 chromatography. Ethanol (500 mM) had marked inhibitory effects of the production of [^{3}H]inositol phosphates elicited by 100 µM norepinephrine, 20 mM KCl, and 1 mM glutamate. No significant effects were observed on inositide hydrolysis stimulated by carbachol, 5-hydroxytryptamine (5-HT), or A23187. Ethanol's inhibitory effect on norepinephrine stimulated inositol lipid hydrolysis was concentration dependent and was significant at 100-500 mM. In addition, the effect of ethanol appeared to be exerted on the maximal effect and not on the ED_{50} for norepinephrine. KCl stimulated inositide breakdown was also decreased by ethanol in a concentration dependent manner. The inhibition by 500 mM ethanol was approximately 80% at 20 mM KCl but only 20% at 70 mM KCl. These results suggest that agonist stimulated inositide hydrolysis is differentially sensitive to the effects of ethanol with the order of sensitivity as follows: norepinephrine > KCl > glutamate with no effect on carbachol, 5-HT, or A23187. The lack of effect of ethanol on A23187 stimulation of inositide hydrolysis indicates that the inhibitory effect seen with other agonists is due to factors other than calcium influx into the cell. Ethanol is known to have membrane disordering effects at the concentrations used in these studies. The different agonist sensitivities to ethanol suggest that the membrane transduction systems from agonist-receptor complex to activated phospholipase C have different membrane order requirements. In addition, the changes in receptor stimulated inositide breakdown caused by ethanol for certain receptor systems and not others may contribute to some of the pharmacological and/or toxic effects of ethanol. (Supported by NIAAA grant AA06069).

87.8 PURINERGIC INVOLVEMENT IN THE BEHAVIORAL INTERACTION OF ETHANOL AND ACUTE AND CHRONIC METHYLXANTHINES IN MICE. M. Saeed Dar and Wallace R. Wooles, Department of Pharmacology, School of Medicine, East Carolina University, Greenville, NC 27834

The effect of acute and chronic administration of the methylxanthines, caffeine, theophylline and isobutylmethylxanthine (IBMX) on acute ethanol-induced motor incoordination has been investigated in mice. In acute methylxanthine studies, a significant potentiation of ethanol-induced motor incoordination was observed at 20, 45, and 75 min after a test dose (1.5 g/kg i.p.) of ethanol in mice pretreated with 62.5 mg/kg i.p. of caffeine and 12.5 mg/kg i.p. of IBMX. Pretreatment with 40 mg/kg i.p. of caffeine potentiated ethanol-induced motor incoordination only at 20 min after ethanol. The ethanol-induced motor incoordination was unaltered by theophylline (50 mg/kg i.p.). The results of methylxanthine pretreatment on ethanol-induced motor incoordination were similar regardless of a shorter (10 min) or a longer (75 min) pretreatment time. The methylxanthines produced no effect on motor coordination or behavior when administered in the same doses alone. In chronic (10 day) studies involving IBMX, the same test dose of ethanol produced a significantly greater motor incoordination in mice receiving either 40 or 65 mg/kg/24 h in the drinking water when compared to control mice which received tap water. Ethanol-induced motor incoordination was greater at 1 and 24 h after the withdrawal of IBMX. This motor incoordination was associated with increased binding of ^{3}H-L-PIA in whole brains of mice treated with IBMX. At 1 h of withdrawal, binding in the group receiving 40 mg/kg/24 h of IBMX was 333.17±23.85 vs 205.67±23.02 fmole/mg protein in the control group and at 24 h binding was 368.17±36.94 fmole/mg protein in the IBMX group and 264.16±22.11 fmole/mg protein in control mice. Binding was increased as the dose of IBMX was increased and in mice given 65 mg/kg/24 h whole brain binding at 1 h of withdrawal was 453.53 ±40.70 vs 201.47±24.75 fmole/mg protein in the control group. At 24 h of withdrawal from this dose of IBMX binding was 315.85 ±27.44 vs 198.33±18.25 fmole/mg protein in the control. In experiments involving chronic administration of 60 mg/kg/24/h of caffeine similar results were obtained; there was an increase in ethanol-induced motor incoordination and ^{3}H-L-PIA binding was increased from 202.44±21.44 fmole/mg/protein in control mice to 381.49±32.66 fmole/mg protein in caffeine-treated mice at 24 h withdrawal. The increased ^{3}H-L-PIA binding associated with increased ethanol-induced motor incoordination further supports our previous study showing that adenosine is involved in some of the CNS effects of ethanol.

87.9 REM-SLEEP DEPRIVATION-INDUCED INCREASE IN ETHANOL INTAKE: ROLE OF BRAIN MONOAMINERGIC NEURONS. K. Kiianmaa* and J. Aalto* (SPON: European Neuroscience Association). Research Laboratories of the Finnish State Alcohol Company (Alko Ltd), SF-00101 Helsinki, Finland.

The ethanol intake of Long-Evans male rats was recorded before, during and after rapid eye movement (REM) sleep deprivation produced with the flowerpot technique modified by using a cuff pedestal and electrified grid floor instead of water. Ethanol intake increased significantly during REM-sleep deprivation. A rebound decrease in ethanol drinking was then observed during the REM-rebound phase immediately after the termination of REM-sleep deprivation.

Since REM-sleep deprivation has been reported to impair the function of central monoamine neuronal systems, which some studies also have implicated in the control of voluntary ethanol intake, we studied whether different monoamine uptake blocking agents could antagonize the REM-sleep deprivation-induced increase in ethanol intake. After three days of REM-sleep deprivation, rats were given two daily injections (5 mg/kg/d, i.p.) of either citalopram, GBR 12909, or talsupram (uptake blocking agents for 5-hydroxytryptamine, dopamine, and noradrenamine, respectively). Citalopram and GBR-12909 did not modify the increased level of ethanol intake. In contrast, talsupram caused a decrease in ethanol intake to levels seen prior to deprivation, and during the REM-rebound phase an even further decrease was found. These effects of talsupram could be antagonized by blocking alpha-1-adrenoreceptors with prazosin (1 mg/kg/d, i.p.). Prazosin alone tended to increase ethanol consumption. These findings suggest that functional alterations in central noradrenergic neurons during REM-sleep deprivation may contribute to the concurrent increase in ethanol intake. This supports an earlier view indicating the importance of these neuronal systems in the regulation of voluntary ethanol consumption.

87.10 ALTERATIONS IN 2-DEOXYGLUCOSE UPTAKE IN BRAIN PRODUCED BY DIAZEPAM IN ETHANOL WITHDRAWING RATS. C.A. Marietta*, K. L. Zbicz, M. J. Eckardt, E. Majchrowicz* AND F. F. Weight. Laboratory of Preclinical Studies and Laboratory of Clinical Studies, DICBR, National Institute on Alcohol Abuse and Alcoholism. Rockville, MD 20852

Diazepam is commonly used to treat the ethanol-withdrawal syndrome. It has been previously shown that regional uptake of glucose, as measured with radiolabeled 2-deoxyglucose (2-DG), is altered during withdrawal from ethanol dependence (Campbell et al., Brain Res. 237: 517, 1982). We investigated the effects of diazepam (DZP) administration on 2-DG uptake in ethanol-withdrawing rats. Male, Sprague-Dawley rats (200-300g) were rendered physically dependent upon ethanol by the oral administration of 20% v/v ethanol (8-11g/kg/day) in Sustacal. Fractional doses were administered over a period of 4 days using a previously published intubation technique (Majchrowicz, Psychopharmacologia, 43:245, 1975). On the day following termination of ethanol administration, the rats were evaluated hourly for the signs of withdrawal (tremors and other behavioral signs of CNS hyperactivity). After 4-6 consecutive hours of withdrawal signs (usually beginning 12-18 hours after the final dose of ethanol), rats were prepared for the determination of local brain glucose uptake using the 2-DG method of Sokoloff et al. (J. Neurochem. 28:897, 1977). 2-DG was injected 30 min after the IP injection of 5 mg DZP/kg of body weight. This dose was selected because it was shown to alleviate the behavioral signs of withdrawal 30 min after injection. Control rats were similarly withdrawing from ethanol but received an IP injection of vehicle 30 min prior to the injection of the 2-DG. A generalized increase in 2-DG uptake was observed in the withdrawing controls, as well as columnar areas of increased uptake in the frontal sensorimotor cortex, ovoid areas of increased uptake in the cerebellar vermis, and increased uptake in various thalamic nuclei. These results are similar to those reported by Campbell et al. (Brain Res. 237: 517, 1982). Compared to the vehicle-injected withdrawing controls, the autoradiographs of withdrawing rats administered DZP revealed a generalized decrease in uptake, a lack of columnar areas of increased uptake in the frontal sensorimotor cortex, and a lack of ovoid areas of increased uptake in the cerebellar vermis. Our observations suggest a correlation between the effects of DZP on the behavioral signs of alcohol withdrawal and 2-DG uptake in the frontal sensorimotor cortex and cerebellar vermis. Further detailed analysis is necessary to determine whether the activity of other brain structures in the withdrawing rat is influenced by DZP.

We thank Hoffman-LaRoche for their gift of diazepam.

87.11 ACETYLCHOLINE (ACh) AND MUSCARINE REDUCE CA1 FIELD POTENTIALS IN THE HIPPOCAMPAL SLICE: POTENTIATION BY ETHANOL. George R. Siggins and Samuel Madamba, Div. Preclinical Neuroscience and Endocrinology, and Alcohol Research Center, Research Institute of Scripps Clinic, La Jolla, CA 92037.

We reported previously that systemic ethanol potentiates the excitatory effects of iontophoretically applied ACh on hippocampal pyramidal neurons (Mancillas et al, Soc. Neurosci. Abst. 10: 968, 1984). However, several concerns arise from such in vivo studies: 1) the anesthetic used (halothane) may have influenced the results; 2) the concentrations of ACh were unknown; 3) understanding the mechanism of this effect requires intracellular recording, a difficult procedure in vivo. Therefore, we have repeated these studies in vitro, using the rat hippocampal slice preparation.

Such slices were prepared by standard procedures (Siggins and Schubert, Neurosci. Lett. 23: 55, 1981) and totally submerged and superfused at the rate of 2-5 ml/min with carbogenated artificial CSF (ACSF). Stratum radiatum was stimulated with a double-pulse paradigm and evoked field potentials were recorded in the CA1 pyramidal layer. Only slices with population spikes of 5-12 mV were used. The potentials were digitized, averaged, stored and analyzed by computer. Drugs were introduced in defined concentrations into the recording chamber, without altering ACSF flow, by means of a manifold-valve system.

In apparent contrast to the excitatory effects of ACh iontophoresis in vivo, ACh superfusion (10-100 μM) consistently reduced the size of both the primary and secondary population spikes recorded in the CA1 pyramidal layer. This effect occurred at 2-4 min after entrance of ACh into the bath and usually persisted for 10-15 min with little evidence of tachyphylaxis. Enlargement of the field potentials was rarely seen. Lower ACh concentrations had no detectable effect. Muscarine, a "pure" muscarinic receptor agonist, gave comparable results at 1-10 μM, suggesting involvement of muscarinic receptors. The 10 μM dose often totally abolished the synaptic field potential and the population spike of both primary and secondary fields, whereas 0.1 μM or less had no effect. Superfusion of ethanol in low concentrations (10-22 μM, equivalent to 50-100 mg%) had little direct effect on the field potentials. However, these concentrations markedly potentiated the effect of threshold amounts of ACh and muscarine in reducing the field potentials.

These results suggest that the ethanol potentiation of ACh effects in vivo does not result from the use of anesthetics or unphysiological concentrations of ACh. However, the mechanisms behind this potentiation and the apparent inhibitory effect of superfused ACh (see also Valentino and Dingledine, J. Neurosci. 1: 784, 1981) in our slice preparation remains to be resolved by intracellular recording. (Supported by USPHS grant AA-06420)

87.12 A DIRECT CORRELATION BETWEEN ETHANOL-INDUCED LOSS OF RIGHTING REFLEX AND ENDOGENOUS AMINO ACIDS RELEASED IN THE MEDIAL SEPTUM AS MEASURED BY IN VIVO DIALYSIS. T.J. McCown and G.R. Breese. Biol. Sci. Res. Ctr., UNC Sch. of Med., Chapel Hill, NC 27514.

It has been proposed that ethanol exerts its depressant effects on the CNS by increasing the fluidity of neuronal membranes. As the neuronal membrane become more fluid, normal functions become impaired. Therefore, ethanol's alterations of a specific behavior would result from the impairment of neuronal function in the CNS sites which mediate the behavior. Identification of such CNS sites could be accomplished by establishing site specific interactions with ethanol. For example, we have previously shown that antagonism of ethanol-induced loss of righting reflex by thyrotropin-releasing hormone (TRH) occurs most potently in the medial septum (McCown and Breese, Alcohol 1:168, 1984), while increasing GABAergic activity in the medial septum potentiates this measure of ethanol-induced depression. If ethanol does alter activity in the medial septum, do endogenous neurochemical changes parallel the behavioral changes?

In order to answer this question, rats were implanted under ether anesthesia with a 2 mm long dialysis fiber (Amicon Vitafiber) in the medial septum. Following a 3 hr perfusion period (2 ul/min., Ringers solution), samples were collected every 20 min., and the concentrations of histidine, glutamine, glutamate, serine, glycine and taurine were determined in the dialysate. At no time was the GABA concentration large enough to quantify. When animals were injected with 3.5 g/kg ethanol (i.p.), the righting reflex was lost and the amino acid concentrations were significantly decreased. The time at which the animals regained their righting reflex coincided with a significant increase in amino acid concentrations towards the control baseline. If the animals received a 5 mg/kg dose (i.p.) of TRH 40 min. after the ethanol treatment, the time necessary for the animals to regain their righting reflex was significantly shortened, and the reversal of ethanol-induced decreases in amino acid concentrations parallelled the return of the righting reflex. In contrast to these data from the medial septum, dialysis of the frontal cortex revealed a totally different pattern of change. Ethanol administration caused a significant increase in taurine concentration, which coincided with the lost of the righting reflex.

From these results, we hypothesize that the medial septum can serve as an in vivo model for the study of ethanol's actions on the CNS, especially in relationship to the righting reflex. (This work was supported by N.C.A.R.A. grant #8304).

87.13 PINEAL AND MELATONIN EFFECTS ON ETHANOL PREFERENCE IN THE SYRIAN HAMSTER. R.J. Salin-Pascual*, H.B. Moss*, and L.Tamarkin*, (SPON: D. Jimerson). Clinical Psychobiology Branch, NIMH and Lab. of Clinical Studies, DICBR, NIAAA, Bethesda, MD 20205

In a free choice experiment, Syrian hamsters will preferentially drink more 5% or 15% ethanol (ETOH) than water. It is unclear why these animals choose ETOH and it is also not known what area(s) of the brain regulates ethanol consumption in these animals. In a previous report surgical removal of the pineal gland was reported to raise ethanol consumption. The present study re-evaluates this observation and determines the effect of pineal hormone replacement by thrice daily melatonin injection on this behavior. Three groups of female hamsters (4 to 6 animals/cage) were exposed to 5% ETOH and water for 1 week, then these 3 groups were presented with 15% ETOH. A fourth group of animals (n=5) was maintained on the 5% ETOH solution. After 4 weeks of exposure to the ETOH/water free choice condition, the hamsters exposed to 5% ETOH and one group (n=4) of hamsters exposed to 15% ETOH were pinealectomized (Px). After a 4 week recovery during which the animals were maintained on the free choice condition, these animals and one (n=6) group of animals were injected thrice daily with 25 ug of melatonin per injection s.c. Daily injections occurred during the light hours (0900h, 1200h and 1500h) of a 14L:10D lighting schedule (lights on 0100h to 1500h). During the baseline period, the melatonin treatment period and the recovery period fluid consumption was monitored daily for each group. For each day an ETOH: water preference ratio was calculated, the data were summarized by week of treatment and significance was determined by analysis of variance.

ETHANOL PREFERENCE RATIOS (EPR)

	Intact	Px(15% ETOH)	Px(5%ETOH)	Intact (saline)
Basal	2.76	2.45	2.92	3.11
Week 1 melatonin	1.42	1.38	1.11	2.69
Week 2 melatonin	1.18	0.92	1.19	2.56
No treatment	1.76	3.76	2.63	2.43

Melatonin treatment resulted in a significant ($p<0.05$) reduction in ETOH consumption in intact and in both groups of Px animals. Pinealectomy itself did not alter the EPR compared to intact animals. Additionally, thrice daily injection did not significantly effect the EPR in intact animals. These data suggest that melatonin alters ethanol consumption which may provide us with some insight into the neurochemical basis of ethanol preference in this species.

87.14 EFFECTS OF ETHANOL ON MID-BRAIN DA AND NON-DA NEURONS. G.L. Gessa*, F. Muntoni*, V. Boi* and G. Mereu. Institutes of Pharmacology and Biology, University of Cagliari, Italy.

The behavioral stimulation induced in rodents and humans by moderate doses of ethanol is thought to be mediated by the activation of central dopamine (DA) transmission. Accordingly, the systemic administration of low doses (0.5-2.0 g/kg) of ethanol increases striatal DA release and DA synthesis, and as we have demonstrated, the firing rate of nigral A9-DA cells. We have also found that a low dose of ethanol depresses the activity of nigral non-DA cells in the pars reticulata (PR), which integrates the striato-nigral feed-back loop and exerts an inhibitory control on the neighboring A9-DA neurons. Thus we proposed that the activation of A9 neurons by ethanol may be the consequence of the preferential depression of such PR inhibitory inter-neurons.

Our question was whether a similar mechanism was also applicable to those DA neurons located within the ventral tegmental area (VTA) which project to limbic and cortical areas (A10 neurons). Indeed VTA-DA neurons have been implicated in the reinforcing properties of cocaine, amphetamine, heroin and brain self-stimulation. Therefore we tested the effect of i.v. ethanol on the activity of DA and non-DA neurons of VTA, comparing it to that observed for A9 and PR cells.

Extracellular single unit recordings of A9 and A10 neurons, as well as PR and VTA non-DA neurons, were performed in paralyzed-locally anesthetized rat preparations. Ethanol was administered intravenously (i.v.) in incremental doses as a 20% (w/v) solution in H_2O.

Ethanol stimulated both A9 and A10 DA neurons. However while the cumulative dose needed to increase by 50% the basal activity (ED_{50}) of A9-DA neurons was 863±72 mg/kg (N=22), the ED_{50} of A10 neurons was 162±25 mg/kg (N=16). By contrast the majority of non-DA cells of both areas were inhibited by i.v. ethanol. About 83% of PR neurons (N=35), whereas only 52% of the non-DA cells of the VTA (N=14), responded to the treatment with the remainder of the cells unaffected. The cumulative dose inhibiting 50% (ID_{50}) of activity in responsive cells was 483±31 mg/kg and 534±63 mg/kg for PR and VTA area, respectively.

These experiments confirm that i.v. ethanol increases the firing of A9 neurons and extend this observation to A10 neurons. The high sensitivity of the latter, more than 5 times that of A9 cells, might be correlated to the fact that meso-limbic and meso-cortical DA projections are proposed to be involved in the behavioral effects of various forms of reward, including those by drugs of abuse. Whether the mechanism of the stimulant action of ethanol on A10 neurons is mediated by an action of non-DA neurons of the same area is presently not clear.
(Supported by CNR grant CT 84.02356.56.)

87.15 TIME COURSE OF ETHANOL EFFECTS ON IMMUNOREACTIVE VASOPRESSIN IN RAT PLASMA. D. L. Colbern, J. ten Haaf*, B. Tabakoff, and Tj.B. van Wimersma Greidanus. Dept. Physiol. Biophys., Univ. Ill. Chicago Med. Ctr., P.O. 6998, Chicago, IL 60680, and Rudolf Magnus Inst. Pharmac., Univ. of Utrecht, The Netherlands.

We previously reported that vasopressin (VP) levels are significantly elevated 5 min after an intraperitoneal (ip) injection of ethanol (2 g/kg, 15% v/v) and inhibited at 60 min. The present study more fully examined the short-term time course of VP release following an acute injection of ethanol. Plasma osmolality and blood ethanol concentration were also measured.

Male, Wistar rats (250-300g) were given food and water ad libitum and maintained on a 14:10, light:dark schedule (lights on 05:00 h). Rats were injected ip with a 15% v/v ethanol solution (2.0 g/kg, 95% ethanol in saline) 5, 15, 30, 60 or 90 min before decapitation. Control animals were given an equal volume of 0.9% saline (1.77 cc/100g). Injections were started at 14:30 h, and decapitations were completed by 17:00 h.

Plasma samples (1.5 ml) were extracted with Vycor glass powder, and VP content was determined by radioimmunoassay using an antiserum (W1E) which had less than 0.01 % crossreactivity with oxytocin. Blood ethanol concentration was determined by gas chromatography, and the osmolality of fresh plasma was measured with a Wescor freezing point osmometer.

Plasma VP levels in saline-treated rats remained unchanged over the 90 minute sampling period. Five min after ethanol injection, VP levels were increased (3.1 ± 0.7 pg/ml) compared to levels in saline-treated rats (1.2 ± 0.2). By 15 min, VP had decreased to control values. VP release was inhibited 30 and 60 min after ethanol injection (0.4 ± 0.1 and 0.3 ± 0.1 pg/ml, respectively), but levels returned to control values at 90 min (1.8 ± 0.9). Ethanol concentration was highest at 5 min (257.6 ± 11.9 mg%), declining thereafter (to 155.9 ± 4.5). Plasma osmolality was inversely correlated with blood ethanol concentration.

The effects of ethanol concentration and injection volume were also examined. Under the conditions described above, ethanol doses of 2.0 g/kg were administered as 10, 15 or 20% solutions. Comparison groups received equivalent volumes of saline (2.66, 1.77, or 1.33 cc/100g) or sham injections 5 or 60 min before decapitation. Again, for all ethanol concentrations, VP levels were increased at 5 min. Neither ethanol concentration nor injection volume differentially affected VP levels. Plasma osmolality and blood ethanol content were also unaffected by different concentrations of ethanol, although plasma from both saline- and ethanol-injected rats was diluted compared to those receiving sham-injections.

Vasopressin levels in response to ethanol follow a biphasic time course, and are not merely inhibited. Rapid, early release of VP may mediate some of the effects of acute ethanol injection.

87.16 INVOLVEMENT OF ENDOGENOUS ADENOSINE-RECEPTIVE SYSTEMS IN THE STIMULUS PROPERTIES AND BEHAVIORALLY DEPRESSANT EFFECTS OF ETHANOL. R.C. Michaelis, F.A. Holloway, and G.A. Hunter*. Dept. of Psychiatry and Behavioral Sciences, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

It has been suggested that ethanol-induced sleep and motor incoordination are mediated in part by stimulation of adenosine-receptive systems in the CNS. This study examined the possibility that the discriminative stimulus properties and response rate-reducing effects of high doses of ethanol are mediated by an agonist action on adenosine-receptive neurons. Two groups of rats were trained to discriminate the stimulus properties of ethanol from those of saline. One group was trained with 1.0 g/kg ethanol throughout the entire study. In the other group, the training dose of ethanol was gradually increased as tolerance developed in order to maintain a significant response rate reduction. Results from both groups suggested that the discriminative stimulus properties of ethanol are not mediated through adenosine-receptive systems. No stimulus generalization was seen after administration of either of the adenosine analogs N6-cyclohexyladenosine (CHA) or 5' -N-ethylcarboxamide adenosine (NECA). In addition, the stimulus properties of ethanol were not antagonized by either caffeine or 8-phenyltheophylline. Finally, neither the adenosine deaminase inhibitor erythro-9-(2-hydroxy-3-nonyl)-adenine (EHNA) nor the adenosine uptake inhibitor dipyridamole were able to enhance the stimulus properties of a low dose of ethanol. In contrast to the stimulus properties of ethanol, preliminary findings suggest a synergism between ethanol and adenosine agonists with respect to the ability of these drugs to reduce operant response rate.

87.17 MORPHOLOGICAL EVIDENCE OF ALCOHOL-INDUCED PRECOCIOUS NEURONAL AGEING. M.M.Paula-Barbosa, M.A.Tavares and M.M.Borges (SPON : R. ROSENBERG). Department of Anatomy, Oporto School of Medicine, Oporto, Portugal.

It is well known that young chronic alcoholics show deficits in cognitive functions that in several respects parallel those found in the aged. Besides, the morphological studies of the effects of chronic alcohol consumption on CNS made on necropsic material emphasise the similarities between brains of young chronic alcoholics when compared with the aged brains of non-alcoholics. From these observations it was advanced the concept that chronic alcohol consumption could induce a premature ageing of neurons. To substantiate this hypothesis a sound morphological basis is nevertheless required. In fact, the identification of neuronal senescence markers, is difficult to establish in necropsic material since apart from bad fixation it is impossible to exclude other factors present in most alcoholic patients, which, per se, may act on neuronal structure. To gain an insight into this problem we studied, using qualitative and quantitative methods, the cerebellar cortex of groups of 6 alcohol-treated rats for 1,3,6,12 and 18 months. Pair-fed animals were used as controls.

Accurate parameters for morphological senescence of neurons were sought. 1. Lipofuscin deposition - a significant increase in the amount of pigment formation was observed in experimental animals as early as 6 months of alcohol consumption, whereas in controls it became evident only in the older group. Purkinje and basket cells in the cerebellar cortex and hippocampus pyramids of both CA_1-CA_3 subdivisions were the most affected neurons. 2. Empoverishment of dendritic arborization - marked abnormalities in dendrites and their spines were depicted after 6 months of alcohol intake, increasing with the duration of the experiment. Dendritic trees areas appeared reduced in overall size, with less complex branching patterns and changes in its spatial orientation. The number of dendritic spines per unit length was conspicuously decreased. 3. Neuritique plaques - scattered single neurites were seen after 3 months of treatment. Neuritic plaques of the primi - tive type were found in the cerebellar cortex molecular layer after 6 months of alcohol intake. 4.Neuronal degeneration -the number of neurons per unit volume of cerebellar cortex (Nv) and their total number were found to be significantly reduced in alcohol treated animals. The most affected were granular cells.

The presence of accurate neuronal ageing indicators appearing together and simultaneously in alcohol-fed animals and its absence in their respective controls, make temtping to suggest that chronic alcohol intake might induce a precocious neuronal ageing.

88.1 DEPENDENCE OF MEPP FREQUENCY AT THE FROG NMJ ON TERMINAL LENGTH AND EXTERNAL Ca^{2+}. P. A. Pawson and A. D. Grinnell, Jerry Lewis Neuromuscular Research Center, UCLA School of Medicine, Los Angeles, CA 90024, USA.

We are seeking physiological explanations for the wide variability in transmitter release properties of frog sartorius neuromuscular junctions (NMJs). These terminals regularly differ by 20-fold or more in quantal content or release per unit length. Previously we have presented evidence that stronger junctions have a greater Ca^{2+} influx per action potential than do weaker junctions (with lower quantal contents or release/unit length) (Pawson & Grinnell, Brain Res(1984)323:311). It is also well known that stronger junctions show higher spontaneous quantal release (i.e. mEPP frequency). We have therefore turned our attention to the spontaneous release phenomena with an eye towards a more complete characterization of physiological differences between junctions.

Identified junctions, where release can be correlated with terminal morphology, were used. We have found that spontaneous release at frog NMJs, similar to their mammalian counterparts, shows a positive dependence on the external Ca^{2+} concentration. Moreover, mEPP frequencies of stronger junctions show a greater dependence on external Ca^{2+}. This phenomena is most striking when all external Ca^{2+} is removed. Under these conditions, all junctions become much more similar in their resting mEPP frequencies. This suggests that stronger junctions have a greater resting Ca^{2+} influx.

We have recently found another possible explanation for some of the physiological differences in mEPP frequency. Although mEPP frequency is positively correlated with quantal content, we have found that often, among junctions of a similar quantal content class, there is a positive dependence of mEPP frequency upon terminal length. This suggests that under some conditions mEPP release and evoked release are not strictly coupled as a function of terminal length. Curiously, we have found that this dependence on terminal length appears to disappear in a Ca^{2+}-free/EGTA Ringer, even under conditions that greatly augment spontaneous release. We are presently investigating this dependence on terminal length, seeking to understand these observations.

(Supported by an MDA Fellowship to PAP and grants from the USPHS to ADG).

88.2 **CHANGES IN RELEASE AT THE FROG NEUROMUSCULAR JUNCTION UPON STRETCH.** M.J. Werle and A.A. Herrera. Neurobiology Section, Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0371.

Both nerve stimulus-evoked and spontaneous transmitter release at the frog neuromuscular junction are known to increase when the muscle is passively stretched (Turkanis, J. Physiol. 230:391, 1973). We have improved upon earlier studies of this phenomenon by examining the effects of stretch at identified junctions, where physiological changes and light microscopic structure can be correlated in detail. Sartorius muscles from adult Rana pipiens were used.

In a sample of 27 junctions, quantal content (m) in low Ca^{2+}/high Mg^{2+} Ringer increased an average of 2.7X when the muscles were stretched from 90% to 120% of in vivo length. After nerve terminal and cholinesterase staining, terminal lengths ranging from 156 to 914 μm were measured for 14 of these junctions. A significant positive correlation was found between nerve terminal length and the increase in m ($r=0.91$, $P<0.01$). In a separate sample of 27 identified junctions, a significant positive correlation was also found between nerve terminal length and the increase in miniature endplate potential frequency (MEPP f; $r=0.46$, $P<0.05$). Thus the enhancement of release by stretch appears to correlate with total nerve terminal length by an as yet unknown mechanism.

Earlier studies (ibid.) showed that tetrodotoxin (TTX) decreased but did not abolish the effects of stretch on MEPP f. To further test whether the presynaptic voltage-dependent Na^+ channel is involved in the stretch enhancement of MEPP release, we replaced Na^+ in the Ringer with dimethylamine, a cation that is impermeable through the voltage-dependent Na^+ channel but permeable through the acetylcholine channel (Hille, J. Gen. Physiol. 75:469,1980). Each of several identified junctions was then tested in the presence and absence of external Na^+ for the effects of stretch on MEPP f. There was no significant difference in the mean increase in MEPP f upon stretch in normal Na^+ (2.4X) or 0 Na^+ (2.3X). The replacement of Na^+ with dimethylamine produced a substantial decrease in resting MEPP f (73%) as well as slight decreases in membrane potential (10%) and MEPP amplitude (19%), but these changes were reversible upon the return of Na^+. Since the stretch effect is not eliminated by TTX or diminished by replacing Na^+ with an impermeant cation, we conclude that the voltage dependent Na^+ channel is not involved in the stretch enhancement of MEPP f. Further experiments are in progress. (Supported by NIH grant NS18186).

88.3 **DIFFERENCES IN SYNAPTIC EFFICACY AT FROG NEUROMUSCULAR JUNCTIONS.** A.A. Herrera, L.R. Banner* and P. Mason*. Neurobiology Section, Deparment of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0371.

Studies of naturally occurring differences in the effectiveness of synaptic transmission at neuromuscular junctions (Herrera, et al., J. Neurocytol. 14, in press, 1985) have proven useful in determining the morphological and physiological basis of long-term changes in synaptic efficacy (Herrera et al., Neuroscience, in press, 1985; Herrera & Grinnell, J. Neurosci., 5, in press, 1985). In a continuing search for preparations in which synapses show large differences in efficacy, we have examined cutaneous pectoris (CP) and cutaneous dorsi (CD) muscles of Rana pipiens.

Both muscles are composed of twitch fibers with identical mean contraction times of 29 ms and similar mean fiber diameters (CD 38 μm, n=168; CP 42 μm, n=223). Reducing $[Ca^{2+}]$ in the Ringer from 1.8 to 1.0 mM causes nerve stimulus evoked twitch tension to fall by an average of 66% in the CD (n=21) while CP tension falls only by 11% (n=17), indicating substantially higher safety margins for neuromuscular transmission in CP muscles. We find no differences in muscle fiber action potential threshold or input impedance, suggesting that this difference in safety margin is due to presynaptic factors. Indeed, in Ringer containing 0.5 mM Ca^{2+} and 3 mM Mg^{2+}, CP junctions showed 4X higher EPP quantal content (CP mean 7.6, n=149; CD 1.8, n=90) and 5X higher MEPP frequency (CP 0.91 Hz, n=148; CD 0.18 Hz, n=82). Nerve terminals in the CP are slightly longer (CP mean 504 μm, n=223; CD 409 μm, n=168) but do not otherwise appear different in the light microscope. Since it seemed that this 23% difference in terminal length could not account for a difference in release of several hundred per cent, these data suggested to us that there are intrinsic differences in release per unit terminal length. Recordings made from single identified junctions in 0.5 mM Ca^{2+}/3 mM Mg^{2+} Ringer confirm this, showing that the CP has 2.5X higher quantal content per unit terminal length (CP 1.18 quanta/100 μm, n=26; CD 0.47 quanta/100 μm, n=21) and a 3.7X higher rate of MEPP release per unit terminal length (CP 1.88 Hz/1000 μm, n=26; CD 0.51 Hz/1000 μm, n=17). We are currently measuring evoked and spontaneous release in normal Ringer (1.8 mM Ca^{2+}) after blocking excitation-contraction coupling and muscle fiber action potential generation with formamide. Correlated morphological observations using freeze fracture electron microscopy suggest that these differences in transmitter release may be related to differences in some aspects of the ultrastructure of presynaptic active zones (Ko et al., Soc. Neurosci. Abstr., this volume). (Supported by NIH grant NS18186 and the Muscular Dystrophy Association).

88.4 **A COMPARISON OF ACTIVE ZONE ULTRASTRUCTURE IN TWO MUSCLES WITH MARKEDLY DIFFERENT SYNAPTIC EFFICACY.** Chien-Ping Ko, Jon W. Propst and Albert A. Herrera. Neurobiology Section, Dept. of Biological Sciences, University of Southern Calif., Los Angeles, Ca. 90089.

Thin section electron microscopy has shown that transmitter release efficacy is correlated with indirect estimates of active zone (AZ) length (Herrera et al., J. Neurocytol., 14: in press, 1985). We examined this question more directly using freeze-fracture electron microscopy. We chose to study AZ ultrastructure from nerve terminals in two muscles: the cutaneous pectoris (CP) and cutaneous dorsi (CD) of Rana pipiens. These muscles differ widely in synaptic safety factor and release per unit nerve terminal length, with the CP being stronger (Herrera et al., Soc. Neurosci. Abstr., this volume).

Average safety factors were determined as described previously (Grinnell and Herrera, J. Physiol., 307:301,1980). After pinning to 1.05x rest length, muscles were fixed in frog Ringer containing 3% glutaraldehyde. Endplate regions were dissected and prepared for freeze-fracture using standard techniques (Ko, J. Cell Biol., 98:1685,1984).

Morphometric analysis of nerve terminals showed differences between CP and CD. Data taken from 11 CP terminals with 342 AZ segments and 9 CD terminals with 388 AZ segments gave the following results. Although AZ spacing did not show any apparent difference between the two muscles, AZ length per 100 microns of nerve terminal length was slightly larger in CP. The length of individual AZ segments was greater in CP, as was the percentage of terminal width occupied by AZ. The number of AZ segments per junctional fold was higher in CD terminals. Preliminary results suggest that differences in synaptic efficacy between strong and weak junctions can be related to some aspects of AZ ultrastructure. (Supported by NIH and MDA grants.)

88.5 **THE CORRELATION BETWEEN SYNAPTIC EFFICACY AND ACTIVE ZONE ULTRASTRUCTURE STUDIED WITH FREEZE FRACTURE OF IDENTIFIED NEUROMUSCULAR JUNCTIONS.** J.W. Propst and C.-P. Ko. Neurobiology Section, Dept. of Biological Sciences, University of Southern Calif., Los Angeles, Ca. 90089.

Since quantal content per unit terminal length can vary widely in the same muscle, it has been difficult to correlate differences in synaptic strength with synaptic structures. We have developed an innovative technique to study the relationship between synaptic efficacy and active zone (AZ) ultrastructure by freeze fracture of physiologically identified neuromuscular junctions.

Cutaneous pectoris muscles from Rana pipiens were dissected and pinned to 1.15x rest length. Quantal content was measured in 0.35mM Ca^{++}/4mM Mg^{++} Ringer solution from individual muscle fibers. The fibers were marked by the injection of Lucifer Yellow. After fixation, endplates were visualized with a cholinesterase stain we modified to be compatible with later freeze fracture. The muscles were glycerinated and identified fibers teased out. Endplates were drawn using a camera lucida. Single fibers were frozen in Freon-22, stored in liquid nitrogen, and fractured in a complementary replica device.

The overall success of our method was quite high, with 20% of fibers fractured showing active zones. The most important result was an apparent correlation between quantal content per 100 microns of terminal length and the amount of active zone per 100 microns (r=0.68). The preliminary data from 5 experiments (m/100u, AZ/100u) is given below: (0.41,114u); (0.41,178u); (0.52,128u); (0.92,173u); and (1.62,193u). In addition, AZ length seemed to be related to AZ spacing and terminal width. Although there has been a recent attempt at single fiber freeze fracture (Pawson and Grinnell, Soc. Neurosci. Abstr., 10:918, 1984), to the best of our knowlege, the present study is the first report showing freeze fracture of physiologically identified endplates, and a relationship between synaptic efficacy and AZ length. Additional experiments are in progress to supplement the results described above, and to examine if other aspects of AZ ultrastructure are related to transmitter release. (Supported by NIH and MDA grants).

88.6 **FREEZE-FRACTURE STUDY OF THE EFFECTS OF PROTEOLYTIC ENZYMES ON ACTIVE ZONES IN THE FROG NEUROMUSCULAR JUNCTION.** R.R. Nystrom* and C.-P. Ko. (SPON: G. Augustine). Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089.

It has been shown that proteolytic enzymes digest the basement membrane and cause synaptic disjunction of nerve terminals and muscle endplates (Betz and Sakmann, J. Physiol. 230:673, 1973). Since the basal lamina (BL) is believed to play an important role in the differentiation of the active zone (AZ) (Sanes et al., J. Cell Biol. 78:176, 1978), it is of interest to study the effect of BL removal by proteolytic enzymes on the AZ ultrastructure.

Cutaneous pectoris muscles from Rana pipiens were treated with 0.1% collagenase and 0.01% protease according to the protocol of Betz and Sakmann. Muscles were then fixed and processed for freeze-fracture. In some cases the nerves were stimulated during slow fixation. Also, other enzyme-treated muscles were incubated with filipin in a fixative solution, in order to obtain information about membrane lipid heterogeneity (Nakajima and Bridgman, J. Cell Biol. 88:45, 1981).

Following the proteolytic enzyme treatment, disorganization of AZs was observed. Although some AZs retained the normal organization of two double rows of intramembrane particles, they were much shorter than normal. In addition, they were located and oriented randomly. Dimples, which might represent openings of synaptic vesicles, were seen even at these disrupted AZs. Filipin-sterol complexes were absent from disrupted AZs in enzyme-treated muscles, as is the case with normal non-disrupted AZs.

This study shows that treatment of frog neuromuscular junctions with proteolytic enzymes causes a disorganization of AZs and that these disorganized AZs are still functional. It is not known, however, whether this effect is due to BL removal or direct action of the enzymes. In addition, the results suggest that the absence of filipin-sterol complexes is closely associated with AZ particles. (Supported by MDA postdoctoral fellowship and NIH, MDA grants).

88.7 PHENOTYPE-SPECIFICITY OF THE MEMBRANE-ASSOCIATED FORMS OF THE CATECHOLAMINE SYNTHESIZING ENZYMES. O. Hwang*, C. Abate* and T.H. Joh. Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

The catecholamine synthesizing enzymes tyrosine hydroxylase (TH) and phenylethanolamine N-methyltransferase (PNMT) have been generally believed to be soluble cytosolic proteins. Although particulate forms had been reported, these were thought to be the aggregated forms of the soluble enzymes as the enzymes' high tendency to aggregate was known. Dopamine -hydroxylase (DBH), on the other hand, is known to exist in two forms: soluble and membrane-bound. We have recently reported (Docherty et al., Brain Res., in press) that anti-TH antibody causes the complement-mediated specific immunolysis of dopaminergic synaptosomes isolated from rat striatum, which suggests the presence of a TH-like protein in the membrane.

To investigate this further, we have carried out a series of proteolytic digestion of the membrane fraction of catecholamine-containing tissues, followed by immunoblot with antibodies to TH, DBH and PNMT. The results showed that in the dopaminergic synaptosomal plasmamembrane, there is a TH population which is protected from the proteolytic digestion by the presence of the membrane suggesting the possibility of a membrane-associated form. In bovine adrenal medulla, which is primarily noradrenergic and adrenergic, however, this proteolytically protected form of TH was not present. Instead, a protected form of PNMT, in addition to the membrane DBH, was found. These results have been confirmed by Triton X-114 extraction studies.

Thus, we found the proteolysis resistant, probably membrane-associated, forms of the catecholamine biosynthetic enzymes. These membrane-associated forms seem to be phenotype-specific: TH in dopaminergic cells, DBH in noradrenergic cells, and PNMT in adrenergic cells. We conclude that the coordinate expression of the soluble and the membrane-associated enzymes may determine the phenotype of the catecholamine-synthesizing cells.

88.8 THE RELEASE OF DOPAMINE AND SEROTONIN FROM TWO POPULATIONS OF SYNAPTOSOMES ISOLATED ON PERCOLL GRADIENTS. P.J. Robinson*, W. Lovenberg*, and P.R. Dunkley* (SPON: H. Pollard), NHLBI, National Institutes of Health, Bethesda, MD 20205, and The Neuroscience Group, Faculty of Medicine, University of Newcastle, N.S.W. Australia, 2308.

A rapid procedure has recently been described for the preparation of synaptosomes from rat brain utilizing Percoll gradient centrifugation (Rostas et al., Abs. Soc. Neurosci. 10, 917, 1984). Two distinct sub-populations of synaptosomes were isolated and their homogeneity and viability were assessed. In this study a modified procedure was employed to isolate the two fractions, to determine their content of dopamine (DA) and serotonin (5-HT), and to demonstrate the release of these neurotransmitters. Rat striatum was homogenized in 0.32 M sucrose/1 mM EDTA, then dithiothreitol was added (to 0.25 mM). After centrifugation for 10 min at 1000 g the supernatant (2 ml) was layered onto gradients of 2 ml steps of 3, 10, 15 and 23% Percoll (in sucrose/EDTA/dithiothreitol) and centrifuged at 32,500 g for 5 min. Synaptosomes collected from the 10-15% interface (fraction 6) and the 15-23% interface (fraction 8) were washed once in 0.32 M sucrose and twice in Krebs solution (containing 0.1 mM calcium). Synaptosomes were preincubated at 37°C for 60 min, followed by 60s incubation in the same buffer, or in depolarizing Krebs. Incubations were terminated by centrifugation and the pellet homogenized in 0.1 M perchloric acid and recentrifuged. DA and 5-HT were determined in the supernatant by HPLC.

Striatal fraction 8 synaptosomes contained a significantly greater amount of endogenous DA (43.6 ng/mg protein) than fraction 6 (29.3 ng/mg), and upon depolarization endogenous levels were significantly reduced to 84% (fraction 8) and 86% (fraction 6). In contrast, endogenous 5-HT levels were greater in fraction 6 (2.46 ng/mg) than fraction 8 synaptosomes (1.39 ng/mg), and upon depolarization levels were reduced to 77 and 72%, respectively. Most of the neurotransmitter released from the synaptosomes was recovered in the extrasynaptosomal buffer as 5-HT, or as DA plus DOPAC. The results demonstrate for the first time that the two synaptosomal populations isolated on Percoll density gradients are functionally capable of releasing endogenous neurotransmitter stores. The results also raise the possibility that a relative enrichment of dopaminergic synaptosomes in fraction 8 and of serotonergic synaptosomes in fraction 6 has been achieved. This supports the suggestion that these fractions may represent two populations of functionally distinct synaptosomes.

88.9 ACETYLCHOLINESTERASE IN CLONAL NICOTINIC SYNAPTIC TRANSMISSION. F.-C. T. Chang and M. Adler. Neurotoxicology Branch, Physiology Division, USAMRICD, APG, MD 21010-5425.

A cell culture model system was utilized to investigate the actions of acetylcholinesterase (AChE) inhibitors on nicotinic synaptic transmission. The presynaptic element consisted of neuroblastoma x glioma hybrid cell NG108-15, which synthesizes, stores and releases acetylcholine (ACh); the postsynaptic element was subserved by the clonal G8-1 myotube, which expresses nicotinic ACh receptors in high density but has low AChE activity. This biclonal synapse is devoid of junctional folds, connective tissues and Schwann cell processes. The primary cleft is approximately 20-50 nm and contains discontinuous basal lamina.

We have previously demonstrated some direct effects of the irreversible organophosphorous agent diisopropylfluorophosphate (DFP) on the ACh receptor-channel macromolecule. These consisted of a depression in the miniature synaptic potential (MSP) amplitude, a shortening in the open channel lifetime and an enhancement in the desensitization rate. However, washout of unreacted DFP did not lead to the typical increases in the synaptic potential decay phase that accompany inhibition of AChE at the motor endplate. In this study, we have investigated possible reasons for the failure of clonal synapses to show prolongation of the synaptic response after AChE inhibition. The absence of prolongation suggests that in the NG108-15/G8-1 synapse, AChE is not rate limiting for removing transmitter from the synaptic cleft. This may arise because AChE is not sufficiently concentrated or correctly localized in the synapse. There are two possible consequences: (1) Diffusion of ACh may be adequate to clear transmitter from the synaptic cleft. If so, the macroscopic miniature synaptic current (MSC) lifetime should approach the limit imposed by the ACh channel gating reaction, irrespective of AChE activity. (2) Alternatively, if diffusion is slow (as at the motor endplate), the MSC decay will be longer than the mean single channel lifetime under all conditions. These two possibilities were examined by comparing the single channel open time measured in patch-clamp experiments with whole cell voltage-clamp recordings of the MSC. Under control conditions, the mean single channel open time at 37°C and -80 mV was 1.82 ± 0.14 msec (n=4). The MSC decay time constant, measured at the same temperature and membrane potential, was found to exceed this value by a factor of 1.5 to 4.3. Neither the mean channel open time nor the MSC decay time constant showed any systematic changes after exposure and subsequent washout of 100-500 μM DFP. These results indicate that the failure of DFP treatment to prolong the MSP and MSC decay stems from the fact that it is already prolonged under control conditions.

88.10 MOLECULAR EFFECTS OF ROUS SARCOMA VIRUS TRANSFORMATION ON CULTURED CHICKEN MYOTUBES. D.T. Anthony* and L.L. Rubin. Rockefeller Univ., New York, NY 10021.

Chicken myotubes infected before fusion with a temperature sensitive mutant (tsNY68) of Rous sarcoma virus (RSV) do not cluster acetylcholine receptors (AChRs) either spontaneously or in response to exogenous clustering factors (Anthony, D.T. et al., PNAS, 81: 2265, 1984). This defect in AChR clustering is observed even at the nonpermissive temperature for viral transformation, but nonetheless is due to the presence of the transforming gene src of RSV, which codes for a membrane associated tyrosine protein kinase $pp60^{src}$. We have tried to identify changes in transformed muscle cells which make them unable to cluster AChRs and might, thereby, prove useful in specifying molecular events which normally contribute to the maintenance of high densities of AChRs at the neuromuscular junction. First, we investigated the possibility that residual $pp60^{src}$ kinase activity at the nonpermissive temperature is sufficient to phosphorylate an AChR cluster-associated molecule; in fact, it appears that AChRs themselves are phosphorylated. AChRs were purified from ^{32}P-orthophosphate labeled cell cultures by chromatography on cobratoxin-Sepharose followed by con A-sepharose. The α-subunit, identified in ^{35}S-methionine labeled cultures, was not phosphorylated. Two other subunits, molecular weights 46-50 kd and 55-60 kd, were phosphorylated on serine and tyrosine residues in infected cells. The function of AChR phosphorylation is currently being explored. We also looked for other differences between infected and noninfected cells and found that a 37 kd protein was greatly decreased in the infected cells. Using anti-chick gizzard tropomyosin antibodies (supplied by Dr. F. Matsumara, Cold Spring Harbor Labs), we identified the 37 kd component as one of several tropomyosin isoforms. Future studies will try to determine whether the 37 kd tropomyosin and its interaction with microfilaments has any role in the clustering of AChRs.

88.11 AMPLITUDE FLUCTUATION ANALYSIS OF GROUP Ia SINGLE-FIBER EPSPs IN CAT SPINAL MOTONEURONS. H.-R. Lüscher and H.P. Clamann. Dept. of Physiology, University of Zürich, Switzerland.

The complex morphology of the Ia-motoneuron synapse determines many aspects of its function. The terminal branches of Ia fibers contact a motoneuron with numerous boutons at different sites. Impulses in a Ia fiber do not activate all these boutons; instead, boutons respond to a variable fraction of the impulses ranging from 0 to 1. It is not justified to lump these diverse boutons with their unique behaviors into a single equivalent bouton and to apply classical quantal analysis to this central synapse.

Analysis of amplitude fluctuations of single fiber EPSPs may be used to gain insight into the junctional mechanisms at these synapses, but is limited by the noise of other EPSPs. It is possible to remove the masking effects of this noise and to calculate the amplitude distribution of the fluctuating EPSP by the process of maximum likelihood estimation (MLE). This requires two assumptions: 1) the mechanisms generating the noise are statistically independent of those producing the EPSP fluctuations, and 2) signal and noise add linearly. The variance σ^2 of the gaussian noise amplitude can be measured directly and the problem reduces to finding the mean (μ_k) and membership probability (p_k) of each component of a gaussian mixture distribution of amplitudes. A Monte-Carlo study evaluated the performance of the MLEs for μ_k and p_k of mixtures of computer-generated normal distributions. The estimator reliably found these parameters when $\min|\mu_k-\mu_{k+1}|>1.2\sigma^2$. No a priori assumptions about the statistical distribution of the EPSP amplitudes are made.

The amplitude of 1024 EPSPs produced by a single Ia-motoneuron contact system were measured and the probability density (PD) of the peak amplitude fluctuations was calculated together with the PD of the noise amplitude. MLEs for μ_k and p_k for each of k components of a finite mixture of normal distributions were used to determine the distribution of amplitudes of the fluctuating EPSPs. Most EPSP amplitudes fluctuated among discrete levels which were integer multiples of the increment between successive levels. This increment ranged from 86 μV to 160 μV (mean 121 μV, n=19 contact systems). The PD of the EPSP peak amplitude could not be described by Poisson or binomial statistics. These results suggest that the incremental EPSP reflects the all-or-none action of a single synaptic bouton and that the probability of transmission failure varies among the boutons making up a single Ia-motoneuron contact system. The results are consistent with the hypothesis of incomplete action potential propagation into the terminal arborization as a mechanism for EPSP fluctuations. (Supported by Swiss National Foundation Grant no. 3.308-0.82.)

88.12 QUANTAL ANALYSIS OF POSTSYNAPTIC CURRENT FLUCTUATIONS IN HIPPOCAMPUS. G. Barrionuevo, S. Bench* and T.H. Brown. Div. of Neurosciences, Beckman Res. Inst. of the City of Hope, Duarte, CA 91010.

The quantum hypothesis and the conventional analytical techniques derived therefrom are valuable for analyzing changes in synaptic microphysiology. Because the conventional methods of quantal analysis are based on release probability models whose assumptions may not hold and are difficult to assess (Brown et al., PNAS, 73:2913, 1976), we have been developing a new method that provides accurate information about the synaptic microphysiology even when these questionable assumptions are relaxed.

The new method, which is based on a cepstral-like algorithm, was tested in three independent circumstances. We first applied the method to computer-simulated synaptic release data that were generated by the convolution of a compound binomial release function with a Gaussian quantal density function and a Gaussian noise density function (Bench et al., Fed. Proc., 44:1388, 1985). Next, the method was applied to experimental data obtained from the crayfish neuromuscular junction (Keenan et al., Soc. Neurosci. Abstr., 11: in press). In both cases the new method accurately extracted the quantal release parameters.

Here we report preliminary results of a third test of the new method. Mossy-fiber postsynaptic current fluctuations were examined in CA3 neurons of the hippocampal slice (cf. Brown and Johnston, J. Neurophysiol., 50:487, 1983; Johnston and Brown, In: Brain Slices, 1984). The object of these experiments was to determine whether the new method could correctly detect predicted changes in the mean quantal content m and the mean quantal size q at this cortical synapse. The postsynaptic cell was voltage-clamped at two different holding potentials (-65 and -95 mV). At each potential a series of paired-pulses were delivered to the mossy-fiber axons and several hundred evoked synaptic currents were collected for each pair of stimulations at both holding potentials. Facilitation of the second response amplitude should increase m but not q. By contrast, voltage clamping at more negative holding potentials, which increases the synaptic driving force, should increase q but not m.

The predicted changes in m and q were confirmed. The results of the three separate tests of the new method suggests that this approach may be useful in determining the quantal basis of long-term synaptic potentiation in hippocampus and other structures in which conventional methods of quantal anlysis may be inappropriate. 88.13 AFFERENT INPUT TO NON-PYRAMIDAL NEURONS IN CA1 OF GUINEA PIG HIPPOCAMPUS: LESION-INDUCED TERMINAL AND TRANS-SYNAPTIC DEGENERATION. D.D. Kunkel* and P.A. Schwartzkroin (SPON: D. Sutton) Dept. Neurological Surgery, Univ. Washington, Seattle, WA 98195.

Dendrites of pyramidal and granule cells have been regarded as the postsynaptic targets of afferents to hippocampus. Recently, it has been reported that commissural axons also terminate on non-pyramidal cells of the hippocampus (Brain Res., 1983, 265:289-293). In the course of our studies of hippocampal interneurons, we have investigated the direct afferent input to these non-pyramidal neurons. In adult guinea pigs, the fimbria/fornix was transected or a unilateral hippocampal lesion was made. Animals were allowed to survive for 1 to 7 days post-lesion, were then sacrificed and the brains prepared for electron microscopy. EM analysis of CA1 strata radiatum and oriens showed significant terminal degeneration associated with pyramidal cell dendrites (spines) at all survival periods.

Non-pyramidal cell types in these regions were identified on the basis of morphological criteria established from combined morphological/electrophysiological studies. Following the lesion, degenerating terminals contacting, or just retracting from, the non-pyramidal neuron profiles were common. The form of terminal degeneration on non-pyramidal neurons progressed through a distinct electron-lucent phase. At early survival periods (1-3 days), vacuolated and swollen terminals were common; they often contained synaptic vesicles in densely packed arrays near the synaptic specialization. At later survival periods (4-7 days), terminals were swollen, vesicles depleted and mitochondria were distorted. The electron-dense form of degeneration was seen only during this latter period. Postsynaptic changes in the dendrites of non-pyramidal cells were also observed in some cases. Particularly at later survival periods (3-7 days), many of the postsynaptic non-pyramidal neurons appeared to be in an early stage of degeneration, with condensed electron-dense cytoplasm. Such postsynaptic alterations were not seen in the pyramidal cell dendrites or somata receiving degenerating afferent terminals. A sub-set of interneuron profiles also seemed unaffected.

It is unclear if the effects of the lesion lead to complete interneuron degeneration. Electrophysiological studies showed that abnormally large EPSPs were produced in lesioned guinea pigs, but that IPSP activity was not completely abolished. Trans-synaptic degenerative effects specific to a sensitive interneuron population could have significant consequences, not only following afferent lesions, but also as a result of abnormal activity in afferent pathways.

These studies were supported by NIH grants NS18895 and NS20482, and NSF grant BNS82009906.

88.14 EFFECTS OF PRE-INCUBATION ON CA3 PYRAMIDAL CELLS OF HIPPOCAMPUS IN VITRO. A.K. Davis*, D. Janigro*, and P.A. Schwartzkroin, Dept. of Neurological Surgery, Univ. of Washington, Seattle, WA 98195

Tissue pre-incubation is a procedure commonly used by investigators studying brain slices in vitro. Maintaining slices in normal, oxygenated medium, often at relatively cool temperatures, is an attractive method of holding large numbers of slices before subjecting individual slices to specific treatments. However, the effects of the pre-incubation procedure itself have not been carefully evaluated. Using the in vitro hippocampal slice technique, we have examined the effects of tissue pre-incubation on cellular properties of hippocampal CA3 pyramidal cells.

Pre-incubated slices were maintained in an oxygenated, static bath holding chamber, at 21 or 30°C, prior to transfer of the slices to an interface chamber (constant perfusion, 35°C.) for electrophysiological study. Characteristics of these cells were compared to those of cells in slices which were transferred directly to an interface chamber after slice cutting. Intracellular recordings from CA3 pyramidal cells revealed significant differences between the pre-incubated (P) and non-pre-incubated (NP) tissue. Pre-incubated tissue showed more negative resting membrane potentials (NP = -57 mV, P = -66 mV); increased input resistance (NP = 39 meghoms, P = 47 meghoms); larger synaptic potentials in response to a given stimulus strength (both EPSPs and IPSPs, with a particularly large effect on the late IPSP); lower threshold for stimulus-induced burst discharge; and larger hyperpolarizing afterpotentials. CA3 cells in pre-incubated slices were also more likely to show spontaneous synchronized burst discharge, as seen in simultaneous recording from pairs of pyramidal cells. The cells in the CA3 region of pre-incubated slices were relatively resistant to hypoxia-induced spreading depression (SD). Latencies to SD in NP slices averaged 3.15 minutes, while SDs in pre-incubated slices were often not elicited by the hypoxic challenge or seen only after exposures of 30 to 55 minutes in 12% O_2. CA1 pyramidal cells in pre-incubated slices showed little difference from their non-pre-incubated counterparts in most cell properties, including sensitivity to hypoxia.

A variety of factors could be involved in the observed differences between pre-incubated and non-pre-incubated tissue. Whatever the mechanisms, however, it is important to note that tissue pre-incubation can alter the character of CA3 activity. Such changes may complicate comparison of data between laboratories and between in vitro and in vivo preparations.

These studies were supported by NIH grants NS15137, NS18895, NS20482, and NSF grant BNS82009906.

88.15 EFFECT OF CHRONIC ETHANOL ADMINISTRATION ON THE FINE STRUCTURE OF THE DENTATE FASCIA IN MICE. J.A. Markham, E. Fifková and A.J. Scheetz*. Dept. of Psych., Univ. of Colo., Boulder, CO 80309.

Long-sleep (LS), short-sleep (SS), and heterogeneous (HS) lines of mice that were bred for differential sensitivity to ethanol at the Institute of Behavioral Genetics, University of Colorado at Boulder, were used in these experiments. Thirty mice from each line were divided into three groups and fed with a standard laboratory diet, control isocaloric liquid diet, and isocaloric liquid diet with ethanol, respectively. The ethanol diet was administered according to the following scheme: for the first 7 days only the liquid control diet was given and was followed by diets with increasing concentrations of ethanol derived calories, 11.6%, 23.3%, and 35% for 2, 11, and 7 days, respectively. Consumption of the liquid diets was monitored twice a day and the body weight once a day. Although all strains tolerated well the ethanol diet, all animals on the 35% ethanol diet started to lose weight during the last two days. The loss represented on the average 6.5% of the body weight. Therefore, the experiment was terminated at this time. However this weight loss was not associated with a decreased consumption of the ethanol diet. Animals were perfused transcardially and prepared for electron microscopy. The liquid control diet had no effect on the weights of the HS and SS as compared with the laboratory diet. However, the LS gained weight significantly (13%) on the liquid control diet. Fifty percent of the material has been so far evaluated morphometrically: cross section area, perimeter, and density of dendritic spines and axon terminals have been measured. Given the distinct stratification of the input to the dentate molecular layer, the layer was divided accordingly into thirds, and the results were expressed as an average per third, per line, and per diet. There were no differences in the dimensions and density of dendritic spines across the lines. The ethanol treatment did not have any consistent impact on these parameters when comparison was made with the laboratory diet. However, with the liquid control diet, variations in dimensions of spines were noted. The density of axon terminals did not change across the lines as a function of the various diets. There was also no consistent effect on axon terminals of the HS with the ethanol diet. However, axon terminals of the SS were consistently smaller with the ethanol treatment in all thirds of the dentate molecular layer. On the other hand, the LS terminals were larger in the proximal and distal thirds of the dentate molecular layer. These results are in agreement with the differential sensitivity of the LS and SS to ethanol administration.

88.16 EFFECT OF CHRONIC ETHANOL EXPOSURE ON THE FINE STRUCTURE OF THE STRATUM ORIENS OF CA_1 HIPPOCAMPAL FIELD. A.J. Scheetz*, J.A. Markham and E. Fifková. Dept. of Psych., Univ. of Colorado, Boulder, CO 80309.

Lines of mice with differential sensitivity to ethanol (10 long-sleep, LS; 10 short-sleep, SS; 10 heterogeneous, HS) obtained from the Institute of Behavioral Genetics (University of Colorado at Boulder) were exposed to a chronic ethanol diet for 20 days during which the percentage of ethanol derived calories was raised from 11.6% to 35%. Prior to the start of the ethanol diet administration, mice were exposed for a week to the liquid isocaloric diet without ethanol. With such a pretreatment mice tolerated the ethanol diet for a longer period of time than they would without the pretreatment. The experiment was terminated when some of the ethanol exposed mice started to lose weight for two days. Mice which were fed with the laboratory diet (10 per line) and with control liquid diet (10 per line) were used as controls. Mice were perfused transcardially with a mixture of aldehyde and prepared for electron microscopy. In order to minimize the possible impact of the aldehyde fixation and tissue preparation on the fine structure of the hippocampus, animals from each line were maintained in groups of three and were fed with the laboratory control diet, control liquid diet, and the liquid ethanol diet, respectively. These groups were perfused and prepared for electron microscopy at the same time. Ultrathin sections were prepared from the stratum oriens of the CA_1 hippocampal field, which contains the basilar dendrites of the CA_1 pyramids and commissural afferents. Cross section area and perimeter of dendritic spines and axon terminals were measured. Preliminary data of these measurements have shown that the average cross section area of spines was the smallest in the HS and the largest in the SS. On the other hand, axon terminals were the smallest ones in the SS and the largest in the HS. With ethanol exposure, axon terminals in the HS and LS became smaller while in the SS they were enlarged. The effect of ethanol on dimensions of dendritic spines is being studied.

88.17 THREE DIMENSIONAL STRUCTURE OF DENDRITIC SPINES IN THE RAT HIPPOCAMPUS (CA1) AND CEREBELLUM. K.M. Harris, J. Trogadis*, and J.K. Stevens. Neuroscience Dept., Children's Hospital, Boston, MA 02115 and Playfair Neuroscience, Univ. of Toronto, Toronto Ontario M5T 2S8.

Several studies have shown that dendritic spine morphology and density varies during development, with location in the CNS, and with synaptic activity. Theoretical models of spine function have suggested that changes in spine shape might provide a mechanism for modulating synaptic efficacy. Quantitative analyses of parameters that might account for differences in spine size and shape should begin to provide a rationale for this variability.

Long-evans hooded rats were perfused with 2% paraformaldehyde and 2.5% gluteraldehyde in .1 M sodium cacodylate buffer at pH 7.35 and 37°C. Hippocampus and cerebellum were removed, sliced at 400 um, postfixed with 1% OsO_4 or K-Fe reduced OsO_4 and some were stained en bloc with uranyl acetate and embedded in epon. Silver serial sections were mounted on formvar coated slot grids and stained with lead citrate. Four dendritic segments, 4-6um long with 51 spines from the middle of stratum radiatum were reconstructed using a computer system (Stevens and Trogadis, Adv. Cell. Neuro., 1985). For comparison, a cerebellar dendritic segment, 4 um long with 27 spines was reconstructed.

Spine volumes ranged from 0.016 to 0.235 um^3 in CA1 and from 0.07 to 0.15 um^3 in cerebellum. Smooth endoplasmic reticulum (SER) occupied about 15% of CA1 and cerebellar spine volume, with larger spines containing more SER (r=.80). CA1 spine surface areas were 0.22-2.14 um^2 and synapses 0.0056 - 0.213 um^2 occupied about 8% of this surface. Cerebellar spine surface areas were .33 - 1.66 um^2 and synapses ranging from 0.035-.265um^2 occupied about 10% of the spine surface. In area CA1, spine lengths, head and neck diameters and neck lengths showed no significant relationships with one another, and long spines were either thin or fat, and thin spines were either short or long suggesting that spine shapes are part of a continuum. Spine shape and size was more uniform in cerebellum.

Sixteen axonal varicosities presynaptic to CA1 spines and 15 varicosities presynapic to cerebellar spines were reconstructed. In CA1, 15 of these varicosities made only the 1 spine synapse. One CA1 varicosity also formed a second synaptic junction on a spine of a neighboring dendrite. In cerebellum, 6 varicosities formed 2 synaptic junctions with 2 spines on the same dendritic segment, and 1 varicosity formed a second asymmetric synapse on the shaft of a neighboring dendrite. In CA1, the volume of these varicosities ranged from .033-.232 um^3 and was correlated with spine volume (r=.72) and synaptic area (r=.67).

These preliminary results suggest that spine size is related to SER content, synaptic area and size of the presynaptic varicosity.

SPECIAL LECTURE

89 SPECIAL LECTURE. NEUROCHEMICAL SPECIALIZATIONS IN THE BASAL GANGLIA: THE OLD MOTOR SYSTEM IN A NEW LIGHT. A.M. Graybiel, MIT.

The fiber pathways of the basal ganglia include through-conduction lines and side loops associated with the striatum, pallidum and substantia nigra. By way of the pallidum and substantia nigra, the basal ganglia can influence not only parts of the premotor and supplementary motor cortex, and brainstem sensorimotor regions such as the superior colliculus, but also regions of prefrontal cortex and other structures associated with the limbic system. A remarkable chemical anatomy has been discovered in relation to the basal ganglia, so that many of the fiber pathways associated with the basal ganglia can now be viewed as making up neurochemically specialized subsystems of the extrapyramidal motor system. Much of this neurochemical specificity becomes established at the main input side of the system, the striatum, by means of a compartmental organization that affects both its neurotransmitter systems and its input-output relations.

Key elements of this compartmental organization are the striosomes ("striatal bodies"), first recognized as macroscopically visible zones of low acetylcholinesterase (AChE) activity in sections through the striatum. In all mammals studied (including human) these AChE-poor striosomes form parts of three-dimensional labyrinths. Nearly all of the neurotransmitter-related compounds known to exist in the striatum are now known to be arranged in patterns reflecting the striosomal mosaics. This is true for a number of neuropeptides and for ligand binding sites thought to serve as neuropeptide receptors, and holds for markers of the classical GABA and acetylcholine transmitter systems of the striatum as well. There is also strong evidence that at least part of the dopamine-containing innervation of the striatum observes striosomal ordering: during ontogeny the early-developing "dopamine island" fibers innervate regions that become striosomes at maturity, and subsets of nigral fibers innervating striosomes can be labeled in adults.

This neurochemical patterning is of increasing interest because of evidence that striosomal compartmentalization reflects a plan of organization impressed on nearly all afferents and efferents of the striatum and on the arrangement of striatal interneurons as well. Fibers from the cortex, thalamus and amygdala either "fill" or avoid striosomes depending on their sites or origin, and neurons of the striosomes and of the extrastriosomal matrix have different efferent connections. It is rapidly becoming possible, therefore, to relate the specialized neurochemical properties of the striosomes and extrastriosomal matrix with different chemically coded efferent pathways, and to relate these to particular afferent and interneuronal modulation. The functional implications of these findings are potentially great, for they suggest that individual subsystems in the basal ganglia may be open to specific intervention in the clinical situation and to finely individuated control under normal physiological conditions.

91 SYMPOSIUM. MOLECULAR SYNAPTOGENESIS: TRANSITION FROM GROWTH CONE TO SYNAPSE. M.C. Fishman, Harvard, MGH, HHMI (Chairperson); C.S. Goodman, Stanford University; P.H. Patterson, California Institute of Technology; R.T. Ambron, Columbia University; M. Nirenberg, NIH.

The growth cone of the presynaptic neuron evidences directed outgrowth, and selective cell contact and fasciculation. It eventually ceases probing and evolves into a mature synapse upon appropriate target neurons. M.C.F. will provide an introductory overview of cellular and molecular mechanisms by which a presynaptic cell may find appropriate targets. He will indicate evidence for changes in gene expression and protein transport in the presynaptic cell during the transition from growth cone to synapse. C.S.G. will discuss the cellular and molecular analysis of cell recognition by neuronal growth cones in grasshopper and Drosophila embryos where experimental manipulations and monoclonal antibodies have suggested the differential expression of many different surface recognition molecules. The genes for these molecules are being isolated. P.H.P. will discuss the identification of neurite outgrowth promoting factors, such as the extracellular matrix proteoglycan, and will emphasize the interplay of neuronal proteases and their inhibitors with this proteoglycan. R.T.A. will discuss the use of large identified Aplysia neurons in culture for combined electrophysiological, biochemical, and morphological studies of the cell cell interactions that accompany selective synaptogenesis, and discuss efforts to isolate proteins of the growth cones of single neurons. M.N. will discuss his observations that elevation of cAMP levels of neuroblastoma or hybrid cells shifts relatively undifferentiated cells to a differentiated state and increases synaptogenesis. Cloned cDNA probes have been obtained for species of mRNA that are positively or negatively regulated by dibutyryl cAMP in these cells.

92 SYMPOSIUM. COORDINATION OF RESPIRATORY AND CARDIOVASCULAR HOMEOSTASIS. J.L. Feldman, Northwestern University (Chairman); D.L. Eckberg, Medical College of Virginia; G.L. Gebber, Michigan State University; C. B. Saper, University of Chicago; K.M. Spyer*, Royal Free Hospital, U.K..

Homeostatic regulation in mammals requires gas exchange between air and blood in the lung and appropriate delivery of this blood to and from the body tissues. Thus, oxidative metabolism is sustained and acid-base balance maintained. This requires precise nervous system control and coordination of ventilation and blood flow. In the past few years, it has become increasingly apparent that there are many common anatomical, physiological and pharmacological features of respiratory and cardiovascular control systems. A central substrate for the coordination of these functions is suggested by the observations: i) respiratory premotor and motor neurons are markedly influenced by cardiovascular variables, and; ii) preganglionic autonomic neurons, e.g. cardioinhibitory vagal motoneurons, are actively inhibited by central inspiratory activity. This symposium is an opportunity to fuse the results of several complementary approaches to cardiopulmonary regulation. The central theme concerns homeostasis and movement, which represent the major actions of the brain; we will address issues of rhythmogenesis and pattern generation and discuss mechanisms for brainstem and spinal cord integration and the role of cortical structures in modulating these functions. Data will be presented from man, cat and rodent. Dwain Ekberg will discuss the respiratory modulation of human autonomic outflow based on experimental observations on humans. Single unit sympathetic nerve activity and sophisticated analysis of heart rate provide the basis for assessment of autonomic cardiovascular outflow. This talk will set the groundwork for the subsequent talks, which address detailed observations in reduced mammalian preparations. Jack Feldman will review nervous system control of respiratory movements with emphasis on the basic neural properties underlying respiratory rhythm generation and sensorimotor integration. Recent evidence inplicating these mechanisms in central modulation of cardiovascular control will be discussed. Gerry Gebber will review the generation of sympathetic nerve discharge. He will discuss the physiology of both intrinsic brainstem and bulbospinal neurons controlling basal sympathetic nerve discharge. Recent results on the brain stem locus of respiratory-sympathetic interactions will be presented. Mike Spyer will discuss central mechanisms coordinating respiratory and cardiovascular functions. He will review the physiology and pharmacology of brainstem mechanisms controlling heart rate and blood pressure. Recent results on the respiratory inputs to cardioinhibitory vagal motoneurons and preganglionic sympathetic neurons will provide a basis for describing the integration of respiratory and cardiovascular control. Cliff Saper will describe the common features of the central nervous system anatomy underlying cardiovascular and respiratory function and will discuss the separation, overlap and pharmacology of brainstem structures important in cardiovascular and respiratory control. This data will lead to a discussion of the structural basis for cardiopulmonary coordination. He will include recent physiological data supporting convergence of respiratory and cardiovascular inputs onto parabrachial nucleus neurons.

OPIOID RECEPTORS

93.1 OPIOID RECEPTOR SUBTYPES IN DROSOPHILA MELANOGASTER. C. Santoro,* L.M. Hall and R.S. Zukin, (SPON: N. Sharpless) Departments of Biochemistry and Genetics, Albert Einstein College of Medicine, Bronx, NY 10461.

Multiple classes of opioid receptors have been defined by many approaches, but the molecular basis of this diversity is not yet clear. The question arises as to whether the different receptor types represent different gene products or are posttranslational modifications of a single gene product. The fruit fly Drosophila melanogaster provides a particularly suitable model system in which to address this issue because of the ease with which it can be manipulated genetically. Opioid receptor types present in membrane extracts prepared from heads of the wild-type Canton-S Drosophila melanogaster have been characterized. The μ selective opioid ligand [^{3}H]dihydromorphine (DHM) binds to an apparent single class of high affinity sites with an affinity constant of 125 nM and a maximal number of binding sites of 1590 fmol/mg protein. Binding of [^{3}H]DHM was also analyzed by a Hill plot; the analysis showed a Hill coefficient of 1.0. The binding is saturable and is inactivated by heat treatment suggesting a proteinaceous component. This binding can be displaced by several μ selective ligands but is unaffected by 10^{-5} M D-Ala^2-D-Leu^5-enkephalin (DADLE, a δ selective ligand). In addition, we have been unable to detect any specific [^{3}H]DADLE binding in these extracts suggesting there are no δ receptors in this preparation. We have also looked at K receptor binding. The prototypic K ligand [^{3}H] ethylketocyclazocine (EKC), in the presence or absence of the μ and δ blockers (DAGO and DADLE), binds to an apparent single class of receptors with an affinity constant of 90 nM and a B_{max} of 750 fmol/mg protein. Preliminary data also suggest the presence of σ receptors. Thus we have defined at least two opioid receptor subtypes in Drosophila. In feeding experiments, when wild-type Drosophila are grown throughout development on medium containing either morphine sulfate or etorphine, development is substantially delayed relative to drug-free controls. At the highest concentrations of morphine sulfate used, only 0 to 10% developed to the adult stage. These experiments provide a pharmacological screening strategy for the isolation of single gene mutations affecting this receptor system. Such mutants can potentially provide the means to manipulate genetically each distinct class of receptors independently of the others. This would allow the determination of the physiological and behavioral significance of each class of receptors.

93.2 CHARACTERIZATION AND VISUALIZATION OF BRAIN KAPPA OPIATE RECEPTORS: A COMPARATIVE STUDY OF RAT AND GUINEA PIG. M. Eghbali*, A. Tempel, S. Henriksen, and R. S. Zukin Departments of Biochemistry and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461 and Department of Preclinical Neuroscience and Endocrinology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

A comparative study of the biochemical properties and anatomical distribution of the K receptor in guinea pig and rat brain was carried out. K receptors were labelled using the prototype K ligand [^{3}H]ethylketocyclazocine ([^{3}H]EKC) in the presence of the D-Ala^2,N-Me-Phe^4,Gly-ol^5-enkephalin (DAGO) and D-Ala^2, D-Leu^5-enkephalin (DADLE), which block the binding of the radioligand to μ and δ receptors. Scatchard analysis of [^{3}H]EKC binding to rat brain membranes (in the absence of blockers) revealed a curvilinear plot which could be resolved into 2 components; K_d1 = 0.73 ± 0.14 nM, B_{max} 1 = 94 ± 19 fmol/mg; K_d2 = 8.7 ± 0.6 nM, $B_{max}2$ = 252 ± 1 fmol/mg. In the presence of DAGO and DADLE, Scatchard analysis gave a straight line; receptor affinity and density were similar to those of the lower affinity component obtained in the absence of blockers. Longer incubation times did not significantly alter these results. In the case of guinea pig brain, the inclusion of μ and δ blockers again afforded a linear Scatchard plot (K_d = 7.3 nM, B_{max} = 118 fmol/mg at 60 min). Increasing the incubation time to 150 min in this case resulted in an increase in K_d and decrease in B_{max}. Possible mechanisms underlying this change in K_d are 1) a time-dependent conformational change in the K receptors, 2) a coupling of the receptors to a second protein such as N_i, or 3) aggregation of receptor proteins. In order to test the first hypothesis, N-ethylmaleimide (NEM) inactivation of K receptors was carried out. K receptors in guinea pig brain homogenate incubated 60 min exhibited a markedly different rate of N-ethylmaleimide inactivation than did K receptors incubated 150 min. These findings suggest that guinea pig brain K receptors undergo a time-dependent conformational change. Visualization of [^{3}H]EKC binding to rat and guinea pig brain slices by autoradiography in the presence of DAGO and DADLE revealed similar distribution patterns of K sites in the midbrain and hindbrain, but striking differences in the thalamic and hypothalamic areas. These data suggest that, although there is a similar density of K receptors in rat and guinea pig brain, the neuroanatomical distributions of the receptors differ in the two species.

93.3

WITHDRAWN

93.4 ELECTROENCEPHALOGRAPHIC CHARACTERIZATION OF MU AND DELTA OPIOID RECEPTOR ACTIVITY IN RATS. F.C. Tortella, L. Robles*, H.I. Mosberg* and J.W. Holaday, Neuropharmacology Br., Dept of Med. Neurosciences, Walter Reed Army Inst. of Research, Washington, DC 20307 and Dept. of Med. Chem., Univ. of Michigan, Ann Arbor, MI 48109.

The availability of highly selective ligands for the μ and δ opioid receptor types has allowed a critical evaluation of the receptor mechanisms responsible for enkephalin-induced electroencephalographic (EEG) responses in rats. For example, we reported that the conformationally constrained δ selective enkephalin analogs D-Pen^2-D-Pen^5 enkephalin (DPDPE) and D-Pen^2-L-Pen^5 enkephalin (DPLPE) do not produce EEG seizure activity in rats (Tortella et al., Neuropeptides 5:233, 1984). Furthermore, the highly selective μ receptor ligand Try-D-Ala-Gly-NMe-Phe-Gly-ol (DAGO) was recently reported to be 9x more potent than the mixed mu- and delta-directed ligand D-Ala^2-D-Leu^5 enkephalin (DADL) as an activator of EEG seizures in rats (Tortella et al., Fed. Proc. 44: 1343, 1985). Consonant with these findings, enkephalin-induced non-convulsive ictal activity appears to be solely mediated at μ opioid receptors. In the present study, DAGO- and DPDPE-induced EEG activity were compared using computer derived spectral analysis, and the opioid antagonists β-funaltrexamine (β-fNA, selective μ), naloxone (μ and δ), and ICI 174,864 (ICI, selective δ) were used to confirm agonist opioid receptor specificity.

Male S.D. rats (225-275 g) were prepared with bipolar cortical electrodes, right lateral i.c.v. cannulae and, when appropriate, external jugular vein catheters. Injections of DAGO (0.25-4.4 nmol, i.c.v.) resulted in two distinct EEG responses: 1). initial nonconvulsive ictal afterdischarges characterized by marked increases in EEG spectral activity in the 1-2 Hz and 12-30 Hz bands, 2). and a sustained period of high voltage slow-wave activity (HVSA) with a peak frequency of 2.0-2.5 Hz. These EEG effects of DAGO were antagonized by naloxone (0.01-1.0 mg/kg, s.c.) and β-fNA (9.8 μg, i.c.v.), but not by ICI (3.0 mg/kg, i.v.). In contrast, DPDPE (35-140 nmol, i.c.v.) failed to cause seizure activity in any of the rats tested. However, the administration of DPDPE produced a complex EEG response characterized by an increase in spectral activity in the 0-10 Hz band: most noteably HVSA with a peak frequency of 4.5-5.5 Hz, and intermittent theta driving (6.5-7.5 Hz) associated with intense behavioral arousal. Similar EEG profiles were observed with DPLPE. The DPDPE-induced HVSA was partially antagonized by high (10 mg/kg)(δ ?), but not low (1.0 mg/kg)(μ ?), doses of naloxone. Furthermore, pretreatment with ICI (3.0 mg/kg, i.v.) clearly antagonized the DPDPE-induced HVSA, causing a 5 fold shift to the right in the EEG power dose-response curve. Studies with β-fNA and DPDPE are in progress. DPDPE-induced theta activity was not altered by any of these antagonists.

Given the respective receptor selectivities for the various agonists and antagonists used, we propose that at least four distinct EEG responses are produced by enkephalins: a μ receptor mediated ictal activity, a μ receptor mediated HVSA (2.0=2.5 Hz), a δ receptor activated HVSA (4.5-5.5 Hz), and a non-opioid theta driving.

We thank M. J. Rance and R. Cotton of ICI Pharm. for ICI 174,864.

93.5 COMPARISON OF CROSS-LINKED β-ENDORPHIN LABELED OPIATE RECEPTORS FROM RAT, LEECH, AND TETRAHYMENA. B. Zipser†*, M.R. Ruff†, W. Higgins* and C.B. Pert†. †Section on Brain Biochemistry, Clinical Neuroscience Branch, National Institute of Mental Health, Bethesda, Maryland 20205, and *University of Maryland, College Park, Maryland.

Cross-linking is a relatively recent biochemical strategy for covalently affixing reversible ligands to their recognition molecules for subsequent electrophoretic analysis. [^{125}I]Tyr^{27}-β-endorphin (prepared as originally described by Smythe and co-workers) binds stereospecifically to rat brain membranes. While some studies have suggested that the β-endorphin receptor is a unique "epsilon" opiate receptor, a larger body of evidence suggest that β-endorphin has high affinity for most if not all of the opiate receptors types and subtypes. Cross-linking opiate receptors from different tissue sources can potentially reveal much information about the molecular basis of apparent opiate receptor heterogeneity. Cross-linking, however, only fixes 1% of the bound trace and SDS-PAGE while exquisitely sensitive, can fail to reveal substantial inter-molecular differences. Cross-linking was performed with the homo bi-functional reagent Disuccinimidyl Suberate (DSS). The iodinated cross-linking products of tetrahymena, leech CNS, and rat brain membranes (both type 1 and type 2 conditions) appeared indistinguishable on SDS-PAGE gel with major cross-linking products at 58K and 100-110K. The strong cross-linked bands produced by incubation in the presence of the inactive opiate ((+)-naloxone) was completely abolished by the same (10^{-6}M) concentration of its active isomer (-)-naloxone. Although we have thus far failed to distinguish between opiate receptors from a mammal, an invertebrate, and a unicellular organism, we continue to explore various conditions of binding, and electrophoresis, (e.g., reduced and unreduced) to examine possible receptor differences, both intra and inter species. Electrophoresis of proteolytic digests of cross linked bands will be performed as a particularly sensitive method for distinguishing heterogeneity. Thus far, our cross-linking experiment suggest that the recognition molecule (the opiate receptor) which binds all opiate alkaloids and peptides is stable across evolution. As proposed, apparent physiological receptor heterogeneity (Bowen, W.D., et al., Proc. Natl. Acad. Sci. USA, 78:4818, 1981) is due to coupling to other membrane components.

93.6 APPARENT DOWNREGULATION OF THE μ NON-COMPETITIVE δ BINDING SITE IN RAT BRAINS FOLLOWING REPEATED ELECTRO-CONVULSIVE SHOCK J.A. Danks*[1], F.C. Tortella [2], J.W. Holaday [2], V. Bykov*[1], A.E. Jacobson*[3], K.C. Rice*[3] and R.R. Rothman[1] [1]Lab. of Preclin. Pharmacol., NIMH, St. Elizabeth's Hosp., Wash., DC 20032; [2]Neuropharm. Branch, Dept. Med. Neurosci., Walter Reed Army Inst. Res., Wash., DC 20307 and [3]Lab. of Chemistry, NIADDK, Bethesda, MD 20205

It has been shown that repeated electroconvulsive shock (R-ECS) in rats results in a potent activation of endogenous opioid systems (Holaday et al, Mod. Prob. Pharmacopsych. 17,142,1981). However, discrepant data on the effects of R-ECS on binding parameters have been reported. The present studies were conducted to reevaluate the effects of R-ECS on opiate receptor binding parameters using selective site-directed agents.

Male S-D rats (275-300 g) were given repeated supramaximal transauricular ECS (50mA, 60Hz, 2sec) or sham ECS (S-ECS) daily for nine days. One day following the last ECS or S-ECS, brains were removed and frozen on dry ice. Brains were thawed, and lysed P2 membrane preparations were made. The lysed P2 preparations were incubated with 0.4M NaCl for one hour at 25°C to remove endogenous opioid ligands. Membranes were then treated with the site-directed opiate alkylating agents, BIT (to eliminate μ-non-competitive sites) or FIT (to eliminate μ-competitive sites) at a concentration of 1 μM (Rice et al, Science 220,314,1983). Membrane pellets were frozen at -80°C until assayed. To determine the Bmax and KD values, binding surfaces were constructed using ^{3}H-D-Ala^2-D-Leu^5 enkephalin (^{3}H-DADL) as the ligand in assay conditions as previously described (Rothman et al, Neuropeptides 4,257,1984). Each experimental group consisted of 54 data points from three separate membrane preparations. Results indicate that R-ECS significantly decreased the μ-non-competitive binding sites (* $p<0.05$):

	KD ± SD (nM)	Bmax ± SD (fmoles/mg prot.)	% of control
μ-competitive remain (BIT treated):			
S-ECS control	1.6 ± 0.1	174 ± 7	100
R-ECS	1.6 ± 0.1	157 ± 8	90
μ-non-competitive remain (FIT treated):			
S-ECS control	8.6 ± 1.0	183 ± 25	100
R-ECS	8.4 ± 1.5	133 ± 36*	72*

It was previously shown that R-ECS increases the apparent number of ^{3}H-DADL binding sites (Holaday et al, Life Sci. 31,2359,1982). The present studies, conducted using a different assay condition along with selective site-directed alkylating agents, provide preliminary evidence of the opposite effect. Specifically, R-ECS decreases (downregulates) the μ-non-competitive δ binding sites by approximately 28%. Further studies are being conducted to confirm and extend these observations on the effects of R-ECS on opiate binding parameters.

93.7 CHARACTERIZATION OF SOLUBLE β_h-ENDORPHIN-LABELED RECEPTORS FROM POST-MORTEM HUMAN STRIATUM. Daiga M. Helmeste and Choh Hao Li*. Laboratory of Molecular Endocrinology, University of California, San Francisco, CA 94143.

Tritiated human β-endorphin (^{3}H-β_h-EP) labeled receptors were solubilized from human striatal membranes using the zwitterionic detergent, CHAPS. Using a polyethyleneglycol precipitation method, we demonstrate that the solubilized receptor binds ^{3}H-β_h-EP in a displaceable manner.

	IC_{50} (nM)	
	membrane	soluble
β_h-EP-(1-31)	1.6	2.3
β_h-EP-(1-5)	22	> 1 μM
β_h-EP-(6-31)	no displacement at 1 μM	
Morphine	24	-
Naloxone	17	-
U50-488H	2112	-

While β_h-EP-(1-31) retained high affinity in the solubilized preparation, β_h-EP-(1-5) (met-enkephalin) lost its ability to compete for binding with high affinity. This phenomenon was also seen in the solubilized rat preparation.

Size differences (Stokes radius) could be demonstrated between human and rat, as estimated by Sepharose 6B molecular exclusion chromatography of prelabeled receptor preparations.

	Stokes radius (Å)
Human Caudate	80 ± 3
Human Putamen	72 ± 3
Rat Whole Brain	64 ± 1

Investigations of differences in other molecular parameters are in progress and their implications for a model of the opiate receptor will be discussed.

93.8 ENDOGENOUS LIGAND FOR THE SIGMA OPIOID RECEPTOR ("SIGMAPHIN") IN THE BRAIN: PRELIMINARY EVIDENCE. T.-P. Su* and A.D. Weissman.* (SPON: W.B. Pickworth) NIDA Addiction Res. Ctr., Baltimore, MD 21224.

The sigma opioid receptor was postulated by Martin, W.R. et al. (J. Pharmacol. Exp. Ther., 197:517, 1976) to mediate psychotomimetic effects of certain opiates and other drugs. Those effects included dysphoria, hallucinations and delirium. Sigma opioid receptors later were identified in guinea-pig brain homogenates using [^{3}H]SKF-10047 (Su, T.-P., J. Pharmacol. Exp. Ther., 223:284, 1982). Ligand selectivities of the sigma opioid receptor indicated that dextro-isomers of certain opioids were more potent than their counterpart levo-isomers and that several antipsychotics such as haloperidol and chlorpromazine were among the most potent ligands in the sigma receptor binding assay (Su, 1982). It was also indicated that sigma receptors were not dopamine receptors (Su, 1982). These findings on the sigma opioid receptors were later confirmed by several laboratories using [^{3}H]EKC (Tam, S.W., Proc. Natl. Acad. Sci., 80:6703, 1983), [^{3}H]3-PPP (Largent, B.L., et al. Proc. Natl. Acad. Sci., 81:4983, 1984) and [^{3}H]d-SKF (Martin, W.R., et al. J. Pharmacol. Exp. Ther. 231:539, 1984). Recently, in vivo data also showed that in pigeons, the increase in responding to food presentation induced by a sigma ligand d-SKF, could be antagonized by haloperidol (Katz, J.L., et al. J. Pharmacol Exp. Ther. 232:452, 1985). Taken together, these findings suggest that the sigma opioid receptor may repesent a psychotomimetic pathway in the brain. This study examined the possibility of existence of an endogenous ligand for sigma opioid receptors.

Guinea-pig brain was homogenized in 12 ml of ice-cold 0.1 N acetic acid using a Polytron. The suspension was further homogenized with a Dounce homogenizer and then stirred at 4°C for 2 hr. The suspension was then centrifuged at 12,000 rpm for 30 min. The supernatant was applied to a Sephadex G-50 column (1.5 x 90 cm). After lyophilization, each fraction from the column was assayed for inhibition of [^{3}H]SKF binding to sigma opioid receptor sites.

Three major peaks inhibiting [^{3}H]SKF binding to sigma opioid receptors were obtained. Peak I had an apparent mol. wt. of about 10,000 daltons. Peak II was broad, containing a larger number of fractions with major inhibitory activity at about 3,000 daltons. Peak III was the most potent and had an apparent mol. wt. of about 300 daltons. The experiment was repeated four times. Each experiment produced a similar inhibitory profile.

These results suggest that endogenous ligands for psychotomimetic sigma opioid receptors may exist in the brain. Results of this study also indicate that endogenous sigma opioid receptor ligands ("SIGMAPHIN") in the brain may be heterogenous.

93.9 OPIOID BINDING SITES INDUCED BY ETHANOL IN NG108-15 CELLS ARE FUNCTIONAL DELTA-OPIOID RECEPTORS. M.E. Charness and L.A. Querimit*, Department of Neurology and The Ernest Gallo Clinic and Research Center, University of California San Francisco, CA. 94110

Long-term ethanol exposure increases the expression of delta-opioid binding sites in cultured neural cells (Science 222: 1246-1248). We investigated whether these binding sites exhibit several pharmacologic properties of the delta-opioid receptor: Na^+ modulation of agonist binding, down-regulation of binding sites by agonists, and inhibition of cAMP production.

NG108-15 cells were cultured in the presence or absence of 200mM ethanol for 48 hours to increase delta-opioid binding sites by 85%. Inhibition of [^{3}H]d-[Ala^2]d-[Leu^5]enkephalin (DADL) binding by Na^+ was unaltered in the ethanol-treated cells. Moreover, 24 hours exposure to 10^{-8} M etorphine caused similar down-regulation of binding sites in ethanol-treated (46% ± 1.1) and control (61 ± 8.9%) cells.

The opioid receptor of NG108-15 inhibits cAMP production through its interaction with the inhibitory GTP binding protein complex, N_i. In this cell line, maximal opioid inhibition of cAMP occurs with fractional occupancy of receptor binding sites. Thus, if the binding sites induced by ethanol are functional receptors, then opiates should inhibit cAMP production more potently than in control cells, but to the same maximal level.

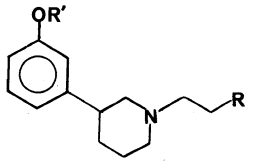
Cyclic AMP production in intact washed cells was determined by RIA. Basal levels were significantly higher in ethanol-treated cells (control 9.4 ± 1.8; ETOH 24.5 ± 1.6 pmol/mg/min), and 10^{-4} M phenylisopropyl adenosine raised cAMP to higher levels in the ethanol-treated cells (control 93.7 ± 8.1; ETOH 131 ± 6.6 pmol/mg/min). In control cells, etorphine inhibited stimulated-cAMP production by a maximum of 73 ± 4.9% with half-maximal inhibition (K_i) occurring at 2.7×10^{-9} M. In ethanol-treated cells, etorphine inhibited stimulated-cAMP production by 89 ± 2.1%, with a K_i of 7.7×10^{-10} M. Thus, ethanol induces the expression of functional opioid receptors, rendering these cells 3.5-fold more sensitive to opiates. The concomitant increase in opiate efficacy suggests that ethanol also alters receptor-effector coupling.

93.10 INHIBITION OF OPIOID BINDING TO RAT NEURAL MEMBRANES BY FAB FRAGMENTS FROM A MONOCLONAL ANTIBODY DIRECTED AGAINST THE OPIOID RECEPTOR. Jean M. Bidlack and Peter C. Mabie. Center for Brain Research, University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642.

A monoclonal antibody, OR-689.2.4, capable of inhibiting opioid binding to rat neural membranes has been obtained (Bidlack and Denton, Neuropeptides, 5: 225-228, 1984). This monoclonal IgM was generated by immunizing a BALB/c mouse with a partially purified opioid receptor preparation. A procedure has been developed for obtaining Fab fragments from this mouse monoclonal IgM. The Fab fragments were able to inhibit opioid binding to membranes to a much greater degree than the whole IgM. The binding of the μ ligand, [^{3}H][D-Ala^2, MePhe^4, Gly(ol)^5]- enkephalin (DAGO) and the δ ligands, [^{3}H][D-Ser^2, Leu^5, Thr^6]- enkephalin (DSLET) and [^{3}H][D-Pen^2, D-Pen^5]- enkephalin (DPDPE), to neural membranes was inhibited noncompetitively by the Fab fragments. To measure κ binding sites, [^{3}H]bremazocine in the presence of μ and δ blockers was used. The Fab fragments were not able to significantly suppress binding to κ sites. The antibody competitively inhibited up to 95% of the binding of [^{125}I-Tyr^{27}] β_h-endorphin to membranes. Heat-denatured antibody or control mouse IgM did not inhibit the binding of [^{125}I-Tyr^{27}]β-endorphin. To ascertain the relative affinity of the antibody for the different types of opioid binding sites, varying concentrations of antibody and the opioid peptides, DAGO, DSLET, β_h-endorphin 1-31, β_h-endorphin 1-27, β_h-endorphin 6-31, were tested for their combined ability to inhibit the binding of 0.4 nM [^{125}I-Tyr^{27}]β-endorphin to membranes. The combination of antibody with opioid peptides did not produce an additive effect but instead, produced an effect suggestive of common or interacting sites. β_h-endorphin 6-31 did not block the inhibition of binding by the antibody. The other peptides were able to block the antibody's inhibition of [^{125}I-Tyr^{27}]β-endorphin binding. The relative affinities were β_h-endorphin 1-31 = β_h-endorphin 1-27 > DAGO > DSLET. The antibody is directed against a 35,000 dalton protein. These studies suggest that the μ, δ and β-endorphin binding sites share a common or interacting site, while the κ opioid receptor does not share this site. (Supported by NIDA grant DA03742.)

93.11 Synthesis and Characterization of New Ligands for Brain Sigma (σ)-opiate Receptors. Frank J. Arnold, Randall B. Murphy, Miroslav Trampota and David I. Schuster: Department of Chemistry, New York University, 4 Washington Place, New York, NY 10003 USA

As part of a study to prepare irreversible ligands for brain sigma opiate receptors, we have synthesized twelve analogs of the putative neuroleptic drug 3-PPP having the following structure:



Several of these compounds are highly potent in a recently described binding assay to rat brain homogenates (Langent, Gundlachand,Snyder, PNAS 81, 4983-4987, 1984). This assay quantifies sigma-opiate like activity using [^{3}H]-Haloperidol, in the presence of 25 nM spiperone to block D_2 receptor binding. The most active compounds are those in which R is phenyl(I), benzoyl (II), Ph-CH(OH)-(III), Ph-C(n-C_5H_{11})(OH)-(IV) or p-N_3-phenyl(V). In this series the values of Kd observed against 2nM [^{3}H]-Haloperidol ranged from 22 nM (for III) to 50 nM (for V). The substitution of R^1 = Me for R^1 = H does not dramatically effect biological activity. For most compounds the Hill slopes were essentially unitary. In general for this series an increase in hydrophobicity appears to be correlated with increased sigma-opiate activity. Substitutions of p-NH_2, p-NO_2 and p-I on the phenyl ring appear to decrease activity somewhat. None of these compounds have significant potency on the rat striatal D_2 receptor, as quantified by the binding of [^{3}H]-spiroperidol.

Due to the relatively selective action and high affinity of these compounds for the putative rat brain sigma-opiate receptor, we suggest that they may prove useful as ligands in this system.

93.12 THE SUBCELLULAR COMPARTMENTATION OF OPIATE RECEPTORS REFLECTS THEIR BIOSYNTHETIC AND FUNCTIONAL STATES. C. Klein*, R. Levy* and R. Simantov. Dept. of Genetics, Weizmann Institute of Science, Rehovot 76100, Israel.

The early analysis of the subcellular distribution of opiate receptors in the brain (Pert et al. Brain Res. 70:184, 1974; Simantov et al. Brain Res. 107:650, 1976) indicated that binding sites for opiates are present in several intracellular structures. Yet, most attention was focused over the years on the membrane-bound receptors and, until recently, little was known about the others. The recent studies conducted by Coscia and associates (J. Biol. Chem., 256:10117, 1981; Brain Res., 250:101, 1982) effectively revealed the properties of brain microsomal receptors. In these studies we have used the clone M8, isolated from NG108-15 neuroblastoma-glioma hybrids, to characterize the intracellular opiate receptors. The cell organelles were separated on a Percoll gradient and four enzyme markers were used to define the fractions containing the plasma membrane, microsomal, lysosomal and Golgi elements. Analysis of receptor density in these fractions from untreated cells shows that in addition to the membranes, all the three intracellular compartments contained opiate binding sites. The enzyme markers indicated that appearance of receptors in these elements does not result from contamination with plasma membranes. Moreover, the study showed that receptors in the lysosomal fraction were resistant to low pH. Yet, the affinity of ^{3}H-DADL to lysosomal and plasma membrane receptors (of untreated cells) was similar. Leu-enkephalin induced time-dependent loss of receptors in all the four compartments but a kinetics analysis showed that the rate of receptor loss in these structures was not identical.The percentage of receptors appearing in the lysosomal fraction that could still bind ^{3}H-DADL was increased upon treating cells with leu-enkephalin, and the extent of this increase was correlated with the extent of receptor loss from the membranes. This supports the notion that the peptide promotes internalization of receptors which are still functional in some lysosomes. Yet, some difference in this respect between two lysosomal fractions was observed. As an additional approach to follow the intracellular fate of the receptors, cells were labeled with ^{3}H-diprenorphine, chased with various opiates, and the distribution of ^{3}H-diprenorphine-receptor in the cells was monitored with a Percoll gradient. Opiate agonists and antagonists altered the distribution of the labeled receptors between the plasma membrane, lysosomal and Golgi elements. Anti-lysosomal agents and primary amines were used to further clarify the opiate mode of action. The study sheds light on the involvement of the Golgi apparatus and the lysosomes in the metabolism of opiate receptors.

CATECHOLAMINES: RECEPTORS I

94.1 **INTERACTION OF β-ADRENERGIC RECEPTORS WITH THE INHIBITORY GUANINE NUCLEOTIDE-BINDING PROTEIN.** Stewart N. Abramson, Robert G. L. Shorr*, T. Kendall Harden and Perry B. Molinoff. Department of Pharmacology, University of Pennsylvania, Philadelphia, PA 19104, Smith Kline and French Labs, Philadelphia, PA 19101, and Department of Pharmacology, University of North Carolina, Chapel Hill, NC 27514.

β-Adrenergic receptors on membranes prepared from wild-type S49 lymphoma cells and the adenylate cyclase-deficient mutant (cyc$^-$) of S49 lymphoma cells have been shown to bind the agonist (^{3}H)hydroxybenzylisoproterenol (^{3}H-HBI) with high affinity and with characteristics consistent with the formation of a ternary complex composed of agonist, β-adrenergic receptor, and a guanine nucleotide-binding protein (Abramson and Molinoff, Neurosci. Abs. 84.7, 1984). To further characterize this process receptors labeled with either the agonist (^{3}H)HBI or the antagonist (^{125}I)iodopindolol (^{125}I-IPIN) were solubilized from wild-type and cyc$^-$ S49 cell membranes with digitonin. The ligand-bound receptor complexes were then passed over HPLC gel exclusion columns. Receptors from wild-type S49 cells labeled with (^{125}I)IPIN were included in the columns as were receptors labeled with (^{3}H)HBI. However, based on their retention times, receptors that were labeled with (^{3}H)HBI had a larger apparent molecular size than receptors that were labeled with (^{125}I)IPIN. Similar results were obtained for receptors from cyc$^-$ S49 cells. These observations are consistent with the hypothesis that receptors from both wild-type and cyc$^-$ cells can interact with another membrane protein, presumably a guanine nucleotide-binding protein, when occupied by an agonist. Wild-type S49 cells contain both the stimulatory (N_s) and the inhibitory (N_i) guanine nucleotide-binding proteins of adenylate cyclase. Cyc$^-$ S49 cells contain a functional N_i protein, however, they do not contain a functional N_s protein. To determine whether the guanine nucleotide-binding protein associated with the β-adrenergic receptor in membranes prepared from cyc$^-$ cells is N_i, cyc$^-$ S49 cells were treated with pertussis toxin to inactivate N_i. Treatment of cells with pertussis toxin inhibited by 95% the subsequent ability of the toxin to label N_i with (^{32}P)-NAD in membranes prepared from treated cells. Treatment of cells with pertussis toxin also reduced the K_{act} values of GTP S and Gpp(NH)p for inhibition of forskolin-stimulated adenylate cyclase activity in membranes prepared from treated cells. Although treatment of cyc$^-$ cells with pertussis toxin did not affect the binding of (^{125}I)IPIN to membranes prepared from these cells, the binding of (^{3}H)HBI was decreased 60-70% in membranes prepared from treated calls. Inhibition of the binding of (^{3}H)HBI to β-adrenergic receptors by treatment of cells with pertussis toxin is consistent with the hypothesis that agonist-bound β-adrenergic receptors interact with N_i. Such an interaction may be physiologically important in regulating the activity of adenylate cyclase or in processes such as desensitization. (Supported in part by USPHS NS 18479 and a Predoctoral Fellowship from the PMA Foundation.)

94.2 **Regulation of β-Adrenergic Receptors on Cultured Cells.** K.A. Neve and P.B. Molinoff. Department of Pharmacology, University of Pennsylvania, School of Medicine, Philadelphia, PA 19104.

The turnover of β-adrenergic receptors on cultured cells was determined by measuring the rate of recovery of the binding of ^{125}I-iodopindolol after irreversible blockade of β-adrenergic receptors. The effect on β-adrenergic receptors of N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ), a pseudobase that irreversibly inactivates α-adrenergic and dopaminergic receptors, was investigated. Scatchard analysis of the binding of ^{125}I-iodopindolol to membranes prepared from L6 myoblasts resulted in linear plots with K_d and B_{max} values of approximately 45 pmolar and 500 fmoles/mg protein, respectively. Nonspecific binding, defined in the presence of 50 μM (-)-isoproterenol, was less than 10% of total binding at a concentration of the radioligand that was close to its K_d value. Addition of EEDQ to the growth medium of L6 myoblasts resulted in a time- and concentration-dependent reduction in the binding of ^{125}I-iodopindolol. Treatment with EEDQ did not alter the K_d value for the binding of ^{125}I-iodopindolol, but caused a decrease in B_{max} that was not reversed by extensive washing of the membranes. At a concentration of 1 μmolar, EEDQ had no effect on the density of β-adrenergic receptors after up to two hours. When the concentraction of EEDQ was 10 μmolar, there was a 35% decrease in the density of receptors after one hour, and a 50% decrease after treatment for two hours. Treating cells with 100 μmolar EEDQ for one hour caused a greater than 90% reduction in the density of β-adrenergic receptors measured on membranes prepared from the cells. When EEDQ-containing medium was replace by fresh medium, the density of receptors on L6 cells treated with 100 μmolar EEDQ for one hour recovered to within 25% of the density on untreated cells within 24 hours. The degradation rate constant calculated from the rate of recovery was 0.053/hour, and the rate of reappearance of receptors was 33 fmoles/mg protein/hour. The recovery of the binding of ^{125}I-iodopindolol was blocked by treatment with cycloheximide (5 μg/ml), and probably represents the synthesis of new receptors. One of the problems involved in determining the turnover rates of receptors in this manner is the possibility that irreversible blockade alters the synthesis or degradation of receptors. To determine if blockade of the receptors by EEDQ will itself alter the metabolism of receptors, the rate of recovery of binding after treatment with EEDQ was determined in the presence of the antagonist sotalol. Blockade of the receptors by sotalol did not alter the turnover rate of β-adrenergic receptors, indicating that the rate constants measured after treatment with EEDQ probably reflect resting rates of metabolism of β-adrenergic receptors. EEDQ is a useful reagent for studies of this nature because it is inexpensive and easily obtained. In addition, when membranes are prepared for assays of radioligand binding, little washing of membranes is required to reduce the residual amount of EEDQ in membranes below concentrations that affect the binding of ^{125}I-iodopindolol (Supported by the USPHS NS 18479 and MH 14654.)

94.3 DETECTION AND CHARACTERIZATION OF β-ADRENERGIC RECEPTORS IN COATED VESICLES OF BOVINE BRAIN. D.M. Chuang*, O. Carter*, J. W. Spain*, D.B. Bennett*, B.L. Roth*, M.B. Laskowski and C.J. Coscia, (SPON: L. de Medinaceli). LPP, NIMH, St. Elizabeths Hosp., Washington, D.C. 20032 and St. Louis Univ. St. Louis, MO 63104

Evidence has accumulated suggesting that β-adrenergic receptors (BAR) are internalized in frog erythrocytes and several cultured cell lines. However, it is uncertain as to whether internalization of BAR occurs in the CNS. Since clathrin-coated vesicles (CVs) have been implicated in both endocytotic and intracellular transport of a variety of receptors, we have isolated these organelles and examined them for the presence of BAR binding and adenylate cyclase (AC) activities. CVs were prepared from bovine forebrain as described by Pfeffer and Kelly. Microsomal pellets were subjected to linear D_2O/Ficoll gradients and the CV-enriched (60-80%) fraction applied to a controlled-pore glass bead column to achieve further purification. The two major bands of protein eluting from the column were monitored by electron microscopy and SDS-PAGE. Peak II contained almost exclusively CVs, whereas Peak I, which appeared in the void volume, contained larger smooth vesicles and few CVs. BAR binding to Peaks I and II was assessed with ^{125}I-cyanopindolol (CYP) as ligand in Sepharose 4B column assays. ^{125}I-CYP was found to bind specifically to sites in both Peaks I and II with a Bmax of 28±4 and 32±3 fmol/mg protein, respectively. Binding of ^{125}I-CYP to both fractions was displaced by various BAR agents in a stereospecific manner. The addition of 50 μM $Gpp(NH)_p$ did not affect displacement of CYP binding to Peak II sites by (-)isoproterenol, whereas a significant "right shift" was noted when Peak I or a synaptic plasma membrane preparation (SPM) from bovine hippocampus was used. ^{3}H-CGP 12177, a hydrophilic BAR ligand, specifically bound to SPM and to a lesser extent to Peak I, but failed to label the BAR present in Peak II, suggesting that receptors present in CVs were cryptic in nature. AC activity could also be detected in both Peaks I and II (spec. act. = 21±0.6 and 24±0.5 pmol cAMP/mg/min, respectively). These activities were unaffected by GTP or isoproterenol+GTP. In contrast, a moderate stimulation of the cyclase activity present in SPM was induced by these agents. Rechromatography of Peak II on the glass bead column revealed that appreciable amounts of protein, CYP binding and AC activity were recovered in Peak I; this change in chromatographic migration was facilitated by pre-exposure of CVs to 0.5 M Tris, a condition known to cause at least partial dissociation of clathrin from these vesicles. This suggests that at least some of the protein, as well as AC and CYP binding activities in Peak I were derived from CVs, possibly due to loss of clathrin. In conclusion, BAR and AC present in brain CV preparations might be molecular entities undergoing endocytotic or intracellular transport.

94.4 COMPARATIVE ANATOMY OF BETA-ADRENERGIC RECEPTORS IN THE RAT AND GUINEA PIG: IN VITRO AUTORADIOGRAPHY WITH [^{125}I]-CYANOPINDOLOL. R.M. Booze, E.A. Crisostomo, and J.N. Davis. VA Medical Center and Depts. of Med. (Neurology) and Pharmacology, Duke University Medical Center, Durham, NC 27705.

Species diffrences have been reported in the distribution of B-adrenergic receptors in mammalian nervous systems. B-adrenergic receptors are present in the brains of some mammals, such as the rat, cow, and human, but are sparse or absent in the brains of swine and guinea pigs. We used in vitro receptor autoradiography to study the species differences in B-adrenergic receptor distribution between rats and guinea pigs.

In vitro receptor autoradiography was performed with [^{125}I]-cyanopindolol (CYP), a specific B-adrenergic receptor antagonist. The selective B-adrenergic antagonists ICI-89,406 and ICI-118,551 wre used to localize the B2- and B1-adrenergic receptor subtypes, respectively. The brains from three adult male rats and guinea pigs were cryostat-sectioned (16 um) in either the coronal, horizontal, or sagittal planes. Adjacent sections were incubated with either [^{125}I]-CYP and the appropriate ICI drug or with dl-propranolol for estimation of non-specific binding. The radiolabeled sections were apposed to film for 30 hours and densitometric measurements performed on the resulting autoradiographs.

Striking qualitative and quantitative species differences were evident in the localization of B-adrenergic receptor subtypes. In guinea pigs, B_2-adrenergic receptors were limited to hippocampal area CA_1 and the cerebellar molecular layer. In rats, the substantia nigra, superior colliculus, cortical layer IV, olfactory tubercle, and cerebellar molecular layer were heavily labeled for B_2 receptors. B_1 receptors were found in cortical layers I and V, hippocampus, substantia nigra, superior colliculus, amygdala, basal forebrain, striatum, and lateral septum of both species, although guinea pigs had lower receptor densities relative to rats. Furthermore, the thalamus was not labeled for B-adrenergic receptors in guinea pigs, but discrete labeling corresponding to specific thalamic nuclei was observed in rats.

The use of in vitro receptor autoradiography has provided the first detailed anatomical description of B-adrenergic receptors in guinea pigs. The results indicate that highly specific qualitative and quantitative variations exist in the neuroanatomical distribution of B-adrenergic receptors in rats and guinea pigs. Thus, caution should be used in generalizing the relationships of neurotransmitters and receptors from studies of a single species.

94.5 EVIDENCE FOR SUBTYPES OF ALPHA-1 ADRENERGIC RECEPTORS LABELLED BY [^{3}H]PRAZOSIN. A. Leslie Morrow and Ian Creese. Dept. of Neuroscience, U.C.S.D. School of Medicine, La Jolla, CA 92093.

[^{3}H]Prazosin (Praz) is considered to be a selective high affinity ligand for the study of central and peripheral alpha-1 adrenergic receptors. [^{3}H]Praz binding is characterized by monophasic saturation in all systems studied. However, phentolamine and WB4101 competitions with [^{3}H]Praz are shallow in rat cortex, exhibiting Hill Coefficients of .62 (1). Praz, indoramine and dihydroergocriptine competitions with [^{3}H]Praz are steep, monophasic and model best to a single binding site, while phentolamine and WB4101 curves model to two binding sites in equal proportion. There is no additivity of the inhibition by phentolamine and WB-4101 at concentrations which saturate their high affinity component of [^{3}H]Praz binding, indicating that WB4101 and phentolamine have highest affinity for the same half of [^{3}H]Praz binding. Antagonist affinities are 0.69, 0.62 and 2.44nM for Praz, WB4101 and phentolamine at the high affinity component, designated alpha-1A. The lower affinity component, designated alpha-1B, has affinities of 0.69, 24.0 and 55.0nM respectively.

[^{3}H]WB4101 labels two binding sites in rat cortex, with picomolar and nanomolar affinity respectively. The nanomolar binding site represent labelling of an S-1 serotonin receptor (2). The picomolar site has characteristics of an alpha-1 receptor binding site. Praz, WB4101 and phentolamine affinities for this [^{3}H]WB41-01 binding site correlate with their affinities for the alpha-1A component of [^{3}H]Praz binding. [^{3}H]WB4101 labels the alpha-1A component of [^{3}H]Praz binding with 0.15nM affinity and Bmax equal to one half of the total [^{3}H]Praz Bmax (5.96 ± .32 vs. 11.03 ± .30 pmoles/g tissue).

Agonist competitions with [^{3}H]Praz are shallow with Hill slopes less than 1.0 and with a rank order of affinity of epinephrine > norepinephrine > phenylephrine. EPI and NE affinities at the two subtypes are the same and the rank order of agonist affinities is preserved when binding to the alpha-1A component is blocked. The ratio of the potency of phentolamine vs. prazosin is between 2 - 10 at the alpha-1A component and between 50 - 100 at the alpha-1B component. Using this ratio as a pharmacological distinguishing criterion, tissues containing only one subtype may be identified. We discuss these data in relation to antagonist potencies of alpha-1 receptor mediated responses which correlate with alpha-1A or alpha-1B binding sites.

94.6 THE EFFECTS OF ALPHA-2 ADRENERGIC AGONIST PREINCUBATION ON RECEPTOR BINDING AND cAMP GENERATION IN THE HUMAN COLON CARCINOMA CELL LINE HT29. Susan B. Jones*, John T. Turner and David B. Bylund. Spon: William S. Stark. Dept. of Pharmacology, University of Missouri, School of Medicine, Columbia, MO 65212.

The term desensitization is used to describe the phenomenon of reduced cellular responsiveness to an agonist following a previous exposure to that agonist. For the alpha-2 receptor desensitization can be experimentally defined by a reduction in the inhibition of the basal or forskolin stimulated adenylate cyclase activity of cyclic AMP accumulation. Downregulation of receptor number often accompanies desensitization.

To date, few desensitization studies of alpha-2 receptors have been reported. In the human platelet, it was found that preexposure of human platelets to 100 μM epinephrine caused a decrease in [^{3}H]yohimbine binding, but that this decrease was caused by competition at [^{3}H]yohimbine sites by epinephrine taken up by platelets (Karliner, Mol. Pharm. 21:36, 1982). Exposure to agonist did not alter the maximum alpha-2 receptor response in NG 108-15 cells, but caused a two-fold reduction in apparent potency of (-)epinephrine in inhibiting cyclase, indicating that NG 108-15 cells have "spare" receptors (U'Prichard, Ann. N.Y. Acad. Sci. 430, 1984). Previously we have done similar alpha-2 adrenergic receptor desensitization experiments with isolated human properitoneal adipocytes. Exposure to epinephrine reduced the B_{max} of [^{3}H]p-aminoclonidine by 43% but not [^{3}H]yohimbine B_{max}. The ability of 10 μM epinephrine (plus propranolol) to lower cAMP levels was not affected.

We have examined the effects of alpha-2 agonist preincubation on receptor binding and cAMP generation in the human colon carcinoma cell line HT29. We found no decrease in receptor number with a 60 min preexposure of HT29 cells to 10 μM UK-14,304 with either [^{3}H]UK-14,304 or [^{3}H]yohimbine binding. There was a decrease in affinity with [^{3}H]UK-14,304 binding indicating possible loss of the high affinity binding site. [^{3}H]yohimbine binding affinity was not affected. In cyclic AMP whole cell assays, preincubation with a low concentration of UK-14,304 caused a marked increase in forskolin stimulated cAMP. The molecular interactions at the alpha-2 adrenergic receptor are complex events in which several mechanisms may be involved.

94.7 CHARACTERIZATION OF ALPHA-2 ADRENERGIC RECEPTOR SUBTYPES IN HUMAN BRAIN: PRAZOSIN INHIBITION OF [^{3}H]YOHIMBINE BINDING. David B. Bylund, and Anton C. Petrash*. Dept. of Pharmacology, University of Missouri, School of Medicine, Columbia, MO 65212.

Pharmacologic differences in the characteristics of alpha-2 adrenergic receptor binding between rodent and non-rodent species has led to the speculation that subtypes of the alpha-2 receptor may exist.

The first pharmacologic difference is that [^{3}H]yohimbine is more potent in non-rodent species with K_D values of 2nM or lower compared to rodent species with values in the range of 5 to 10 nM. The second difference is that while oxymetazoline tends to be more potent in non-rodent than in rodent species, prazosin tends to be more potent in rodent than in non-rodent species. In rat brain, we found that prazosin inhibited [^{3}H]yohimbine binding with Hill slopes less than 1.0. These data were consistent with equal densities of low (approx. 300nM) and high (approx. 7 nM) affinity binding sites. We have tentatively called these A and B subtypes, respectively (Bylund, D.B., Pharmacol Biochem Behav 22(5), 1985 (in press)). The alpha-2 receptors of the human platelet for example are all of the "A" subtype.

In order to further characterize these putative subtypes, inhibition binding studies were conducted in our laboratory using human brain tissue from three regions: cerebral cortex, cerebellum, and caudate nucleus. The K_i values for prazosin inhibition of [^{3}H]yohimbine binding were determined and the results analyzed using standard computer techniques. In the cerebral cortex and cerebellum, the prazosin inhibition curves generally modeled as a single site. However, in the caudate we were able to resolve the prazosin inhibition data into high (B subtype) affinity and low (A subtype) affinity sites, with K_i values of about 5 nM and about 300 nM respectively. Approximately 60% of the sites were of the B subtype and 40% were of the A subtype.

In saturation binding studies in the same tissues, [^{3}H]prazosin binding had a K_D of 0.04 nM, indicating that the affinity of prazosin for alpha-1 receptors is about 250X the affinity of the alpha-2B site. In addition, the K_D for [^{3}H]yohimbine binding in the caudate is about 0.5 nM, or about 10X more potent than prazosin at the alpha-2B site. Thus, the alpha-2B site does not appear to be an alpha-1 receptor.

94.8 QUANTITATIVE ASSESSMENT OF RAT CORTEX α_2-ADRENOCEPTOR RADIOLIGAND BINDING AND REGULATION. J.M. Stolk* and D.C. U'Prichard; Maryland Psychiatric Research Center, University of Maryland School of Medicine, Baltimore, MD 21228 and Nova Pharmaceutical Corporation, Baltimore, MD 21224.

Considerable evidence supports the heterogeneous interaction of agonists and some antagonists at α_2-adrenoceptors (α_2AR). Allosteric regulation of low and high affinity states for agonists have been postulated from data on modulation of equilibria between states by guanine nucleotides and divalent cations. During studies to characterize α_2AR binding site regulation in rat cortex, we observed an apparent lack of conservation between agonist affinity state binding sites and pursued the issue further.

We systematically evaluated the binding of agonists (p-aminoclonidine, UK-14304) and antagonists (Idazoxan [RX]; rauwolscine [Rau]) to washed rat cortical membranes under defined conditions using a modified Latin-Square design. Displacement of labelled ligands (0.3-0.6 nM final conc.) was measured using common membrane suspensions in the presence or absence of Mg^2 (0.3 mM final conc.) or GppNHp (10^5 M final conc.); data from each multiple ligand study were analyzed together using the non-linear curve-fitting program, LIGAND (Munson and Rodbard). As anticipated, high affinity agonist binding was facilitated in Tris buffer (50% of total sites displayed high affinity for PAC and UK), whereas Rau binding to the site with low affinity for agonists was facilitated in Na/K-phosphate buffer (10% of total sites displayed high affinity for PAC and UK); RX bound with equal affinity to both states of the α_2AR in rat cortex. Contrary to predictions by the allosteric model of α_2AR regulation, the total number of binding sites in Tris buffer was significantly lower in the presence of GppNHp than in the presence of Mg^{2+} (134 ± 11 vs. 190 ± 17 fmol/mg), and the site with high affinity for agonists was selectively affected (62 ± 13 vs. 124 ± 13 fmol/mg). The binding site density changes were accompanied by significant alterations in K_D values for both agonist and antagonist ligands at the high affinity site for agonists (for example, K_D values for p-aminoclonidine and Rau were 2.14 ± 0.41 and 48.8 ± 18 nM, repectively, in the presence of GppNHp, and 1.07 ± 0.15 and 209 ± 28 in the presence of Mg^{2+}). We currently are evaluating changes in total binding site density in independent studies with RX (which binds with equal affinity to both states of the α_2AR) to verify the results observed in the multiple ligand analyses.

We tentatively conclude that the present model for allosteric regulation of α_2AR may be insufficient to account for the quantitative data obtained in the present study. (Supported in part by USPHS Research Grant MH32842 and RSDA MH00018)

94.9 RECEPTOR RESERVE AT CENTRAL DOPAMINE (DA) AND ALPHA$_2$ AUTORECEPTORS. E. Meller*, E. Matyjek*, C.H. Adler, K. Bohmaker*, A.J. Friedhoff, and M. Goldstein. Department of Psychiatry, New York University Medical Center, New York, NY 10016.

The extent of receptor reserve at central DA and alpha$_2$ autoreceptors was studied using the irreversible antagonist N-ethoxy-carbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ; Meller et.al., JPET, in press; Adler et. al., Fed. Proc. 44, 1833,1985). The in vivo GBL method was used for assessing receptor reserve at striatal DA autoreceptors. Rats were treated with vehicle or EEDQ (6 mg/kg, i.p.) and 24 hr later dose-response curves for apomorphine (APO;0.1-10 mg/kg, i.p.) reversal of GBL-induced L-dopa accumulation were generated. The dose-response curve for APO was shifted 4.3 fold to the right in EEDQ-treated animals relative to controls (ED_{50} (control) = 0.19 mg/kg; ED_{50} (EEDQ) = 0.83 mg/kg); however, at this dose of EEDQ the maximum response was not reduced. Utilizing the methods of Furchgott (Ann. NY Acad. Sci. 144:882-889, 1967) the fraction (q) of receptors remaining after EEDQ treatment was found to be 0.31 (i.e. 31%). Thus a large receptor reserve (≥ 70%) appears to exist at terminal DA autoreceptors in the rat striatum. Since the presence of a large receptor reserve (relative to its absence) has the effect of reducing the ED_{50} of an agonist, the reported autoreceptor selectivity of several DA agonists (EMD 23, 448, 3-PPP, CGS 14948A, ciladopa) may be related to differences in receptor reserve at pre- and postsynaptic DA D_2 receptors. EEDQ was also used to study receptor reserve in vitro at rat central alpha$_2$ autoreceptors mediating inhibition of NE release. Cumulative dose-response curves for the inhibition of K^+ (20mM)-stimulated ^{3}H-NE release by the full alpha$_2$ agonist UK-14,304 were obtained in rat occipitoparietal cortex slices of control and EEDQ-treated (0.8 mg/kg, i.p., 4 hr) animals (Frankhuyzen and Mulder, 1982; Adler et. al., Fed. Proc. 44, 1833, 1985). EEDQ did not affect either ^{3}H-NE uptake or its spontaneous release; however, K^+-evoked release was increased slightly (10-20%). In slices of cortex from EEDQ-treated rats, maximal inhibition of ^{3}H-NE release by UK-14,034 (100μM) was reduced by 34% relative to controls; the EC_{50} was shifted 7-fold to the right (control: 0.024μM; EEDQ-treated: 0.17μM). The following parameters were calculated: q = 0.15 ± 0.03 and K_A (dissociation constant) = 1.41 + 0.8μM (n=7). A plot of receptor occupancy vs. response resulted in a hyperbolic curve indicative of the presence of spare receptors; 50% response was obtained at 1.6% receptor occupancy. These studies demonstrate the utility of EEDQ as a tool to investigate the presence of receptor reserve at central alpha and DA receptors and to provide new insights into CNS receptor function. 94.10 DOPAMINE-D2 RECEPTORS AND LIGHT COUPLE TO CYCLIC GMP-PHOSPHODIESTERASE, PHOSPHOLIPASE A2 AND PHOSPHOLIPASE C IN ROD OUTER SEGMENT MEMBRANES. C. L. Jelsema, Y. Ishihara, M. R. Brann*(SPON: S. P. Fracek) Lab of Cell Biology, NIMH, Bethesda, MD 20205.

Recent reports of a non-cyclase role of G_i in the activation of phospholipase A_2 and C in neutrophils and mast cells raised the possibility that transducin, the G_i-like GTP-binding protein of rod outer segment (ROS) membranes, might similarly activate phospholipases either in conjunction with its role in the light activation of cGMP phosphodiesterase (cGMP PDE) activity, or in distinction from it. The existence of dopamine-D2 receptors(R) and their coupling to a pertussis toxin, cholera toxin-sensitive G protein has been recently demonstrated in the ROS membranes (see abs. M. R. Brann and C. L. Jelsema), suggesting the possibility that transducin may also couple D2 Rs to their effector system. Since D2 Rs appear to couple to G_i in the pituitary, their role in phospholipase and cGMP PDE activation was investigated along with the effect of light on these enzyme activities in ROS membranes.

In dark-adapted ROS membranes, D2 R activation lead to increased cGMP-PDE activity in a manner analogous to light activation, suggesting that D2 Rs similarly couple to transducin. The amount of increase in cGMP PDE activity in response to 10 uM apomorphine(APO) was about a third that of light-induced activation. The specificity of the APO effect for the D2 R was evidenced by the capacity for (-)sulpiride and (+)butaclamol to block the response. Both light and D2 R activation of cGMP PDE were accompanied by increases in phospholipase A_2 and C activity in dark-adapted membranes, supportive of a role for transducin in phospholipase A_2 and C activation. APO increased the phospholipase A_2 activity of dark-adapted ROS membranes nearly four-fold, whereas light induced a 12-fold increase. With phospholipase C activity, APO induced a 50% increase, while light lead to a 3-fold increase in activity. The effects of APO on both phospholipases, similar to effects of APO on cGMP PDE activity, were D2-R-specific as both (-)sulpiride and (+)butaclamol reverse the effect of APO in dark-adapted ROS membranes. These results suggest that D2 Rs are coupled to transducin in the ROS membranes, consistent with a more general role for transducin in signal transduction. In addition, our results support a role for transducin in phospholipase activation.

94.11 "D_1-LIKE" DOPAMINE RECEPTORS: RECOGNITION SITES WITH SELECTIVITY FOR SCH23390 THAT ARE NOT LINKED TO ADENYLATE CYCLASE

Richard B. Mailman, David W. Schulz, and Clinton D. Kilts*.
Biological Sciences Research Center, University of North Carolina School of Medicine, Chapel Hill, N.C. 27514 and Department of Psychiatry, Duke University Medical Center, Durham, N.C. 27710

It has been generally accepted that dopamine receptors are divisible into two major classes: D_1 linked to stimulation of cAMP synthesis; and D_2 which is not so linked (Kebabian and Calne, 1979). Until recently, the D_2 class was believed to be responsible for most of the important functional changes mediated by dopamine receptors, including psychopharmacological, behavioral, and neurochemical effects. However, in 1981 it was reported that SCH23390 was a biochemically selective D_1 antagonist, inhibiting adenylate cyclase with a K_i three orders of magnitude lower than the K_i for competing with D_2 radioligands. Recent studies have demonstrated that SCH23390 also has extremely potent behavioral and psychopharmacological effects, suggesting that previously unknown functional roles exist for D_1 receptors.

In 1984, we reported that the amygdala has no detectable dopamine-sensitive adenylate cyclase activity (Soc. Neurosci. Abstr. 10:881, 1984). According to accepted criteria, this requires there to be no D_1 receptors in this region. Contrary to this notion, we have found significant quantities of high affinity specific binding sites for SCH23390. In addition, results from the same tissue samples demonstrate that the ratio of binding of [^{3}H]-SCH23390 and [^{3}H]-spiperone is similar in striatum versus amygdala, whereas only the former region has detectable dopamine-sensitive adenylate cyclase activity.

These data clearly demonstrate that commonly used definition of D_1 receptors must be revised to include sites not linked to adenylate cyclase. The results demonstrate multiplicity of D_1 receptors at the functional level, whether or not significant multiplicity exists in the affinity of these sites for [^{3}H]-SCH23390.

94.12 IN VIVO EEDQ SPECIFICITY FOR D-1 DOPAMINE RECEPTOR BLOCKADE: LACK OF EFFECT ON Ns OR THE CATALYTIC SUBUNIT OF ADENYLATE CYCLASE.

Ellen J. Hess*, George Battaglia, Andrew B. Norman* and Ian Creese. Dept. of Neuroscience, U.C.S.D. School of Medicine, La Jolla, CA 92093.

Peripheral administration of EEDQ (N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline) acts to potently and irreversibly block binding to striatal D-1 dopamine receptors (Hamblin, M.W. and Creese, I., Life Sciences, 32:2247, 1983). The specificity of in vivo EEDQ modification of receptors versus Ns or the catalytic subunit was investigated to assess the feasibility of using EEDQ to investigate the stoichiometry of receptor/effector interactions. Rats were injected with EEDQ (1-10mg/kg i.p.) and sacrificed 4 hours after treatment. Striatal homogenates from each animal were individually assayed for D-1 dopamine receptor-stimulated adenylate cyclase and D-1 dopamine receptor binding using the novel selective D-1 antagonist, [^{3}H]SCH 23390. [^{3}H]SCH 23390 binding exhibits a pharmacologic profile similar to the non-selective D-1 dopamine receptor radioligand [^{3}H]flupentixol with the advantage of yielding greater percent specific binding (90%).

We examined the characteristics of D-1 dopamine receptor-stimulated adenylate cyclase and also assayed for possible EEDQ induced modification(s) of the guanine nucleotide sensitive and catalytic moieties by assessing both guanine nucleotide and forskolin-stimulated cAMP production. No difference in basal adenylate cyclase activity was observed between EEDQ-treated and control animals. Comparable stimulation over basal activity was also observed in the presence of 0.1mM GTP (186%), 0.1mM Gpp(NH)p (789%) and 10mM NaF (633%). Likewise, 1uM forskolin (2049%), and 1uM forskolin +0.1mM GTP (3710%) stimulated treated and untreated tissue equally. However, EEDQ treatment markedly reduced D-1 receptor-mediated stimulation of cAMP production. Thus, EEDQ appears to be receptor specific in this system, leaving catalytic and guanine nucleotide sensitive subunits functionally intact. Both an EEDQ dose-dependent reduction in D-1 dopamine-stimulated adenylate cyclase activity and [^{3}H]SCH 23390 Bmax with no change in K_D was observed. This EEDQ-induced reduction in D-1 dopamine-stimulated adenylate cyclase and [^{3}H]SCH 23390 binding could be prevented by pretreatment with SCH 23390 (0.5mg/kg i.p.). Interestingly, the loss in [^{3}H]SCH 23390 binding did not correlate directly with the reduction in adenylate cyclase activity (e.g. at 4mg/kg EEDQ, 80% of receptor binding was lost while D-1 stimulated adenylate cyclase was reduced by only 64%). These data suggest that peripherally administered EEDQ may be used to selectively modify D-1 dopamine receptor binding sites, without modifying effector moieties. In addition, they may indicate that the stoichiometry of receptor/effector interaction may not be 1:1.

ACTION POTENTIALS AND ION CHANNELS II

95.1 ION CHANNELS IN ASCIDIAN OOCYTES: SPECIES VARIATION AND SPATIAL DISTRIBUTION.

R.E. Hice* and W.J. Moody* (SPON: W.M. Roberts) Dept. of Zoology, Univ. of Washington, Seattle, WA 98195.

Properties of macroscopic currents in two species of tunicate oocytes (Boltenia villosa & Ciona intestinalis) have been studied using two-electrode and whole cell patch voltage-clamp techniques. We have successfully obtained two-microelectrode impalements with resting potentials of -77mV to -88mV in both species of oocytes. Even small leakages (<100pA) from impalement of the ca. 150μm diameter oocytes resulted in loss of membrane potential to -20mV to -10mV because of the I-V characteristic of the inwardly rectifying K current, which comprises most of the resting conductance of the cell. Long-lasting action potentials were obtained from both oocytes in response to short, depolarizing stimuli.

Under voltage-clamp, Boltenia showed a rapid Na current (peak, 1-7nA at -30mV) and a slow, small Ca current (peak, 35-100pA at 0mV). The currents superficially resemble those reported by Takahashi et al. in Halocynthia oocytes, but with the major difference that in Boltenia, Ca current inactivation appears to be Ca-dependent, rather than voltage-dependent as in Halocynthia. The contribution of this calcium component to the action potential is variable since at the lower Na current densities the action potential often fails to reach threshold (-10 to 0mV) for regenerative Ca response. Ciona, in contrast, shows two inward currents (peak ca. 700pA for both, at -30mV & +10mV, respectively) both of which are carried by Ca ions. Both of these Ciona Ca currents are considerably slower than the Boltenia Na current, and consistently produce action potentials with large positive overshoots.

To investigate the spatial distributions of these channels, we have surgically bisected oocytes and studied the resulting animal or vegetal half-eggs ("merogones"). Two-microelectrode impalements of merogones have yielded high, stable resting potentials indicating minimal cell damage in the surgical procedure. We have also applied the "half-cell" variation of the patch clamp to the merogones. Preliminary results on the Na current using both techniques indicate no major differences in current density between the animal and vegetal halves.

Supported by GM07270 to R.E.H. and by HD17486 and an NIH Research Career Development Award to W.J.M., also,in part, by HD07098, M.B.L., Woods Hole, MA.

95.2 ACTION POTENTIALS PERSIST AT RESTRICTIVE TEMPERATURES IN TEMPERATURE SENSITIVE PARALYTIC MUTANTS OF ADULT DROSOPHILA.

J. C. Nelson* and D. H. Baird (SPON: R. J. Wyman), Dept. of Bio., Yale U., New Haven, CT 06511.

Action Potentials (APs) are not blocked in the Giant Fiber (GF) pathway of adult Drosophila when using temperature sensitive (ts) paralytic mutations above the temperature at which paralysis occurs. This is surprising because two mutations, nap and para, were reported to reversibly block APs in larval preparations (Wu, et. al., PNAS 75:4047, 1978; Wu and Ganetzky, Nature 286:814, 1980). We studied three ts-paralytic mutants postulated to affect sodium channel function and/or AP propagation - nap^{ts-1}, $para^{ts-2}$, and $seizure^{ts-1}$ (Jackson, et. al., Nature 308:189, 1984; Wu and Ganetzky, 1980). $shibire^{ts-1}$ was used as a control.

The GF pathway was stimulated by two electrodes in the brain. The GFs run from the brain to the thoracic neuropile where each makes two electrical synapses: one with the Tergotrochanteral motoneuron (TTMN) which drives the jump muscle (TTM); and the other with the Perhiperally Synapsing Interneuron (PSI), which chemically synapses with the motoneurons (DLMNs) to the wing depressor muscle (DLM). Electrical recordings were taken from the DLM and the TTM, while behavioral paralysis was monitored visually. Responses persist in the GF pathway up to 45°C in wildtype (wt) flies. The response requires sodium channels: they can be eliminated by perfusing flies with 20 nM TTX, which blocks neuron APs, but not muscle responses.

Some ts-paralytics affect the pathway as expected. shibire shows behavioral paralysis, loss of synaptic transmission (Salkoff and Kelly, Nature 273:156, 1978), and blockage of the GF pathway all at 30°C. As expected the GF pathway is blocked at chemical synapses. Thus, behavioral paralysis corresponds with physiological paralysis. However, while para flies are behaviorally paralysed and spontaneous neuronal activity stops at 30°C, the GF pathway responds up to 45°C. Similarly, in a large majority of nap flies, the GF pathway responds up to 45°C. The other nap flies have a variety of defective responses. Even at 22°C, the latency from brain stimulation to TTM response is longer than wt. Around 35°C the GF pathway may fail, but it will return if the stimulus voltage is increased slightly - higher temperatures require higher voltages. Sometimes above 35°C, part of the pathway (DLM) remains, but part (TTM) fails and does not return with higher voltage. We find no physiological abnormality in seizure around 40°C, but the paralytic temperature is so close to wt that defects may not be experimentally detectable. Deficiencies uncovering nap and seizure did not lower the behavioral paralysis temperature, or make the physiology more abnormal.

APs are not blocked in the GF pathway in para, seizure, and most nap flies. shibire reliably blocks the GF pathway at known synaptic sites. (support: NIH - GM 75027-08; NS-07314)

95.3 DIFFERENTIAL SENSITIVITY TO TTX OF Na-POTENTIALS IN NOCICEPTIVE NEURONS FROM FOUR SPECIES OF LEECHES. J. Johansen and A.L. Kleinhaus Dept of Neurology, Yale U. Sch. Med. New Haven, Ct. 06510.

We have recently shown that the nociceptive neurons (N cells) in the leech can be segregated into a medial type (Nm) and a lateral type (Nl) according to their physiological and pharmacological properties. We now report that the Na-dependent action potential (AP) of the two cell types have differential sensitivities to TTX and that the AP's of the N cell homologues from different leech species also vary considerably in their response to TTX.

The normal AP of the N cells was exclusively Na-dependent; its AP varied logarithmically with $\{Na\}_o$ was unaffected by the presence of Mn and absence of Ca, and could not be elicited in Na-free Ringer. The TTX block of the maximal rate of depolarization (Vmax) of the Na-dependent AP of the Nm cell in Macrobdella followed a reverse Langmuir curve for bimolecular reaction with an ED50 of 9 uM. Almost complete blockage was obtained at 50 uM. In contrast, TTX inhibition of Vmax in the Nl cell reached saturation at a level of only 55% reduction in Vmax even when doses in excess of 200 uM TTX were applied. The simplest interpretation of this data is that there are two types of Na-channels in the Nl cell. This is further supported by the fact that the dose-response data could be well fitted by a reverse Langmuir curve assuming that the Nl cell possesses two populations of Na-conductances: one insensitive to TTX and one (like the Nm cell) with an ED50 to TTX of 9 uM, with the two populations present in a 0.45 to 0.55 ratio respectively. Similar results were obtained for the two pairs of N cells in Haemopis. In the N cells of Hirudo 50 uM TTX blocked Vmax by only 25% with no difference between Nm and Nl. In the phylogenetically more distant glossiphoniid leech Haementeria which possesses only one N cell homologue, the AP was completely blocked by 50 nM TTX with an approximate ED50 of 10 nM.

These results provide evidence that the Nl cell of Macrobdella has two types of Na-channels that can be segregated by their different sensitivity to TTX. The Nm cell only possesses one type with an ED50 in the low uM range. In contrast, the Nm cell of Haementeria is a 1000 times more sensitive with an ED50 in the low nM range as is the case for most mammalian Na-channels. This diversity in sensitivity to TTX may reflect structural differences in Na-channels of leech N cells at the molecular level both between species and within a single cell type. Furthermore, the variation in pharmacological sensitivity of identified homologous neurons in different leech species may provide insight into leech phylogeny and evolution of ion-conductances.

95.4 DISTRIBUTION OF SODIUM CHANNELS IN DENERVATED SKELETAL MUSCLE. J. H. Caldwell and R. L. Milton*. Dept. of Molecular and Cellular Biology, National Jewish Hospital and Dept. of Physiology, Univ. of Colorado Medical School, Denver, CO, 80206.

Voltage-gated sodium channels are not uniformly or randomly distributed along the length of a normal skeletal muscle fiber. Loose patch voltage clamp recording has been used to show that sodium channels are 5-10 fold more concentrated near the nerve terminal than in extrajunctional membrane (Beam, Caldwell & Campbell. Nature 313:588, 1985; Roberts and Almers, Biophys. J. 47:189a, 1985). This increased density occurs only within 100-200 μm of the endplate.

Two other regions of the muscle fiber have concentrations of sodium channels that are strikingly different from extrajunctional membrane; (1) membrane underneath the nerve terminal has a high density of Na channels and (2) membrane near the tendon has a low density of Na channels with most of the decrease (~10 fold) occurring within 250 μm of the tendon (Caldwell, Campbell & Beam, unpublished).

We have studied the effect of denervation upon the distribution of Na channels in both snake and rat muscle. Measurements of sodium current with the loose patch clamp were made from endplate, perijunctional, extrajunctional, and near-tendon membrane. The nonuniform distribution found in innervated muscle persists in both rat flexor digitorum brevis (denervated two weeks) and the snake external abdominal oblique (denervated four weeks). Current density (referred to the area of the pipette orifice) remained 100-125 mA/cm^2 at both snake and rat endplate membrane. The perijunctional density in rat muscle increased ~20% (from 25 mA/cm^2 to 31 mA/cm^2). The abrupt decrease in current density near the tendon also remained.

It is not known when or how this nonuniform distribution is formed during development, but it is likely to be imposed upon the muscle by the nerve. The present experiments show that the nerve is not required for the maintenance of the sodium channel distribution.

95.5 THE SODIUM CURRENT OF DISSOCIATED BULLFROG SYMPATHETIC NEURONS. Stephen W. Jones, Department of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, NY 11794.

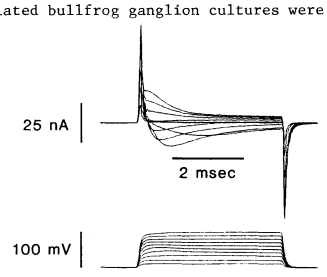
Neurons of vertebrates clearly have voltage-sensitive sodium currents closely analogous to that of the squid giant axon, but technical problems have limited detailed characterization of somatic sodium currents. Neurons dissociated from bullfrog paravertebral sympathetic ganglia by the method of Kuffler & Sejnowski (J. Physiol. 341:257, 1983) are suitable for patch electrode recording techniques. The dissociated cells are essentially spherical, and lack an axon.

Sodium currents were recorded in the whole-cell configuration with cesium-containing pipets in nominally calcium-free Ringer's, at room temperature, from neurons dissociated 1-5 days previously and stored at 4°C. A single electrode voltage clamp amplifier (Axoclamp 2, 30-50 kHz switching frequency) was used with .5-2 MΩ electrodes; capacity transients generally settled in 0.2-0.5 msec and clamp error at peak current was typically 4 mV. Large depolarizing commands (to +50 to +100 mV) sometimes also evoked outward currents activating over several msec, which were largely separated from the more rapid sodium currents.

The sodium current in dissociated bullfrog sympathetic neurons turns on and off rapidly (see figure). The voltage sensitivities of peak activation and of steady-state inactivation are near 7 mV per e-fold. Half maximal peak conductance occurs near +5 mV, with half maximal steady-state inactivation near -35 mV. Recovery from inactivation is rapid at -80 mV (half maximal in 1-3 msec). The reversal potential for the current changes appropriately for changes in external sodium concentration. 1 μM tetrodotoxin reversibly blocks most of the current.

These properties are generally consistent with those of sodium currents in other preparations.

Supported by NIH grants NS 20751 to S. W. J. and NS 18579 to Dr. Paul R. Adams. The dissociated bullfrog ganglion cultures were prepared by Claire Adams.



Sodium currents evoked by depolarizing steps from -40 mV. Each trace is the average of 4 records; capacity transients and leak not subtracted.

95.6 SOLUBILIZATION AND PURIFICATION OF THE VOLTAGE-SENSITIVE SODIUM CHANNEL FROM *DROSOPHILA MELANOGASTER*. K. Hubbard*, S.D. Wilson*, and L.M. Hall. Dept. of Genetics, Albert Einstein College of Medicine, Bronx, NY 10461.

At least five different single gene mutations in Drosophila melanogaster appear to affect the structure and/or regulation of the voltage-sensitive sodium channel involved in propagation of action potentials in neurons. All of these mutants have the phenotype of temperature- or stress-induced paralysis. Some have been implicated as affecting sodium channel activity or regulation on the basis of mutant-induced effects on ^{3}H-saxitoxin binding (Jackson et al., Nature, 308: 198, 1984) while others have been implicated on the basis of their interactions with mutants which affect ^{3}H-saxitoxin binding and/or propagation of action potentials (Ganetzky, Genetics, 108: 897, 1984). It is of interest to determine which of these mutants define structural genes for the sodium channel and which define gene products which affect channel regulation or environment. In this regard, it would be helpful to know how many structural proteins comprise the sodium channel in Drosophila. Purification studies of sodium channels from vertebrate sources suggest the channel consists of 1 to 3 subunits depending on the source of material (Agnew, Ann. Rev. Physiol., 46: 517, 1984). As a first step in the purification of sodium channels from Drosophila, we have developed a procedure for the stable solubilization of the channel. While several nonionic and zwitterionic detergents can be used for solubilization, the Drosophila sodium channel, like that of other species, appears to be sensitive to its detergent/lipid environment and binding activity is often unstable following solubilization. One zwitterionic detergent, 3-[(3-cholamidopropyl) dimethyl-ammonio]-1-propanesulfonate (CHAPS), allowed stable solubilization of ~75% of the total saxitoxin-binding activity from membrane preparations. Stability of the solubilized sodium channels was improved further by optimizing the lipid:detergent ratio using phosphatidylcholine. When the solubilized saxitoxin-binding component was chromatographed on a Sepharose 6B column and its elution profile compared with molecular weight markers including catalase (MW 248,000), ferritin (MW 450,000), and β-galactosidase (MW 540,000), the Drosophila sodium channel: detergent complex was found to be a large macromolecular complex similar to that described for vertebrate sodium channels. Solubilization followed by Sepharose chromatography represents a useful first step for the purification of the saxitoxin receptor from normal and mutant Drosophila strains. (Supported by a grant from the Muscular Dystrophy Association and by NIH grant NS16204. LMH is an Irma T. Hirschl-Monique Weill-Caulier Career Scientist Awardee).

95.7 SEPARATION AND CHARACTERIZATION OF THE POLYPEPTIDE SUBUNITS OF THE RAT BRAIN SODIUM CHANNEL. Donald J. Messner* and William A. Catterall. (SPON:M. Leibovitz). Department of Pharmacology, University of Washington, Seattle, WA 98195.

The voltage-sensitive Na channel from rat brain consists of 3 polypeptide subunits that have been designated α, β1, and β2. Their molecular weights as determined by SDS-polyacrylamide gel electrophoresis or gel filtration chromatography in SDS are 260,000 for α, 36,000 for β1, and 33,000 for β2. β2 is attached to α by disulfide bonds, while β1 is attached to the αβ2 complex non-covalently. All three subunits contain complex carbohydrate chains as shown by specific binding of wheat germ agglutinin. Chemical or enzymatic deglycosylation of the subunits gives polypeptide chains with apparent molecular weights of 220,000 for α, 23,000 for β1, and 21,000 for β2. Partial proteolytic maps of the SDS-denatured β1 and β2 subunits indicate they are non-identical polypeptides.

The β1 subunit dissociates from the detergent-solubilized Na complex upon incubation in high salt. Treatment with 2M $MgCl_2$ causes complete loss of the β1 subunit and of [^{3}H]saxitoxin (STX) binding activity. At intermmediate concentrations of $MgCl_2$, the loss of β1 and the loss of [^{3}H]STX binding activity are closely correlated. Tetrodotoxin (TTX) quantitatively stabilizes the solubilized complex against both the loss of β1 and the loss of [^{3}H]STX binding activity, indicating a cause-and-effect relationship between dissociation and loss of activity.

Treatment of the solubilized Na channel with dithiothreitol causes release of the β2 subunit. Dissociation of β2 is not blocked by TTX. Preliminary experiments suggest there is no correlation between the amount of β2 in the Na channel complex and the ability of the preparation to bind [^{3}H]STX. We conclude from these studies that the presence of β1, but apparently not of β2, is required for the integrity of the [^{3}H]STX binding site of the solubilized and purified rat brain Na channel.

95.8 BIOSYNTHESIS OF THE VOLTAGE-SENSITIVE SODIUM CHANNEL FROM RAT BRAIN. J.W. Schmidt* and W.A. Catterall. Department of Pharmacology, University of Washington, Seattle, WA 98195.

The voltage-sensitive sodium channel from rat brain has three glycoprotein subunits called α, β1, and β2. The α and β2 subunits are linked by disulfide bonds. We have begun to study how the channel is assembled and compartmentalized by using the technique of immunoprecipitation of subunits from metabolically labeled rat brain cells. Primary cultures of brain cells isolated from 15 day embryos and maintained in vitro for 21 days were pulse labeled with [^{35}S]-methionine for 0.5 hrs and chased for 0 to 4 hrs. Cell membranes were solubilized, glycoproteins isolated by affinity chromatography on wheat germ agglutinin (WGA)-Sepharose, α subunit immunoprecipitated with antiserum that was raised against purified sodium channel, proteins resolved by SDS-PAGE, and visualized by autoradiography. α subunits with complex carbohydrate chains capable of binding to WGA appear with $t_{1/2}$ of 45 minutes. Glycoproteins that failed to adsorb to WGA were affinity purified on lentil lectin-Sepharose. Immunoprecipitates of this glycoprotein pool show a single autoradiographic band that migrates slightly more rapidly than mature α and is rapidly ($t_{1/2}$=45 min) converted to a form that will bind to WGA. These experiments identify newly synthesized α subunits and show that they are first made with high mannose carbohydrate side chains which are processed to complex chains.

To determine when subunit assembly occurs, cells were pulse labeled for 2 hrs and chased for 0 to 24 hrs. Soon after attainment of capacity to bind to WGA, 1/3 of the newly synthesized α subunits are disulfide-linked to β2 subunits ($t_{1/2}$=90 min). We have previously shown that, in brain cells of this developmental stage, only 1/3 of the α subunits are disulfide-linked to β2 and located on the cell surface. Most α subunits are not linked to β2 subunits and exist in an intracellular pool. Cell surface channels were selectively isolated by incubating intact cells with antiserum at 4°C after pulse/chase labeling. Only the newly assembled α-β2 complex is located at the cell surface. Free α subunits are found only in the intracellular compartment. At least 50% of newly synthesized α subunits are degraded within the first 12 hours. In contrast, both the cell surface α-β2 and intracellular free α pool that remains after 12 hr are metabolically stable, with apparent half-life >5 days. These results indicate that, when α subunits reach their mature glycosylation state, they can be linked to β2 subunits and transported to the cell surface. Early in development, most α subunits do not immediately form disulfide bonds to β2 and remain as an intracellular pool of inactive subunits. The metabolic stability of this pool suggests that it may be readily available for formation of functional cell surface channels.

95.9 SINGLE K^+ CHANNELS FROM RAT BRAIN INCORPORATED INTO LIPID BILAYERS ON PATCH-CLAMP PIPETTES. J.Farley and B.Rudy. Prog. in Neurosci., Princeton Univ., Princeton, NJ 08544 and Dept. of Physiol. Biophysics, New York Univ. Med. Ctr., NY,NY 10016.

The diverse functional properties of K^+ channels in many neurons, their role in neuromodulation, and their apparent cell-specific control by calcium and cyclic nucleotides raise interesting questions as to their role in the regulation of neuronal excitability. We have used planar bilayers on patch-clamp electrodes[1] and a special flux assay[2] to detect and characterize K^+ channels in rat brain synaptosomal membranes. This flux assay allows the selective study of specific ion channels present in only a small fraction of a heterogeneous population of vessicles.

Artificial membranes (2-40 GΩ) were formed on the tips of fire-polished patch clamp electrodes from a 70:30 molar ratio of bovine brain lipids (PE:PC). Incorporation of ionic channels proceeded within 2-6 min in 109 of 117 experiments, following the addition of membrane vessicles to a 100 mM KCl^-/500 μ MCaCl solution.

To date, we have identified and characterized two different K^+ channels and a Cl^- channel, on the basis of their selectivity, unitary conductance(γ), gating kinetics, and sensitivity to calcium and TEA ions. The most commonly observed channel (seen in 88 experiments) displays: 1) a γ = 220 pS in a symmetrical 100 mM KCl solution, 2) cation selectivity (Pk:Pna ∿ 100:1), 3) voltage-dependent block by TEA (<10 mM) applied to the intracellular (bath) face of the channel, 4) modest voltage-sensitivity: at 200 μ M Ca^{2+} concentrations, the channel is often open at -80 mV, and 5) sensitivity to "intracellular" Ca^{2+}: the channel is reversibly activated and inactivated by EGTA-buffering of the calcium concentration. High(>200 μM) concentrations of Ca^{2+} partially inhibit this channel, which can be overcome by greater depolarizations. This channel appears to be similar to the "BK" channels described in many tissues[3-6]. The second channel, distinguished clearly in 63 experiments, displayed: 1) a γ =140 pS, 2) cation selectivity, 3) complex gating characteristics with at least two closed states, 4) resistance to intracellular TEA (10mM) and 4-AP (1mM) block, 5) strong voltage-dependency, and 6) greater sensitivity to intracellular Ca^{2+} than the large conductance channel.

Other classes of K^+ channels, Ca^{2+}- insensitive and with smaller conductances, have also been seen. A fourth Cl^- channel has also been studied. It displays: 1) γ =50 pS, 2) little voltage- or Ca^{2+}-dependency, and is not blocked by TEA or 4-AP.

95.10 A NEW INTERPRETATION OF THE EFFECTS OF TETRAETHYLAMMONIUM IONS (TEA^+) ON SQUID GIANT AXONS. J.R. Clay* (SPON: W.J. Adelman, Jr.). Lab. of Biophysics, NINCDS, NIH at the Marine Biological Lab., Woods Hole, MA 02543.

Internal application of TEA^+ in squid axons produces a marked prolongation of action potential duration (Tasaki, I. and S. Hagiwara, J. Gen. Physiol.,40:859, 1957) and a significant reduction of outward going potassium ion current (Armstrong, C.M. and L. Binstock, J. Gen. Physiol.,48:859, 1965). These results suggest that the effect of TEA^+ on the action potential is caused by potassium channel blockade. The mechanism of blockade proposed by Armstrong, C.M. (J. Gen. Physiol.,50:491, 1966) is based on the hypothesis that a potassium channel must open before TEA^+ blockade can occur. The primary evidence for this model is the time course of potassium ion current in the presence of TEA^+ (and TTX) following a membrane depolarizing step. The current initially rises with a time course similar to that of the control followed by a slow decline of outward current, which is reminiscent of sodium channel inactivation. This result is consistent with a link between channel activation and TEA^+ blockade, although the correlation could be fortuitous since membrane depolarization is required for both processes to occur. The results in this study concerning the effects of moderately large TEA^+ concentrations (10-20 mM) on inward-going tail currents with elevated levels of external potassium ion concentration indicate that TEA^+ blockade is, in fact, independent of channel gating. The tail exhibits a slight, initial increase in the inward direction lasting about 0.2 msec (Armstrong and Binstock, 1965) followed by a return to baseline with a time constant which is identical to that of the control. This result suggests that TEA^+ blockade is, by definition, independent of channel gating. The Armstrong (1966) model predicts a tail current time constant in the presence of 10-20 mM TEA^+ which is significantly greater than the control An alternative model for TEA^+ effects is proposed based on Eyring rate theory.

Computer simulations of the action potential demonstrate that TEA^+ blockade of potassium current produces surprisingly little prolongation of action potential duration. TEA^+ also effects the sodium current by increasing the steady-state, non-inactivating component of sodium conductance for potentials positive to 0 mM (Yeh, J.Z. and T. Narahashi, J. Gen. Physiol., 69:293, 1977). Simulations with this effect alone also produce relatively little increase in action potential duration. However, the simulated results are in close agreement with the experimentally observed action potentials, when the effects of TEA^+ on both the sodium and the potassium currents are incorporated into the computer model.

95.11 PSYCHOTOMIMETIC "SIGMA OPIATES" AND PHENCYCLIDINES SELECTIVELY BLOCK THE SAME K CHANNELS IN PRESYNAPTIC NERVE TERMINALS. D.K. Bartschat*, R. G. Sorensen* and M. P. Blaustein. (SPON: E.K. Krueger) Univ. of Maryland, Sch. of Med., Baltimore, MD 21201.

Rat brain synaptosomes have at least four different types of K channels, as shown by ^{86}Rb and ^{42}K efflux studies (J. Physiol. 361:419, 1985). One type of channel, a voltage-regulated, non-inactivating K channel ("S_V"), is selectively blocked by the psychotomimetic agent, PCP, and behaviorally active analogues (Soc. Neurosci. Abstr. 10:863, 1984): the rank order of potency for block of these K channels closely parallels the behavioral potency of these drugs and their relative ability to displace ^3H-PCP from a high affinity binding site on synaptic plasma membranes. Of interest are several stereoisomer pairs of "sigma opiates", one isomer of which produces PCP-like behavioral effects and displaces bound ^3H-PCP more potently than the other. In the presence of 10 μM naloxone, which blocks classical opiate effects, dexoxadrol blocks S_V at 1000-fold lower concentrations than does its stereoisomer, levoxadrol; (+) SKF 10,047 (N-allyl-normetazocine or NANM) is 10-fold more potent than (-) SKF 10,047; and (-) cyclazocine is 2-3-fold more potent than (+) cyclazocine. This stereoselectivity for block of S_V closely parallels the effects of these isomers in behavioral and binding experiments (Table I). Furthermore, block of S_V by the phencyclidines and "sigma opiates" occurs at nano- to micromolar concentrations. This high affinity block of presynaptic K channels should prolong the action potential duration and increase voltage-gated Ca entry, thereby producing excessive neurotransmitter release, as is observed in PCP intoxication. These results are consistent with the view that the behavioral effects of PCP and "sigma opiates" may be related to blockade of some presynaptic K channels, and that the PCP/"sigma opiate" receptor is associated with a specific class of K channels. Supported by NIH grant NS-16106 & NRSA NS-07611.

Table I

Drug Pair	Relative Potency for: Block of S_V	Displacement of Bound ^3H-PCP	PCP-like Behavior
Dexoxadrol: Levoxadrol	~1000:1	418:1	>1000:1[a]
(+) NANM: (-) NANM	~10:1	6.4:1	~3:1[b]
(-) Cyclazocine: (+) Cyclazocine	2-3:1	1.8:1	~5:1[c]

a. J. Pharm. Exp. Ther. 228: 147, 1984.
b. Eur. J. Pharm. 84:225, 1982.
c. J. Pharm. Exp. Ther. 222:146, 1982.

95.12 THE RAT BRAIN PHENCYCLIDINE RECEPTOR CONSISTS OF TWO POLYPEPTIDES (M_R = 95 kD and 80 kD) THAT ARE SPECIFICALLY LABELLED BY ^3H-AZIDO-PHENCYCLIDINE. R.G. Sorensen* and M.P. Blaustein, Dept. of Physiol., Univ. of Maryland, Sch. of Med., Baltimore, MD 21201.

Phencyclidine (PCP) and behaviorally-active analogues bind with high affinity to synaptic membranes (Biophys. J. 47:384a, 1985) and selectively block voltage-regulated, non-inactivating K channels ("S_V") in rat brain presynaptic terminals (Bartschat & Blaustein, Soc. Neurosci. Abstr. 10:863, 1984). Thus, elucidation of the molecular composition of this PCP receptor may provide direct information about the subunit structure of certain rat brain K channels. To identify the brain PCP receptor, we prepared a tritiated photoaffinity analogue of PCP, m-azido- [^3H]-phencyclidine (^3H-Az-PCP); this photolabile ligand binds with high affinity ($K_{0.5}$ ≈ 0.9 μM) to the PCP receptor (Soc. Neurosci. Abstr. 10:863, 1984).

Synaptic membranes were incubated for 30 min at 37°C in 5 mM sodium phosphate, pH 7.0, with 0.5 - 2 μM ^3H-Az-PCP, without or with a 500 to 2000-fold excess of unlabelled PCP or other ligands (see below). The samples were then irradiated with 254 nm UV light for 5 min to photolyze the Az-PCP. The membranes were solubilized in SDS dissociation buffer and subjected to SDS-PAGE. The resulting gels were impregnated with "Fluoro-Hance" (RPI), dried, and fluorograms were prepared. Several polypeptides incorporated the label. However, in the presence of excess unlabelled PCP, incorporation of the label was markedly reduced in only two polypeptides, M_R 80 kD and 95 kD, respectively. The M_R = 95 kD peptide was labelled more heavily, and may therefore include the primary PCP binding site. Covalent labelling of these two polypeptides was also specifically blocked by other PCP analogues such as TCP (the thienyl analogue of PCP), by some K channel blockers (4-aminopyridine and tetrabutylammonium), and stereoselectively by certain behaviorally-active ("PCP-like") "sigma" opiates (dexoxadrol >> levoxadrol). The latter results parallel the ability of these ligands to displace ^3H-PCP from rat brain membranes and to block "S_V". The acetylcholine receptor (AChR) of Torpedo electric organ is also a PCP "receptor". However, this nicotinic AChR, with about 10-fold lower affinity for PCP than the brain "receptor" and with specific ^3H-Az-PCP labelling to subunits of M_R <66 kD (Haring et al., J. Neurosci. 4:627, 1984), differs from that of the rat brain PCP "receptor". Our data are consistent with the view that the rat brain PCP receptor is the voltage-regulated, non-inactivating K channel, and that this channel consists of at least two subunits of M_R = 80 kD and 95 kD, respectively. Supported by grant NS-16106 and NRSA NS-07611.

SENSORY SYSTEMS: SUBCORTICAL VISUAL PATHWAYS II

96.1 RESPONSES OF PRIMATE LATERAL GENICULATE NEURONS TO COLOR CONTRAST INDEPENDENT OF BRIGHTNESS CONTRAST. P. Gouras and H.U. Evers*. Dept. Ophthalmology, Columbia University, New York, N.Y. 10032

An edge formed by spectral (wavelength) contrast across which brightness (effective light energy) contrast can be independently controlled is used as a stimulus in order to determine what forms of pure color can be distinguished by neurons in the lateral geniculate nucleus (LGN) of anesthetized (Nembutal 10 mg/kg/hr) cynomolgus monkeys. The edge is projected onto a tangent screen focused on the monkey's retinas through a 1-2mm pupil and moved at 10 deg/sec or slower across the center of the receptive field of each neuron. Responses to the same stimulus are averaged and analyzed on a computer display. The precise alignment of each response provides a good monitor of any eye movement. The parvocellular layers contain mostly tonically responding neurons with small receptive field centers; but some very phasically responding cells are also found. Tonic on-center cells tend to be in the upper and off-centers in the lower layers. Most of the tonic cells show antagonistic interactions between two different cone mechanisms which we believe to be the middle (M) and long (L) wavelength sensitive cones. We have not yet encountered a cell subserving S cones. The phasic cells do not show cone opponent interactions but respond similarly to all wavelengths. In the magnocellular layers only phasic cells are found, also without overt cone opponent interactions. All cells studied so far cannot distinguish white from any other color (red, yellow, green or blue). It is therefore impossible for visual cortex to distinguish white from other colors given this input. Many of the tonic on- and off-center cells can distinguish reddish orange from greenish blue and they do this better when brightness contrast across the edge is minimized; presumably this brings their cone opponent inputs to a more optimum balance. For example, the so called "concealed" cone opponent cells tend to become overt cone opponent cells as brightness contrast is minimized. Phasic cells cannot distinguish any part of the spectrum from any other but they have high sensitivity for brightness contrast and movement. Their response to brightness contrast is minimal at approximately the same range that we see equal brightness contrast across the edge. These tonic cells are not so; some see yellow brighter than white, others see white brighter than yellow and at a different brightness scale than we. This arrangement must guarantee that a white/yellow edge can always be detected as a brightness gradient. For all these cells blue is darker than the other colors and a blue/black edge is an extremely ineffective stimulus. In order to tell white from yellow or blue from green as a color difference another input is required. We believe that this input must be transmitted by a small fraction of cells which receive an input from S cones. We have detected such cells in the retina where they represent about 5% of all optic nerve fibers. We expect to detect them in the LGN.

96.2 THE PROCESSING OF CONTRAST INFORMATION IN THE MAMMALIAN LATERAL GENICULATE NUCLEUS. E. Kaplan* and R.M. Shapley* (SPON: F. Brink)
The Rockefeller University, New York, NY 10021.

Contrast is one of the most important aspects of a visual stimulus, and it is thus important to understand the way in which it is encoded and processed by various stages of the visual system.

We used simultaneous recordings of synaptic (S) potentials and action potentials from lateral geniculate nucleus (LGN) neurons in cats and monkeys in order to study the way in which the LGN processes contrast information. The S potentials faithfully reflect the activity of the retinal ganglion cells which drive the LGN units. The stimuli were spots, annuli or gratings, presented on the face of a CRT screen and modulated or drifted at various temporal frequencies. Their contrast ranged from 2% to 80%.

Our preliminary results show that the contrast-response functions of most LGN units saturate before their inputs do. The amplitude ratio of the LGN response/retinal ganglion cell response decreases and the phase difference increases as contrast increases. This result appears to hold for a range of temporal frequencies, patterns and cell types. At this stage, neither the mechanism nor the functional significance of this compression of contrast information at the thalamus is clear.

96.3 GABA IMMUNOREACTIVITY IN MONKEY LATERAL GENICULATE NUCLEUS (LGN) AT LIGHT AND ELECTRON MICROSCOPIC LEVELS. P. Pasik, T. Pasik, J. Hamori* and G. R. Holstein. Depts. Neurol. & Anat., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029, and 1st Dept. Anat., Semmelweis Univ. Sch. Med., 1450 Budapest, Hungary.

The recognition of presumably GABA-ergic elements in the LGN has been based on indirect methods that permit the visualization of neurons which uptake tritiated GABA (by autoradiography), or the identification of sites for GABA synthesis (by GAD immunocytochemistry) or catabolism (by GABA-T histochemistry). We have used the direct labeling of GABA-containing elements with an antiserum, raised against GABA-BSA conjugate, of proven specificity (Hodgson et al., J. Histochem. Cytochem., 1985), and further treatment with Sternberger's PAP technique. The procedure was made on preembedded 50 µm Vibratome sections and resin-embedded 1 µm sections from 3 M. mulatta and 1 M. fascicularis. No labeling was observed in control tissue. Light microscopy showed immunostained neuronal bodies in the pars dorsalis (LGNd). Most of them were smaller than unlabeled neurons and belonged to a bipolar type with poorly arborized long dendrites. The proportion of immunoreactive cells was higher in magnocellular than parvocellular laminae. Somata were also consistently labeled in the pars ventralis (LGNv) or pre-geniculate nucleus. The reaction product appeared in both cytoplasm and karyoplasm, the nucleolus always being negative. No stained glial elements were ever observed.

Ultrastructurally, GABA immunoreactivity was found in perikarya similar to those described for interneurons in our earlier work, exhibiting an occasional cluster of synaptic vesicles. Heavy label was present in dendrites as well as in vesicle-containing profiles which were postsynaptic to unlabeled terminals of retinal origin, and presynaptic to either unstained dendrites of principal cells, or to other immunoreactive dendrites. These elements, considered to be interneuron presynaptic dendrites, frequently formed triadic synaptic arrangements. In addition, there were other immunostained profiles in the LGNd neuropil of exclusively presynaptic character, with considerably larger mitochondria and lighter labeled synaptic vesicles.

These findings provide direct identification of GABA-ergic neurons in both the LGNd and LGNv, and strongly suggest that they are of inhibitory nature. That such cells are the LGNd interneurons (I-cells) is supported by: (1) similar differential proportion in the two laminar types as found for I-cells (Hamori et al., Exp. Brain Res., 1983); (2) same synaptology of labeled profiles as those of earlier defined I-cell presynaptic dendrites (Hamori et al., Brain Res., 1974); (3) frequent synapses between labeled profiles as with the previously described I-cell to I-cell junctions (Pasik et al., Exp. Brain Res., 1976). The second type of labeled bouton probably represents terminals of afferent axons from the thalamic reticular nucleus and/or the LGNv.

Aided by NIH Grants #NS18657, NS11631, F32NS06954 and EY01867.

96.4 GABA ANTISERUM REACTIVITY IN THE LATERAL GENICULATE NUCLEUS OF THE TREE SHREW (TUPAIA BELANGERI): A LIGHT AND ELECTRON MICROSCOPIC ANALYSIS. R.N. Holdefer, T.T. Norton and R.R. Mize. Dept. of Physiological Optics, Sch. of Optometry, Univ. of Ala. at Birmingham, AL 35294 and Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163.

Recent reports of GAD immunoreactivity and ^{3}H-GABA uptake in the lateral geniculate nucleus have suggested that GABAergic neurons participate in the inhibitory circuitry of the LGN. In order to examine this issue more directly, we utilized an antiserum specific for GABA. Tree shrews were perfused with a phosphate buffered 4% paraformaldehyde, 0.2 - 0.5% glutaraldehyde fixative. 50 µm sections were reacted with GABA antiserum (Immuno Nuclear) and stained using the avidin-biotin (ABC) technique. Selected sections were prepared for electron microscopy.

At the LM level, dense, labelled neuropil was found throughout the LGN but was quite sparse within the interlaminar zones. Darkly-labelled cells were distributed homogeneously in all 6 layers of the LGN, in both the monocular and binocular segments. In many labelled cells, 1 - 4 proximal dendrites could be seen. These dendrites occasionally crossed laminar boundaries. The proportion of labelled cells was approximately 25 - 30% in semithin sections counterstained with toulidine blue. The mean area (± s.e.) of the labelled cells was 99.8 ± 5.0 µm^2 in contrast with the mean area of 186.5 ± 7.0 µm^2 for the unlabelled cells in the same section.

At the EM level the labelled cells were characterized by a relatively thin rim of cytoplasm surrounding a prominent nucleus. The nucleus usually was labelled more darkly than surrounding cytoplasm and was deeply invaginated. We found no clearly labelled glia. Other labelled profiles included myelinated axons, large dendrites and several types of vesicle-containing profiles. Many examples were found of labelled F2 profiles that were postsynaptic to retinal terminals within a glomerulus and that contained pleomorphic vesicles. The presence of numerous labelled axons in the LGN suggests that part of the labelled neuropil may come from extrinsic sources. Indeed, darkly-labelled cells were found in the thalamic reticular nucleus.

In conclusion, the homogeneous distribution of labelled cells across all 6 LGN layers suggests that similar, GABA-mediated inhibitory processes occur throughout the LGN. Our EM data support the conclusion that, as in other species (cat, galago, and macaque), GABAergic neurons in tree shrew participate in F2 synaptic interactions and may mediate feed-forward inhibitory processes in the LGN.

96.5 TWO TYPES OF GABA-CONTAINING INTERNEURONS IN THE A-LAMINAE OF THE CAT LGN: A DOUBLE-LABEL HRP AND GABA-IMMUNOCYTOCHEMICAL STUDY. J. Zempel* and V.M. Montero. (SPON: C.N.Woolsey). Dept. of Neurophysiology, Waisman Center, Univ. of Wisconsin, Madison, WI 53705.

The A-laminae of normal and HRP-retrogradely labeled LGN of the cat were examined after immunocytochemistry with a GABA antiserum with three main objectives: a) to see whether the GABA antiserum labels the same type of cells that were previously identified with GAD antisera (Fitzpatrick et al. '84; Montero and Singer '85); b) to examine whether GABA+ cells can be retrogradely labeled from the visual cortex after massive injections of HRP in cortical areas 17 and 18; and c) to analyze quantitatively the size distribution of GABA+ cells in the medio-lateral extent of LGN.

The results showed that GABA+ cells were similar in several respects (distribution, size, proportion) to the population of cells identified with GAD antibodies, reinforcing the notion of the GABAergic nature of these cells. In vibratome (50 µm) or plastic-embedded semithin (1 µm) sections doubly reacted with HRP and GABA antiserum, the relay cells were characterized by black HRP Co-DAB grains in the cytoplasm and absence of the brown anti-GABA reaction product in the nucleus. In contrast, GABA+ cells showed the brown anti-GABA reaction product in the cytoplasm and nucleus, and absence of black HRP grains in the cytoplasm. As control, sections of the cortex surrounding an HRP injection site showed many double-labeled HRP-GABA+ cells. In the semithin sections (treated with post-embedding GABA immunocytochemistry) geniculate neurons were labeled either retrogradely with HRP or with anti-GABA reaction products, the GABA+ cells being about 23% of the total population. The results of the double labeled material suggest the interneuronal nature of GABA+ cells.

Cell body area measurements showed that the population of GABA+ cells in the A-laminae is composed of a large proportion (about 79%) of small cells (50-220 µm^2) and a smaller proportion (about 21%) of medium size cells (220-440 µm^2), corresponding to the beta and alpha GAD+ cells, respectively, previously described by Montero and Singer '85. The proportion of medium size (alpha) cells, however, increases from medial to lateral parts of LGN, resembling a similar medio-lateral increase of Y and type I cells in the A-laminae (Hoffmann et al. '72; LeVay and Ferster '77). These results suggest that the beta and alpha GABAergic interneurons are related to the X and Y relay cells, respectively, and are consistent with the notion of separate feedforward inhibitory pathways to X and Y relay cells in cat LGN (Lindström and Wróbel '84), via X and Y intrinsic interneurons (Dubin and Cleland '77).

96.6 LOCALIZATION OF GABA IN TYPE 3 CELLS OF CAT LGN AND DEMONSTRATION OF THEIR SOURCE TO F2 TERMINALS: A STUDY USING A NEW DOUBLE-LABEL GOLGI-EM GABA-IMMUNOCYTOCHEMICAL METHOD. V.M. Montero. Dept. of Neurophysiology, Waisman Center, Univ. of Wisconsin, Madison, WI 53705.

Presumptive GABAergic cells in cat LGN have been identified by 3H-GABA uptake and immunoreactivity to GAD and GABA antisera by several workers. The pattern of dendritic arborization of these cells is, however, unknown. Furthermore, there is no direct evidence linking GABA processes in cat LGN (F1, F2 terminals) to intrageniculate GABA cells. To answer these questions, typical Guillery's types 1, 2 and 3 geniculate cells were selected in Golgi gold-toned sections embedded in plastic for subsequent processing with GABA immunocytochemistry. After drawing and photography of the cells, alternate semithin (1 µm) and thin sections were collected serially of dendritic and perikaryal regions. Post-embedding immunocytochemistry using a GABA antiserum was done in the semithin sections containing the perikarya. Taking advantage of the fact that the GABA antiserum labels not only the cytoplasm but also the nucleus of neurons (which is, fortunately, spared by the Golgi gold-toned impregnation), it was possible to differentiate double-labeled Golgi-GABA cells from cells that were only Golgi impregnated. Not surprisingly, only the perikarya of type 3 cells were found to contain GABA immunoreactivity. The GABA+ type 3 cells identified in this material were characterized by few slender, scarcely branching dendrites bearing many, or few, long stalked appendages and by extensive filiform, axon-like processes with appendages, taking origin from different regions of dendrites. Several of these Golgi gold-toned appendages were examined at the EM and identified as typical F2 processes; i.e., they contain pleomorphic synaptic vesicles and are postsynaptic to retinal terminals and presynaptic to dendrites.

In conclusion, the results provide supporting evidence for the GABAergic nature of type 3 cells in cat LGN, and for their giving origin to F2 terminals. In addition, since GAD+ and GABA+ cells in cat LGN are not retrogradely labeled with HRP from the visual cortex (Fitzpatrick et al. '84; Zempel and Montero '85, accompanying abstract) the results support the notion of the interneuronal nature of type 3 cells.

96.7 PATTERNS OF DISTRIBUTION OF X ON AND OFF AND Y ON AND OFF CELLS IN THE A LAYERS OF THE DORSAL LATERAL GENICULATE NUCLEUS (LGNd) OF THE CAT. Douglas B. Bowling and Elzbieta Wieniawa-Narkiewicz, Depts. of Med. Physiology & Anatomy and the Lions Sight Centre, University of Calgary, Calgary, AB., Canada T2N 4N1.

Ganglion cells in the cat retina and cells in the LGNd can be classified based on whether they sum the effects of light linearly (X) or non-linearly (Y) within their receptive fields and on the sign of contrast to which they respond (On-center or Off-center). While these distinctions are usually clear, the functional roles and interactions of the different cells are not well understood. A likely place to look for clues to the functional relationship between the cells is in the A layers of the LGNd. Here the axons of the different kinds of ganglion cells converge and terminate with the potential for interaction or for specific patterns of segregation.

To examine the relationship in the LGNd between X and Y and On and Off cells in more detail we made tangential electrode penetrations through the A layers. We were able to measure the positions (depths) of cells more accurately than previously possible because the electrodes ran parallel to the layers.

We recorded from 239 cells in layer A and 177 cells in layer A_1. It is clear from the sample that cells of different physiological types have specific and well-ordered arrangements across layer A but are only weakly organized in their distributions across layer A_1. In layer A the Y cells are heavily concentrated near the dorsal and ventral borders with Y off cells being predominant ventrally. X cells are distributed more uniformly across the layer but are arranged in an On/Off/On tri-laminar pattern. X on cells outnumber X off cells by nearly 2 to 1 in dorsal and ventral thirds of the layer and this ratio is reversed in the central third of the layer. In layer A_1 there is a small but clear shift in the proportion of X on and Y off cells across the layer with X on cells being slightly more common near the dorsal border and X off cells more comon near the ventral border. Too few Y cells have been sampled in A_1 to determine their distributions there.

These results may reflect differential interactions between X on, X off, Y on and Y off cells at different depths in the layers as well as differential patterns of projection from geniculate to cortex.

96.8 RELAY CELLS AND INTERNEURONS IN THE CAT'S LATERAL GENICULATE NUCLEUS WITH EXCITATORY INPUT FROM MORE THAN ONE RETINAL X-CELL. D. N. Mastronarde* (SPON: M. W. Dubin). Dept. of MCD Biology, Univ. of Colorado, Boulder, CO 80309.

This study continues the description of how the retinal input to the cat's lateral geniculate nucleus (LGN) diverges to form different types of cells with differing properties. Experiments involved recording from a single LGN cell, assessing its receptive field properties, and searching in the retina for ganglion cells that provided input to the LGN cell, as judged from cross-correlations. Elsewhere, I described two distinct types of relay cells that receive essentially only one excitatory retinal X-input: X_S-cells, whose responses to visual stimuli replicate the basic form of the response of a single retinal X-cell; and X_L-cells, whose responses lag behind those of retinal X-cells (Invest. Ophthalmol. Vis. Sci. Suppl. 24:265). Here I report on three kinds of cells that receive significant excitatory input from more than one retinal X-cell: multiple input X-relay cells (X_M-cells) with no Y-input, multiple X-input relay cells with Y-input (X/Y-cells), and X-interneurons. Results from the retinal searches indicated that these cells with multiple X-input form one or more cell types, all distinct from the single-input X-cells. Compared to X_S-cells, X_M and X/Y-cells had, on average, larger receptive field centers, better responses to a large moving or flickering stimulus, somewhat weaker suppressive (inhibitory) fields, shorter conduction times to visual cortex (0.45 to 1.15 ms, mean 0.7 ms, vs. 0.7 to 2.1 ms, mean 1.2 ms, for X_S-cells), and a higher probability of responding to stimulation of the optic chiasm (usually near 100%, vs. less than 50% for X_S-cells). The X/Y-cells differed from X_M-cells primarily in having significantly lower spatial resolution. The period of the finest grating resolved by the cells was: X_S = 0.38 ± 0.03; X_M = 0.59 ± 0.04; X/Y = 0.81 ± 0.08; Y = 1.15 ± 0.10 (degrees, mean ± SEM). This suggests that the functional role of X_M and X/Y-cells may be to fill in the large, 1.5-octave gap in spatial resolution between X_S and Y-cells with half-octave steps.

Some X-cells could not be antidromically activated from visual cortex, even though antidromic stimulation was routinely successful in activating even X_L-cells that had high thresholds and long latencies (2.5-5 ms). The X-interneurons had receptive field properties most closely resembling those of X_M-relay cells; however, they showed much weaker suppressive field effects and usually had higher maintained firing rates than X-relay cells. Searches for retinal inputs to eight cells all yielded evidence for input from more than one retinal X-cell but no evidence for Y-input. Thus, the X-interneurons identified by lack of antidromic activation also have a set of common properties that differ from those characteristic of the various types of X-relay cells.

96.9 FUNCTIONAL SUBGROUPS AMONG X-CELLS IN THE LATERAL GENICULATE NUCLEUS OF THE CAT. A.L. Humphrey and R.E. Weller, Department of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

The X-cells in the cat lateral geniculate nucleus have been considered a single functional class. However, Mastronarde (ARVO Abstr. 24:265, 1983) demonstrated heterogeneity among X-cells in their retinal inputs and patterns of discharge to flashed spots of light and suggested that there may be two X subclasses, termed "normal" and "lagged". We have confirmed this heterogeneity and found additional correlates to it. We recorded from physiologically identified X-cells in laminae A and A1 of the LGN. Of 161 cells, 63% showed similar responses to a small flashing spot centered on the receptive field: 1) a brisk response onset at a latency ≤60 msec.; 2) achievement of 90% of peak response in ≤80 msec.; 3) no detectable inhibition; and 4) a rapid return to background firing at stimulus offset. This response pattern matches that of Mastronarde's "normal" X-cells. We tentatively refer to these as X_N-cells. Most of the remaining X-cells (27%) had a different response pattern to flashing spots: 1) following stimulus onset, an early period of reduced firing, probably due to inhibition; 2) a delayed onset of firing, having a latency ≥50 msec.; 3) achievement of 90% of peak response at ≥90 msec; and 4) in most of the cells, a transient increase in firing at stimulus offset. This pattern matches that of Mastronarde's "lagged" X-cells. We tentatively refer to them as X_L-cells. The remaining X-cells (10%) were intermediate in their latencies and discharge patterns, in agreement with Mastronarde's observations.

Despite some overlap, the X_N- and X_L-cells differ in other features as well. The geniculocortical conduction latencies for X_N-cells are smaller than those of the X_L-cells (<1.9 vs. >2.1 msec., respectively). Although both groups discharge at similar latencies to stimulation of the optic chiasm, the probability of firing is generally higher for X_N-cells (median=.5, range=.08-1.0) than for X_L-cells (median=.03, range=0-.07). Finally, our additional studies using drifting sine gratings reveal differences in the optimal temporal frequencies of the X-cell groups. Of X_N-cells, 91% prefer frequencies >2 Hz, while 71% of X_L-cells prefer frequencies ≤2 Hz. The lower optimal temporal frequencies and chiasm firing probabilities among X_L-cells may reflect strong, stimulus induced inhibition impinging upon them.

In conclusion, our data confirm the existence of physiological heterogeneity among X-cells and the presence of two major subgroups (X_N and X_L). However, due to overlap of the subgroups, and the existence of intermediate cells, it is not yet clear whether the subgroups comprise distinct classes or opposite ends of a continuum. (Supported by USPHS grants EY04091, EY03038 and EY05674.)

96.10 STRUCTURAL CORRELATES OF FUNCTIONAL SUBGROUPS AMONG X-CELLS IN THE CAT LGN. R.E. Weller and A.L. Humphrey, Department of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

Functional heterogeneity exists among X-cells in laminae A and A1 of the cat lateral geniculate nucleus. Two major subgroups, termed X_N and X_L, have been defined which differ in terms of their latencies and patterns of discharge to visual stimuli and their axon conduction velocities (see preceding abstract). The goal of these experiments was to determine the correspondence between the two functional subgroups and the heterogeneous morphological cell types previously associated with the X-cell population (Friedlander et al., J. Neurophysiol. 46:80, 1981).

Single X-cells were recorded in the A-laminae with micropipettes filled with horseradish peroxidase. Each cell's functional subgroup was identified from its response to a small spot stimulus flashed on and off in its receptive field. Cells were classified as X_N if: 1) their response onset was <60 msec.; and 2) they attained 90% of maximal response at <80 msec. Cells were classified as X_L if: 1) they showed an early inhibition following spot onset; 2) their response onset occurred at >60 msec. and 3) was 90% maximum at >90 msec.; and 4) a transient discharge occurred at stimulus offset. Each identified cell was labeled with HRP to visualize its morphology.

We found consistent morphological differences between 7 X_L-cells and 5 X_N-cells recovered. All X_L-cells exhibit class 2 or class 2-3 morphologies (Guillery, J. Comp. Neurol. 128:21, 1966). Their small to medium sized somata (200-300μm^2) give rise to 3-7 primary dendrites, which issue narrow, sinuous dendrites distally. The most consistent feature is large clusters of grapelike appendages located at or near dendritic branch points. Depending on the cell, the distal dendrites may be smooth or beaded and they variably possess hairlike appendages or a few complex stalked appendages. The extrageniculate axons are the smallest observed (<1.0μm).

Three of the X_N-cells have medium sized somata (300-405μm^2) and exhibit class 1 morphology: 7-9 primary dendrites, straight, smooth distal dendrites having only a few grapelike appendages, and forming a radially symmetric dendritic tree. Their axons are >1.0μm in diameter. Until now, class 1 morphology has been associated exclusively with Y-cells, but X_N-cells may also show it. Two other X_N-cells exhibit class 3 morphology: very small (110-150μm^2) somata, fine, highly sinuous dendrites with numerous complex stalked appendages, and no extrageniculate axon.

These results suggest that the functional subgroups X_N and X_L have different morphological features. To confirm this, we are injecting additional X_N- and X_L-cells as well as cells with intermediate physiological properties. (Supported by USPHS grants EY04091, EY03038, and EY05674.)

96.11 EARLY DIFFERENTIAL EFFECTS OF VISUAL DEAFFERENTATION ON X AND Y CELLS IN THE LATERAL GENICULATE NUCLEUS (LGN) OF THE CAT. W. Guido, W.L. Salinger, & C.E. Schroeder. Dept. of Psychology, Univ. North Carolina-Greensboro, NC 27412.

Previous studies have shown that signal transmission through retino-geniculate synapses terminates 3-4 days after visual deafferentation. Because LGN X and Y cells receive their inputs from axons that are functionally and morphologically distinct, we re-examined the early consequences of visual deafferentation to determine whether the breakdown of signal transmission proceeds at different rates for each of these cell types. Extracellular single unit recordings were made from sedated, unparalyzed cats, both before and immediately after one eye was removed. The proportion of X and Y cells in both normally innervated and deafferented layers was determined during repeated penetrations through the A-laminae of the LGN. Cells in layers with intact retinal inputs were classified as X or Y on the basis of their receptive field properties and axonal conduction velocity. Receptive field classification was made possible by surgical immobilization of the intact eye. Cells in the deafferented layers were found by monitoring responses to visual stimulation of the intact eye, or to electrical stimulation of the optic chiasm. Deafferented LGN cells were classified as X or Y solely on the basis of axonal conduction velocity. Within 5 hours and throughout the time tested (30 hrs), visual deafferentation resulted in a reduction in the number of cells recorded per electrode penetration as well as a decrease in cell threshold to electrical stimulation of the optic chiasm. Five to 10 hours after visual deafferentation, a progressive decline in the relative encounter rate of X cells began. By 20-30 hours it was evident that this decline was due primarily to a reduction in the proportion of X cells receiving input from retinal axon stumps with slow conduction velocities (slow X: 10-17 m/s; fast X: 18-25 m/s). By 30 hours, retino-geniculate transmission had collapsed to such an extent that one rarely recorded more than a single cell per penetration in the deafferented layers. Cells recorded in layers with intact retinal inputs remained stable with respect to these measures. Thus, prior to the complete collapse of retino-geniculate transmission, there appears to be an early, selective breakdown of signal transmission through the X cell pathway. The fact that this breakdown occurs earliest for a sub-population of X cells that receives its main input from slowly conducting afferents suggests that specific morphological features of the remaining axon stump (e.g., diameter, or axoplasmic volume) may play a critical role in determining the temporal course of degeneration in synaptic transmission. The use of a sedated unparalyzed preparation and choice of dependent measure may account for our detection of these early degenerative effects.

VESTIBULAR SYSTEM I

97.1 VERTICAL CANAL AFFERENT ACTIVITY AND ITS RELATIONSHIP TO CONTINUOUS NYSTAGMUS DURING PITCH WHILE ROTATING. T. Raphan, W. Waespe*, B. Cohen. Dept. of CIS, Brooklyn College and Depts. of Neurology, Mt. Sinai Sch. Med., New York, Univ. of Zurich, Switz.

Pitching the head back and forth while rotating about a vertical axis induces continuous horizontal nystagmus by activation the velocity storage integrator (Raphan et al. 1983). Canal and otolith afferents were recorded during sinusoidal pitching of the head while rotating to determine how their activation is related to specific parameters of slow phase eye velocity and how they might activate the velocity storage mechanism. Neurons were tested with rotational velocities up to 180°/sec and pitch amplitudes up to 40° about a plane coincident with the plane of the horizontal canal. Horizontal canal afferents responded with a jump in frequency at the start of rotation and decayed to their spontaneous levels as rotation continued. During sinusoidal pitching activity was modulated about the spontaneous level at twice the pitching frequency. The depth of modulation was proportional to the pitch angle and the peak excitation occurred with the lateral canal close to the horizontal plane over a pitching frequency of .05 to .2 Hz. Similar activity was observed during roll while rotating when continuous nystagmus was not prominant. This supports the contention that horizontal canal afferents do not contribute to the generation of continuous nystagmus during pitch while rotating. Otolith afferents were modulated according to pitch position depending on their polarization vectors and their activity was independent of the velocity of rotation about the horizontal axis. This shows that Coriolis forces during pitching while rotating are not significant in modulating the activity of otolith afferents and that excitation of the otoliths alone is not responsible for the continuous nystagmus. Vertical canal afferents were excited by pure pitching with depths of modulation being proportional to pitching velocity. Peak excitation occurred in phase with peak pitching velocity and 90° out of phase with otolith excitation. However, during pitching while rotating about a vertical axis there was a phase shift of the peak firing frequency so that it tended to be in phase or 180° out of phase with otolith afferent activity. This phase shift increased with rotational velocity for a pitching frequency of .05 to .2 Hz, consistent with the range over which continuous horizontal nystagmus is generated. The results suggest that during pitching while rotating the central vestibular system utilizes phase information from vertical semicircular canal afferents and the otoliths to generate a signal related to head velocity that excites the velocity storage integrator. Direct projections from afferents of horizontal and vertical canals and otoliths contribute to the modulation in horizontal slow phase eye velocity about the steady state value. Supported by EY-04148 and Swiss National Foundation.

97.2 COMBINED ANATOMICAL AND PHYSIOLOGICAL STUDY OF SEMICIRCULAR CANAL ORIENTATION IN THE RHESUS MONKEY. H. Reisine, J.I. Simpson, D. Rudinger* and V. Henn. Dept. of Neurology, University Hospital Zurich, 8091 Zurich, Switzerland and Dept. of Physiol. and Biophysics, NYU Medical Center, NY, NY, 10016.

Experiments were performed to examine the relationship between the morphology of the bony portion of the semicircular canals (SCCs) and the neural coding of head velocity in the spike train activity of single axons in the vestibular nerve. Twelve SCCs and nerves were examined in two juvenile rhesus monkeys. For nerve recordings animals were alert and rotated sinusoidally (± 25 deg; 0.333 Hz) on a three-axis turntable about either an earth horizontal or the vertical axis. Animal position with respect to the rotational axis could be oriented as desired. Modulation of unit activity varied with the animal position; a single axis relative to the head was determined about which rotation effected the largest response. The unit vector for this axis was specified in a stereotaxic system and was termed the neuronal sensitivity vector. An average sensitivity vector was calculated for each nerve from 2 to 6 neuronal sensitivity vectors. The angles between the neuronal sensitivity vectors for the same nerve ranged from 0.3 to 13.4 deg. Angles between average sensitivity vectors for the three SCC nerves from the same labyrinth ranged from 90.3 to 103.4 deg. The angles between average sensitivity vectors for individual SCCs of push-pull pairs varied between 167.4 and 177.7 deg.

Following perfusion, labyrinths were injected with a plastic casting resin, which when hardened, was exposed by removing the overlying bone. From coordinate measurements of 8 to 13 points along the circumference of each SCC cast the best fit plane was determined using principal component analysis. Angles between vectors normal to the planes of different SCCs from the same labyrinth ranged from 84.1 to 102.2 deg. The angle between normal vectors for individual SCCs of push-pull pairs ranged from 162.8 to 177.1 deg.

The angle between the average sensitivity vector and the normal vector for each SCC averaged 6.3 deg (range: 1.5 to 11.7 deg). This angle was smallest for lateral SCCs (1.5 to 6.0 deg), largest for anterior SCCs (6.4 to 11.7 deg) and intermediate for posterior SCCs (3.0 to 9.3 deg). This study provides the first physiological and anatomical measurements of SCC orientation made in the same animals. Therefore, the differences in these measurements probably reflect the degree with which physiological values can be predicted from anatomical measurements of the SCCs. Despite the differences, for both types of measurements angles between SCCs of the same labyrinth differed from 90 deg by, in some cases, more than 10 deg and angles between individual SCCs of push-pull pairs differed from 180 deg by as much as 17 deg. Supported by Swiss Foundation for Scientific Res.(3.718.80), EMDO Foundation, NASA (NAG2-336).

97.3 PATIENTS WITH PERILYMPH FISTULAS GATE VESTIBULAR INPUTS TO POSTURE, DEPENDING ON THE CONDITIONS OF SUPPORT. F.O. Black, D. Lilly, and L.M. Nashner, Neurological Sciences Institute of Good Samaritan Hospital and Medical Center, Portland, Oregon 97209.

If patients with perilymph fistulas, i.e. small holes in the round and/or oval windows, are subjected to changes in external ear canal pressure, stimulation of the vestibular end organs results. In this study we have applied external canal pressure under altered support surface conditions. We show that, in most patients standing with eyes closed, vestibular inputs to posture are gated "off" when the support surface is fixed. As motion of the surface increases, however, a threshold is reached at which vestibular inputs are suddenly gated "on".

Patients with clinical signs of perilymph fistulas were exposed to sinusoidally modulated pressures (400 mm water, 0.1-0.5 Hz) to the external canal of one ear at a time while standing with eyes closed. Conditions were termed "normal" when the support surface was fixed and "sway-referenced" when the support surface rotated in proportion to the sway rotations of the body measured at the center of gravity. Under sway-referenced conditions, the gain of support surface to body sway rotation could be varied in increments from 0 (surface fixed) to 0.5 (surface rotates half as much as the body). Postural movements were measured by recording leg muscle EMG's, forces exerted by each foot on the surface, and the AP sway motions of the body center of gravity.

To determine the extent of postural movements in the absence of pressure stimulation, movements were recorded for 20 sec intervals under fixed and then sway-referenced conditions. Then, with the surface fixed, the pressure stimulus was imposed on one ear at a time (asymptomatic or least symptomatic ear first) for 20 sec. If postural movements following the waveform of the stimulus did not occur, the stimulus was re-imposed under sway-referenced conditions with the support surface gain incrementally increased during subsequent 20 sec trials. Finally, the process was repeated for the other ear.

Of 133 patients tested to date, 36 demonstrated postural movements correlated with pressure in the symptomatic ear but not the normal ear, 4 demonstrated responses to pressure bilaterally, and 94 were unresponsive to pressure. Correlated movements occurred in 13 patients under fixed support surface conditions. In the remaining 27, movements emerged only under sway-referenced conditions; in 5 patients at 0.12 gain, in 15 at 0.25 gain, and in 7 at 0.5 gain. Emergence of correlated movements under sway-referenced conditions appeared to be a gating phenomenon rather than the result of postural instability. The onset of pressure induced movements was frequently abrupt and occurred when the patient was stable.

This work sponsored, in part, by NIH Grants No. 19222 (Dr. Black) and 12661 (Dr. Nashner).

97.4 OTOLITH CONTRIBUTION TO ADAPTIVE CHANGE IN VOR DIRECTION. J. Baker, R. Harrison, N. Isu*, C. Wickland*, & B. Peterson. Dept. Physiol., Northwestern University Medical Sch., Chicago, IL 60611.

The vestibuloocular reflex (VOR) can adapt its size, direction, or dynamics in order to reduce retinal image motion that occurs during vestibular stimulation. In an accompanying abstract Harrison et al. describe adaptive modification of VOR direction by vertical optokinetic motion coupled to horizontal rotation. They show that adaptive changes in the VOR can occur during vestibular stimulation of horizontal semicircular canals only. Here we examine the VOR adaptation which occurs when pitch vertical rotation is coupled with horizontal optokinetic motion (Schultheis & Robinson, 1981). We show that rotational vestibular stimulation of either vertical canals or otoliths alone can produce modification of VOR direction.

Horizontal and pitch vertical eye movements were recorded from two normal alert cats and one cat with vertical semicircular canals inactivated by plugging (thanks to R. Schor). Whole body 0.25 Hz pitch oscillations of the cats were produced in two ways and coupled with optokinetic rotations that produced image motion in the horizontal direction on the retina: (1) Upright pitch (o) stimulated vertical canals and otoliths. The animal was placed in the normal upright position and rotated about a horizontal axis perpendicular to the cat's sagittal plane. Optokinetic motion occurred about a vertical axis. (2) Sideways pitch (+) stimulated vertical canals only. The animal was placed on its side and rotated about a vertical axis perpendicular to the cat's sagittal plane. Optokinetic motion occurred about a horizontal axis.

The gains and phases of horizontal VOR eye movements measured during pitch rotations in the dark after two hours of combined optokinetic and vestibular stimulation are shown below, with transfer function models. Each set of data shows the average adaptive smooth horizontal eye movements of the two cats after subtracting the very small horizontal movements measured before the adaptation. Sideways pitch gain was maximal at the training frequency. The added otolith stimulation in upright pitch produced a higher gain at low frequencies. The cat with plugged vertical canals developed horizontal eye movements during upright pitch adaptation, but had no VOR during sideways pitch. Thus, otolith stimulation contributes to adaptive changes in VOR direction.

97.5 DYNAMICS OF DIRECTIONAL CHANGE IN THE VESTIBULOOCULAR REFLEX PRODUCED BY ADAPTIVE MODIFICATION. R.E.W. Harrison, J.F. Baker, Naoki Isu*, C.R. Wickland*, and B.W. Peterson (Spon. R.S. Eisenberg) Dept. of Physiology, Northwestern University School of Medicine, Chicago, IL 60611.

Through various neural networks, the vestibuloocular reflex (VOR) and the optokinetic reflex generate eye movements which assist retinal image fixation during angular rotation of head or environment. It is well known that alteration of the relation between visual and vestibular rotations in one plane produces plastic adaptive changes in VOR gain. More recently, Schultheis and Robinson (NYAS 374:501, 1981) showed that the direction of the VOR could be changed by pairing pitch vestibular rotation with horizontal optokinetic image rotation. These investigators used a complex vestibular stimulus where both the otoliths and the vertical canals were stimulated. We sought to determine if similar directional changes in eye movement occur when only canals are stimulated and to characterize dynamic properties of the change.

Prior to training, animals were tested in the dark for residual vertical eye movements produced by whole body constant velocity sinusoidal yaw rotation at .05-2.5 Hz. Cats were then trained by exposing them to yaw plane rotation which was coupled with simultaneous vertical optokinetic stimulation that had the same frequency and same or differing phase. After 2-4 hrs. training, the cats were again tested in the dark at the above frequencies for yaw-induced vertical eye movements. Pre- and post-adaptation vertical eye movements were compared by vector subtraction.

We observed the following: 1)After training, horizontal vestibular stimulation in the dark gave rise to vertical eye movements which were in the direction of the training optokinetic stimulus. 2)At .25 Hz, adaptation occurs rapidly within 15-30 minutes, followed by a prolonged but less rapid adaptation. In total darkness, an unrestrained animal will retain the post-adaptation effects for at least 14 hours. 3) Adaptation-associated vertical eye movements elicited by yaw vestibular stimulation alone are greatest at the training frequency. At test frequencies lower than the training frequency, the response was smaller and phase advanced; at test frequencies higher than the training frequency, the response was also smaller but phase lagged. These dynamic features could be modeled by a bandpass filter with time constants of 0.1 and 1.0 Hz. Studies with pseudorandom binary test stimuli confirm these results and suggest other mechanisms may be present at higher frequencies. 4)Preliminary observations with different training stimuli indicate phase lead or lag in vertical eye movements when the phase of the optokinetic portion of the training is correspondly advanced or retarded; training at 1 Hz. shifts induced VOR gain maxima towards that training frequency.

97.6 VESTIBULAR COMPENSATION: THE RELATIONSHIP OF EYE NYSTAGMUS AND NECK BENDING. David W. Jensen. Dept. Otorhinolaryngology and Program in Neuroscience, Baylor College of Medicine, Houston, TX 77030.

A unilateral labyrinthectomy in the guinea pig induces profound spontaneous postural asymmetries that largely abate in two days. Data are presented here concerning the interdependence of two of the most prominent asymmetries (neck bending and eye nystagmus) and their compensations. This study expands upon unpublished observations mentioned by Schaefer and Meyer (in Memory and Transfer of Information, H.P. Zippel, ed., 1973).

A group of 14 guinea pigs received a unilateral peripheral vestibular neurectomy and labyrinthectomy which spared the vestibular ganglion. Five of the animals were suspended in a sling for 24 hours immediately after performing the surgery, in order to prevent standing contact with a solid surface. After the 24 hour suspension period, these animals were placed on a solid surface, and measurements of eye nystagmus and lateral head deviation taken over the next 2 to 3 days. Nine other animals placed on a solid standing surface immediately after the operation served as controls. Spontaneous eye nystagmus was measured using electro-oculography, and neck bending in yaw was measured with a goniometer. The mean rates of asymmetry abatements over consecutive two hour periods were also calculated and plotted.

The suspension period selectively delayed the compensation of neck bending in yaw, but did not affect the compensation of eye nystagmus. Twenty-five hours after the operation, the eye nystagmus intensity (beats/sec) of the suspension group was equal to that of the non-suspension group. However, the amount of neck bending in yaw as well as the ability to stand for the suspension group at 25 hours post-op was equal to that for the control group at only one hour post-op. The time course of neck bending compensation in the suspension group from 24-48 hours was the same as for the control group from 0-24 hours. Thus, the neck bending compensation was not "primed" during the delay period.

The results are consistent with the hypothesis that the central pathways that underlie the compensations for eye nystagmus and neck bending are distinct, with the capacity for independent operation. To date we have not been able to demonstrate that the compensation of eye nystagmus can be interfered with without affecting the compensation of neck bending. Therefore, we cannot rule out the possibility that there are some common pathways for the two compensations.

97.7 EFFECT OF UTRICULAR AND SACCULAR MACULAR ABLATION ON FREQUENCY AND LATENCY OF MOTION SICKNESS-INDUCED EMESIS IN THE SQUIRREL MONKEY. K. R. Brizzee and M. Igarashi. Dept. of Neurobiology, Delta Regional Primate Research Center, Covington, LA 70433 and Dept. Otorhinolaryngology and Communicative Sciences, Baylor College of Medicine, Houston, TX 77030.

The etiological role of the vestibular labyrinth in the genesis of motion sickness has been demonstrated in a large number of studies spanning just over a century. These investigations showed conclusively that the vestibular labyrinth plays an essential role in the genesis of motion sickness. However, the relative role of the semicircular canals on the one hand, and the otolith organs on the other, in the elicitation of motion sickness has remained uncertain. It is the purpose of the present study to determine whether selective ablation of all of the otolithic sensors in the maculae utriculi and maculae sacculi but preserving the cristae ampullares of the semicircular canals, may eliminate the emetic response to normally effective motion stimuli in squirrel monkeys. In these studies three previously motion emetic-sensitive squirrel monkeys were rendered refractory to a standard motion-emetic regimen, consisting of both horizontal rotary and vertical motion, by a two-stage utriculo-sacculectomy procedure which left the semicircular canals, including the cristae ampullares intact. Three non-operated control squirrel monkeys tested on the same motion-emetic regimen time schedule as the operated animals remained motion-emetic sensitive with regard to incidence, frequency and latency of motion-induced emetic responses. Sham utriculo-sacculectomy (stapedectomy) later performed on two of the latter animals and one additional new animal did not alter the incidence, frequency or latency of motion-emetic responses to the same motion regimens.

Although several investigators have supported the view that motion sickness is generated by stimuli arising from both the otolith organs and semicircular canals, experimental proof of the necessity of having intact otolith organ structures has been lacking prior to the observations in the present study. The negative results in post-operative motion-emetic tests suggests strongly that the existence of the otolith organs (and their afferents which continually inform the direction change of linear accelerations) is essential, and the semicircular canal afferents alone are not sufficient for the elicitation of emesis by the combined rotary and vertical stimulus employed in the present investigation paradigm.

97.8 CAT VESTIBULAR NUCLEAR NEURONS THAT EXHIBIT DIFFERENT RESPONSES TO ACTIVE AND PASSIVE HEAD ROTATIONS. F. Robinson, J. Hollerman*, and D. Tomko. Dept. of Physiology and the Center for Neuroscience, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261

When a cat moves through its normal enviornment its vestibular system is stimulated almost exclusively by voluntary movements of the head initiated by the animal. In contrast externally applied passive movements have almost always been used to study the properties of vestibular neurons. There are at least two plausible mechanisms which could cause neurons in the vestibular nuclei to respond differently to active movements than they do to passive movements. First, the vestibular nuclei receive a variety of non-vestibular sensory inputs including proprioceptive and somatosensory which could be active during a voluntary but not externally applied head rotations. Second, motor outflow could influence the sensitivity of neurons in the vestibular nuclei.

The current study was undertaken to determine how neurons in the vestibular nuclei of alert cats respond during active voluntary head rotations. Each cat was confined in a net bag and placed on a turntable so that the table's axis of rotation, which was oriented vertically, passed directly through the cat's C_1-C_2 joint. A head holder previously mounted to each cat's skull allowed the head to be fixed to the turntable or, when the head was free to move, made it possible to monitor the movements with a precision potentiometer attached by a rigid arm to the head holder. Single unit activity was recorded with etched tungsten microelectrodes driven through the cerebellum to the vestibular nuclei with a miniature mechanical microdrive which attached to a chronic recording chamber mounted over a craniotomy on the dorsal surface of the skull.

During voluntary movements the activity of most of the recorded neurons in the vestibular nuclei that responded to horizontal (yaw) rotation was predictable from their activity during externally applied rotation. A few vestibular nuclear neurons however showed little or no response to passive rotations but fired vigorously during active head rotations. The activity of these cells seemed related to velocity of the head rotation in one direction. Activity sometimes led the associated movement and sometimes followed it. To date these cells have been histologically confirmed in only the posterior region of the medial vestibular nucleus. Studies are continuing to determine the origin of the response of these neurons during active movement.

97.9 THE ACETYLCHOLINE RECEPTORS OF THE SEMICIRCULAR CANAL. Paul S. Guth, Charles H. Norris, and H. Williams*. Depts. of Pharmacology and Otolaryngology, Tulane University School of Medicine, New Orleans, LA 70112

Acetylcholine (Ach) is very likely the transmitter released by the efferents to the cochlea and lateral line. There is also evidence that Ach may be the transmitter of the efferents to the semicircular canal (S.C.). However, unlike the cochlea and lateral line, stimulation of the efferents to the S.C. produces both facilitation and inhibition of the firing rate of afferent fibers. This has been demonstrated in frog (Rossi et al., 1980), goldfish (Hartmann and Klinke, 1980)* and monkey (Goldberg and Fernandez, 1980). This biphasic effect can be mimicked by the application of Ach to the isolated S.C. of the frog. The facilitatory effect is mediated by muscarinic receptors, being mimicked by muscarine and carbachol and antagonized by low concentrations of atropine. The inhibitory effect is partially antagonized by d-tubocurarine and completely antagonized by strychnine and is therefore not a classical nicotinic receptor but is similar to the Ach receptor of the cochlea at which strychnine is also antagonistic. A receptor which is tonically exposed to Ach even in the isolated S.C. must be postulated because of our results with the anticholinesterase agents, eserine and echothiophate. The application of these substances causes an inhibition of the afferent firing rate. Since these agents are thought to have little or no intrinsic activity, acting only through the preservation of released Ach, we may presume that there is a tonically active cholinergic synapse in the isolated S.C. Caston (1972) reported that the spontaneous activity in the efferents is lost one hour after sacrifice of the frog. Our experiments are performed many hours after sacrifice. Therefore, we suggest that the reciprocal synapse, described by Dunn (1980) may be the site of possible tonic Ach release in this preparation and therefore may be a cholinergically mediated synapse. It appears from the existing evidence that there are at least three populations of cholinergic receptors associated with the semicircular canal. One of these mediates facilitation and the other two appear to mediate inhibition.

97.10 DIFFERENTIAL PROJECTIONS OF REGULARLY AND IRREGULARLY DISCHARGING VESTIBULAR PRIMARY AFFERENTS ONTO IDENTIFIED SECONDARY VESTIBULAR NEURONS IN THE BARBITURATE ANESTHETIZED SQUIRREL MONKEY. A. K. Moschovakis*, S. M. Highstein, and J. M. Goldberg Washington University, St. Louis, MO. 63110 and University of Chicago, Chicago, Il. 60637.

An electrophysiological paradigm was previously described (Soc. Neurosci. Abstr. 7: 39) that determined whether central vestibular neurons, monosynaptically related to the ipsilateral vestibular nerve (Vi), received their peripheral inputs predominantly from regular (R) afferents, from irregular (I) afferents, or else received mixed (M) inputs from both kinds of afferents. The paradigm is based on the fact that, when electric shocks are delivered via the perilymphatic space, there is an approximately 10-fold variation in thresholds systematically related to each afferent's discharge regularity (J. Neurophysiol.,47: 1236). I afferents have lower thresholds than do R afferents. The kind of vestibular-nerve input a secondary neuron receives is ascertained by plotting the size of the monosynaptic EPSP as shock strength is increased over a 16 to 32-fold range. The paradigm has now been used to characterize the peripheral inputs of secondary neurons contributing to various central pathways. Intracellular recordings were made in the superior, medial and lateral vestibular nuclei. Three classes of neurons were identified by antidromic activation and/or by intrasomatic HRP injections as projecting rostrally to the region of the oculomotor (Oc) nucleus, to the spinal cord (Sp), or to the flocculus (Fl). Twenty-five of 27 Oc neurons received either R or M inputs. All 13 Sp neurons received I or M inputs. Fl neurons could receive either an R input (7/25), an M input (9/25) or an I input (9/25). The difference in the monosynaptic Vi inputs of Oc and Sp neurons are consistent with the hypothesis that the response dynamics of vestibular nerve afferents are matched to the dynamic loads of the particular reflex pathways to which they contribute. Vc IPSPs were more commonly seen in Fl neurons (21/24) than in Oc (9/27) or Sp neurons (3/9). Latent periods of the Vc IPSPs were usually short (1.4-3.0 msec) and this was so for all classes of neurons, including those receiving I or R inputs. Virtually all neurons having a monosynaptic Vi EPSP also had a Vi disynaptic IPSP. Eighteen HRP-labeled neurons were recovered in the vestibular nuclei. Thirteen of these neurons were located in the superior and 5 in the lateral nucleus. Among the superior nucleus neurons, there was no apparent correlation in their soma location, type of Vi input and somadendritic morphology. (Supported NIH EY 05433 EY 01670 and NS 01330 and NASA NAG 2-148)

97.11 FINE STRUCTURE OF VESTIBULAR EFFERENT NEURONS IN THE ALBINO RAT. J.S WHITE Dept. of Anatomy, Creighton Univ. Sch. of Med., Omaha, NE 68178

As part of a study to determine the origins of the olivocochlear bundle in the albino rat (White, J.S. and W.B. Warr, J. Comp Neurol., 219:203-214, 1983), the locations of vestibular efferent neurons were also detected, using retrograde axonal transport of horseradish peroxidase following injections of the enzyme into the round window of the cochlea. In the present study, the fine structure of those HRP-labeled vestibular efferent neurons was investigated, particularly with regard to the types and distribution of their synaptic inputs, as a step toward understanding what drives this centrifugal bundle.

In all cases, two groups of labeled vestibular efferents were detected bilaterally both medial and lateral to the genu of the facial nerve. To date, examination of thin-sectioned material has concentrated on HRP-labeled vestibular efferents, detected using DAB as the chromogen, that were situated laterally, ipsilateral to the injected labyrinth. Most vestibular efferents tended to be small, fusiform neurons with major and minor axes measuring in the range of 15 x 10 microns. Usually, one or two primary dendrites could be seen arising from each pole. A nucleus with a slightly indented nuclear membrane largely fills a cytoplasm containing several small Nissl bodies consisting of four or five parallel cisternae and associated polysomes. Axon terminals are only occasionally seen in synapse with vestibular efferent cell bodies, and are only slightly more prevalent on the proximal parts of dendrites. Small terminals containing almost exclusively round vesicles were found on both the soma and dendrites. These terminals show a slight postsynaptic density adjacent to small synaptic junctions. A second, larger terminal, seen in synapse only with dendrites, contained small round or pleomorphic vesicles interspersed with elongate vesicles.

Anterogradely labeled axon terminals of primary vestibular afferent fibers were observed in synapse with small dendritic profiles near the labeled cells, but have not been seen to terminate directly upon a positively identified process of a vestibular efferent neuron. The presence of a primary vestibular afferent in synapse with a vestibular efferent neuron would suggest that a monosynaptic feedback mechanism exists between the vestibular labyrinth and the central nervous system. (Supported by NSF Grant BNS 83-20336)

97.12 EFFECTS OF IMAGINED TARGET DISTANCE ON VESTIBULOOCULAR RESPONSES. J. Goldberg and E. Icaza* Dept. of Otorhinolaryngology, Baylor College of Medicine, Houston, TX 77030.

We are studying factors that contribute to variability of vestibuloocular reflex (VOR) responses in humans. The VOR in the dark can be enhanced by imagining a stationary fixation target. It has also been shown that the gain of eye rotation required to fixate a target during head rotation increases above 1.0 as the distance between the target and the eye decreases. This report concerns the influence of location of imagined targets on VOR responses.

Eye movements were recorded electro-oculographically from the left eye of normal subjects seated in a chair rotating sinusoidally at 0.2 Hz and peak amplitudes from 8 to 48 degrees. The center of chair rotation was 10cm behind the centers of eye rotation. Subjects were asked to fixate a small stationary light spot that could be positioned as close as 10 cm in front of the eyes on the midline.

Calculations of VOR gains as a function of target distance have been in the past based on simplifying assumptions and resulted in overestimates of true gains. We used a geometric model to find the compensatory eye movements for an arbitrary target position exactly. Eye movements measured during fixation of near targets qualitatively confirm predictions of our model:

(1) the responses are distorted sinusoids for all amplitudes
(2) incremental gains at peak velocity points are asymmetrical
(3) these gains vary systematically with amplitude of rotation
(4) gains over 1.5 can be achieved for the 10 cm target distance

On some experimental runs, the target light was extinguished after several cycles of rotation. The subjects received prior instructions to remember target location and keep looking at it for the rest of the run, in the dark. The eye movement waveforms remained qualitatively unchanged except for an increase in the frequency of forward saccades. These types of saccades aid in tracking of a smoothly moving target as in pursuit, in contrast to anticompensatory quick phases normally present in vestibular nystagmus. Although the gain of compensatory eye movements decreased after the target was turned off, it still remained above 1.0 and often 1.2 until the completion of the 10-cycle run.

These results indicate that during passive rotations in the dark humans can boost the gain of compensatory eye movements to well over 1.0 through the effort of spatial localization. Distortion observed during localization of imagined near targets suggests that VOR circuitry is capable of nonlinear processing of incoming sinusoidal vestibular signals into eye movement waveforms appropriate for compensation.

STRUCTURE AND FUNCTION: CORTICAL AND SUBCORTICAL ORGANIZATION I

98.1 INITIAL FINDINGS IN A STUDY OF THE BRAIN MICROVASCULATURE OF HUMAN HYPERTENSIVES USING AN ALKALINE PHOSPHATASE STAIN WITH MICRORADIOGRAPHY AND LIGHT MICROSCOPY. M. A. Bell*, D. M. Moody*, and T. C. Johnston* (SPON: A. J. Sweatt). Department of Radiology, Bowman Gray School of Medicine, Winston-Salem, NC 27103

Staining thick (100 μ) celloidin sections of brain for alkaline phosphatase has proven to be an attractive and useful method for demonstrating the microvasculature of the cerebral cortex (Saunders and Bell, J. Neurosurg., 35: 128-140; Bell and Scarrow, Microvas. Res., 27: 189-203). Methods based on vascular red blood cell content or the introduction of injection media are liable to certain artefacts. The phosphatase enzyme on the other hand is active in arteriolar and capillary endothelium, and thus offers a more direct approach to the study of hypertensive vascular changes in human brains. We are currently extending the application of the phosphatase stain to deep grey and white structures of normal and hypertensive brains in an attempt to establish normal and altered vascular appearances in areas most vulnerable to damage. Preparations cover a wide range of magnifications and detail: 500-1000 μ celloidin sections are studied by microradiography (the standard metallic staining method for phosphatase is modified to produce a lead reaction product), while 100 μ celloidin and 1-3 μ resin sections are used with a light microscope to clarify vascular patterns and structure at low powers and at the cellular level.

In many tissues, arteries and large arterioles do not show phosphatase activity. Preliminary indications are that in the human brain relatively large penetrating arteries and arterioles do stain; variations in staining patterns, including a streaky effect, will be illustrated. The vascular patterns of all areas studied to date are well demonstrated, and some familiar and unfamiliar alterations of vascular structure have been observed; examples will be shown.

98.2 THE SPHENOID (Sph), DORSAL TEGMENTAL (DTg) AND POSTERODORSAL TEGMENTAL (PDTg) NUCLEI. G. Paxinos, I. Tork, T. Hokfelt*, L.L. Butcher, and A. Dorfman*. School of Psychol. and Anat., Univ. of New South Wales, Kensington, Australia, Karolinska Inst., Stockholm and Dept. Psychol., U.C.L.A.

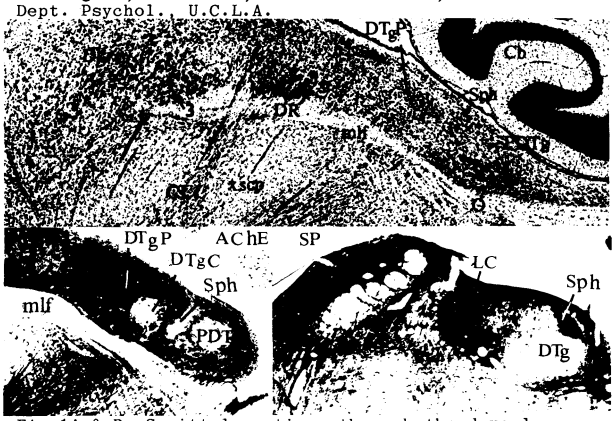

Fig 1A & B: Sagittal sections through the dorsal tegmentum of the rat, stained for Nissl and acetylcholinesterase (AChE); Fig 1C coronal section stained for substance P (SP).

Chemo- and cytoarchitectonic considerations were used to provide further evidence for delineation of nuclei in the dorsal tegmentum. AChE reactivity delineates the central (DTgC) and pericentral (DTgP) part of the DTg as well as the PDTg. An AChE poor nucleus wedged between the DTg and PDTg has recently been described (Paxinos and Butcher, In G. Paxinos, Ed., The Rat Nervous System, Academic Press, Sydney, 1985). The Sphenoid nucleus is densely stained in Nissl (A) as well as SP (C) and enkephalin preparations (Hamill & Jacobowitz, Soc. Neurosc. Ab., 10, 1984, 435). Nucleus O is densely stained in Nissl. The average cell sizes (in um) of the DTgC, DTgP, PDTg, Sph and O nuclei are 12.8 + 3, n = 52, 12.8 + 3, n = 142, 13.2 + 3, n = 48, 12.1 + 3, n = 67, 16.3 + 4, n = 18, respectively. For abr. see Paxinos and Watson (1982).

98.3 THE SEROTONIN-CONTAINING CELLS OF THE DORSAL AND MEDIAN RAPHE: A THREE-DIMENSIONAL ANATOMIC RECONSTRUCTION. B.E. Kosofsky, Eric S. Suchanek*, Loren E. Buhle* and M.E. Molliver. The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

A three-dimensional reconstruction of the position of serotonin-containing cells in the midbrain of the rat is displayed in a motion picture. Transverse sections from the midbrain of rats were cut at 30 um and processed freely floating for 5-HT immunocytochemistry (antibody courtesy of H.G.W. Lidov). Fourteen reference levels (spaced 180 um apart) were analyzed. At each level, the positions of serotonin immunoreactive neurons in the dorsal raphe (DR) and median raphe (MR) nuclei were digitized and stored in a computer, as were the contours defining the ventricle, the periaqueductal grey, and the surface of the midbrain. The reference levels were aligned one with the other. The data set was loaded onto an Evans and Sutherland PS300 graphics workstation. Software was developed to dynamically rotate the reconstructed rat midbrain in order to obtain a 3-D appreciation of the size and shape of the DR and MR in relation to other brainstem structures. The DR was observed to be narrowest mediolaterally at its rostral limit (at the level of the III nerve nucleus) and narrowest dorsoventrally at its caudal limit (at the level of the dorsal tegmental nucleus of Gudden). In between, where the DR expands greatly in size, the "core" of the DR exhibits a clustering of 5-HT immunoreactive cell bodies; a dorsomedial subdivision, a ventromedial "fountain" subdivision, and two lateral wing subdivisions are discerned. Cells of the MR are more restricted in numbers and in mediolateral distribution. Clustering of MR cells into distinct subdivisions was not evident. The 3-D reconstruction served as a template for localizing the injection sites in a series of anterograde transport experiments. The bean lectin, PHA-L, was delivered iontophoretically into discrete DR and MR sites. Anterogradely labeled fibers in the cerebral cortex following every DR and MR injection form multifocal, widely distributed patches of innervation. Each site in the DR and MR projects to a specific set of cortical targets; cell clusters in different subnuclei project to different sets of targets with laminar patterns of innervation that are specific to each subnucleus. Frontal cortex is preferentially innervated by DR neurons, and there is a complex but systematic topography relating positions within the DR nucleus to additional sets of cortical targets. Taken together, topographic organization and regional differences in innervation pattern suggest that 5-HT neurons may have a selective and restricted effect in each area of cortex. This neuronal system provides an anatomic substrate by which subsets of raphe cells may independently influence particular combinations of cortical targets. (Support: NIH GM7303, NS15199, NS21011, and M552338)

98.4 DORSAL RAPHE PROJECTIONS TO FRONTAL CORTEX AND STRIATUM ARISE FROM DISTINCT POPULATIONS OF NEURONS. M.A. Wilson* and M.E. Molliver Johns Hopkins University School of Medicine, Baltimore, MD 21205.

In order to determine whether different populations of cells within the dorsal raphe nucleus (DR) project to cortical and subcortical targets, the cells which project from the DR to frontal cortex and striatum were mapped in the rat. Two retrogradely transported, fluorescent dyes, true blue (TB) and diamidino yellow (DY), were injected via stereotaxically positioned micropipettes into the rostral pole of frontal cortex and rostral striatum, and labeled neurons were mapped in the midbrain raphe nuclei. The sites of TB and DY injections were reversed in some animals, to compensate for the different sensitivities of these tracers. Immunofluorescent labeling for serotonin or tyrosine hydroxylase was combined with retrograde tracing in some sections.

Distinct, partially overlapping populations of DR neurons project to frontal cortex and striatum, predominantly ipsilaterally, with few cells projecting to both forebrain structures. Striatally projecting neurons comprise a large diamond-shaped group in transverse sections of the DR, rostral and dorsal to the suprafascicular subdivision. Few striatally projecting neurons are found in the caudal DR. Neurons which project to the frontal cortex are found predominantly in the suprafascicular group, and in the caudal half of the dorsomedial group; scattered cortically projecting cells are found throughout the rest of the DR. Preliminary studies indicate that DR neurons projecting to occipital cortex are found caudal to the frontally projecting group, and primarily in the ventromedial division.

The cortically projecting cells in the ventral group are predominantly serotonergic, whereas almost half of those in the dorsomedial group are non-serotonergic. Both serotonergic and tyrosine hydroxylase immunoreactive neurons are present in the most rostral portion of the dorsal raphe, where the striatally projecting neurons are found. Most of the striatally projecting neurons are serotonergic; about one quarter are non-serotonergic, and very few of these (less than 5%) are tyrosine hydroxylase immunoreactive.

These results indicate that the DR can be fractionated on the basis of its projections and neurotransmitters. The rostral subdivision projects heavily to the striatum; the caudal dorsomedial subdivision, along with the ventral fountain, projects to the frontal cortex. Thus, DR projections to the telencephalon are topographically organized: morphologically different populations of cells project to striatum and cortex. (Support: NIH GM07445, NS15199 and NS21011.)

98.5 PARIETO-PREFRONTAL CONNECTIONS IN THE MONKEY: TOPOGRAPHIC DISTRIBUTION WITHIN THE PREFRONTAL CORTEX OF SECTORS CONNECTED WITH THE LATERAL AND MEDIAL POSTERIOR PARIETAL CORTEX. C. Cavada* and P.S. Goldman-Rakic (SPON: C. Avendaño). Sect. Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

The posterior parietal cortex is an important link between several sensory areas and the prefrontal cortex. The goal of our ongoing investigation is to elucidate the full extent and topography of the cortico-cortical connections between posterior parietal and prefrontal areas. Our study has revealed a sizable new reciprocal connection between the medial parietal cortex and the principal sulcus, and a medio-lateral topographic arrangement of parieto-prefrontal connections. HRP-WGA was injected into various prefrontal and parietal sites in adult rhesus monkeys and the distributions of anterogradely labeled terminal fields and retrogradely labeled neurons were analyzed. Following injections of tracer in the dorsolateral prefrontal cortex, HRP-positive terminals and neurons were observed in Brodmann's area 7, both on the medial and lateral surfaces of the posterior parietal lobe. The topographic distribution of these connections was elucidated by systematic injections of HRP-WGA into the parietal cortex. After injections in medial area 7, transported label was observed mainly in the upper bank of the posterior half of the principal sulcus, whereas after lateral area 7 injections (convexity of the posterior parietal lobe), the heaviest anterograde and retrograde labeling in the principal sulcus was observed in the posterior half of its lower bank. Other differences between medial and lateral parietal connections with prefrontal regions outside the principal sulcus were also noted. Lateral area 7 is interconnected with the cortical convexities above and below the principal sulcus, with the anterior part of the orbitofrontal cortex, and with the cortex of both limbs of the arcuate sulcus. In contrast, the connections of the medial parietal cortex are largely limited to the convexity above the principal sulcus and to the upper limb of the arcuate sulcus.

The segregation within the prefrontal cortex of territories connected with the medial and lateral aspects of area 7 indicates that further evaluation of the morphological and functional characteristics of these posterior parietal sectors is needed in order to better understand the involvement of area 7 in visuo-spatial and visual attentional functions, and to shed light on the nature of the neural information transferred between parietal and prefrontal sectors.

Supported by NIH Grants MH-38546 and MH-00298. C.C. is a Fogarty International Fellow # 1 F05 TW03445-01.

98.6 COMMON CORTICAL AND SUBCORTICAL TARGET AREAS OF THE DORSOLATERAL PREFRONTAL AND POSTERIOR PARIETAL CORTICES IN THE RHESUS MONKEY. L.D. Selemon and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

Behavioral and clinical studies have long suggested a functional liaison of the prefrontal and parietal cortices. Lesions of either the dorsolateral prefrontal cortex (DPC; Brodmann's areas 9, 10) or the posterior parietal cortex (PPC; area 7) disrupt the performance of monkeys on a variety of spatial tasks and produce unilateral sensory neglect in both human and non-human primates. Moreover, the presence of dense, reciprocal corticocortical projections between the DPC and PPC provides an anatomical basis for this functional linkage.

Common efferent projections of the DPC and PPC were examined in three rhesus monkeys using a double anterograde labeling strategy. In two monkeys, horseradish peroxidase was placed in the PPC while tritiated amino acids were injected into the DPC. Placement of tracers was reversed in a third case. Terminal labeling originating from both DPC and PPC injection sites was observed in numerous ipsilateral cortical areas, including the posterior principal sulcal cortex, the dorsomedial (supplementary motor) cortex, the anterior bank of the arcuate sulcus, the anterior and posterior cingulate cortices, the frontal-parietal operculum, the fundus of the superior temporal gyrus, the parahippocampal gyrus, the presubiculum and the caudomedial lobule. In some of these common target areas, as for example in the cingulate cortices, DPC and PPC afferents terminate in an array of interdigitating columns, an arrangement much like that observed for callosal and associational projections to the principal sulcus (Goldman-Rakic and Schwartz,'82). In other areas, DPC and PPC terminals exhibit a laminar complementarity: e.g., in the fundus of the superior temporal gyrus, parietal terminals are densely distributed within laminae 4 and 6, whereas prefrontal terminals occupy mainly laminae 1 and 5 directly above the parietal bands. Several subcortical structures also receive efferents from both injection sites. Perhaps most prominent are the projections of the DPC and PPC to adjacent, longitudinal domains of the neostriatum as has been described previously (Selemon and Goldman-Rakic,'85). Similarly, DPC and PPC projections are in close apposition throughout the ventral anterior, dorsomedial, lateral dorsal and pulvinar nuclei of the thalamus. In the brainstem, DPC and PPC afferents terminate in the deep layers of the superior colliculus and the midline reticular formation of the pons.

The present study has uncovered a remarkably large number of cortical and subcortical areas that receive input from both the DPC and PPC. We propose that these common prefrontal and parietal efferent pathways constitute part of a complex anatomical circuit that mediates spatial behavior.

98.7 TOPOGRAPHY AND LAMINAR ORIGIN OF CORTICAL VISUAL INPUT TO THE PREFRONTAL CORTEX OF THE RHESUS MONKEY. H. Barbas. Dept. of Health Sci. and Anatomy, Boston Univ. and Sch. of Med., Boston MA 02215.

The sources of ipsilateral cortical projections from visual association regions to peri-arcuate (Walker's areas 8 and 45), peri-principalis (area 46), and orbitofrontal (areas 11 and 12) regions were studied with horseradish peroxidase (HRP) in macaque monkeys. Projections from visual association regions to the prefrontal cortex originate in the depths and caudal bank of the superior temporal sulcus, and in and around the banks of the anterior and posterior middle temporal, occipitotemporal, parieto-occipital, inferior occipital, and lunate sulci. The above regions are included in area TE, and in peristriate areas OA and OB of Von Bonin and Bailey, or in areas IT, MT, V4, V3, V3A, VP and V2 according to more recent classification of the visual cortex.

Area TE is the principal source of visual projections to areas 11 and 12 and to the dorsolateral part of caudal area 46. On the other hand, input from peristriate regions is directed to the peri-arcuate cortex and particularly to its most caudal extent. In addition, the caudal bank of the intraparietal sulcus (area POa), where neurons have visual and visuomotor properties, projects to peri-arcuate and peri-principalis, but not to orbital regions.

Most visual association neurons projecting to the prefrontal cortex are situated in cortical layer III, and the rest are located in layers V and VI. The supragranular preponderance of labeling is most pronounced in peristriate parakoniocortical regions, where more than 90% of all HRP-labeled neurons are situated in layer III. There is a gradual decrease in supragranular labeling in progressively more rostral visual association regions, so that less than 70% of prefrontally directed neurons in rostral TE are situated in layer III. The regional decrease in the supragranular labeling closely parallels the cytoarchitectonic transitions observed in visual areas. Thus the proportion of labeled neurons in layer III progressively decreases from regions showing the highest, to those showing the lowest degree of laminar differentiation.

The data indicate that the most cytoarchitectonically differentiated peristriate regions project to the most differentiated prefrontal areas in the peri-arcuate zone. Similarly, the least differentiated portion of TE projects to the lesser differentiated orbital regions. In addition, cytoarchitectonic differentiation seems to be also closely associated with the laminar origin of corticocortical projections.

98.8 ORIGIN OF AUDITORY CORTEX. K. K. Glendenning, M. Kudo*, S. Frost*, P. Hodges* and R. B. Masterton. Department of Psychology, Florida State University, Tallahassee, FL 32306.

Auditory thalamocortical projections as now seen in mammals are evolutionary derivatives of thalamo-noncortical projections of reptiles. In reptiles or birds the auditory thalamic nucleus, n. reuniens, medialis or ovoidalis, projects not to cerebral cortex but to the dorsal ventricular ridge--a dorsal outcropping of the striatal or basal ganglionic complex of the telencephalon. In sharp contrast, the mammalian medial geniculate projects mostly if not entirely to neocortex--giving rise to a true auditory konio-cortex with tonotopic organization. In the hope of viewing the evolutionary transformation of a noncortical to a cortical-based sensory system, we have examined the ascending projections of the medial geniculate in four of the most neurologically primitive mammals now alive, using first retrograde degeneration and then anterograde and retrograde axonal transport techniques.

The results show that these mammals retain a substantial reptile-like projection from their medial geniculate to basal telencephalic structures (including putamen, lateral amygdaloid nucleus, and caudate nucleus) in addition to a mammal-like projection to neocortex.

These two telencephalic projection targets are not as disparate in these mammals as they would be in some modern mammals because the basal ganglionic targets lie just ventromedial to the rhinal fissure while auditory cortex lies just above it. Thus, the two sets of geniculate efferents travel together, first forward and then laterally--the primitive one then ends promptly while the other continues dorsally into the internal capsule to end in nearby neocortex.

Because retrogradely transported fluorescent dyes applied to cortical and basal targets in opossum have consistently failed to double-label more than a few medial geniculate cells while single-labeling virtually all of them, the two projections probably arise from separate cell populations--the neocortical projection from rostral geniculate, the basal ganglionic projection from caudal geniculate.

The presence of these substantial non-neocortical projections in more primitive mammals suggests that the evolutionary bridge from reptile-like auditory systems to the mammal-like system can still be viewed in an arrested form among carefully selected extant mammals.

98.9 THE EFFECTS OF REVERSIBLE COLD LESIONS IN THE MIDDLE AND INFERIOR TEMPORAL GYRI AND SUPERIOR TEMPORAL SULCUS ON PERFORMANCE OF A VISUAL TASK. James A.Horel, Dorothy Joiner* and Mary Lou Voytko. Dept. of Anatomy and Cell Biology, SUNY, Upstate Med. Cntr., Syracuse, NY 13210.

Lesions in the inferotemporal cortex (IT) produce severe deficits in the performance of visual tasks. These lesions typically extend from the depths of the superior temporal sulcus (sts) to the occipitotemporal sulcus, encompassing both the middle (mtg) and inferior (itg) temporal gyri as well as the lower bank of sts. The cortex in sts is anatomically and functionally distinct from the gyri and there is evidence that the two gyri may differ from one another as well. In this experiment we compared the effects of separate reversible cold lesions to these three structures on the performance of delayed match to sample (DMS), a task that is particularly sensitive to IT lesions. Four Macaca fascicularis were trained using liquid reward and photographs of objects for stimuli. The animals were held in a restraining chair facing three rear projection screens and responded by pressing the screens. At sample, the animals responded to a stimulus that was projected to the center screen. This stimulus disappeared and there was a delay of either 0, 15, 30 or 45 sec. after which a stimulus that matched the sample appeared at one side screen and a nonmatching stimulus appeared at the other screen. Response to the match was rewarded. Cryodes were then implanted bilaterally over the anterior half of IT, one pair each over sts, mtg and itg. These cryodes were stainless steel loops of tubing approximately 3 x 20 mm and each was shaped to fit an area. The upper bank of sts was removed to allow a cryode to cover the inferior bank. Cooled methanol pumped through the tubing brought the metal to 0° C. The three structures were cooled separately in randomly presented blocks of 20 trials. Control blocks without cooling were randomly mixed with experimental blocks. The effects of the cold were in all cases completely reversed by removing the cold. Cooling sts or mtg was without effect; performance was indistinguishable from controls. Cooling itg produced powerful deficits at all delays. As a check on the cooling method, animals were trained on the same task and were given ablative mtg or itg lesions. The behavioral effects of the ablations duplicated those of the cold. We conclude that something critical for the performance of this task is in itg. The complete absence of an effect from mtg or sts lesions suggests that these structures may not normally participate in the performance of this task. Supported by NINCDS grant NS 1829-03.

98.10 THE PREMOTOR CORTEX OF MACAQUE MONKEYS: NEURAL ACTIVITY IN ANTICIPATION OF PREDICTABLE ENVIRONMENTAL EVENTS. Steven P. Wise and Karl-Heinz Mauritz*, Laboratory of Neurophysiology, National Institute of Mental Health, Bethesda, MD 20205.

The activity of premotor cortex neurons was studied in unanesthetized macaque monkeys that were operantly conditioned to perform a visually guided motor task. The monkeys were given a visuospatial instruction stimulus (IS) that provided the target for a limb movement, but the monkey was not allowed to execute the movement until the presentation, 1.5, 2.25, or 3 s later, of a trigger stimulus (TS). After its initial presentation, the IS was sometimes removed or changed during the interval between the IS and TS.

Three anticipatory patterns of activity were observed during performance of the task: (i) certain neurons became active during the 1 s intertrial interval preceding the IS, appearing to anticipate its location or time of occurrence; (ii) some of these and other neurons changed their discharge prior to a possible removal or change in the IS, which might occur 1 s after the initial presentation of the IS; and (iii) other cells showed neuronal modulation that preceded a time, during a trial, when a TS might occur. From a sample of 176 premotor cortex neurons from two monkeys, 52 showed the first pattern, 34 the second, and 24 the third.

The properties of some of these neurons were examined under conditions in which the timing of the behavior-guiding visual signals or their probability of occurrence was changed to make them less predictable. In general, the anticipatory neuronal activity was strongly influenced by changing event predictability. For example, increasing the intertrial interval led to a gradual decrease in the anticipatory activity preceding the IS. Further, if the probability that the IS would change during a trial was reduced to zero for a large number of consecutive trials, there were marked decreases in the anticipatory discharge preceding the time, during a trial, when a change in the IS might occur. The present findings suggest that neuronal activity within the premotor cortex reflects the anticipation of predictable environmental events.

98.11 CORTICOPONTINE PROJECTIONS IN THE TREE SHREW TUPAIA GLIS.
M. Glickstein, C. Legg* and B. Mercier*. MRC Unit on Neural Mechanisms of Behaviour, 3 Malet Place, London WC1E 7JG and Department of Social Science and Humanities, The City University, Northampton Square, London. EC1V OHB, England.

There is a massive projection from the mammalian cortex to the pons. Corticopontine fibers arise from layer V pyramidal cells in the cerebral cortex and terminate on neurons in the pontine nuclei. Pontine cells in turn send their axons to the cerebellar cortex where they end as mossy fibers.

In rats, nearly all areas of the cerebral cortex project to the pons. In monkeys there is a projection from only about half of the cortex. Monkeys have few or no projections to the pons from temporal and frontal association areas or from striate and immediate prestriate cortex. We studied corticopontine projections in the tree shrew to compare the distribution of corticopontine cells in a non-primate mammal with a well demarcated striate cortex.

Multiple injections of horseradish peroxidase (HRP) were made in the pontine nuclei of three tree shrews. The injection cannulae were angled towards the pons from a caudal approach via the cerebellum. The animals survived for 2 days after which they were perfused and their brain processed to reveal the location and extent of the injection and the distribution of retrogradely labelled cells.

In a tree shrew with complete unilateral filling of the pontine nuclei, HRP labelled cells were found widely distributed in the ipsilateral neocortex. All retrogradely labelled neurons were layer V pyramidal cells. Like rats and monkeys there was a high density of corticopontine cells in motor, somatosensory and parietal association areas. Like rats but unlike monkeys all of frontal neocortex contained labelled cells. Also like rats but unlike monkeys the entire striate cortex and immediate extrastriate area all contained HRP labelled cells.

An area of the temporal lobe adjacent to the rhinal fissure contained few or no labelled cells. This area includes the thalamic projection fields of the medial geniculate and part of the pulvinar. There is an analogous region of sparse pontine projection from the temporal lobe in rats.

The distribution of corticopontine neurons in tree shrews closely resembles that seen in previous studies of rats. All area 17 projects to the pontine nuclei in both rats and tree shrews. In monkeys only that portion of area 17 which maps the far peripheral visual field projects to the pons. The results suggest that in these species there is a grossly different organization of cortical efferent pathways for the visual guidance of movement.

98.12 COMMISSURAL AND CALLOSAL CELLS IN PRIMITIVE MAMMALS.
E. Moreland-Granger*, K. K. Glendenning, P. Hodges* and R. B. Masterton. Department of Psychology, Florida State University, Tallahassee, FL 32306. (SPON: Friedrich K. Stephan).

In premammalian tetrapods (amphibians, reptiles and birds) and in pre-placental mammals (monotremes, marsupials), interhemispheric fibers are contained almost entirely within the anterior commissure. These animals have no corpus callosum whatever. With the appearance of the corpus callosum in placental mammals, both the corpus callosum and the anterior commissure share the interhemispheric fibers--the callosum containing most of the interneocortical fibers. In order to view the neocortical distribution of interhemispheric cells, we have cut and HRP-filled the commissural fibers in the common opossum (Didelphis virginiana) and the pouchless, short-tailed opossum (Monodelphis domesticus) and the callosal fibers in hedgehog (Erinaceus europaeus) and rat. Although there are a number of differences in the details of the cytoarchitectonic distribution of the cells in the two types of interhemispheric systems, one of the most striking differences is found in the cortical laminae of their origin. In most cytoarchitectonic areas of marsupial cortex, the commissural cells are most heavily concentrated in layer 3. In contrast, the callosal cells in hedgehog and rat are concentrated in layer 5 as well as in layer 3. This marked difference suggests that the evolutionary development of the direct neocortical-neocortical fibers in the corpus callosum was accompanied by a significant modification in their layers of origin. With many more interneocortical fibers emanating from layer 5 in placental mammals, a potentially significant shift in function is also implied.

TRANSMITTERS IN INVERTEBRATES I

99.1 LOCALIZATION OF ACETYLCHOLINESTERASE IN THE SYNGANGLION OF THE AMERICAN DOG TICK, DERMACENTOR VARIABILIS.
K.A. Carson , D.E. Sonenshine , L.M. Boland and D. Taylor . Department of Biological Sciences, Old Dominion University, Norfolk, VA 23508 and Department of Anatomy, Eastern Virginia Medical School, Norfolk, VA 23501

Biochemical and pharmacological studies have provided evidence supporting the hypothesis that the tick nervous system includes cholinergic neurons. The presence of acetylcholine, choline acetyltransferase, and acetylcholinesterase (AChE) has been verified in tick nerve tissues. Very little is known about which compartments of the tick nervous system may contain cholinergic elements. Initial studies to localize the cholinergic components of the tick nervous system were undertaken using AChE ultrastructural cytochemistry.

Adult ticks were injected with fixative made up of 3% paraformaldehyde, 1% glutaraldehyde in 0.1 M cacodylate buffer pH 7.4. The brains were excised and fixed by immersion for 3 hours at 4 degrees C. Following an overnight buffer rinse the brains were stained for 1-4 hrs to demonstrate AChE activity using a copper thiocholine procedure. The tissues were then fixed in Dalton's chrome osmium, dehydrated in ethanol, and embedded in epoxy resin.

Light microscopy of 1-2 micron epoxy sections revealed intense AChE stain in the synganglion (brain) and several peripheral nerves. The reaction product was particularly dense in the central neuropil area of the synganglion. The neurons were located around this central neuropil and appeared to be unstained although there was dense reaction product adjacent to the plasma membrane of most neurons. Electron microscopic observations showed that there were very large amounts of AChE reaction product in the neuropil region. This stain was in the extracellular space adjacent to profiles of neuronal processes and other neuropil structures. AChE activity was evident throughout the neuropil, and did not appear to vary a great deal between any anatomically distinct neuropil areas. In the outer neuronal zone of the synganglion there was intense AChE activity adjacent to the neuronal plasma membrane of the Type 1 neurons and large Type 2 neurosecretory neurons. The small, Type 3 globuli neurons had very little if any associated AChE activity. In addition, there was pronounced AChE activity associated with membranes of many axons in the rostral nerves. Preliminary data also indicates that AChE may also be associated with particular sensilla on tick appendages. Further information on neurotransmitter systems involved in tick sensory and reproductive processes may provide new strategies for control of ticks. Supported by NIH Grant AI 10986.

99.2 CHARACTERIZATION OF MUSCARINIC RECEPTORS IN CRUSTACEAN NERVOUS TISSUE BY L-[^{3}H]QNB BINDING.
D.L. Barker, T.F. Murray, G.J. Mpitsos and J.F. Siebenaller*. Dept. of Biochemistry and Biophysics, Coll. of Pharmacy, Coll. of Oceanography, Oregon State Univ., M.O. Hatfield Marine Science Center, Newport, OR 97365.

Acetylcholine is used in Crustacea as a primary sensory transmitter. Acetylcholine may also play a role as activator or modulator of bursting pacemaker activity, and physiological evidence suggests that this effect is mediated by muscarinic receptors. We find that the selective muscarinic antagonist L-[^{3}H]quinuclidinyl benzilate (QNB) binds with high affinity (K_d=0.2 nM) to a single population of specific sites in nervous tissue of the crab, Cancer magister. The density of L-[^{3}H]QNB binding sites is 105 fmol/mg protein in the membrane fraction prepared from the fused thoracic ganglionic ring. Other areas containing neuronal cell bodies and neuropil (brain and eyestalks) also have high densities, whereas specific L-[^{3}H]QNB binding is low or absent in membranes of peripheral nerve, artery and skeletal muscle. The binding site is stereoselective, as (-)QNB is over 200 times more potent than (+)QNB in competing with specific L-[^{3}H]QNB binding. The muscarinic antagonists scopolamine (K_i=2 nM) and atropine (K_i=5 nM) are over 10,000 times more effective inhibitors of L-[^{3}H]QNB binding than the nicotinic antagonists decamethonium and d-tubocurarine. In addition, muscarinic agonists have the expected relative potencies: oxotremorine > pilocarpine ≅ arecoline > carbamyl choline. This pharmacological profile of the L-[^{3}H]QNB binding site strongly suggests the presence of classical muscarinic receptors in crustacean nervous tissue.

This work was supported by Air Force Office of Scientific Research contract F49620-83-C-0063 to G.J.M.

99.3 IMMUNOCYTOCHEMICAL STUDY OF ARTHROPOD NEURONS WITH ANTIBODIES SPECIFIC TO MOLLUSCAN SMALL CARDIOACTIVE PEPTIDE AND SEROTONIN: A COMPARATIVE STUDY. Joseph C. Callaway, Boris Masinovsky and John S. Edwards, Department of Zoology, University of Washington, Seattle, WA 98195.

Small cardioactive peptide B (SCP_B), a nonapeptide in Aplysia californica (Morris et al., Nature 300, 1982) is a cardioaccelerator and modulates specific behavior, e.g. feeding (Lloyd, Fed. Proc. 41:2948, 1982).

With a monoclonal antibody against SCP_B (Masinovsky et al., 1985, in prep.) We have localized SCP-like and serotonin-like immunoreactive neurons in the CNS of the barnacle, Semibalanus cariosus, the cricket Acheta domesticus and the firebrat, Thermobia domestica (Thysanura).

SCP-like immunoreactivity of S. cariosus is limited to one pair of neurons in the supraoesophageal ganglion (SEG) and a cluster of four somata in the ventral ganglion (VG). The pair of neurons in the SEG appear to project neurites into the sheath of that ganglion. Acheta and Thermobia have SCP-like immunoreactive somata or neurites in each segmental ganglion and paired lateral posterior clusters of somata in each thoracic ganglion. Processes from these clusters in Acheta lead to the medial nerve.

Serotonin-like immunoreactivity in Thermobia, Acheta, and Manduca sexta (Lepidoptera) is conspicuously localized in two pairs of H-shaped neurons with posterior bilateral somata in each ganglion excluding the brain. Comparable neurons occur in the cockroach Periplaneta americana (Bishop and O'Shea, J. Neurobiol. 14:251, 1982). Fused ganglia contain sets of paired bilateral neurons equal to the number of fused segments. Insects and lobster ganglia typically have comparable bilateral H-shaped serotonin immunoreactive neurons; except that, in one thoracic and the abdominal ganglia of the lobster cell somata are submedial rather than lateral (Beltz and Kravitz, J. Neuroscience, 3:585, 1982). Sets of paired H-shaped neurons with paired midline somata, similar to those in the lobster, occur in the S. cariosus VG, each set associated with a presumed fused segment.

Though the location and morphology of serotonin-like immunoreactive neurons is apparently conserved in all arthropods studied, uniformity is greater among the insect orders than between decapod cirrepede crustaceans. No obvious homologies between insect and cirripede SCP-like immunoreactive neurons are evident. Insects of different orders have homologus serotonin-like immunoreactive neurons in each ganglion posterior to the suboesophogeal ganglion; homologous SCP-like immunoreactive neurons are only apparent in the thoracic ganglia. Supported by NIH grant NB0778 and the University of Washington GSRF.

99.4 IMMUNOCYTOCHEMICAL IDENTIFICATION OF THE NEUROSECRETORY CELLS THAT PRODUCE THE PEPTIDE ECLOSION HORMONE IN THE MOTH MANDUCA SEXTA. P.F. Copenhaver and J.W. Truman. Dept. of Zoology, Univ. of Washington, Seattle, WA 98195.

We are interested in the mechanisms that control the release of Eclosion Hormone (EH), which triggers the stereotyped motor program of adult emergence in the moth Manduca sexta. This 4000 dalton peptide is produced in the animal's brain and transported out to a pituitary-like organ (the corpora cardiaca/allata, or CC/CA) for release at the culmination of adult development. The timing of this release event is tightly regulated by two factors: the declining titer of the steroid 20-hydroxy-ecdysone determines the day of EH release, while a circadian input determines the time of day (Truman J.W, Am. Zool. 21:655, 1981). This system thus presents an excellent opportunity to determine how these factors affect the individual neurosecretory cells within the central nervous system.

By dissection and bioassay of identified neurosecretory cell clusters from the moth brain, we have shown previously that a bilaterally paired group of neurosecretory cells in the dorsolateral protocerebrum produce EH, and that electrical stimulation of individual cells within this group will induce the release of bioassayable EH into the hemolymph surrounding the CC/CA (Copenhaver P.F. & Truman J.W, Soc. Neurosci. Abs. 14:153, 1984). To further characterize these putative EH cells, we have developed a serum antibody to the peptide. EH was extracted from the CC/CA of approximately 30,000 animals by high pressure liquid chromatography (a single CC/CA is estimated to contain 1-10 ng. of EH). The peptide was then conjugated to bovine serum albumin and delivered to a rabbit in a series of injections over the course of several months. The resulting polyclonal antibody possesses a strong affinity for EH as shown by immunoprecipitation. Pre-incubation of the serum with a sample containing the peptide blocks its ability to precipitate EH, while pre-incubation with homogenates of muscle, fat body, and optic lobes do not. In addition, immunohistochemical staining of serially sectioned moth brains consistantly reveals 5-6 of the large neurosecretory cells within the lateral clusters but does not produce any reaction in the other cell groups.

We are currently employing both intracellular recordings in a semi-intact preparation and patch-electrode recordings from isolated neurosecretory somata to characterize the physiological changes that these cells undergo around the time of adult emergence, in order to examine the cellular mechanisms underlying the regulation of this peptide hormone's release.

Supported by NIH 2T32-GM07270 and NS-13079.

99.5 CEREBRAL NEUROENDOCRINE SYSTEM OF MANDUCA SEXTA: LOCALIZATION AND RELEASE OF FMRFAMIDE-LIKE IMMUNOREACTIVITY. L.S. Carroll* and G.M. Carrow (SPON: J.L. Rosenbaum). The Biological Laboratories, Harvard University, Cambridge, MA 02138.

Immunoreactivity to the neuropeptide FMRFamide (Phe-Met-Arg-Phe-NH_2) has previously been localized to neurosecretory cells and corpora cardiaca of insects. We studied the distribution and possible neurohormonal function of FMRFamide-like substances in the cerebral neuroendocrine system of the tobacco hornworm, Manduca sexta. Indirect immunofluorescence in whole mount preparations was used to localize FMRFamide-like immunoreactivity (FLI) to about 25 bilaterally symmetrical pairs of somata in the brain. Processes in the cerebral neurohemal organs, the corpus cardiacum (CC) and corpus allatum (CA), also showed FLI. Preabsorption of the primary antiserum with an excess of synthetic FMRFamide eliminated staining.

The protocerebrum of Manduca contains two bilaterally symmetrical clusters of identified neurosecretory cells (NSCs) whose axons project to either the CC or the CA. The NSCs have been subdivided into four groups (Ia, Ib, IIa, IIb) on the basis of morphology (Carrow et al., J. Neurosci. 4:1034, 1984). NSCs within the Ib, IIa, and IIb groups were shown to contain FLI by combining intracellular injection of Lucifer Yellow with indirect immunofluorescence.

The amount of FMRFamide-like equivalents in homogenized extracts of prepupal brains, CC, CA, and combined CC and CA (retrocerebral complexes) was quantified by radioimmunoassay (RIA). The following values (mean $\pm$ SEM) were obtained: brain, 28.0 $\pm$ 3.8 fmol; CC, 2.5 $\pm$ 0.2 fmol; CA, 0.9 $\pm$ 0.1 fmol; retrocerebral complexes, 4.1 $\pm$ 0.2 fmol. The antiserum used throughout this study was specific for the C-terminus of FMRFamide (O'Donohue et al., Peptides 5:563, 1984). Inhibition binding curves generated from serial dilutions of synthetic FMRFamide and brain extracts were parallel, indicating the antiserum has a similar affinity for both antigens.

To determine whether FMRFamide-like substances could be released from the neurohemal organs, isolated retrocerebral complexes were incubated in a high potassium medium; the amount of FMRFamide-like equivalents released into the bathing medium was assayed by RIA. Approximately 16% of the FLI extractable from a retrocerebral complex was released. Release was shown to be calcium dependent.

These data suggest that FMRFamide-like substances are stored in cerebral NSCs and are released from terminals in the CC and CA, possibly to exert neurohormonal effects.

We thank T. O'Donohue and W. Watson for their generous gift of anti-FMRFamide antiserum. Supported by NSF grant PCM-8215638 and NIH grant R01 NS 21232-01.

99.6 A MONOCLONAL ANTIBODY ACTS AS A FUNCTIONAL BLOCKER OF CARDIOACCELERATORY PEPTIDE ACTIVITY IN THE TOBACCO HAWKMOTH, Manduca sexta. N.J. Tublitz, P.H. Taghert and P.D. Evans. AFRC Unit of Insect Neurophysiology and Pharmacology, Dept. of Zoology, Univ. of Cambridge, Cambridge CB2 3EJ, UK., and Dept. of Anatomy and Neurobiology, Washington Univ. School of Medicine, St. Louis MO 63110

Investigations into neuropeptide function have been hindered by a paucity of pharmacological compounds that specifically inhibit peptide action, usually by blocking the peptide receptor. In the absence of an amino acid sequence for the peptide under study, identification of a specific peptide antagonist is extrememly difficult and time-consuming. We have circumvented this problem by utilizing a monoclonal antibody that acts as a functional blocker of peptide action both in vivo and in vitro.

This role for a monoclonal antibody has been studied in the cardioacceleratory peptide (CAPs) system of the tobacco hawkmoth, Manduca sexta. Co-synthesized and co-released from the Manduca central nervous system, the two CAPs function as cardioregulatory neurohormones increasing heart rate during adult emergence and wing spreading behaviors (Tublitz and Truman, J. of exp. Biol., in press). Originally identified using a histological screening procedure, one of the monoclonal antibodies, 6C5, appeared to be specifically directed against both CAPs in several different ELISA and immunoprecipitation tests.

In vivo injections of 6C5 completely abolished the rise in CAP haemolymph titres that normally occurs in wing spreading animals. In addition, 6C5 treatment markedly depressed by 80% the increase in heart rate seen during wing spreading. Neither CAP haemolymph levels nor the CAP-induced elevation in heartbeat frequency were altered in controls injected with either saline or pre-immune mouse serum. Furthermore, the duration of wing spreading behavior was significantly prolonged by 6C5 injection, suggesting that wing spreading behavior is facilitated by the presence of the CAPs. Thus, by preventing the rise in CAP titres during wing spreading with its resultant physiological and behavioral effects, the monoclonal antibody 6C5 appears to act as a functional inhibitor of the CAPs. (Supported by an American Heart Association-British Heart Foundation grant to N.J.T.)

99.7 IMMUNOCYTOCHEMICAL AND CHROMATOGRAPHIC EVIDENCE FOR THE PRESENCE OF THE NEUROPEPTIDE PROCTOLIN IN THE CNS AND PERIPHERY OF DROSOPHILA. H.Keshishian, Biology Department, Yale University, New Haven, CT 06511.

Several neuronal precursor cells and their progeny in the fruitfly are homologous to cells previously identified in the grasshopper embryo (Thomas et al., Nature 310: 203-207). Here we show that there is conservation between these two species in the number, distribution and putative targets of several neurons expressing a common neuropeptide. Proctolin is a pentapeptide neurotransmitter found in cells of the CNS and periphery of a number of invertebrate species. The distribution of putative proctolin containing neurons was examined in the larvae of Oregon-R Drosophila using immunocytochemistry (PLI) and HPLC with a sensitive proctolin-specific bioassay. The CNS PLI reveals a small and conserved population of neurons whose distributions are restricted to the brain hemispheres and abdominal neuromeres of the ventral ganglion, and are stable through larval development. Within the brain hemispheres are two pairs of large (10 μ) neurons lying dorsal-laterally; other brain PLI consists of a bilateral pair of anterior dorsal-medial clusters consisting of 3-4 neurons each. In each neuromere from abdominal segment 1 through 7 there is a single prominently staining dorsal pair of neurons, along with several lightly staining dorsal-medial cells. In the 8th segment neuromere there is a cluster of usually six large (10-12μ) strongly staining neurons distributed between the dorsal and ventral sides. The cells are likely homologous to a cluster of 6 proctolinergic grasshopper motoneurons, that innervate the intrinsic hindgut muscles. Colabelling experiments in the fly are still in progress - we have to date succeeded in demonstrating that: 1) Lucifer yellow dye-fills of efferent neurons projecting into the gut nerve, and 2) somata revealed by cobalt backfills from the hindgut, colocalize to the proctolinergic cluster. The peripheral immunocytochemistry was also studied. Prominent axonal staining is observed in the intestinal region of the hindgut. The axons are varicose, and align with the longitudinal muscles. The midgut staining is characterized by occasional intrinsic multipolar proctolinergic neurons , as well as by very fine arborizations on posterior midgut. Also fine, proctolin staining motor endings are found on a number of abdominal bodywall muscles. To corroborate the immunoreactivity described above, proctolin was recovered by reverse phase C-18 acetonitrile gradient HPLC from tissue, and quantitatively biassayed. Recovered putative Drosophila proctolin from CNS coelutes with authentic proctolin, and shows qualitatively similar physiological effects on proctolin sensitive muscles. Sample tissue PLB levels for each 3rd instar larvae are: whole larvae range from 4-5 fmoles; isolated CNS, about 1 fmoles; bodywall muscles, 2-3 fmoles; hindguts, about .8 fmoles. Proctolin antiserum #9 was a kind gift to the author by Dr. M. O'Shea, Université de Genève.

99.8 NEURAL RELEASE OF A PEPTIDE CO-TRANSMITTER GREATLY ENHANCES TENSION GENERATION IN A CRAYFISH TONIC MUSCLE. C.A. Bishop, J.J. Wine, and M. O'Shea. Dept. of Psychology, Stanford Univ., Stanford, CA 94305 and Dept. of Animal Biology, Univ. of Geneva, Geneva, Switzerland.

The peptide proctolin coexists with a 'conventional' neurotransmitter in three of five excitatory motor neurons innervating the tonic flexor muscle of the crayfish abdomen, and is released from these motor neurons by nerve stimulation. Superfused proctolin acts postsynaptically to increase muscle tension in a membrane voltage dependent manner. However, proctolin has no detectable effect on the resting transmembrane potential or input resistance of the muscle fibers or on postsynaptic potentials (PSPs) (Bishop,C.A., Wine,J.J. and O'Shea,M. J. Neurosci. 4:2001-2009,1984; Bishop,C.A., Nagy,F., Wine,J.J. and O'Shea,M. Neurosci. Abst. 14:151,1984). We have now shown that proctolin release from neuronal terminals significantly amplifies muscle tension produced by the conventional transmitter.

Our experiments were made possible by the discovery that proctolin release can be significantly reduced without altering the release of the conventional transmitter. Proctolin release experiments, in which neurally stimulated peptide release from terminals of proximally severed motor neuron axons was monitored directly by a sensitive bioassay, indicated that low frequency stimulation produced a reduction in peptide release. Release from the proctolinergic motor neuron #1 (MN1) fell 32% after 5 min of stimulation at 10 Hz. A fifteen min, 10 Hz stimulation resulted in a barely detectable proctolin level.

To assess the effect of proctolin depletion on neurally evoked tension, MN1 was stimulated at a low frequency (5-10 Hz) for several sequential 5-10 min periods and short duration (5 sec) neurally evoked tension responses were recorded, after washes, before and after low frequency stimulation periods. PSPs were recorded throughout to monitor conventional transmitter release. Neurally evoked tension decreased after each low frequency stimulation period, and eventually plateaued at a level significantly lower than the initial level. Tension plateaued after stimulation periods totalling 30 min at 10 Hz stimulation and after totalling 45 min at 5 Hz. The amplitude of the EPSPs remained unchanged throughout all stimulation periods. Therefore, drop in tension did not result from lower levels of the conventional transmitter or changes in muscle conductance. The tension decrease is best explained by the reduction in proctolin release.

This is further indicated by the following: 1)No comparable drop in tension was detected after long term, low frequency stimulation of the non-proctolinergic motor neuron #6. 2)The tension change from the initial level to the reduced plateau level resulting from low frequency stimulation, demonstrated a voltage dependency similar to tension change due to proctolin perfusion. 3)Superfused proctolin amplified MN1 evoked tension to a much greater extent after tension was reduced to plateau level.

The percentage drop in neurally evoked tension for MN1 after tension was reduced to plateau level depended on the stimulation frequency of the evoked tension. The tension drop was 36% for 33 Hz, 63% for 20 Hz and 100% for 16.7 Hz. Thus, at physiologically relevant stimulating frequencies, neurally released proctolin is required before measurable tension is generated by MN1.

99.9 PROCTOLIN IS A CO-TRANSMITTER FOR THE SETI MOTONEURON. M.K. Worden, J.L. Witten, and M. O'Shea. Lab. of Neurobiology, University of Geneva, CH-1211 Geneva 4, Switzerland and Committee on Neurobiology, University of Chicago, Chicago, Illinois 60637.

Here we provide our evidence that the identified slow excitatory motoneuron (SETi) of the locust extensor tibialis muscle (the ETi muscle) is peptidergic. All four of the neurons innervating the ETi muscle have been uniquely identified and transmitters have been assigned to each. These are the fast FETi motoneuron (glutaminergic), the slow SETi motoneuron (glutaminergic), the common inhibitory or CI motoneuron (GABA-ergic) and the dorsal unpaired median DUMETi neuron (octopaminergic). Several lines of evidence suggest that SETi uses the peptide proctolin (Arg-Tyr-Leu-Pro-Thr) as a neuromuscular transmitter in addition to glutamate. Staining with an antibody to proctolin reveals proctolin-immunoreactive axon collaterals and terminals on the slow fibers of the muscle. A proctolin-immunoreactive bilaterally symmetric pair of cell bodies is found in the CNS (metathoracic ganglion) co-positional with the paired somata of the SETi motoneurons. Proctolin is released from potassium-depolarized nerve terminals by a calcium dependent mechanism. Moreover proctolin can be isolated by HPLC from regions of the muscle innervated by SETi (2.5 fmoles/mg) where it is fifty times more concentrated than in non-SETi innervated regions. Physiological experiments also indicate a co-transmitter role for SETi-proctolin. Stimulation of SETi at a high frequency produces two effects that outlast the transient contractures normally attributed to glutamate. These are 1) an increase in the frequency of a myogenic rhythm of contraction and 2) an increase in tension that decays slowly. Both effects are mimicked by nanomolar amounts of proctolin but not glutamate. The postsynaptic effects of SETi stimulation are therefore consistent with the co-release of proctolin and glutamate.

We are now examining the interactions of other transmitters with the SETi-evoked proctolin effects and the modes of action of proctolin in this simple system. There may be differences in the mechanisms that underlie proctolin's two basic actions. For example, stimulation of the GABA-ergic CI motoneuron decreases the magnitude of the persistent or residual tension evoked subsequent to SETi stimulation but it does not affect the myogenic rhythm.

We hope this simple system consisting of four identified motoneurons will allow us to understand how different transmitter systems interact at a cellular level. Supported by NIH, NSF, E.I. du Pont de Nemours and Company.

99.10 CYCLIC NUCLEOTIDE-DEPENDENT PROTEIN PHOSPHORYLATION APPEARS TO DETERMINE BEHAVIORAL SENSITIVITY TO A PEPTIDE HORMONE IN THE MOTH MANDUCA SEXTA. D.B. Morton* and J.W. Truman. Department of Zoology, University of Washington, Seattle, WA 98195.

Eclosion hormone (EH), a 4,000 dalton neuropeptide, acts directly on the CNS of insects to trigger ecdysis behavior (the stereotyped motor pattern used to shed the old cuticle at the end of each molt). Previous studies have shown that the action of EH on the CNS at pupal ecdysis in Manduca is mediated by cGMP (Morton and Truman (1984), Soc. Neurosci. Abstracts 10, 1040).

The CNS is behaviorally responsive to EH only at times that just preceed the normal time for ecdysis. Interestingly, EH is capable of elevating cGMP levels in the CNS at least 9 hours before the CNS will respond behaviorally to the peptide. This result suggests that EH receptors, the guanylate cyclase and the phosphodiesterase are present at this time, but some element in the cascade of events distal to cGMP is lacking, thereby rendering the system nonresponsive. Measurements of the levels of cGMP-dependent protein kinase in the CNS show that there are no differences in the levels of activity before and during behavioral sensitivity. This suggests that a substrate for the kinase may be involved in determining behavioral sensitivity.

Protein phosphorylation, using ^{32}P ATP, of CNS homogenates was carried out and the products separated using SDS polyacrilamide gel electrophoresis. Autoradiography of the gels revealed a protein, with a molecular weight of 54,000 daltons, which was phosphorylated in the presence of cGMP or cAMP. Exposure of sensitive animals to EH resulted in the disappearence of this labeled protein, presumably because it was phosphorylated in vivo, thus blocking its in vitro phosphorylation with labeled phosphate. Importantly, this protein only appears in the nervous system when the animals become behaviorally responsive to the peptide. Thus the synthesis of this protein may be the key step in rendering the CNS competent to respond to the EH peptide.

99.11 FMRF-amide like peptides in Homarus americanus: distribution, immunocytochemical characterization and possible function L. Kobierski*, B.A. Trimmer*, B. Beltz, E.A. Kravitz, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

The molluscan cardioexcitatory peptide FMRF-amide is one member of a large peptide family found in many vertebrate and invertebrate species (Greenberg and Price, Ann. Rev. Physiol. 45:271-88, 1983). We have used immunocytochemistry to map the localization of FMRF-amide-like material in the nervous system of the lobster, Homarus americanus. Radioimmunoassay (RIA) methods also have been used to quantify the FMRF-amide-like material.

The FMRF-amide antibody, kindly supplied by Thomas O'Donahue (NIH), was generated against succinylated thyroglobulin conjugated to FMRF-amide. The antibody labels about 225 cell bodies in the nerve cord using wholemount immunocytochemical techniques. In addition staining is seen in: 1) brain neuropil regions similar in morphology to the olfactory and accessory lobes identified in other crustaceans (Hanstrom, J. Comp. Neurol. 38:221, 1925); 2) axons going out nerve roots to as yet unidentified peripheral targets; 3) a plexus of varicosities located in the connective tissue sheath surrounding the ventral nerve cord. This places endings in close proximity to the circulating haemolymph, suggesting a neurohormonal role for the FMRF-like material.

The specificity of the immunostaining was tested by preabsorbing the primary antisera with synthetic FMRF-amide and three FMRF-amide analogues: 1) Met-enkephalin-Arg-Phe; 2) bovine pancreatic polypeptide; 3) Phe-Met-Arg-Tyr-amide, all at 10^{-4}M concentrations. Preabsorption with FMRF-amide completely eliminates staining; preabsorption with each of the three FMRF-amide analogues results in approximately a 10% loss in the number of immunoreactive cell bodies while staining of other immunoreactive structures (neuropil, fibers) is not affected.

RIA studies in 1 lb lobsters show that: 1) the ventral nerve cord contains approximately 13.5 pmoles of FMRF-amide-like material/tissue; 2) about 1/6 of the total material found in the nerve cord is in the connective tissue sheath that surrounds the cord; 3) the haemolymph that surrounds and baths the nerve cord contains 1.8 x 10^{-11}M FMRF-amide-like material (3.15 pmoles total/1 lb. lobster). These findings further support a neurohormonal role for the FMRF-amide-like material. Present studies are: characterizing the FMRF-amide-like peptide, exploring its release from the sheath endings and examining its physiological role. (Supported by NIH).

99.12 CHARACTERIZATION OF IMMUNOREACTIVE FMRFamide- LIKE MATERIAL IN THE LOBSTER NERVOUS SYSTEM. B. A. Trimmer*, L. Kobierski and E. A. Kravitz. (SPON: M. Livingstone). Dept. of Neurobiology, Harvard Medical School, Boston. Mass. 02115.

The pattern and distribution of immunoreactive FMRFamide (Phe-Met-Arg-Phe-NH_2) - like material (FLI) in the nervous system of the lobster Homarus americanus has been mapped using an antiFMRFamide serum (Kobierski et al, Neurosci. abstr. 1985). These data suggest that FLI may play a role as a neurohormone. To facilitate the study of its functions we have begun to characterize and purify the immunoreactive material.

Antibody was kindly supplied by T.O'Donahue (NIH) and is specific for the amidated carboxyl dipeptide -Arg-Phe-NH_2. It shows only limited cross reactivity with -Arg-Tyr-NH_2 containing peptides such as bovine pancreatic polypeptide. Using this antibody as the basis for a radioimmunoassay (RIA) we have determined that the neurosecretory pericardial organs (PCO's) are the richest source of FLI. These organs show calcium dependent release of immunoreactivity when incubated in high (100 mM) potassium saline.

FLI can be extracted from PCO's by acidified methanol, and in our standard liquid phase competition RIA, displaces a labelled FMRFamide analogue from the antibody in a fashion parallel to authentic FMRFamide. FLI is a peptide or protein that is degraded by trypsin and in the process loses its ability to bind to the antibody, indicating that an arginyl or lysyl cleavage point lies within the antigenic determinant. Sephadex gel filtration chromatography reveals that lobster FLI has a larger apparent molecular weight than FMRFamide itself and that it consists of two separable components, one larger than 5000 daltons the other only slightly larger than FMRFamide. Both are more hydrophobic than FMRFamide and co-migrate in gradiant elution from a reverse phase HPLC column.

HPLC has also been used to fractionate FLI extracted from the nerve cord. This revealed, in addition to the material identified in the PCO's, a more hydrophobic substance which may be associated with the presence of cell bodies in the central nervous sytem. We are at present attempting to purify and identify the releasable FLI. The sequenced lobster analogue of FMRFamide will enable us to study the physiological role of FMRFamide related peptides in the lobster central nervous system. CONTROL OF MOVEMENT: ARM AND WRIST

100.1 RAPID WRIST FLEXION MOVEMENTS IN HUMANS: COMPENSATION FOR UNEXPECTED PERTURBATIONS. W. J. Becker*, R. Hayashi, R. G. Lee, and D. White*. Dept. of Clinical Neurosciences, University of Calgary Faculty of Medicine, Calgary, Alberta, Canada T2N 1N4.

Rapid (ballistic) movements are thought to be generated by a central motor program which can produce the movement without sensory feedback. Even though pre-programmed, however, rapid movements can be influenced to some extent by peripheral feedback (Hallett and Marsden, J. Physiol., 294:33, 1979). We have investigated the influence of peripheral inputs on "pre-programmed" rapid movements further by introducing unexpected perturbations just before and during rapid wrist flexion movements.

The subject's wrist position and a target zone were displayed on an oscilloscope. Subjects were trained to perform rapid 30° wrist flexion movements to the target in response to an auditory signal. Wrist flexor and extensor EMG, wrist position, velocity and torque were recorded. After training, extensor and flexor wrist perturbations produced by a torque motor were randomly interposed in 10% of trials among control movement trials to alter the initial starting position of the wrist.

Wrist position during control trials rapidly moved to maximum movement amplitude (MMA), usually overshooting the target, and then returned to the target zone. With "early" extensor perturbations beginning during the reaction time to the auditory signal and before the onset of the first agonist EMG burst, subjects over compensated for the perturbations, with an increased MMA and an increase in movement peak velocity. In contrast, with "late" extensor perturbations beginning after the onset of the first agonist EMG burst, under compensation occurred with a reduced MMA and a reduced peak velocity. "Early" and "late" flexor perturbations produced less marked changes in MMA and peak velocity.

In conclusion, afferent inputs prior to the onset of the first agonist EMG burst can interact with descending motor commands to modify early motor output during rapid movements, leading to changes in MMA and peak velocity. In contrast, later afferent inputs have much less effect on MMA and the peak velocity of movement.

100.2 HUMAN MOTOR UNIT RECRUITMENT DURING STATIC CONTRACTIONS IN DIFFERENT DIRECTIONS AND DURING DYNAMIC UNRESTRAINED MOVEMENT. B.H. Ross*, C.K. Thomas*, and B. Calancie (SPON: A. French). Dept. of Physiology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Spike triggered averaging (Stein, R.B. et al., Brain Res. 40: 187, 1972) for twitch amplitudes was used to determine the apparent recruitment order of 127 single motor units in the first dorsal interosseous muscle (FDI) of 5 subjects. Subjects produced static contractions in three directions: 1) flexion and 2) abduction of the index finger, and 3) flexion of the index finger coupled with adduction of the thumb. Twitch amplitudes for contractions in each direction were plotted against the respective recruitment thresholds. A similar procedure was used to study the recruitment of 48 motor units in the abductor pollicis brevis muscle (APB) of two subjects, who produced opposition and abduction contractions of the thumb. Finally the actual recruitment order of motor unit pairs in both FDI and APB was determined based on the relative onset of unit firing during a repeated scissoring movement in 3 subjects. These data from dynamic contractions were then compared to the apparent recruitment order of these same units as measured during static contractions.

The results show that the recruitment of motor units during various directions of static contraction of both FDI and APB muscles is strictly ordered. The units with the smallest twitch tensions (2-3 mN) were recruited at the lowest static forces (~5% maximum voluntary contraction), while those units with the highest twitch tensions (175-215 mN) fired at the largest static forces recorded. For the most part, this strict ordering of motor unit recruitment has been preserved during the dynamic scissoring task. That is, of 12 unit pairs studied to date, 10 demonstrated a recruitment order consistent with that observed during static contractions. Thus it appears from these data that the size principle of orderly recruitment adequately describes motor unit recruitment for both static and dynamic contractions of the FDI and APB muscles.

100.3 TRAJECTORY PROPERTIES OF PLANAR ARM MOVEMENTS AND THE EFFECT OF VISUAL GUIDANCE. Thomas Zeffiro and Deborah Claman. Neurology Service, Massachusetts General Hospital, Boston MA 02114.

We have investigated the influence of visual feedback on the spatial and temporal properties of visually triggered arm movements confined to a horizontal plane. Trajectory properties examined include error in final hand position, movement size, movement time, peak velocity, peak acceleration, peak deceleration, and the duration of accelerative and decelerative phases of movement.

Ten subjects performed a step tracking task in darkness, moving along the surface of a 20" by 20" digitizing tablet. They were instructed to move as quickly and accurately as possible to a target that would appear after they had reached the proper starting position. In one condition (no visual feedback) the target was extinguished as the movement commenced and in the other condition (visual feedback) the target remained lit until the end of the trial. The hand trajectory was sampled and stored for later analysis.

We examined relationships between various trajectory properties and movement size using linear and non-linear regression procedures. In both feedback conditions movement time, peak velocity, peak acceleration, and peak deceleration all increased monotonically with movement size. Although the duration of the accelerative and decelerative components of the movement increased monotonically at the same rate with increasing movement size, the ratio was less than 1, reflecting the asymmetry of the velocity profiles. Visual feedback invariably resulted in overall faster movements with larger peak velocities, accelerations, and decelerations. In addition, there was a tendency for the velocity profiles to become more symmetric, reflecting a shift in the relative duration of the accelerative and decelerative phases of movement.

While final position error increased monotonically with increasing movement size in the absence of visual feedback, this relationship was not observed when visual guidance was allowed.

The effects of visual guidance on the accuracy and kinematic properties of planar arm movements suggest that visual information about target and hand position, if available, is used to generate ongoing trajectory corrections. The kinematic effects of these corrections may be observed during the earliest components of the movement.

100.4 KINEMATIC VARIABILITY IN A THREE-JOINT FINGER-THUMB GRASP: DIGIT TRAJECTORIES AND JOINT ACTIONS ARE SUBORDINATE TO THE GOAL OF CONTACT CLOSURE. K.J. Cole and J.H. Abbs. Speech Motor Control Labs., Waisman Center, Univ. of Wisconsin, Madison, WI 53705-2280.

Reaching movements of the arm appear to be planned at the level of the hand trajectory, as indicated by straight-line hand paths, single-peaked tangential velocity profiles and joint kinematics that vary with target location (Morasso, P. Exp. Brain Res.,42, 1981). These data support the hypothesis that movements are planned at a goal level rather than at the joint or muscle level. Rapid grasp, if planned at a goal level, should show evidence of organization at the level of contact closure, rather than digit trajectory. As such, the constituent joint kinematics and digit trajectories toward closure may vary subordinately.

Movements of the thumb interphalangeal (IP) joint and index finger metacarpophalangeal (MP) and proximal interphalangeal (PIP) joints were monitored electro-goniometrically in humans producing rapid movements from an open hand position to a brief contact of the thumb and index finger. Subjects produced peak contact forces consistently between .75 and 1.25 N, as instructed. The finger tip position was monitored using an LED-distributed photodiode system. Intrinsic and extrinsic hand muscle EMG was recorded simultaneously.

Whereas finger-thumb contact was always achieved, the 2-D spatial location of contact varied significantly for repetitions of the task; the peak angular position of the thumb and the trajectory of the finger covaried to achieve distal pulpar contact. Finger trajectory variations were achieved via robust reciprocal actions of the MP and PIP joints, while the PIP and thumb peak positions varied directly. The observed motor equivalence and the specific joint pattern variations therein appeared to be controlled directly rather than being due to imprecision permitted by the oppositional nature of the task and/or to passive coupling. In this regard, the first lumbricalis muscle, which exerts only net extensor torques on the PIP joint and is normally inactive for hand closure, was phasically active for this task. Also, finger paths of greater distance and joint movements of greater amplitude were produced with greater peak tangential and instantaneous velocities, respectively.

Because there were striking motor equivalence variations in the constituent trajectories and joint kinematics, the redundant mechanical degrees of freedom afforded by the multijoint, multidigit action of grasp appear to be exploited as a control strategy. These results are consistent with goal level planning; the constituent trajectories and joint actions for precision grasp movements were subordinate to the goal of contact closure. (Supported by NIH grant NS-13274 and HD-03352.)

100.5 DRAWING MOVEMENTS IN THREE-DIMENSIONAL SPACE. J. F. Soechting and C. A. Terzuolo. Laboratory of Neurophysiology, University of Minnesota, Minneapolis, MN 55455.

We have studied the angular motion at the shoulder and elbow during drawing movements performed in different planes in free space. Specifically, we asked subjects to draw simple geometric figures such as circles and ellipses with different inclinations. Subjects, while drawing such figures, produced motion at the wrist which was close to sinusoidal in two orthogonal directions in the plane of the motion. Furthermore, the angular motion at the shoulder and elbow, when described in a coordinate system which has been previously identified psychophysically, was also approximately sinusoidal. (Note that theoretically, a given motion at the wrist can result from infinite combinations of angular motions at the shoulder and elbow since the arm has four degrees of freedom while linear motion at the wrist has only three.) Thus, as is the case for other arm movements which have been studied, there is a unique relationship between motion at the wrist and angular motion at the proximal joints.

The data indicate that drawing movements in arbitrary planes are produced by regulating the phase relations among the sinusoidal motions of the angles. A fixed phase relation (180^{o}) between the angular elevation of the upper arm and of the forearm was found, irrespective of the plane of the motion. Instead, the phase of the yaw angle of the upper arm was related to that parameter, while the phase of the yaw angle of the forearm was correlated with the slant of the ellipses. In light of previous psychophysical experiments, we conclude that the topology of the sensorimotor map used for the production of a movement is the same as the one used for its perception. Furthermore, the mapping between wrist position and the orientation angles of the arm utilized for the production of drawing movements is not geometrically accurate and leads to predictable and consistent distortions of the motion of the wrist.

Supported by NSF Grant BNS-84-18539 and USPHS Grant NS-15018.

100.6 GENERALIZED JOINT INTERPOLATION EXPLAINS STRAIGHT AND CURVED ARM MOVEMENTS. J.M. Hollerbach, S.P. Moore*, and C.G. Atkeson, Center for Biological Information Processing and Department of Psychology, M.I.T., Cambridge, MA 02139.

For unrestrained vertical arm movements measured with a Selspot system, it had been previously found that significantly curved end-point trajectories occur in certain regions of the workspace, but that in other regions the trajectories are approximately straight (Atkeson and Hollerbach, *J. Neurosci.*, in press). Straight-line trajectories in hand space have been taken as evidence for movement planning in hand coordinates, but the curved trajectories are a relatively new observation that were unexplained. When trajectories are specified as straight lines in joint space (joint interpolation), curved Cartesian trajectories could in principle result (Hollerbach and Atkeson, *Exp. Brain Res. Suppl.*, in press). We have studied whether the experimentally observed curved trajectories can be explained in this way.

Joint angles were inferred from positions of Selspot LEDs placed at various points on the arm, and the shoulder angle corresponding to upper arm flexion was plotted against the elbow angle. The results showed that most of the curved trajectories could indeed be characterized as straight lines in joint space.

Rather than accept a hypothesis that two different coordination strategies are in effect in different parts of the workspace, the straight trajectories in hand space were examined more closely for a possible alternative explanation. One class of straight hand-space trajectories actually intersected the shoulder joint, a known degenerate situation in which the joint-space trajectory is also straight. The other class of Cartesian straight-line trajectories could be generated if joint interpolation were generalized to allow one joint to be phase shifted and scaled in time relative to the other joint. Some remaining curved trajectories could also be accounted for similarly.

It is concluded that all trajectory classes can be explained by joint interpolation in its generalized form. Generalized joint interpolation can only approximate a Cartesian straight path if a joint does not reverse itself. The experimental curved movements correspond to regions where a Cartesian straight-line path requires joint reversal. It is hypothesized that subjects opt for strict joint interpolation for these movement regions, and that for the other movement regions find a good compromise to a straight line by judicious choice of interpolation parameters. Since it was not realized before that joint-based planning could yield relatively straight paths, these results illustrate again the dangers of arguing too closely from superficial features of data.

Supported by NIH Grant 26710 (JMH and CGA) and an NSERC Fellowship (SPM).

100.7 FUNCTIONAL RELATIONSHIP BETWEEN TASK DEMANDS AND THREE-DIMENSIONAL MOVEMENT KINEMATICS. R.G. Marteniuk and S. Athenes*. Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

Simple arm movements involving pointing to a target or reaching and grasping for an object are not only products of a relatively complex movement system but also may be functionally related to task demands. In the present study, pointing and grasping movements were compared to determine if type of movement task affected the kinematic characteristics of the movement. The grasping movements were further examined to determine if there was a relationship between the initial reaching component and the grasp component. Moreover, an analysis was done to determine if the grasp component was functionally related to the size of the object being grasped.

Five subjects were instructed to move as quickly and accurately as possible to either place their index fingers on targets or grasp one cm thick objects that were 2 or 4 cm in diameter and either 20 or 40 cm from the hands' starting position. Five trials for each of the eight conditions were given with data derived from sampling (200 Hz) infrared emitting diodes placed on the index finger, the thumb, and two locations on the wrist. Movement times for both movement types generally followed Fitts' Law with the grasping movements requiring an additional 50 ms. In terms of peak speed (resultant velocity), however, both movement types produced amplitudes of equal value. Moreover, peak speed for the grasping movements occurred both relatively and absolutely earlier than for pointing movements resulting in a longer deceleration phase for the grasping movements. These results might indicate that the requirement to grasp an object not only places an additional level of difficulty on movement control but results in a motor control strategy that may optimize the use of visual feedback by lengthening the decelerative phase of the movement.

To determine if there was some functional relationhsip between the reaching and grasp components of the grasping movement, time of peak speed of the wrist was correlated with time of maximum grip aperture. The correlation was near zero and it appeared that each subject performed the task in different ways. Finally, size of object to be grasped affected grip aperture but maximum aperture was not invariantly related to object size. The small disk resulted in a larger relative aperture than did the larger one. Thus, the grasp component of the movement was not seen to be systematically related to the reach component nor to the physical dimensions of the objects to be grasped.

100.8 CONTROL PROPERTIES OF MOTOR UNITS IN HUMAN SYNERGIST-ANTAGONIST MUSCLES. C.J. De Luca, and J.L. Creigh*. NeuroMuscular Research Center, Boston University, Boston, MA 02215.

The electrical activity of several concurrently active motor units has been simultaneously recorded from the human extensor carpi radialis longus (ECRL) and the extensor carpi ulnaris (ECU). These muscles participate in controlling wrist movement and can function synergistically or antagonistically, depending on the task. The detected multichannel myoelectric signals have been decomposed into their constituent motor unit action potential trains using a computer assisted algorithm, allowing accurate calculation of the firing times of up to 11 concurrently active motor units.

The forearm and hand were secured in a specially designed device able to independently measure orthoganal forces isometrically generated by the wrist in a plane perpendicular to the forearm. The subjects were asked to track a circular force pattern, thus involving the muscles to be sequentially used in synergistic and antagonistic modes.

To date a total of 106 motor units in 12 contractions have been analyzed. The results indicate the following:

1) Small 1-2 Hz common fluctuations with no phase shift in the mean firing rates of motor units were noticed within the muscles studied; this was consistent with earlier work on other muscles. Common fluctuations also exist between the firing rates of ECU and ECRL motor units but with a variable phase shift. The variable phase shift suggests that the muscles are not necessairly considered as a functional unit by the CNS during synergistic function.

2) Cross-correlation analysis of the motor unit firing rates of either the ECU or the ECRL indicated that synchronization exists among the motor units within each muscle. No other significant interaction between the trains within a muscle were detected. Cross-intensity analysis performed across the muscles showed no significant interaction between the motor units of the two synergist muscles.

3) Analysis of the firing rate of motor units active during functionally related changes from wrist extension to adduction or abduction demonstrated a motor unit discharge behavior which is consistent with a notion indicating a multichannel input to sets of motor units in the two muscles.

100.9 RESPONSE OF SYNERGISTS TO LOAD PERTURBATIONS IN A MULTI-JOINTED LIMB. F. Lacquaniti* and J. F. Soechting. Laboratory of Neurophysiology, University of Minnesota, Minneapolis, MN 55455.

A transient force applied to a limb segment will induce angular motion at joints proximally and distally to the point of application of the force. For example, a force applied to the upper arm in the backward direction results in extension at the shoulder and flexion at the elbow while a force acting on the forearm in the downward direction induces extension at both joints. We have begun to study the electromyographic responses of shoulder and elbow muscles to such perturbations. Last year, we showed that short latency responses in biceps and triceps were not correlated with the direction of the angular motion at the elbow joint resulting from such load perturbations. In fact, in both examples cited above, activation of biceps is observed. The observed behavior is not consistent with that expected from a feedback control of elbow angle; however it is consistent with a feedback control of elbow torque.

Since biceps and triceps span the shoulder joint as well as the elbow joint, there is one other possible interpretation of those results, namely that the patterns of activation of biceps and triceps reflect their dual action. Brachioradialis and brachialis are elbow flexors which do not span the shoulder joint. We have recorded EMG activity from those muscles in response to perturbations applied to the forearm and to the upper arm. As is the case for biceps, brachioradialis and brachialis responses are influenced also by motion at the shoulder joint and are not uniquely related to the motion at the elbow joint. However, the patterns of activity of the latter two muscles are not identical to that of biceps under all experimental conditions. Thus, the response of a given muscle to a load perturbation depends on the dynamical state of the entire limb and also on the particular function of that muscle, i.e. whether it spans one or two joints.

101.1 THE ROLE OF VARIOUS AMYGDALA PROJECTION AREAS (BED NUCLEUS OF STRIA TERMINALIS, ROSTRAL LATERAL HYPOTHALAMUS, SUBSTANTIA NIGRA) IN FEAR-ENHANCED ACOUSTIC STARTLE. J.M. Mondlock* and M. Davis (SPON: D. Gallager). Depts. of Psychology and Psychiatry, Yale University, Conn. Mental Health Ctr., Ribicoff Res. Fac., 34 Park St., New Haven, CT 06508

We have previously shown that bilateral lesions of the central nucleus of the amygdala block fear-enhanced startle in the rat (increased acoustic startle in the presence of a light previously paired with shock; Mondlock & Davis, 1985), consistent with a large literature implicating the amygdala in fear conditioning. Previous work in this laboratory has attempted to delineate the neural pathway that mediates the acoustic startle reflex and the visual pathway that carries the visual conditioned fear information to the startle circuit (Davis et al., 1982; Tischler and Davis, 1983). The present study sought to begin to delineate the neural pathway by which the amygdala could influence fear-enhanced startle (potentiated startle).

Rats were given 10 light-shock pairings on each of 2 successive days. At 24-48 hrs following training, separate groups of rats received bilateral electrolytic lesions of the bed nucleus of the stria terminalis or interruption of the ventral amygdalofugal pathway at the level of the rostral lateral hypothalamus (using a knife cut transection) or at the level of the substantia nigra (using electrolytic lesions). Control animals were sham-operated. Approximately 3 days after surgery, the rats were tested for potentiated startle. Potentiated startle was blocked by lesions of the substantia nigra, but not by lesions of the bed nucleus of the stria terminalis or transection of the part of the ventral amygdalofugal pathway that projects to the rostral lateral hypothalamus and substantia innominata. These results indicate that the substantia nigra may be a component in the pathway from the amygdala to the startle circuit, since the amygdala projects to the substantia nigra and both are necessary for potentiated startle. Lesions of the intermediate and deep layers of the superior colliculus also block potentiated startle (Tischler & Davis, 1983). Therefore, the superior colliculus, which receives efferents from the substantia nigra and which projects to the ventral nucleus of the lateral lemniscus, a part of the startle circuit, may provide the final link between the amygdala and the startle circuit. Further studies will test the role of medial vs. lateral aspects of the superior colliculus in potentiated startle as well as the effect of more selective damage to the substantia nigra pars reticulata vs. pars compacta using electrolytic, 6-hydroxydopamine, or ibotenic acid lesions.

101.2 THE EFFECTS OF HIPPOCAMPAL AND SUBICULAR CELL LOSS PRODUCED BY INTRACEREBRAL IBOTENATE ON THE PARTIAL REINFORCEMENT EXTINCTION EFFECT. J.A. Gray*, L.E. Jarrard, J.N.P. Rawlins, and J.D. Sinden* (SPON: H.E. King). Dept. of Experimental Psychology, Univ. of Oxford, Oxford, England, and Dept. of Psychology, Washington and Lee Univ., Lexington, VA 24450.

Intracerebral injections of ibotenate were used to produce, in rats, extensive cell loss in the hippocampus and dentate gyrus ('complete hippocampal', CH), in the CH plus subiculum (SUB + CH), or in the subiculum plus entorhinal cortex (SUB + EC). These rats and sham-operate controls were trained to run in a straight alley for food reward delivered on a continuous (CR) or partial (PR) reinforcement schedule. In controls PR training gave rise to the well-known partial reinforcement extinction effect (PREE), i.e., greater resistance to extinction than that observed in CR-trained animals. The PREE survived CH lesions, which however caused generally greater resistance to extinction in both CR and PR training conditions, in the start and run sections of the alley only. Subicular cell loss (in both SUB + CH and SUB + EC groups), in contrast, abolished the PREE in the goal section only, partly by increasing resistance to extinction in the CR condition and partly by decreasing resistance to extinction in the PR condition. In addition, some of the effects of PR training on start and run speeds during acquisition were altered by the CH and SUB + CH lesions. These results confirm previous data showing that the hippocampal formation plays a role in mediating the behavioural effects of PR training, and demonstrate a double dissociation between the effects of hippocampal and subicular cell loss. The effects of complete hippocampal cell loss resembled those we have previously reported after medial septal electrolytic lesions; the effects of subicular cell loss resembled those seen after dorsolateral septal electrolytic lesions. A model is proposed to account for these findings, in which (a) nonreward usually leads to inhibition of behaviour via the medial septal projection to the hippocampus; and (b) a PR schedule attenuates such behavioural inhibition via a feedback loop (hippocampus → subiculum → lateral septal area → medial septal area).

101.3 SELECTIVE IBOTENIC ACID LESIONS OF HIPPOCAMPUS AND SUBICULUM: EFFECTS ON PERFORMANCE OF A COMPLEX PLACE AND CUE TASK. L. E. Jarrard. Dept. Psychol., Washington & Lee Univ., Lexington, VA 24450

In previous research we found that interrupting the intrahippocampal circuit either by lesioning the CA3 cells with kainic acid or the cells in the dentate gyrus with colchicine had minimal effects on performance of a complex place and cue memory task. In contrast with these results, performance was impaired when all of the hippocampus was removed by aspiration and when pathways and/or structures related to hippocampus (fimbria-fornix, entorhinal cortex) were lesioned (Jarrard et al., Behav. Neurosci., 1984, 98, 946-954). In order to study the effects of selectively damaging all the cell fields in the hippocampus (CA1-CA3, dentate gyrus) without interrupting fibers-of-passage, multiple injections of ibotenic acid (IBO) were used in the present research. In addition, the effects of IBO lesions of the subiculum were determined.

Using a within-subjects design, rats were trained before the operations to run on an 8-arm radial maze with a procedure that involves two kinds of learning (place, cue) and two memory functions (reference memory (RM), working memory (WM)). In the place task the same 4 arms were baited from trial to trial and room cues (door, cages, lights) remained in the same spatial location. In the cue task 8 removable inserts of different materials were placed in the arms but the location was changed in a random order from trial to trial -- 4 of the 8 cues were consistently baited.

After learning the two tasks, rats were divided into 2 control (operated, unoperated) and 3 lesion groups. In one lesion group the hippocampus was removed with aspiration. Multiple injections of IBO were used in the other groups to lesion either hippocampus or subiculum. Subsequent histology indicated that in some animals IBO spread to include damage to both hippocampus and subiculum -- these animals formed a combined Hippocampal-Subiculum group. Following recovery the rats were retrained to approach the last 4 arms (and 4 cues) that had been learned before the operations.

Even though histology indicated that most cells in the hippocampus were removed with the IBO injections, performance was minimally affected. Rats with lesions limited to the subiculum and those with aspiration lesions of hippocampus were impaired only on the place task. The most impaired animals were those that had combined IBO damage to both hippocampus and subiculum. Analysis of the pattern of errors indicated that animals with combined lesions were generally impaired on the place task making both RM and WM errors, whereas, errors on the cue task were limited to repeating arms already visited (WM).

These findings indicate that (a) if care is taken to avoid damaging fibers-of-passage, the hippocampus can be removed with only a minor, temporary effect on performance of the place and cue task; and (b) damage to subiculum, especially combined cell loss in both hippocampus and subiculum, results in impaired performance.

101.4 EFFECTS OF HIPPOCAMPAL LESIONS ON FEATURE-POSITIVE DISCRIMINATION CONDITIONING OF THE NICTITATING MEMBRANE RESPONSE IN RABBIT. K. J. Loechner*, J. J. Lo Turco*, and D. J. Weisz. Department of Psychology, Yale University, New Haven, CT 06520.

The specific aim of this experiment was to investigate the hypothesis that stimulus salience is an important variable in explaining the effects of hippocampal lesions on complex discrimination tasks. The paradigm chosen was simultaneous feature-positive discrimination conditioning of the nictitating membrane response in rabbit. Three groups of animals (hippocampal + cortical, cortical, and sham lesioned) were presented with two types of trials, a simultaneous tone-light compound reinforced with a corneal air puff (TL+) and a nonreinforced element (T- in the first experiment, or L- in the second experiment). Consequently, the feature-positive stimulus (the one presented only in the compound and never in isolation) predicted the unconditioned stimulus (UCS) with 100% accuracy whereas the other stimulus only had a 50% predictive value.

In the two experiments, the reinforced compound was the simultaneous presentation of a tone (1 kHz, 70 db) and a light (28 lx) for a duration of 850 msec co-terminating with the unconditioned stimulus, a 100 msec corneal air puff. Nonreinforced trials consisted of 850 msec tone or light presentations. We operationally defined salience as the rate at which conditioned responses are acquired to a particular stimulus in simple delay conditioning. In our laboratory conditioned responses to the 1 kHz tone appear in 150-300 trials in a simple delay conditioning paradigm, in contrast to the 400-500 trials required for the light. We predicted that hippocampally lesioned animals would perform as well as normals when the most salient stimulus in the compound was the feature-positive, but that they would fail to exhibit normal discriminative responding when the less salient stimulus was the better predictor of the UCS.

The results of the two experiments confirmed our prediction. In the first experiment, hippocampally lesioned animals were markedly disrupted in their ability to discriminate as evidenced by inappropriately high response levels to nonreinforced tone presentations. In the second experiment, in which tone was the feature-positive stimulus, there were no significant differences across the three experimental groups. In both experiments, there were no differences in acquisition rates to the reinforced tone-light compound. The results indicate that stimulus strength may be an important consideration in the interpretation of hippocampal lesion effects.

101.5 IBOTENIC ACID LESIONS OF THE MEDIAL SEPTAL AREA AND NUCLEUS BASALIS MAGNOCELLULARIS CAUSE DIFFERENTIAL IMPAIRMENTS IN TEMPORAL MEMORY. W.H. Meck, R.M. Church, G.L. Wenk and D.S. Olton. Depts. of Psychology, Brown University, Providence, RI 02912 & The Johns Hopkins University, Baltimore, MD 21218.

Three groups of ten rats were trained preoperatively on a 40-s peak-interval (PI) timing procedure. In this task white-noise signals are separated by a 120-s inter-trial interval. On a random half of the trials food is primed after the signal has been present for 40s and the rat's first lever press after the fixed interval causes the termination of the signal and the delivery of a 45 mg food pellet. On the remaining trials (peak trials) no food is given and the signal continues for 120s. On peak trials the rat's response rate increases as a function of time since signal onset until the time that food is sometimes available. The time of the maximal response rate during a trial is referred to as the peak time and the response rate at the peak time is referred to as the peak rate. Once the maximal level of responding is obtained the rat's response rate declines in a fairly symmetrical manner when response rate is plotted on a linear time scale. The peak time measure serves as an indicator of the rat's remembered time of reinforcement, a value that is stored in reference memory. The median baseline peak time for all three groups of rats was 40s ± 0.5s. Following initial PI training bilateral lesions of either the medial septal area (MSA) or the nucleus basalis magnocellularis (NBM) were made by injection of 25 nmoles of ibotenic acid or vehicle into each brain area. One week after surgery PI training was resumed. The effects of the various treatments were as follows: Rats given sham operations continued to maintain normal peak times at 40s ± 0.5s. Rats given MSA lesions gradually shifted their peak time values leftward on the time scale and eventually maintained a lateral shift in their peak functions at 34s ± 0.4s. In contrast, rats given NBM lesions gradually shifted their peak times rightward on the time scale and eventually maintained a lateral shift in their peak functions at 46s ± 0.6s. The conclusion is that ibotenic acid lesions placed in anatomically distinct cholinergic pathways produce differential impairments in temporal memory as evidenced by opposite effects on the remembered time of reinforcement. These quantitative changes in the content of temporal memory suggest a modification of the translation constant that determines the remembered duration of events.

101.6 IBOTENIC ACID LESIONS OF THE NUCLEUS BASALIS OF MEYNERT IMPAIR SPATIAL-REFERENCE MEMORY IN THE MORRIS WATER TASK. Carl P.J. Dokla*1, L.J. Thal*1, E.L. Gardner*1, David Hann*2, Janice C. Passabet*2, Larry Fitzgerald*2, and Mark Leiman*2. (SPON: J.J. Boitano). 1Departments of Neurology and Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y. 10461, and 2Department of Psychology, Fairfield University, Fairfield, CT 06430.

Ibotenic acid (IBO) lesions of the nucleus basalis of Meynert (NBM) produce significant depletions of cholineacetyltransferase (CAT) in the cortex of rats thereby disrupting working-memory tasks and providing an animal model for Alzheimer's disease. However, IBO lesions of the NBM also impair reference-memory tasks. Suction ablation of the frontal and parietal cortex has been shown to profoundly impair both spatial-reference memory (e.g., Morris water task) and working memory (Kolb, Sutherland, Whishaw; Behav. Neurosci. 97(1): 13-27, 1983). The present investigation examined the effects of nucleus basalis IBO lesions using a reference-memory task, the Morris water task, that minimized the effects of proximal cues and has been shown to be sensitive to frontal-parietal cortical damage. Male Fischer 344 rats were stereotaxically injected in two-stages (bilaterally) with 18 ug of IBO dissolved in buffered saline (1 ul). Sham-operated rats served as controls. Following postoperative recovery, rats were tested in the Morris water task. The rats were required to learn the position of a fixed, submerged platform in a small, circular pool filled with water rendered opaque by powdered milk. For the first two days of testing, trials were conducted in blocks of four with the rats started at random locations. For the next three days all rats were given a single trial which was started at a single fixed location (North). Rats in the IBO group displayed a profound impairment on the water task with significantly elevated escape latencies and repetitive swimming around the pool's periphery. On day 1 of testing the IBO group had significantly longer escape latencies than the sham-operated group (Median latency = 115 sec vs. shams 50 sec, $p<.005$). On day 2 a significant groups by trials interaction was found ($p<.05$); the IBO group had significantly longer escape latency than the sham-operated group on the first trial of the four trial block ($p<0.001$) but displayed progressively shorter latencies over the remaining test session. On day 4 the IBO group displayed significantly longer escape latencies than the sham-operated group ($p<0.02$). The present results very closely paralleled those reported by Kolb et al. (1983) for suction ablation lesions and indicate that IBO rats are significantly and profoundly impaired in a reference-memory task. However, IBO rats can display considerable learning within a day's session though impaired severely in long-term retention between days.

101.7 ACQUISITION AND RETENTION IN THE RADIAL ARM MAZE BY RATS WITH ISCHEMIC-INDUCED CA-1 HIPPOCAMPAL DAMAGE. H.P. Davis, W.A. Pulsinelli & B.T. Volpe*. Dept. Psychol., Univ. Colorado, Colo. Spgs., CO 80933 and Dept. Neurol., Cornell Univ. Med. Coll., NY, NY 10021.

Rats subjected to 30 min. of forebrain ischemia by 4-vessel occlusion demonstrate ischemic injury in the CA-1 zone of the hippocampus, an area implicated in the etiology of postcardiac arrest human amnesic syndrome. For some patients surviving cardiac arrest, cognitive disturbance and in particular a memory impairment may cause persistent morbidity. These studies examine whether ischemic brain damage in rats, particularly to CA-1 neurons, results in learning and memory deficits similar to those seen in humans.

In Experiment 1, control and post-ischemic rats (PI rats) were trained in a radial 8-arm maze task with 5 of 8 arms baited. By baiting the same 5 arms on all daily trials it is possible to measure reference performance (entering baited arms only) and working performance (not reentering a baited arm after the food is taken). On 95 trials, started 30 days after surgery, the PI rats with primarily CA-1 neuronal loss made significantly more reference and working errors than controls ($p<0.05$). PI rats and controls had comparable reference performance during the last 20 trials. However, PI rats demonstrated a persistent working memory deficit ($p<0.08$).

In Experiment 2, rats were pretrained for 70 trials and then sham operated or subjected to cerebral ischemia. PI and control rats did not differ on retention of the reference component when tested 30 days post-surgically. However, working memory of PI rats was impaired ($p<0.05$). Normal retention of reference memory by pretrained PI rats suggests that surgery per se does not induce a performance deficit. Consequently, the slower rate of acquisition by PI rats in Experiment 1 likely reflects impaired learning rather than a nonspecific impairment of performance.

Thus, rats with CA-1 loss after ischemic insult have impaired reference and working performance. Reference memory appears to eventually recover. PI rats demonstrate normal retention of the highly practiced reference component if learned prior to cerebral ischemia. The memory deficit of PI rats is similar to the human amnesic syndrome which may be characterized by impaired learning and memory for events after cerebral injury, but with normal retention of highly practiced premorbid skills such as language and social behavior.

101.8 REGIONAL GLUCOSE METABOLIC CHANGES IN AN ANIMAL MODEL OF POST-CARDIAC ARREST AMNESIA. B. T. Volpe*, H. P. Davis., W. A. Pulsinelli, Dept. of Neur.,Cornell Univ. Med. Sch.,NY,NY 10021.

We have been exploring an animal model for the human amnesic syndrome that may follow cardiac arrest (Volpe et al., Stroke 15:558, 1984). Most rats subjected to transient cerebral ischemia for 30 minutes survive indefinitely, and have selective injury to neurons in CA1 hippocampus and the dorsolateral (dl) striatum. We have shown previously that these post-ischemic (PI) animals eventually acquire and remember the "reference" aspects of a radial 8-arm maze as well as controls, but demonstrate delayed learning and persistently impaired memory for the "working" aspects of the task. We used 14C-2 deoxyglucose autoradiography to identify patterns of metabolic activity in PI rats that might correlate with permanent working performance impairment and recovery of reference performance. Four rats were subjected to 30 minutes of ischemic injury, and four rats were sham operated. All animals recovered and performed on a radial 8-arm maze in which 5 of 8 arms were baited. Behavioral results after 75 trials showed that reference performance was comparable between PI and controls, but working performance remained impaired for PI animals compared to controls. Months after finishing maze training, the regional metabolic rate for glucose (rCGU) was measured. The rCGU's in morphologically normal brain regions in PI and control rats were comparable (corpus callosum, sup. and inf. colliculus, medial geniculate, motor, entorhinal, subicular and cingulate cortex, and also CA2 and CA3). In areas of confirmed morphological damage (CA1 and dl striatum) the rCGU's of PI animals were significantly decreased compared to control values (see Table). In the mamillary bodies and the thalamus, regions with little or no morphologic damage, PI animals had significantly increased rCGU compared to control animals (Table). The decreased rCGU in CA1 and dl striatum probably represents neuron loss. We cannot determine whether the increase in rCGU in the mamillary and thalamic region is due to maze training or post injury modification of glucose metabolism. In either case, our results suggest that a lesion in CA1 participates in disinhibition of the mamillothalamic area, and further that the hippocampus may influence some forms of behavior through mechanisms of inhibition.

Regional Cerebral Glucose Metabolism (um/100g/min)

	Control (n=4)	Post Ischemic (n=4)
CA3	41	36 (p>.2)
CA1	38	25 (p<.05)
DL Striatum	55	35 (p<.01)
Mamillary Bodies	63	84 (p<.01)
VA Thalamus	56	76 (p<.004)

101.9 THE CONTINUING SEARCH FOR A ROLE OF THE CEREBELLAR CORTEX IN EYELID CONDITIONING. D. S. Woodruff-Pak, D. G. Lavond, C. G. Logan,* J. E. Steinmetz, & R. F. Thompson. Department of Psychology, Stanford University, Stanford, California 94305

We report here on cerebellar cortical aspiration studies on 17 rabbits run in several different eyelid conditioning paradigms to further examine the hypothesis that the cerebellar cortex is essential for the retention of the conditioned eyelid response. Twelve rabbits were first trained to a light CS, then trained to a tone CS then trained until they presented 80% CRs on alternating blocks of 8 tone and 8 light CSs. An additional 5 rabbits were trained to tone CS only. Left lateral cerebellar cortex was aspirated in 15 of the rabbits, and vermis alone was aspirated in 2. Rabbits were retested 5 days after aspiration. Histological identification of the lesions using Larsell's terminology revealed that in all 15 cases the entire ventromedial extent of HVI was removed. In 8 of the lateral cerebellar lesions all of HVI and HVIIA were removed, and in 7 animals complete removal of ventromedial HVI and medial HVIIA was achieved. Thirteen animals had CRs after the lesion. Of the 4 rabbits showing few or no CRs after aspiration, all showed clear evidence of interpositus nucleus deterioration. Five rabbits were retested 26 days post aspiration. Whatever behavior they had shown 5 days post-aspiration, they also showed 3 weeks later. Histological examination revealed slight to moderate inferior olive degeneration in the brains of rabbits with cortical lesions but no interpositus nucleus damage.

A subgroup of the above rabbits had lesions of the cerebellar cortical area involving lateral vermis and medial lateral cortex which projects to the interpositus nucleus (called zone C). These lesions ranged from a minimum of partial removal of vermian lobule IV and ventromedial HVI and medial HVIIA to partial removal of vermian lobules II-VI and complete removal of HVI and HVIIA. The interesting result from these lesions was that animals showed a deficit in CRs on the first day of retesting, but were able to relearn pre-aspiration levels of responding. These data indicate that the large portion of zone C lesioned was not essential, but it may have been involved as relearning was required. None of our zone C lesions, or in fact any lesions described here, eliminated all cortical input to the interpositus nucleus. Hence the possibility remains that there is cerebellar cortical tissue essential to conditioning.

We have pursued a number of hypotheses to examine when the cerebellar cortex might be essential for eyelid conditioning, and we still have found no essential role of the cerebellar cortex.

101.10 DELAYED NON-MATCH TO SAMPLE WITH TRIAL-UNIQUE ODOR STIMULI IN INTACT AND FORNIX-DAMAGED RATS: A NEW TEST FOR RECOGNITION MEMORY AND MODEL OF TEMPORAL-LOBE AMNESIA. H. Eichenbaum, T. Parikh* & N. J. Cohen. Dept. Biol. Wellesley College, Wellesley, MA 02181, Center for Adaptive Systems, Boston University, Boston, MA 02215, and Dept. Psych., Johns Hopkins University, Baltimore MD 21218.

Modifications of the delayed match to sample (DMS) memory test by Mishkin & Delacour (J. Exp. Psych. 1:326, 1975) led to the creation of a recognition memory task that monkeys acquire rapidly and perform reliably. Their modifications of the paradigm included the use of trial-unique stimuli to eliminate inter-item interference and a non-match response requirement that monkeys adopt readily. Their paradigm has been used to develop a primate model of the human amnesic syndrome by demonstrating marked impairment of memory across delay in monkeys with medial temporal-lobe damage. We have adapted Mishkin & Delacour's procedures to our go, no-go odor discrimination paradigm and successfully developed a new recognition memory test for rats that exploits rodents' exceptional learning capacities in the olfactory modality.

Control rats and rats with bilateral fornix lesions were trained on a 10-sec delayed non-match to sample (DNMS) task using trial-unique odor cure chosen from a library of 200 pure chemical odorants. In the sample phase, a rat was required to maintain its nose in the odor sampling port for 2-sec (R+) during exposure to a novel odor in order to receive a water reward. During the match phase, the rat could sniff a second odor which was either identical to the sample or was another novel odor. Rewards were given only for R+ responses to the novel odor.

Control and fornix-damaged rats acquired the task at equivalent rates. On subsequent days, DNMS testing sessions at 10-sec delays were intermingled with sessions at 20, 30, and 60-sec delays. Control subjects consistently performed at 90% correct at all delays. In striking contrast, rats with fornix damage demonstrated significantly poorer performance at all delays beyond 10-sec, falling to chance performance at the 30-sec retention interval.

The development of measures for memory and models of amnesia in non-human subjects benefits by exploitation of stimulus modalities dominant in the species under study. This study has demonstrated for the first time, to our knowledge, rapid acquisition and high stable performance of rats in a recognition memory task with specific sensory cues. Furthermore, using this paradigm we have succeeded in modeling in rats with fornix damage the profound memory deficit observed in monkeys and humans with damage to the medial temporal-lobe. (Supported by HHS NS18744 & ONR N00014-83-K0337. We thank International Flavors & Fragrances and Naarden International for odor stimuli.)

101.11 INNERVATION OF THE SUBCORTICAL FOREBRAIN BY THE MEDIAL GENICULATE NUCLEUS: ANATOMICAL STUDIES OF AN EMOTIONAL CONDITIONING PATHWAY. J.E. LeDoux, D.A. Ruggiero, D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll. New York, NY 10021

The medial geniculate nucleus (MG) is generally described as a thalamo-cortical realy nucleus, receiving its major inputs from acoustic nuclei in the midbrain and projecting primarily to auditory cortex. However, lesions of the MG, but not of its cortical projection field, disrupt emotional conditioning to acoustic stimuli in rats (LeDoux et al, J. Neurosci. 4: 683-698, 1984). Since sensory signals ascending in the primary acoustic pathway to MG and then transmitted to a subcortical target may mediate emotional conditioning, we have sought to determine whether neurons in cytoarchitectural subregions of the MG give rise to subcortical projections and if so whether the same subregions are innervated by the inferior colliculus (IC), the major acoustic relay nucleus in the midbrain.

The rat MG was parcelled into three major subnuclei on the basis of gross morphological features and cellular cytoarchitecture: the ventral, dorsal and medial divisions. These are surrounded by several nuclei of the posterior thalamus, including the marginal zone, the posterior limitans nucleus, the posterior intralaminar nucleus, and the peripeduncular region.

Connections of the rat MG were studied using WGA-HRP as an anterorgrade and retrograde axonal marker. WGA-HRP (2%; 3-10nl) was microinjected into local brain areas. After 24h the rat was perfused transcardially and the tissue was processed histochemically using tetramethylbenzidine as the chromagen.

Following injections in the central nucleus (n=2) of IC anterograde transport was seen in the ventral and medial divisions of the MG. Injections of the external nucleus (n=3) or the dorsal cortex (n=2) of IC produced labeling throughout the MG, as well as in the surrounding areas of the posterior thalamus.

Large injections of MG (n=10) resulted in anterograde labeling of cortex and several subcortical areas, including the posterior caudate-putamen (CPU), the dorsal amygdala (AMY), the ventromedial nucleus of the hypothalamus (VMH), and the subparafascicular thalamic nucleus (SPF), as previously described (LeDoux et al, ibid). Injections centered in the ventral (n=2) or dorsal (n=1) divisions mainly resulted in cortical labeling, while injections in the medial division (n=5) produced anterograde transport in cortex and in CPU, AMY, and less consistently in in VMH and SPF. Injection of CPU or AMY retrogradely labeled neurons in the medial division of MG and in surrounding areas of the posterior thalamus. Injections in VMH or SPF only labeled the posterior thalamus.

The medial division of MG thus receives inputs from the central nucleus of IC and projects to the CPU and AMY. Recent behavioral studies indicate that selective interruption of connections between MG and AMY disrupts emotional conditioning (Iwata et al, this vol.). We conclude that neurons in the medial division of the MG constitute a pivotal link between acoustic and emotional processing systems of the brain. (Supported by Grants from the Am. Heart Assoc. and NIH/NHLBI).

102.1 THE IMMATURE ASTROCYTE:ITS ROLE DURING NORMAL CNS AXON TRACT DEVELOPMENT AND ITS ABILITY TO REDUCE SCAR FORMATION AND PROMOTE AXONAL REGENERATION WHEN TRANSPLANTED INTO THE BRAINS OF ADULTS.

J. Silver, G.M. Smith*, R.H. Miller* and P.R. Levitt. Dept. of Devl. Genetics and Anat., Case Western Res. Univ. Sch. of Med., Cleve.,OH 44106 and Dept. of Anat., Med. Col. Penn., Phil.,PA 19129.

During normal development of the mouse brain, a "sling" of glial tissue that forms transiently along the presumptive path of the corpus callosum plays an important role in guiding the pioneering contingent of commissural axons across the cerebral midline (Silver, et al., J.C.N.210,1982). We have now discovered a similar structure in the embryonic cat brain using immunohistochemical localization of antibodies to GFAP. The "sling" is one of only 7 such structures in the cat forebrain that express GFAP at very early (E 39) stages. Each GFAP+ structure is associated with a major boundary in the brain, and several form at the borders of major developing axon tracts. The GFAP+ cells are radially arranged and collectively form beautifully organized sheets or plates. The 7 regions are (1) the midline "sling" (2) a tube of cells surrounding the anterior commissure at the midline (3) the glial "knot" (Silver, J.C.N.223,1984) at the rostral edge of the chiasm (4) a row of cells at the dorsal border of the olfactory tract (5&6) two plates of cells, one between the habenula and thalamus, the other between the thalamus (lower border) and hypothalamus, and (7) a collection of cells along the dorsal edge of the hippocampal fimbria. The role of these cells in creating boundaries for developing axon tracts will be discussed.

It has also been shown that when the "sling" is lesioned, the would-be commissural axons whirl into massive neuromas that persist indefinitely at the cerebral midline. Silver and Ogawa (Science, 220,1983) have shown that an untreated Millipore implant inserted between the neuromas in acallosal neonates can support the migration of immature astrocytes which, in turn, stimulate the denovo growth of callosal axons across the midline. Smith, Miller and Silver (Neurosci. Abs.,1985) have shown that only astrocytes within the brains of animals younger than P10 can serve this axon growth promoting function. In older mice astrocytes form dense scars at the implant surface. Glia in scars do not promote axon outgrowth. In the present study we have harvested immature astrocytes on Millipore from pre-critical stage mouse forebrains and have transplanted the glial coated prostheses into the brains of post-critical stage (P17 or P34) acallosal hosts. Such transplants greatly reduce glial scarring in the host, they inhibit bleeding and secondary necrosis, and again promote commissural axon growth across the midline in a malformed brain that normally would never reform a callosum with an untreated Millipore implant alone. Our results suggest that axonal regeneration in the post-critical CNS may be stimulated by recapitulating an embryonic glial environment at the lesion site. Supported by NIH (NS15731)and NSF(BNS8218700)

102.2 AFFINITY OF AFFERENT PIONEER GROWTH CONES FOR THE EPITHELIAL SUBSTRATE INCREASES PROXIMALLY WITHIN LEG SEGMENTS OF GRASSHOPPER EMBRYOS.

Michael Caudy and David Bentley. Biophysics Group and Dept. of Zoology, University of California, Berkeley, CA 94720.

The T1l pioneer neurons differentiate from the ectodermal epithelium at the tip of the embryonic limb bud. Their afferent growth cones follow a characteristic pathway along the inner surface of the epithelium. The dominant guidance cue for these growth cones is a set of non-adjacent, identified "guidepost cells". Another prominent cue is a limb segment boundary, along which the pioneer growth cones circumferentially reorient after completing an "initial path" of proximally directed growth (Cold Spring Harbor Symp. Quant. Biol. 48: 573-585).

In typical legs, the Fel and Trl guidepost cells contribute to proximal guidance on the initial path. However, several observations have suggested the presence of at least one additional proximal polarity cue along the initial path (ibid.).

One possible proximal guidance cue is an adhesion gradient on the epithelial substrate. Growth cones cultured on substrates of high adhesivity exhibit characteristic morphologies - increased degree of branching and spreading, growth cone lamellae, and filopodial retention - which produce increased neuronal apposition to the substrate. We have used these characterisics as criteria for assaying neuronal adhesion at different locations along the path. We find marked increases in degree of neuronal apposition at segment boundaries and in more proximal regions of segments.

The pioneer growth cones cross the proximal border of the tibia. Lateral lamellae or branches are extended, and lateral filopodia are preferentially retained there. As the leg segments develop further, the pioneer axons extend prominent lateral branches in the proximal region of the tibia, but not in the adjacent distal region of the femur.

The T1l growth cones exhibit a higher degree of branching in the proximal region of the femur than in the distal region when they are not in contact with guidepost cells there and can therefore respond to less dominant cues on the epithelial substrate. When they reach the distal boundary of the coxa, they abruptly reorient along the boundary, and do not extend branches proximally into the distal region of the coxa except along filopodia in contact with proximally located guidepost cells.

These observations suggest a pattern of proximally increasing neuronal apposition within each segment. This may reflect the differential expression of guidance molecules on the epithelial substrate. Guidance molecules could be adhesive in nature, or non-adhesion molecules which actively regulate growth cone extension.

102.3 NEURONAL GUIDANCE IN DISSECTED LIMB BUDS, IN CELL CULTURE, AND AT ECTOPIC LOCATIONS IN HOST LIMB BUDS.

Frances Lefcort* and David Bentley. Neurobiology Group and Department of Zoology, University of California, Berkeley, CA 94720.

The first sensory neurons which extend axons in the embryonic grasshopper limb are the T1l pioneer neurons. Their axons grow proximally towards the CNS along a stereotyped, characteristic route. To investigate the cues which might guide axon growth, we have conducted the following experiments.

Limb bud manipulations: Prior to the onset of pioneer axonogenesis (29% of development), the right metathoracic leg was detached from the body, split open lengthwise along the posterior side, flattened and pinned. After two days in culture, the pioneer axon trajectories in both the experimental leg and the contralateral control leg were normal; axons extended proximally to the coxa/trochanter segment boundary and grew ventrally along the boundary. Normal pathway formation under these conditions is evidence against guidance by factors diffusing from the body, axial electrical currents within the limb, limb curvature, or local diffusable factors. These observations are consistent with the idea that local cues on the surfaces of cells with which the pioneer growth cones interact serve as proximally orienting guidance cues.

Cell culture: Embryonic limb buds were dissociated, and separated cells were plated in culture on poly-l-lysine coated cover slips. After 2 - 9 days in culture, neural, mesodermal and epithelial cells each differentiate and exhibit distinctive morphologies. These cell types can be unequivocally distinguished from one another on the basis of their morphology and cell surface properties. Neurons are recognized by anti-HRP antibody, while the lectin WGA binds to epithelial cells and not to mesodermal cells. Afferent neurons differentiated similarly both in situ and in vitro. Their axons were monopolar with a broad axon hillock, were as long as 90 µm and had lamellar growth cones, often with numerous filopodia. In mixed cell cultures, neurons contacted other neurons preferentially. Thus, neurons in vitro behave as they do in situ, where guidepost neurons serve as the highest affinity substrate for extending afferent axons.

Transplanted neurons: Dissociated neurons were isolated and labeled with a fluorescent probe. Labeled neurons were transplanted onto the inner surface of limb buds which were (a) un-opened but with the mesoderm removed, (b) split open and flattened. After two days in culture, transplanted neurons, in both preparations, adhered to the limb surface, produced growth cones with filopodia, and extended axons of up to 50 µm. The routes taken by axons of transplanted neurons serve as a test of several models of guidance features within the limb.

102.4 **PATHFINDING BY IDENTIFIABLE GROWTH CONES IN THE EMBRYONIC FISH SPINAL CORD.**

J. Y. Kuwada. Dept. of Biological Sciences, Stanford University, Stanford, CA 94305.

Analysis of pathfinding in the CNS during embryogenesis can be highly successful when individual neurons are identifiable at all stages of development and the environment through which their growth cones navigate is simple. Such is the case with the early embryonic spinal cord of the fish. In Medaka oryzias the earliest neurons are relatively large, can be visualized in living embryos with Nomarski optics, and are accessible to single cell techniques. I have utilized intracellular injection of dyes and electron microscopic analysis of the fish embryo to study axonogenesis by these neurons.

At approximately 40-46 hr of development when 12-15 somites are present in the embryo, three kinds of neurons based on their initial growth cone trajectories and cell body locations are evident in the cord. These populations of neurons are distributed up and down the longitudinal axis of the cord, and are the dorsally located Rohon-Beard (RB) mechanosensory neurons, ventrally located axial motor neurons, and the laterally located commissural neurons. Additionally the cord contains smaller neuroepithelial cells which have numerous endfeet processes in contact with the basal lamina which delimits the neural tube. All three kinds of neurons project growth cones during this time period. So far the temporal sequence of axonogenesis has been followed for the RB neurons. These cells initially project two growth cones, one anterior and the other posterior, from the lateral pole of the cell body. Filopodia up to 10 um in length project longitudinally from these growth cones. At this time only one or two axonal profiles, which are in contact with the endfeet of the dorsal neuroepithelial cells, are present in the dorsal cord in EM sections. Later a well formed longitudinal tract is present in the same part of the cord. This indicates that RB neurons pioneer this dorso-lateral tract and raises the possibility that the endfeet of dorsal neuroepithelial cells may play a significant role in pathfinding by their growth cones. In the next 10 hr these growth cones extend up to 10 somites in each direction and the axons of RB cells fasciculate in the dorso-lateral tract. Also during this period a peripheral growth cone extends from the longitudinal axon near the cell body to begin innervating the skin. Another 60 hr later the RB central axons extend to fewer somites, project collateral longitudinal axons, and have become monopolar. Thus it appears that the earliest growth cones in this vertebrate CNS grow in a stereotyped manner. Experiments to elucidate how this is done are presently being pursued.

102.5 AXON GUIDANCE IN ANEURAL WINGS OF DROSOPHILA. S.S. Blair and J. Palka, Dept. Zoology, NJ-15, Univ. Washington, Seattle, WA 98195

The wing of the fruitfly Drosophila melanogaster is formed during metamorphosis from the wing imaginal disc. This epithelial sac everts during the first hours of pupariation and then flattens, bringing the originally separate dorsal and ventral epithelia of the wing together to form the future wing blade. During this process a set of identifiable sensory neurons arise within the wing; by staining these neurons using immunohistochemical techniques, we have shown that they arise in a stereotyped sequence and lay down a characteristic set of nerve bundles which project proximally into the CNS.

It was demonstrated previously, using surgical and genetic techniques, that the initial, correctly oriented outgrowth of these neurons is not dependent upon the presence of other neurons ("guidepost" or "landmark" hypothesis) or upon physical constraints ("channel" hypothesis) within the developing wing. In fact, normal outgrowth can take place in a surgically altered wing which lacks both physical channels and putative guidepost neurons. Axons are thus being guided by some other cue or cues, either within the wing environment (extrinsic cues) or within the neuron itself (intrinsic cues).

To test for extrinsic cues, an experiment has been devised in which ectopic neurons are transplanted into a mutant, aneural wing, which is then reared in vitro; growing axons from the transplant in effect assay the inner surface of the aneural host wing for the presence of extrinsic guidance cues. The neuron-containing transplant was derived from the marginal bristle region of a wild-type wing, while the aneural host wing was from the mutant scute 10-1. Initial results indicate a marked preference for axonal outgrowth along the proximo-distal axis of the wing, in a position corresponding approximately to the site of the nerve of the third vein in normal wings. Since the transplants were oriented randomly in the host wing, axonal outgrowth into host tissue is apparently being directed by some form of extrinsic cue. As the host wing lacks neurons, transplant neurons cannot merely be following endogenous, intrinsically oriented nerve bundles. The nature and distribution of extrinsic cues is the object of further experimentation.

102.6 Results of Experimental Manipulation of the Neural Tube in Xenopus laevis Embryos on the Growth of Spinal Cord Axons. S M Bunt, T M Scott* and F G Inglis*, Department of Anatomy, University of Dundee, Dundee DD1 4HN UK, and *Health Sciences Centre, Faculty of Medicine, Memorial University of Newfoundland, St Johns, Newfoundland A1B 3V6, CANADA.

Many workers have described the pathways taken by fibres in the developing spinal cord and have attempted to deduce the guiding factors from observations of the normal neural tube. However, there has been little experimental manipulation of the system to test whether the mechanisms suggested can actually cause the fibres to grow in a particular direction. We have attempted to assess the role of spatially localised cues such as glial channels or fibronectin or laminin pathways in the guidance of the growth of spinal cord axons by rotating a section of neural tube and then investigating the effects this has on later growing axons.

A short section of the neural tube and surrounding tissues from a stage 22 Xenopus laevis embryo was excised and replaced by a section from another embryo labelled with tetramethyl rhodamine isothiocyanate (TRITC). The transplant was rotated around the vertical axis so that the previously rostral end of the transplanted section of tube was placed caudally in the host embryo. Scanning and Transmission electron microscopy had shown that no fibres were present at this time. Time lapse photography and the fluorescent labelling showed that the transplant healed in and survived without derotation.

The animals were left to grow to stages between 45 and 50 when HRP was applied to selected areas of the cord cross section. When processed as wholemounts these animals showed that the rotation only rarely disturbed the pathways of the later growing axons. In 20 cases out of 23 the fibres grew directly through the rotated region with no detectable disturbance to their normal parallel pattern of fibre growth. It therefore appears that the fibres cannot, on the basis of guidance cues present at stage 22, show a preference for the right or left side of the neural tube, nor for their direction of growth along the tube.

The existence of structural cues at the stages studied is also doubtful. We have examined developing neural tube by light microscopy, and by transmission and scanning electron microscopy to determine whether or not specialised structures capable of guiding growing axons are present. Only relatively unspecialised intercellular clefts were seen, with no evidence of grooves or channels. (Neuroscience Letters Suppl. 21,567, 1985).

102.7 BASEMENT MEMBRANES AND NERVOUS SYSTEM DEVELOPMENT IN THE GRASSHOPPER EMBRYO. H. Anderson. Department of Zoology, University of California, Davis, CA 95616.

The growth cones of the first axons in the central nervous system of the grasshopper embryo progress along a basement membrane overlying the developing nervous system (Bate, C.M. & Grünewald, E.B., J. Embryol. exp. Morph. 61: 317, 1981). They do so in particular patterns characteristic for each axon, to produce a simple arrangement of nerves which later play the important role of providing the pathways for growth of later developing neurons. The growth cones of the first axons in the peripheral nervous system grow towards the CNS along the inner surface of the embryonic epidermis with their filopodia extending beneath the epithelial basement membrane (Bentley, D. & Caudy, M., Cold Spring Harbor Symp. Quant Biol. XLVIII: 573, 1983; Berlot, J. & Goodman, C.S., Science 223: 493, 1984). These axons also grow in particular patterns with a general tendency for growth to be directed proximally.

The basement membrane thus appears to act as a generally preferred substrate for the outgrowth of early axons in the grasshopper embryo. In addition to this role, particular components of the basement membrane could provide directional information for growth cone navigation.

Little is known about the structure and composition of any insect basement membrane. We have begun an investigation of the basement membrane of grasshopper embryos at stages between 25% and 35% of embryonic development - the period during which the first central and peripheral neurons establish their pathways.

We have used histochemical methods combined with light microscopy and electron microscopy to describe the overall appearance of the basement membrane. To investigate the distribution of individual molecular components within the basement membrane, we have examined the labelling patterns obtained after treating wholemount preparations and frozen sections of embryos with a variety of lectins and with affinity-purified polyclonal antibodies to identified components of vertebrate basement membranes which we have found bind to discrete bands on immunoblots of embryonic material.

We are now extending this investigation by generating monoclonal antibodies to embryonic grasshopper basement membrane itself.

Supported by NIH grant NS 21355.

102.8 GENES AFFECTING AXONAL GROWTH AND GUIDANCE OF LUMBAR NEURONS IN THE NEMATODE CAENORHABDITIS ELEGANS. S. S. SIDDIQUI and J. G. CULOTTI. Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

Earlier we have reported that antibodies to horseradish - peroxidase(HRP) stain a specific subset of identified neurons in the nematode C. elegans, including 4 pairs of lumbar neurons (PHA, PHB, PVN & PHC) in the tail of the animal. Using indirect immunofluorescence on wholemount squashes of the nematode with antibodies to HRP, we have screened more than 100 uncoordinated mutants of C. elegans. Mutants in 7 genes(unc-13, unc-33, unc-44, unc-51, unc-61, unc-71, unc-73, unc-98, and unc-106), show abnormal growth and guidance of postembryonic lumbar neurons PVN and PHC. A variety of axon guidance errors were observed in a fraction of the mutant animals. In most cases, the stained lumbar axons grew in abnormal lateral positions instead of running along the ventral nerve cord. Occasionally, these abnormal axons reached the ventral cord further anterior than in wild type and bifurcated randomly. Morphologies of the other two embryonic lumbar neurons(PHA/PHB) were determined previously by Hedgecock et al.(Develop.Biol.1985). This allows the axon growth mutants to be classified in 4 categories based on whether the mutant gene affects embryonic(PHA/PHB), the post-embryonic (PVN & PHC) lumbar neurons, or both; as summarized below.

Class	Embryonic neurons PHA&PHB (FITC uptake)	Post-embryonic neurons PVN&PHC (anti-HRP)
1. unc-106	misdirected	misdirected
2. unc-33, unc-44, unc-51	premature termination	misdirected
3. unc-13, unc-61, unc-73, unc-98	normal	misdirected
4. unc-76, unc-107	premature termination	normal

Interestingly, mutant unc-13 is resistant to Aldicarb, an inhibitor of AChE (J. Culotti) and the mutant unc-98 has a known defect in the body musculature(H. Epstein et al.)

102.9 HOW THE FLY'S EYE FINDS THE FLY'S BRAIN. D.F. Ready, J.M. Goldsmith* and J.L. Ecker*. Department of Biology, Princeton University, Princeton, N.J. 08544.

To find their appropriate central targets, sensory neurons first have to find the CNS. We have used scanning electron microscopy of dis-sected *Drosophila* embryos to trace the development of the connection between the fruit fly eye and brain.

Nine hours after fertilization, the non-optic portion of the embryonic fly brain is a bilateral mass of neuroblasts that have budded from the dorsal and lateral head ectoderm. Optic brain development begins at about 9 hours with an infolding of the embryonic ectoderm along the posterior of the underlying brain (Poulson,D.F., in Biology of Drosophila, (M. Demerec, ed.), 1950; Turner, F.R. and Mahowald, A.P., Devel. Biol. 68:96-109, 1979). This ectodermal inpocketing fuses with the brain and later produces neuroblasts which will populate the optic lobes . Closure of the mouth of the optic lobe inpocketing erases its external opening, but preserves the connection between the ectoderm and the CNS. At about 10 hours, the brain begins to move posteriorly into the embryo, and the overlying head ectoderm is peeled away from the brain. At the site of contact between the ectoderm and optic lobe a thin cellular bridge, the optic stalk, is drawn out. As the brain continues its rearward migration, head ectoderm is rolled off the lateral face of the brain and the stalk is drawn foward over the surface of the brain. The trajectory of the stalk leads to a second region of adherence between the ectoderm and the front of the brain. Further backward migration of the brain drags a pocket out of the ectoderm at this adhesion site. This pocket is the future retinal epithelium, and is continuous with the future optic lobe via the optic stalk. Subsequent development retains this cellular bridge.

The precursors of the eye and optic lobe of *Drosophila* are thus connected from the outset on the two-dimensional ectodermal sheet of the embryo. This connectedness is preserved throughout the complex foldings of embryogenesis and subsequent development via the optic stalk. Consequently, axons of photoreceptors generated four days later in the retinal epithelium are directed to their appropriate central targets through this remnant of the ectodermal surface.

102.10 TRANSIENT EXPRESSION OF ANTIGENS IN THE PRIMARY OPTIC PATHWAYS OF THE FETAL MOUSE. M.A. Edwards and M. Yamamoto. Southard Lab., E.K. Shriver Ctr. for Mental Retardation, Inc., Waltham,MA 02154

The elongation of axons to their targets and the elaboration of terminal ramifications within them have been proposed to comprise two distinct modes of axonal growth that are under differential regulatory control (Jhaveri, Edwards & Schneider, Neurosci. Abst. 9, 702, '83). One way to begin to evaluate this hypothesis is to look for clear differences in the molecular species associated with axons or their substrates during the two phases of growth. Monoclonal antibodies (MAb's) were generated with conventional hybridoma methods following immunization of pigmented mice with fetal rat forebrain homogenates, and patterns of immunocytochemical staining of two such MAb's were assessed in serial cryostat sections of the fetal mouse primary visual system (fixation on slide with paraformaldehyde or acetone; HRP-coupled secondary antibody; DAB chromogen). The MAb 7C7 recognizes the disialo-ganglioside, GD3, as well two minor species of uncharacterized gangliosides (Yamamoto & Schwarting, in preparation); the other MAb, 4D7, recognizes two protein species of 110 and 140kD (Yamamoto et al, Neurosci. Abst.,'85). For comparison, alternate sections were stained with C2, a MAb recognizing a neurofilament component (op. cit.), thereby revealing the pattern of axonal outgrowth. A leading front of optic axon fascicles extends into the ventral peripheral optic stalk by E12, through the chiasm by E13, and along the optic tract into the superior colliculus by E15. Over the same interval, axons are recruited to the efferent outflow from a progressively greater proportion of the retinal surface, proceeding in a dorsocentral to peripheral progression. The MAb 4D7 selectively stains optic axons (and a few other CNS fiber systems) in the interval from E12 to E15. Subsequently, such staining diminishes and becomes undetectable by birth (E19). The MAb 7C7 similarly recognizes a determinant transiently associated with optic axons in the fetal period (along with numerous other CNS fiber systems). Against a background of diffuse perisomatic staining present in most CNS regions, dense immunoreactivity also occupies presumptive optic axonal pathways in advance of the arrival of the axons. As early as E12, 7C7 immunoreactivity delineates the marginal zones of the entire vitreal surface of the retina, the ventral optic stalk, the chiasmatic region, the lateral diencephalon, and the superior colliculus. As optic axons advance and accumulate on subsequent days, the dense staining appears to become associated with the axon fascicles themselves. From E15 to birth, staining in most regions of the CNS disappears, including the visual system. These results suggest a potential role for particular antigens in regulating optic axonal growth selectively during elongation to their targets. (Supported by EY404549 and HD05515).

102.11 AXONAL REGENERATION AND SPROUTING AFTER DAMAGE TO THE HEART. Ron Maron*, (SPON: U.J. McMahan). Dept. of Neurobiology, Stanford University, Stanford, CA 94305.

The interatrial septum of the frog's heart is bounded on each of its two surfaces by endothelium and it contains scattered cardiac muscle fibers, the parasympathetic neurons that innervate them, and connective tissue cells. It is transparent so that the fine details of the cells can be clearly seen in a living isolated preparation. Individual post-ganglionic axons can be traced several hundred micrometers from their nerve cell bodies to where they make contact with cardiac muscle fibers. As in mammalian hearts, the terminal region of the axons consists of series of varicosities which lie at varying distances from the muscle fibers. The varicosities are probably transmitter release sites. Unlike axon terminals in skeletal muscles, the postganglionic axons in the septum have no Schwann cell covering. Indeed the axons directly face the extracellular matrix (McMahan and Kuffler, 1971).

Here, I describe the sequence of events following axonal damage which heretofore has been unknown for heart. Many of these events differ from those that occur after damage to motor axons in skeletal muscles. I observed these events in organ cultures of the septum by time-lapse videomicroscopy. In each preparation I crushed only a single parasympathetic axon. The following account is based on 5 preparations; all events were detected in each.

1) Within minutes after crushing a postganglionic axon over a length of 10-20 μm, the axonal continuity in that stretch was completely interrupted. 2) By 2 days after damage, one to three connective tissue cells migrated into the region of damage and hovered over the damaged stretch of the axon. 3) Beginning at about 5 day, the connective tissue cells left the site of damage and the portion of the axon that remained connected to the cell body began to elongate. The elongation was followed for several days. It covered several hundred microns. 4) The direction of the elongation did not follow the course of the severed segment of axon, but rather, it appeared to be random. The axon did not necessarily establish contact with the muscle fibers it originally innervated. 5) The regenerating axon formed varicosities before they reached myofibers. 6) Undamaged axons in the vicinity of the crush began to sprout processes at the same time the damaged axon began to regenerate. The regrowth of the crushed axon, the sprouting of nearby undamaged axons and the accumulation of the connective tissue cells was directly related to axonal damage; in all of several preparations crushing a connective tissue cell near a group of axons did not cause the axons to sprout or induce the accumulation of other connective tissue cells. Supported by NIH grant NS 14506 and a Weizmann Postdoctoral Fellowship.

102.12 An Integral Membrane Glycoprotein Complex that Participates In Axonal Guidance And Organization Of The Neuromuscular Junction. D. Bozyczko* and A. Horwitz* (SPON: R. Hogue-Angeletti). Dept. of Bioch. and Biophys. Univ. of Penn., School of Med., Phila, PA 19104.

We have used the CSAT monoclonal antibody which is directed against a laminin and fibronectin receptor to elucidate its role in axonal extension, guidance, and synaptogenesis. This antibody disturbs the adhesion of several classes of fibroblasts and muscle (Decker, et al. JCB (1984) 99: 1398-1404). Two peripheral nervous systems have been investigated, the dorsal root and ciliary ganglia. Both respond similarly. Neurons plated in the presence of CSAT do not adhere to the substratum and process formation is inhibited completely for at least 24-48 hours. When neurons are first allowed to extend processes, prior to CSAT addition, the results depend on the particular substrate. With some substrates neurites fasiculate and detach from the substratum, whereas with others, they retract and regrow to form bundles of processes. The antigen has been localized, using immunofluorescence, on the cell bodies, axons and growth cones. This distribution correlates with its biological effects on all parts of the neuron. The affinity purified antigen from fibroblasts, muscle, and peripheral nerve is very similar from all sources. It is a 110-160 kd integral membrane glycoprotein complex.

Using the CSAT monoclonal antibody and a polyclonal antisera directed against the affinity purified antigen we have also localized the antigen to concentrations of AchR hot spots and neuromuscular junction sites. On chick myotubes treated with brain extract, the antigen co-localizes with AchR clusters and laminin, as visualized with TMR-BGT and a monoclonal antibody against chick laminin, respectively. The antigen is also concentrated in regions of high AchR density on sections of post-hatch anterior latissimus dorsi.

Our observations implicate the CSAT antigen in the organization of AchR clusters at the neuromuscular junction and in axonal extension and guidance. With respect to the former, the observations presented here along with those on fibroblasts, where the antigen co-localizes with cytoskeletal and extracellular matrix components, suggests that the CSAT antigen contributes to the organization of the neuromuscular junction as a transmembrane link between the cytoskeleton and the basal lamina. In axonal migration, the antigen contributes not only to extension but to fasiculation as well.

103.1 THE USE OF THE VOLTERRA SERIES EXPANSION TO CHARACTERIZE DIRECTION SELECTIVITY. N.M. Gryzwacz* and C. Koch (SPON.: B. Dawson). The Center for Biological Information Processing, M.I.T., Cambridge MA, 02139.

Recently, psychophysicists have formulated different models of human motion perception. These models can be considered as arising from the simplest type of directional system, based on quadratic (2nd-order) interactions between neighboring channels and which are best described by a Volterra series expansion. Such an approach was pioneered by Reichardt and Poggio for the optomotor response of the fly. Moreover, it was shown that a localized interaction between excitatory and inhibitatory synapses, with a reversal potential close to the resting potential of the cell, in the dendritic tree may be the biophysical mechanism implementing these quadratic systems (Koch, Poggio, and Torre, 1982). We will discuss three properties of 2nd-order-models relevant for directional selectivity, comment on their physiological significance for the underlying circuitry and biophysical mechanisms and propose some critical experiments to test these properties. Phase invariance: the time averaged response of a 2nd-order system to a combination of several moving sinusoidal waves does not depend on the relative phase between the components. Thus, gratings which appear different but have the same Fourier components will lead to the same response of the motion system, as shown in the fly. Factorization: The response of the system to a single grating can be expressed as the product of a function depending on the spatial wavelength of the stimulus λ and a function only depending on the contrast frequency $\omega=v/\lambda$. Thus, for a fixed λ the normalized dependence of the response in ω is invariant. This property, however, holds only if the spatial and temporal characteristics of the receptive field of the motion system are independent, and if different inputs have similar receptive fields. Temporal behavior: The direction selective component of the response of the 2nd-order system does not depend on time, provided that either the spatial or the temporal filter making up the temporal-spatial receptive field is of the high-pass type.

We will discuss different biophysical schemes compatible with directional selectivity in the vertebrate retina (e.g., nonlinear interaction between synaptic inputs in the dendritic tree of the ganglion or the (starburst) amacrine cell; linear synaptic interaction followed by a synaptic rectification or by a spike threshold) emphasizing physiological experiments to distinguish between these different possibilities.

This research was supported by the Sloan Foundation and ONR.

103.2 SYNAPTIC ORGANIZATION OF ON-OFF DIRECTIONALLY SELECTIVE GANGLION CELLS IN RABBIT RETINA. E. V. Famiglietti. Dept. of Anatomy, Wayne St. Univ. Sch. of Med., Detroit, MI 48201.

Correlative morpho-physiological studies prompted the suggestion that type 1 bistratified cells are the ON-OFF directionally selective ganglion cells of rabbit retina (Famiglietti, E., Invest. Ophthal. 20 (Suppl.): 204, '81), recently confirmed by intracellular staining (Amthor, F. et al., Brain Res. 298: 187, '84). These cells have two dendritic arbors, narrowly stratified (2 um thick substrata), one each in the middle of sublamina a and of sublamina b of the inner plexiform layer (IPL), and are thus optimally positioned to receive both ON and OFF inputs. These are also precisely the same two strata occupied by starburst/cholinergic amacrine cells (Masland, R. and Mills, J., J. Cell Biol. 83: 159, '79; Famiglietti, E., Brain Res. 261: 138, '83). The recurving dendrites give rise to many short (5 to 20 um) branches, covering the plane rather evenly within the dendritic field perimeter. In the present study, Golgi-impregnated type 1 bistratified ganglion cells have been serially sectioned and reconstructed from montages of electron micrographs.

In one example, located about 2 mm ventral to the visual streak, more than 60% of the linear extent of the dendritic tree was reconstructed from > 3,000 electron micrographs. About 20% of the input comes from cone bipolar cells, and the remainder from amacrine cells. Quantitative analysis of the dendrites in sublamina b yielded 449 synapses equally distributed between 2 major dendritic systems originating from opposite poles of the cell body. Amacrine inputs were subdivided when possible into "probable cholinergic/ excitatory" and "probable GABAergic/ inhibitory" based upon ultrastructural criteria, but no more than 10% could be so classified. No input was found upon the cell body or proximal dendrites below the substratum of extensive branching. Inputs were high in density and increased from mainstem to terminal dendritic branches (up to 3.3 per 10 um^2), with concomitant increases in all classes of input. The following conclusions may be drawn: 1. there is no obvious, globally organized asymmetry of inputs in the dendritic tree which might account for the characteristic directionally selective response, 2. the high density of mixed inputs to thin (0.35 um) terminal dendrites maximizes the proximity of excitatory and inhibitory inputs at many points throughout the dendritic tree, in a manner consistent with a model in which local and distributed multiplicative interactions are proposed to underly the mechanism of directional selectivity (Torre, V. and Poggio, T., Proc. Roy. Soc. B 202: 409, '78); 3. to the extent that the model's optimal "on path" placement of inhibitory inputs (Koch, C. et al., P.N.A.S. 80: 2799, '83) is achieved, however, it appears to be a function of profusion of inputs, rather than selective placement during development.

(Supported by N.I.H. grants RO1 EY 03547 (E.F.) and P30 EY 04068)

103.3 THE SHAPE AND DISTRIBUTION OF THE INDOLEAMINE-ACCUMULATING CELLS IN THE RABBIT RETINA. J.H. Sandell and R.H. Masland, Massachusetts General Hospital, Boston MA 02114.

Although indoleamine-accumulating amacrine cells are found in most vertebrates (Ehinger & Floren, 1976), the dendritic shape of these neurons is unknown. We have developed a method which allows systematic injection of these cells with Lucifer Yellow CH; and have used it to examine the individual morphology and dendritic mosaic of the indoleamine-accumulating cells in the rabbit retina.

The indoleamine-accumulating cells were labelled by intravitreal injection of 5,7 dihydroxytryptamine (5,7 DHT, 50 μg, 2 hr survival) followed by whole mount fixation in 2.5% paraformaldehyde/0.01-0.20% glutaraldehyde for 1 hr. 5,7 DHT produced green fluorescence in the sparse catecholamine-accumulating cells (which were not studied further) and yellow fluorescence in the indoleamine-accumulating cells. Lucifer Yellow was injected into the indoleamine-accumulating cells under visual control. Two cell types with distinct morphologies were revealed. Their somas were equally labelled with 5,7 DHT throughout changes in 5,7 DHT concentration, incubation time and fixation parameters.

Type 1 cells have large, irregularly shaped somas with 5-8 primary dendrites that branch sparsely in a radiating pattern. These processes have large distinctive varicosities separated by long regions of smooth dendrite. In vertical sections the dendrites curve down through the inner plexiform layer to form a dense plexus in sublamina 5. The shape of the Type 1 indoleamine-accumulating cell in the rabbit retina resembles that of A17 in the cat. The density of Type 1 cells is ~450/mm^2 in the visual streak and 146/mm^2 in the periphery. The dendritic field diameter averaged 376 μm for 48 Type 1 cells and was unrelated to retinal eccentricity. Thus the coverage factor for these cells decreased from the center to the periphery. This is the opposite of the coverage pattern for the ACh amacrines; and also differs from that of the horizontal cells and most retinal ganglion cells, which maintain uniform coverage at all eccentricities. Presumably the distinct coverage patterns of these cells reflect the different roles they play in retinal circuitry.

The Type 2 indoleamine-accumulating cells have small round somas with many fine dendrites. The dendrites have many small varicosities. Type 2 cells branch in the scleral portion of the inner plexiform layer, and join the Type 1 cells in forming the dense plexus of indoleamine-accumulating dendrites in sublamina 5.

As more cell types are studied, further examples of morphological diversity within homogeneously labelled populations may be observed. While the aldehyde-induced fluorescence of the amine-accumulating cells made them particularly amenable to the injection methods used here, any cells that are visible in the fluorescence microscope could be similarly injected.

103.4 EFFECTS OF DOPAMINE ON FROG GANGLION CELL RESPONSES. D.W. Rickman* and M.C. Citron. Neurology Research, Childrens Hospital of Los Angeles, Los Angeles, CA 90027.

We recorded responses of ON-OFF type (class 3) retinal ganglion cells in the frog, Rana pipens, to a white noise stimulus, and studied changes in the linear component after application of dopamine (DA).

The stimulus consisted of a grid of 16 X 16 square picture elements, each of which was independently modulated by a binary, random signal that changed every 16 msec. The resulting spatiotemporal random stimulus was videotaped and presented on a video monitor.

Extracellular spikes were recorded from an eyecup preparation. The stimulus image was reduced to 1 mm^2 and focused on the retina. Control recordings were made from retinas bathed in Ringers solution. The eyecup was then drained, and 5 ul of 100 uM DA in Ringers was applied. The cell's responses were again recorded, and linear spatiotemporal response properties of the receptive field were determined by first order cross-correlation (Wiener kernel analysis).

Spatiotemporal contour plots of first order kernels were constructed by cross-correlating the luminance values for the 256 spatial positions (16 X 16) of the stimulus with the ganglion cell spikes, binned in 16 msec intervals. These plots provide a comprehensive description of spatial and temporal aspects of the linear component of the receptive field.

Although cells treated with DA showed no spatial changes compared to controls, temporal changes were noted; the peak value of the kernel at the center of the receptive field occurring at a later poststimulus time. When kernels from DA treated cells were used to model the cell's response to a 0.5 sec flash, an increased ON response, compared to control, was found. Furthermore, individual first order kernels from treated cells showed greater correlation of the response with the stimulus, indicating an increase in the stimulus driven component of the response. Analysis of the effects of DA on the nonlinear response components is underway. (RO1 E04711 and KO4 EY00250)

103.5 EFFECTS OF GLYCINE, TAURINE AND MET-ENKAPHALIN ON DIRECTIONALLY SENSITIVE (DS) GANGLION CELLS IN TURTLE RETINA. M.Ariel* and A.R.Adolph, Eye Research Institute, Boston, MA 02114.

We have previously reported that, as in rabbit retina, GABA and ACh are essential elements in a mechanism by which many retinal ganglion cells respond to specific directions of stimulus movement. The pharmacological analysis of DS cells has been extended by studying effects of glycine, taurine, met-enkephalin and their receptor blockers in superfused turtle retinal eyecup.

Application of glycine and taurine totally suppressed the extracellularly recorded spike firing of DS ganglion cells. Millimolar concentrations of these amino acids were equally potent inhibitory agents whose actions were antagonized by micromolar concentrations of strychnine. GABA, on the other hand, was an inhibitory agent whose actions were not blocked by strychnine but were antagonized by picrotoxin. When tested in a low Ca++/EGTA perfusate which blocked synaptic transmission yet did not suppress spike firing, GABA inhibited ACh-induced activity but glycine had no effect. These results indicate that a strychnine-sensitive inhibitory receptor is not pressent on the DS cell membrane but may be elsewhere in pathways to DS cells.

Met-enkephalin and DALA- met-enkaphalinamide application occasionally caused small increases in the light responses of DS cells. Naloxone, a broad-spectrum opiate antagonist, moderately decreased these cells' overall responsiveness. Neither naloxone nor strychnine had any consistent effects on directional tuning of DS cells. Thus the functions of glycine, taurine and met-enkephalin are not yet known and may be revealed by studying other receptive field properties of DS cells. GABA and ACh remain the prime transmitter candidates involved in directional sensitivity. (Supported by EY-03383).

103.6 ANALYSIS OF DENDRITIC STRUCTURE OF CAT RETINAL GANGLION CELLS. Dennis Dacey. Committee on Neurobiology, University of Chicago, Chicago, Ill. 60637.

Previous morphological studies of alpha and beta cat retinal ganglion cells demonstrate a characteristic increase in dendritic field size with increasing distance from the central area of the retina for both of these cell classes. This study examines related changes in the detailed dendritic structure of alpha and beta cells with increases in eccentricity. Small, iontophoretic injections of horseradish peroxidase (HRP) were made directly into the retina and the morphology of HRP filled ganglion cells was studied in cobalt-enhanced, diamino-benzidine-reacted retinal wholemounts.

The dendritic tree of ganglion cells, including alpha and beta cells, exhibits two major components, the dendritic shafts and the dendritic appendages. The dendritic shafts comprise the primary dendrites that extend from the soma, and branch by successive bifurcation. They are principally smooth and tapered but bear a small number of fine spicules and other spine-like extensions that are less than 0.5 um in diameter. The dendritic appendages are short branchlets that arise commonly as thin (less than 0.5 um in diameter) side branches from the dendritic shafts. By contrast with the smooth dendritic shafts, the appendages are irregularly varicose and scalloped and are often recurved.

Changes in these dendritic components with eccentricity were examined by comparing changes in the length and numbers of dendritic shaft segments (a shaft segment was defined as the shaft length between branch points) and appendages at various distances from the area centralis. For both alpha and beta cells, dendritic shaft segments increased in length with increasing distance from the area centralis, accounting for the overall increase in dendritic field size. By contrast, the appendages for both cell classes showed a constant length (mean = 26 μm for alpha cells, 23 μm for beta cells) from 1 to 12 mm eccentricity. The numbers of appendages also remained constant for both cell classes (mean = 163 for alpha cells, 58 for beta cells) from 1 to 12 mm eccentricity. Thus with increasing eccentricity, the mean shaft length increases relative to the mean appendage length, so that central cells appear appendage-dominated while peripheral cells appear shaft-dominated.

It is hypothesized that the shafts and appendages represent functionally distinct components of the dendritic tree of alpha and beta cells.

103.7 CONE INPUTS TO CAT GANGLION CELLS. R.W. Rodieck and J. Dineen*, Department of Ophthalmology, University of Washington, Seattle WA 98195.

The great majority of cat ganglion cells show no spectral antagonism. Though most investigators have found these cells to receive from rods and a single cone type, some have reported that they can occasionally receive from two, three, or even seven spectrally distinct cone types.

We used a raster-based color stimulator to investigate the cone inputs to single X and Y cells in the cat retina. In the paradigm experiment, a blue spot, matched to the center of the receptive field, was flashed, thereby substituting for part of a larger green background. The blue intensity required to give a null response was determined. Neutral filters before the eye reduced this value, indicating a rod contribution. However, bleaching adaptation, or background adaptation outside the blue, which saturated the rod response also caused the null intensity to decrease. A change in cone pigment density would act to increase this value. Background adaptation to monochromatic lights showed that, in addition to the common 'green' cones, the ganglion cells were also receiving from cones having a peak spectral sensitivity consistent with the 'blue' cones that contribute to the rare 'color-coding' cat ganglion cells.

The receptive fields of ten X cells and thirteen Y cells were tested for their cone inputs. Every one showed a contribution of both blue and green cones to the center region. The surround region of ten of these cells were also tested, and all showed an input from both cone types.

103.8 EVIDENCE FROM PERCEPTION SELECTS AVERAGE LOCAL CONTRAST OVER THE RETINEX THEORY R. Shapley (Spon. Floyd Ratliff)
The Rockefeller University, New York, NY 10021

The Retinex Theory, originally proposed by Land and McCann (1971), was devised to account for the perception of brightness and color. A quantitative prediction of this theory is that equiluminant targets should appear equally bright, even when they are placed on unequally luminant uniform backgrounds. This Retinex prediction does not agree with the visual perception of normal humans, as I will demonstrate. This particular disconfirmation of Retinex prediction is not a special case. For example, equally luminant regions of so-called "Mondrian" patterns appear to be of different brightness if their average local contrasts are unequal, and appear equally bright if their average local contrasts are equal. These results suggest that (to a first approximation) the brightness of an object depends on the Average Local Contrast around the border of the object - the Theory of Average Local Contrast (TALC).

There is a plausable neurophysiological reason for TALC. I have found that the response amplitudes of retinal ganglion cells in the cat depend on local contrast rather than luminance or reflectance. Thus, the neural signal from the eye to the brain is coded in terms of contrast. Central visual cells combine these retinal contrast-dependent signals in order to compute the brightness of objects in a complex scene. The retinal calculation of contrast is a result of the neural and receptoral mechanism of light adaptation.

103.9 THE RELATION BETWEEN VISUAL RESOLUTION AND ECCENTRICITY FOR THE GANGLION CELLS OF THE MONKEY RETTINA. B.B. Lee, J.M. Crook* and A. Valberg*. Max Planck Inst. für biophys. Chemie, D-3400 Göttingen, West Germany.

The ability of ganglion cells to resolve fine gratings presumably sets a limit to the visual acuity of the intact animal. We measured the visual resolution shown by monkey retinal ganglion cells of various types as a function of retinal eccentricity. Cell activity was recorded directly from the inner plexiform layer, animals being anaesthetised with halothane and nitrous oxide. Stimulus luminance was 100 cd/m² with a 2 mm artificial pupil. Responses to black-white square-wave gratings of high spatial frequencies with a temporal frequency of 8 Hz were Fourier analysed and the amplitude of the first harmonic plotted against spatial frequency. In neither wavelength-opponent nor phasic cells was there a DC response component at high spatial frequencies. A response of 5 impulses/sec was defined as the resolution limit.

Visual resolving ability of both opponent and phasic cells showed the expected decrease with increasing eccentricity. Blue on-centre cells showed poor resolution. At a given eccentricity, wavelength-opponent (red on-centre, green on-centre) and phasic cells resolved gratings of comparable spatial frequency, despite the larger centre size of the latter cell type. This may be due on the one hand to the high contrast sensitivity of phasic cells and on the other to the poor responsiveness of most opponent cells to achromatic modulation of a stimulus. The results contrast with those from the cat where modulated responses are obtained from sustained cells at spatial frequencies at which neighbouring transient cells show no such modulation.

103.10 SPATIO-TEMPORAL VISION OF MACAQUES WITH SEVERE LOSS OF P_β RETINAL GANGLION CELLS. William H. Merigan and Thomas A. Eskin*, University of Rochester Medical Center, Rochester, NY 14642

Macaque monkeys treated with acrylamide, a neurotoxic chemical, show a pronounced loss of medium-sized (P_β) retinal ganglion cells, but sparing of the larger (P_α) retinal ganglion cells. Combined histologic, HRP transport and cytochrome oxidase studies reveal a deafferentation of parvocellular P_β-recipient layers of the lateral geniculate, but apparently normal input to magnocellular P_α-recipient layers. This preparation has allowed us to examine the visual role of the large cell retinogeniculate pathway in monkeys in the absence of the medium cell pathway. This study was of particular interest because physiological studies show different properties in these two pathways; the medium cell pathway shows higher spatial resolution but lower contrast sensitivity and temporal resolution than the large cell pathway.

Achromatic spatio-temporal vision was studied in two controls and three treated monkeys with standing and counterphase modulated gratings. A pronounced loss of contrast sensitivity (approximately one log unit) was found at all spatial frequencies for standing gratings. However, with moderate to higher rates of temporal modulation, reduced sensitivity was found only for higher spatial frequencies. The peak of the spatio-temporal contrast sensitivity function dropped and shifted from low temporal and middle spatial frequencies to higher temporal and low spatial frequencies.

These results suggest a close correspondence between the physiological and psychophysically measured spatio-temporal properties of large and medium cell visual pathways. However, they also suggest that the very high contrast sensitivities measured psychophysically depend on the medium cell pathway, in which the contrast sensitivity of individual neurons is rather low.

INTERACTIONS BETWEEN NEUROTRANSMITTERS I

104.1 QUINOLINIC ACID AND TAURINE: INTERACTIONS IN THE BRAIN EXAMINED IN VIVO AND IN VITRO. A.Vezzani, E.D. French, W.O. Whetsell, Jr.[1] and R. Schwarcz, Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228 and [1]Dept. of Pathology, Vanderbilt University Medical Center, Nashville, TN 37232.

Using an in vivo dialysis procedure in the unanesthetized rat, we have shown previously that intrahippocampal injections of 156 nmol of the excitotoxic brain metabolite quinolinic acid (QUIN) results in a rapid and selective increase in extracellular taurine (TAU) levels (Soc. Neurosci. Abst. 10, 11.6, 1984). We have now further investigated the interactions between QUIN and TAU using a spectrum of in vivo and in vitro paradigms.

Measurements of TAU were made in hippocampal dialysates following local co-application of 156 nmol QUIN and 468 nmol kynurenic acid, an antagonist of QUIN's excitotoxic effects. No TAU increases were found to occur under these conditions, indicating that QUIN-induced elevations of extracellular TAU levels were receptor-mediated. The question if the TAU response is related to the early stages of QUIN-induced neuronal degeneration was addressed by inserting a dialysis fiber into the cerebellum, an area which is quite resistant to QUIN-toxicity. Indeed, infusion of 156 nmol QUIN did not alter extracellular TAU levels in this area of the brain.

The mechanism of QUIN-TAU interactions was further explored in vitro. At 10mM, QUIN increased the efflux of ^{3}H-TAU from preloaded hippocampal slices by 56±8%(N=7). No such effect was observed with the non-excitotoxic QUIN-analog 3,5-pyridine dicarboxylic acid. 10mM QUIN did not, however, block the Na^+-dependent uptake of ^{3}H-TAU into hippocampal slices or into synaptosomal P_2 fractions.

Iontophoretic application of QUIN excited hippocampal pyramidal cells. This effect was completely inhibited by concurrently applied TAU.

Since the excitotoxic hypothesis postulates that inhibition of excitation be parallelled by a blockade of neurotoxicity, attempts were made to antagonize QUIN-toxicity by TAU. Intrahippocampal or systemic TAU, administered either acutely or chronically, failed to show such a protective effect in vivo, possibly due to the effective removal of TAU from the extracellular space. However, protection by TAU could be unequivocally demonstrated in organotypic hippocampal cultures (21 days in vitro) using 10^{-3}M QUIN as the degenerative agent and 10^{-3}-10^{-1}M TAU as the antagonist. While the specificity of these anti-excitotoxic actions of TAU with regard to excitatory receptor types remains to be examined, the possible role of TAU as an endogenous modulator of excitotoxic phenomena, which may take place in neurologic and/or psychiatric disorders, deserves further attention.

104.2 VASOPRESSIN-INDUCED NEURONAL MECHANISMS IN THE HIPPOCAMPUS. R.E. Brinton and B.S. McEwen Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY 10021.

Vasopressin (AVP) is postulated to be a neuromodulator in the CNS and to influence psychological processes associated with the hippocampus. Discretely localized receptors for AVP have been detected in specific hippocampal cellular laminae (Brinton et al., PNAS, 1984; Biegon et al., NS. Lett., 1984). The purpose of our ongoing studies is to explore and define biochemically the neuronal mechanisms induced by AVP. These studies could lead to insights into how AVP modulates neuronal responses in the hippocampus and provide data relevant to adrenergic function and memory formation.

Initially we undertook experiments to characterize the dose response for AVP potentiation of adrenergic (NA) stimulated c-AMP accumulation, as originally reported by Church (Peptides,1983), in hippocampal slices from rat brain. We found a dose dependent AVP potentiation characterized by a bell-shaped dose response curve. Low concentrations of AVP, 5, 10, 25, and 50 nM, had no effect on NA stimulated c-AMP. 100 nM AVP showed a 30% increase over control while 250 nM AVP showed a maximal potentiation of 52%. At 500 nM and 1 uM AVP potentiation declined in magnitude to 33% and 20% over control respectively.

This potentiating effect was not shared by oxytocin at doses of 10, 100 nM or 1 uM and thus appears to be specific for the neurohypophyseal peptide AVP. The behaviorally active potent metabolite peptide AVP_{4-9} was ineffective at 10 and 100 nM in potentiating NA stimulated c-AMP. Interestingly, in autoradiography we found a distribution of AVP_{4-9} receptors within the hippocampus which was remarkably distinct from that of the parent peptide (Brinton et al., Life Sci. 1985).

Lastly we asked whether the AVP vasopressor antagonists, $d(CH_2)_5$tyr(Me)AVP, dPVAVP, and dEt_2VAVP, would block AVP potentiation of NA stimulated c-AMP. At an agonist concentration of 250 nM AVP and an antagonist concentration of 1 uM, approximately comparable to the agonist/antagonist ratio used in behavioral studies (Koob et al.Reg. Pep., 1981), the vasopressor antagonists did not block AVP potentiation and appeared to have alight agonist properties.

Studies are currently in progress to explore the mechanism by which AVP modulates NA stimulated c-AMP in the hippocampus.

The authors are very grateful to Dr. Maurice Manning for his generous gift of vasopressor antagonists. This research is supported by a Postdoctoral Research Fellowship Award (MH-09224) to R.E.B. from the NIMH.

104.3 CHOLECYSTOKININ AND NEUROTENSIN DURING INTRACRANIAL SELF-STIMULATION AFTER SYSTEMIC AND INTRACEREBROVENTRICULAR INJECTIONS: EFFECT OF SUBDIAPHRAGMATIC VAGOTOMY. Ph. De Witte and J.J. Vanderhaeghen. Lab. of Psychobiology, Université Catholique de Louvain, 1 place Croix du Sud, 1348, Louvain-La-Neuve and Lab. of Neuropathology and Neuropeptides Research, Université Libre de Bruxelles, Erasme Hospital, 808 route de Lennik, 1070 Bruxelles, Belgium.

Dopamine nerve fibers in the nucleus accumbens have been implicated in the mechanisms reponsable for intracranial self stimulation (ICSS). ICSS has been a fruitfull tool to study the action of several drugs having dopamine agonist (amphetamine, apomorphine) or antagonist (neuroleptics) properties. Since cholecystokinin (CCK) and neurotensin (NT) have been reported to be either, closely related to, or even, colocalized with dopamine in some nerve fibers of the mesolimbic system, we have thus investigated the relationship between dopamine, CCK and NT in that ICSS model. Rats with chronic electrodes implanted into the posterolateral hypothalamus were able to self stimulate during sixthy minute session. ICSS was estimated quantitatively by computing the rate of bar pressings for brain reinforcing electrical stimulation every five minute. CCK and NT were injected using the intraperitoneal (IP) or the intracerebroventricular (ICV) route. Given ICV, CCK and NT were effective at the dose of 100 picomole per kilo. Given intraperitoneally, NT was effective at the dose of 4 nanomole, i.e. five time more effective than CCK which work at the dose of 20 nanomole per kilo. With both peptides we observe decrease of ICSS immediately after ICV injection, only after five minute after IP injection. We observe this decreasing ICSS effect during approximately 20 minute. The potentiation of ICSS induced by 0.64 mg per kilo of d-amphetamine was reduced also for 20 minute by CCK given either IP or ICV. The fact that CCK and NT are respectively 200 and 50 time more potent using the ICV instead of the IP route, strongly suggests a central action for these peptides in ICSS modulation. It has been reported that the satiety effect on the feeding behaviour induced by CCK was mostly mediated by the periphery, since it disappeared after bilateral vagotomy. Quite the contrary eigthy per cent of the decrease of ICSS after CCK injection remains after the bilateral subdiaphragmatic vagotomy.

104.4 HYPOLOCOMOTION INDUCED BY ACTIVATION OF DOPAMINE AUTORECEPTORS: EFFECTS OF NEUROTENSIN. S. T. Caln and C. B. Nemeroff. Departments of Psychiatry and Pharmacology, Duke University Medical Center, Durham, N. C. 27710.

The brain-gut tridecapeptide, neurotensin (NT) has a number of seemingly anomalous effects on dopaminergic neurotransmission. For example, centrally-administered NT inhibits amphetamine-induced hyperactivity (Nature, 291:73, 1981). In contrast, NT increases dopamine release from slices of striatum and nucleus accumbens (Eur. J. Pharmacol., 93:27, 1983). To explain these disparate effects, we have proposed that NT may antagonize the effect of dopamine (DA) activation of both postsynaptic and presynaptic receptors. As one test of this hypothesis, we have undertaken a series of studies designed to test the effect of NT on the hypolocomotion resulting from dopaminergic autoreceptor activation.

To determine the optimal conditions for observing a possible behavioral interaction between NT and DA autoreceptors, we first monitored the effect of autoreceptor activation on locomotor activity during both the light and dark phases of the circadian cycle. Either apomorphine (.048 mg/kg) or N-n-propyl-3-(3-hydroxyphenyl)-piperidine (3-PPP, 8.5 mg/kg) were administered IP and locomotor activity measured for 30 minutes in photocell cages. During the light cycle, apomorphine decreased ambulatory activity by approximately 40%. During the dark phase of the cycle, both apomorphine and 3-PPP decreased ambulatory activity by approximately 60%. To investigate the potential effects of NT on this hypolocomotion, we therefore conducted experiments during the dark phase of the cycle.

After the rats were lightly anesthetized with ether, NT (30 µg/10 µl) or saline was injected intracisternally (IC). Thirty min. later, the animals were injected IP with 3-PPP and locomotor activity monitored for 30 minutes. This protocol was chosen because the time period between 30 and 60 minutes post IC NT is the time of maximal increases in the concentrations of the dopamine metabolites DOPAC and HVA (J. Pharmacol. Exp. Ther., 222:1, 1982). There was an almost 80% decrease in locomotor activity in animals injected with saline IC and 3-PPP IP relative to animals with saline both IC and IP. NT did not significantly alter the hypolocomotion induced by 3-PPP. Because of the reported ability of NT to reduce the binding affinity of the dopamine agonist N-propylnorapomorphine (NNPA) (Acta Physiol. Scand., 119:459, 1983), studies are in progress to determine the behavioral and biochemical sequelae of combined NT/NNPA treatment. (Supported by NIMH MH-39415)

104.5 ROLE OF VASOACTIVE INTESTINAL PEPTIDE (VIP) IN STRIATUM AND CULTURED STRIATAL NEURONS: RELATIONSHIP TO GABA, SOMATOSTATIN AND DOPAMINE. M.H. Makman*, J.A. Kessler, L.L. Brown, J.F. Cubells, L. Thal* and L.I. Wolfson. (SPON: E.L. Gardner). Departments of Biochemistry, Molecular Pharmacology, Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Previous studies of VIP and dopamine (DA) stimulated adenylate cyclases in adult rat striatum and in fetal rat striatal neurons cultured in vitro (Soc. Neurosci. Abstr. 10:762, 1984; Regulatory Peptides, 6:317, 1983), suggest that VIP and DA (at D_1 receptors) have partly similar and partly different functions in striatum. In the present study synaptosomes from adult striatum or cultures of intact striatal neurons derived from dissociated striatum of 17 day old rat embryos were first labeled with ^{3}H-glutamate. The preparations were washed and release of newly formed ^{3}H-GABA into the medium was measured. VIP (10 uM) stimulated the release of ^{3}H-GABA from both adult synaptosomes and fetal neurons. DA (10 uM) also stimulated ^{3}H-GABA release. In addition, both VIP and DA stimulated release of somatostatin immunoreactivity (SIR) from adult striatal synaptosomes. In preliminary studies forskolin and 8-thiomethyl cyclic AMP had no effect on release of either ^{3}H-GABA or SIR; hence these effects of VIP and DA may not be due to stimulation of AC. Injection in vivo of VIP (12.5 pmole/.25 ul) into a cannula chronically implanted in the dorsal striatum did not elicit rotational behavior. However, injection of VIP but not saline 10 min before intracannula injection of carbachol (1 ug/.25 ul) inhibited 78% of the contraversive rotational effect of carbachol. The rotational effects of carbachol and DA agonists acting at D_2 receptors in the dorsal striatum are qualitatively the same. We propose that VIP and possibly also DA at D_1 receptors antagonize striatal production of movement (rotation) by stimulation of GABA and somatostatin release from striatal interneurons. GABA and somatostatin may be co-localized in these neurons. Alternatively, VIP might release GABA from collaterals of neurons projecting to globus pallidus or substantia nigra. In preliminary studies ^{3}H-GABA release from nigral synaptosomes was also stimulated by VIP, but to a lesser extent than by DA. The ability of VIP to stimulate GABA release from fetal striatal neurons suggests a role for VIP-GABA interaction in striatum during development as well as in the adult (USPHS NS-09649, NS-20013, AG-00374 and GM-07260.)

104.6 RECEPTOR MEDIATED, Ca^{2+}-DEPENDENT RELEASE OF TYROSINE FROM BRAIN SLICES BY MET-ENKEPHALIN AND OTHER NEUROPEPTIDES. S.P. Arnerić, M.P. Meeley, M. Honig* and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

We sought to establish whether the neuropeptide met-enkephalin (m-ENK) modulates the release of specific endogenous amino acids (AA) from slices of rat corpus striatum (CS), which contains very high levels of m-ENK (Neuropharmacol. 16:303, 1977). Slices (0.3-0.5 mm) of CS and, for comparison, cerbral cortex (Cx) were prepared from male rats and incubated with Kreb's bicarbonate buffer containing bacitracin (10uM) and physostigmine (100uM). The release of endogenous Tyr, GABA, Asp, Glu, Gly, Tau, Phe and Val was measured using HPLC.

Incubating m-ENK (1 uM) with slices of CS, but not Cx, increased not only the basal release of the putative transmitters Glu (+155%), Tau (+80%) and Gly (+50%), but also, surprisingly, Tyr (+81%) ($p < 0.05$; n=5-6). Facilitation of the basal release of Tyr, Glu, Tau and Gly by m-ENK was Ca^{2+}-dependent, and abolished in the presence of naloxone (1uM), an opiate receptor antagonist which, by itself, had no effect on the release of any of the AAs measured.

The increase in basal release of Tyr in slices of CS was dependent on the concentration of m-ENK present (0.1-10uM): release increased by 125% with 10uM m-ENK ($p < 0.001$; n=5). In contrast, depolarization with potassium (5-55mM) did not affect the release of Tyr in CS. The release of Val and Phe was not affected by incubation with m-ENK (10uM), or by depolarization with potassium (5-55 mM). However, the potassium-evoked release of Glu, Gly, GABA and Asp was both graded (5-55mM K^+) and Ca^{2+}-dependent. For all of the AAs measured, evoked release in the presence of 35mM K^+ was not altered by m-ENK (1 uM).

To determine the specificity of the m-ENK facilitation of Tyr release we examined the effect of three other peptides (1uM) in CS and Cx: cholecystokinin octapeptide (CCK-8), thyrotropin releasing hormone (TRH) and vasoactive intestinal peptide (VIP). Values are the mean % change from basal release of Tyr; * $p < 0.05$.

Treatment	m-ENK	CCK-8	TRH	VIP
Corpus Striatum	+81*	+49*	+44*	-7
Cerebral Cortex	+25	+18	+10	+69*

We conclude: a) Ca^{2+}-dependent, receptor-mediated release of Tyr is elicited by m-ENK in slices of CS, but not CX. b) CCK-8, TRH and VIP also increase basal release of Tyr in a regionally specific manner. c) Although the source of Tyr released in CS is unknown, in some brain areas it is conceivable that this amino acid functions as a transmitter. d) Alternatively, since it is a substrate for catecholamine biosynthesis, receptor-mediated release of Tyr may be a mechanism by which peptides modulate neurotransmitter synthesis.

104.7 SOMATOSTATIN-14 DIRECTLY DEPRESSES NEURONAL DISCHARGE BUT ENHANCES EXCITATORY RESPONSES TO ACETYLCHOLINE IN THE RAT CORTEX AND HIPPOCAMPUS J.R. Mancillas, G.R. Siggins and F.E. Bloom. Scripps Clinic and Res. Fdn, La Jolla, CA 92037

Interactions between somatostatin 14 (SS-14) and acetylcholine (ACh) were studied in areas CA1 and CA3 of the dorsal hippocampus, and in the parietal cortex, all areas which receive SS-14 and ACh innervation.

The activity of single identified CA1 and CA3 hippocampal pyramidal cells was recorded with five-barrel micropipettes, in rats anesthetized with halothane (0.75-1%). ACh (0.1 M, pH 4), Glutamate (GLU) (0.1 M, pH 8) and scopolamine (.002 M, pH 5) were applied by microiontophoresis, whereas SS-14 (3 mM, pH 6.5) was applied by electroosmosis. Twenty cortical, sixteen CA1 and fourteen CA3 pyramidal cells were studied.

SS-14, applied alone, had inhibitory effects on the spontaneous firing of 90% of all pyramidal cells tested, had no effect on 6% and a biphasic effect on 4%. No excitatory effects of SS-14 on pyramidal cells were observed in the absence of ACh in the drug barrels. SS-14 inhibitions displayed an extended time course, with a slow onset and the duration of the effect oulasting the pulse duration. ACh, on the other hand, produced facilitation of firing, with a much faster time course. When short pulses of ACh were applied within a sustained period of exposure to SS-14, the effects were dose-dependent. At small doses, SS-14 depressed the basal firing between ACh pulses, but did not affect the magnitude of ACh-induced excitations. At higher doses of SS-14, we observed an increased responsiveness in 78% of the test neurons to the ACh pulses (no effect in 22%), with much larger (up to 10-fold higher) and somewhat longer excitatory responses to ACh. At still higher SS-14 currents, cells initially showed an enhancement of responses to ACh followed by depression of basal firing and ACh responses. There were no such synergistic interactions between SS-14 and glutamate.

Pulses of SS-14, applied to a cell tonically driven by small (leak) amounts of ACh, caused an increase in neuronal firing by phasically "enabling" the ACh-induced tonic discharge. These increases in neuronal firing were blocked by scopolamine. Thus, iontophoretic application of SS-14 can yield qualitatively different effects on target cell activity depending on other presynaptic inputs or the presence of other chemical messengers. Such findings could explain the diverse neuronal effects of SS-14 reported in the literature. Supported by an APS fellowship to J.R.M., the USPHS (AA 06420 and AM 26741).

104.8 EVIDENCE SUPPORTING A ROLE OF ENDOGENOUS INTRA-NUCLEUS ACCUMBENS SUBSTANCE-P IN D-AMPHETAMINE-INDUCED LOCOMOTOR ACTIVITY: USE OF A MONOCLONAL ANTIBODY AGAINST SUBSTANCE-P.

P.J. Elliott, C.D. Kilts, and C.B. Nemeroff (Spon: T. Slotkin). Depts. of Psychiat. and Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710.

Substance-P (SP) is found in high concentration in proximity to dopamine (DA) cell bodies in the ventral mesencephalon. In addition, SP binding sites have been identified in the terminal regions of DA pathways originating from the A-10 DA cell body group in the ventral tegmental area (VTA). Infusion of SP into the nucleus accumbens (NAS), a mesolimbic terminal area, has been reported to produce an increase in DA metabolism in this nucleus and to potentiate the locomotor hyperactivity of simultaneously infused DA (Kalivas and Miller, 1984, Neurosci. Lett., 48, 55-59). Electrical, drug and peptide stimulation of the VTA can all mimick these effects suggesting VTA-NAS dopamine system activation. However, 6-hydroxydopamine lesions of the VTA do not block the locomotor activity induced by infusions of SP into the lateral ventricles (Elliott and Iversen, unpublished observations). Thus it would appear that other neuronal mechanisms are involved in these behavioral and biochemical events. In the present experiments the effects of intra-NAS infusions of a monoclonal antibody directed against SP (Sera-Lab; NCL/34) on d-amphetamine-induced locomotor activity were investigated. Use of this antibody is preferential to the SP antagonists currently available because they have been found to be toxicand rather non-selective. Furthermore this antibody has been previously used successfully to demonstrate a role for SP in modulating meso-cortical DA neurons (Bannon et al., 1983, Nature, 306, 791-792). Adult male Sprague-Dawley rats with bilateral cannulae aimed at the NAS were infused with the SP antibody or a control antibody (Sera-Lab; rat monoclonal against mouse IgG) in a 2 µl volume/side. The effect on i.p. amphetamine (1.0 mg/kg) was investigated in photocell cages (Columbus Inst., Ohio) over a 90 min test period. Subjects receiving the SP antibody (n=9) exhibited a 40% decrease in d-amphetamine-induced locomotor activity when compared to rats infused with the control antibody (n=6). These findings suggest a role for endogenous intra-NAS substance-P in the locomotor activity induced by d-amphetamine. The effects of intra-NAS SP antibody on DA metabolism in this nucleus are currently under study.

104.9 SUPRACHIASMATIC NUCLEUS SYNAPTIC RELATIONSHIPS: A DOUBLE ULTRASTRUCTURAL IMMUNOCYTOCHEMISTRY STUDY WITH PEROXIDASE AND GOLD SUBSTITUTED SILVER-PEROXIDASE. A. N. van den Pol and T.J.Gorcs*. Section of Neurosurgery, Yale Univ.Med.Sch., New Haven, Ct. 06510 and Dept.Physiol., UNC, Chapel Hill, NC 27514.

To investigate the neurotransmitter content of both the presynaptic and post-synaptic structures in the hypothalamic suprachiasmatic nucleus (SCN), the use of a double ultrastructural immunocytochemical analysis was tested. Several permutations of antisera against different putative neuroactive substances found in both cell bodies and axonal endings in the SCN were used; antigens studied included gastrin releasing peptide (GRP), vasoactive intestinal polypeptide, vasopressin-neurophysin, and the GABA synthesizing enzyme glutamate decarboxylase (GAD). The first antigen was stained with gold substituted for silver catalytically precipitated on polymerized diaminobenzidine. This method of immunostaining gave a punctate gold label distrubuted diffusely through the cytoplasm of immunoreactive cells; it also increased the sensitivity of the diaminobenzidine (DAB) reaction several fold and increased antigen detectability with both light and electron microscopy. The sensitivity of the gold substituted silver staining on HRP blots compares favorably with the use of tetramethylbenzidine in the detection of HRP; unlike TMB, the final gold immunolabel is stable in a wide range of pH and buffers. With ultrastructural analysis the metalic particles ranged in size up to 80 nm or more. The second antigen was labeled with HRP and DAB as the substrate, giving a non-granular reaction product.

GRP immunoreactive cells, dendrites, and axons labeled with gold substituted silver particles were found within the SCN, with the majority of immunoreactive profiles concentrated in the ventral part of the nucleus. Gold substituted silver particles were located only in immunoreactive neurons, and background metalic labeling was absent. GAD and GABA immunoreactive axons occurred in large numbers throughout the SCN, frequently making synaptic contact with dendrites and somata. Pre-synaptic GABA boutons had small clear vesicles, an occasional dense core vesicle, and a symmetrical contact zone. GRP immunoreactive axons contained both small clear vesicles and larger dense core vesicles, and made synaptic contact with unlabeled dendrites. GAD immunoreactive axons made synaptic contact with GRP immunoreactive cells and dendrites. Similarly, GAD immunoreactive axons made synaptic contact with vasopressin-neurophysin immunoreactive profiles within the SCN, mostly in the dorsomedial part of the SCN. GABAergic axons may play an important role in mediation of activity of both GRP- and vasopressin- containing SCN neurons.

104.10 TWO-COLOR IMMUNOFLUORESCENCE COMBINED WITH A FLUORESCENT RETROGRADE TRACER TO DEMONSTRATE POSSIBLE AFFERENTS TO DESCENDING MONOAMINERGIC NEURONS. M.W. Wessendorf and R.P. Elde. Dept. Anatomy, Univ. Minnesota, Minneapolis, MN 55455

The spinally-projecting monoaminergic neurons of the medulla have been implicated in the modulation of sensory, motor, and autonomic functions. In the present study, two-color immunofluorescence (Wessendorf and Elde, J. Histochem. Cytochem., in press) has been used to identify putative transmitters which might affect the activity of serotonergic (5HT) and catecholaminergic neurons. Additionally, fluorescence retrograde tracing has been used to identify possible afferents to spinally-projecting monoaminergic neurons.

The spinal cords of rats were hemisected at C1-C2 and a pleget of gelfoam soaked in 1% fast blue (FB) was inserted. After a survival time of 2-4 days, 5HT levels were elevated by the administration of 300 mg/kg tryptophan and 60 mg/kg tranylcypromine to make 5HT cells visible. Animals were then killed by perfusion fixation with Zamboni fixative. Ten micron sections were cut and stained for the simultaneous demonstration of 5HT-immunoreactivity (5HT-IR) and immunoreactivity for either enkephalin (ENK-IR), dynorphin 1-8 (DYN-IR), substance P (SP-IR), or the catecholamine-synthesizing enzyme tyrosine hydroxylase (TH-IR). The protocol was such that 5HT-IR fluoresced red, and the other substances fluoresced green.

Green-fluorescing SP-IR fibers were found in apposition to red-fluorescing 5HT-IR cells in all areas where the latter were found, but were especially prominent in n. paragigantocellularis lateralis and n. raphe pallidus. The same pattern was also seen for ENK-, DYN-, and TH-IR. In addition, TH-IR fibers were also frequently found in close proximity to large calibre 5HT-IR processes, presumably dendrites, in n. gigantocellularis pars alpha. Conversely, 5HT-IR fibers were found in apposition to TH-IR cell bodies and dendrites in the A1 cell group.

In rats in which FB was administered, 5HT-IR somata labeled with FB were frequently observed. Fibers positive for ENK-, DYN-, SP-, and TH-IR were found in apposition to these cells in n. raphe magnus, n. paragigantocellularis lateralis, and n. gigantocellularis pars alpha. 5HT-IR fibers were also found in apposition to TH-IR, FB-labeled cells in the A1 catecholamine cell group.

These data suggest that the activity of descending serotonergic neurons could be modulated by a number of different neurotransmitter systems. They also suggest the presence of an anatomical substrate allowing interaction between 5HT neurons and descending catecholamine neurons.

These studies were supported by DA 05226, DA 02148, and ImmunoNuclear Corporation.

104.11 RESPONSES OF SMOOTH MUSCLE STRIPS FROM PENILE ERECTILE TISSUE TO DRUGS AND TRANSMURAL NERVE STIMULATION. W.G. Dail, L. McGuffee*, N. Minorsky*, and S. Little*. Departments of Anatomy and Pharmacology, University of New Mexico School of Medicine, Albuquerque, NM 87131.

Histochemical studies of penile erectile tissue reveal acetylcholinesterase positive fibers, a dense adrenergic plexus and fibers which are immunoreactive for vasoactive intestinal polypeptide (VIP). Acetylcholine has long been regarded as the inhibitory substance which effects relaxation. However, contradictory evidence exists for acetylcholine and VIP, the more recent candidate for inhibition of penile smooth muscle. The present study examines the effects of putative neurotransmitter substances on the penile erectile tissue of the rat since more information is available on the chemical neuroanatomy of the erectile tissue in this species than in other animal models. Mechanical responses of smooth muscle strips from the penile crura were measured by a force-displacement transducer coupled to a polygraph. Norepinephrine (1 X 10^{-7} M) caused the muscle to contract while acetylcholine (1 X 10^{-5} M) did not alter the baseline tension or relax a norepinphrine-contracted muscle strip. The norepinephrine response was greatly reduced by the alpha adrenergic blocking agent phentolamine but was not altered by propanolol, a beta blocker. Muscle strips were not responsive to VIP. Stretch muscle strips and norepinephrine-contracted muscle strips were field stimulated. Field stimulation of the stretched muscle strips (3 Hertz, 12 volts) provoked a vigorous contraction which was totally blocked by tetrodotoxin (1 X 10^{-7} M) and greatly attenuated by the catecholamine-depleting drug, reserpine. Addition of acetylcholine during field stimulation of the muscle strip markedly inhibited the contractions. The muscarinic antagonist atropine blocked the inhibitory effect of acetylcholine while the nicotinic antagonist pentolinium was without effect. Contractions from transmural nerve stimulation were not affected by the addition of VIP. Field stimulation of norepinephrine-contracted muscle strips produced a relaxation. The relaxation was not affected by physostigmine or blocked by atropine. These studies support the role of norepinephrine as the excitatory neurotransmitter in penile erectile tissue. The failure of exogenous acetylcholine and VIP to alter tension of smooth muscle strips suggests that these substances are without postsynaptic effects. The data supports an initial hypothesis that acetylcholine indirectly causes relaxation of penile smooth muscle by inhibiting the release of the excitatory neurotransmitter norepinephrine. The mediator of the field stimulated relaxation of the contracted muscle strip is unknown. Supported by NIH 1RO11NS19839-02 and NIH RR08139-10.

104.12 INHIBITION OF AMINO ACID STIMULATED NEUROTRANSMITTER RELEASE FROM THE NUCLEUS ACCUMBENS BY PHENCYCLIDINE. S.M. Jones, L.D. Snell and K.M. Johnson. Dept. Pharmacol. & Toxicol., Univ. Texas Medical Branch, Galveston, TX, 77550.

We have previously reported that excitatory amino acids stimulate the release of ^{3}H-acetylcholine (ACh) and ^{3}H-dopamine (DA) from superfused rat striatal slices and that the release of both these neurotransmitters is inhibited by nanomolar concentrations of the psychotomimetic phencyclidine (PCP). This effect of PCP is selective for ACh release stimulated by action at the N-methyl-D-aspartate (NMDA)-sensitive glutamate receptor subtype and is shared by those members of the benzmorphan class of opiates and dioxolane dissociative anesthetics that demonstrate PCP-like properties in assays for the PCP/ sigma binding site and in several behavioral tests. We have now extended our findings to the nucleus accumbens septi (NAS) and the substantia nigra (SN).

Slices of rat brain NAS and SN were incubated in the presence of 50nM ^{3}H-choline or 50nM ^{3}H-dopamine for 30 min. Slices were superfused in plexiglas chambers supported by stainless steel mesh with physiological buffer containing 10μM hemicholinium-3 for ACh release experiments or 10μM pargyline and 1mM ascorbate for DA release experiments. Aliquots of superfusate collected in 3ml fractions were assayed for radioactivity by liquid scintillation spectroscopy. The amount of tritium efflux produced by 1mM NMDA alone was compared with that produced by NMDA in the presence of varying concentrations of PCP.

NMDA stimulated the release of both ACh and DA from NAS but only DA from the SN. NMDA-stimulated accumbens ACh release was completely inhibited by 0.5μM tetrodotoxin (TTX) and physiological concentrations of magnesium. Kainate (KA) and quisqualate (QA), agonists at the other glutamate receptor subtypes, also stimulated ACh release but were inhibited only 50% and 80%, respectively by TTX. Additionally, 1.2mM $MgCl_2$ did not significantly reduce the ACh release evoked by KA and QA. NMDA-stimulated ACh release was inhibited by PCP with an IC_{50} of 0.16μM. PCP (0.1μM) also significantly inhibited KA- and QA-induced ACh release.

The release of DA from the NAS by NMDA was inhibited by PCP with an IC_{50} of 0.11μM. PCP (0.1μM) did not significantly inhibit QA-stimulated DA release and significantly enhanced KA-stimulated DA release.

Similar to our previous work in the striatum, NMDA-stimulated ACh and DA release were potently inhibited by PCP with IC_{50}'s near 0.1μM and were selectively sensitive to physiological concentrations of magnesium. Unlike the striatum, PCP inhibited ACh release in the NAS stimulated by all three amino acid agonists. Interestingly, KA-stimulated DA release was enhanced by the inclusion of PCP in the superfusion buffer. Supported by DA-02073

FEEDING AND DRINKING IV

105.1 CONCENTRATIONS OF B-ENDORPHIN (BE) AND MET-ENKEPHALIN (ME) IN THE HYPOTHALAMUS OF SHEEP AFTER PERIPHERAL INJECTION OF CHEMICALS AFFECTING FOOD INTAKE. C.A. Baile, C.L. McLaughlin, D.H. Krestel-Rickert and M.A. Della-Fera. Washington University Medical School, St. Louis, MO. 63110.

There is increasing evidence that endogenous brain peptide concentrations may be related to degree of hunger and therefore may be affected by exogenous administration of chemicals which influence food intake. In the present experiments the effect of elfazepam (8 mg/kg), a food intake stimulant and of naloxone (.25 mg/kg), an opiate antagonist which decreases food intake, on concentrations of B-endorphin and met-enkephalin were measured in sheep. After a 4-hr fast following a meal, DMSO or the chemical were injected IV and sheep were fasted or allowed to eat a meal. Upon termination of the meal sheep were sacrificed and the following hypothalamic areas dissected out: anterior (AH), paraventricular (PVN), ventromedial (VMH), dorsomedial (DMH), lateral (LH) and posterior (PH). Tissue was extracted in .1N HCl and extracts assayed for peptide concentration. In the first experiment food intake was greater in elfazepam- than DMSO-injected sheep (290 vs 146g, p<.03). BE concentrations were lower in fed than fasted sheep in the AH (140 vs 155 pg/mg tissue, p<.04), LH (142 vs 174 pg/mg, p<.004) and PH (105 vs 137 pg/mg, p<.04). In addition, BE was lower in fed than fasted sheep injected with DMSO, but higher in fed than fasted sheep injected with elfazepam in the DMH (p<.02). ME concentrations were lower in elfazepam- than DMSO-injected sheep in the DMH and were higher in fed compared to fasted sheep in the AH (114 vs 87, p<.03), PVN (124 vs 90, p<.04), DMH (94 vs 50, p<.001), VMH (89 vs 53, p<.02) and PH (53 vs 33, p<.03). There were no interactions of drug and hunger condition in any area. In the second experiment, BE concentrations were lower in naloxone than saline-injected sheep in the PVN (148 vs 191 pg/mg, p<.05) and VMH (170 vs 194, p<.03) and were lower in fed than fasted sheep in the DMH (137 vs 164, p<.03) and PH (82 vs 96, p<.05). BE was higher in fed than fasted sheep injected with saline, but higher in fasted than fed sheep injected with naloxone in the AH (p<.05), PVN (p<.05), and VMH (p<.002). ME concentrations were not affected by drug or hunger condition alone, but analysis of significant interactions showed that ME was higher in fasted than fed sheep after saline injection and lower in fasted than fed sheep after naloxone injection in the AH (p<.03), PVN (p<.04), VMH (p<.002) and PH (p<.003). Thus, concentrations of opioid peptides were influenced not only by the degree of hunger, but also by peripheral administration of chemicals shown to influence food intake. Supported in part by NIH NS20000 and Monsanto Company.

105.2 PROLONGED NOREPINEPHRINE ADMINISTRATION FAILS TO STIMULATE BROWN FAT THERMOGENESIS IN SYRIAN HAMSTERS. J.M. Hamilton*, T.J. Bartness* and G.N. Wade. Dept. Psychology, Univ. Mass., Amherst, MA 01003 and Worcester Fdn. Expt. Biology, Shrewsbury, MA 01545.

Cold- and diet-induced nonshivering thermogenesis in rats are associated with increased sympathetic nervous system activity in brown adipose tissue (BAT). Daily injections of norepinephrine (NE) mimic these effects of temperature and diet on BAT of rats (Bartness, T.J. et al., unpublished; Rothwell, N.J. et al., Am. J. Physiol. 243:R339, 1982). Recently, however, Triandafillou, J. et al. (Am. J. Physiol. 247:E793, 1984) have reported a failure to elicit thermogenic responses in BAT of Syrian hamsters with daily injections of doses of NE which reliably stimulate BAT thermogenesis in rats (.4 mg/kg and .8 mg/kg). They concluded that the BAT response to cold acclimation or consumption of a palatable high-energy diet is not mediated by NE in Syrian hamsters.

Syrian hamsters require a higher dose of NE than rats to produce maximal thermogenic responses (Heldmaier, G. In: Effectors of Thermogenesis, eds. L. Girardier and J. Seydoux, 1978). It is possible that the doses used by Triandafillou et al. were insufficient to stimulate BAT of hamsters. We therefore conducted a partial replication of their study using .8 mg NE/kg and the recommended dose of 1.6 mg NE/kg for Syrian hamsters. In addition, we employed the twice daily injection regimen used for rats.

Adult male Syrian hamsters housed singly under a 16:8 h light: dark cycle with ad lib access to food and water were injected at 8 AM and 4 PM. Groups of hamsters (n=8) received two daily s.c. injections of vehicle or 1.6 mg NE/kg or an AM injection of .8 mg NE/kg and PM injection of vehicle. Hamsters were killed 14 days later and interscapular BAT (IBAT) removed and weighed. IBAT protein and NE content and mitochondrial GDP binding were measured.

Daily morning injections of .8 mg NE/kg had no effect on any of the parameters measured. Twice daily injections of 1.6 mg NE/kg resulted in significant decreases in body weight gain, food intake, and IBAT mass. Total IBAT GDP binding was decreased, but not significantly. NE content of IBAT was not affected.

These findings confirm those of Triandafillou et al. and therefore lend support to their conclusion that cold- or diet-induced changes in BAT of hamsters are not mediated by NE. This is consistent with the recent observation that thermogenic activity in BAT of high-fat-fed hamsters is not dependent on sympathetic stimulation (Hamilton, J.M. et al., unpublished). However, desensitization of BAT to sympathetic stimulation may also explain these results. We are currently investigating this possibility in hamsters with surgically denervated IBAT and in short day-housed hamsters in which BAT sympathetic activity might also be reduced.

105.3 POSTPRANDIAL INSULIN AND GLUCOSE ARE ELEVATED FOLLOWING AREA-POSTREMA ABLATION. Francoise J. Lacour*, Karon J. Sande*, Anne Robbins, Jon N. Kott, Daniel J. Porte, Jr., Stephen C. Woods and Nancy J. Kenney. (Spon. D. Finocchio) Department of Psychology, University of Washington and VA Medical Center, Seattle, WA 98195.

The area postrema and subjacent caudal medial nucleus of the solitary tract (AP/cmNTS) are reported to be closely connected with the autonomic nervous system. Thus, lesions of this region might be expected to alter gastric emptying rate, glucose absorption and/or insulin secretion. Therefore, in this study, the effect of meal ingestion on plasma glucose and insulin levels of fasted AP/cmNTS- and sham-lesioned rats was measured.

Twelve AP/cmNTS-lesioned and 11 sham-lesioned rats were studied beginning 25 wks after surgery. All rats were deprived of their standard laboratory chow for 15 hr prior to testing. Fifteen min after collection of 500 µl of tail blood for measurement of basal glucose and insulin (t_0), the rats were offered dilute sweetened condensed milk for 30 min. A second sample of tail blood was collected after the feeding session (t_{45}).

Lesioned rats did not differ from shams in either body weight at the time of testing or caloric intake during the test session. Lesioned rats weighed 418.3 ± 17.4 g and consumed 34.5 ± 2.6 kcal during the test. Sham-lesioned rats weighed 455.5 ± 16.4 g and ate 30.0 ± 2.3 kcal during the test session. Lesioned rats did not differ from the controls in basal levels of either insulin or glucose but had greater postprandial increases both of insulin ($F(1,21)=7.9$, $p<.01$) and of glucose ($F(1,21)=6.2$, $p<.05$) than did the sham-lesioned controls.

	Insulin (µU/ml)		Glucose (mg/dl)	
	t_0	t_{45}	t_0	t_{45}
APX[1]	6.8 ± 0.7	66.1 ± 14.1	144.8 ± 5.9	185.0 ± 7.8
Sham	9.6 ± 1.7	23.0 ± 4.2	147.7 ± 4.0	166.4 ± 5.9

[1] APX = AP/cmNTS lesioned

The increased glucose response and insulin release of the AP/cmNTS-lesioned rats may indicate a more rapid rate of glucose absorption following such ablation and suggests that this brainstem region may be involved in the physiological processes responsible for gastric emptying.

105.4 ATTENUATION OF HYPOPHAGIA FOLLOWING AREA-POSTREMA ABLATION BY CONTINUOUS DIET CHANGE. Naomi Tomoyasu and Nancy J. Kenney. Department of Psychology, University of Washington, Seattle, WA 98195.

Ablation of the area postrema and adjacent caudal-medial nucleus of the solitary tract (AP/cmNTS) results in a temporary reduction of food intake and a permanent decline of body weight. The reduction of food intake may be due, at least in part, to the development of an aversion to foods presented during the perisurgical period. Changing the lesioned rats' food results in a temporary increase of intake. However, intakes of the "new" food will decrease if access is continued for more than a few days. This study examines the possibility that continuous change of the lesioned rats' diet will attenuate the hypophagia which typically results from AP/cmNTS ablation.

Beginning immediately after surgery, 10 lesioned and 8 sham-lesioned rats were fed pelleted lab chow and one supermarket food (e.g., milk, salami, etc.) which was changed each day (ISM). For another 7 lesioned and 8 sham-lesioned rats (DSM), access to the supermarket foods was delayed for 5 days during which they were fed only the lab chow. An additional 7 lesioned and 7 sham-lesioned rats were fed only pelleted chow for the duration of the experiment. Intakes and body weights were measured daily.

Total daily caloric intakes of both ISM-fed ($F(1,16)=61.4$, $p<.01$) and DSM-fed ($F(1,13)= 6.9$, $p<.05$) lesioned rats were greater than those of lesioned rats fed only pelleted chow. But, intakes of the supermarket-fed, AP/cmNTS-lesioned rats remained below those of their similarly fed controls ($F(1,17)=34.8$, $p<.01$ for the ISM groups and $F(1,14)=20.4$, $p<.01$ for the DSM groups).

Whether the lesioned rats had access to the supermarket foods immediately after surgery or with some delay affected their choice of foods. The lesioned rats which had access to the supermarket foods immediately after surgery ate fewer calories from the supermarket foods than did their sham-lesioned controls ($F(1,17)=77.2$, $p<.01$). ISM-fed lesioned rats did not differ from their controls in the number of calories taken as pelleted chow. Lesioned rats for which access to the supermarket foods was delayed took fewer calories from the pelleted chow than did their controls ($F(1,13)= 20.0$, $p<.01$). These lesioned rats did not differ from their controls in the number of calories taken from the supermarket foods.

Thus, presentation of a choice of foods after surgery attenuates the hypophagia of AP/cmNTS-lesioned rats and results in a shift of preference for foods presented immediately after surgery.

105.5 PERSISTENCE OF GLYCOGEN DEPLETION IN CAUDATE AND HINDBRAIN PARALLELS PERSISTENCE OF FEEDING AFTER INSULIN-INDUCED GLUCOPRIVATION. L. Nzuzi* and S. Ritter, Dept. of Food Science and Human Nutrition, and College of Veterinary Medicine, Washington State University, Pullman, WA 99164-6520

It has been assumed that the glucoprivic control of feeding is activated by decreased availability of glucose to critical brain receptors in the caudal hindbrain. However, it has been demonstrated by R.C. Ritter et al. (Am J Physiol 234: E617, 1978) that if food is withheld after a high insulin dose, rats will still increase their intake even after the glucoprivic episode has abated spontaneously ("delayed glucoprivic feeding"). The fact that the delayed increase in feeding occurs when blood glucose, and presumably brain glucose availability, have returned to normal, suggests that the delayed feeding response may be controlled by some metabolic stimulus other than glucose itself. We speculated that brain glycogen levels may play such a role. Glycogen is the only form of stored energy in the brain and is stored in small amounts which are vulnerable to fluctuations in glucose availability. Although it is known that whole-brain glycogen levels are closely tied to blood glucose levels, regional glycogen levels during the development of and recovery from insulin-induced hypoglycemia have not been measured. For these reasons, we analyzed glycogen content in major brain regions during the 8 hrs following insulin injection.

Male Sprague-Dawley rats were injected with insulin (2.5 U/kg, i.p), and 6 rats were sacrificed by focused microwave irradiation 0, 2, 4, 6 and 8 hrs later. Plasma glucose was measured at each of these time points until sacrifice. Microwaved brains were dissected into the following regions: cortex, caudate, thalamus, hypothalamus, cerebellum and caudal hindbrain. Glycogen was measured fluorometrically, using a modification of the amyloglucosidase technique (Nahorski and Rogers, Anal Biochem 49: 492, 1972).

Plasma glucose levels fell to 25 ± 2.1 mg% by 2 hrs after insulin injection and recovered to basal values of approximately 100 mg% by 6 hrs. Glycogen (% of control) fell to the following levels by 2 hrs after insulin: 32.0% (hypothalamus), 13.9% (thalamus), 2.3% (cortex), 6.5% (caudate), 15.7% (cerebellum, and 4.6% (caudal brain stem). Recovery of basal glycogen levels closely paralleled recovery of blood glucose levels in all brain regions except caudate and caudal brain stem. In these two regions glycogen levels were still reduced at 6 hrs (63.5% and 62.7% of control) and 8 hrs (74.1% and 76.6%) after insulin. Thus, our results would be consistent with the possibility that delayed feeding after insulin may be controlled by glycogen depletion in the caudal hindbrain or caudate.

105.6 SUPPRESSION OF FOOD INTAKE BY LOW DOSE INFUSION OF BOMBESIN INTO THE FOURTH VENTRICLE. E.E. Ladenheim* and R.C. Ritter. Dept. of VCAPP, Washington State University, Pullman, WA 99164 and WOI Regional Program in Veterinary Medical Education, University of Idaho, Moscow, ID 83843.

Several investigators have shown that bombesin administered into the lateral ventricles produces marked suppression of food intake. Suppression of food intake, however, is accompanied by enhancement of behaviors, such as grooming and increased locomotion, which are atypical of normal satiety. For example, Kulkosky et al. (1982) have shown that lateral ventricular infusion of bombesin increases grooming and scratching and decreases resting behaviors in rats. Therefore, it has been suggested that suppression of food intake by lateral ventricular bombesin results from activation of behaviors which compete with feeding and is not indicative of a direct effect of bombesin on neural substrates for the control of food intake.

Recently, however, high affinity binding sites for bombesin-like peptides have been described in several hindbrain structures implicated in the control of food intake. Therefore, we have examined the effects of fourth ventricular bombesin administration on food intake and motor activity of rats. Doses of 1, 5, and 25 ng were administered prior to presentation of a palatable solid food, cookies. Dose-dependent reductions in food intake were statistically significant by fifteen minutes after infusion, producing suppressions of 36.4 ± 8.6%, 55.0 ± 10.2% and 79.7 ± 7.1%, respectively. Computer-assisted monitoring of movement was examined and a behavioral inventory was obtained by direct observation following bombesin doses of 1 and 25 ng. Although significant reductions in food intake were apparent at both the 1 and 25 ng doses, increased motor activity was negligible at the 1 ng dose. The 25 ng dose, however, elicited a significant increase in activity confirming the increased grooming reported by Kulkosky et al.

These results demonstrate that bombesin administered into the fourth cerebral ventricle of the rat is a potent suppressor of food intake at doses which are lower than those previously reported for lateral ventricle infusion. In addition, increases in motor activity attributed to ventricular infusion of bombesin were not apparent at the lowest dose shown to produce significant suppressions of feeding. These findings suggest that the hindbrain may be a sensitive site for bombesin-induced suppression of food intake.

105.7 SUPPRESSION OF FEEDING BY GLUCAGON AFTER SELECTIVE HEPATIC VAGOTOMY IN RATS. S.C. Weatherford and S. Ritter. College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Selective hepatic vagotomy (HV) has been reported to abolish glucagon-induced suppression of food intake (Geary and Smith, Physiol Behav 31: 391, 1983). However, HV rats have been tested for glucagon satiety under a limited set of conditions: i.e., with a palatable liquid food during the light phase of the circadian light cycle. Therefore, we tested the effects of glucagon on food intake of HV rats (n = 12) and sham operated controls (n = 8) under several testing conditions. In agreement with Geary and Smith, glucagon (200 µg/kg ip) did not inhibit feeding in non-deprived HV rats tested 6 hr after lights on with a palatable liquid food. Controls ate 82 ± 7% ($p < .02$) and HV rats ate 99 ± 4% of their baseline intake under these conditions. Furthermore, after 10 hr food deprivation in tests conducted 2 hr after lights on, glucagon (100 µg/kg) did not suppress feeding in either HV rats or controls. HV rats consumed 95 ± 5% ($p > .1$) and controls consumed 120 ± 12% of their baseline intake ($p < .03$) under these conditions. However, when tested 2 hr after lights off following 8 hr of deprivation, glucagon reduced food intake in both HV rats and controls (83 ± 6% and 78 ± 9% of baseline, respectively, $p < .01$ for both groups).

We reported previously that hepatic portal injection of subdiabetogenic doses of alloxan impairs glucagon satiety. Alloxan-treated (AT) rats fail to suppress their food intake in response to glucagon when tested during the day with a palatable liquid food or when tested 1 or 2 hr after lights off with pelleted food. Although mechanisms responsible for alloxan's effect are still under investigation, our data are compatible with the possibility that alloxan damages hepatic vagal fibers. If so, glucagon-induced suppression of feeding might be observed in AT animals, as it is in HV rats, if the feeding test were moved farther into the dark phase of the light-dark cycle. Indeed, we found that when food deprived for 8 hr and tested 3 hr after lights off, both AT rats and controls suppressed their food intake in response to glucagon (74% and 76% of baseline, $p < .008$).

Our results suggest that the hepatic vagus participates in the behavioral response to glucagon, but does not account for all of glucagon's effects on feeding since glucagon inhibits feeding in vagotomized animals under some circumstances. Furthermore, the similarity of AT and HV rats in this respect supports the hypothesis that alloxan-induced impairment of glucagon satiety is mediated by vagal damage.

105.8 AN ANIMAL MODEL OF CHRONIC ANOREXIA NERVOSA? Michael Buck*, Steve Efthyvoulidis*, Mary Ann Marrazzi and Elliot D. Luby*. Depts. of Pharmacology & Psychiatry, Wayne State University School of Medicine, Detroit, Michigan 48201.

An auto-addiction opioid model of chronic anorexia nervosa has been proposed by our laboratory (Marrazzi & Luby, Int. J. Eating Disorders, in press, Winter 1986). According to this model, an initial period of dieting induces the release of endogenous opioids. These opioids are then the substrate for a positively reinforcing elation associated with dieting and induce an enduring life-threatening weight loss. An addiction to dieting results. Endogenous opioids may play a dual role in the response to starvation. 1) They increase food intake to correct it. 2) They adapt the organism for survival until nutritional repletion can occur. This involves down-regulating physiological and metabolic processes to the minimum essential. If these two responses become uncoupled, disorders of either anorexia or obesity can occur. Addiction to the second response may result in chronic anorexia nervosa. Evidence in the literature support these opioid actions and such opioid release and/or changes in the opioid systems with starvation. Evidence exists for disturbances of endogenous opioids in anorexia nervosa. The clinical picture of anorexia nervosa resembles that observed in the addictive disorders. Because endogenous opioids may mediate the auto-addictive state, narcotic antagonists may be therapeutically very useful. Clinical studies are beginning on the use of opiate blockade in the eating disorders and will be reported elsewhere.

We propose that the endogenous opioid systems of chronic anorexia nervosa patients may resemble those of mice as contrasted to those of most species including the normal human subject. Morphine causes sedation and increases food intake and blood glucose in most species. Mice are atypical in that they increase their locomotor activity in response to morphine. We report here that in female BALB/C mice, morphine decreases rather than increases both food intake and blood glucose, as well as increasing locomotor activity. Thus, the mice become hyperactive and anorexic as in anorexia nervosa.

105.9 THE ROLE OF FOOD INTAKE IN ADIPOSITY REDUCTIONS PRODUCED BY MORPHINE IN THE RAT. R. Ottaviani, J. P. MastroPaolo, & A. L. Riley. Psychopharmacology Lab, The American University, Washington, D.C. 20016

Although morphine reduces adiposity within a variety of paradigms, at present it is not certain that a single mechanism can account for this effect in every situation. In vitro reductions in adiposity may be reasonably attributed to a direct breakdown of fat by morphine, but the reductions in 24-h food intake following morphine administration (Heft, M., Daniels, G., Buller, A., & Riley, A., Neurosci, 1981; Riley, A., West, D., Sipol, A., & Woods, S., Neurosci, 1983) may account for the in vivo reduction in adiposity. Following the demonstration in Experiment 1 that both food intake and adiposity were concurrently reduced following in vivo morphine administration, Experiment 2 was conducted to examine the contribution of this reduction in 24-h food intake to the in vivo reduction in adiposity. Specifically, 24 rats in Experiment 2 were divided into two groups, one injected for 21 days with 40 mg/kg of morphine and the other with equivolume distilled water. Throughout these 21 days, immediately following the injection half of the morphine-injected rats and half of the distilled-water injected rats were presented with the amount of food consumed by morphine-injected rats in Experiment 1. The remaining rats in each group were presented with the amount of food consumed by control animals in Experiment 1. Prior to the daily injection, animals were gavaged with any food remaining from the 24-h ration. Both retroperitoneal and ovarian fat pads and gastrocnemius muscles were removed and weighed at the end of the study. Relative to the distilled-water injected rats, animals administered morphine had reduced fat pad weight. This reduction was independent of their daily food intake, i.e., there was an equivalent reduction in adiposity in morphine injected subjects given the morphine diet and the control diet. In addition, there was no reduction in adiposity evident in either of the control groups, even when the diet was restricted, i.e., the morphine diet. These data suggest that the in vivo reductions in adiposity are not related to changes in food intake and are instead a more direct effect of morphine, e.g., an increase in lipolysis or a decrease in LPL activity. Independent of the mechanism responsible for the morphine induced reduction in adiposity, these data are consistent with the possible role the endorphins play in both homeostatic feeding and stress reactions.

105.10 INTERACTION BETWEEN GLUCOSE AND LIPID METABOLISM IN THE CONTROL OF FOOD INTAKE IN RATS. M.I. Friedman*, M.G. Tordoff and I. Ramirez* (SPON: E. Kosar). Monell Chemical Senses Center, Philadelphia, PA 19104.

Changes in glucose and lipid metabolism are believed to provide separate but complimentary signals in the control of short- and long-term food intake. To determine whether glucose and fat metabolism interact directly in the control of eating, we examined the combined effects on food intake of intracellular glucopenia produced by injection of 2-deoxyglucose (2DG) and pharmacological inhibition of either fatty acid oxidation or lipolysis.

Male albino rats were given the fatty acid oxidation inhibitor, methyl palmoxirate (MP; 10mg/kg, p.o.) or vehicle (0.5% methyl cellulose) 2 hr prior to i.p. injection of either saline or 100, 200 or 400 mg/kg 2DG. Whereas MP did not affect food intake (6 hr test) in saline-treated rats, rats given MP ate significantly more than vehicle-treated rats after injection of 100 and 200 mg/kg 2DG. For example, relative to when they were given saline, vehicle-treated rats injected with 100 mg/kg 2DG failed to significantly increase intake in the first 2 hr (0.11 ± 0.04 vs. 0.72 ± 0.28). In contrast, MP-treated rats markedly increased food intake after injection of 100 mg/kg 2DG during the same interval (0.07 ± 0.03 vs. 3.46 ± 0.58). MP did not affect the response to 400 mg/kg 2DG, although intakes of MP-treated rats at the lower doses of 2DG were comparable to those at the 400 mg/kg dose, suggesting a maximal response to the low doses in MP-treated rats. MP did not alter plasma glucose levels at the time of 2DG injection nor did MP reduce the hyperglycemia produced by 100 mg/kg 2DG. This shows that the differential eating response of MP- and vehicle-treated rats was not due to differences in the competition between endogenous, circulating glucose and the glucose analogue. Consistent with its inhibitory action on fatty acid oxidation, MP reduced plasma ketone and elevated plasma free fatty acid levels in saline- and 2DG-treated rats.

The antilipolytic agent, nicotinic acid (NIC; 150 mg/kg, s.c.) given 10 min prior to i.p. injection of 100 mg/kg 2DG also potentiated the eating response to 2DG, whereas NIC alone had no effect on food intake.

These synergistic effects of combined treatment with 2DG and MP or NIC indicate that controls of food intake associated with changes in glucose and fat metabolism share a common mechanism.

105.11 HYPERPHAGIC AND ANORECTIC DRUG EFFECTS IN NONDEPRIVED RATS GIVEN A HIGH PALATABILITY DIET. S.J. Cooper, A. Jackson* and D.B. Gilbert*. Dept. Psychology, University of Birmingham, Birmingham B15 2TT, U.K.

A method which allows limited daily access to a high palatability diet has been used with male rats maintained on ad libitum food and water to investigate the effects on food consumption of kappa opiate receptor agonists, dopamine (D) receptor agonists and antagonists, and benzodiazepine (BZ) receptor agonists and inverse agonists. The aim has been to develop a sensitive and reliable method for detecting both hyperphagic and anorectic drug effects. The rats were first familiarised with the palatable diet, composed of powdered standard rat diet, sweetened condensed milk and water, before the drugs were administered.

A series of experiments was carried out with several kappa receptor agonists administered subcutaneously: the selective drugs, U-50,488H and tifluadom, each produced significant increases in food intake. Bremazocine and ethyketocyclazocine (EKC), however, both decreased food consumption. However, when rats were allowed to consume a pre-load before the drug administration and subsequent testing, 0.01 mg/kg bremazocine and 0.1 mg/kg EKC each produced hyperphagic effects. Morphine (0.3 - 10.0 mg/kg, s.c.) did not have a hyperphagic effect in either case. The degree of feeding satiation may be an important factor, therefore, in the sensitivity of the test to hyperphagic effects of some kappa agonists.

Hyperphagia was also produced by agonists (e.g. clonazepam, lorazepam, diazepam, zopiclone, CL218,872) acting at BZ receptors. Conversely, compounds which are believed to act as 'inverse agonists' at BZ receptors (e.g. DMCM, FG 7142, CGS 8216) produced a dose-dependent attenuation of food intake. These interesting data suggest a possibility of a bidirectional control of the appetite for palatable food operating through differential ligand actions at BZ receptors (Cooper, S.J. and L.B. Estall, Neurosci. Biobehav. Rev. 5: 5-19, 1985).

Anorectic effects were also obtained using either d- or l-amphetamine, and using the specific D1 receptor agonist SKF 38393. The anorectic effect produced by 0.3 mg/kg d-amphetamine (i.p) was reversed by the D1 receptor antagonist, SCH 23390 (0.01 - 0.1 mg/kg s.c.) but not by the D2 receptor antagonist, sulpiride (3.0 - 30.0 mg/kg, i.p). Such data suggest an involvement of D1 receptors underlying amphetamine-induced anorexia, in part at least, and more generally, in the control of feeding responses.

105.12 BEHAVIORAL EFFECTS INDUCED BY QUALITATIVE CHANGES IN DIETARY FAT. D.V. Coscina, S. Yehuda and C.E. Leprohan. Sect. of Biopsychol., Clarke Inst. of Psychiatry, and Dept. of Nutr. Sci., Univ. of Toronto, Toronto, Ontario, Canada M5T 1R8.

Past research has shown that altering the nutrient composition of diets can produce a variety of biochemical and/or behavioral changes in experimental animals. Perhaps the best known of these changes are those associated with brain catecholamine and indoleamine metabolism following manipulations of their dietary precursors, tyrosine and tryptophan, respectively (e.g., J.D. Fernstrom Ann. Rev. Med., 32: 413, 1981). Contrasting to this, relatively little is known about the potential importance of dietary lipid to behavior and brain chemistry. We have begun to assess this question by measuring a variety of behaviors in rats fed diets differing only in the type of fat supplied. Subjects used were male albino (Sprague Dawley) or hooded (Long Evans) animals weighing 80 - 100 g at the outset of study. Across three separate replications, rats were offered ad libitum access to standard Purina Lab Chow (4% fat; n = 15) or one of two semi-purified diets containing equal protein (casein; 200 g/kg), carbohydrate (corn starch; 402 g/ kg), fat (200 g/kg) and vitamin/mineral mix (76 g/kg). However, the source of fat varied for the two groups (soya, n = 32; lard, n = 22). After 3 wk of eating these diets there were no differences across groups in total kcal consumed or body weight gained. Also, 15 min tests of activity in an open field revealed no differences in the number of horizontal crossings or vertical rears made. However, latencies to lick paws when placed on a 58° C hot plate were consistently longer for soya-fed rats (13.0 ± 4.8 sec., M ± SEM) compared to lard-fed (9.4 ± 3.3) or chow-fed (8.3 ± 2.1) animals. In addition, the ability of 10 or 15 mg/kg amphetamine sulfate i.p. to induce hypothermia in a 4° C ambient environment for 60 min was prevented in soya-fed (+1.3 ± 0.8° C colonic temperature change from baseline) but not lard-fed (-1.2 ± 0.8) or chow-fed (-2.7 ± 0.9) animals. Finally, preliminary results suggest that soya-fed rats show improved performance of a spatial learning task compared to rats in either of the other two groups. Taken together, these findings provide striking new evidence that the quality of dietary fat can produce robust changes in several rodent behaviors. Further work is underway to elucidate the behavioral and biochemical substrates of these modest dietary manipulations.

105.13 MONKEY LATERAL HYPOTHALAMIC ACTIVITY (LHA) DURING FEEDING TASK: PARTICIPATION OF CATECHOLAMINES AND OPIATE. Y. Oomura, H. Nishino, S. Aou and L. Lénárd*. Dept. of Physiol., Fac. of Med., Kyushu Univ. 60, Fukuoka 812; National Inst. Physiol. Sci., Okazaki 444, Japan; Univ. Med. School, Pécs, Hungary.

Correlation between single LHA neuron activity, bar press feeding, and modulation by electrophoretic catecholamines and an opiate were investigated. The paradigm was: i) Cue light on to start bar pressing. ii) Bar pressing (fixed ratio, FR, 30). iii) Short cue tone and food reward at end of bar pressing. iv) Taking and ingesting food. Of 171 neurons tested, 94 (55%) changed activity in one or more phases. Of 94 responding neurons, 15 (16%) responded at cue light on, 73 (78%) during bar press, 17 (18%) at cue tone, and 48 (51%) during reward. Bar press responses increased in trials for more palatable food, and decreased during no reward (extinction) or satiation. Dopamine (DA) excited 18%, and inhibited 26% of 200 neurons tested. Noradrenaline (NA) and morphine inhibited ½ of the neurons tested.

Glucose-sensitive (GS) neurons (38% of 143 tested) responded more than non-GS neurons in feeding tasks. Most GS neuron responses were decrease of activity during bar press and reward phases, but not at onset of initial light cue. Responses disappeared during high blood glucose level due to i.v. glucose injection. When non GS neurons responded, it was more often increase of activity at cue light on, before start of bar press and during reward. Reward responses of GS neurons (especially inhibitory) were probably opiate mediated, since they were blocked by naloxone, which did not affect other responses. Cue tone responses were suppressed by α-adrenoceptive blocker, and bar press responses were (in 3/11 cases) suppressed by β-adrenoceptive blocker. Non GS neurons that responded to cue light on and bar press initiation appeared to be DA sensitive, since DA antagonist blocked the responses. A mediator for bar press responses is not yet known.

Summary: Many LHA neurons responded during task; magnitudes and numbers of responses depended on motivational state. Opiate and catecholamines modulated effects, especially reward related responses. DA is important to external sensory integration and task initiation, NA to drive reduction (motor termination), and opiate to reward perception. DA sensitive neurons might integrate external information while GS neurons integrate internal information. A working hypothesis to guide later investigation presents GS neurons as integrating elements that combine various aspects of internal conditions and then project to effector neurons to control both initiation and termination of overt feeding related behavior.

106.1 ROLE OF KINASE C IN NEUROTRANSMITTER RELEASE. C.T. Giambalvo, Rhode Island Psychiatric Research & Training Center, University of Rhode Island and Brown University, Cranston, RI 02920

Protein kinase C is a Ca/phospholipid requiring enzyme that has been implicated in the release process. The experimental support for this hypothesis has been derived mostly from platelet studies and as yet, there is no direct evidence linking kinase C with the release of neurotransmitters in nervous tissues. In order to study the relationship between kinase C activity and the release of neurotransmitters, the effects of drugs on kinase C activity and release were examined in striatal synaptosomes in vitro and after injections in vivo.

In the release experiments, a striatal synaptosomal preparation was prelabelled with 0.01 μM - ^{3}H-DA and KCl (25mM) was added to induce depolarization. The amount of radioactivity released into the medium was expressed as a percent of total radioactivity. Kinase C activity was determined in tissue homogenates in an incubation medium containing Ca (16μM), phosphatidylserine (32μg/ml), diolein (3μg/ml), histones (0.2mg/ml), Tris buffer with $MgCl_2$ (6mM) (pH 7.4) and ^{35}S-ATP (12μM). After incubating 4 minutes at 30°C, the reaction was terminated with TCA. The precipitated protein was then counted.

Results indicated that: (1) there was a correlation between drugs affecting kinase C activity and the release of DA from striatal synaptosomes in vitro; (2) acute injection of drugs into rats that affect the firing rate of the nigrostriatal pathway and release of DA also affected kinase C activity, in both the striatum and substantia nigra; and, (3) chronic injections of neuroleptics into rats which inhibited release and firing rate also resulted in a decrease in striatal kinase C activity.

These results support the hypothesis that kinase C plays an important role in the release of DA in the nigrostriatal pathway.

106.2 A VINBLASTINE SENSITIVE HIGH AFFINITY CHOLINE UPTAKE SYSTEM M.T. Ivy* and J.G. Townsel. Department of Physiology and Biophysics, University of Illinois at Chicago, College of Medicine, Chicago, IL 60680 and Department of Physiology, Meharry Medical College, Nashville, TN 37208.

There is significant evidence that the high affinity choline uptake system (HAChUS) associated with cholinergic terminals may not be restricted to cholinergic neurons [Masland, R.H. and Mills, J.W., Proc. Natl. Acad. Sci. 77: 1671-1675, 1980]. Recent evidence implicates the HAChUS in the synthesis of phosphorylcholine (PCh), an intermediate of membrane phospholipid [Pu, G.A. and Masland, R.H., J. Neurosci. 4: 1559-1576, 1984]. We have recently characterized a non-cholinergic HAChUS in the cardiac ganglion (CG) of Limulus [Ivy, M.T., et al., J. Comp. Biochem. Physiol., (In Press)]. A physiologically significant property of the Cholinergic HAChUS is that of post-depolarization stimulation. Preincubation of the CG in 90 mM K^+ Chao's resulted in a 46% increase in high affinity choline uptake. The CG HAChUS appears related to the spontaneous electrical activity of this tissue. Micromolar concentrations of 5-hydroxytryptamine (5-HT) have been shown to reduce the spontaneous activity of the CG. The CG HAChUS was inhibited nearly 40% following 10 μM 5-HT preincubation. When the CG was preincubated in Chao's solution containing 10, 100 and 500 μM vinblastine (VB), high affinity choline uptake was inhibited 40, 51 and 64%, respectively. Similarly, 2, 4 and 8 hour preincubations of the CG in 500 μM VB Chao's resulted in a 52, 64 and 71% decrease in the HAChUS, respectively. In pulse-labelling experiments we examined the relative distribution of [^{3}H] in the soluble versus the insoluble fraction following high affinity uptake in the CG. The CG was incubated in 0.1 μM [^{3}H]choline Chao's for 60 min. Following several Chao's washes, the CG was incubated for 1, 2 or 4 hours with unlabelled choline (1 mM). After 2 hours, a 3-fold increase of radioactivity above basal level was measured in an insoluble (pellet) fraction of the CG. Subsequent studies revealed that prior exposure of the CG to 500 μM VB completely eliminated this increase of radiolabel in the pellet fraction. Treatment of the labelled pellet with trypsin resulted in the solubilization of a substantial proportion of the radioactivity. These results are interpreted as supportive of a possible role of the CG HAChUS in the supply of choline subserving the synthesis of membrane phospholipid associated with synaptic vesicle turnover.

106.3 SUBCELLULAR STORAGE OF SEROTONIN IN A PARANEURON J.M. Barasch*, M.D. Gershon, E.A. Nunez* and H. Tamir. NY State Psych. Inst. and Dept. Anatomy & Cell Biol., Columbia Univ. P&S, NY 10032.

Serotonin (5-HT) is a neurotransmitter of central and enteric neurons. It is also found in parafollicular (PF) cells of the sheep thyroid. Within both neurons and PF cells, 5-HT appears to be stored in specialized subcellular storage vesicles, sometimes with a peptide, as for example calcitonin (CT) in PF cells. Neither the mechanism of uptake of 5-HT by vesicles, nor their means of retaining 5-HT, have been established. Although 5-HT-containing synaptic vesicles cannot be isolated from mixed populations of neural vesicles, purified PF cells can be obtained by the novel technique of phagocytic chromatography. Since PF cells, like neurons, are neurectodermal derivatives and contain the specifically neuroectodermal type of serotonin binding protein, we have used PF cells as a model system to investigate the properties of 5-HT storage organelles (5-HT/CT vesicles). 5-HT/CT vesicles were isolated by separating organelles by size and by density on two sequential Metrizamide gradients. Fractions were monitored using enzymatic markers, 5-HT and CT content, and by quantitative electron microscopy (EM). EM techniques included the demonstration of 5-HT and CT in vesicles by immunocytochemistry with colloidal gold. 5-HT/CT vesicles were found to take up ^{3}H-5-HT by a reserpine-sensitive mechanism. Luciferin-luciferase assays and uranaffin cytochemistry demonstrated that 5-HT/CT vesicles contain little or no ATP. Using acridine orange trapping, we found that 5-HT/CT vesicles have an ATP driven (N-ethyl maleimide sensitive, oligomycin insensitive) proton pump and can acidify their interior; however, the degree of acidification appears to be limited by the generation of a transmembrane potential difference (intravesicular positive) secondary to the translocation of H^+. Collapsing this potential with the K^+ ionophore, valinomycin, increased the pH gradient. Using acridine orange trapping with a fluorescence-activated cell sorter, PF cells were found to vary greatly in their content of acid granules. EM immunocytochemical detection of weak base accumulation confirmed the heterogeneous acidification of 5-HT/CT vesicles in intact PF cells. H^+ pumping into vesicles was increased by the K^+ ionophore, valinomycin, by the 5-HT secretagogues TSH and Ca^{+2}, and was blocked by the K^+/H^+ exchange ionophore, nigericin. This investigation represents the first isolation of a neuroectodermal type of 5-HT storage organelle. These vesicles appear to be different from other neurotransmitter vesicles in that they contain little or no ATP and have a proton pump that appears to be susceptible to physiological regulation. The effect of secretagogues suggests that vesicle acidification may be involved in the exocytotic release of hormones. Supported by NIH grants NS12969, AM19547, NS07062, NIMH37575.

106.4 EFFECTS OF AGE AND INCUBATION TIME ON NOREPINEPHRINE UPTAKE AND Na^+-K^+ ATPase ACTIVITY IN SHR AND WKY SYNAPTOSOMES. K.L. Hough, J.H. Rho, Y.T. Jeng, and A.A. Ross. Depts. of Medicine and Pathology, Schools of Medicine and Pharmacy, Univ. of Southern California, Los Angeles, CA 90033.

In order to examine the hypothesis that the transmembrane NE uptake system is affected by aging in spontaneously hypertensive rat (SHR) and Wistar Kyoto (WKY) controls, we studied the reuptake process directly in the synaptosomes from the hypothalamus of SHR and WKY between 4 and 41 weeks of age. The gradient-purified synaptosomes demonstrated NE uptake that was highly Na^+-dependent (90% average) and ouabain sensitive (50-60%). Initial uptake was measured using a 2 minute incubation at 30° C. In 13 paired experiments, from age 4 to 7 weeks, SHR had a significantly higher uptake of NE than WKY ($p < .05$), a trend which continued up until 10 weeks of age ($N=20$, $p < .02$). However, 13 additional paired experiments between ages 11 and 41 weeks failed to show any appreciable difference in initial uptake between SHR and WKY.

Our previous work utilized similar conditions but a 10 minute incubation. Under these conditions, 13 paired experiments of SHR and WKY between 8-10 weeks of age showed that WKY accumulates an average of 23% more NE than SHR ($p < .01$).

To better examine the effect of incubation time upon synaptosomal uptake and accumulation, synaptosomes from 3 SHR and 3 WKY rats (4 weeks old) were pooled, and tested for NE uptake and EM analysis. In two different experiments SHR took up more NE than WKY at 2 minutes incubation, but at all following time points WKY accumulated more NE than SHR. Minus Na^+ and 0° C. conditions remained low at all time points up to 30 minutes incubation, indicating minimal effects of vesicular or nonspecific uptake. EM analysis verified that synaptosomes remain remarkably intact at all incubation times up to 30 min.

In addition, Na^+-K^+- ATPase activity was examined in the same brain from which the hypothalamic synaptosomes were prepared. SHR enzyme activity is not only parallel to the rates of initial NE uptake but also age-dependent. Thus, the enzyme activity of SHR was higher than that of WKY (5-25%) during 5-9 weeks of age and then declined below those of WKY samples. We postulate that such an increased Na^+-K^+- ATPase activity in brain of juvenile hypertensives may be a compensatory increase for a reduced fractional sodium excretion by young SHR.

106.5 SYNEXIN INDUCES FUSION OF CHROMAFFIN GRANULE MEMBRANES BY A MECHANISM THAT IS INDEPENDENT OF CALCIUM AND ARACHIDONIC ACID. A. Stutzin*, P.I. Lelkes*, I. Cabantchik*, E. Rojas*, H.B. Pollard (SPON: C.R. Creveling). Laboratory of Cell Biology and Genetics, NIADDK, National Institutes of Health, Bethesda, MD. 20205.

Membrane fusion is a key event in numerous biological processes, including neurotransmission and exocytosis, and may be regulated by intracellular proteins, such as synexin, a calcium binding protein found in adrenal medulla and other secretory tissues. It has been shown that synexin promotes massive aggregation of chromaffin granules in a calcium dependent manner, followed by fusion if arachidonic acid is subsequently added. To study the mechanism of synexin-induced fusion we devised a novel on-line fluorescence assay in which chromaffin granule ghosts (CGG) were loaded with a self-quenched concentration of fluorescein-tagged Dextran (m.w. 20000) using a freeze-thaw technique. The labelled CGG were mixed with identically treated empty CGG in a ratio ranging between 1:5 - 1:10 and in the presence of specific rabbit antifluorescein antibodies in the medium. These antibodies quenched the fluorescent signal occurring during leakage, so that any increase in fluorescence came from dequenching of the dye due to dilution of the marker molecule into a space not accessible to the antibody, i.e. mixing of the CGG contents upon fusion. Under these conditions a rapid but clearly resolved increase in the fluorescence signal was observed after the addition of purified synexin. The changes were dependent on the synexin concentration and were inhibited by a specific polyclonal antisynexin antibody. Fusion occurred even at 10^{-9} M free calcium concentration and raising the free calcium concentration to 10^{-2} M had no influence on the reaction. The fusion event was pH dependent and the time course of the event was on the order of minutes, in agreement with other in-vitro fusion assays. The addition of other proteins like BSA or non-specific IgG failed to induce fusion events. The fusion event could also be coincidently followed by mixing of membrane lipids using octadecylrhodamine B, a non-exchangeable lipid analog. The validity of this fusion assay was confirmed using the well known terbium/dipicolinic acid fusion assay in a phosphatidylserine liposome system. The data support the notion that synexin could play an important role in membrane fusion during exocytosis, and that some aspects of synexin action may not depend on calcium.

106.6 INFLUENCE OF CALCIUM AND CYCLIC ADENOSINE MONOPHOSPHATE ON SEROTONIN SECRETION FROM THE HYPOTHALAMUS. H.A.F. Navarro*, R.F. Walker*, and V.J. Aloyo. Sanders-Brown Center on Aging, University of Kentucky Medical Center, Lexington, KY 40536.

Potassium (K^+) stimulates the release of monoamines from brain tissue in vitro. Calcium (Ca^{++}) and its binding proteins, as well as inositol phospholipid (PI) and cyclic nucleotide second messengers are thought to contribute to the secretory process. In the present study we examined the effects of Ca^{++}, A23187 (a Ca^{++} ionophore), phorbol 12-myristate 13-acetate (PMA; protein kinase C activator), and forskolin (adenylate cyclase activator) upon K^+-induced release of serotonin (5HT) from slices of hypothalamus (0.5mm) that were prepared rapidly from the brains of decapitated Long-Evans rats (male; 6 months old). Their endogenous 5HT pool was radiolabeled by incubating the slices in ^{3}H-5HT (1.0 mM; 30 min.). Afterwards, they were perifused with oxygenated buffer [Krebs-Ringer-Hepes (KRH), $CaCl_2$=2.5mM; KCl=6mM; ascorbate and pargyline-10^{-4}M] at a flow rate of 480ul/min. ^{3}H-5HT content of 1 min. fractions was monitored and a stable baseline efflux was achieved after perifusion for 30 min. When the concentration of KCl was increased to 45mM in osmotically equivalent buffer, ^{3}H-5HT release significantly exceeded baseline values. The magnitude of the K^+-induced ^{3}H-5HT release, but not the basal efflux was attenuated when Ca^{++}-free buffer plus EGTA was added. In contrast, preincubation of tissue slices in A23187 prior to K^+ stimulation potentiated ^{3}H-5HT release by the cation. However, the magnitude of ^{3}H-5HT release after perifusion with standard KRH buffer containing the ionophore was not comparable to that produced by K^+. Thus K^+ induced secretion does not occur solely as the result of Ca^{++} influx into the tissue. Instead, Ca^{++} may complement other factors which mediate ^{3}H-5HT release. PMA and forskolin were then used to determine if PI or cAMP second messengers, respectively, participate in the secretory process. Forskolin (100mM) but not PMA (0.1 or 1.0uM) significantly enhanced ^{3}H-5HT release in standard as well as EGTA containing KRH. These findings indicate that cAMP dependent processes contribute to ^{3}H-5HT release from hypothalamic slices in vitro. The inability of EGTA to block the forskolin effect suggests that extracellular Ca^{++} is not required for cAMP-mediated release of ^{3}H-5HT. However, synergistic interactions of intracellular Ca^{++} and cAMP dependent processes may occur and is the subject of ongoing investigation.

106.7 **MECHANISTIC STUDIES OF ACETYLCHOLINE STORAGE AND DRUG INHIBITION.** S.M. Parsons, B. Bahr*, and D.A. Anderson*. Department of Chemistry, University of California, Santa Barbara, CA 93106.

Highly purified cholinergic synaptic vesicles isolated from Torpedo electric organ actively transport [^{3}H]acetylcholine(ACH) in the presence of MgATP. The steady state inital velocity uptake exhibits Michaelis-Menten like kinetics with an ACh K_m of about 0.3 mM and a V_{max} of about 1 nmol/min/mg, depending on the preparation of vesicles. Nonradioactive ACh is a competitive inhibitor with respect to [^{3}H]ACh. The potent tertiary amine inhibitor dl-trans-2- (4-phenylpiperidino)cyclohexanol (AH5183) is a noncompetitive inhibitor with respect to [^{3}H]ACh with K_i 41 nM. Inhibition is not readily reversed by washing of vesicles. The l-optical isomer of AH5183 is 55-fold more potent than the d-isomer. Some 60 analogs of the drug have been synthesized and evaluated. Drug potency is very dependent on analog structure. However, the more the analog structure resembles ACh the less potent it becomes. It is clear that a specific receptor for AH5183 exists, and based on the similarity of the K_i value to typical vesicle molarities used in these experiments it is likely that one or less AH5183 receptor is present per synaptic vesicle. Levorotary [^{3}H]AH5183 (2.9 Ci/mmol) recently has been synthesized and used in preliminary studies demonstrating that it is highly but reversibly bound by vesicles in the absence or presence of MgATP. Taken as a whole, the above data is not easily reconciled to a model where AH5183 acts as an analog of ACh by binding to the ACh transporters in a homogeneous population of synaptic vesicles to inhibit ACh storage.

106.8 RECEPTOR MEDIATED ENDOCYTOSIS OF BIOTIN-LABELED CRF ANALOGS BY PITUITARY OPIOCORTIN CELLS: ULTRASTRUCTURAL STUDIES. G. V. Childs (Moriarty)*, K.N. Westlund, G. Unabia*, J. L. Morell*, and G. Aguilera* (Spon: A. A. Perachio) Dept Anat. Univ. Texas Med. Br., Galveston, TX, 77550, NICHD, NIH, Bethesda, Md.

Biotin-labeled CRF binds to specific cells in the anterior pituitary. It is localized with avidin-biotin-peroxidase complexes (ABC). Double immunocytochemical stains for adrenocorticotropin or beta-endorphin are used to confirm the identity of the target cells (Westlund et al, Peptides 5: 627, 1984). In these ultrastructural studies, 2 biotin labeled CRF analogs were used. Bio-CRF-1 was conjugated to biotin as described in the previous publication. Bio-CRF-2 was synthesized with biotinylated-serine substituted for the N terminal serine. Binding assays showed that the biotinylated analogs exhibited no loss in binding affinity or potency for ACTH release when they were compared with unlabeled ovine or rat CRF. Extraction of the biotinylated analogs with avidin-sepharose resulted in no activity indicating that they were 100% biotinylated. Dispersed anterior lobe (AL) or intermediate lobe (IL) cells were stimulated in suspension for 1-60 min at 37°C with doses of 0.1-1 nM. In some experiments, the AL cells had been separated into fractions by centrifugal elutriation. Stimulated and control suspensions were fixed in glutaraldehyde, stained with the ABC technique, postfixed in osmium tetroxide, and embedded in a pellet for electron microscopy. Cell counts showed that both biotinylated analogs bound 7-10% of AL cells and 68 ± 4% of dispersed IL cells. Elutriation Fractions 5 and 6 showed a 5-6 fold enrichment in percentage of Bio-CRF reactive cells. Competition with excess (100-1000 fold) unlabeled CRF prevented binding by Bio-CRF and reduced staining to 1-2% of AL or IL cells. After 1-3 min of stimulation, patches of stain for Bio-CRF were seen on membranes near microvilli. Internalization in AL cells was evident in small vesicles 2-3 min after initial exposure to the Bio-CRF. Within 5 min labeling was seen in lysosomes, on membranes of the Golgi Complex vacuoles, and in the core of some of the immature secretion granules. At later times, stain was seen in multivesicular bodies (MVB) and in a subpopulation of secretion granules. IL cells showed staining in small vesicles as early as 1 min after exposure. At later times, stain was on secretory granule membranes, and in MVB. The ultrastructural analysis thus shows 2 internalization routes for the CRF. The lysosomal route may signify degradation or modification of the peptide whereas the MVB or secretion granule route may be the mechanism for receptor recycling to the surface. Cytochemical evidence suggests that the Golgi Complex is involved in the production of granules that contain the CRF receptors in the AL cells. In the IL cells, the granules may be labeled by direct contact with the small vesicles. Supported by RCDA HD-00395 (GVC) and NIH NS-0739 (KNW).

106.9 LABELLING IN VIVO OF SEROTONIN UPTAKE SITES J. Wolfe*, C. Goodman* and D.J. Brunswick*, (SPON: P. Conway). VA Medical Center and Dept. of Psychiatry, Univ. of Pennsylvania, Phila, PA 19104.

^{3}H-Cyanoimipramine (^{3}H-CN-IMI) has previously been shown to label sites associated with serotonin uptake in both platelets and brain homogenates. In this study we have investigated the binding properties of ^{3}H-CN-IMI following administration in vivo. Approximately 2uCi ^{3}H-CN-IMI was administered i.v. (tail vein) to two groups of rats; one received the potent serotonin uptake blocker fluoxetine (10mg/kg) 5 minutes before ^{3}H-CN-IMI; and the other received saline. The ratio of the radioactive concentration in the hypothalamus to that in the cerebellum (radioactivity ratio) was determined 15 minutes and up to 4 hours after ^{3}H-CN-IMI administration. These brain regions were chosen since previous in vitro studies using ^{3}H-imipramine have shown that the highest concentration of binding sites in the brain is in the hypothalamus, whereas the lowest is in the cerebellum. The radioactivity ratio thus provides a measure of receptor occupancy. The highest ratio in the saline pretreated animals was obtained 2 hours after ^{3}H-CN-IMI administration (1.80 $\pm$ .07, n = 19, mean $\pm$ S.E.). This ratio was significantly reduced ($p < .01$) in the fluoxetine pretreated animals (1.07 $\pm$ .07, n = 9). A number of other drugs which are potent serotonin uptake inhibitors caused a significant reduction ($p < .01$) in the radioactivity ratio including chlorimipramine (2mg/kg), sertraline (1mg/kg) and cyanoimipramine itself (0.3mg/kg). Other drugs which are not potent inhibitors of serotonin uptake did not reduce the ratio including dl-propranolol (5mg/kg), maprotyline (10mg/kg), metergoline (10mg/kg) and haloperidol (5mg/kg). These results indicate that ^{3}H-CN-IMI can be given to rats to provide an index of serotonin uptake sites in the CNS in vivo.

106.10 A POTENTIAL PHOTOAFFINITY PROBE FOR THE CATECHOLAMINE/SEROTONIN PORTER OF SYNAPTIC VESICLES FROM MAMMALIAN BRAIN. J.A. Near*, S. Detwiller* and L. Shelton* (SPON: R.S. Gurd). Dept. of Pharmacology and Medical Sciences Program, Indiana University School of Medicine, Bloomington, IN 47403.

Catecholamines and serotonin are sequestered in synaptic vesicles by an energy-dependent, stereoselective transport system. Tetrabenazine and Dihydrotetrabenazine (DH-TBZ) are potent competitive inhibitors of transport (K_i^{app}=1-10nM) and previous work in this laboratory has shown that [^{3}H]-DH-TBZ binds to both energized and unenergized bovine striatal synaptic vesicles with an apparent dissociation constant of approximately 3nM. Since the binding properties of DH-TBZ suggest it specifically blocks the substrate binding site of the porter, a photolabile nitroaryl azide derivative of tetrabenazine has been prepared and evaluated for use as a photoaffinity probe to covalently label this binding site.

ANP-TBZ (2-(4-azido-2-nitrophenoxy)-3-isobutyl-9,10-dimethoxy-1,2,3,4,6,7-hexahydro-11b-H-benzo[a]-quinolizine) was prepared from dihydrotetrabenazine and 4-fluoro,3-nitrophenyl azide. ANP-TBZ exhibits an optical absorbance peak at 350nm that is typical of nitroaryl azides. Irradiation (UVS Mineralite) causes a dramatic shift in absorbance at this wavelength ($T_{1/2}$<1min) that probably reflects photolysis of the azide to the nitrene and subsequent reaction with solvent.

In the absence of light, ANP-TBZ is a competitive inhibitor of dopamine accumulation by bovine striatal synaptic vesicles, with K_i^{app}=200nM. Competitive inhibition of [^{3}H]-TBZ binding is also observed with similar K_i. Energization of the porter by addition of Mg-ATP has no effect on inhibition of TBZ binding by ANP-TBZ. When vesicles are preincubated with ANP-TBZ (300nM) and subjected to irradiation prior to determination of dopamine transport activity, V_{max} is decreased 30-40% when compared with controls irradiated in the absence of ANP-TBZ, suggesting irreversible binding to the porter. In contrast, little difference in the K_m^{app} for dopamine was observed between samples irradiated in the presence and absence of ANP-TBZ, suggesting the K_i for inhibition of catecholamine transport is increased considerably by photolysis.

These results imply that ANP-TBZ binds reversibly to the substrate binding site of the catecholamine/serotonin porter in the absence of light, and that photolysis induces covalent coupling of the bound compound with the porter. Photolysis is rapid, and the product of photolysis appears to have a substantially lower affinity for the porter than ANP-TBZ itself. Because of these properties ANP-TBZ may be a useful photoaffinity probe for use in studies of neurotransmitter transport by synaptic vesicles in the CNS.

106.11 ACCUMULATION OF ^{3}H-NOREPINEPHRINE, ^{3}H-DOPAMINE AND ^{3}H-5-HYDROXYTRYPTAMINE BY RAT BRAIN STORAGE VESICLES OCCURS IN KINETICALLY DISTINCT COMPARTMENTS DIFFERENTIALLY SENSITIVE TO NEUROTOXINS. J.A. Ruth, E.A. Ullman*, B.S. Liptzin*, J.V. Cuizon*, W.R. Wilson* and S.H. Park*. School of Pharmacy, University of Colorado, Boulder, CO 80309

We have previously shown that in membrane-impermeant media, the ATP-stimulated accumulation of ^{3}H-norepinephrine (NE), ^{3}H-dopamine (DA), and ^{3}H-5-hydroxytryptamine (5HT) by rat brain storage vesicles is saturable and stable for extended periods at 37°. The characteristics of NE, DA and 5HT accumulation were significantly different to suggest the possibility of selective amine accumulation by vesicle subpopulations. To further examine this possibility, the following studies were performed. Intraventricular administration of 6-hydroxydopamine (6OHDA) resulted in a 57% decrease in endogenous NE tissue content accompanied by a 40% decrease in ^{3}H-NE accumulation by rat brain vesicles. The effect was prevented by prior administration of desipramine. Vesicular ^{3}H-DA accumulation was unaffected by 6OHDA, although endogenous DA levels were reduced 80%. Intraventricular administration of 5,7-dihydroxytryptamine reduced endogenous 5HT tissue levels by 72% and reduced vesicular accumulation of ^{3}H-5HT by 40%, without affecting accumulation of ^{3}H-NE or ^{3}H-DA.

Competition kinetics demonstrated that accumulation of ^{3}H-NE (Km 5×10^{-6}) was noncompetitively inhibited by 5HT (Ki 3.5×10^{-6}) and DA (Ki 1.7×10^{-4}); accumulation of ^{3}H-5HT (Km 3×10^{-7}) was noncompetitively inhibited by NE (Ki 6×10^{-6}) and DA (Ki 6×10^{-6}); and that accumulation of ^{3}H-DA (Km 5×10^{-5}) was noncompetitively inhibited by NE (Ki 2.8×10^{-6}) and 5HT (Ki 2.2×10^{-5}).

Spontaneous efflux of endogenous NE (linear; t1/2 = 10 min), 5HT (linear t1/2 = 3 min) and DA (biphasic t1/2 = 1 min, 13 min) was paralleled by efflux of ^{3}H-amines.

The results further support selective amine accumulation by vesicles subpopulations in a rat whole brain vesicle preparation.

107.1 COMPARATIVE IDENTIFICATION OF NEUROPEPTIDES IN THE SPINAL CORD OF DOG, CAT, MONKEY AND SLOTH. S. Michener*, G. Harty*, D. Lucas*, D. Roddy*, V. Go* and T. Yaksh* (SPON: J. Szurszewski). Gastroenterology/Neurosurgical Units, Mayo Clinic, Rochester, MN 55905.

Despite many physiological studies which have shown that neuropeptides may function as neurotransmitters, no complete survey of neuropeptides in the spinal cord has been reported. Therefore, spinal cords and ganglia from cat, dog, owl monkey (Aotus trivirgatus) and two-toed sloth (Choloepus didactylus) were immediately removed post mortem and dissected into dorsal horn (DH), ventral horn (VH) and dorsal root ganglia (DRG) for each cord segment. Neuropeptides were extracted into boiling 0.1 N HCl, homogenized, neutralized and measured in the following specific radioimmunoassays: substance P (SP), met-5-enkephalin (met-Enk), vasoactive intestinal peptide (VIP), peptide histidine-isoleucine (PHI), cholecystokinin (CCK-8), neurotensin (NT) and bombesin (BLI). Results of four peptides are summarized below for the cat (n=5). The mean of the peptide concentrations for each region is reported (ng/g wet weight).

		Cervical	Thoracic	Lumbar	Sacral
SP	DH	110	106	232	369
	VH	39	40	47	107
	DRG	18	26	25	22
met-Enk	DH	51	46	87	257
	VH	24	27	30	89
	DRG	<4	<4	<4	<4
VIP	DH	<1	<1	6	210
	VH	<1	<1	2	7
	DRG	1	5	3	29
PHI	DH	2	2	8	271
	VH	3	2	3	11
	DRG	3	3	3	26

SP, met-Enk, VIP and PHI concentrations were highest in the sacral region, with the dorsal horn peptide concentrations higher than the ventral horn and DRG in all segments examined. Similar findings were observed for CCK-8, NT and BLI, and comparable distributions were observed in all animal species examined. Peptides were characterized using reverse phase HPLC, with detection by RIA. The principle peaks of immunoreactivity in dorsal-sacral samples co-eluted respectively with the following standards: SP-11; met-Enk5; VIP-28; PHI-27; CCK-8 and NT-13. The HPLC for BLI identified two peaks eluting shortly before the calibrations of bombesin 10 and gastrin-releasing peptide 27.

Conclusion: These results suggest that regulatory peptides in the spinal cord have different regional but comparable species distributions.

107.2 INTRA- AND INTERSEGMENTAL DISTRIBUTION OF THYROTROPIN-RELEASING HORMONE (TRH) IN RAT SPINAL CORD: TOPOGRAPHICAL VARIATION AND PRESENCE IN THE DORSAL HORN. D.H. Harkness* and M.S. Brownfield* (SPON:M. Javid). School of Veterinary Medicine, University of Wisconsin, Madison, WI 53706.

TRH distribution was studied in spinal cords of control and pharmacologically treated adult male rats by immunocytochemistry (ICC) and radioimmunoassay (RIA). Anesthetized rats were perfused intracardially with 4% paraformaldehyde-0.2% glutaraldehyde in 0.10 M phosphate buffer, pH 7.5. Cryostat sections of all segments were processed for ICC using PAP ICC with and without nickel intensification. Antisera were usable at dilutions of 1:1,000 to 1:20,000 and were specific for TRH amide as shown by differential absorption tests with TRH acid, cyclo-His-Pro, LHRH and other peptides. Unfixed rat spinal cord segments were dissected on ice, extracted with 90% methanol, and dried. Samples were reconstituted in buffer, and TRH was measured by RIA.

ICC showed the unexpected presence of immunoreactive TRH-containing cells and fibers in dorsal horn lamina II and superficial lamina III throughout the spinal cord. Confirming other reports, the peptide was also present in the intermediolateral (IML) and ventral horns. Staining was intense along thoracic lamina V-VII border and in the IML, weak in these same intermediate lamina of the lumbar cord, and moderate to heavy at all levels of the somatic motor column. Colchicine treatment (100 ug, ivt), 24 hours before death, led to the demonstration of large numbers of cell bodies along the border of lamina II-III. Cell bodies were not found in any other lamina. Administration of 5,7-dihydroxytryptamine (5,7-DHT, 200 ug) 14 days before death resulted in a severe reduction of serotonin everywhere in the spinal cord as shown by ICC and HPLC. While TRH immunoreactivity was diminished in the ventral horn in parallel with serotonin, dorsal horn TRH staining was unaffected by 5,7-DHT. Despite the loss of serotonin in the IML staining for TRH was resistant to the effects of the neurotoxin.

RIA of extracts of whole segments showed a wide range of TRH concentrations (7.5± 1.2 to 59±3.7 pg/mg wet weight) and segmental specificity in its distribution that was generally reflective of ICC results. Highest levels (greater than 40 pg/mg wet weight) were measured in C8-T1, T7-T8, and T12-S3, while lowest levels (below 10 pg/mg wet weight) were observed in segments C2-C7. Other segements were intermediate in TRH concentration.

These studies show (1) an intrinsic TRH system exists in the dorsal horn separate from serotonin, (2) TRH in the IML and ventral horn is differentially responsive to 5,7-DHT, and (3) the segmental variation in TRH concentration suggests selective involvement of the peptide in sympathetic and somatic motor function. (Supported by UWGS)

107.3 CAPSAICIN INDUCES NEURONAL DEGENERATION IN THE BRAIN AND SPINAL CORD OF ADULT RATS. T.T. Dinh* and S. Ritter. College of Veterinary Medicine, Washington State University, Pullman, WA 99164

Capsaicin is a potent neurotoxin which is highly selective for small-diameter primary afferent neurons. The prevailing view has been that capsaicin causes degeneration of these neurons only in neonatal animals. Silver stain studies of adult animals after systemic capcaicin treatment have not revealed evidence of degeneration. However, intracisternal administration of capsaicin to adult rats produces neuronal degeneration. In addition, systemic capsaicin treatment of adult rats decreases levels of certain peptides in the central nervous system and is associated with certain specific behavioral and physiological deficits, suggesting that neuronal damage has occurred. Therefore, we re-evaluated the neurotoxicity of systemic capsaicin treatment in adult rats, using a modification of the Carlsen-de Olmos cupric silver stain for degenerating neurons.

Adult male Sprague-Dawley rats were injected with a single dose of capsaicin (50 mg/kg, i.p.) or the capsaicin vehicle solution. Both vehicle solutions commonly used for capsaicin administration, 50% dimethyl sulfoxide (DMSO) in saline and 10% alcohol/10% Tween 80, were evaluated. Rats were sacrificed and perfused at 6, 12, 24 and 96 hrs after injection. Capsaicin-induced degeneration was present at all time points analyzed, but the greatest amount of staining was present in most regions at 12 and 24 hrs after the capsaicin injection. Capsaicin caused degeneration in areas previously shown to be affected by capsaicin in the neonatal rat. These areas include those associated with known projections of small diameter primary afferent neurons: the dorsal horn of the spinal cord, the spinal trigeminal nucleus and the nucleus of the solitary tract. In addition, we observed degeneration in several novel areas not previously described as being susceptible to capsaicin toxicity, including the inferior olive (medial nuc), interpeduncular nuc, supramammillary nuc, bed nuc of stria terminalis, and possibly the median eminence. The distribution of capsaicin-induced degeneration was similar for both vehicles, although DMSO tended to reduce the quality of the staining and predisposed to staining artifacts. In addition, DMSO itself appeared to cause degeneration in the subfornical organ.

Our results reveal that capsaicin produces degeneration in areas containing projections of primary afferent neurons in adult rats and in several areas of the brain not known to be recipients of primary afferent terminals.

107.4 SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE CAT SPINAL CORD. T.L. Krukoff, J. Ciriello, and F.R. Calaresu. Dept. of Physiology, University of Western Ontario, London, Canada. NCA 561

Recent anatomical and physiological evidence suggests that somatostatin likely plays a neurotransmitter role in the CNS, including the spinal cord. However, existing information about the distribution of somatostatin-like immunoreactivity (SS) in the spinal cord is incomplete. Therefore we have made a detailed investigation of the distribution of SS in the entire spinal cord of cats either treated or untreated with colchicine. In the treated group, 570 µg of colchicine were applied via an intrathecal polyethylene cannula to the spinal cord of cats anesthetized with ketamine (35 mg/kg i.p) and cats were allowed to survive for 24-48 hr. These animals and a group of untreated cats were anesthetized and perfused with Zamboni's fixative and frozen transverse and longitudinal sections (50 µm) from all segments of the cord were cut. Sections were placed into somatostatin-28 antiserum for 16-18 hr at 4°C. The biotin-avidin immunohistochemical procedure using a Vecta Stain Kit (Vector Labs, Burlingame, CA) was used to demonstrate SS.

In the dorsal horn SS was found in small neurons (less than 15 µm in diameter) within laminae II and III at all levels. Laminae IV to V contained smaller numbers of immunoreactive neurons at all levels that were medium (between 15 and 25 µm in diameter) to large (greater than 25 µm in diameter) in size. In addition, a small number of medium-sized neurons was found at the dorsal and dorsomedial borders of the gray and white matter in segments C1 to C5. In the sacral cord, a group of medium-sized bipolar neurons was found in the dorsolateral funiculus. In the intermediate and central gray matter, but excluding the intermediolateral nucleus and nucleus intercalatus (see Krukoff et al., 1985. J. Comp. Neurol. In press), multipolar neurons containing SS were found in lamina VII at all levels and in lamina X of the thoracic and upper lumbar cord. The former were medium to large in size and the latter were generally small in size. Finally, a small number of medium- to large-sized neurons with SS was found in the ventral horn of the cervical and upper thoracic cord. All neurons containing SS appeared to possess short processes. The distribution of nerve terminals and fibers containing SS was similar to that previously described in other species. Although the function of somatostatin in the spinal cord is not clear, its presence in neurons with short processes in numbers much larger than was previously reported suggests that it may act to modify local activity in the regions where it is found, including areas involved in sensory, visceromotor, and motor functions.

107.5 VIP IN GANGLIONECTOMIZED CAT SPINAL CORD. J. N. Young*, E. Rossitch, Jr.*, J. Ovelmen Levitt, B. S. Nashold, Jr. Division of Neurosurgery, Duke University Medical Center, Durham, NC 27710.

Vasoactive intestinal polypeptide (VIP) is a polypeptide which has been found in the GI tract, and in the central and peripheral nervous systems of various mammals. It has been found in small diameter sensory neurons, the superficial dorsal horns and the tract of Lissauer. Specifically, it has been localized to afferents at sacral levels and laterally projecting fibers at S2 and S3. This study attempted to exploit the high degree of localization of VIP to assess whether VIP-staining fibers sprout after deafferentation in the cat.

Ten cats were included in this study. Five cats underwent unilateral lumbosacral ganglionectomy of 3-5 dorsal roots: [L4, L5], L6, L7, and S1. They were sacrificed at varying times after surgery ranging from 2 weeks to 4 years. Five cats served as controls and received no surgery. All the animals were perfused by aortic cannulation with PBS, 4% paraformaldehyde in 0.1M phosphate buffer, and 5% sucrose in 4% paraformaldehyde buffer. Forty micron frozen sections were incubated overnight at 4° C in VIP antiserum diluted at 1:2000 in 1% goat serum/PBS. The secondary phase was performed using the ABC method. The sections were then stained with DAB and mounted on slides. Control sections were prepared with antiserum preabsorbed with VIP.

In the control cats, dense VIP immunoreactivity (VIPIR) was seen in the tract of Lissauer and surrounding the central canal in all sacral segments and less densely in L6 and L7. At the S2 and S3 level, VIPIR was also seen in ventrally projecting fibers at the lateral edge of the dorsal horns. These latter fibers occasionally extended as far as the posterior commissure and in a few sections were seen to cross the midline.

In the ganglionectomized animals, although there was increased nonspecific staining in white matter surrounding the deafferented dorsal horn, VIPIR of the laterally projecting fibers was qualitatively reduced on the deafferented side in cord segments below the level of the ganglionectomies. No increase in VIPIR was seen on the deafferented side at levels L6, L7, or S1.

The distribution of VIPIR in control animals is consistent with that found by other researchers. We found no evidence for increased VIP-fiber input to deafferented segments. In fact, our findings suggest that there is some VIP-fiber input from the S1 level, which was ganglionectomized. While this study does not show evidence for sprouting, it may be that lost input at the S1 level reduces our ability to demonstrate sprouting by this method.

107.6 NEUROPEPTIDE DISTRIBUTION IN THE SACRAL SPINAL CORD OF THE DOMESTIC FOWL, GALLUS DOMESTICUS. S.L. Freedman, L.F. May*, J.A. Morton*, D.C. Foss*, and R.M. Kriebel. Depts. of Anatomy & Neurobiology and Animal Sciences, Univ. of Vermont, Burlington, VT 05405.

Substance P, somatostatin, and met-enkephalin fibers have been localized by others in the spinal cord of the domestic fowl, Gallus domesticus (J. Comp. Neur. 213:406, 1983). In the present study the distribution of substance P and met-enkephalin fibers was confirmed. However, the primary objective of this investigation was to determine immunohistochemically the occurrence and distribution of gut-related and other peptides specifically within the sacral spinal cord. Hens were perfused intracardially with 4% paraformaldeyde in phosphate lysine-periodate buffer. The spinal cord and associated spinal nerves were carefully dissected and the spinal cord segmentally blocked according to each spinal nerve's contribution to the formation of the pudendal-pelvic nerve plexus (Anat Rec. 147:431, 1963). Thoracic and lumbar spinal cord were also obtained from each specimen for comparison with the peptide distribution in sacral segments. The tissues were immersed in fixative for 4 h followed by storage in sucrose phosphate buffer at 4°C. Frozen sections were cut at 30μm either horizontally or transversely and processed free-floating for immunohistochemistry; adjacent sections were stained with cresyl violet for orientation. Peroxidase anti-peroxidase methods were used to visualize antisera to substance P, leu- and met-enkephalin, LHRH, VIP, CCK, bombesin, and neuropeptide Y. Substance P and met-enkephalin fibers were distributed in the dorsal and intermediate areas of the gray matter at all levels of the spinal cord examined. Immunoreactive fibers for VIP, CCK, bombesin, and neuropeptide Y were observed only in sacral cord levels. In decreasing order, the immunoreactivity of nerve fibers in the sacral cord was VIP, CCK, neuropeptide Y, and bombesin. Each of these peptides was concentrated in the dorsal horn (laminae I-II) and around the central canal. The intermediate gray distribution corresponds to the bilateral intermediomedial cell column. In mammals it has been suggested that the gut-related peptides, such as VIP, are preferentially contained in pelvic visceral afferent fibers. The present study suggests that gut-related peptides are present also in the avian spinal cord at levels associated with pelvic visceral innervation.

107.7 IMMUNOHISTOCHEMICAL AND ULTRASTRUCTURAL STUDIES OF THE CAUDAL NEUROSECRETORY COMPLEX IN THE PADDLEFISH (POLYODON SPATHULA) AND THE GAR (LEPISOSTEUS PLATYRHINCHUS). D. Onstott, K.E. Miller, and R. Elde. Department of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

The morphology of the caudal neurosecretory complex (CNC) and the pharmacology of its major hormones, urotensins I and II (UI,UII), have been extensively studied in teleost fish. More recently, the nature of its innervation has been explored and urotensins immunohistochemically localized within this system in teleosts. However, little is known about the CNC in the other major actinopterygian groups, the Chondrostei and Holostei, in which it may retain some ancestral characteristics. We have used an antiserum to corticotropin-releasing factor (CRF) that cross-reacts completely with UI and an antiserum raised against synthetic UII to localize UI/CRF and UII immunoreactivities within the caudal spinal cords of the paddlefish (Polyodon spathula) and the gar (Lepisosteus platyrhinchus). In addition, we have used electron microscopy to examine the ultrastructural organization of the CNC in these species.

For immunohistochemical studies the vertebral column was fixed in 2% paraformaldehyde and 15% saturated picric acid and decalcified. Cryostat sections were processed using the indirect immunofluorescence method. Two spinal cords were fixed and processed for electron microscopy.

In both species, the neurosecretory termination area was visible as a thin band of intense UII or somewhat weaker UI/CRF immunoreactivity closely apposed to the ventral surface of the spinal cord. Similar immunoreactivity was also found in numerous perikarya, which, however, differed between the two species in their morphology, number, and distribution. Partial co-containment of UI/CRF and UII immunoreactivities was observed in cells of both species. Many rostro-caudally and dorso-ventrally oriented UI/CRF- and UII-immunostained fibers were also visible. The ultrastructure of CNC neurons was similar to other species with the cytoplasm containing numerous large granular vesicles (150nm). CNC perikarya were often apposed by glial processes and also received synaptic contacts. Synaptic terminals most commonly contained small clear vesicles (40nm) or small clear vesicles and small dense core vesicles (70nm). A thin layer (2-4um) of neurosecretory terminals was observed on the ventral and ventro-lateral surface of the spinal cord. Unlike teleosts, the neurosecretory terminals did not contact capillaries, but terminate at the spinal cord surface. The neurosecretory granules appear to release their content into the meninx of the spinal cord.

107.8 LUTEINIZING HORMONE-RELEASING HORMONE (LHRH)-IMMUNOREACTIVE (IR) CELLS OF THE TERMINAL NERVE, BUT NOT OTHER LHRH-IR NEURONS IN THE GOLDFISH BRAIN, ARE ALSO FMRFAMIDE- AND TACHYKININ-IR. Ann L. Kyle*, W.K. Stell, and O. Kah*. Dept. of Anatomy and Lions' Sight Centre, University of Calgary, Calgary, Alberta, Canada. T2N 4N1

Several cell groups within the teleost brain are immunoreactive (IR) for luteinizing hormone-releasing hormone (LHRH). In the goldfish, the LHRH-IR cells of one of these groups, the terminal nerve, are also IR for the molluscan cardiac excitatory peptide, FMRFamide (Stell, Walker, Chohan and Ball, PNAS, 81: 940), and a tachykinin-like peptide (TK) that is similar to, but not identical with, substance P (Stell, Chohan and Kyle, Invest. Ophthalmol. Vis. Sci. Suppl. 1984). We asked whether colocalization of LHRH- with FMRFamide- and/or TK-IR was a general feature of LHRH-IR cells or a characteristic specific to the terminal nerve.

Alternating, serial sections of goldfish brain were incubated with antiserum to teleost LHRH (Sherwood GF4) and adjacent sections with antiserum to FMRFamide (O'Donahue 232); other brains received antisera to LHRH and substance P (ImmunoNuclear AB 353, lot 8352022). IR was visualized using the avidin/biotin immuno-peroxidase method (Vector Labs.).

LHRH-IR was found consistently in three locations: 1. in the terminal nerve ganglion, consisting of large bipolar and multipolar cells embedded within the olfactory nerve; 2. in a loose array of ventro-laterally located bipolar cells extending through the telencephalon, preoptic area (majority of cells), and hypothalamus to the pituitary stalk; and 3. in large, multipolar cells between the posterior commissure and the midbrain tegmentum (synencephalon). Neither the ventro-lateral bipolars nor the large cells of the synencephalon were IR for either FMRFamide or TK. In contrast, as previously reported, the terminal nerve was IR for all three peptides. This suggests that the LHRH-IR cells of the terminal nerve represent a population different from the other LHRH-IR neurons in the goldfish brain.
This work was supported by The Natural Sciences and Engineering Research Council of Canada, and The Alberta Heritage Foundation for Medical Research.

107.9 ULTRASTRUCTURE OF LUTEINIZING HORMONE-RELEASING HORMONE(LHRH) NEURONS IN INTACT AND CASTRATED MALE HAMSTERS. M.N. Lehman and A.-J. Silverman. Dept. Anatomy & Cell Biology, Columbia Univ. Coll. Phys. & Surg., New York, NY 10032.

As preliminary observations to examining possible photoperiodic influences upon the structure and synaptology of LHRH neurons, we studied the morphology of these cells, using ultrastructural immunocytochemical procedures,in intact and long-term (3-6 months) castrated male hamsters housed under a 14L:10D photoperiod. Animals were perfused with 4% paraformaldehyde/0.2% glutaraldehyde. Vibratome sections (60um) were incubated with primary antiserum LR-1 (gift of R. Benoit) containing .02% saponin and processed using an avidin-biotin-immunoperoxidase kit (Vectastain). Areas of interest were osmicated, and embedded in Epon. Thick sections (1 um) were cut to locate immunostained perikarya, and subsequently serial thin sections were collected. LHRH cells in the medial septum, vertical limb of the diagonal band, and medial preoptic area were identified by a granular reaction product which was unevenly distributed within the cytoplasm of each neuron. Reaction product was most often associated with the rough endoplasmic reticulum (RER), particularly that RER adjacent to the nucleus, and was also associated with secretory granules, but not with the Golgi apparatus, nor the nucleoplasm. The nuclei of immunoreactive (IR) cells in both intact and castrated animals had several prominent identations and contained multiple nucleoli; dense reaction product was seen in aggregates along the cytoplasmic face of the nuclear membrane, and within their identations. The soma and dendrites of LHRH cells in this species receive extremely few, if any synaptic inputs. Of a subset of nine cells extensively analyzed through serial sections, we found only one example of synaptic input to an LHRH neuron. In that case two non-IR axon terminals containing clear round vesicles contacted the distal end of a tortuously bent dendrite and formed symmetrical synapses. In contrast, adjacent non-IR soma and dendrites in the surrounding neuropil were richly innervated. The plasma membrane of LHRH neurons was often separated from the adjacent neuropil by thin glial processes. Occasionally close somatic appositions were seen between LHRH cells and non-IR neurons, and in one instance between two LHRH perikarya, but no evidence of gap junctions between adjacent plasma membranes was seen. The extreme paucity of axosomatic and axodendritic synapses onto LHRH neurons in this species is in striking contrast to the synaptic arrangements of LHRH cells in the guinea pig (Silverman, JCN 227:452) and suggests that the regulation of their pulsatile activity may occur either at the level of their terminals within the median eminence, or by humoral signals. Supported by HD 10665 (AJS) and MH 15174 (MNL).

107.10 IMMUNOCYTOCHEMICAL LOCALIZATION OF LUTEINIZING HORMONE (LH) IN RAT BRAIN. G. Hostetter, A. Eaton* and M. S. Brownfield*. Department of Cell Biology and Anatomy, Medical School, Oregon Health Sciences University, Portland, OR 97201, and Department of Structural and Functional Sciences, School of Veterinary Medicine, University of Wisconsin, Madison, WI 53706.

The distribution of luteinizing hormone (LH) in rat brain was traced by immunocytochemistry. Immunocytochemical processing was conducted on tissue from ten adult male Sprague-Dawley rats, six untreated and four pretreated with intracerebroventricular injections of 100µg colchicine 24 hours before sacrifice. The animals were sacrificed under deep anesthesia by perfusion through the aorta with phosphate-buffered saline (PBS), followed by 4% paraformaldehyde in 0.1M phosphate buffer, pH 7.5. Brains and pituitaries were removed, post-fixed, and cut into 50µm-thick sections. The sections were processed by pre-embedding immunocytochemistry using the peroxidase anti-peroxidase (PAP) and avidin-biotin (ABC) methods. Four LH antisera were employed as the primary antibody, two generated against the intact LH molecule and two against LH beta (generous gifts of Drs. H. Papkoff and B. Kerdelhue). Immunocytochemical specificity was established by pre-incubating the LH antibodies with rat LH, TSH, prolactin, growth hormone, ovine FSH, and synthetic ACTH, as well as by examining the LH staining in the pituitary. The primary antisera were used in brain at a dilution of 1:250-1:1000 for 16 hours at 4°C. Following incubation in the primary antibody, the bridging antibodies and PAP or ABC were applied sequentially. Bound peroxidase was visualized with 30mg % diaminobenzidine tetrachloride with 0.01% hydrogen peroxide in Tris buffer.

Cell bodies, immunoreactive for LH, were localized within the hypothalamic arcuate nucleus, ventromedial nucleus, and the periarcuate area ventral to the ventromedial nucleus. Immunopositive fibers were traced to numerous structures, including discrete regions of the hypothalamus, thalamus, septal area, amygdala, and the brainstem, including periaquaductal gray, raphe nuclei, brainstem reticular nuclei, and the locus ceruleus. This pattern reflects the distribution shown by previous radioimmunoassay studies of LH in brain extracts (Hostetter et al, 1981; Emanuele et al, 1981). Continuing research in our laboratories focuses on the function of this widespread system of brain LH.

Supported by a grant from the Medical Research Foundation of Oregon to GH and from the University of Wisconsin Graduate School to MSB.

107.11 IMMUNOHISTOCHEMICAL EVIDENCE FOR A SUBCHIASMATIC PATHWAY CONTAINING LUTRINIZING HORMONE RELEASING HORMONE, SOMATOSTATIN, NEUROPEPTIDE Y AND TYROSINE HYDROXYLASE. Clive W.Coen[1], Peter R.C.Howe[2]* & Nihal C.de Lanerolle[3]. [1]Dept. Anatomy, King's College, London University, London WC2R 2LS, [2]CSIRO Division of Human Nutrition, Adelaide and[3]Section of Neurosurgery, Yale University.

The presence of a subchiasmatic pathway in the female rat containing luteinizing hormone releasing hormone (LHRH) immunoreactivity was first described by Flerkó, Sétálo and associates (Brain Res. 152: 401, 1978 and 198: 63, 1980; Acta Morph. Acad. Sci. Hung. 29: 259, 1981); this was subsequently confirmed in the male rat by Hoffman & Gibbs (Neuroscience 7: 1979, 1982).

We have undertaken further immunohistochemical investigations of this pathway in females of various species. Rats and rhesus monkeys were perfused with 5% acrolein; human tissue was fixed by immersion in the same solution. Serial sections (50um) were cut by vibratome coronally or parasagittally through the hypothalamus and attached optic chiasm. Using a modified PAP method, the immunoreactive distribution of LHRH, neurophysin, somatostatin (SOM), neuropeptide Y (NPY), tyrosine hydroxylase (TH), dopamine β-hydroxylase and phenylethanolamine N-methyltransferase was examined in the rat; in the human and monkey tissue immunohistochemistry for only LHRH was performed. Fibres containing immunoreactive LHRH were found running on the inferior surface of the optic chiasm in the midline in each of the three species. Subchiasmatic fibres containing TH- or, but more rarely, SOM- or NPY- immunoreactivity were also identified in the rat; no staining occurred at this site with the primary antisera against the other substances.

The possibility of a functional relationship between the LHRH-, SOM-, NPY- and TH- containing processes identified in this study remains to be examined. Considerable evidence exists implicating hypothalamic catecholamines, especially adrenaline, in LH release (Coen & Coombs, Neuroscience 10: 187, 1983) and both dopamine and noradrenaline in the secretion of SOM (Chihara et al. Endocrinology 104: 1656, 1979); nevertheless, in this particular pathway only the enzyme for dopamine synthesis (TH) was observed.

These results indicate that a remarkably superficial subchiasmatic pathway, possibly involved in the regulation of luteinizing hormone release from the anterior pituitary gland, is common to rats and primates. In this context, it should be noted that attempts to disrupt the menstrual cycle in monkeys by hypothalamic deafferentation may fail when a dorsal approach is made (Krey et al., Endocrinology 96: 1073, 1975) but be successful with a transorbital procedure (Cogen et al., Endocrinology 107: 677, 1980); the latter approach (from the inferior aspect) would necessarily sever the subchiasmatic LHRH fibres in addition to those in more dorsal planes. This study indicates the importance of assessing hypothalamic deafferentations immunohistochemically.

The functional significance and the sites of origin and termination of the subchiasmatic fibres containing LHRH-, SOM-, NPY- or TH- immunoreactivity are under investigation.

107.12 THE ORIGIN OF IMMUNOREACTIVE SOMATOSTATIN FIBERS IN THE DENTATE GYRUS OF THE RAT I Bakst*, JH Morrison, CA Avendano*, DG Amaral. (SPON:G.Banker) The Salk Institute, La Jolla,Ca 92037.

We have immunohistochemically localized somatostatin immunoreactivity in the dentate gyrus of the rat. Antiserum (SS320) directed against somatostatin 28(1-12), a 12 amino-acid fragment of somatostatin 28, stains a dense plexus of fibers in the outer half of the molecular layer in the rat as well as the monkey. Antiserum SS309, which is directed against somatostatin 28, a NH_2 -terminally extended form of somatostatin, stains neuronal cell bodies in the hilar region, but there are no observable somatostatin positive processes that extend to the outer molecular layer. We have performed a series of experimental manipulations to determine the cell bodies of origin of the somatostatin immunoreactivity in the molecular layer.

To exclude that the somatostatin in the molecular layer of the dentate gyrus originates from cell bodies in the entorhinal cortex (the origin of the major projection to the somatostatin dense region) ten rats underwent unilateral deafferentation of the entorhinal projection to the dentate gyrus, and were allowed a two week survival, before being processed. This resulted in unilateral shrinkage of the molecular layer on the side of the lesion, but an apparent increase in somatostatin(SS320) immunoreactivity, possibly due to the fibers being more densely packed in a narrower area. In contrast, the injection of 0.5 microliters of 0.1% kainic acid into the hilus of 12 rats followed by a 10-14 day survival period, resulted in a general loss of hilar neurons as determined by Nissl staining, a severe loss of somatostatin immunoreactive neurons in the same region, aaccompanied by a virtual depletion of somatostatin (SS320) immunoreactive fibers in the molecular layer at the level of the injection site. Acetylcholinesterase histochemistry of adjacent sections showed a normal distribution of acetylcholinesterase fibers in the dentate gyrus including the molecular layer. Six additional rats were injected with 50 nanoliters of a 2% WGA-HRP solution in various regions of the dentate gyrus and processed 24 hours later, for the concurrent demonstration of the retrograde tracer, and somatostatin (SS309) immunoreactivity in the same tissue section using a modified histochemical method for HRP. In cases where the injection of WGA-HRP filled the hilus at septal levels, double labeled neurons (HRP and SS309) were found temporal to the injection, but confined to the hilar region; a smaller number of double labeled neurons was found in the contralateral hilus but no double labeled neurons were found in sub-cortical regions. Thus the major source of somatostatin positive fibers in the molecular layer of the dentate gyrus is from cells in the hilar region. There is evidence of a commissural somatostatin projection to the dentate gyrus as well. Supported by grant NS-20004 to DGA.

107.13 SOMATOSTATIN IMMUNOREACTIVITY IN SECOND-ORDER AUDITORY NEURONS OF THE RAT, M. von Krosigk*, S.R. Vincent, J.C. Brown* and E.G. McGeer (SPON: J. Steeves). Division of Neurological Sciences, Depts. of Psychiatry and Physiology, Univ. of British Columbia, Vancouver, B.C., V6T 1W5, Canada.

The immunohistochemical localization of somatostatin in the central auditory system of the rat was examined using monoclonal antibodies to synthetic cyclic somatostatin. Large numbers of somatostatin-positive neurons were present in the temporal cortex, the inferior colliculus and the ventral nucleus of the lateral lemniscus. Also, a large number of intensely stained neurons were found in the ventral cochlear nuclei. Large multipolar somatostatin-positive neurons were sparsely scattered in both the anterior and posterior ventral cochlear nuclei. In addition, a great many small immunoreactive cells were present throughout the anterior ventral cochlear nucleus. Many of these had eccentric unstained nuclei and resembled the globular cell type (Osen K.K., J. Comp. Neurol. 136: 453, 1969).

The globular cells send thick axons to the contralateral medial nucleus of the trapezoid body, which terminates in large calyces. Large somatostatin-positive terminals were found surrounding the principal neurons of the medial nucleus of the trapezoid body and in thick sections these appeared to correspond to the calyces of Held. The morphology of these terminals was also examined using electron microscopy. Large somatostatin-positive terminals were observed, often in symmetric contact with cell bodies and major dendrites. The terminals contained round vesicles and the contacts were often interrupted by extracellular spaces. These features are consistent with the morphology of the calyces of Held.

Injections of the fluorescent tracer True Blue into the nucleus of the trapezoid body retrogradely labelled many of the neurons in the anterior ventral cochlear nucleus. These retrogradely labelled neurons could be simultaneously stained immunohistochemically for somatostatin.

These results suggest that somatostatin is contained in second-order auditory fibers arising in the anterior ventral cochlear nucleus and terminating in the medial nucleus of the trapezoid body of the rat.

In the cat, somatostatin-positive neurons were present in the temporal cortex, the inferior colliculus, and the ventral nucleus of the lateral lemniscus. However, only a few of the large multipolar cells of the ventral cochlear nuclei were stained. The small globular cells in this nucleus and the calyces of Held in the medial nucleus of the trapezoid body were not stained. Thus, there may be important species differences in the transmitters present in central auditory pathways. (Supported by the Medical Research Council of Canada.)

107.14 DISTRIBUTION OF SOMATOSTATIN IMMUNOREACTIVE NEURONS IN FRONTAL NEOCORTEX AND UNDERLYING "WHITE" MATTER OF THE HUMAN FETUS AND PRETERM INFANT. I. Kostović and A. Fučić*, Section of Neuroanatomy, Department of Anatomy, Medical Faculty, University of Zagreb, Šalata 11, 41001 Zagreb, Yugoslavia.

Somatostatin immunoreactive neurons are present in all cell-rich layers and underlying white matter of the primate adult cortex (Sorensen, Neurosci., 7:1227, 1982; Morrison et al., Brain Res., 262: 344, 1983; Hendry et al., J. Neurosci., 4:2447, 1984). In order to determine developmental appearance of somatostatin immunoreactive neurons in cortical layers we have investigated laminar distribution of somatostatin immunoreactive neurons in frontal neocortex of human fetus and preterm infant with immunohistochemical peroxidase-antiperoxidase and avidin-biotin conjugate systems. The examination of telencephalic wall in late fetuses (4,5-6 months of gestation) revealed the presence of somatostatin immunoreactive neurons below the cortical plate in the transient fetal, synapse-rich subplate zone. In addition, somatostatin immunoreactive neurons were found in the fetal "white" matter (defined as a zone of large bundles of parallel fibers). The vast majority of somatostatin immunoreactive neurons have relatively large cell bodies (13x9 micrometers in diameter). The main morphological feature of subplate somatostatin immunoreactive neurons are long, radiating dendrites. In preterm infants (6-8 months of gestation) there is an increase in number of small (8x4 micrometers in diameter) somatostatin immunoreactive neurons in the zone of transition between the deep cortical plate (prospective layers VI and V) and subplate layer. The major part of the cortical plate (prospective layers II-IV) does not contain somatostatin immunoreactive neurons at this age. In newborn infant somatostatin immunoreactive neurons were occasionally found within the layer III of the superficial cortex.
In conclusion, somatostatin immunoreactivity of the intrinsic neurons in the subplate zone and white matter appears before immunoreactivity of neurons in the cortical plate. This earlier appearance of somatostatin immunoreactive neurons within the deep cortical anlage and "white" matter may simply reflect an earlier differentiation of deep cortical layers. However, subplate and interstitial neurons may play a developmental role as special, fetal type of local circuitry neurons.

107.15 NEUROPEPTIDE LIKE IMMUNOREACTIVITY IN HUMAN SPHENO-PALATINE AND TRIGEMINAL GANGLIA.
Patrick A Sibony*, Benjamin Walcott, Kent Keyser*, Harvey Karten; Departments of Ophthalmology, Neurology, Anatomical Sciences, and Neurobiology, State University of New York at Stony Brook, Stony Brook, N.Y. 11794.

Studies have shown the widespread occurrence of Vasoactive Intestinal Polypeptide (VIP), substance-P (SP), and Leu-Enkephalin (L-ENK) immunoreactivity in sensory or parasympathetic ganglia from a number of different animal models. The distribution, function and pathological significance of neuropeptides in human ganglia remains essentially unexplored. Neuropeptide studies in humans have been hampered by the problem of post mortem cellular autolysis evident within 12 hours of death. We have been able to obtain human specimens incidental to autopsy within 4-10 hours of death. In a number of these cases, fixation with phosphate buffered 4% paraformaldehyde produced tissue with adequate cytology. We have examined the sphenopalatine and trigeminal ganglia for VIP-like, SP-like and L-ENK-like immunoreactivity. Many of the cells in the sphenopalatine ganglia show VIP-like and L-ENK-like immunoreactivity diffusely throughout the soma cytoplasm . Reactive fibers can be seen occasionally within the ganglia. SP-like immunoreactivity was seen in a few small cells scattered among the larger cells. The trigeminal ganglia showed little or no VIP-like immunoreactivity but intense L-ENK-like and SP-like immunoreactivity was present in a number of cells. These results are similar to those obtained in animal models.

Supported by NIH NS 19350 (BW) and NEI 02146 (HK)

107.16 STRUCTURE AND PEPTIDE-CONTENT OF THE PARACERVICAL GANGLION INCLUDING ATRIAL NATRIURETIC FACTOR- AND ENKEPHALIN-IMMUNOREACTIVE TERMINALS. R.E. PAPKA, H.H. TRAURIG AND P. KLENN*. Dept. Anatomy, Univ. KY. Sch. of Med., Lexington, KY 40536.

Some of our recent studies have examined the presence, distribution and origin of peptide-containing nerves in the female rat reproductive system, as well as the neuropeptide content of the dorsal root ganglia, paracervical ganglia (PG) and inferior mesenteric ganglion (IMG); these are the major sources of fibers innervating the reproductive organs. Neuron cell bodies in the PG project axons immunoreactive for neuropeptide tyrosine (NPY) and vasoactive intestinal polypeptide (VIP) to the reproductive tract whereas IMG neuron cell bodies project NPY-immunoreactive axons. Peptide-containing nerve fibers and terminals in the PG include those immunoreactive for substance P, VIP and Leu-enkephalin (L-ENK). The present study was undertaken to further characterize the structure of, and neural interactions in, ganglia which have inputs to the reproductive tract. Standard immunofluorescence methods, electron microscopic immunocytochemistry employing colloidal gold techniques and routine transmission electron microscopy were used to examine additional synaptic inputs to the PG and IMG and to examine the ultrastructure of the PG. VIP-immunoreactive fibers and terminals were present in the IMG. Atrial natriuretic factor (ANF)- and L-ENK-immunoreactive terminals were identified in the PG with both fluorescent and electron microscopic immunocytochemistry. These terminals were found adjacent to and in synaptic contact with PG neurons. Immunoreactivity was localized exclusively to large (90-100nm) dense-core vesicles in these terminals. Small intensely fluorescent (SIF)-catecholamine containing cells were numerous throughout the PG and adjacent nerve trunks. The SIF cells were present as isolated cell clusters and as individual cells closely adjacent to PG neurons. Specialized contacts between the SIF cells and PG neurons have not been observed. L-ENK- or ANF-immunoreactive terminals have not been observed contacting the SIF cells. These data have further defined the complex synaptic relationships and transmitter content of autonomic neurons which innervate the female reproductive tract. These complex interactions may provide a neural substrate which could play a significant role in the regulation of the female reproductive tract. (Supported in part by NIH-BRSG #RR05374).

107.17 **ANATOMICAL LOCALIZATION OF CALCITONIN GENE-RELATED PEPTIDE ON CEREBRAL ARTERIES.** S.H. Tsai, J.H. McLean, J.M. Tew and M.T. Shipley, (SPON. R. Cardell), Departments of Anatomy/Cell Biology and Neurosurgery, University of Cincinnati Medical Center, 231 Bethesda Avenue, ML 521, Cincinnati, Ohio 45267-0521

Calcitonin gene-related peptide (CGRP) is a fascinating molecule recently discovered by recombinant DNA technology (Amara et al Nature, 1982). In thyroidal 'C' cells the calcitonin gene produces an mRNA that encodes a precursor to the hormone calcitonin. However, in neural tissues alternative processing of the same gene leads to an mRNA that encodes CGRP and antibodies to CGRP stain a subset of CNS neurons in brainstem and forebrain circuits involved in a discrete set of functions including autonomic regulation. In particular, CGRP-like immunoreactivity is prominent in the nucleus of the solitary tract, trigeminal nucleus and nucleus parabrachialis - all structures implicated in neural regulation of cardiovascular function (Rosenfeld et al Nature, 1983). It was of interest, therefore, to determine whether this novel peptide is associated with cerebral vascular structures. Here we report that cerebral arteries are abundantly supplied by CGRP containing fibers and that these fibers are distributed in an intriguingly regular grid-like pattern.

Immunocytochemical staining with CGRP antisera (generously supplied by W. Vale - Salk Institute) was performed on whole mounts of the internal carotid, vertebral, basalar, posterior communicating, middle cerebral and anterior cerebral arteries. CGRP fibers were found on all arteries but the density of axons was highest on the posterior communicating, middle and anterior cerebral arteries. The distribution pattern of CGRP fibers is distinctly different from that of noradrenergic, cholinergic and other peptidergic fiber. In many instances CGRP fibers form a strikingly regular gridwork of longitudinal and circumferential fibers. These fibers are studded with numerous varicose swellings. The origin of the cerebrovascular CGRP fibers is currently under investigation. One possible source is the trigeminal nerve since we find that the trigeminal ganglion, especially the opthalamic division, is extremely rich in CGRP reactive neurons.

Given the intriguing localization of CGRP in brain sites involved in cardiovascular regulation and the present findings that cerebral arteries are richly supplied by CGRP axons, it will be of interest to study the potential physiological actions of CGRP on cerebral arteries and to investigate possible changes in the distribution of fibers following vasospasm. Studies of this kind are in progress.

MOLECULAR BIOLOGY OF GENE EXPRESSION AND NUCLEIC ACIDS II

108.1 IDENTIFICATION OF GENES USING LIGAND PROBES: CALMODULIN-BINDING PROTEINS IN λgt11 EXPRESSION LIBRARIES. J. M. Sikela* and W. E. Hahn. Dept. of Anatomy, Univ. of Colorado Sch. Med., Denver, CO 80262.

Screening of expression libraries with antibodies to proteins of interest has become a powerful approach to the isolation of specific genes. Moreover, fusion proteins produced by recombinant DNA systems often display appropriate biological activity. Therefore we considered the use of various ligands as direct probes to identify the genes of the respective binding proteins (receptors).

Because calmodulin is known to bind several specific brain proteins (even as dissociated polypeptides) in the presence of Ca^{++} and because of calmodulin's major role in modulating the effects of Ca^{++} in the brain and other tissues, we chose to use calmodulin as a "model" probe to screen an expression library.

An adult mouse brain cDNA expression library was constructed in phage λgt11 and directly screened with ^{125}I calmodulin. Three clones were isolated that bound the probe in a Ca^{++} dependent manner. Lysogens were prepared from each phage clone and proteins produced by the lysogens used in dot blot analyses. Binding of ^{125}I calmodulin to the protein extracts was reduced in a competitive manner by addition of unlabeled calmodulin, was Ca^{++} dependent (EGTA sensitive), and only occurred in clones that had been induced to produce fusion proteins. SDS electrophoresis of the protein extracts from the induced clones yielded a band of the expected size for the fusion protein, whereas no similar sized band appeared using protein from uninduced lysogens.

When the proteins were electro-blotted onto nitrocellulose after SDS electrophoresis and the filter probed by ^{125}I calmodulin, only the band corresponding to the fusion protein bound calmodulin.

Characterization of the insert sizes of the clones indicates that they have a coding capacity of no more than 200 amino acids and, because of the cloning strategy used, represent the C-terminal end of the encoded proteins.

108.2 NERVOUS TISSUE SPECIFIC EXPRESSION OF CALMODULIN mRNA IN APLYSIA. K. Kruger*, M. Swanson, M. Palazzolo, S. Sturner*, J.H. Schwartz, (SPON: E. Shapiro). Howard Hughes Medical Institute, Columbia Univ. Coll. Physicians & Surgeons, New York, NY 10032.

Calmodulin is the common Ca^{2+}-binding protein that mediates ubiquitous cellular responses to increases in intracellular Ca^{2+}. In nervous tissue, Ca^{2+} is important for nerve cell transmission and synaptic plasticity. We have used the techniques of recombinant DNA to study the gene structure of this important regulatory molecule in the marine mollusc Aplysia, and to determine how its expression differs in nervous tissue from that in other parts of the body.

Calmodulin cDNA clones from electric eel and Torpedo were used as hybridization probes to isolate a partial calmodulin clone from an Aplysia abdominal ganglion cDNA library. This clone codes for the sequence of amino acids at the C-terminal third of Aplysia calmodulin which is identical to the amino acid sequence of vertebrate calmodulin. The Aplysia calmodulin cDNA was used as a hybridization probe to examine its gene organization in Aplysia. Southern blotting analysis with DNA isolated from the sperm of several individual specimens suggests that Aplysia calmodulin is encoded by a single gene locus, but with at least three polymorphic alleles. Thus, to characterize the nature of these genomic DNA sequences further, four unique genomic clones were isolated from an Aplysia sperm genomic library (provided by R.H. Scheller, Stanford University) using the Aplysia cDNA clone as hybridization probe. Restriction site analysis indicates that three of the four clones were derived from a larger contiguous 40Kb segment of the Aplysia genome. The fourth clone contained some restriction site variations when compared to this 40Kb genomic fragment and may be a second allele of this locus.

A mRNA specific to nervous tissue was identified by northern blot analysis of poly A^+ RNA from several Aplysia tissues, using the Aplysia calmodulin clone as hybridization probe. Abdominal ganglion and ring ganglia each contained three abundant mRNAs (2.5Kb, 3.0Kb, and 3.8Kb), while atrial gland, ovotestis, hepatopancreas, and buccal mass each contained only two mRNAs (2.5Kb and 3.0Kb). How is the larger mRNA generated and what is its function? Translation of hybrid-selected mRNA and mapping of the extra sequences in the 3.8 Kb mRNA should provide clues to the possible function of this specific neuronal mRNA.

108.3 HIPPOCAMPAL AND AMYGDALOID GENE EXPRESSION: NOVEL mRNAs IDENTIFIED BY SUBTRACTED cDNAs AND IN SITU HYBRIDIZATION. G.A. Higgins* and M.C. Wilson*. (SPON: K. Heidenreich) Department of Molecular Biology, Research Institute of Scripps Clinic, La Jolla, CA 92037

We have used subtractive hybridization to isolate cDNAs which recognize mRNAs expressed by different neuronal cell types of the hippocampus and amygdala, but not other regions of the mammalian central nervous system. Single-stranded cDNA generated from poly(A^+) RNA from the hippocampus or amygdala was hybridized with a 20-fold excess of poly(A^+) RNA from cerebellum or cerebral cortex of the rabbit. Hydroxyapatite chromatography was used for isolation of cDNA sequences which did not hybridize to cerebellar or cortical RNAs, and thus are not expressed in, or are present in low abundance in these regions. Hippocampal- and amygdala-specific cDNA were rendered double-stranded and cloned into pBR322. Four cDNA libraries: hippocampus-cerebellum (H-Cb), hippocampus-cerebral cortex (H-Cx), amygdala-cerebellum (A-Cb) and amygdala-cortex (A-Cx) were screened by colony hybridization with a twice-subtracted cDNA probe and/or plus-minus screening with whole hippocampal and cerebellar cDNA. Regional specificity was assayed by hybridization of individual nick-translated cDNAs to blots containing fractionated RNA from several rabbit brain regions, whole mouse brain and liver.

Several different regionally distributed transcripts were identified. For example, H-CbE3 detects a 4.3 kb mRNA present at high abundance in the hippocampus, amygdala, and cerebral cortex, but expressed at lower levels in the cerebellum, and virtually absent from whole mouse brain and liver. Genomic blotting indicates that this cDNA hybridizes to multiple Eco RI and Bam HI restriction fragments in both mouse and rabbit. In contrast, A-CbE7 recognizes 1.1 and 0.6 kb mRNAs in all regions and tissues studied, but hybridizes to a 5.3 kb mRNA expressed only in the amygdala. We are currently mapping the cellular distribution of these hippocampal and amygdaloid mRNAs by in situ hybridization, and have begun sequencing to determine the identity of proteins encoded by these transcripts.

108.4 DETECTION OF mRNA BY IN SITU HYBRIDIZATION HISTOCHEMISTRY USING COMPLEMENTARY RNA (cRNA) PROBES. Ruth E. Siegel and W. Scott Young, III (SPON. G. David Lange), Lab. of Cell Biology., NIMH, Bethesda, Maryland 20205

Neuropeptide mRNAs in tissue sections have been detected by in situ hybridization histochemistry with labelled, complementary polynucleotide probes. Generally, nick-translated probes are used but suffer from random labelling, probe size variation and self-annealing. Single-stranded DNA or RNA probes of high specific activity are now easily made and avoid the above problems. The RNA:RNA hybrids formed also have higher melting temperatures than DNA:RNA hybrids.

We have made cRNA (and mRNA) probes using bacteriophage SP6 promoter and polymerase. We subcloned the mouse proopiomelanocortin (POMC) cDNA from MKSU16 (922bp; courtesy of Dr. E. Herbert) into pSP64 and pSP65. Two overlapping cholecystokinin (CCK) cDNA clones (courtesy of Dr. J. Dixon) were ligated at the XmaIII site and a 530bp fragment was inserted into pSP64 and pSP65. Drs. Yoshikawa and Sabol kindly supplied a 940bp preproenkephalin A (ENK) cDNA in pSP64 and pSP65. RNA probes were labelled with α-^{35}S- UTP to >10^8DPM/μg.

Mice and rats were perfused with 4% paraformaldehyde and 10% sucrose. Twelve micron frozen sections were hybridized according to the protocol of Harper (Science, 227, 177, 1985) with modifications. The sections were then apposed to emulsion-coated coverslips and exposed concurrently with ^{35}S-impregnated brain-paste standards.

We confirmed that POMC mRNA is located predominantly in the pituitary intermediate lobe and in scattered anterior lobe cells as well as arcuate nucleus neurons. We estimate that the most heavily labelled arcuate cells contain about 250 copies of POMC mRNA each. In these regions, there is an exact correspondance between ACTH immunostaining and hybridization signal. In addition to these regions positive for ACTH immunostaining, lateral hypothalamic neurons are stained for α-MSH, also believed to be encoded by the POMC gene. However, we do not detect any POMC mRNA in these cells at a sensitivity of less than 10 copies per cell. Therefore, we suspect that these neurons contain a non-POMC gene product. Still, a lower level of POMC mRNA synthesis may occur in these cells. Longer autoradiographic exposures, lower hybridization stringency, and synthetic oligonucleotide probes (Young et al., this volume) may resolve this issue.

Other neuropeptide mRNAs have been detected using cRNA probes. Using a CCK probe, we have observed specifically labelled neurons in the rat neocortex and pyriform cortex, for example. We have also observed ENK mRNA in neocortex, amygdala and hypothalamus. Studies to extend these observations are in progress.

108.5 MOLECULAR CLONING OF cDNAs FROM DIFFERENTIALLY-EXPRESSED HIGH AND LOW ABUNDANCE mRNAs OF DIFFERENTIATED AND UNDIFFERENTIATED MOUSE NEUROBLASTOMA CELLS. B.K. Schrier, Molecular Neurobiology Unit, Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda, MD. 20205

In our previous work (Grouse et al., J. Biol. Chem. (1980)255: 3871-3877) we examined, by mRNA-cDNA hybridizations, changes in polysomal poly(A)$^+$ mRNA sequences during a Bu$_2$cAMP-induced differentiation step in mouse NS20Y neuroblastoma cells. We found that differentiation resulted in the disappearance of approximately 250 sequences which had been expressed in the undifferentiated (S) cells and the appearance of approximately 320 new sequences in the differentiated (P) cells. We have now purified the cDNAs of sequences unique to S and P cells by three cascade hybridizations. These cDNAs were made double-stranded using random hexamers as primers and were cloned using the Pst I site of pBR322 and E. coli strains C-600 and RR1. Based on samplings of the two libraries, they consist of >2700 (S-unique) and >1700 (P-unique) tet^R amp^S clones. Among 175 amp^S S-clones examined so far, 77 (44%) contained inserts <100 bp, which were considered likely to be of limited value; the average insert length of the remaining 98 clones (66% of those examined) was 356 bp, and 58% of these had inserts >200 bp (avg. 555 bp). Among 14 amp^S P-clones examined so far, 5 clones (36%) had inserts >185 bp (avg. 453 bp). These 103 S- and P-clones were grown on filters and probed with cDNA preparations made from total poly(A)$^+$ mRNAs from either S or P cells. Thirty-four of the S-clones (avg. 219 bp) and 2 of the P-clones (avg. 483 bp) appeared to be from middle-high abundance (HA) mRNAs; the remaining 64 S-clones (avg. 429 bp, 65%) and 3 P-clones (avg. 457 bp, 60%) were presumed to be low abundance (LA). Some HA and LA S-clones were used to hybridize to S-cell and P-cell mRNAs blotted onto nitrocellulose filters out of saturated NaI. Among 14 clones for which the result was clear, 8 were S-specific (i.e., did not hybridize to P-cell mRNAs), 3 reacted with S>>P, one reacted with S>P, one with S = P, and one appeared to be P-specific. This indicated that the cascade purification of S-cDNAs was successful, albeit imperfect. Further analyses of these and other clones from these libraries are continuing.

108.6 CLONING OF STAGE-SPECIFIC DORSAL ROOT GANGLION GENES. S.C. Ng, K. Wood*, M.C. Fishman. Neuroscience Group of the Howard Hughes Medical Institute, and the Department of Medicine, Harvard Medical School and Massachusetts General Hospital, Boston, MA 02114.

In order to help identify molecular changes that characterize the presynaptic neuron during various stages of synaptogenesis, we have begun isolation of stage specific cDNA from rat dorsal root ganglia (DRG). Five to ten thousand DRG were utilized to generate poly(A) RNA from embryonic day 14 (E-14), embryonic day 17 (E-17), and newborn (NB) rats. The majority of neurons in E-14 DRG have finished their final mitosis, and some have extended fibers to the spinal cord (SC). By E-17 DRG neurons are actively engaged in synaptogenesis with target cells in the SC, and these contacts evidence continued morphological maturation through birth.

The complexity of poly(A)$^+$RNA from each stage was examined by in vitro translation and subsequent two-dimensional gel electrophoresis of the translational products. Comparison of the electrophoretic profiles of the translational products at E-14, E-17, and NB revealed an essentially uniform pattern throughout development, with a very restricted subset that appeared to be developmentally regulated. These differences in translatable RNA suggested that each stage might indeed be marked by expression of a set of specific mRNAs.

Thus, cDNA cloning was performed using poly(A) enriched RNA from the three stages. A modification of the RNAase H method of Okayama and Berg (1982) was utilized for generation of the second strand, followed by methylation, addition of Eco RI linkers, and ligation into the Eco RI site of λgt10 and λgt11 vectors. Cloning efficiency was about 10^6 recombinants per microgram of poly(A)$^+$ RNA. Those clones representing mRNA expressed in a stage-specific manner are being isolated by examining each library using: (1) total ^{32}P labelled cDNA probes from different ages, and, (2) subtracted ^{32}P-cDNA probes that have been enriched for sequences representing one specific stage.

108.7 NGF INDUCTION OF GLUTAMATE DECARBOXYLASE (GAD) MRNA IN PHEOCHROMOCYTOMA CELL LINES.
N.J.K. Tillakaratne*, S.L. Huttner*, and A.J. Tobin (SPON: M. Wexler). Department of Biology and Molecular Biology Institute, University of California, Los Angeles, CA 90024.

We are using our recently isolated recombinant DNA probe to study the induction of GAD mRNA in two pheochromocytoma cell lines -- PC-12 and PCG2. PCG2 is a clonal cell line established by Goodman and Herschman (1978) from an experimentally induced rat pheochromocytoma. Unlike PC-12 cells, PCG2 cells continue to divide after NGF induction and produce increased levels of tyrosine hydroxylase (TH) and TH mRNA.

To analyze the mechanisms by which NGF induces changes in these cell lines, we are measuring GAD mRNA levels in cells after different times of exposure to 7S NGF. Total RNA was isolated by the guanidine thiocyanate-cesium chloride method, and GAD mRNA was measured by "slot blot" hybridization to ^{32}P-nick translated GAD cDNA. This technique allows the quantitative determination of the concentrations of individual mRNAs. We have measured the sensitivity of this method using purified RNA transcribed by sp6 polymerase from GAD cDNA subcloned in pSP65 and can detect less than 1 pg of GAD mRNA.

Total RNA (10ug) from untreated PC-12 and PCG2 cells contains no detectable GAD mRNA sequences; that is GAD mRNA must be less than 0.1 ppm of the total, or less than 10 ppm of the poly (A) RNA. NGF-treated PCG2 cells contain detectable GAD mRNA after 3 days. PC-12 cells also contain GAD mRNA sequences after exposure to NGF for 10-14 days. We are now in the process of examining the time course of induction of GAD mRNA by NGF in both cell lines.

We have employed electrophoresis in methyl mercury followed by RNA blot hybridization to examine the size distribution of GAD mRNA sequences in PC-12 cells exposed to 7S-NGF for 14 days. The GAD mRNA sequences appear as a single size component, 3.7 kb long. This is the same size as the GAD mRNA in the brains of humans, cats, mice, and rats.

We are now using these cell lines to examine the regulation of GAD gene expression.

108.8 CATECHOLAMINERGIC MODULATION OF PROOPIOMELANOCORTIN mRNA IN RAT PITUITARY INTERMEDIATE LOBE.
J.E. Kelsey, S.J. Watson and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109, U.S.A.

The intermediate lobe (IL) of the rat pituitary contains both dopaminergic and beta-adrenergic receptors on cells that synthesize and secrete proopiomelanocortin (POMC) peptides. Dopoaminergic agonists decrease release of POMC peptides from the IL, whereas beta-adrenergic agonists increase release. To investigate if these compounds also exert opposite effects on POMC mRNA levels in IL cells we treated rats with a variety of catecholaminergic agents and determined POMC mRNA levels with a dot blot assay. Isoproterenol, a beta-adrenergic agonist, (5mg/kg ip, 4 days) produced a 30-35% increase in POMC mRNA, this increase was not seen with a lower dose (2mg/kg) given for 4 days, but injection of 2mg/kg on days 1,2 and 4 with sacrifice on day 5 produced a 23% increase suggesting that repeated administration might have produced desensitization. Haloperidol (2mg/kg ip, 4 days) produced a 25-35% increase in POMC mRNA which was also obtained by alternating injections of haloperidol (2mg/kg) and isoproterenol (5mg/kg) for 4 days ie. haloperidol on days 1 and 3, isoproterenol on days 2 and 4. Combined injections of haloperidol (2mg/kg) and isoproterenol (5mg/kg) produced an additive increase. In vitro studies using NIL primary cultures showed apomorphine (1 uM, 4 days) to produce a reversible decrease of approxiamately 50% in POMC mRNA levels. Isoproterenol (1 uM, 4 days) showed only a slight increase, due perhaps to either desensitization of the response as seen in vivo, or the removal of the tonic dopaminergic inhibition also found in vivo. These studies suggest that dopaminergic and beta-adrenergic compounds exert opposite effects on POMC mRNA levels. This might be modulated via cAMP formation as the two receptors are oppositely coupled to adenylate cyclase.

108.9 STUDIES ON PROENKEPHALIN GENE EXPRESSION IN PC12 CELLS.
J. C. Byrd, I. Lindberg, J. R. Naranjo* and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032 and Dept. Biochemistry, L.S.U. Medical Center, New Orleans, LA 70119.

PC12 cells are widely used as a model to study neuronal differentiation. Unlike the adrenal medulla from which they are derived, these pheochromocytoma cells contain exceedingly low levels of opioid peptides. By using butyric acid, a differentiation promotor, we have been able to induce in these cells a twenty-fold increase in the levels of met^5-enk-arg^6-gly^7-leu^8-immunoreactive (met^5-enk-RGL-IR) peptides in a time and dose dependent manner. This increase is preceded by the appearance of proenkephalin mRNA, which is not readily detectable in untreated cells. This increase does not appear to be due to a general stimulation of DNA transcription, since the content of other specific mRNA species is simultaneously decreased. This suggests a direct action of butyrate on transcription; however, a post-transcriptional effect cannot be completely excluded. The molecular weight profile of the met^5-enk-RGL-IR peptides was examined using Bio-Gel P-30 chromotography. The antiserum used was very sensitive (IC_{50} = 10 fmol) and directed against the C-terminal end of met^{5}enk-RGL, thereby permitting detection of high molecular weight, N-terminally extended precursors. Butyrate-treated PC12 cells contained predominately low molecular weight (approx. 1kDal) and intermediate weight (5-10 kDal) met^5-enk-RGL-IR peptides. This contrasts with the profile of the met^{5}enk-RGL-IR peptides in the adrenal medulla of the adult New England Deaconess (NED) rat -the source of the PC12 cell line-which contains approximately equal amounts of intermediate and high molecular weight (15-20 kDal) IR peptides. When PC12 cells are grown in vivo as a tumor in the NED rat, they express low levels of met^5-enk-RGL peptides which are exclusively of the high molecular weight class. In summary, these results suggest that butyrate elicits the expression of the proenkephalin gene. This tool may be useful for investigating the molecular mechanisms involved in the expression and processing of proenkephalin-derived peptides.

108.10 THE REGULATION OF PRO-OPIOMELANOCORTIN GENE EXPRESSION IN AtT-20/D16-16 ANTERIOR PITUITARY CELLS.
R. M. Knight*, M. Blum, J. L. Roberts, J. M. Farah., J. F. Bishop, T. L. O'Donohue. National Institutes of Health, NINCDS, Building 10, Room 5C 207, Bethesda, MD. 20205. Department of Biochemistry and Center for Reproductive Sciences, Columbia University Medical School, New York, NY 10032.

The AtT-20/D16-16 cell line offers an excellent model for studying the regulation pro-opiomelanocortin (POMC) gene expression. POMC is the precursor of several pituitary peptides that include β-endorphin, the melanocyte-stimulating hormones (α- and γ-melanocyte-stimulating hormones), and adrenocorticotropin hormone (ACTH). In studying the regulation of POMC gene expression, AtT-20/D16-16 cells were incubated with various doses and for various periods of time with a known stimulus of ACTH secretion, corticotropin-releasing factor (CRF). POMC mRNA levels were determined with a dot blot hybridization assay using a [^{32}P]-POMC cDNA probe labeled by nick translation. POMC mRNA was bound to nitrocellulose filters, incubated with labeled POMC cDNA probe, exposed to x-ray film and the mRNA levels were quanitated by densitometry. There was a gradual increase in POMC message levels up to 24 hours after treatment with 0.1μM CRF. It was also found that a maximum increase in POMC message was obtained after an incubation period of 24 hours with CRF. α-aminatin, a known transcription blocking agent, was shown to have an significant inhibition effect on POMC mRNA levels at a concentration of 1.0 μg/ml after 48 hours of exposure with and without CRF stimulation. This data indicated that CRF increased mRNA by inducing transcription. To directly determine if CRF affected the transcription rate of the POMC gene, nuclear run-off transcription assays were preformed. After treatment with 0.1 μM CRF, extracted nuclei were then incubated with [^{32}P]UTP. Nuclear RNA was then purified and hybridized to POMC cDNA probes bond to nitrocellulose filters with PBr322 plasmids as controls. A significant and maximal increase in POMC gene transcription was observed after 30 minutes of CRF stimulation. The results of these studies indicate that CRF induction of POMC gene expression is regulated at the transcriptional level.

108.11 GLUCOCORTICOIDS AND CYCLIC AMP SYNERGISTICALLY ELEVATE ENKEPHALIN-PRECURSOR mRNA IN NG108-15 HYBRID CELLS AND C6 GLIOMA CELLS. S. L. Sabol and K. Yoshikawa, Lab. Biochem. Genetics, NHLBI, National Institutes of Health, Bethesda, MD 20205.

NG108-15 mouse neuroblastoma x rat glioma hybrid cells contain very low amounts of Met- and Leu-enkephalin that are increased 2-3 fold by glucocorticoids such as dexamethasone (Dex) or by cyclic AMP (cAMP) derivatives (Glaser, et al. (1982) J. Neurochem. 39, 59; Braas et al. (1983) J. Neurosci. 3, 1713). This cell line was chosen by us as a model system to study mechanisms that regulate preproenkephalin (ppEnk) gene expression in neuronal cells.

NG108-15 cells were cultured in medium containing 10% steroid-depleted serum or in serum-free steroid-free medium and treated with Dex (varied concentrations) and/or 8-Br-cAMP (1 mM) or an adenylate cyclase (AC) activator (forskolin (10 μM) or prostaglandin E1 (10 μM)). Total RNA was electrophoresed, blotted, and hybridized with ^{32}P-labeled rat ppEnk cDNA (Yoshikawa, et al. (1984) J. Biol. Chem. 259 14301). PpEnk mRNA (1500 bases) was quantitated by densitometry of autoradiograms. To estimate absolute abundances of ppEnk mRNA, known amounts of RNA identical to the coding portion of ppEnk mRNA, prepared by SP6-polymerase dependent transcription of a pSP65-derived plasmid, were blot-hybridized as internal standards. The abundance of ppEnk mRNA in untreated NG108-15 cells was 50-100 fg/μg total RNA. Treatment with Dex alone (1 μM) for 48 hr elevated this level to 3 X the control; the half-maximally effective Dex concentration was 0.01 μM. Other glucocorticoid hormones were fully active while other classes of steroid hormones were inactive. 8-Br-cAMP or AC activators alone weakly elevated ppEnk mRNA levels to 1.4-1.6 x the control in serum-supplemented medium and had no effect in serum-free medium. In contrast, the combination of Dex + 8-Br-cAMP or AC activator elevated the ppEnk mRNA level to 6-8 X the control at 24 hr and 13 X the control at 5 days of culture in either medium. Similar stimulations of the ppEnk mRNA abundance were found when equal amounts of poly A+ RNA were analyzed. Actinomycin D, an inhibitor of transcription, almost totally suppressed the responses to Dex + 8-Br-cAMP. The ppEnk gene expressed in the hybrid cells is the rat rather than the mouse gene, as determined by hybridization with a rat-preferring probe of the 3' untranslated region of the mRNA.

C6 and C6BU-1 rat glioma cells (the latter a parent of NG108-15) were found unexpectedly to contain 2-3 pg ppEnk mRNA per μg total RNA, i.e. 20-60 times as much as NG108-15 cells, although the enkephalin content of C6BU-1 cells was reported to be generally lower than that of NG108-15 cells (Glaser et al.). The ppEnk mRNA levels in C6 cells were elevated to 6 X the control by Dex + 8-Br-cAMP, while treatment with Dex or 8-Br-cAMP alone had little or no effect. Beta-adrenergic receptor agonists, which stimulate C6 AC, elevated the ppEnk mRNA in the presence but not absence of Dex.

These findings demonstrate that the rat ppEnk gene can be transcriptionally activated by the synergistic action of glucocorticoids and elevated cAMP. This activation may be important in neuronal development as well as in certain types of stress. The results with C6 cells also suggest that the ppEnk gene may be expressed, at least transcriptionally, during the development of glial cells.

108.12 CLONED cDNA PROBES FOR SPECIES OF mRNA THAT ARE POSITIVELY OR NEGATIVELY REGULATED BY DIBUTYRYL cAMP IN NEUROBLASTOMA AND HYBRID CELLS. M.Y. Giovanni*, B. Raj*, B.S. Schrier, and M. Nirenberg. (SPON: M. P. Daniels.) NIH, Bethesda, MD, 20205.

Elevation of cellular cAMP levels of NG108-15 neuroblastoma-glioma hybrid cells or NS20-Y neuroblastoma cells for 5 or more days shifts relatively undifferentiated cells to a differentiated state with respect to some neural properties and increases the ability of the cells to form synapses. Cytoplasmic poly A$^+$ RNA was prepared from undifferentiated (D$^-$) logarithmically dividing NG108-15 and NS20-Y cells and from differentiated (D$^+$) cells that had been treated with 1 mM dibutyryl cAMP for 5-7 days. cDNA was synthesized from D$^+$ poly A$^+$ RNA and cloned into pBR322 by G-C tailing. Approximately 400,000 and 800,000 recombinants were obtained in the NG108-15 and NS20-Y cDNA libraries, respectively.

Some recombinants from each library were screened with D$^-$ and D$^+$ ^{32}P-cDNA probes prepared from cytoplasmic poly A$^+$ RNA of D$^-$ and D$^+$ cells by colony hybridization on replica filters after amplification of plasmid DNA. Four classes of recombinants were found: (1) colonies with more D$^+$ ^{32}P-cDNA hybridized than D$^-$ ^{32}P-cDNA, (2) colonies with less D$^+$ ^{32}P-cDNA hybridized than D$^-$ ^{32}P-cDNA, (3) colonies with approximately equal amounts of D$^+$ and D$^-$ ^{32}P-cDNA hybridized, and (4) colonies with little or no D$^+$ or D$^-$ ^{32}P-cDNA hybridized, i.e., either cloned cDNA for low abundance species of mRNA or plasmids that lack DNA inserts. In addition, dot blots of cytoplasmic poly A$^+$ RNA from D$^+$ or D$^-$ cells were hybridized with ^{32}P-DNA from different recombinant plasmids labeled by nick translation. The results show that prolonged treatment of NG108-15 or NS20-Y cells with dibutyryl cAMP results in increases in the abundance of some species of poly A$^+$ RNA, decreases in the abundance of other species of poly A$^+$ RNA, but has no effect on the abundance of most species of mRNA studied. The cloned DNA can be used as probes to study the mechanisms of regulation of mRNA abundance.

108.13 PROTO-ONCOGENE EXPRESSION IS INDUCED IN PC12 CELLS BY NERVE GROWTH FACTOR. T. Curran* and J. Morgan* (SPON: R. Wurzburger). Dept. of Experimental Oncology and Roche Institute of Molec. Biol., Roche Research Center, Nutley, NJ 07110.

Several retroviral genes, termed oncogenes (v-onc), are capable of subverting normal growth regulation thus resulting in malignant transformation. The viral genes have normal progenitor counterparts or proto-oncogenes (c-onc) in chromosomal DNA. The proto-oncogenes are presumed to function as critical modulators of cell proliferation and differentiation. Further, a number of polypeptide growth factors are known to induce proto-oncogenes in a variety of cell types.

This study has addressed the question of whether nerve growth factor (NGF) induces any c-onc in PC12 cells. Such information may then provide clues as to the mode of action of this trophic agent. A very specific stimulation of the c-fos oncogene has been detected in PC12 cells 30 minutes following addition of NGF. This stimulation can be detected by an increase in the c-fos protein after immunoprecipitation of pulse labeled proteins from PC12 cells as well as by an increase in total c-fos mRNA resolved by Northern blotting. Changes in the levels of mRNA for other oncogenes (c-ras^{Ha}, c-ras^{Ki}, c-myc and N-myc) were small, never exceeding 3-fold stimulation, and occurred at later times after addition of NGF. It has been established that certain peripheral type benzodiazepines (BZDs) can modify the response of PC12 cells to NGF. These actions include effects on neurite outgrowth and induction of ornithine decarboxylase. When these agents are present in the culture with NGF there ensues the superinduction of c-fos to at least 100-fold over basal expression. It should be noted that dose-response curves for both NGF and BZDs in inducing c-fos are indistinguishable from those for the induction of neurite growth and the ability of the latter to modify this action of NGF. Furthermore, the structure-activity relationship for the BZDs in modifying NGF-induced neurite outgrowth is identical to that for the superinduction of c-fos. Since the induction of c-fos is one of the most rapid genomic actions of NGF it may be that this gene plays a key role in mediating later transcription-dependent events.

In addition to the above results, BZDs may be used to begin to dissect the events that link NGF receptor binding with the induction of genes such as c-fos or ornithine decarboxylase.

108.14 ABUNDANT RAS IMMUNOREACTIVITY IN APLYSIA NEURONS. M. Swanson, T. Aldrich,* A. Elste,* M. Furth,* S.M. Greenberg and J.H. Schwartz. Howard Hughes Med. Inst., Columbia Univ. Coll. Physicians & Surgeons, New York, NY 10032; and Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

Cellular homologs of the ras oncogenes of Harvey and Kirsten rat sarcoma virus have been isolated in phylogenetically diverse organisms including human, rodent, Drosophila, and yeast. Although the physiological functions of cellular ras proteins are not yet known, mammalian ras genes have been shown to code for guanine nucleotide-binding proteins with M_r 21,000. These are homologous to two higher molecular weight proteins in yeast that are required for GTP-stimulated adenylate cyclase activity; the ras p21 proteins also are related to the G proteins and to transducin.

Because cAMP mediates the presynaptic facilitation that underlies simple forms of learning in Aplysia and because of the possibility that ras genes are also important for cAMP metabolism in higher organisms, we have used a monoclonal antibody to p21-transformed protein encoded by Harvey murine sarcoma virus to identify molecules that might modulate the adenylate cyclase of Aplysia. Ras-immunoreactive antigen was detected by indirect rhodamine immunofluorescence in 16-um sections of nervous tissue. Strong immunofluorescence was detected in cell bodies, neuropil and axons of abdominal and cerebral ganglia, but not in the connective tissue sheath. Bright immunofluorescence was also detected in dissected sensory cells of the pleural ganglion. Some immunofluorescence was also seen in ovotestis, sperm, and eggs. Salivary gland was only weakly immunofluorescent and buccal muscle showed little or no fluorescence. Four of 8 monoclonal antibodies raised against viral H-ras p21 protein precipitated ^{35}S-methionine-labeled protein from Aplysia nervous tissue. These 4 antibodies cross-react with both cellular K-ras and H-ras proteins in all mammalian cells so far examined. Gel electrophoresis of immune precipitates revealed major labeled proteins of M_r 21,000, which are similar to mammalian ras proteins on two-dimensional gels, and a minor M_r 26,000 protein also seen in mammals. One of the 4 antibodies also precipitated labeled Aplysia proteins with M_r of 36,000 and 86,000. Similar cross-reactive proteins also were seen in many mammalian cell lines. Using the technique of genomic Southern blotting, we have identified two distinct Aplysia DNA sequences, one homologous to Harvey sarcoma virus ras DNA and the other to Drosophila ras DNA. We are currently cloning these sequences and shall determine their relationship to the conserved ras gene family.

108.15 DIFFERENTIAL EXPRESSION OF BETA-TUBULIN GENES WITH NEURITE GROWTH INDUCED BY NERVE GROWTH FACTOR.
S.L. Huttner*, P.H. O'Lague, and A. Tobin. Dept. Biology, Jerry Lewis Neuromuscular Research Center, Molecular Biology Institute, University of California, Los Angeles, CA 90024.

Microtubules consisting of tubulin proteins and microtubule-associated proteins are a major component of the neuritic cytoskeleton. They are important both for the structural integrity of the neurite and for axoplasmic transport. Tubulin proteins are encoded by several closely related genes that form a multigene family. It appears likely that individual members of this family are expressed in tissue- and function-specific manners. We have been studying the patterns of expression of tubulin mRNA before and during the period of neurite growth induced in PC-12 pheochromocytoma cells by nerve growth factor (NGF) with the use of cDNA probes isolated from a cDNA library produced from NGF-treated PC-12 cell mRNA.

We have found that RNA of untreated PC-12 cells contains two size classes that hybridize with a chicken beta-tubulin (pT2) cDNA probe in RNA filter blot hybridizations while NGF-treated cells contain only one size class (Huttner et al, 1984, Dev Biol Abstr 57). As a first step towards determining whether this changing pattern is due to differential gene expression within the tubulin gene family a cDNA library was created in lambda-GT 11 using mRNA of PC-12 cells treated 14 days with NGF. Several beta-tubulin encoding clones have been selected from this library by plaque hybridization screening with the chicken pT2 probe. The inserts of these clones have been partially characterized by restriction mapping and their 3' and 5' untranslated regions identified.

The gene-specific untranslated region fragments of these inserts are being used as hybridization probes with RNA filter blots containing RNA of NGF-treated and untreated PC-12 cells. Preliminary observations indicate that one of these contains cDNA for a beta-tubulin gene that is expressed only in NGF-treated cells. We are continuing to characterize the patterns of expression of the other clones, as well.

REGULATION OF PITUITARY FUNCTIONS II

109.1 CHARACTERIZATION AND REGULATION OF ION TRANSPORT IN CULTURED MONOLAYERS OF BOVINE PITUITARY FOLLICULAR CELLS.
N. Ferrara*, M. Moss, J. Widdicombe*[1] and R. Weiner. Dept. of OB/GYN and Repro. Sci. and CVRI[1], UCSF, San Francisco, CA 94143.

We have reported a method for the culture of follicular cells (FC) of the bovine anterior pituitary (AP) or pars tuberalis. FC grown on plastic or on extracellular matrix form homogeneous, contact-inhibited monolayers which rapidly develop domes. It is well established that domes are an expression of active transepithelial ion and fluid transport observed in morphologically and functionally polarized cells. The ultrastructure of FC, i.e. tight junctions and apical microvilli, is also consistent with such a function. We investigated the ion transport properties of FC monolayers mounted in Ussing chambers. Primary cultures of FC were grown in DMEM 0.1% glucose supplemented with 15% fetal bovine serum, glutamine and antibiotics. At confluency, cells were passaged and cultured onto Nucleopore filters coated with human placental collagen. A detectable potential difference (PD) and resistance developed 2-3 days after plating and rapidly reached a steady-state of 2-4 mV and 80-400 ohms x cm^2, respectively. Amiloride (10^{-4}M) dramatically decreased PD and short circuit current (I_{sc}) when applied on the luminal side of the chamber but was ineffective on the serosal side. The addition of serosal but not luminal ouabain (10^{-4}M) almost completely abolished the residual PD and I_{sc}. Serosal application of isoproterenol or epinephrine induced an immediate dose-dependent increase in PD and I_{sc} followed by a decline to levels higher than the original. The complete prevention of these effects by propranolol (10^{-5}M) was consistent with an action mediated by β-adrenergic receptors. The stimulatory action of β-adrenergic agonists on I_{sc} was not prevented by amiloride, but was significantly decreased in the absence of Cl, suggesting that at least some of the increase in I_{sc} was due to stimulation of active Cl^- secretion. Receptor binding studies on FC membrane preparations, using ^{125}I-iodocyanopindolol as a ligand, demonstrated the presence of a high affinity saturable β-adrenergic binding site. These studies demonstrated the ion transport properties of FC and the regulation of ion transport by β-adrenergic agonists. It is tempting to speculate that in vivo FC are involved in the regulation of the ion concentration and osmolarity of the interstitial fluid of the AP. This work supported by NIH grant HD08924 and NIH PPC-HL-24136.

109.2 PRESENCE OF ARTERIOGENESIS IN SPONTANEOUS ANTERIOR PITUITARY TUMORS OF OLD AGE MICE.
K.A. Elias*, C. Finch, and R.I. Weiner. DEPT. OF OB/GYN and REPROD SCI, UCSF, San Francisco 94143 and GERONTOLOGY CENTER, USC, Los Angeles, CA. 90089.

We have reported that the development of estrogen-induced prolactin-secreting anterior pituitary gland (AP) tumors in rats is accompanied by the development of a direct arterial blood supply (arteriogenesis) to the AP. Since systemic arterial blood contains subphysiological concentrations of the prolactin inhibitory hormone, dopamine, regions supplied by the artery escape tonic dopaminergic inhibition. Removal of dopamine inhibition was hypothesized to be involved in the etiology of tumor formation. In the present study, we examined the development of arteriogenesis coincident with the presence of spontaneous tumors in old age mice. Approximately 50% of this strain of mouse develops prolactin secreting tumors by 24 months. Fifteen- and 30-month-old mice C57B6/6J (USC colony) were anesthetized and 0.2 ml saline containing 300,000 microspheres (15 μm in diameter) were injected into the left ventricle of the heart. The pituitary was removed, fixed in paraformaldehyde, embedded in JB-4 plastic, 5 μm sections cut, and every other section microscopically examined for the presence of microspheres. Because of their size, microspheres are trapped in the primary portal capillaries and normally do not reach the AP. If a direct arterial supply has developed, microspheres can reach the gland. In nine 15-month-old mice (pit. wt $\bar{X}$ = 2.5 ± 0.1 mg), no AP tumors were observed. Eight of 12 AP from 30-month-old mice contained grossly identifiable tumors. Histologically, the tumors were composed of cords of secretory cells surrounded by vascular lakes consisting of extravasated red blood cells. The four AP from 30-month-old mice (pit. wt $\bar{X}$ = 2.2 ± 0.1 mg) without identifiable tumors and the nine AP from the 15-month-old mice contained no microspheres. Three AP from 30-month-old mice with tumors contained 15, 65, or 76 microspheres. The total pituitary weight of these pituitaries was 6.6, 43.6, and 5.7 mg, respectively. The additional five AP with tumors (pit. wt $\bar{X}$ = 3.3 ± 1.5 mg) contained 3 or less microspheres. These data demonstrate the occurrence of arteriogenesis in some spontaneously formed AP tumors in old aged mice, and are consistent with our previous observations in estrogen-induced prolactin-secreting tumors in rats. The findings further support a role for vascular changes in the etiology of AP tumors. Supported by NIH Grants HD 08035, HD 06243, and AG 00117.

109.3 POTASSIUM STIMULATED CALCIUM 45 UPTAKE INTO GH_3 PITUITARY CELLS: EFFECTS OF INHIBITORS OF LIPOXYGENASE AND PHOSPHOLIPASE A_2. L. Baird* and L. Grandison (SPON: A. Sinha) UMDNJ-Rutgers Medical School, Piscataway, N.J. 08854.

The intracellular processes regulating secretion of prolactin from pituitary cells involve several second messenger systems. Recently we and others have suggested that arachidonic acid or its metabolites may participate in the intracellular processes modulating secretion. Part of the evidence supporting involvement are the observations that pharmacological blockade of arachidonic acid release or metabolism potently inhibits prolactin release. Phospholipase A_2 (PLA2) hydrolyzes phospholipids thereby releasing arachidonic acid. Lipoxygenase (LPO) catalyzes the conversion of arachidonic acid to leukotriene (LT) products. In order to characterize the processes affected by PLA2 and LPO inhibitors we examined their action on potassium stimulated calcium uptake. The PLA2 inhibitors quinacrine, dibromacetophenone and U10029A blocked potassium induced calcium 45 uptake. The LPO inhibitors nordihydroguaiaretic acid (NDGA), BW 755C, ETYA and 15 HPETE also blocked induced uptake. None of the agents tested prevented potassium induced depolarization of the membrane. In further studies using cells preloaded with calcium 45 NDGA was found to block efflux induced by arachidonic acid. The actions of the PLA2 and LPO inhibitors on prolactin release occurred within the dose range found in other cell types to block phospholipase A_2 and lipoxygenase activity. The ability of PLA2 and LPO inhibitors to block calcium uptake can account for their ability to reduce prolactin release, a process partially dependent on calcium influx. Still unclarified, however, is the relationship between the ability of these agents to affect calcium influx and to inhibit PLA2 and LPO activity. If the activities are unrelated, these agents are inappropriate for investigating the involvement of arachidonic acid in the functioning of intact cells. However, these agents could be blocking the formation of arachidonic acid products that modulate calcium mobilization. (Supported in part by NIH Grant AM 32827)

109.4 INVESTIGATION INTO THE INVOLVEMENT OF DIACYLGLYCEROL LIPASE IN PROLACTIN SECRETION FROM GH_3 PITUITARY CELLS. A.M. Camoratto and L. Grandison. UMDNJ-Rutgers Medical School, Piscataway, N.J. 08854

Recent evidence suggests that arachidonic acid may modulate secretion of prolactin from the anterior pituitary. Arachidonic acid can be released from membrane phospholipids by the action of phospholipase A_2; alternatively, arachidonic acid can be derived from 1,2-diacylglycerol by the sequential actions of diacylglycerol lipase (DG lipase) and monoacylglycerol lipase (MG lipase). In this study we examined the involvement of DG and MG lipases in prolactin secretion from GH_3 cells using RHC80267, an inhibitor of DG and MG lipases. Incubation of the cells with RHC80267, at concentrations ranging from 10-100uM, resulted in a dose-related inhibition of basal prolactin secretion. Inhibition persisted for up to four hours, the longest time period examined. We next examined the effects of RHC80267 on secretagogue-induced prolactin release. The stimulatin of prolactin secretion produced by thyrotropin releasing hormone (TRH) could be reduced by a dose of RHC80267 which did not effect spontaneous prolactin release. The mechanism of TRH action is believed to include the activation of an inositol lipid-specific phospholipase C. Treatment of the cells with exogenous phospholipase C resulted in an increase in prolactin secretion; this increase could be blocked by a low dose of RHC80267. Both TRH and phospholipase C increase the levels of diacylglycerol in GH_3 cells. In contrast RHC80267 did not block stimulation of prolactin release produced by phorbol myristate acetate (PMA) or by melittin. The actions of PMA and of melittin occur by pathways which do not result in generation of diacylglycerol. In order to further characterize the mechanisms involved in the inhibition of basal and stimulated prolactin release by RHC80267 we examined the effect of this compound on potassium-stimulated 45-calcium uptake. RHC80267 blocked depolarization-induced calcium uptake into GH_3 cells at the same doses which had been effective in reducing prolactin secretion. The ability of RHC80267 to block TRH- and phospholipase C-stimulated prolactin release may be related to its effect on calcium influx. This action could be due to a direct effect of RHC80267 on calcium uptake which is not related to its ability to inhibit DG and MG lipase activity; however, inhibition would also occur if the products of DG and MG lipases were able to modulate calcium influx. (Supported in part by NIH Grant AM 32827).

109.5 GNRH RAPIDLY STIMULATES POLYPHOSPHOINOSITIDE BREAKDOWN IN ANTERIOR PITUITARY CELLS IN CULTURE. M.A.Sortino*, P.L. Canonico, C. Speciale*, R.M.MacLeod and W.S.Evans* (SPON: R.J.Krieg). Department of Pharmacology (MAS, PLC, CS), University of Catania, Catania, Italy and Department of Internal Medicine (RMM, WSE), University of Virginia, Charlottesville, VA 22908.

The mechanism of action of gonadotropin-releasing hormone (GnRH) seems to involve membrane phospholipids. An increase in [^{32}P] incorporation into phosphatidylinositol and phosphatidic acid by the peptide in cultured rat pituitary cells has been reported. It is now generally agreed that the initial reaction following receptor activation is the breakdown of inositol lipids, while phospholipid labeling may represent only a secondary effect. Therefore, to investigate the direct effect of GnRH on phosphoinositide breakdown we measured water soluble products (inositol phosphates) released during the hydrolysis of phosphatidylinositol by phospholipase C. During a 60 minute incubation, GnRH in a concentration dependent manner (and in the presence of 10 mM LiCl), caused a progressive increase in total [^{3}H]-inositol phosphate content in anterior pituitary cells from female rats in primary culture. The effect was significant at 1 pM ($p < 0.01$) and maximal (4-5-fold increase) at 100 nM. This effect was completely abolished by a 10 min preincubation with the potent antagonist [Nac-L-Ala^1,pCl-D-Phe^2,D-Trp^{3,6}] GnRH. Ten nM GnRH significantly stimulated total [^{3}H]-phosphate accumulation within 1 min. The fractionated measurement of inositol phosphates showed that inositol triphosphate (IP_3) and inositol bisphosphate appearance preceded that of inositol monophosphate. Ten nM GnRH also significantly reduced the level of [^{3}H]-phosphatidylinositol-4,5-biphosphate and [^{3}H]-phosphatidylinositol-4-phosphate, an effect that was already present within 20 sec. These results indicate that GnRH may act at the gonadotroph through a stimulation of polyphosphoinositide breakdown and a consequent increase of IP_3 and diacylglycerol responsible for gonadotropin secretion.

109.6 TRANSMEMBRANE SIGNALS MEDIATING NEURAL PEPTIDE SECRETION: ROLE OF PROTEIN KINASE C ACTIVATORS IN LHRH RELEASE. M. M. Valenca* and A. Negro-Vilar. Reproductive Neuroendocrinology Section, Lab. Reprod. Dev. Tox., NIEHS, NIH, Research Triangle Park, NC 27709

A variety of neurotransmitters and several intracellular messengers (Ca^{2+}, cAMP, PGE_2) have been shown to be involved in the secretion of LHRH from hypothalamic neurons. In few cases, however, activation of a given receptor has been linked with a specific intracellular messenger system to elicit release of this peptide. Many recent reports suggest that a variety of secretagogues act in different cells by enhancing metabolism of inositol phospholipids. This leads to the formation of a series of compounds which result in Ca^{2+} mobilization, activation of protein kinase C and also release of arachidonic acid. The latter can be metabolized to different products, including PGE_2, which we have shown to be a potent secretagogue of LHRH (Endocrinology 104:617, 1979). The present experiments were designed to determine the effects of a diacylglycerol and a phorbol ester, two specific activators of protein kinase C, on the secretion of LHRH in vitro. Phorbol 12,13-dibutyrate (PDBu) and a synthetic diacylglycerol, 1,2-didecanoylglycerol (DiC_{10}), were used to evaluate their effects on release of LHRH from median eminence (ME) fragments incubated in vitro. Adult intact male rats were used as tissue donors and all incubations were run at 37C in Krebs Ringer bicarbonate buffer. PDBu significantly increased LHRH secretion at concentrations of 50-200 nM. This stimulatory effect was also observed when tissues were incubated in Ca^{2+}-free, EGTA-containing media. The stimulation of LHRH by PDBu was apparently not dependent on an enhanced formation of arachidonic acid metabolites, since PDBu stimulated LHRH release in the presence of cyclooxygenase and lipoxygenase blockers. DiC_{10} produced a small increase in LHRH release at a concentration of 100 uM, while markedly enhancing PGE_2 formation. Blockade of lipoxygenase (NDGA,10-30 uM) greatly enhanced the LHRH release induced by DiC_{10}, an effect also observed in the absence of extracellular calcium. In conclusion, our results indicate that these well-known activators of protein kinase C can stimulate secretion of a neuropeptide, LHRH, from nerve terminals in vitro and, further, that endogenous 1,2-diacylglycerol may represent an important intracellular messenger participating in the events leading to LHRH release in response to a given secretagogue.

109.7 Leukotriene C_4 plays a role in prolactin release from 7315a tumor cells. A. M. Judd*, K. Koike*, I. S. Login*, and R. M. MacLeod. Dept. of Internal Medicine and Neurology, University of Virginia School of Medicine, Charlottesville, Virginia 22908.

Arachidonate metabolism and hormone release appear to be closely linked processes in several endocrine organs. We have studied the effects of maitotoxin, a calcium channel activator, on arachidonate metabolism and on prolactin release from 7315a tumor cells. Primary cultures of 7315a cells were labeled for 90 minutes with [^{3}H] arachidonate (1 uCi/ml) to incorporate the fatty acid into esterified lipids. The cells were then washed with buffer without [^{3}H] arachidonate, incubated 30 minutes with vehicle or an inhibitor of arachidonate metabolism, and then exposed for an additional 30 minutes to vehicle or an inhibition of arachidonate metabolism and/or maitotoxin (5 ng/ml). The incubation medium was analyzed for prolactin by RIA; arachidonate and prostaglandins by TLC, and leukotrienes by HPLC. In 7315a cells maitotoxin significantly increased release of prolactin (300%), arachidonate (400%), prostaglandins E_2 and F_2 (PGE_2, PGF_2 , 300%), and leukotriene C_4 (LTC_4, 500%). We were unable to detect any production of leukotrienes B_4 or D_4 by the tumor cells. The increase in arachidonate metabolism produced by maitotoxin was related to calcium mobilization because maitotoxin had no effect on prolactin or arachidonate release in low calcium incubation medium. In order to assess the role of arachidonate metabolites on prolactin release, 7315a cells were exposed to inhibitors of arachidonate metabolism. Quinacrine, an inhibitor of arachidonate liberation from phospholipids decreased LTC_4 and prolactin release. BW755c, an inhibitor of conversion of arachidonate to its metabolites, inhibits maitotoxin-induced prolactin, PGE_2, PGF_2 , and LTC_4 release but did not alter arachidonate release. Indomethacin, an inhibitor of PG systhesis, decreased PGE_2 and PGF_2 release but did not modify prolactin, LTC_4, or arachidonate release. In contrast nafazatrom and NDGA inhibitors of leukotriene production decreased LTC_4 and prolactin release but did not alter PGE_2, PGF_2 or arachidonate release. In summary, calcium mobilization, arachidonate release and prolactin release are closely coupled processes in 7315a tumor cells. Furthermore LTC_4 production and prolactin release are closely related events. It is hypothesized that LTC_4, a potent activator of intracellular calcium, may have a major role to augment prolactin release from 7315a tumor cells. (Supported by NIH Grant CA 07535).

109.8 PROPERTIES OF WHOLE-CELL CALCIUM AND POTASSIUM CURRENTS IN IDENTIFIED LACTOTROPHS FROM DISSOCIATED RAT ANTERIOR PITUITARY (AP). C.J.Lingle, S. Sombati*, M. Truman* and M.E. Freeman*. Dept. Biol.Sci.,Florida State University, Tallahassee, FL 32306.

The study of the electrophysiological properties of cultured primary cells is frequently compromised by the inability to identify specific cell types in a heterogeneous population. In our studies of the properties of rat AP cells, we have overcome this problem by using the reverse hemolytic plaque assay (Neill & Frawley, Endocr. 112:1135, 1983) to identify lactotrophs for concurrent electrophysiological examination with standard patch-clamp techniques (Lingle, et.al. Biophys. J.47:136a,1985).

Inward currents of plaque-identified lactotrophs from long-term ovariectomized rats were examined following rupture of cell-attached patches (inside solution: 130 mM CsCl, 20 mM EGTA, 10 HEPES; outside: 0.5-1 uM TTX, TRIS and 10 or 50 mM $CaCl_2$). Inward currents following subtraction of leak and capacitative currents appears to consist of two components: a transient (3-10 ms to peak) component activated at low voltages (-30 to 0 mV) which inactivates almost completely over 100 ms and a sustained inward current. 0.5 mM Cd^{++} exerts a differential effect on the two components, blocking the sustained current completely, while the transient component is somewhat resistant particularly at depolarizations to less than 0 mV. For over 10 cells, peak inward current in 10 mM Ca^{++} was approximately 50 pA, and, in 50 mM Ca^{++}, near 100 pA. The magnitude of Ca^{++} currents from AP cells of untreated ovariectomized rats appears to be substantially smaller than observed for clonal AP lines.

Three outward current components have been resolved (in: 115 KCl, 10 EGTA, 10 HEPES; out: TTX, 1.6 Ca^{++}). On depolarizing steps from -60 mV, outward currents contain a transient shoulder which decays to a steady-state current. 30 mM TEA or 0 Ca^{++} blocks most of the late-sustained current, revealing an almost isolated transient current. Following inactivation of the transient current by conditioning steps to -20 mV, an additional small current was observed that activated with a sigmoidal time course over 20-50 ms and did not inactivate over 200 ms. The transient current appears to be an A current, the TEA- and Ca^{++}-sensitive current is a BK calcium-activated K^+-channel, and the sigmodal current appears to be a delayed rectifier current. Candidates for the unitary channels underlying each of these outward currents have been identified in cell-attached patch recordings. (Supported by NS-19139 to CJL and HD-11669 to MEF)

109.9 SEROTONIN AND DOPAMINE RECEPTORS IN THE RAT PITUITARY GLAND: AUTORADIOGRAPHIC LOCALIZATION. Errol B. De Souza and Theresa A. Kopajtic*. Laboratory of Neuroscience, Addiction Research Center, NIDA, Baltimore, MD 21224, and Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Serotonin and dopamine have been shown to regulate pituitary hormone secretion both through effects in brain and by direct actions on the pituitary gland. In addition to the primary role for dopamine in the portal blood as an inhibitor of prolactin secretion from the anterior pituitary gland, dopamine-containing fibers that terminate on intermediate lobe cells of the rat pituitary have been shown to inhibit the release of proopio-melanocortin derived-peptides. High serotonin concentrations have been detected and serotonergic nerve fibers have been localized in the intertermediate lobe of the rat pituitary. Radioligand binding studies in homogenates have identified and characterized dopamine receptors in anterior, intermediate and posterior lobes of the pituitary gland; however, serotonin receptors remain to be identified in the pituitary. In the present study, we used ^{3}H-spiperone to identify and localize dopamine D-2 and serotonin 5HT-2 receptors in rat pituitary by in vitro labeling light microscopic autoradiography. Differential drug sensitivity allowed the selective displacement of ^{3}H-spiperone from D-2 receptors by the dopamine agonist ADTN (1 uM) and from 5HT-2 receptors by the serotonin receptor antagonist cinanserin (0.3 uM). A very high concentration (fmoles/mg protein; mean + SEM) of dopamine D-2 receptors was found in the intermediate lobe (985 + 28) with much lower concentrations present in the anterior lobe (89 + 7); ^{3}H-spiperone binding in the posterior lobe was variable. A significant concentration of cinanserin-displaceable ^{3}H-spiperone binding sites was present only in the intermediate pituitary (290 + 28). There was a fairly uniform pattern of distribution of ^{3}H-spiperone binding sites within each lobe of the rat pituitary. To selectively visualize 5HT-2 receptors in the intermediate lobe of the pituitary gland, we examined the autoradiographic distribution of ^{125}I-LSD which binds with a high affinity to 5HT-2 receptors. The specific serotonin 5HT-2 receptor agonist ketanserin (100nM) was used to define ^{125}I-LSD binding to 5HT-2 receptors. Ketanserin-displaceable ^{125}I-LSD binding sites were present in significant quantities and were uniformly distributed in the intermediate lobe of the rat pituitary. In summary, our results provide the first identification of serotonin 5HT-2 receptors in the pituitary gland and confirm the heterogeneous distribution of dopamine D-2 receptors within the rat pituitary. These data provide further evidence for the functional importance of dopamine in regulating pituitary function and suggest a physiological role for serotonin in regulating intermediate lobe hormone secretion. Supported by DA00266, NS15080 and MH00053 and the McKnight Foundation.

109.10 THE ROLE OF SEROTONIN RECEPTOR SUBTYPES IN THE REGULATION OF CORTICOSTERONE AND BETA-ENDORPHIN SECRETION IN THE RAT. J.I. Koenig, G.A. Gudelsky and H.Y. Meltzer. Dept. of Psychiatry, Univ. of Chicago and Ill. State Psychiatric Inst., Chicago, IL. 60637.

The activation of serotonin (5-HT) receptors by quipazine has been found to stimulate the secretion of corticosterone (B) in the rat. Ketanserin, a highly selective 5-HT_2 antagonist, potently inhibited the effect of quipazine, suggesting that 5-HT_2 receptor activation mediated the B-releasing effect of quipazine (Res. Comm. Chem. Path. Pharm. 46:151). Quipazine and the serotonin precursor, 5-hydroxytryptophan, have also been shown to elevate plasma levels of beta-endorphin (END) in the rat (Endocrinology 109:421). The goal of the present study was to ascertain the role of the 5-HT_1 receptor and further clarify the role of 5-HT_2 receptors in the regulation of the secretion of B and END in the rat. Adult male Sprague-Dawley rats were used in all studies. Thirty min after the administration of the 5-HT_1 agonist 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) or the 5-HT_2 agonist 6-chloro-2-(1-pipraziny1)pyrazine (MK-212) or their respective vehicles, the animals were sacrificed by decapitation. When antagonists were employed, these drugs were injected 30-60 min before the agonists. Trunk blood was collected into chilled plastic tubes containing EDTA and plasma was collected following centrifugation. Plasma concentrations of B and END were determined by RIA. The administration of the 5-HT agonists 8-OH-DPAT (0.03-0.3 mg/kg) or MK-212 (0.3 mg/kg-3.0 mg/kg) caused dose-related elevations in plasma levels of both B and END. The injection of the vehicle did not change the concentration of either B or END in the plasma. The B- and END-releasing effects of MK-212 were potently blocked by the selective 5-HT_2 antagonists ketanserin (1 mg/kg) , mianserin (10 mg/kg) and altanserin (1 mg/kg). Activation of B and END secretion by 8-OH-DPAT (0.1 mg/kg) which selectively activates 5-HT_1 receptors was not antagonized by ketanserin, mianserin, altanserin or ritanserin. However, the B-releasing activity of 8-OH-DPAT was blocked by spiroperidol(1.0 mg/kg),which has substantial activity at the 5-HT_1 receptor subclass. Although 8-OH-DPAT also has dopaminergic properties, its effects on B and END were not blocked by haloperidol. Therefore, our data would suggest that B and END secretion can be stimulated by the activation of the 5-HT_1 or 5-HT_2 receptors. The effects of 5-HT_2 agonists may be blocked selectively by 5-HT_2 antagonists whereas activation of 5-HT_1 receptors is only antagonized by compounds possessing affinity for the 5-HT_1 receptors.
Supported, in part, by USPHS MH 30938.

109.11 EFFECTS OF FLUOXETINE, A SEROTONIN - UPTAKE INHIBITOR, ON SEROTONIN-IMMUNOREACTIVE INNERVATION OF THE PITUITARY NEUROINTERMEDIATE LOBE. L.C. Saland, J.A. Wallace and F. Comunas*. Dept. of Anatomy, Univ. of New Mexico School of Medicine, Albuquerque, NM 87131.

We have previously demonstrated that serotonin-immunoreactive (5-HT-IR) nerve fibers to the pituitary gland are differentially affected by anti-serotonin and anti-catecholamine (CA) drugs (Saland et al, 1984, Soc. Neurosci. Abst. 10:87 and Manuscript submitted). P-chlorophenylalanine eliminated 5-HT-IR in the entire neurointermediate lobe, while 6-hydroxydopamine only eliminated intermediate lobe fiber staining. These results suggest that nerves that sequester the CA neurotoxin, might also take up and/or synthesize 5-HT. To further examine possible 5-HT uptake by pituitary innervation, we administered the 5-HT uptake inhibitor, fluoxetine hydrochloride, and studied 5-HT-IR in the rat neurointermediate lobes. Adult male Sprague-Dawley rats received 10 mg/kg fluoxetine hydrochloride (a gift of Eli Lilly and Co.) by intraperitoneal injection, while controls received saline vehicle. Two to three hours post-injection, animals were ether-anesthetized and perfused via the heart with cold phosphate-buffered saline (PBS) followed by 4% paraformaldehyde in 0.1 M phosphate buffer. Pituitary glands were routinely dehydrated and paraffin embedded. Sections were incubated with 1:1000 or 1:2000 dilution of anti-5-HT primary antibody, and immunoreactive sites were visualized using an avidin-biotin peroxidase technique. Sections from controls contained a fine varicose pattern of pars intermedia fiber staining, with heavier staining in the pars nervosa. Fluoxetine treatment induced a diminution or elimination of fiber staining in the pars intermedia, but had little or no effect on the pattern or intensity of pars nervosa staining. We interpret the effects of fluoxetine to indicate that 5-HT-stained fibers of the pars nervosa derive from indoleamine neurons of the CNS. However, a significant portion of pars intermedia 5-HT-IR fibers may be present as a result of uptake of 5-HT. We are presently comparing 5-HT and tyrosine hydroxylase staining patterns in the pituitary to determine the possibility that 5-HT and CA co-exist in fibers innervating the pars intermedia. Supported by NIHRR08139 (LCS), NIH20039 and NSF BNS 82-08433 (JAW)

109.12 RADIOAUTOGRAPHIC LOCALIZATION OF β-ADRENERGIC RECEPTORS IN THE RAT AND RABBIT PITUITARY. S. Schimchowitsch*, L. Williams*, P. Poyet* and G. Pelletier, MRC Group in Molecular Endocrinology, CHUL, Quebec G1V 4G2, Canada.

It is well documented that catecholamines can stimulate the release of POMC-related peptides from the intermediate lobe of the pituitary via interaction with β-adrenergic receptors (Meunier et al., Eur. J. Pharmacol. 81: 411, 1982). This mechanism which has been extensively studied in the rat has recently been demonstrated in the intermediate lobe of the rabbit pituitary. In order to identify the sites of β-adrenergic receptors in the pituitary of both the rat and rabbit, we used a technique which allows the localization and characterization of receptors on slide mounted cryostat sections (Herkenham, M. and Pert, C.B., J. Neurosci. 2: 1129, 1982). Cryostat sections (15 to 20 μm thick) from rat and rabbit pituitaries were incubated with [^{125}I]cyanopindolol, a high affinity ligand which binds equally to both β_1 and β_2 subtypes. Labelling was localized by radioautography. Characterization of receptor subtypes was achieved by measuring in scrapped off sections or in radioautographs (densitometry) the inhibition of [^{125}I]cyanopindolol binding by varying concentrations of two drugs, practolol which has a greater affinity for β_1 subtype and zynterol which has a greater affinity for β_2 subtype. In the rat pituitary receptors which appeared to be of the β_2 subtype were almost exclusively located in the intermediate lobe although light labelling could also be detected in the anterior and posterior lobes. In the rabbit pituitary the IC_{50} values for zinterol and practolol for inhibiting [^{125}I]cyanopindolol binding were 60.7 ± 4.8 nM and 2.35 ± 0.47 μM, respectively, thus indicating that the receptors were mostly of the β_2 subtype. As observed in the rat pituitary, the receptors were mainly concentrated in the rabbit intermediate lobe. However, radioautographic data showed that a moderate concentration of receptor sites was homogenously located in the anterior lobe. The demonstration of high concentration of β_2 receptors in the intermediate lobe of the two species are in agreement with previous physiological and pharmacological studies. The exact role of these receptors in the anterior and posterior lobes however remains to be clarified.

109.13 DOPAMINERGIC MODULATION OF PEPTIDE SECRETION AND ANATOMICAL FEATURES OF THE INTERMEDIATE LOBE OF THE RAT PITUITARY GLAND. B.M. Chronwall, W.R. Millington, G.P. Mueller, W.S.T. Griffin, J.L. Roberts, T.L. O'Donohue. Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205; Dept. of Physiology, USUHS, Bethesda, MD 20014; Dept. of Cell Biology, Univ. Texas Southwestern Med. School, Dallas, TX 75235 and Dept. of Biochemistry and Center for Reproductive Sciences, Columbia Univ. Medical School, New York, NY 10032.

The secretion of α-MSH and β-endorphin (α-END) by the intermediate lobe (IL) is regulated predominantly by dopamine releasing neurons projecting from the arcuate nucleus, which inhibit the spontaneous depolarization of melanotrophs. Chronic treatment of rats with haloperidol (2 mg/kg/d; 21 d), a dopamine antagonist, stimulated the release of α-MSH and β-END from the IL and increased IL peptide content. Chronic administration of bromocriptine (4 mg/kg/d; 21 d) had the opposite effect. Similar to the changes in pro-opiomelanocortin (POMC) derived peptides, the POMC mRNA level was increased by haloperidol and decreased by bromocriptine.

To determine the cellular basis for dopamine regulation of melanotrophs, their ultrastructure was investigated after haloperidol and bromocriptine treatment. In control rat IL, approximately 15% of the melanotrophs stain lighter than the rest with toluidine blue on plastic semithin sections. In EM preparations, the light staining cells contain fewer metabolically active organelles (RER 50%, mitochondria 33%, Golgi complex 25%) and have less dense cytosol than the dark staining cells. Short term (2 d) haloperidol treatment increased both the total number of cells and the proportion of dark staining cells in the IL. Long term treatment (21 d) resulted in a great increase in the cell number in the IL. These cells are predominantly dark staining. Short term bromocriptine treatment had the opposite effect; it decreases the cell number in the lobe and increased the proportion of light staining cells. With long term treatment, the IL is reduced to a thin layer of cells containing a considerable amount of heterochromatin.

Dopamine seems to modulate the IL peptide secretion at three different levels. Acutely there is a change in POMC mRNA synthesis; with subchronic treatment the biosynthetic capacity is altered by increase or decrease of the metabolic rate of the melanotrophs and with chronic treatment the mitotic rate of the IL cells is changed. Current studies are using in situ hybridization employing a POMC cDNA probe and a POMC riboprobe to compare POMC mRNA levels in dark and light staining cells and to study changes in message levels during pharmacological manipulation.

109.14 PEPTIDE AMIDATION IN INTERMEDIATE PITUITARY CELL CULTURES. V. May and B. A. Eipper*. Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The rat intermediate pituitary contains high levels of two pro-ACTH/endorphin-derived α-amidated product peptides, αMSH and joining peptide, and high levels of a copper and ascorbate dependent peptidyl glycine α-amidating monooxygenase (PAM) capable of converting glycine-extended peptide precursors (-X-Gly) into amidated products (-X-NH_2). The present studies investigate the relationship of cellular ascorbate content to both PAM activity and ability of cultured pituitary cells to produce α-amidated peptide products (αMSH and joining peptide). Intermediate pituitary tissue was enzymatically dispersed and cultured in complete serum-free medium. After various times in culture, the cells were harvested in 20 mM NaTes buffer, pH 7.0, for PAM assays and in 50 mM perchloric acid, containing 1 mM EDTA and 2 mM thiourea for ascorbate determinations by HPLC/electrochemical detection. The ability of cultured cells to accumulate ascorbate was measured using [^{14}C]-ascorbic acid. The ability of the cultured cells to α-amidate newly-synthesized peptides was determined by analyzing αMSH-related molecules biosynthetically labeled with [^{3}H]Trp and joining peptide-related molecules biosynthetically labeled with [^{3}H]Pro. Primary intermediate pituitary cells in culture rapidly lose their ability to produce both the Val-NH_2 at the C-terminus of αMSH and the Glu-NH_2 at the C-terminus of joining peptide. A 2-fold decline in intermediate pituitary culture PAM activity assayed in vitro under optimized conditions failed to account for the lack of α-amidated αMSH production while a simultaneous 100-fold decline in cellular levels of ascorbate could account for the lack of production of α-amidated product. Incubation of cultured cells with ascorbate partially restored the ability of the cells to produce α-amidated αMSH and joining peptide without increasing PAM activity levels. In intermediate pituitary cultures that were made competent to α-amidate 75% of the newly-synthesized αMSH by the addition of 500 μM ascorbate to the culture medium, the effect of various secretagogues on the extent of amidation was determined. Chronic (72h) treatment with the dopaminergic agonist, bromocriptine, consistently decreased the ability of cells to α-amidate newly-synthesized αMSH to 55-60%. Acute or chronic treatment with CRF resulted in an increased synthesis of α-MSH-related material but a significant decline in the percent of newly-synthesized material that was α-amidated. Incubation with cAMP, GABA, isoproteronol, or serotonin failed to alter the extent of amidation. Production of amidated products therefore appears to be regulated by cellular levels of ascorbate, cellular levels of PAM activity and by the specific secretagogues to which the cells are exposed. Supported by AM-32949, ES-07094, DA-00266 and DA-00098.

109.15 LESIONS OF THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS PREVENT STRESS-INDUCED INCREASES IN PITUITARY CYCLIC AMP. J.L. Meyerhoff, E.H. Mougey*, C.B. Wormley*, L.L. Pennington*, and G.J. Kant. Dept. Med. Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307-5100.

We have previously shown that stress elevates pituitary cyclic AMP in vivo. These increases were associated with increased plasma levels of pituitary hormones (ACTH, β-endorphin and β-LPH) thought to be chiefly regulated by the hypothalamic peptide, corticotropin-releasing factor (CRF). CRF is one of several substances reported to increase pituitary cyclic AMP in vitro. The paraventricular nucleus (PVN) of the hypothalamus has been identified as a major center involved in the regulation of ACTH secretion from the anterior pituitary gland, and it has been recently shown that CRF is highly concentrated in the PVN. To determine the role of the PVN in the stress-induced increase of pituitary cyclic AMP in vivo, we lesioned the PVN bilaterally in male Sprague-Dawley rats.

Lesioned and sham-operated rats were killed by decapitation immediately after being subjected to 15 minutes of unavoidable, variable-interval footshock at 1.6 mA intensity. A control group of lesioned and sham-operated rats was decapitated immediately upon removal from their home cages. Whole pituitaries were rapidly dissected and immediately placed in 90°C sodium acetate buffer to inactivate adenylate cyclase and phosphodiesterase. Following sonication and centrifugation, supernatants were stored at -70°C until cyclic AMP levels were measured by radioimmunoassay, using antibodies characterized in our laboratory. Brains were immersed in 10% formalin, sectioned and stained with cresylecht violet to permit evaluation of the lesions.

While footshock markedly increased levels of pituitary cyclic AMP in sham-operated rats, this effect did not occur in the rats with bilateral lesions of the paraventricular nucleus of the hypothalamus. The lesions had no effect on pituitary cyclic AMP in unshocked rats. The results of the present experiment provide support for the role of CRF as an endogenous mediator of the stress response, and indicate that an intact hypothalamic paraventricular nucleus is essential for the stress-induced increase of pituitary cyclic AMP in vivo.

109.16 PRELIMINARY OBSERVATIONS OF PULSATILE ACTH SECRETION IN CONSCIOUS UNRESTRAINED RATS. M. Carnes*, N.H. Kalin*, C. Barksdale*, and M.S. Brownfield*. (SPON: L. Hegstrand). Veterans Administration Medical Center, Depts. of Medicine and Psychiatry, and the School of Veterinary Medicine, University of Wisconsin, Madison, WI 53705.

The circadian rhythm of pituitary adrenocorticotropin (ACTH) secretion has been well characterized in a number of animal species and humans. The ultradian rhythms have been less thoroughly investigated and have been derived primarily from human and dog studies. Such work in the rat has been limited by the relative insensitivity of previous ACTH assays and the need for large sample volumes. We have been able to investigate pulsatile secretion of ACTH in the rat by using a direct RIA which allows measurement of ACTH in 10-20 µl of plasma. Male 275-300 g Sprague-Dawley rats housed in a sound attenuated, environmently controlled box were bled continuously with a peristaltic pump. Samples were collected at 5 (N=2) and one (N=4) min intervals for approximately 60 min per rat. Hemorrhagic induced ACTH secretion had a rapid onset which consistently occured at 2.5-3.0 ml blood volume loss. Pulse parameters were evaluated before this observed ACTH rise. A pulse was identified when the coefficient of variation (CV) of the peak and trough values was two times greater than the CV of the assay for 10 plasma replicates at similar ACTH levels.

Sampling Freq (min)	N	# Time Points	ACTH ($\bar{x}$ ±SEM) (pg/ml)	Pulse Interval (min)	Pulse Freq (#/ hr)	Amplitude ($\bar{x}$ ±SEM) (pg/ml)
5	2	27	45.7 ± 3.0	31.7 ± 12.0	2.2 ± 0.8	17.7 ± 2.3
1	4	186	93.0 ± 5.1	5.3 ± 0.5	11.6 ± 1.4	32.8 ± 3.3

Analysis of our data indicates that ACTH is episodically secreted in rats. The detection of pulse interval and frequency varies greatly depending on the sampling interval. The detection of 11.6 ±1.4 ($\bar{x}$ ±SEM) pulses per hour at one min intervals may indicate that previous studies in other species using longer sampling intervals have underestimated the true pulse frequency. We are currently investigating sampling frequencies of less than one min.

109.17 ROLE OF CORTICOTROPIN RELEASING FACTOR AND VASOPRESSIN IN THE STIMULATION OF ACTH RELEASE BY ANGIOTENSIN II. C.K.Klingbeil*, L.C.Keil*, D.Chang* and I.A.Reid. Dept. of Physiology, Univ. of California, San Francisco, CA. 94143; Peninsula Labs, Belmont, CA. 94002; Ames Res. Center, Moffett Field, CA. 94035.

Angiotensin II (AII) stimulates ACTH release in dogs but the mechanism is not known. Corticotropin releasing factor (CRF) and vasopressin (VP) are potent secretogogues of ACTH and may be involved. Evidence supporting this possibility includes the observation that AII stimulates VP release and potentiates the ACTH response to CRF in anesthetized rats and in cultured rat pituitary cells. The aim of the present study was to determine if the stimulation of ACTH by AII in conscious dogs results from potentiation of the action of CRF or VP by AII. Experiments were performed in five chronically prepared dogs: 1) i.v. saline infusion; 2) AII (10 ng/kg/min) alone; 3) VP(1ng/kg/min) alone; 4) CRF (0.001, 0.01, 0.1 ug/kg) i.v. bolus; 5) AII and VP together; 6) VP and CRF(0.1ug/kg) together; 7) CRF (0.001, 0.01, 0.1 ug/kg) and AII together. Blood samples for assay of ACTH and VP were collected at 15 min intervals. AII, VP and CRF alone increased plasma ACTH concentration (Table). AII and VP together only had an additive effect on plasma ACTH concentration as did AII together with three doses of CRF. Thus AII did not potentiate the ACTH responses to VP or CRF. In contrast, the ACTH response to CRF was potentiated by VP. As expected, AII increased plasma VP concentration (2.4±0.2 to 4.2±0.5 pg/ml, $p<0.01$). Unexpectedly, CRF also increased plasma VP concentration. The highest CRF dose increased plasma VP from 2.7±0.3 to 4.8±0.4 pg/ml($p<0.01$) and the intermediate dose increased VP from 2.2±0.6 to 4.1±0.9($p<0.01$). In summary: 1) AII, VP and CRF increase ACTH release in conscious dogs; 2)AII does not potentiate the ACTH response to VP or CRF; 3) VP potentiates the ACTH response to CRF; 4) CRF increases VP release. These results indicate that the stimulation of ACTH release by AII in conscious dogs does not result from potentiation of the action of CRF or VP by AII.

Plasma ACTH Concentration (pg/ml)(*$p<0.05$; **$p<0.01$)

	Control	15 min	30 min
Saline	48.4 ± 7.3	50.4 ± 7.3	52.0 ± 6.5
AII	59.6 ± 6.0	67.0 ± 7.2*	70.8 ± 7.8*

109.18 MODULATION OF ADRENOCORTICOTROPIN (ACTH) SECRETION: IMPLICATION OF THE AMYGDALOID CENTRAL NUCLEUS, THE NORADRENERGIC, DOPAMINERGIC AND SEROTONINERGIC SYSTEMS. S. Beaulieu, T. Di Paolo and N. Barden. MRC Group in Molecular Endocrinology, CHUL, Quebec, G1V 4G2, CANADA.

The high concentration of corticotropin-releasing factor (CRF) within the amygdaloid central nucleus (ACE) supports the hypothesis that the amygdala might be involved in the control of ACTH secretion. In order to verify this hypothesis, we have studied the effect of bilateral lesions of the ACE on ACTH secretion in response to immobilization stress. Moreover, we have assessed the possible implication of the noradrenergic (NA), dopaminergic (DA) and serotoninergic (5-HT) systems within specific hypothalamic and amygdaloid nuclei in the control of ACTH secretion in response to stress and/or lesion of the ACE.

Intact or ACE-lesioned rats were left undisturbed (controls) or immobilized (stressed) for a period of one hour during which time blood was periodically sampled by a chronically implanted jugular cannula. Plasma and pituitary ACTH levels were measured by radioimmunoassay. The concentration, in discrete brain nuclei, of norepinephrine, dopamine, serotonin and their metabolites, was measured by HPLC coupled with electrochemical detection and turnover rates determined.

Bilateral lesions of the ACE diminished the secretion of ACTH in response to immobilization stress and increased the pituitary ACTH concentration in both control and stressed animals. Stress increased the NA activity within the ACE, the anterior and lateral hypothalamic areas , while it decreased the DA activity in the ACE, the amygdaloid cortical nucleus, the dorsomedial and ventromedial nuclei of the hypothalamus and the ventral tegmental area. The 5-HT activity was not modified by one hour of stress in any of the structures studied. When compared to intact stressed animals, the NA activity in stressed ACE-lesioned animals was decreased in the bed nucleus of the stria terminalis, the paraventricular and arcuate nuclei of the hypothalamus and in the anterior and lateral hypothalamic areas, while the 5-HT activity was increased in the glucocorticoid receptor-rich medial, basolateral and cortical amygdaloid nuclei.

These results support the hypothesis of a stimulatory role of the ACE in the control of ACTH secretion. They also substantiate the hypothesis that the NA system stimulates and the DA system inhibits ACTH secretion by acting in the ACE and other amygdaloid and hypothalamic nuclei, while the 5-HT system is possibly involved in the mediation of the negative feedback action of glucocorticoids at the level of the amygdaloid complex.

109.19 PEPTIDE REGULATION OF ACTH SECRETION IN NORMAL HUMANS AND PATIENTS WITH MAJOR DEPRESSION. R.S. Jaeckle, J.F. Lopez*, and R.C. Kathol*. Department of Psychiatry and Neuroscience Program, The University of Iowa, Iowa City, Iowa, 52242.

Corticotropin releasing hormone (CRH) is the principal brain peptide involved in stimulating ACTH secretion from pituitary corticotrophs, and this effect of CRH is potentiated by several other hormones, including arginine-vasopressin (AVP) and catecholamines. Insulin-induced hypoglycemia (IH) is another potent stimulus for ACTH secretion which is thought to be mediated by CRH, AVP, and catecholamines (Federation Proceedings, 44: 207-213, 1985). Major depressive disorder (MDD) is characterized by abnormalities of pituitary-adrenal function, including increased ACTH and cortisol secretion. There have been no previous studies comparing ACTH secretory responses to exogenous CRH, exogenous AVP, and IH in normal human controls and patients with MDD. We studied ACTH secretory responses to these 3 stimuli in 18 healthy controls and in 15 MDD patients (DSM-III diagnoses). Subjects received ovine CRH (1 ug/kg IV), AVP (0.18 pressor units/kg IM), or regular insulin (0.15 u/kg IV) at 1600 hours on separate days, and serum ACTH immunoreactivity was determined at several times before and after giving each stimulus. In the controls, CRH was a more potent stimulus for ACTH than was AVP. In the controls, mean serum ACTH rose from a baseline of 24 pg/ml to a peak of 58 pg/ml 30-45 minutes after giving CRH, and serum ACTH rose from a baseline of 32 pg/ml to a peak of 42 pg/ml 15 minutes after giving AVP. IH was a significantly more potent stimulus for ACTH than either CRH or AVP in both groups. In controls, serum ACTH rose from a baseline of 22 pg/ml to a peak of 324 pg/ml 45 minutes after giving insulin. Baseline ACTH levels prior to CRH, AVP, or IH were similar in the MDD and control groups. However, the MDD group had significantly reduced peak ACTH responses to IH (157 pg/ml, $p<0.02$ vs. controls) and to CRH (34 pg/ml, $p<0.05$ vs. controls). Peak ACTH responses to AVP were similar in the two groups, although 9 of 15 MDD patients and only 3 of 18 controls had maximal ACTH increments >14 pg/ml after AVP ($p<0.02$).

To summarize, we have shown that in normal humans, the order of potency for stimulating ACTH secretion is IH$>>$ CRH$>$ AVP. Since the ACTH secretory response to IH was much greater than could be predicted from the sum of the ACTH responses to CRH or AVP in the same subjects, the findings suggest that IH stimulates ACTH secretion by releasing several hormones (CRH, AVP, and perhaps peripheral catecholamines) which have synergistic effects on ACTH secretion at corticotrophs. The ACTH secretory responses to IH and to exogenous CRH were attenuated in MDD, and the MDD group had increased ACTH increments after exogenous AVP compared with controls. These findings suggest that the increase in ACTH and cortisol secretion observed in MDD may be the result of dysregulation of corticotroph function by hypothalamic peptides, including CRH and AVP. A possible explanation could be increased secretion of these peptides.

109.20 THE ACTH RESPONSE TO HYPOTENSIVE HEMORRHAGE IS MEDIATED BY THE PARAVENTRICULAR NUCLEUS AND NOT BY CIRCULATING EPINEPHRINE IN THE ANESTHETIZED RAT. D.N. Darlington,* J. Shinsako,* and M.F. Dallman* (SPON: D.G. Ward). Dept. of Physiology, University of California, San Francisco, CA 94143 USA.

Hypotensive hemorrhage leads to increases in plasma ACTH and epinephrine. The rise in plasma ACTH is thought to be mediated by neural structures that include the peripheral cardiovascular receptors, the nuclei of the tractus solitarius and the paraventricular nuclei. Recent evidence suggests that high circulating epinephrine levels may play a role in hypoglycemia induced release of ACTH. It is not known whether high circulating levels of epinephrine, that are normally seen after hemorrhage, or whether neural structures such as the paraventricular nuclei mediate ACTH responses to hypotensive hemorrhage.

Pentobarbital anesthetized (45mg/kg, ip) male Sprague-Dawley rats had femoral artery and vein cannulas placed for measuring arterial blood pressure and for blood withdrawal respectively. Each rat was allowed one hour for stabilization from surgery and than received a hemorrhage of 15ml/kg*3 minute. Plasma ACTH and epinephrine were determined from the first 2ml of hemorrhaged blood and from blood taken 20 minutes later. The red blood cells from these samples were suspended in saline and reinfused into the rat. The paraventricular nuclei were then lesioned with a triangular knife that was lowered 1.6mm caudal to bregma on the midline and rotated. Sham lesions were made by lowering but not rotating the knife. Each rat received a 15ml/kg*3 minute hemorrhage after placement of the lesion and ACTH and epinephrine were determined as described above. Histology confirmed complete destruction of the paraventricular nucleus in the lesioned group and minimal damage of the paraventricular nucleus (PVN) in the sham group.

Mean arterial blood pressure (MABP) in the sham- (n=7) and PVN- (n=5) lesioned groups decreased during hemorrhage from 130±5 and 135±5 to 40±5 and 45±5 mmHg respectively before placement of lesion. After placement of lesion, the MABP response during hemorrhage was similar (115±5 and 120±5 to 35±5 and 40±5 mmHg respectively). Plasma ACTH rose significantly during hemorrhage before placement of lesion in both the sham- and PVN-lesioned groups (+191±36 pg/ml and +165±18 pg/ml respectively). However, only the sham-lesioned group demonstrated a significant rise in plasma ACTH (+144±23 pg/ml) postlesion whereas the PVN-lesioned group did not (+18±19 pg/ml). This strongly suggests that the paraventricular nuclei are involved in the ACTH response to hypotensive hemorrhage. Baseline ACTH levels were low (118±29 before PVN lesion and 76±15 after PVN lesion). Also, plasma epinephrine rose significantly during hemorrhage (from 385±151 to 11,713±4,093 pg/ml) after lesion of the PVN suggesting that the high circulating levels of epinephrine seen during hemorrhage are not involved in the ACTH response to hemorrhage. These data suggest that a neural pathway that includes the paraventricular nucleus is involved in the ACTH response to hypotensive hemorrhage and that circulating epinephrine is not. This study was supported by HL29714, AM28172 and NS07565.

BASAL GANGLIA: IMMUNOCYTOCHEMISTRY AND PHYSIOLOGY

110.1 GLUTAMIC ACID DECARBOXYLASE, SUBSTANCE P AND LEU-ENKEPHALIN-IMMUNOREACTIVE NEURONS IN THE RAT NEOSTRIATUM THAT PROJECT TO THE GLOBUS PALLIDUS AND SUBSTANTIA NIGRA.
S. Afsharpour, H. Kita, G.R. Penny, and S.T. Kitai. Div. of Neurosci., Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163

We have previously reported the distribution and proportion of glutamic acid decarboxylase (GAD), substance P. (SP) and leu-enkephalin (L-Enk) immunoreactive neurons in the neostriatum of the rat and cat (Afsharpour et al., Neuro. Abs. '84). In the present study we have asked how these immunoreactive neurons are organized with regard to their projections to the major neostriatal efferent targets: the globus pallidus (GP) and the substantia nigra (SN).

The proportion of the GAD, SP, and L-Enk-immunoreactive neostriatal neurons projecting to GP, and SN were quantitatively analyzed using retrograde tracing combined with immunocytochemistry. WGA-HRP or HRP was injected in the SN or GP. A two color method was used to localize retrogradely labeled cells with a brown reaction product and, on the same section, cells immunocytochemically labeled by the ABC method with a green reaction product. From representative parasagittal sections, plots were made of every neuron only labeled for HRP transport and every neuron labeled for both HRP and a transimitter marker. These plots were used as samples to provide estimates of the proportion of neuroactive substance.

The samples sugguest that about 20% of the striatopallidal neurons are immunoreactive for GAD, 20% for SP, and 40% for L-Enk. In contrast, about 45% of the striatonigral neurons are immunoreactive for GAD, about 35% for SP and only about 0.2% for L-Enk. Of course, we know that these are not mutually exlusive populations; we know from our previous colocalization studies that there is partial overlap of these sets, that is many neurons contain more than one of these neuroactive substances.

From these result we infer (1) that the principal population of striatopallidal neurons is enkephalinergic, and that the populations of SP or GABAergic neurons are lesser, each only half as large as the enkephalinergic population; (2) that the principal population of striationigral neurons is GABAergic, a slightly smaller population contains SP, and an almost negligible population leu-enkephalinergic; (3) that GABAergic neurons form a relatively greater part of the striatonigral pathway than the striatopallidal pathway; (4) that the SP neurons form a relatively greater part of the striatonigral pathway than the striatopallidal pathway; and (5) that leu-enkephalinergic neurons are almost entirely confined to the striatopallidal pathway.

Supported by NIH Grant NS-20702 to STK and NIH Fellowhip 07421 to GRP.

110.2 EFFECTS OF [D-ALA^2]-METHIONINE ENKEPHALINAMIDE AND CARBACOL RECORDED INTRACELLULARLY FROM RAT NEOSTRIATUM IN SLICE PREPARATION. T. Kita, H. Kita and S.T. Kitai. Div. of Neurosci., Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163

Morphological studies have well documented that the neostriatum is rich with nerve terminals containing enkephalin and acetylcholine (ACh). What is sparse, however, is the information concerning neuropharmacological action of the above mentioned neuro-active substances in the neostriatum. We have therefore launched an investigation to examine the effects of carbacol (a stable ACh analogue) and [D-Ala^2] methionine enkephalinamide (a stable enkephaline analogue) on the synaptically induced responses (i.e., EPSPs) intracellularly recorded from rat striatal neurons in **in vitro** slice preparation.

Brains removed from the decapitated rats were blocked to contain the neostriatum and were sectioned using a Vibratome (400 um) in the parasagittal plane. Slices were placed in a recording chamber and were continuously superfused by the oxygenated Ringer solution (concentration in mM= NaCl 124, kCl 5.0, $MgSO_4$ 2.0 KH_2PO_4 1.25, $CaCl_2$ 2.0, $NaHCO_3$ 26 and glucose 10, pH 7.2-7.4). Local stimulation was applied through a pair of bipolar electrodes placed on the surface of a slice. Glass pipettes filled with 2M K-methylsulfate were used for recording. Drugs were applied to the superfusing Ringer solution with a concentration of 10 to 100 um.

Applications of carboral or enkephalin consistently led to hyperpolarization of the membrane by a few millivolts with a slight increase in the membrane conductance. It was also observed that the amplitude of depolarizing postsynaptic responses induced by local stimulation was clearly reduced by these drug applications. Carbacol effects were totally abolished by application of atropine but were only partially reduced by d-tubocurarine. The effects of enkephalin were clearly antagonized by naloxon but not by atropine. These results suggest that the action of ACh and enkephalin in the neostriatum is to hyperpolarize the neostriatal cell membrane and to reduce the efficacy of excitatory synaptic inputs. Even though the observed effects of these neuro-active substances are similar, they are likely to be mediated through different receptors; ACh through muscalinic receptors and enkephalin opioid receptors.

Supported by NIH Grant NS20702 to STK.

110.3 ELECTROPHYSIOLOGY OF RAT SUBTHALAMIC (STH) NEURONS: INTRACELLULAR STUDY IN **IN VITRO** SLICE PREPARATIONS. H. Nakanishi*, H. Kita and S. T. Kitai (SPON: J. Whitaker), Div. of Neurosci., Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163.

Rat STH slices (350-450mm thick) in the parasagittal plane were prepared for intracellular recording. Slices were placed in a recording chamber and continuously superfused with the oxygenated Krebs-Ringer solution. Most of STH neurons showed spontaneous repetitive firing with the frequency of 5 to 40 Hz. The input resistance of the neurons estimated from the membrane potential shifts to hyperpolarizing current injection was 90-250 Meg Ohms. The resistance showed an anomalous rectification when large hyperpolarizing currents were applied. STH neurons generated two distinct patterns of firing to depolarizing current pulses depending on their resting membrane potentials. At zero current injection (membrane potential -50 to -70 mV), depolarizing current pulses generated fast repetitive firings with the maximum frequency of up to 500 Hz. When the same neuron was hyperpolarized by a continuous current injection (e.g., -0.2 to -0.5 nA), depolarizing current pulses triggered a burst response characterized by slow depolarizing potential with fast action potentials. Often the burst response was followed by long lasting depolarization (up to 500msec) with fast spikes which outlasted the current pulse. The burst response followed by long lasting depolarization was also observed at the offset of hyperpolarizing current pulse. The slow depolarizing potential and the prolonged depolarization were TTX resistant but were blocked by Co++ or replacement of Ca++ with Mg++ and augmented by Ba++ or TEA. Succession of repetitive action potentials or the burst response produced by direct stimulation was followed by hyperpolarization which was diminished by a replacement of Ca++ with Mg++.

Electrical stimulation of the internal capsule (IC) at 0.5-1 mm rostral to STH induced monosynaptic IPSPs in STH neurons with the latency of 1 to 3 msec. The polarity of IPSPs was reversed in the depolarizing direction after intracellular injection of Cl^-. Bath application of either bicuculline methiodide or strychnine (50-100 uM) markedly or completely suppressed IPSPs. With the suppression of IPSPs, IC stimulation evoked monosynaptic EPSPs with the latency of 3.5 to 4 msec. If a neuron is hyperpolarized by a continuous current injection, these EPSPs triggered the burst response or depolarization which may last up to 700 msec. These results demonstrated that STH neurons in **in vitro** preparation have spontaneous discharges, very high input resistance, capability to generate high frequency firings, and Ca++dependent conductances. The pattern of responses of the STH neuron to synaptic inputs is also very much dependent on its membrane potential. (Supported by NIH Grant NS20702 to STK)

110.4 INTRACELLULAR STUDY OF RAT SUBSTANTIA NIGRA PARS RETICULATA NEURONS IN **IN VITRO** SLICE PREPARATION: ELECTRICAL MEMBRANE PROPERTIES AND RESPONSE CHARACTERISTICS TO SUBTHALAMIC STIMULATION. S. T. Kitai, H. Nakanishi* and H. Kita. Div. of Neurosci., Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163

Rat brain slices containing substantia nigra pars reticulata (SNr) and subthalamus (STH) were sectioned (350-450 um thick) in the parasagittal plane using a Vibratome. Brain slices were placed in a recording chamber and continuously superfused with the oxygenated Krebs-Ringer solution. Two populations of SNr neurons were identified on the basis of their membrane properties. One population demonstrated spontaneous repetitive firings with the frequency of 1 to 6 Hz. Injection of depolarizing current pulses generated high frequency repetitive firings in these neurons. Termination of the depolarizing current pulse was followed by a long duration hyperpolarization. After bath application of TTX and TEA, depolarizing current pulses generated a slow spike potential accompanied by a long duration depolarization (up to 2 sec) which outlasted the current pulses. These responses were considered to be mediated by Ca++conductances. The other population of neurons had no spontaneous activity. Injection of depolarizing current pulses generated slow depolarization from which action potentials were triggered. Membrane responses to hyperpolarizing current pulses showed an existence of strong anomalous rectification. The membrane potential after the offset of the current often showed a slow ramp-shaped return to the base line (probably early K+conductance). The membrane properties of the second population of the neurons were very similar to those observed from the neurons of the substantia nigra pars compacta.

Electrical stimulation of STH evoked monosynaptic EPSP-IPSP sequence of responses in both populations. The latency of EPSPs ranged from 1 to 2 msec. The polarity of IPSPs was reversed in the depolarizing direction after intracellular injection of Cl^-. Recordings from SNr neurons in slices, incubated in the solution containing bicuculline methiodide (100 uM) or in slices obtained from the rats with chronic internal capsule transection at the level immediately rostral to STH, revealed only monosynaptic EPSPs to stimulation of STH. These results suggest that: (1) SNr contains two populations of neurons having different membrane properties and (2) both populations of neurons receive monosynaptic excitation probably originating from STH and inhibition originating from the sites rostral to STH.

110.5 SUBTHALAMIC AFFERENTS TO THE GLOBUS PALLIDUS AND THE SUBSTANTIA NIGRA IN THE RAT; LIGHT AND ELECTRON MICROSCOPIC STUDIES USING PHA-L METHOD. H. Kita and S. T. Kitai. Div. of Neurosci., Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163

Anatomical and electrophysiological studies have shown that single subthalamic neurons send their branching axons to the globus pallidus (GP) and the substantia nigra (SN). However, the function of these projections is still a matter of controversy. We have conducted light microscopic (LM), and electron microscopic (EM) analysis of rat STH branching axons labeled by anterograde nerve tracer, phaseolus vulgaris leucoagglutinin (PHA-L). PHA-L injection and immunocytochemical procedures were slightly modified from the procedures originally described by Gerfen and Sawchenko (Brain Res. 290:219-238, 1984). Fixatives for perfusion of animals consisted of 0.15M acetate and borate buffers with 4% paraformaldehyde and 0.15% glutaraldehyde. Brains were sectioned (40mm thick) on a Vibratome. Some of the sections prepared for EM were processed for PHA-L immunohistochemistry without treating them with Triton-X. They were postfixed by osmium tetroxide, infiltrated with Spurr's plastic, and mounted on Teflon-coated glass slides. Sections for light microscopy were prepared in accordance with Gerfen and Sawchenko's protocol (Brain Res. 290:219-238, 1984).

PHA-L labeled STH afferent plexus in GP and SN were thin fibers with both boutons enpassage and boutons terminaux. The sites of the labeled terminal axonal plexus in their target nuclei differed with different PHA-L injection sites in STH, suggesting the existence of some topographically organized STH projections to GP and SN. Electron microscopic analysis revealed that the morphological features of the labeled processes were very similar in both EP and SN. They were both unmyelinated and relatively large myelinated labeled axons. The labeled terminals were 1-2 um in size and contained many small (20-50mm) spherical or ellipsoidal shaped synaptic vesicles. They were making contact with thin (less than 2 um) dendritic shafts with asymmetrical postsynaptic specialization. Based on these morphological data, we suggest that the subthalamic afferents to GP and SN will be likely to have similar physiological action on their target neurons. (Supported by NIH Grant NS20702 to STK).

110.6 ULTRASTRUCTURAL MORPHOLOGY OF VENTRAL PALLIDAL NEURONS INTRACELLULARLY LABELED WITH HRP. H.T. Chang and S.T. Kitai, Div. of Neurosci., Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN. 38163.

In our previous light microscopic analysis of ventral pallidal (VP) neurons intracellularly labeled with HRP (Teng et al., 1984), we have demonstrated that VP neurons have long dendrites which could radiate up to 1 mm away from the somata, but these dendrites remained bounded by the borders of the nucleus. Additionally, we have shown that VP neurons have extensive local collateral arborizations which also terminated mainly within the nuclear boundaries of VP. In order to determine the morphology and the distribution of different types of axon terminals which form synapses on individual VP neurons, we analyzed the morphology of several labeled VP neurons at the electron microscopic level. In addition, targets contacted by labeled axon collaterals of individual VP neurons were also examined.

The somata of all labeled VP neurons are characterized by large amount of rough endoplasmic reticulum and nuclei with deeply invaginated nuclear envelope. The somatic surfaces as well as the surfaces of all dendrites are ensheathed with numerous unlabeled axon terminals forming mainly symmetrical, and occasionally asymmetrical synapses. The appearance of such dense innervation resembles very closely the neurons of the globus pallidus and the substantia nigra pars reticulata reported previously. The intrinsic collaterals of labeled VP neurons are myelinated. However, these collateral fibers usually become unmyelinated a short distance prior to giving rise to either boutons en passant or boutons terminaux. These boutons, densely packed with large pleomorphic vesicles and many mitochondria, form symmetrical synapses with somata and dendrites of unlabeled VP neurons.

These findings suggest that VP neurons receive converging inhibitory inputs, probably from medium spiny neurons of the ventral striatum, and that they form recurrent inhibitory synapses with neighboring VP neurons.

Supported by NIH Grant NS20702 to STK.

110.7 ELECTROPHYSIOLOGY AND MORPHOLOGY OF RAT THALAMO-CORTICAL RELAY NEURONS: AN **IN VIVO** INTRACELLULAR RECORDING AND LABELING STUDY. K. Yamabe*, H. Kita and S. T. Kitai (SPON: G. R. Penny) Div. of Neurosci., Dept. of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163

Intracellular recordings and HRP-labelings of thalamo-cortical neurons were performed on anesthetized male hooded rats (250-400g). In some rats, acute decortication was made by subcortical cuts rostral, dorsal and lateral to the neostriatum using a Halaz's knife. Bipolar electrodes consisting of a pair of insect pins (No.00) were used for stimulation of the frontal cortex (frontal pole) and the neostriatum. In the decorticated rats, stimulation electrodes were placed in the neostriatum to stimulate cortico-thalamic and thalamocortical fibers. Glass micropipettes filled with 3-4% HRP in 0.05 M Tris buffer (pH 7.6) and 0.5 M K-methylsulfate, and having DC-resistances of 50-80 Meg Ohms were used for intracellular recording and labeling. At the end of the experiment, the rat was perfused with a solution of 1% paraformaldehyde and 2% glutalaldehyde in 0.15 M phosphate buffer (pH 7.4). Serial parasagittal 50 um sections were made on a Vibratome and reacted with diaminobenzidine. Sections containing labeled neurons were postfixed in 1% osmium tetroxide in phosphate buffer, embedded in Spurr's plastic, and examined under light microscope.

Results were obtained from the neurons located in either the mediodorsal, paracentral, ventromedial or centrolateral nucleus. Stimulation of the frontal cortex evoked a sequence of responses; antidromic spike, initial depolarization, long lasting hyperpolarization and short depolarization. The initial depolarization was considered to be a monosynaptic EPSP which overlapped with an IPSP. Major constituents of the long lasting hyperpolarization were considered to be short duration IPSP and long duration disfacilitation of cortical inputs. These neurons also generated membrane responses corresponding to the low-threshold Ca++spike, Ca++dependent K+ and early K+ conductances that have been previously reported in **in vitro** studies of thalamic neurons. Somata of the HRP-labeled neurons were polygonal in shape with their diameters ranging from 20 to 30μm. Three to six thick primary dendrites arose from the soma. They soon formed thinner secondary and tertiary branches, some of which arborized further. The axon emerged either from the soma or from a primary dendrite. The axon was traced rostrally toward the internal capsule.

110.8 PALLIDAL INFLUENCES ON NECK AND SHOULDER MUSCLES IN THE RAT. M.D. Kelland, D. Asdourian, D.J. Zawisa*, and R.Y. Shen*, Dept. of Psychology, Wayne State University, Detroit, MI 48202.

Electrical stimulation of the globus pallidus (GP) in adult male rats (N=25) was used to determine the nature and extent of the control exerted by the GP over activity in the trapezius, biventer cervicis, rectus capitis, and scalenus dorsalis muscles. Muscle activity was recorded electrically.

Experiment 1. Electrical stimulation of the GP resulted in driven contralateral activity in all muscles studied, and weaker ipsilateral activity in the rectus capitis. The parameters of the contralateral activity are as follows: maximal response amplitudes of 0.2-1.7 mV; response latencies of 4-14 msec. (the time between the stimulus artifact and the beginning of the response); durations of 4-13 msec.; and recruitment latencies of 0.3-13.6 sec. (the time it takes for muscle activity to appear following the initiation of stimulation). Spontaneous muscle activity was often inhibited totally by ipsilateral GP stimulation. These results were obtained with optimal stimulation parameters of 15 twin pulses per sec., each pulse having a 1.0 msec. duration with a 1.0 msec. interpulse interval, at 15V (approximately 0.75 ma).

Experiment 2. Animals received a unilateral electrolytic lesion of the substantia nigra pars reticulata (SNr) or the subthalamic nucleus (SubTh) prior to GP stimulation in an attempt to determine the degree to which each of these pathways are involved in the control exerted by the GP over the periphery. Lesions of the SNr had no effect on activity driven by GP stimulation. Lesions of the SubTh blocked activity in all of the muscles studied. Preliminary evidence with ibotenic acid lesions of the SubTh suggests that our results are not due to damaging fibers of the internal capsule. Thus, the pathway through the SubTh seems to be necessary for mediating the control exerted by the GP over the neck and shoulder.

Extensive electrolytic lesions of the motor relay nuclei of the thalamus (VA,VL,VM) were made in order to determine whether these nuclei are part of the pathway mediating the driven activity. These lesions had no effect on activity driven by GP stimulation.

That the muscle activity driven by GP stimulation is primarily contralateral may serve as an explanation for the contraversive motor asymmetry and circling behavior (MAC) seen during GP stimulation. The ipsilateral inhibition of muscle activity during GP stimulation may also contribute to contraversive MAC.

110.9 NIGRAL INFLUENCES ON NECK AND SHOULDER MUSCLES IN THE RAT. D. Asdourian, C. Geula, M.D. Kelland, R.Y. Shen*, D.J. Zawisa*, W. Lipinski*, Dept. of Psych., Wayne St. Univ., Detroit, MI 48202.

Unilateral electrical stimulation of the substantia nigra pars reticulata (SNr) was used to determine the effects of SNr output on muscles of the neck and shoulder of anesthetised male rats (N=22). Muscle activity was recorded electrically.

Experiment 1. Stimulation of the SNr drove bilateral activity in the trapezius, biventer cervicis, rectus capitis, and scalenus dorsalis. Twin square waves were used with durations of 1.0 msec. and an interpulse interval of 1.0 msec. The voltages needed to drive maximal responses varied from animal to animal and from muscle to muscle and ranged from 6-13V. The ipsilateral responses for a given muscle pair were always greater in amplitude than the contralateral. Ipsilateral responses (over all muscles) ranged from 1.5-10.0 mV while contralateral responses ranged from 0.5-3.0 mV. The most effective stimulation frequencies were between 1-2 twin pulses per sec. and 10-15 per sec. At frequences between 3-9 per sec. responses often became inconsistent and sometimes disappeared altogether. When responses were consistently driven, they appeared with stimulus onset - no recruitment latency delayed the onset of muscle activity. The latency between stimulus onset and driven activity ranged between 2-7 msec.

Experiment 2. Two of the major targets of SNr projection fibers are (1) the middle and deep layers of the superior colliculus (SC) and the reticular formation (RF) immediately ventral to the SC and (2) the thalamic motor nuclei - especially the ventromedial (VM) but also perhaps the ventral anterior (VA) and ventrolateral (VL). Neither unilateral lesions in the SC-RF nor extensive lesions that included VA, VL, and VM had any effect on muscle activity driven by SNr stimulation.

That unilateral SNr output had its greater effect on ipsilateral muscles may serve as an explanation for the finding that SNr stimulation causes ipsiversive rotation in unanesthetised animals. The failure to block SNr output with SC-RF or thalamic lesions leaves unanswered questions concerning the pathways utilized by SNr in gaining access to the motor periphery.

110.10 PAIRED-PULSE FACILITATION AND INHIBITION IN RAT STRIATUM IN VITRO. J.L. Stringer*, G.F. Wooten, and E.W. Lothman, Dept. of Neurology, Univ. Virginia, Charlottesville, VA. 22908.

Local electrical stimulation in rat striatal slices evokes two negative field potentials: N1, direct activation of neurons, and N2, synaptic activation. Paired-pulse inhibition has been described for the N2 response when the interstimulus interval (ISI) is less than 25 msec and the $[Ca^{2+}]$ of the medium is at least 2.3 mM (Lighthall et al.,1981). This study examined the responses of N2 field potentials and single units to paired stimuli in media of different $[Ca^{2+}]$. "Low Ca^{2+}" medium contained (in mM): NaCl 127, KCl 2, $MgSO_4$ 1.5, KH_2PO_4 1.1, $NaHCO_3$ 25.7, $CaCl_2$ 1.5, and glucose 10. In this medium, slices (425 μm thick) showed paired-pulse inhibition of N2 responses at 10 msec ISI. At longer ISI, the N2 responses to the second stimulus showed a marked decrease in latency to peak, but no change in amplitude. This observation was confirmed with recordings from N2 neurons; the neuron consistently fired sooner after the second stimulus. Since the latency of N2 neurons depends on stimulus voltage and varies at a given stimulus intensity, it is difficult to quantitate this facilitation using latency measurements. However, we found that paired-pulse facilitation is also characterized by a decrease in threshold for single unit discharges and this is useful analytically. The change in threshold of the neuron exhibits a linear relationship with ISI which is remarkably constant ($r = .99$; $n = 6$). The threshold difference varies from 0.9V at 10 msec ISI to 0.1V at 120 msec. Paired-pulse inhibition of the firing of a single unit was seen in only one neuron at 10 msec ISI. The "high Ca^{2+}" medium was the same as above except the $CaCl_2$ was 3.5 mM. N2 field potentials recorded in this medium showed paired-pulse inhibition at ISI of 20 msec and less. Beyond 20 msec the N2 field showed no significant decrease in latency or change in amplitude. Single unit responses were more complex. Three of 8 cells showed a decrease in latency, but only at 10 msec; only 1 of the 8 showed paired-pulse inhibition, also only at 10 msec ISI. Thresholds for single unit firing were measured in 4 neurons from 10-160 msec ISI. All 4 neurons showed an equal or greater threshold for firing after the second stimulus at 20 msec or greater (ave. increase of 0.4V). One cell demonstrated a decrease in threshold at 10 msec ISI. The data indicate that synaptic behavior in the striatum critically depends on the ambient ionic environment. A change in the calcium concentration from 1.5 to 3.5 mM changes the response to paired-stimuli from facilitation to inhibition. The former value approximates the $[Ca^{2+}]$ in vivo. Therefore, the importance to neuronal function of paired-pulse inhibition found in vitro with high Ca^{2+}, remains to be clarified. Supported, in part, by The United Parkinson Foundation.

110.11 SYNAPTIC ORGANIZATION OF FETAL STRIATAL TRANSPLANTS IN THE NORMAL AND KAINATE LESIONED RAT CAUDATE NUCLEUS. M. DiFiglia, L.Schiff* and W.A. Deckel. Depts. of Neurology, Mass. General Hosp.,Boston, MA 02114 and Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Recent studies have shown that fetal striatal transplants can reverse locomotor deficits produced by a kainic acid (KA) lesion of the caudate nucleus (Deckel et al, Eur. J. Pharmacol., 93:287, 1983). The anatomical correlates to this functional recovery were examined in fetal striatal transplants in normal and KA lesioned host caudate nucleus. Sprague-Dawley rats (N=8) were anesthetized and given bilateral injections of either KA (0.8 µgs in 0.4 µl PBS) or PBS (Sham lesion), which were placed stereotactically in the anterior region of the neostriatum. Seven days later transplants of 17/18 day fetal striatum (2 mm^3) were introduced into the same injection sites. Following 5-6 wks or 9-10 mos survival, animals were perfused and tissue sections of caudate were processed for anatomical study. In the light microscope transplants in all animals were distinguished from surrounding host caudate by their pale appearance and absence of bundles of myelinated fibers. Cell counts in 1 µm thick sections showed higher proportions of medium-sized neurons with indented nuclei in the 5-6 wk and 10 mos transplants as compared to host caudate. Large neurons were not found in the 5-6 wk tranplants and were present in the 10 mos transplants in higher proportions than in host caudate. At the ultrastructural level, synaptic organization in the 5-6 wk and 10 mos transplants was well developed in KA and sham lesioned animals. Axon terminals contained round or pleomorphic vesicles and made symmetric and asymmetric synapses with cell bodies, dendrites, spines, and axon initial segments. Dendrites ensheathed by synapsing terminals were frequently present in the 10 mos transplants. Compared to host caudate neuropil synaptic density was somewhat higher in the 5-6 wk transplants and lower in the 10 mos transplants and the proportion of axodendritic synapses was higher in both transplant groups. Results suggest that fetal striatal transplants 1) develop a complex synaptic organization in either KA lesioned or normal host caudate; 2) may exhibit neuronal changes over time; and 3) show differences to host neostriatum in their neuronal organization. Supported by grant NS 16367 to M.D.

	transplants				host caudate
	5-6 wk		10 mos		
	KA	Sham	KA	Sham	
medium cells (indented nuclei)	26%	21%	50%	40%	6%
large cells	--		5%	10%	0.8%
density synapses/100μm^2	20		13		17
axodendritic synapses	24%		44%		20%

110.12 MOTOR-LIMBIC INTEGRATION: COLLATERAL NIGRAL PROJECTION TO THE CINGULATE CORTEX AND STRIATUM. M. Takada* and T. Hattori (SPON: R.M. Clavier). Dept. of Anatomy, Univ. of Toronto, Toronto, Ontario, Canada M5S 1A8.

A direct projection from the pars compacta of the substantia nigra (SNc) to the cingulate cortex in the rat was examined using several retrograde tracing techniques.

After injecting horseradish peroxidase (HRP) into the cingulate cortex, retrogradely-labeled neurons were found in the SNc as well as the limbic nuclei such as the hypothalamus and the anterior nuclear group, mediodorsal nucleus and laterodorsal nucleus of the thalamus. HRP-positive neurons in the SNc were bilaterally distributed mainly in the rostromedial parts of the nucleus, and to a lesser degree in the caudomedial portions with an ipsilateral predominance. No labeled neurons were detected in the ventral tegmental area of Tsai.

These SNc regions, containing presumed dopaminergic neurons, also project to the medial parts of the caudate-putamen (CPU). When we injected True Blue (TB, 5% suspension) into the cingulate cortex, and Diamidino Yellow (DY, 2% suspension) into the medial CPU, most of TB-positive neurons in the medial SNc were double-labeled with DY. These findings indicate that majority of the SNc neurons sending their axons to the cingulate cortex, also have axon collaterals projecting to the CPU. Moreover, injections of 3H-dopamine (20-40 Ci/mmol) into the cingulate cortex resulted in retrogradely-radiolabeled neurons in the medial SNc.

The present study strongly suggests that the dopaminergic neurons in the medial portions of the SNc have a key role in integrating limbic with motor functions.

110.13 POTASSIUM EFFECT ON ELECTROTONIC CONSTANTS OF NEOSTRIATAL NEURONS. J. Bargas*, E. Galarraga*, and J. Aceves*. (SPON: J. Alanís). Dept. of Physiology and Neuroscience. Centro de Investigación del IPN. 0700-México, D.F., México.

It has been found (Sugimori et al. J. Neurophysiol. 41: 1662, 1978; Kita et al. Brain Res. 300: 129, 1984) that the membrane time constant of neostriatal neurons is significantly longer when determined in vivo than in vitro. We have explored whether the difference could be mostly explained by differences in extracellular K^+ in one condition as compared to the other. The experiments were done in rat neostriatal slices. Intracellular electrical activity was recorded by conventional microelectrode techniques. The slices were bathed in a medium either with 6.25 or 3 mM K^+. In higher K^+ (n=10), RMP was 67 ± 7 mV; input resistance (Rn): 29 ± 6 MΩ; τ_o : 7 ± 2 msec; τ_1 : 1.3 ± 0.3 msec; electrotonic length (L): 1.2 ± 0.1; ρ : 3.1 ± 1.5. While in lower K^+; RMP was 80 ± 7; Rn : 87 ± 4; τ_o : 16.2 ± 2; τ_1 : 1.7 ± 0.8; L: 0.7 ± 0.1; ρ: 1.4 ± 0.7. As seen, lowering K (in a physiological range) significantly increased input resistance and neuronal time constant. To see whether closing of K channels was involved in the observed changes of electrical constants when was lowered, the effect of TEA was studied at the higher K concentration. The parameters that, as compared to those without TEA, significantly changed were: R_n : 87 ± 9 and τ_o : 16 ± 3. τ_1 tended to be longer, and L and ρ tended to be smaller, as in low K. Other ionic conductances seem not to be as important as K conductance determining the electrotonic parameters of these neurons because TTX, 4-AP (1Mm) and Co apparently did not modify the parameters at 6.25 mM K^+. These results suggest that, at low K concentrations, neuronal electrical "constants" are not constants but depend on extracellular K. They also suggest that the opening of voltage-dependent K channels located mainly on dendrites (see that ρ tended to be smaller) are responsible of the changes in electrical parameters when K is decreased. The differences in time constant in vivo as compared to in vitro might be due to differences in extracellular K in one condition as compared to the other. (Supported by grant PCCBBNA-020884 from the CONACyT of México).

110.14 DOSE-DEPENDENT EXPRESSION OF THE WEAVER GENE ON THE DOPAMINE-CONTAINING INNERVATION OF THE FOREBRAIN AND EFFECTS OUTSIDE OF THE STRIATUM. S. Roffler-Tarlov and A.M. Graybiel, Depts. Neurology and Anat., Tufts Univ. Sch. Med., Boston, MA 02111 & Dept. of Psychology and Whitaker College, M.I.T., Cambridge, MA 02139

Two defects, one obvious and the other quite hidden, are present in the brains of mice carrying the autosomal recessive gene, weaver (wv). In homozygous weavers this mutation results in ataxia and a marked atrophy of the cerebellum consequent to massive loss of granule cells. Several studies point to the granule cell as a direct target of the gene and to dose-dependent effects in cerebellum of heterozygous weavers ($^+$/wv). The second abnormality exists in parts of the forebrain of weaver mice and is concealed from view as it results in no marked atrophy or disruption of cellular architecture. However, the defect in the forebrain can be revealed biochemically as a reduction in dopamine (DA) content in selected regions and anatomically by reduced catecholamine histofluorescence. Our previous report showed that a severe depletion of DA occurs in the dorsal striatum (caudoputamen, CP) of ^{wv}/wv mice relative to $^+$/wv controls, whereas the DA content in the nucleus accumbens (NAc) (part of the ventral striatum) was entirely conserved. A third striatal area, the olfactory tubercle (OT) showed a moderate reduction in DA. (Nature 307, 62-66, 1984).

The present study had two aims. One was to establish whether the affected DA-containing system is likely to be another primary target of the action of the weaver gene or whether the deficits in the DA-containing innervation are secondary, perhaps to cerebellar damage inducing ataxia. We studied striatal DA content in two other cerebellar mutants (Purkinje cell degeneration and staggerer) which are also ataxic and found no changes in the DA content of any striatal region. We compared striatal DA content in adult ^{wv}/wv, $^+$/wv, and $^+$/+ mice. We established that the presence of one weaver gene in the heterozygote results in a reduction of DA in vulnerable striatal areas. Compared to that in $^+$/+ animals, the content of DA in the CP was reduced by 13% in $^+$/wv and by 71% in ^{wv}/wv mice. Values for DA in the NAc were roughly equivalent in the three genetic types. Our second aim was to examine DA-containing regions outside the striatum. We found a 32% reduction of DA in the septum of ^{wv}/wv mice, and a 30% reduction in the hypothalamus. By contrast, the DA content of the frontal cortex, the amygdala, the olfactory bulb and the retina was spared.

The results show that the effects of the weaver gene on the DA-containing innervation of the forebrain are not confined to striatal targets but also extend to the septum and hypothalamus. Lack of DA depletion in other ataxic mutants and the presence of an effect in heterozygote weavers suggests that a subpopulation of DA neurons are likely to be a primary target of the weaver gene. Thus the weaver gene has at least two cellular targets and its effects on these must share some common molecular mechanism. Supported by NIH-NS 20181.

110.15 LATERAL SEPTUM AND CORPUS STRIATUM DIFFER IN THEIR IN VIVO ELECTROCHEMICAL RESPONSES TO CIRCLING BEHAVIOR AND TO AMPHETAMINE ADMINISTRATION. C.R. Freed and P.A. Mason, Depts. of Med. and Pharm., Univ. Colo. Health Sci. Ctr., Denver, CO 80262.

The lateral septum (LS) and anterodorsal striatum (AS) both contain abundant dopamine (DA) nerve terminals but are innervated by different cell groups, lateral septum by A10 and striatum by A9. Previous work in our laboratory has shown an increase in contralateral striatal DA content and apparent release during trained circling for a sucrose water reward (Nature 298:467,1982; Life Sci. 30:2155,1982) but an increase in ipsilateral DA and DOPAC content in lateral septum during circling. (IUPHAR Abstr 1180P, 1984). We have now compared the in vivo electrochemical (EC) responses of the two nuclei to a behavioral stimulus--trained circling--and to amphetamine (AMPH) administration. Male Sprague-Dawley rats 250-350 gm had carbon paste in vivo EC electrodes implanted bilaterally in LS for the circling studies and in both LS and AS for AMPH studies. After 24 hr recovery from surgery, linear sweep voltammetry was performed from -0.2V to +0.5 V at a rate of 10 mV/sec using a DCV-5 cyclic voltammetry device. (Bioanalytical Systems). Electrodes were scanned alternately every five minutes. At both brain sites, a peak was seen at +0.19 V. During 60 min of circling behavior, there was a significant increase ($p<.05$) in the EC peak on the ipsilateral side which was maximally increased by 27±5% over baseline after 35 min and returned to baseline values by the end of circling. In drug experiments, AMPH 5 mg/kg i.p. increased the EC signal in striatum by 88±20% within 40 minutes. By contrast, the peak in lateral septum initially showed a small but not significant reduction and then began to increase at 40 min as the striatal peak reached its asymptote. The septal peak reached a maximum 120 min after AMPH and was 12±2% increased over baseline. The EC peak in LS was characterized by inhibitors of catecholamine synthesis. Animals implanted with in vivo EC electrodes were given pargyline 75 mg/kg, fusaric acid 100 mg/kg, or alpha-methylparatyrosine 300 mg/kg. Pargyline produced an 18±2% decrease in peak height; fusaric acid, a 10±2% reduction; and alpha-methylparatyrosine, a 26±2% decrease. These results indicate that the EC catechol peak in LS may be a composite of norepinephrine, DA and DOPAC. Because of the ambiguity of the EC signal, other animals were implanted with in vivo dialysis catheters masked with epoxy to perfuse either AS or LS and the dialysate was assayed by HPLC with EC detection. AMPH 5 mg/kg caused a large increase in DA release and a reduction in DOPAC release from AS, while in LS no DA release was seen. These data show that motor behavior leads to lateralization of catechol release in LS and AS but on opposite sides of brain. Amphetamine causes an increase in dopamine release from striatum but little or none from lateral septum.

INVERTEBRATE LEARNING AND BEHAVIOR I

111.1 CONTROL OF MOTILITY IN PARAMECIUM BY CYCLIC AMP AND CALCIUM. N.M. Bonini* and D.L. Nelson* (SPON: P. Claude). Neurosciences Training Program and Dept. Biochemistry, Univ. Wisconsin, Madison, WI 53706.

Paramecium, a ciliated protozoan with an excitable membrane, is a model system for studying the molecular mechanisms which regulate motility. The cell has two basic behaviors which reflect the membrane potential: backward and forward swimming. At the resting potential, the cell swims slowly forward; membrane hyperpolarization causes faster forward swimming, while Ca^{++} entry upon membrane depolarization causes backward swimming. We (Bonini, Gustin, and Nelson) have previously shown that increased cAMP correlates with the fast forward swimming of membrane hyperpolarization.

To explore the action of cAMP, and the relationship between Ca^{++} and cAMP in the control of swimming behavior, we are using detergent-permeabilized cells, or "models", to study proteins whose phosphorylation is correlated with specific swimming behaviors. Models are immotile, but the addition of MgATP reactivates them to swim forward. Addition of cAMP causes a two-fold increase in the forward swimming speed, and stimulates protein phosphorylation. The major phosphoproteins are 47, 45, 17, and 15 kD. Some phosphoproteins are associated with the ciliary fraction, including a protein of 55 kD which may be tubulin. These results suggest that at least one of the in vivo effects of elevated cAMP upon membrane hyperpolarization is to increase ciliary beat, possibly through protein phosphorylation.

Ca^{++} addition, which causes backward swimming in models, also stimulates phosphorylation, but of a partially different set of proteins. The major phosphoproteins are 64, 58, 47, 45, 25, and 17 kD. We have also found that, whereas cAMP causes fast forward swimming, and Ca^{++} backward swimming, addition of both cAMP and Ca^{++} results in slow forward swimming. This suggests that cAMP and Ca^{++} may be acting antagonistically to control ciliary beat direction.

In summary, the in vivo fast swimming behavior of the cell in response to membrane hyperpolarization may be mediated by cAMP-stimulated protein phosphorylation. Furthermore, Ca^{++} and cAMP may be acting antagonistically, perhaps both through phosphorylation mechanisms, in the control of swimming direction.

111.2 PHARMACOLOGICAL AND GENETIC STUDIES OF C.ELEGANS EGG-LAYING. E.J. Wolinsky and H.R.Horvitz. Department of Biology, Massachusetts Institute of Technology, Cambridge MA 02139.

We are using mutations and neuroactive drugs to study the egg-laying behavior of the nematode C.elegans. We believe it is feasible to attempt understanding of the physiology of the egg-laying system because of the small number of neurons involved (only eight innervate the egg-laying muscles), the ease of measuring the behavior (by counting eggs), and the availability of genetic variants and manipulations (e.g., Trent et.al. [1983] Genetics 104:619-47).

Previous experiments suggested that serotonin (5HT) and acetylcholine (ACh) stimulate egg-laying, while octopamine inhibits egg-laying. Additional experiments with the following drugs have strengthened these conclusions: tomoxetine, an inhibitor of 5HT uptake; gramine, a 5HT receptor blocker; synephrine, which interacts with octopamine receptors in other invertebrates. Mecamylamine, a cholinergic blocker, stimulates egg-laying, consistent with earlier results with curare, suggesting that an inhibitory cholinergic input to the egg-laying system exists as well.

Another approach we are taking to studying the regulation of egg-laying is to seek egg-laying constitutive mutants, i.e., mutants that lay more eggs than does the wild-type in the absence of an exogenous stimulus. Unlike the many egg-laying defective mutants previously isolated, many of which are likely to be disrupted in the machinery needed for egg-laying (i.e., the vulva and vulval muscles), egg-laying constitutive mutants seem likely to be disrupted in regulatory functions. In addition, the contrasting phenotypes of the two types of mutants can be used to help define functional pathways based upon whether a particular constitutive mutation can overcome the blockade of egg-laying caused by a particular defective mutation. By screening an existing set of behaviorally "uncoordinated" mutants, we have identified six genes that can mutate to both perturb locomotion and to cause constitutive egg-laying. In addition, we have isolated several new egg-laying constitutive mutants, all of which also have defective locomotion. The mutant che-3(e1124), a chemosensory mutant with normal locomotion, but lacking octopamine, is also constitutive for egg-laying. These egg-laying constitutive mutations are currently being categorized with respect to drug responses and ability to suppress specific classes of egg-laying defective mutations in order to define different functional steps in the egg-laying pathway.

111.3 HABITUATION AND SENSITIZATION OF THE TOUCH-ELICITED SHORTENING REFLEX IN THE LEECH, *HIRUDO MEDICINALIS*. D. S. Stoller* and C. L. Sahley. (SPON: R. J. Contreras) Dept. of Psychology, Yale University, New Haven, CT. 06520.

The two forms of non-associative learning, habituation and sensitization, have been studied extensively in a number of invertebrates. Habituation refers to a decrement in the response elicited by a given stimulus following repeated presentations of that stimulus. Sensitization is defined as the facilitation of a response following the occurrance of a noxious stimulus, such that presentations of a moderate stimulus now elicit a response of increased magnitude. In the leech, habituation of swimming and photo-elicited habituation of shortening have been demonstrated (Debski & Friesen, 1985; Lockery, 1985). We have investigated plasticity of the touch-elicited shortening reflex and of a monosynaptic pathway which may mediate this reflex in *Hirudo medicinalis*.

Thirty leeches were randomly divided into two groups of fifteen. One group received twelve training presentations of a moderate touch stimulus with an interstimulus interval of one minute. A mild shock was presented to the second group four minutes prior to training . A decrease in the magnitude of whole body contraction in response to touchwas observed in the first group. Exposure to the shock stimulus prior to training appeared to retard the response decrement.

To decrease behavioral variability habituation was further studied in leeches with tail sucker denervation. These leeches also demonstrated a decrement in responding to repeated stimulation. Spontaneous recovery of the response was evident 30 min following training.

Using a semi-intact preparation, the activity of both a mechanosensory neuron (P) and a motoneuron (L) in response to skin stimulation delivered according to the temporal parameters used to produce habituation was recorded. The P neuron responds to moderate touch stimulation. The L excites the longitudinal muscles which produce whole-body contractions. The P sensory cell is monosynaptically connected to the L motoneuron via both electrical and chemical synapses (Nicholls and Purves, 1970). No change was seen in the number of action potentials elicited by the P sensory neuron following repeated skin stimulation but a profound decrease was observed in the level of excitation of the L motoneuron. It is suggested that a decrease in the efficacy of the synaptic connections between these particular neurons may be found to account for the habituation of whole body shortening reflex observed in the intact animal.

111.4 ASSOCIATIVE LEARNING MODIFIES TWO BEHAVIORS IN *HIRUDO MEDICINALIS*. C. L. Sahley and D. F. Ready. (SPON: M. J. Cohen) Dept. of Psychology, Yale University, New Haven, CT. 06520 and Dept. of Biology, Princeton University, Princeton, N. J. 08544.

The simple, stereotyped CNS of the leech makes it a favorable preparation for studying the neuronal basis of behavior (Nicholls, Muller and Stent 1981) including learning (*Macrobdella decora*) (Henderson and Strong, 1972). We report here that the medicinal leech, *Hirudo medicinalis*, can modulate a simple reflex, touch elicited shortening, as well as a complex behavior, stepping, based on a learned association. In the first experiment we asked if leeches could learn to associate a light touch to the head (CS) which normally elicits a shortening response with an electric shock to the tail (US). Forty leeches were randomly assigned to four groups of ten. Leeches in group 1 experienced 20 paired presentations of a light touch to the head (CS) paired with an electric shock to the tail (US) . Leeches in Group 2 experienced 20 explicitly unpaired presentations of the CS and US. Leeches in Groups 3 and 4 experienced 20 presentations of either the CS alone, or the US alone, respectively. Leeches in all groups were tested after every fifth trial. Animals that experienced paired touch and shock showed an increase in shortening to touch. In contrast, leeches in the unpaired, CS alone, or US alone groups all showed decreased responding to the touch over trials. The change in behavior occurs only with an interstimulus interval of 1-2 sec. Thus, associative learning can modify a simple reflex in the leech. Learning is retained for 24 hrs but is not present at 36 hrs.

In a second experiment we asked if associative learning could modulate a more complex behavior such as stepping. A leech in shallow water will reliably step in an inchworm-like fashion away from a shock applied to the tail. Stepping has been characterized by Tomlinson and Kristan (1984). A light touch applied to the mid-body of the leech normally results in only local bending. Following 30 touch-shock pairings, 7 out of 10 leeches stepped to touch alone. To control for nonassociative increases in stepping we compared leeches which had experienced the touch-shock pairings with leeches which had experienced either the CS or US alone, or the CS and US in an explicitly unpaired relationship. Two of ten leeches in the unpaired group stepped to the test touch and none of the leeches which had experienced either the CS or US alone leeches stepped to the touch in the test.

Support: NIMH 5RO1-MH37902, NIH BRSG 2-507-RR-07015, and Sloan BR2486 to C.L.S. and NIH PHS NS 16515 and Sloan BR2040 to D. F. R.

111.5 ASSOCIATIVE LEARNING IN FLATWORMS. M. Hauser*, B. Kolb* and H. Koopowitz. Developmental and Cell Biology, University of Ca., Irvine, CA 92717.

For the last three decades many researchers have employed a number of classical conditioning paradigms in attempts to demonstrate that planaria can learn associatively. Many conflicting results were reported thus failing to provide conclusive evidence that these primitive metazoans can learn associatively. Since the time that the planarian learning controversy was at its peak, it has been demonstrated that the more advanced marine polyclads can undergo the behavioral modification of habituation. We now report the demonstration of associative learning in the marine polyclad flatworm Notoplana acticola, using an avoidance conditioning paradigm. Notoplana feed regularly on commercially available frozen brine shrimp which was used as the conditioning stimulus (CS). If the supernatant from a shrimp homogenate is placed in a capillary tube and presented to a worm, the normal, unconditioned response (UR) is for the worm to grip the tube. The unconditioned stimulus (US) used was a 0.02 ml squirt of 0.75M KCl delivered to the tail of the animal. In response to this stimulus the animal recoils and rapidly walks or swims away. The paradigm consisted of presenting the shrimp extract (CS) to the animal, and delivering the US when it gripped the tube. Paired trials were delivered at thirty second intervals. The conditioned response (CR) was achieved when the worm no longer reached for the capillary tube or engaged in avoidance behavior upon presentation of the CS. Under these conditions the mean number of trials to response criterion was 4.2 $\pm$ 0.3 (n=33). The mean retention time for this associative change was very short, lasting only 4.1 $\pm$ 0.3 minutes (n=32). Control animals received random, unpaired presentation of the CS and US and did not exhibit CR. There was no evidence of enhancement of learning with testing on sucessive days. Decerebrate animals can be made to habituate to vibration however, they do not demonstrate associative learning in the paradigm studied. This indicates that the presence of the brain is essential if the animal is to learn associatively.

111.6 OCTOPAMINE MAY MEDIATE CENTRAL EXCITATORY STATE RESPONSE IN THE BLOW FLY. Terry R. McGuire* and Lawrence Friedman* (Spon: M.F. MacDonnell). Department of Biological Sciences and Bureau of Biological Research. Rutgers University, Piscataway N.J. 08854

The central excitatory state (CES) is a non-associative component of proboscis extension in the blow fly Phormia regina. Previous work has shown that phenotypic differences in the CES reflect underlying genetic differences (McGuire, Behav. Genet., 11:313, 1981; Tully & Hirsch. Behav. Genet., 12: 395, 1982a). Strains of blow flies have been bidirectionally selected for the expression of high or low CES response. These selected strains differ at a single major genetic locus (Tully & Hirsch, Anim. Behav., 30:1193, 1982b). In addition, the expression of CES is positively correlated with the expression of classical conditioning and CES seems to function as a "primer" or precondition for learning.

We have attempted to determine the role that octopamine plays in the mediation of CES responses through a pharmacological study. Flies from each of the selected strains were injected with 0 (sham), 5, 10, 20 or 100 μg of drugs that specifically affect the octopaminergic system. Two hours later these flies were tested for their CES response. Drugs acting at the level of the beta receptor (propranolol and isoproterenol) had no effect on CES response in either selected strain. Drugs that acted on the alpha receptors (naphazoline, benextramine) showed significant dosage effects in at least one of the selected strains. In the low CES strain, the alpha-agonist, naphazoline, produced a 2 to 4.5 fold increase in mean proboscis extensions over sham-injected flies. The change in mean proboscis extensions in the high-CES strain was in the same direction but was non-significant. The alpha-receptor antagonist, benextramine, produced a significant decrease (0.5 to 4 fold) in CES response in the high-CES strain. Benextramine had no effect on CES response in the low-CES strain.

These results suggest that the octopaminergic system is involved in the mediation of CES at the receptor level. Octopamine may also mediate the expression of classical conditioning.

111.7 BRAIN BIOGENIC AMINES AND BLOWFLY FEEDING BEHAVIOR. G.L. Brookhart*, R.S. Edgecomb, and L.L. Murdock. Dept. of Entomology, Purdue University, W. Lafayette, IN 47907

The adult blowfly, Phormia regina Meigen, detects food by means of chemosensory hairs on its tarsi. When these hairs contact adequate stimuli, the proboscis is extended. Flies deprived of food require a much weaker stimulus to elicit a proboscis extension than do fed flies. Responsiveness to food stimuli like aqueous sucrose can be expressed quantitatively as the mean acceptance threshold (MAT), the minimum log concentration of sucrose to which the average fly will respond. d-Amphetamine can markedly alter the MAT (Edgecomb, R.S. et al., Soc. Neurosci. Abst. 10, pt 2, p. 1065). When d-amphetamine (12 μg/fly, 0.5 hr.) was injected into three-day-old, unfed flies, the MAT rose from the control value of 3.9 mM sucrose (log value 0.59 ± 0.05 S.E.M.) to about 1600 mM (log value 3.2 ± 0.07). Analysis of brains from the amphetamine-treated flies by HPLC with electrochemical detection revealed reduced levels of octopamine, dopamine, and 5-hydroxytryptamine (5-HT). The time course of d-amphetamine action on the tarsal taste-proboscis extension response and brain amine levels indicated an inverse relationship between MAT and amine levels. By 2 minutes after injection with d-amphetamine (12 μg/fly) the MAT was significantly greater than that of saline-injected flies and brain octopamine was significantly depleted. The highest MAT was observed at 0.5 hr., at which time the octopamine level was reduced from the control value of 2.0 ± 0.29 to 0.30 ± 0.19 picomoles/brain. At 0.5 hr., dopamine had declined from 2.4 ± 0.18 to 0.84 ± 0.16 picomoles/brain and 5-HT had fallen from 1.55 ± 0.12 to 0.44 ± 0.06 picomoles/brain. By 3 hr. the MAT and amine levels of the treated flies had returned to values near those of the controls. dl-Fenfluramine (8 μg/fly, 0.5 hr.) also increased the MAT to 390 mM (log value 2.6 ± 0.39) and depleted octopamine and dopamine, while 5-HT was only weakly affected.

These results suggest that d-amphetamine and dl-fenfluramine, which markedly affect blowfly feeding behavior, act by depleting aromatic biogenic amines in the CNS.

111.8 APPETITIVE LEARNING IN THE TERRESTRIAL MOLLUSC, *LIMAX MAXIMUS*. K. Martin,* A. Diamond*, J. Dubin*, C. Sahley.(SPON: J.A. London. Dept. of Psych, Yale University, New Haven, CT. 06520.

We are interested in the role of learning in the modulation of feeding behavior of the gastropod mollusc *Limax maximus*. Previous work has demonstrated that slugs can learn to associate a food odor and/or taste (CS) with a bitter taste consequence (US), quinidine sulfate (Sahley et al, 1981). This effect has been demonstrated both behaviorally as well as in a semi-intact preparation (Chang & Gelperin, 1981). After an odor-taste pairing slugs no longer show a preference for the odor that had been paired with quinidine. Associative learning in *Limax*, like in vertebrates, is critically dependent upon two inter-event relationships: temporal specificity and predictability (Sahley, et al, 1981). To further study the role of learning in feeding behavior we have been exploring these variables in an appetitive task. In these experiments the CS was a non-food odor and the US was a food. After several CS-US pairings, *Limax* can acquire a preference for the odor paired with food.

Slugs in the appetitive task are trained with a differential training procedure. Each slug is presented with two odors, amyl acetate (AA) and methylcyclohexanol (MCH). For each experimental animal one of these odors was designated as the CS+, during training this odor was consistently paired with food. The other odor, CS−, was never paired with food. The CS-US interval was varied between experimental groups. Slugs in control groups experienced either explicitly unpaired presentations of the CS and US, CS alone or US alone presentations. To assess the effects of this training each slug's odor preference was tested in a two-choice procedure. Each slug was placed in the test chamber in which the two odors, AA and MCH, were localized to opposite sides of the chamber. From a series of 3,60-sec tests the percentage of total time spent over each odor was calculated. We found that only the animals which had experienced an odor-food pairing showed an increase in time over that odor. This result, excitatory conditioning, is only seen when the CS and US are temporally arranged such that the CS precedes by a short time interval, 10-20 sec, the presentation of the US and is terminated shortly after the US begins. If the CS precedes the US by a long period, 30 sec, the animal does not develop a preference for the odor which preceded the food. Also, if the CS both precedes and is presented throughout the US the animal not only does not show a preference for the CS+ but may avoid this odor. This indicates the possibility of inhibitory learning. Further research is exploring the possibility of conditioned inhibition in this paradigm. Support: NIMH 5RO1-MH37902, NIH BRSG 2-507-RR07015, and Sloan BR2486 to C.L.S.

111.9 MAPPING AND PHARMACOLOGY OF NEUROTRANSMITTERS IN THE FEEDING CONTROL SYSTEM OF LIMAX. Ian Cooke* and Alan Gelperin, (SPON: L. Symonds). Dept. Biology, Princeton University, Princeton, N.J. 08544 and Dept. of Molecular Biophysics, AT&T Bell Laboratories, Murray Hill, NJ 07974.

As part of our study of the associative learning mechanism used to modify information transmission in the taste input-feeding motor program (FMP) output pathway, we are using immunocytochemical and pharmacological techniques to investigate the importance of several neurotransmitters for the operation of this pathway in the cerebral and buccal ganglia of the terrestrial mollusc Limax maximus. Immunohistochemical techniques applied to whole-mount and sectioned tissue revealed a large number of FMRFamide-like immunoreactive (FLI) neurons, ranging in size from 10 to 200 um. FLI axons are present in all the central connectives and commissures and in a large number of peripheral nerves. Varicose FLI fibers ramify extensively throughout the neuropil of central ganglia and in the connective tissue ensheathing the central ganglia.

FMRFamide has a potent inhibitory effect on the expression of FMP by isolated lip-brain preparations. Bath application of $3x10^{-6}$M FMRFamide reduces by 50% the intensity of bouts of FMP elicited by a standard chemostimulus applied to the lips. FMRFamide also has direct inhibitory effects on the autoactive salivary fast burster (FB) neuron. Application of $3x10^{-6}$ M FMRFamide in low calcium, high magnesium saline strongly hyperpolarizes the FB neuron and abolishes the slow ramp depolarization that underlies its spontaneous bursting.

Stimulated by the finding that acetylcholine (ACh) triggers FMP in the marine slug Pleurobranchaea (Davis, personal communication), we applied $3x10^{-6}$M ACh to the cerebral and buccal ganglia of the Limax lip-brain preparation and compared the output elicited by ACh with the output elicited by lip chemostimulation. The buccal outputs elicited by ACh and taste input are very similar. ACh application to the cerebral ganglia alone, but not to the buccal ganglia alone, produced FMP. Dopamine ($5x10^{-5}$M) shows the reverse pattern, producing FMP when applied to the buccal ganglia but not when applied to the cerebral ganglia. Extensions of this work will involve mapping the location of cholinergic neurons in the cerebral ganglia and determination of the transmitter(s) contained in the cerebral-buccal interneurons which can trigger FMP (Delaney & Gelperin, 1985, Soc. Neurosci. Abstr. 11). (Supported by NIMH Grant 39160).

111.10 TRAINING AND TESTING DETERMINANTS OF PHOTOTAXIC BEHAVIOR IN HERMISSENDA. (Spon:M.Lampert) L.Vold*, L.Grover*, and J.Farley. Prog. in Neurosci., Princeton Univ., Princeton, NJ.

Five pairings of light and rotation result in a pairing-specific suppression of Hermissenda's phototaxic behavior which persists for ∿20-25 min. Here, we describe those variables which are important determinants of phototaxic behavior, - and thus the sensitivity of retention tests - and those factors which determine the degree of original learning.

In experiment one, 5,10, or 15 min dark adapted animals received four successive hourly tests of phototaxis in either a horizontal or vertical orientation. Repeated tests increased start & finish latencies in all conditions, more so for animals tested in the horizontal vs. the vertical orientation (6 vs. 2 fold increases). In addition, longer dark-adaptation times resulted in longer phototaxic latencies. Additional experiments indicated that both repeated handling and interruption of the diurnal cycle by the repeated dark-adaptation periods were responsible for the increased latencies. In further experiments, we systematically varied both test orientation (horizontal vs. vertical), and training light intensity (moderate BB:170 μW; 510: 140 μW vs. bright 430 μW; 330 μW), for paired vs. random control animals and obtained measures of both phototaxic as well as negative geotaxic behavior. Animals which received 5 pairings of the moderate intensity training light and rotation, and were tested in the vertical orientation, exhibited significantly greater suppression of phototaxic behavior ($\bar{x}$ ± S.D.; .24 ± .19, n=20) than comparable random controls (.43 ± .24, n=15; $p < .01$). Negative geotaxic behavior was not significantly affected (paired .31 ± .18 random: .39 ± .30; n's=18;). Thus, the changes were both pairing- and stimulus-specific. In contrast, animals trained with the moderate-intensity light but tested in the horizontal orientation (paired: .28 ± .20, n=14; random: .26 ± .21, n=15), or trained with the bright light and tested in either the horizontal (paired: .16 ± .12, n=24; random: .25 ± .20, n=23) or the vertical orientation (paired: .31 ± .21, n=22, random: .27 ± .17, n=18) all showed suppression of phototaxic behavior. It was, however, neither pairing- nor stimulus-specific.

Thus, whether one obtains short-term, pairing- and stimulus-specific reductions in phototaxic behavior resulting from small numbers of training trials depends upon: 1) the use of a moderately intense training light, 2) a sensitive testing orientation. These results may help to explain the failure to obtain pairing-specific suppression of phototaxic behavior (following 5 or 10 pairings) reported by Crow (1983, J.Neurosci.) who tested animals in the horizontal orientation and trained animals with a very bright light (70 times brighter than the one he has previously used and ∿100 times brighter than ours).

111.11 NEURONAL ANALOGUES OF CONDITIONING PARADIGMS IN APLYSIA . R.E. Clymer* and M.J. McCreery*. (SPON:D.R. Livengood).Dept. of Physio., Armed Forces Radiobiology Research Institute, Bethesda, MD 20814.

This study examined the conditionability of various abdominal ganglion cells of the Aplysia californica and the role of postsynaptic cell firing in producing any observed conditioning.

Suction electrodes were attached to the left and right connectives of the dissevered ganglion. Intracellular recodings were obtained using potassium acetate filled electrodes and a Dagan Model 8100 single elctrode voltage clamp operating in current clamp mode.

Mild electrical stimulation of one connective was adjusted to produce a postsynaptic potential (PSP) in a cell. The PSP was repeatedly paired with each of 4 forms of stimulation. In the "conditioning" procedure the PSP was followed in 300 msec. by repeated firing of the cell induced by intense stimulation of the other connective . In the "pseudoconditioning" procedure the stimulation induced firing followed the PSP by 10 seconds. In the "clamp" procedure the cell was hyperpolarized to prevent cell firing in response to the intense stimulation of the connective which was presented as in the conditioning procedure. In the "current injection" procedure the PSP was followed in 300 msec. by repeated cell firings induced by injection of depolarizing current into the cell. The order of the 4 procedures was counterbalanced.

Following the conditioning and clamp procedures the PSP was significantly larger. This was not true of the pseudoconditioning procedure. The current injection procedure resulted in a decreased PSP. These results rule out a role for postsynaptic cell firing in producing conditioning.

The pseudoconditioning procedure had an inhibitory effect upon an immediately following conditioning procedure. This appeared to be analogous to the conditioned inhibition observed in behavioral studies. Other demonstrations of a neuronal analogue of conditioned inhbition are unknown to the authors.

Cells were classified according to their response to the conditioning and pseudoconditioning procedures. Cells which did not respond to the conditioning procedure were called unconditionable. If they responded to both the conditioning and the pseudoconditioning procedure they were called pseudoconditionable. If they responded to the conditioning procedure but not the pseudoconditioning procedure, they were truly conditionable. Pseudoconditionable cells were more responsive to the clamp procedure than the other two cell types. This suggests that the mechanism of pseudoconditioning differs from that of true conditioning.

The electrophysiological procedures produced results which were directly analogous to in vivo conditioning experiments. Postsynaptic cell firing does not appear to play a role in producing conditioning. Whatever the mechanism, sophisticated information processing appears to occur in simple neuronal systems.

111.12 DIRECTED DEFENSIVE RESPONSES IN APLYSIA CALIFORNICA. M.T. Erickson* and E.T. Walters (SPON: R. Levine). Dept. of Physiol. & Cell Biol., Univ. of Texas Med. Sch., Houston, TX 77225.

While defensive responses in Aplysia have been used extensively for neurobiological investigations of learning, interesting questions remain about the organization and function of these behaviors. For example, are defensive responses in Aplysia under directional control? We have now found that important features of several defensive responses (inking, siphon withdrawal, and escape locomotion) depend upon the site of noxious stimulation, and that these features are involved in directing behavior either towards or away from an apparent threat.

Animals were placed in the center of a round plastic tub (15" diameter) filled with artificial seawater. After 3 min a noxious tactile stimulus was delivered (40 ma shock or mechanical pinch) to either the left or right side of the body (tentacle, neck, parapodium, or tail) or to the siphon. Videotape analysis showed that the initial jet of ink from the mantle cavity was always directed towards the stimulation site: stimulation of anterior sites elicited anterior ink ejection, tail stimulation elicited posterior ejection, and parapodial or siphon stimulation elicited simultaneous anterior and posterior ejections. Using a 5-point rating scale for direction, we found that anterior vs. midbody, anterior vs. posterior, and midbody vs. posterior stimulation sites produced significantly different directions of initial ink ejection ($p < .001$ in each case). In addition, anterior stimulation caused the siphon to constrict or funnel (presumably to prevent ink ejection through the siphon) and to assume a vertical orientation. By contrast, posterior stimulation caused the siphon to flatten without constricting and to point towards the tail (presumably to direct the ink backwards). Whereas inking is directed towards the threat, escape locomotion is directed away from a source of tactile disturbance: anterior stimulation caused turning and escape locomotion away from the stimulus, while posterior stimulation produced little change in direction (anterior vs. posterior turn angle was significantly different; $p < .001$). Anterior stimulation also produced significantly fewer steps during escape locomotion than did posterior stimulation ($p < .025$).

This directedness of defensive responses in Aplysia adds a new dimension that should be addressed in both neural and functional analyses of these behaviors. It also adds an interesting parameter to explore in studies of learning in this simple preparation. (Supported by grant MH 38726 from the NIMH to E.T.W. and by an NIH summer fellowship to M.T.E).

111.PO *DISRUPTION OF PHEROMONE-GOAL DIRECTED BEHAVIOR WITH AMBIENT CATIONS IN T-CASTANEUM. R.H.Loiselle, A.J. Giannini, W.A.Price, G.F.Ludrik‡ L.Kerr‡ Dept. of Psychiatry, Northeastern Ohio Medical College, P.O. Box 2169 Youngstown, Ohio 44504.

High levels of ambient cations have been shown to produce anxiety and elevated levels of peripheral serotonin in human and other mammalian populations. Some have postulated that this is due to cation-induced inhibition of the enzyme, monoamine oxidase (MAO). To test this hypothesis the authors used the beetle T-castaneum which has repeatedly been shown to possess no MAO activity. One hundred male beetles were placed in a field width measuring 6" x 24". Random movement was observed and nineteen beetles crossed a finish line after twenty minutes. When a species specific pheromone was placed at the finish, seventy-three beetles crossed the line within twenty minutes. When an ion generator was placed behind the finish line and used to raise atmospheric cation levels to 2400 cations/cm^3 (normal: 1050-1150/cm^3), only twenty-eight beetles crossed the line. The avoidance behavior seen indicated that cations also have an adverse affect on beetles. The absence of a MAO system suggest that atmospheric cationic action may be independent of this enzyme.

112.1 INTERACTIONS BETWEEN MUTATIONS AFFECTING CHOLINE ACETYLTRANSFERASE AND ACETYLCHOLINESTERASE IN THE NEMATODE C. ELEGANS. J. B. Rand, C. D. Johnson*, and R. L. Russell*. Dept. of Biological Sciences, Univ. of Pittsburgh, Pittsburgh, PA 15260 and Zoology Dept., Univ. of Wisconsin, Madison, WI 53706.

In C. elegans, the gene cha-1 is the structural gene for choline acetyltransferase (ChAT; Rand and Russell, Genetics 106:227), and the unlinked genes ace-1, ace-2, and ace-3 are the apparent structural genes for for class A, class B, and class C acetylcholinesterase (AChE), respectively (Johnson et al., Genetics 97:261; Culotti et al., Genetics 97:281; and unpublished). Severe cha-1 mutants, which contain less than 2% residual ChAT activity, and are severely uncoordinated and slow-growing, show no apparent alteration in the amount of any of the classes of AChE. Furthermore, the distribution of different molecular weight forms of AChE within each of the classes is unaffected by the presence of a severe cha-1 mutation. We also find that animals homozygous for any one or two of the ace mutations do not show any compensatory changes in the levels of either ChAT or the remaining class(es) of AChE. It therefore seems that the levels of ChAT and AChE activity are not dependent on each other or, presumably, on acetylcholine levels.

Nevertheless, we have observed two cases of phenotypic interaction between ChAT and AChE mutations. The presence of all three ace mutations simultaneously leads to lethality in late embryos or early larvae. However, we have demonstrated that quadruple mutants, containing cha-1 and all three ace mutations, are viable and become fertile adults. We therefore conclude that near-total ChAT deficiency can apparently overcome the lethality caused by near-total AChE deficiency.

We have also found that ace-3 mutations significantly improve the deficient growth rate of severe cha-1 mutations, although such double mutants are clearly not completely wild type. Thus, deficiency of a specific AChE class can partially compensate for secondary effects caused by ChAT deficiency.

Supported by a grant from MDA.

112.2 CLASS D, A FOURTH CLASS OF ACETYLCHOLINESTERASE FROM CAENORHABDITIS ELEGANS. B. D. Stern and R. L. Russell (SPON: G. H. Fromm). Department of Biological Sciences, University of Pittsburgh, Pittsburgh PA 15260.

The free-living soil nematode Caenorhabditis elegans contains three well characterized classes of acetylcholinesterase (AChE) which are designated A, B, and C. AChE forms in each of these classes can be differentiated from those in other classes on the basis of kinetic differences and genetic control, with the genes ace-1, ace-2, and ace-3 the likely structural genes for the three classes. We report here the discovery of a fourth class of AChE, which has been designated class D.

Class D is a relatively minor form representing only a few percent of wild type AChE activity present in extracts. It was first detected in a mutant deficient in class C and was then shown to be present in wild type extracts. All of the biochemical characterizations described below were performed on class D which had been partially purified by an affinity chromatography method from animals deficient in classes B and C.

Only a single class D form has been detected and it has a sedimentation constant of about 3.5s which is distinct from the sedimentation constants of the forms in the other classes (5s, 7s, 11s, and 13s). Class D shows a K_m for acetylcholine of 1 micromolar which is also distinct from the K_m's of the other classes: 15 micromolar, 70 micromolar, and 20 nanomolar for classes A, B, and C respectively. Classes A and B are relatively sensitive to the AChE inhibitor eserine while class C is highly resistant to this inhibitor. Class D also shows a high resistance to eserine, similar to that of class C. However class D is considerably more thermostable than class C. Also, use of a polyclonal antibody to class C indicates that there is no crossreactivity between classes C and D. Double mutant animals deficient in either class A and class B or class B and class C contain class D enzyme, suggesting that the class D is not controlled by the structural genes for any of the other classes.

All of these data taken together suggest strongly that wild type C. elegans contains a class of AChE which has properties which distingish it from the three other known classes. The function of class D is unknown. However it is noteworthy that animals triply deficent in all of the three other classes are inviable while animals deficient in any one or any two of the other three classes are viable. This suggests that class D does not substantially overlap in function with any of the other classes.

112.3 GENETIC MOSAICS OF CAENORHABDITIS ELEGANS WHICH LACK NEURAL EXPRESSION OF THREE GENES FOR ACETYLCHOLINESTERASE ARE VIABLE Carl D. Johnson* and Robert K. Herman*† (SPON: J. Adler) Dept. of Zoology, Univ. of Wisconsin, Madison,WI 53706 and Dept. of Genetics and Cell Biology, Univ. of Minnesota, St. Paul, MN 55108

The acetylcholinesterase (AChE) activity of the nematode Caenorhabditis elegans is heterogeneous. Each of the separable form which has been described, can be assigned to one of three kinetic classes (ACh Kms: 80uM for class A, 15uM for class B and 0.01uM for class C forms). Mutations in the ace-1 gene eliminate the class A forms, ace-2 mutants lack the class B forms. Although ace-1;ace-2 double mutants are uncoordinated and hypercontract abnormally when touched (the Ace-Unc phenotype), strains mutant in either ace-1 or ace-2 alone have no apparent effect on behavior. Recently, mutants which eliminate class C AChE have been isolated; these define the new gene, ace-3. The ace-3 mutants have no visible locomotory defects and display normal responses to touch. Ace-1;ace3 and ace-2;ace-3 double mutants are also apparently normal. In contrast, triple mutant strains are inviable (the Ace-Let phenotype).

Mosaic individuals, in which some cells carry a wild type allele of the ace-1 gene whereas other cells carry only mutant alleles of the ace genes, have been used to investigate the cellular requirements for ace-1 gene expression. Mosaics for the ace-1 gene are generated through somatic loss of a small free chromosomal duplication carrying the wild type allele of ace-1. By using the mutations unc-3, daf-6, osm-1 and sup-10, which are also carried on the duplication, as cell markers (see Herman, Genetics 108, 165) we suggest that the lack of $ace\text{-}1^+$ gene expression in muscle cells is responsible both for the Ace-Unc phenotype (in an ace-1;ace-2 background; Herman and Kari, Cell 40, 509) and for the Ace-Let phenotype (in an ace-1;ace-2;ace-3 background). Animals which lack expression of all three ace genes within all but two of the total 282 somatic neurons, are viable and superficially normal. Although the behavior of such mosaics has yet to be analyzed in detail, this result is consistent with the notion that central cholinergic synapses in this nematode have no requirement for expression of these three ace genes in either pre- or post-synaptic cell.

112.4 IMMUNOAFFINITY PURIFICATION OF CHOLINE ACETYLTRANSFERASE FROM HUMAN BRAIN. D. Casper[a], B. H. Wainer[b], and P. Davies*[a]. [a]Depts. of Neuroscience & Pathology, Albert Einstein College of Medicine, Bronx, NY 10461, and [b]Depts. of Pathology & Pediatrics, University of Chicago, Chicago, IL 60637.

Choline acetyltransferase (ChAT; E.C 2.3.1.6) was purified from human basal ganglia over 35,000-fold in one step using an immunoaffinity column made from F(AB)2 fragments of a monoclonal antibody to ChAT.

Rat monoclonal antibody AB8 reacts with the human form of ChAT by immunoprecipitation assay. This monoclonal was affinity purified on a goat anti-rat Affi-Gel 10 column and the purified antibody was digested with pepsin to yield F(AB)2 fragments, further purified from undigested material on sephadex G-150. F(AB)2 fragments were deemed necessary for the purification because purified AB8 on reducing SDS polyacrylamide gels was shown to have doublet heavy chain bands with apparent molecular weights of 53,000 and 55,000 daltons. Reported molecular weights for ChAT are 50-80 Kd. The use of goat anti-rat serum as a reagent in attempts to develop Western blots of ChAT reveal intense direct staining of the heavy chain doublet transferred to nitrocellulose. In control experiments, both human and rat brain tissues were shown by Western blots to contain appreciable amounts of immunoglobulin with heavy chain bands in the 50-55 Kd region.

In a representative preparation, an acetone powder was made from 319 grams of human basal ganglia, solubilized in PBS with protease inhibitors and spun at 100,000 x g. The supernatant containing ChAT activity was loaded onto a column of anti-Chat F(AB)2 fragments and all of the ChAT activity was retained by the column. After extensive washing, the column was eluted with 3M potassium thiocyanate and the protein-containing fractions were run on a reducing SDS-polyacrylamide gel. The final yield of protein was 0.8mg. The protein profile as seen by silver stain consisted of a doublet at 68,000 and 70,000 daltons, with single bands at 55,000, and 50,000, and lower molecular weight species. Western blotting experiments demonstrated AB8-dependent staining of the 55,000 dalton band, but this is thought to be non-specific binding as this band is also present in the flow through fractions from the affinity column which contain no ChAT activity. Hence an upper limit for the abundance of ChAT is estimated to be 0.003%, assuming the eluted protein to be 100% ChAT. This confirms reports by others that this enzyme is present in extremely low quantities in brain; even those regions where cholinergic neurons are relatively abundant.

Supported by NRSA training grant MH-15788 from NIMH.

112.5 IMMUNOAFFINITY PURIFICATION OF CHOLINE ACETYLTRANSFERASE FROM CHICK BRAIN AND OPTIC LOBES. M.E. Epstein, D.D. Bloom*†, J.L. Dahl†, and C.D. Johnson*‡ (SPON: C.D. Geisler). Departments of Anatomy, Pharmacology†, and Zoology‡, University of Wisconsin-Madison, Madison, WI 53706.

Choline acetyltransferase (ChAT) has been purified to apparent homogeneity from chick brain and optic lobes. The initial steps involved polyethylene glycol precipitation, followed by chromatography on CM-Sephadex. The final purification step was accomplished by chromatography on Affi-Gel 10 to which had been coupled a monoclonal antibody which binds chick ChAT [Soc. Neurosci. Abstr. 9, 959 (1983)]. More than 90% of the ChAT activity in the CM-Sephadex fraction, applied in the presence of 0.15 M NaCl, was bound to the monoclonal antibody affinity column. After extensive washing of the column with buffer containing 0.5 M NaCl, active enzyme was eluted with 0.1 M citrate, pH 2.2, containing 0.15 M NaCl. Fractions were collected into tubes containing 2.5 M Tris, pH 10.5, so that exposure to acid conditions was minimized. Approximately 25% of the enzyme activity applied to the column was recovered. The specific activity of the purified enzyme was generally in the range of 40 to 60 μmoles/min/mg, although a specific activity of 185 μmoles/min/mg was achieved in one experiment. Affinity-purified enzyme ran as a single band with an apparent molecular weight of 64,000 daltons when subjected to SDS-polyacrylamide gel electrophoresis. The enzyme was stable for months when stored at -50°C in 50% glycerol. The procedure described above enables rapid, large-scale purification of the enzyme; for example, 2000 g of optic lobes can be processed in two weeks to yield 1.2 mg of enzyme. Supported by NIH grant AM32978 to MLE and funds provided by the Research Committee of the University of Wisconsin Graduate School to JLD.

112.6 ACETYLCHOLINESTERASE-CONTAINING NEURONS IN PRIMARY CULTURES OF DISSOCIATED RAT CEREBRAL CORTEX. W.E. Thomas. Dept. of Physiol., Meharry Medical College, Nashville, TN 37208.

The high affinity uptake of choline and subsequent synthesis of acetylcholine (ACh) by primary cultures of cerebral cortical cells has recently been reported (Thomas, W.E., Brain Res., 332:79, 1985). This ACh synthesis was shown to be attributable to the enzyme choline acetyltransferase and supported the existence of cholinergic cells in the cortical cultures. In initial efforts to establish the identity of these cholinergic cells, histochemical staining for cholinesterase enzyme has been employed. Cholinesterase reaction product was observed in the somata and processes of morphologically identified neurons. This neuronal staining was substantially greater than the background staining. While there was some variability in the intensity of neuronal staining, through optimization of the staining reaction time a clearer distinction between stained and unstained neurons was achieved. This allowed the quantitation of stained neurons by direct counting.

To investigate the nature of the activity producing the reaction product, various pharmacological compounds were included in the staining solution. The general cholinesterase inhibitor neostigmine abolished all of the neuronal staining. The pseudocholinesterase inhibitors ethopropazine and tetraisopropylpyrophosphoramide were without effect on the mean number of stained neurons per culture. The acetylcholinesterase (AChE) inhibitor 1,5-bis-[4-allyldimethyl-ammoniumphenyl]pentan-3-One dibromide always reduced the mean number of stained neurons to zero. On the basis of these pharmacological properties, all or most of the neuronal staining was attributable to the enzyme AChE. The mean number of AChE-stained neurons per culture ranged from 113 ± 23 to 555 ± 102 in cultures from twelve different platings. For six of these platings the percentage of AChE-containing neurons was determined after counting the total number of neurons in cresyl violet-stained sister cultures. The mean percentage of AChE-containing neurons in the cortical cultures was 2.17. Finally, the morphology of the stained neurons was evaluated. Entire cultures were scanned and all neurons stained enough to reveal their detailed morphology were classified as pyramidal, stellate, bipolar or bitufted. The accumulative results for the morphological distribution of stained neurons in 34 different cultures (a total of 2,708 cells) was as follows:10.3% pyramidal, 11.1% stellate, 66.9% bipolar and 11.7% bitufted.

These findings provide further support for the presence of cholinergic cells in the cortical cultures and suggest that the upper limit for such neurons is approximately 2.0%. Stained neurons of all morphologies were observed; however, the majority of the AChE-containing neurons exhibited bipolar morphology.

This work was supported by MBRS Grant No. RR-08037 and NSF Grant No. R11-8313599.

112.7 CHOLINE ACETYLTRANSFERASE NEURONS AND THEIR ACETYLCHOLINESTERASE STAINING PATTERNS. E. Gould*, N. J. Woolf, and L. L. Butcher, (SPON: D. W. Zaidel). Dept. of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Using a sequential staining protocol (Eckenstein & Sofroniew, J. Neurosci., 3:2286, 1983; Woolf et al., Neurosci. Lett., 40:93, 1983), individual neurons demonstrating choline acetyltransferase (ChAT)-immunofluorescence were further evaluated for acetylcholinesterase (AChE) staining intensity after subsequent counterstaining for the cholinergic degradative enzyme. AChE staining patterns of ChAT-positive neurons were rated as intense, moderate, or light.

Intrinsically organized cholinergic cells found in the caudate-putamen complex, nucleus accumbens, and olfactory tubercle all stained heavily for AChE. 91-96% of cholinergic neurons in these regions stained intensely, and the remainder stained moderately for AChE. No intensely stained AChE cells were found in these regions that were not immunoreactive for ChAT.

In basal forebrain regions slightly lower percentages of ChAT cells stained intensely for AChE. The percentages of ChAT-positive cells that stained intensely for AChE are as follows: 80% in the medial septal nucleus, 80% in the lateral preoptic area, 86% in the diagonal band, 85% in the nucleus basalis, and 93% in the substantia innominata. A few ChAT cells in the basal forebrain were found that stained only lightly for AChE, but these were never more than 2-6% of all ChAT neurons. The remaining ChAT cells of the basal forebrain stained moderately for AChE.

In the various cranial nerve nuclei the majority of the ChAT cells stained intensely for AChE, and the rest stained moderately. 73% of the ChAT cells found in the nucleus of cranial nerve X stained intensely for AChE, which was the lowest percentage found for any cranial nerve nucleus.

The AChE staining patterns of ChAT-containing somata in the pontine tegmentum differed depending on where the cholinergic neurons were found. ChAT cells associated with the pedunculopontine tegmental nucleus were similar to cholinergic basal forebrain cells in that 88% were intensely stained for AChE and the remainder were moderately stained. Unlike cholinergic cells in preceding brain regions however, ChAT cells found in the dorsolateral tegmental nucleus were markedly different in that only 12% stained intensely for AChE, whereas 57% stained moderately, and 30% stained lightly for AChE. This suggests that in certain areas of the brain ChAT cells do not necessarily contain high levels of AChE.

[Support: NS 10928 to L.L.B.]

112.8 ACETYLCHOLINESTERASE DISTRIBUTION AND ANTICHOLINESTERASE-AGENT BINDING IN THE BRAIN OF GUINEA PIG. R.R. Pindzola, Karen R. Olson* and Robert E. Foster. Neurotoxicology Branch, US Army Med Rsch Inst of Cml Def, Aberdeen Proving Ground, MD 21010-5425.

The distribution of acetylcholinesterase (AChE) in the guinea pig brain was assayed biochemically and histochemically. For the biochemical assays, whole brains were dissected (over ice) into ten areas and subsequently kept frozen at -80°C until homogenized. The fresh brain homogenates were then assayed for AChE activity, utilizing the radiometric method of Siakotos et al. (1969). AChE activities (measured at 20°C, pH 7.2) ranged from the high of 159.1±16.1 nmoles ^{14}C-acetylcholine hydrolyzed/min/mg wet weight in tissue from striatum to the low of 2.0±0.2 nmoles ^{14}C-acetylcholine hydrolyzed/min/mg wet weight in cerebral cortex. The ten brain areas listed in descending order of measured AChE activities are striatum, cervical spinal cord, cerebellar neocortex, cerebellar vermis, medulla, midbrain, olfactory bulbs, diencephalon, hippocampus, and cerebral cortex. As expected, a modified Koelle histochemical stain for AChE in brain slices revealed staining density distributions much more complicated than the biochemical assays of acetylcholine hydrolysis could reveal. In a parallel study, the binding of radiolabelled anticholinesterase-agent, ^{3}H-pinacolyl methylfluorophosphonate (^{3}H-soman), to individual 20 micrometer slices of fresh frozen brain was determined via section autoradiography and biochemical assay. The biochemical assay consisted of scintillation counting of radioactivity in tissue sections which were first incubated in ^{3}H-soman alone or soman followed by ^{3}H-soman, dehydrated, defatted, dryed and then scraped into vials. Tritiated-soman binding to parasagittal 20 micrometer slices from fresh frozen brains revealed an average of 45 femtomoles of covalently bound soman per tissue slice (or, 1 DPM/ug tissue using 1.25Ci/mmole ^{3}H-soman; ave. weight/slice = 130 ug). This amount of bound soman is approximately 2 times greater than the amount of binding sites attributable to AChE. Thus, approximately 50% of covalently bound soman in brain tissue slices is distributed to "non-specific" sites. The calculated 1:1 ratio of soman binding to AChE sites versus non-specific binding sites in brain slices (in vitro) is supported by the results of experiments where, prior to ^{3}H-soman incubation, the non-specific binding sites in the tissue sections were blocked by pretreatment with CBDP (cresylbenzodioxaphosphorin oxide). Finally, from the autoradiographic analysis of ^{3}H-soman binding, an areal distribution of bound ^{3}H-soman was revealed that corresponded, in part, to the density distribution of AChE (determined by the Koelle stain).

112.9 VARIABILITY OF CHOLINE ACETYLTRANSFERASE AND ACETYLCHOLINESTERASE ACTIVITIES IN NEOCORTEX OF SQUIRREL MONKEYS. L. C. Walker, K. R. Brizzeet, M. B. Kaack*† and D. L. Price. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205; †Delta Regional Primate Research Center of the Tulane University Medical Center, Covington, LA 70433.

In primate neocortex, the majority of the activity of choline acetyltransferase (ChAT), the enzyme which synthesizes acetylcholine, resides in axons and terminals emanating from neurons in the basal forebrain cholinergic system. On the other hand, the hydrolytic enzyme acetylcholinesterase (AChE) is associated with both cholinergic and noncholinergic elements. It is important to specify the levels of these enzymes in various neocortical regions of primates for the following reasons: to estimate the degree of innervation of heterogeneous cortical areas by neurons of the basal forebrain cholinergic system and to relate ChAT levels to AChE content in those areas; to determine the normal variability of the two enzymes among cortical regions; and to establish the interindividual variation in overall levels of ChAT and AChE in neocortex of a New World primate. To determine interindividual and interareal patterns of variation, we analyzed the activities of ChAT and AChE in five neocortical regions of eight 30-day old squirrel monkeys (Saimiri sciureus). Fresh tissue blocks were removed from right motor, somatosensory, auditory, visual, and prefrontal association cortices, and ChAT and AChE were measured in homogenized samples (Kaack, B., Walker, L., Brizzee, K. R. and Walker, M., J. Neurochem., 34:1772-1775, 1980). Results show that ChAT levels vary significantly across cortical areas ($p < 0.01$, ANOVA), the activity being highest in motor and auditory cortices, lowest in visual cortex, and intermediate in somatosensory and frontal cortices. This pattern closely parallels that in rhesus monkeys (Lehmann J., Struble, R. G., Antuono, P. G., Coyle, J. T., Cork, L. C. and Price, D. L., Brain Res., 322:361-364, 1984). Whereas AChE levels also differ significantly across the five cortical regions and correlate significantly with ChAT levels, the ratio of AChE to ChAT was generally lowest in motor cortex and highest in frontal association cortex. Differences among individuals in overall ChAT levels and AChE levels were not significant, although some variation in individual levels and patterns of enzyme activity was apparent. Thus, cholinergic innervation of the neocortex of Saimiri is not uniform, and AChE activity is a significant, but somewhat variable, correlate of cortical cholinergic innervation.

112.10 BRAIN ACETYLCHOLINE - A VIEW FROM THE CEREBROSPINAL FLUID. R. Becker, E. Giacobini, R. Elble, T. Mattio*, M. McIlhany* and G. Scarsella* (SPON: J. Couch). Depts. Pharmacology, Psychiatry, Medicine and Surgery, Southern Illinois University School of Medicine, Springfield, IL 62708 USA and Dept. Cell Biology, University of Rome, Rome, ITALY

Our understanding of the origin of the four major cholinergic components in human CSF has become increasingly more important in connection with early diagnosis and treatment of Alzheimer's disease (AD). Our studies of the molecular forms of acetylcholinesterase (AChE) in CSF, plasma and brain of the dog, as well as in CSF of normal controls and AD patients have shown that 1) most of the cholinesterase (ChE) activity present in CSF is AChE (more than 85%); 2) AChE in CSF originates primarily from brain tissue as a result of secretory process; and 3) the major form found in human CSF is the 10S molecular form corresponding to the globular tetramer G_4. The origin of choline acetyltransferase (ChAc) activity in CSF is probably neuronal while acetylcholine (ACh) might be, in part, the product of local (CSF) synthesis. The origin of choline (Ch) is multiple and only a small percent might reflect neuronal ACh synthesis. In order to correlate variations in levels and activity of the four main cholinergic components in CSF, brain and plasma, we have compared the effect of two routes (intravenous and intracerebral ventricular) of administration of physostigmine (Phy) in beagle dogs. The dosage has varied between 20 and 1,000 ug. Implanted reservoirs communicating with the respective lateral ventricle through a silastic catheter were used. Significant (50-90%) and persisting (3-9 hrs) inhibition in CSF and brain AChE activity as well as an increase in ACh levels were seen only with i.c.v. administration. At comparable dosages, intravenous administration produced only small and short-lasting effects. Therefore, intracerebral administration of Phy appears to be the route of choice if maximal central AChE inhibition and ACh levels increases are the goal of the treatment. Three of the cholinergic CSF components showed a decrease in our group of AD patients. In addition, changes seen in AChE, and ChAc activities and in Ch levels at 3-6 month intervals in the same patient seem to be indicative of the progression of the disease. In conclusion, our studies, both in dogs and humans, support the concept that ACh metabolism in brain is reflected by variations of cholinergic parameters in CSF. The diagnostic value of such variations in pathological conditions such as AD is under scrutiny. (Supported in part by funds for a pilot project from S.I.U. School of Medicine; E.F. Pearson Foundation and S.I.U. Alzheimer Research Fund.)

112.11 KITTY-ChAT: IMMUNOHISTOCHEMISTRY OF CHOLINE ACETYLTRANSFERASE IN THE FELINE BRAIN. S.R. Vincent and P.B. Reiner. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5 Canada.

The distribution of choline acetyltransferase (ChAT) in the feline brain was examined using monoclonal antibodies (Eckenstein, F. & Thoenen, H., EMBO J. 1:363, 1982). The well characterized cholinergic systems previously described in various species were readily detected. These include the ventral horn motoneurons and the intermediolateral preganglionic sympathetic neurons of the spinal cord, the motor nuclei of cranial nerves III, IV, V, VI, VII, XI and XII, and the preganglionic parasympathetic nuclei of nerves III, VII, IX and X.

The distributions of the large striatal neurons, the magnocellular cells of the rostral column in the basal forebrain, and the caudal column in the central tegmental field and the laterodorsal tegmental nucleus were examined in detail. Furthermore, the topographic relationship of the caudal cholinergic column to the catecholamine cells in the midbrain and pons was determined by comparing the localization of ChAT-positive neurons with that of tyrosine hydroxylase and dopamine-β-hydroxylase immunoreactive cells.

More controversial cholinergic cell groups were also detected. In the basal forebrain, smaller cells were intermingled with the magnocellular neurons, often capping the islands of Calleja. Positive neurons were also found in the central nucleus of the amygdala and intercalated within adjacent fiber tracts. The ventral medial habenula contained a dense cluster of ChAT-positive neurons, and a few cells were present in the lateral habenula. Many weakly stained cells were scattered throughout the lateral hypothalamus, some extending medially to the paraventricular and arcuate nuclei. Small cells were found in the superficial layers of the superior colliculus which also contained a well organized terminal field. Virtually all neurons in the parabigeminal nucleus showed moderate ChAT immunoreactivity, and cells showing similar staining were seen in the parabrachial nuclei, which were clearly separate from the more intensely staining cells of the caudal column. In the medulla a cluster of cells was noted in the prepositus hypoglossal nucleus, and small intensely stained cells were found just ventro-lateral to the abducens nucleus along the 7th nerve and in the periolivary portion of the superior olivary complex, while scattered larger cells were present in the gigantocellular tegmental field. Neurons were also observed in laminae III-V of the dorsal horn of the spinal cord and around the central canal. These results suggest a more widespread central cholinergic system than has been previously indicated.

(Supported by the B.C. Health Care Res. Found. and the MRC)

112.12 IS THE VERATRIDINE INDUCED HYDROLYSIS OF CYTOPLASMIC ACETYLCHOLINE IN CENTRAL CHOLINERGIC NERVE ENDINGS MEDIATED BY THE BACKWARD REACTION OF CHOLINE-O-ACETYLTRANSFERASE EC 2.3.1.6? P.T. Carroll, M. Badamchian and P.J. Craig Dept. Pharmacol. Texas Tech Univ. Health Sciences Center, Lubbock, TX 79430.

The depolarizing agent veratridine not only stimulates the release of acetylcholine (ACh) from a vesicular fraction (P_3) by a Ca^{2+} dependent process but also causes the breakdown of cytoplasmic (S_3) ACh (Carroll & Benishin, 1984; Carroll, 1984). The purpose of the present study was to trace the fate of the choline derived from hydrolyzed S_3 ACh; also to determine whether this hydrolysis might be caused by the soluble, cytoplasmic fraction of ChAT running backwards. Rat hippocampal minces were loaded with (N methyl [^{3}H]ACh), post-incubated with veratridine in the absence or presence of Ca^{2+}, and the effect of veratridine on the subcellular levels and release of both [^{3}H]ACh and [^{3}H]choline determined. In some experiments the poorly penetrating acetylcholinesterase (AChE) inhibitor echothiophate was used to prevent the extraterminal breakdown of [^{3}H]ACh. The results indicated that veratridine stimulated the release of [^{3}H]ACh from the P_3 fraction of the minces by a Ca^{2+} dependent process and simultaneously caused the breakdown of the [^{3}H]ACh in the S_3 fraction. Some of the [^{3}H]choline derived from this hydrolyzed [^{3}H]ACh was transferred to the P_3 fraction where it was acetylated and released as [^{3}H]ACh by a Ca^{2+} dependent process. Some of the [^{3}H] choline was released from the S_3 fraction independently of Ca^{2+}. When the "penetrating" AChE inhibitor paraoxon was substituted for echothiophate during the loading and release phases, veratridine no longer stimulated the Ca^{2+} dependent release of [^{3}H]ACh or the Ca^{2+} independent release of [^{3}H]choline. Rather, it then stimulated only the Ca^{2+} independent release of [^{3}H]ACh and this occurred from the S_3 fraction. Paraoxon was also found to inhibit the backward reaction of soluble ChAT in a dose dependent fashion. These results indicate that veratridine causes the breakdown of S_3 ACh and that at least a portion of the choline derived from this hydrolyzed ACh is used at vesicular site of synthesis to form releasable ACh. They also suggest that the veratridine induced hydrolysis of S_3 ACh may be mediated by either a soluble fraction of S_3 ChAT running backwards or by an intraterminal form of AChE. 112.13 CHOLINERGIC STIMULATION RELEASES STRIATAL ASCORBATE AND DOPAMINE IN THE CONSCIOUS RAT. James A. Clemens and Lee A. Phebus*, The Lilly Research Laboratories, A Division of Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285.

Several studies have demonstrated that cholinergic agents can stimulate the release of dopamine from neostriatal tissue in vitro. Cholinergic neuronal dendrites in the neostriatum form synaptic connections with dopaminergic axons and are believed to be involved in the modulation of dopamine release. The effects of the cholinergic agonist, pilocarpine, and the acetylcholine esterase inhibitor, physostigmine, on dopamine and ascorbate release in conscious animals were investigated using in vivo electrochemistry.

Experiments were conducted in awake, freely-moving rats that were previously implanted unilaterally in the neostriatum and nucleus accumbens with graphite paste-tipped, electrochemical working electrodes. Reference (Ag/AgCl) and auxiliary electrodes were implanted in the contralateral neocortex. On the day of an experiment, semi-differentiated linear sweep voltammograms were recorded at half-hour intervals until a stable baseline was reached. A scan rate of 5 mV/sec was used. Drugs or saline were then injected i.p. and changes from this baseline observed. When this electrochemical measurement system is utilized, the resulting voltammogram consists of three distinct peaks. The first peak is mainly ascorbic acid (AA), the second contains uric acid and 5-hydroxyindoles, and the third peak is homovanillic acid (HVA).

Administration of 10.0 mg/kg of pilocarpine nitrate produced a significant elevation in both ascorbate and HVA voltammetric peaks in the striatum that lasted several hours. A significant elevation in HVA but little effect on AA was observed in the nucleus accumbens. Similar changes in AA and HVA were observed after physostigmine (0.5 and 1.0 mg/kg) treatment. Although dopamine was not directly measured, the rise of its principle metabolite, HVA, indicates that dopamine release must have occurred. The rise in AA in the neostriatum may have been related to dopamine release because dopamine agonists release AA in the neostriatum. The results of this study are consistent with the hypothesis that acetylcholine can induce the release of dopamine in the neostriatum and also provide evidence that cholinergic stimulation releases dopamine in the nucleus accumbens.

112.14 DISTRIBUTION OF CHOLINE ACETYLTRANSFERASE (ChAT) IN THE INTERPEDUNCULAR NUCLEUS (IPN). T.C. Eckenrode*, W. Battisti, and M. Murray (SPON: L. Greenberg). Dept. of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

The IPN is a complex nucleus comprised of several cyto-architectonically distinct subnuclei. Substance P (SP), norepinephrine (NE), and serotonin (5-HT) have different patterns of localization to specific subnuclei. The origins of these neurotransmitters have been identified, and the effects of lesions on their distribution among the subnuclei have been determined. Acetylcholine (ACh) and ChAT levels in the IPN are among the highest in the brain. Most of the ACh is thought to be conveyed to the IPN via the fasciculi retroflexi (FR). We have used an antibody to ChAT, kindly obtained from Bruce Wainer, to identify its subnuclear distribution and to examine the effects of FR lesions on its localization.

We examined the localization of ChAT in adult rats using the unlabelled antibody (PAP) method of Sternberger. In intact animals, staining is present in the FR. Within the IPN, moderately dense ChAT staining is seen in the rostral and central subnuclei. The staining is distributed in mediolaterally oriented parallel bands that occupy most of these two subnuclei. This pattern resembles the pattern of axons revealed with a Bodian stain. The intermediate subnuclei, which demonstrate no SP staining, contain dense, coarse ChAT staining. The dorsal subnucleus contains sparse ChAT immunoreactivity. The lateral subnuclei, which contain exceptionally dense SP staining, are virtually devoid of ChAT staining.

Ten days after bilateral FR lesions the FR still show ChAT staining, however it has lost its fascicular appearance. Within the IPN, the ChAT in the central, rostral, and intermediate subnuclei decreases markedly, indicating that this staining is associated with FR axons. Staining in the dorsal subnucleus is less depleted, indicating that there may be an additional source of ACh to this subnucleus. Unilateral lesions produce a symmetrical pattern of staining which suggests that the ACh projection to the IPN, from the FR is bilateral and overlapping.

The pattern of staining thus differs from the pattern of SP staining and 5-HT staining but is similar to the localization of NE. The axons in the FR which contain SP and those which contain ACh therefore diverge in the IPN. The pattern of overlapping projections suggests an interaction between the ACh and NE systems in the IPN.

112.15 MODULATION OF HIPPOCAMPAL CHOLINE ACETYLTRANSFERASE BY PEPTIDES: POSSIBLE INVOLVEMENT OF ADENOSINE-3',5'-MONOPHOSPHATE. P.A. Lapchak* and B. Collier. Dept. of Pharmacol. & Ther., McGill University, McIntyre Medical Bldg., Montreal, Quebec, Canada, H3G 1Y6.

Choline acetyltransferase (ChAT) and numerous peptides have been shown to coexist in various regions of the rat CNS, including the cerebral cortex and hippocampus. Vasoactive intestinal polypeptide (VIP) has been reported to activate ChAT; in addition, VIP has also been shown to enhance adenylate cyclase activity in hippocampal homogenates. The present work was undertaken to study the effects of various peptides on ChAT activity, and to test whether these effects may be mediated by adenylate cyclase.

First, we studied the possible modulation of ChAT in hippocampal homogenates by the following related peptides: peptide histidine isoleucine (PHI), VIP, secretin and glucagon. Both PHI and VIP rapidly activated ChAT, with a maximal effect occurring at 10 minutes of preincubation. This effect was dose-dependent, with a maximum activation of 18.0 ± 2% (n = 4) and 14.0 ± 1.5% (n = 6) for PHI (10^{-6}M) and VIP (10^{-7}M), respectively. Secretin and glucagon were ineffective over the concentration range tested (10^{-8} to 10^{-5}M).

Second, adenosine-3',5'-monophosphate (cAMP) was shown to activate ChAT over a similar time course as did PHI and VIP. At 10^{-8}M, cAMP enhanced ChAT activity by 25-38% (n = 3). In addition, a less polar derivative of cAMP, dibutyryl cAMP, also enhanced ChAT activity at a concentration of 10^{-8}M (12-17%, n = 6) and 10^{-6}M (32-44%, n = 4). The increase in ChAT activity corresponded to a decrease in the K_M for choline (50-63%), with no change in the apparent V_{max}.

In conclusion, the results suggest the possibility that peptides like VIP or PHI might have a modulatory role in cholinergic transmission as the result of activating ChAT and that this activation might occur by an adenylate cyclase/cAMP dependent mechanism. 112.16 ^{3}H-ACETYLCHOLINE SECRETION IN GUINEA-PIG ILEUM MYENTERIC PLEXUS IS EQUALLY ENHANCED BY FORSKOLIN, 8-BROMO ADENOSINE 3',5'-CYCLIC MONOPHOSPHATE OR 3-ISOBUTYL-1-METHYLXANTHINE. P. Alberts and V. Ögren*. Division of Experimental Medicine, National Defense Research Institute, S-901 82 Umeå, Sweden.

The possible involvement of cyclic nucleotides in receptor-mediated control of ^{3}H-acetylcholine (^{3}H-ACh) secretion was studied. The guinea-pig ileum longitudinal muscle preparation was preincubated with ^{3}H-choline and subsequently mounted in an organ bath and superfused with Tyrode's solution containing eserine and hemicholinium-3. The preparation was stimulated with trains of 150 monophasic shocks (25 V/cm) at 0.5 Hz (0.5 ms). Two control stimulations preceeded two stimulations made in the presence of drug. The effect of drugs on the secretion is expressed as a quotient of the secretory response obtained in the presence and absence of drug. After incubation with choline kinase the ^{3}H-ACh collected in the superfusate was separated from ^{3}H-choline in tetraphenylboron-containing 3-heptanone.

The potent adenylate cyclase activator forskolin enhanced the ^{3}H-ACh secretion in a concentration-dependent manner. From the linear regression analysis of the double-reciprocal plot of the data (10^{-6} - 10^{-4} M, n=8) the 'maximal enhancement' at 'infinitely' high concentration of forskolin was calculated to be 205 ± 11% of control. The concentration yielding half-maximal enhancement (EC_{50}) was (2.3 ± 0.4) x 10^{-6} M. The secretion of ^{3}H-ACh was enhanced by 8-bromo adenosine 3',5'-cyclic monophosphate (8-Br cyclic AMP), also in a concentration-dependent manner. The effects of 8-Br cyclic AMP in the range 0.25 - 2 mM (n=9) yielded a 'maximal enhancement' of 270 ± 45% of control and an EC_{50} value of 1.3 ± 0.43 mM. Addition of the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (IBMX) (1 - 5 mM, n=9) enhanced the secretion of ^{3}H-ACh yielding a 'maximal enhancement' of 239 ± 27% of control. The EC_{50} value was 2.6 ± 0.7 mM. Simultaneous addition of forskolin (2.5×10^{-5} M) and IBMX lowered the EC_{50} value for IBMX to 0.45 ± 0.24 mM (n=5) without changing the 'maximal enhancement' for IBMX (248 ± 30% of control).

Since the 'maximal enhancement' values for forskolin and IBMX, and for IBMX in the presence of forskolin, are similar to that for the 'exogenous' cyclic AMP compound used, the results suggest that forskolin and IBMX accomplish their effects on ^{3}H-ACh secretion by elevating 'endogenous' neuronal cyclic AMP levels.

The results suggest that regulation of intraneuronal cyclic AMP levels is a possible mechanism for receptor-mediated control of ^{3}H-ACh secretion in the cholinergic terminals of guinea-pig ileum myenteric plexus.

112.17 ENZYMATIC SYNTHESIS OF A FALSE CHOLINERGIC NEUROTRANSMITTER: DIETHYLAMINO ETHYLACETATE AS A SPECIFIC MUSCARINIC AGONIST ANALOG OF ACETYLCHOLINE. Peter K. Chiang, George A. Miura, Richard K. Gordon, Michelle M. Richard, Felipe N. Padilla, and B. P. Doctor. Division of Biochemistry, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

Upon incubation with bovine brain choline acetyltransferase (acetyl-CoA: choline O-acetyltransferase; EC 2.3.1.6), diethylamino ethanol and acetyl-CoA, an acetylcholine analog, diethylamino ethylacetate was formed. The new product co-chromatographed with authentic diethylamino ethylacetate on silica thin layer plates, and its formation was proportional to the duration of incubation and protein concentrations. When tested on guinea pig ileum, diethylamino ethylacetate was found to be an agonist, albeit weak, with an ED_{50} of 1.3×10^{-4} M, compared to an ED_{50} of about 2.0×10^{-7} M for acetylcholine. The contraction of guinea pig ileum induced by diethylamino ethylacetate could be blocked by atropine. Moreover, diethylamino ethylacetate induced a secretion of α-amylase from isolated pancreatic acini cells; this effect was blocked by atropine. Diethylamino ethylacetate could also block the binding of radioactive quinuclidinyl benzilate to the muscarinic receptors of N4TG1 neuroblastoma cells, with an I_{50} of 0.5 mM. It was very interesting that diethylamino ethylacetate has neither agonist nor antagonist activity on the isolated frog rectus abdominis muscle, and is hence not a nicotinic cholinergic neurotransmitter. Judging from our data, diethylamino ethylacetate can be a false cholinergic neurotransmitter generated in vivo when drugs such as aprophen or procainamide are administered to animals or patients, since either of these drugs can undergo enzymatic hydrolysis to generate diethylamino ethanol as one of the products.

BRAIN METABOLISM I

113.1 POSSIBLE MECHANISMS OF POST-HYPOXIC HYPEREXCITABILITY IN HIPPOCAMPAL SLICES. S.J. Schiff and M. Balestrino*. Division of Neurosurgery and Department of Physiology, Duke University Medical Center, Durham, NC 27710.

In rat hippocampal slices exposed to 30 min moderate hypoxia at 29°C, irreversible increases in CA1 population spike amplitude are observed during reoxygenation, often accompanied by the appearance of a second population spike (Schiff, S.J. and Somjen, G.G., Brain Res., in press). This study examined the changes in neuronal excitability and recurrent inhibition that accompany these phenomena.

In response to orthodromic Schaffer collateral stimulation, presynaptic volley, focal-EPSP (fEPSP), and population spike were recorded in stratum radiatum and stratum pyramidale of CA1. In response to alveus stimulation, antidromic population spikes were recorded in CA1. Recurrent inhibition was evaluated using paired antidromic and orthodromic pulses. Only those slices demonstrating intact recurrent inhibition were studied. In hypoxia experiments, data were collected prior to the induction of 30 min hypoxia and after 45 min reoxygenation; in control experiments, data were collected over the same time span without hypoxia.

Recurrent inhibition was lost in most slices following hypoxia. This loss correlated well with the appearance of a second population spike, but correlated poorly with the increase in first population spike amplitude; indeed, in some slices an increase in first population spike amplitude was observed despite the preservation of recurrent inhibition. The population spike evoked by a given amplitude of presynaptic volley was increased after hypoxia. The fEPSP evoked by a given presynaptic volley was not changed by hypoxia, while the population spike evoked by a given fEPSP was increased. The amplitudes of antidromic population spikes were not changed after hypoxia.

These data suggest that changes in the excitability of postsynaptic neurons, rather than changes in presynaptic fibers or transmitter release, are responsible for the increased first population spike amplitude. Although the loss of recurrent inhibition may be the cause of the appearance of a second spike, recurrent inhibition loss appears to occur independently of the increase in first population spike. A decrease in action potential threshold, perhaps due to slight pyramidal cell depolarization, may be important in increasing the first population spike; in addition, enhanced conduction in the postsynaptic dendritic tree, or reduced feed-forward inhibition, might also conceivably play a role in this phenomenon.

Supported by the Research Foundation of the AANS and USPHS grant NS 18670.

113.2 CHLORPROMAZINE IMPROVES RESISTANCE OF HIPPOCAMPAL SLICES TO HYPOXIC DAMAGE. G.G. Somjen and M. Balestrino*. Department of Physiology, Duke University Medical Center, Durham, NC 27710.

Chlorpromazine (CPZ) has been shown to have a protective effect against hypoxic damage in the liver and in the heart (Am. J. Pathol.,88:539-553,1977; J. Mol. Cell. Cardiol.,15:603-620, 1983; J. Mol. Cell. Cardiol.,15:621-628, 1983). We have investigated its possible usefulness in brain tissue hypoxia. Rat hippocampal slices 400μ thick were incubated in an interface chamber at 35°C. The perfusion fluid was bubbled with 95% O_2, 5% CO_2 and the same mixture was used for the gas phase above the slices. CPZ was administered i.p. (30 mg/Kg) to rats 30 minutes prior to sacrifice and added (7 μM/l or 70 μM/l) to the perfusion bath. Control slices, obtained from age-matched rats having received a comparable amount of i.p. saline solution 30 minutes prior to sacrifice, were incubated in CPZ-free medium. Extracellular potentials were evoked in stratum radiatum and stratum pyramidale of the CA1 region by stimulation of the Schaffer collaterals. DC sustained potentials in stratum pyramidale were also recorded. Two hours were allowed for recovery after dissection, following which hypoxia was induced by switching the gas phase to 95% N_2, 5% CO_2. After 9 minutes of hypoxia, reoxygenation was started. In both treated and untreated slices, evoked responses failed 1-3 minutes after induction of hypoxia. Shortly thereafter, a slow, slight negative shift in sustained potential was evident, and eventually an abrupt, spreading depression-like fall in this potential occurred. In CPZ-treated slices, the latter tended to occur later than in control ones (controls: 237 ± 51 seconds after induction of hypoxia; CPZ 7 μM/l: 311 ± 75 seconds; CPZ 70 μM/l: 442 ± 138 seconds; 1-way ANOVA: $p<.02$). Upon reoxygenation, no postsynaptic potential recovery was seen in control slices (two hours follow-up). In contrast, 50% of slices treated with 7 μM/l CPZ and 100% of slices treated with 70 μM/l CPZ showed full recovery of postsynaptic responses ($\chi^2 = 7.47$, df = 2, $p<.03$). Therefore, CPZ seems to counteract the hypoxia-induced SD-like response and to enhance the chances for functional recovery in this preparation.

(Supported by grants NS 17771 and NS 18670 of the USPHS.)

113.3 SELECTIVE NEURONAL VULNERABILITY TO HYPOXIA IN VITRO. P.G. Aitken and S.J. Schiff, Dept. of Physiology (PGA) and Division of Neurosurgery (SJS), Duke Univ. Med. Ctr., Durham, NC 27710.

Different regions of the brain are selectively vulnerable to ischemia. In the hippocampus, the CA1 region is particularly vulnerable while the fascia dentata (FD) is relatively resistant. It has not been possible to determine which aspect(s) of in situ ischemia (e.g., hypoglycemia, tissue acidosis, or hypoxia) is responsible for the differential vulnerability. Using the in vitro hippocampal slice, we have demonstrated that the CA1 region is more vulnerable to damage from a purely hypoxic insult than is FD.

Hippocampal slices 400μM thick were prepared with standard techniques and maintained at 35.5°C in an interface chamber, superfused at 2cc/min with oxygenated artificial cerebrospinal fluid. Except during hypoxic periods, the gas phase above the slices consisted of warmed, humidified 95% O_2 - 5% CO_2 flowing at 225cc/min. Hypoxia consisted of replacing the gas phase with 95% N_2 - 5% CO_2 flowing at the same rate. Extracellular field potentials were recorded in stratum pyramidale of CA1 (in response to Schaffer collateral stimulation) and in st. granulosum of FD (in response to perforant path stimulation). Ninety minutes after dissection, baseline recordings were taken and then the slices were exposed to a sequence of hypoxic periods of increasing duration: 2, then 3, then 4 minutes. Each hypoxic period was followed by a 15-20 minute recovery period of full oxygenation. Starting 10 minutes into each recovery period, recordings were taken. A region was considered responsive if any postsynaptic population spike or excitatory postsynaptic potential could be evoked, and unresponsive if neither could be evoked. If a region was unresponsive, stimulation intensity was increased and electrode positions changed to verify the lack of postsynaptic response. Following the last hypoxic period slices were oxygenated for at least 1 hour to verify the permanence of any loss of postsynaptic response.

In experiments on 14 slices, postsynaptic activity disappeared during all hypoxic periods in CA1 and FD. This loss was always temporary in FD and sometimes temporary in CA1; the loss was permanent in CA1 (within the time periods studied) after 2 minutes of hypoxia (1 slice), after 3 minutes (7 slices), or after 4 minutes (6 slices). CA1 presynaptic fiber volleys were always preserved.

These data demonstrate that the relative vulnerabilities of CA1 and FD to ischemia in situ can be replicated by a purely hypoxic insult in vitro. Since this preparation lacks a vascular system, the differential vulnerability must derive from factors intrinsic to the neural tissue. Other components of ischemia may, of course, play a role in situ. (Supported by the Research Foundation of the Amer. Ass'n. of Neurological Surgery, and by NIH grants NS 18670 and 17771.)

113.4 ELECTROPHYSIOLOGICAL CORRELATES OF ANOXIC DAMAGE TO HIPPOCAMPAL CA1 PYRAMIDAL CELLS: ROLE OF OXYGEN FREE RADICALS. J.J. Miller and P. Leung*, Department of Physiology, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Alterations in the electrophysiological properties of hippocampal CA1 pyramidal cells during and following anoxia were investigated using the in vitro slice preparation. During the initial phase of anoxia (95% N_2, 5% CO_2) the stratum radiatum evoked field potentials recorded in dendritic and somatic regions exhibited a slight increase in amplitude followed by multiple spike discharges and then complete blockade of synaptic transmission. Upon reperfusion with normal oxygen concentration (95% O_2, 5% CO_2) the extracellular EPSP response exhibited a relatively early recovery beginning 4-5 min post-anoxia and attained control levels usually by 7-8 min. Reappearance of the population spike was considerably delayed (8-9 min) and the magnitude of recovery was variable. In some cases only partial recovery (<50%) in the amplitude was observed by 45 min following the anoxic insult. In others there was a brief period of potentiation 8-18 min post-anoxia following which the response rapidly deteriorated such that the population spike could not be elicited using pre-anoxia stimulation intensities.

Intracellular records show a parallel sequence of events. The resting membrane potential remained relatively stable during the initial phase of anoxia followed by a rapid depolarization of approximately 40-60 mV. Full recovery was usually observed by 20 min post-anoxia. The synaptically evoked IPSP reappeared first following anoxia (9-10 min) while the late hyperpolarizing potential was slightly delayed. There was a striking increase in the threshold for both current and synaptically evoked spike generation. No long-term alterations were observed in either extra- or intra-cellular paired pulse inhibition.

In an attempt to reverse the anoxic damage, as reflected by the delayed onset and deterioration of somatic spike generation, slices were pre-treated with the free radical scavenger allopurinol (10 uM) for 10 min prior to the onset of anoxia. In almost all cases, both dendritic and somatic responses exhibited a rapid recovery to control levels and no evidence of prolonged anoxic damage was observed. On the basis of these data, it may be suggested that the long term decrease in somatic excitability induced by anoxia results from the production of oxygen free radicals and thus may ultimately be involved in the degeneration of neuronal elements.

113.5 MEDIATION OF HYPOXIC DAMAGE BY FREQUENCY OF SYNAPTIC TRANSMISSION IN MOUSE HIPPOCAMPAL SLICES. H.Itagaki and J.Parmentier. Anesthesia Res. Lab., Univ. of South Alabama, Mobile, AL 36688.

Recent studies using dispersed cultures of rat hippocampal neurons have shown that prevention of depolarization by exogenous glutamate, or the blockade of synaptic transmission by Mg++ can reduce the neuronal death caused by anoxic exposure (Rothman, J. Neuroscience 4(7):1884-1891). In order to study the degree to which synaptic activity in mature central neurons may protect or contribute to hypoxic damage, we have monitored the loss and recovery of synaptic transmission in slices of mouse hippocampus exposed to conditions of hypoxia and reflow. 400u thick slices of mouse hippocampus were allowed to stabilize for 60 minutes in an interface chamber under conditions of 95% oxygen, 5% CO_2. Extracellular recordings of transmission from stimulated Schaffer collaterals to CA1 pyramidal dendrites were used to monitor synaptic activity. EPSP amplitudes were monitored and periodic input-output curves were determined. Following 40 minutes of baseline recording the chamber gas supply was changed to a mixture of 95% N_2, 5% CO_2 for seven minutes and then returned to the original 95% O_2/5% CO_2 mixture for a recovery period of 40 minutes. During the course of these experiments, intervals of synaptic stimulation of 200 msec, 500 msec, 1 sec, 5 sec, 10 sec and 30 sec were examined. Frequency facilitation was noted in almost all cases over the 40 minutes of baseline recording, although slices stimulated at 200 and 500 msec intervals showed an initial decrease in their EPSP amplitudes prior to facilitation. While a high degree of variability was noted in EPSP amplitudes for both the hypoxic and recovery periods, our results show that most slices stimulated at 1 sec or longer intervals recovered from hypoxic exposure to their facilitated pre-hypoxic amplitude levels. However, the mean amplitudes of EPSPs in slices stimulated at 200 and 500 msec intervals did not recover to their initial, unfacilitated levels within the 40 minute observation period. A stimulus interval of 1 sec appeared to produce the most efficient recovery. These observations agree with the suggestion that some component of synaptic activity mediates the degree of hypoxic damage to central neurons, and that increased levels of this component or its characteristics result in enhancement of hypoxia damage. These results also provide support for using anticonvulsant or other drugs which depress neuronal firing frequency in the treatment of stroke or hypoxic brain injury. We are presently investigating the protective effects against hypoxia of various synaptic blockers in this system.

113.6 EFFECTS OF BLOCKING CALCIUM ENTRY WITH NIMODIPINE AND MAGNESIUM IN ANOXIC HIPPOCAMPAL BRAIN SLICES. I.S. Kass and J.E. Cottrell*. Department of Anesthesiology, SUNY/Downstate Medical Center, Brooklyn, New York 11203.

Increased cell calcium concentration has been implicated in producing irreversible neuronal damage. We have utilized the in vitro hippocampal slice model of anoxia (Kass + Lipton 1982, J. Physiol 332:459) to examine agents that block calcium entry for their ability to improve recovery from anoxic damage in vitro.

High Mg physiological buffer (10mM Mg) protected against anoxic damage; the tissue recovered to 76±5% of its preanoxic amplitude. This protected better than normal physiological buffer (0±0) but not as well as either Zero Ca - High Mg buffer or Cobalt buffer with which we have previously showed complete recovery.

Nimodipine is an organic Ca entry blocker that has been shown to improve neurological outcome following ischemia in vivo (Steen et al 1983 J. Cereb Blood Flow and Metab. 3:38). We tested its direct effect on neuronal recovery. Nimodipine (10-5M), added to the perfusate one hour before and continued until 10 minutes after the anoxic epoch did not improve recovery post anoxic (12±12). Thus Nimopidine does not protect neurons directly against anoxic damage.

Data from the studies of others indicate that nimodipine may not block Ca entry into neurons. Nimodipines inability to block Ca entry into neurons is supported by our studies. The size of the population spike is only slightly effected by Nimodipine before anoxia (90±6). If Ca channels in neurons, were blocked a greater reduction or a complete loss of the population spike after Nimodipines addition would occur. Such a loss was seen in Cobalt buffer, Zero Ca - High Mg buffer and High Mg buffer.

In order to determine whether blocking Ca entry protects by preventing the fall in ATP during anoxia we measured ATP levels in the dentate region. A 10% increase in ATP levels during anoxia was found in studies with 0 Ca - 10 mM Mg buffer when compared to studies with normal buffer. Other experiments indicate that this small increase in ATP can account for only a small part of the increased protection seen with 0 Ca-10mM Mg buffer. Studies with nimodipine indicate it also causes a 10% increase in ATP during anoxia, however additional studies are needed to account for shifts in control values with nimodipine.

Blocking Ca entry with High Mg, during anoxia protects against the irreversible anoxia damage. Nimodipine does not protect in vitro and probably does not block calcium entry into neurons.

113.7 GM_1 TREATMENT IN VIVO PROTECTS MEMBRANE ATPase ACTIVITIES AND PREVENTS MITOCHONDRIAL DAMAGE IN HIPPOCAMPAL SLICES. R. Bianchi*+, F. Milan*°, D. Janigro*°, D. Di Gregorio*° and A. Gorio*°. (SPON: L. Valzelli).
+Istituto di Ricerche Farmacologiche "Mario Negri", Milan, Italy.
°FIDIA Research Laboratories, Abano Terme, Italy.

Ganglioside incubation of hippocampal slices in vitro was recently reported to double the latency between the onset of hypoxia and dramatic cell depolarization simultaneously involving all the neurons (spreading depression). Similar protection against Na^+,K^+-ATPase inhibition was obtained in muscles incubated in the presence of ganglioside mixture ($5x10^{-8}$M) or dissected from mice injected with 10 mg/kg ganglioside mixture daily for three days) in K^+-free physiological solution for several hours or in hypoxic medium. These observations suggest a protective effects of gangliosides on membrane structures under stress. To check this hypothesis, we measured Na^+,K^+-ATPase specific activity, which can be considered a marker of membrane integrity, in hippocampal slices frozen immediatly after a preparation or after 35 minutes incubation. The loss of enzymatic activity after incubation was over 30% in control hippocampi, but lower than 10% in hippocampal slices from GM_1 pretreated rats (10 mg/kg i.p. daily, for three days). These biochemical data correlated with the ultrastructural evidence. The most dramatic difference between the two groups at 35 minutes was in mitochondrial structure. Untreated animals showed a high percentage of swollen mitochondrial profiles almost completely lacking cristae, while the remaining mitochondria (18%) had a normal configuration, were minute and had a dense matrix. In GM_1 treated animals the vast majority of mitochondria (85%) showed normal ultrastructure though minor modifications such as swelling were detectable in a small percentage (6%). These data suggest that maintenance of healthy hippocampal slices in vitro might be improved by pretreating the animals with GM_1.

113.8 SLICE CHAMBER FOR BIOCHEMISTRY AND MORPHOLOGY. F. Hospod*, P. Wu* and G. Newman (SPON: A. Sterman), Department of Neurology, SUNY, Stony Brook, New York 11794.

The in vitro slice chamber used for physiology is not well-suited to biochemistry or morphology because of its small volume, open atmosphere and difficulty with rapid, atraumatic slice removal. A slice chamber that overcomes these problems has been designed and tested. Up to 5 slices rest between 2 Nylon mesh screens stretched on nested glass rings separated by 500 μ Teflon spacers. The slices are immersed in 6 ml of buffer flowing at 2.2 ml/min and covered with 24 ml of 95% 02-5% C02 flowing at 50 ml/min. A drain permits rapid buffer changes for drug or substrate exposure and rinsing. The ring system is easily removed without disturbing the slices allowing rapid fixation or freezing followed by cryostat-sectioning or punch (modified Palkovitz technique).

Using this chamber we have established that rat suprachiasmatic nucleus in hypothalamic slices continues to take-up 14C-2-deoxyglucose consistent with the diurnal phase of the sacrificed animal even after 8 hours of incubation. (See Abstract by Newman et al.). Slices incubated with 35S-methionine (9.8μCi/ml) incorporate radioactivity linearly. After 4 hours, over 200,000 cpm are incorporated into proteins of an SCN punch sample, allowing resolution of over 80 proteins by SDS-PAGE.

Examination of incubated slices by light and electron microscopy, after immersion in Bouin's fixative or 4% paraformaldehyde-2.5% glutaraldehyde, reveal moderate disruption of neuronal perikarya at the slice surface but little disruption of the slice interior after 1 hour. After 8 hours, these changes increase considerably at the slice surface but much less so in the interior. In contrast to the perikaryal changes, SCN axon terminals of all types appear intact from surface to surface after either 1 hour or 8 hours of incubation. Similarly, the 14C-2-deoxyglucose experiments reveal no differences in uptake between the slice surface and interior. Thus, at least for adult rats, these in vitro studies suggest, but do not prove, that uptake of 2-deoxyglucose correlates with synapse metabolism rather than events in the perikarya.

In summary, an inexpensive and versatile chamber has been designed to optimize homogeneity of incubation conditions for biochemical and morphologic studies.

113.9 COMPARISON OF IODOANTIPYRINE AND NEUTRAL RED AS INDICATORS OF RELATIVE PERFUSION IN BRAIN FOLLOWING MIDDLE CEREBRAL ARTERY OCCLUSION. T.S. Whittingham, W.D. Lust, J.C. LaManna(#), G. Rodziewicz*, R.A. Ratcheson and C.A. VanDerVeer*. Div. of Neurosurgery and (#) Dept. of Neurology, Case Western Reserve Medical School, Cleveland, OH 44106.

The study of metabolic events during focal ischemia in the rat brain is being facilitated by the use of neutral red, a diffusible dye. The staining pattern following occlusion of the left middle cerebral artery generally shows three distinct types of neutral red labelling: 1) uniform red, 2) white (unstained) and 3) mottled or lightly stained tissue. ATP, PCr, glucose and lactate analyses from different portions of the neutral red staining pattern indicate that dye intensity can be used as a qualitative indicator of tissue perfusion. The possibility of using neutral red as a quantitative marker of cerebral perfusion is currently being investigated. Labelling patterns identical to that of neutral red are obtained in autoradiographs when [14-C]-iodoantipyrine is infused just prior to fixation by funnel freezing. The present technique involves injection of neutral red following MCA occlusion in rats and 30 min prior to in situ brain fixation for metabolite analysis. In other animals, the neutral red procedure is followed by infusion of radiolabelled iodoantipyrine for the 30 sec prior to decapitation and serial blood samples are obtained. The frozen brain is then sectioned in a cryostat and the sections are either mounted on glass slides for autoradiography or freeze dried for microdissection and metabolite analyses. The tissue block face is photographed and the following section is used for autoradiography. The photographs provide a record of neutral red staining, and the autoradiographs a record of iodoantipyrine labelling. Comparison of neutral red photographs and corresponding iodoantipyrine autoradiographs suggests that increased resolution can be obtained from neutral red dye intensity. A monochromatic densitometer can be used to quantitate both neutral red staining intensity throughout a given tissue photograph and iodoantipyrine distribution in the corresponding autoradiograph. The two results can then be compared to determine the validity of using neutral red as a quantitative marker of cerebral perfusion.

113.10 ROLE OF POLYPHOSPHOINOSITIDE IN FREE FATTY ACID PRODUCTION DURING BRAIN ISCHEMIA. M. Ikeda*, S. Yoshida*, R. Busto*, M. Santiso* and M.D. Ginsberg (SPON: P. Scheinberg). Cerebral Vascular Disease Research Center, Univ. Miami School of Medicine, Miami, FL 33101.

The possible contribution of polyphosphoinositide degradation to the release of free fatty acids (FFAs) in the brain during ischemia was evaluated in the rat. Ischemia was induced by decapitation. Major portions of triphosphoinositide (TPI) and diphosphoinositides (DPI) were extracted with chloroform/methanol (2:1) containing 0.25% HCl after bulk lipids including monophosphoinositide (MPI), phosphatidic acid (PA), diacylglycerol (DG) and a portion of TPI and DPI had been extracted with chloroform/methanol (1:1). The lipids were separated by one-dimensional TLC. The fatty acid composition of the isolated lipids was quantified by GLC following transmethylation with anhydrous HCl-methanol. FFAs were methylated by diazomethane.

The fatty acid composition and the contents of isolated lipid in control animals are shown in the Table.

	Fatty acid composition (mol%)					Content (μmol/g)
	C16:0	C18:0	C18:1	C20:4	C22:6	(mean ± SD, n=6)
TPI	10	47	2	41	0	0.41 ± 0.09
DPI	10	49	2	39	0	0.29 ± 0.01
MPI	10	50	2	37	0	1.40 ± 0.10
PA	22	28	41	7	1	0.86 ± 0.07
DG	37	20	27	13	1	0.035 ± 0.002
FFA	36	26	21	12	5	0.146 ± 0.024

Ischemia caused a rapid and time-dependent decrease of TPI and DPI and a concurrent increase of DG and FFAs. At 1 and 3 min of ischemia, the decrease of TPI and DPI corresponded in amount to the increase of DG and FFAs. TPI, DPI and DG reached their respective plateau levels at 10 min of ischemia: (% of control) TPI, 50%; DPI, 40%; DG, 500%. Thus there appeared to be two pools of polyphosphoinositide which have different metabolic rates, as suggested by several authors. However, FFAs continued to increase up to 30 min of ischemia. There was no change in MPI and PA. Among individual fatty acids in the FFA pool, increases of C18:0 and C20:4 were prominent at 1 and 3 min. Free C16:0, C18:1 and C22:6 increased slowly but linearly up to 30 min. DG containing C18:0 and C20:4 increased markedly during the first 3 min. These results indicate that at the onset of ischemia, hydrolysis of TPI and DPI by phosphodiesterase (phospholipase C) and subsequent deacylation of DG by DG lipase and/or monoacylglycerol lipase are primarily responsible for the production of FFAs. At later times during ischemia, deacylation of other lipids likely contributes to the continuous increase of FFAs as well. Supported by NIH grant NS 05820.

113.11 METABOLISM OF ARACHIDONOYL-DIGLYCERIDE IN RAT BRAIN. J.A. Kelleher* and G.Y. Sun. (SPON: W. G. Wood) Biochem. Dept. and Sinclair Comparative Med. Res. Farm, Univ. of Missouri, Columbia, MO 65203.

The receptor-mediated phosphodiesteric hydrolysis of poly-phosphoinositides (PI) has recently been recognized to be the key step for transduction of extracellular signals to intracellular events mediated through protein kinase C. According to this scheme, diacylglycerols (DG) generated from poly-PI breakdown would serve as a second messenger for modulating the protein kinase C activity. The DG of neuronal membranes is enriched in 18:0 and 20:4, reflecting a metabolic relationship with the poly-PI. The functional role of DG may be regulated by enzymes metabolizing the DG, namely, DG-kinase and DG-lipase. We have generated membrane-bound DG labeled at the arachidonoyl-group by two methods: (1) Activation of endogenous phospholipase C acting on [^{14}C]arachidonoyl-PI by incubation of brain membranes with deoxycholate and Ca^{2+}. The DG-enriched membranes were then washed and heat-treated before use. (2) Use of phospholipase C from B. cereus. This enzyme effectively converts the arachidonoyl-labeled PI and PC to DG, thus allowing one to examine endogenous DG-lipase and DG-kinase activity in the same membrane preparation. Using the heat-treated DG-enriched membrane as substrate, DG-lipase and DG-kinase activities were found in brain cytosol as well as in the membranes. DG-kinase activity was observed when the fresh DG-labeled microsomes or the heat-treated membranes with brain cytosol were incubated in the presence of Mg^{2+}, ATP and NaF. In general, DG-kinase more actively metabolized the DG than did the DG lipase. DG-lipase, which is more active in the cytosol, may be enhanced slightly by Ca^{2+}. Using the DG-labeled membranes generated from B. cereus, we clearly demonstrated that DG-kinase is activated by deoxycholate. This latter assay system is suitable for elucidation of membrane active agents which may be affecting the kinase and lipase activities in brain.

113.12 DETERMINATION OF INTRACELLULAR pH FROM FREEZE TRAPPED RAT BRAIN. J.C. LaManna, T.S. Whittingham, K.A. McCracken, and W.D. Lust. Dept. Neurology and Div. Neurosurgery, Case Western Reserve University Medical School, Cleveland, Ohio 44106.

Intracellular pH (pHi) is a critical factor in brain function in normal and pathological states. There is a need for reliable methods for measuring pHi that are quantitative and regional, do not require equilibrium conditions, and that also allow determination of other metabolic and functional variables such as high energy phosphates, substrate levels, and extracellular ion concentrations. We have shown previously that the pH indicator dye, neutral red, can be administered intravenously or intraperitoneally to rats (Anal Biochem, 142:117, 1984). This dye is taken up and concentrated in the brain parenchyma, acting as an in vivo brain pH indicator that can be quantitated by scanning reflectance spectrophotometry of the cortical surface. In order to study regional variations in pHi, we have developed a method whereby this information can be obtained from frozen in situ rat brains. Neutral red was administered intravenously to anesthetized rats 30 minutes prior to funnel freezing with liquid nitrogen. Frozen brains were removed and mounted in a microtome at -30°C. Color photographic slide transparencies were made of each block face at different levels through the brain as it was being coronally sectioned. The sections were later processed for microregional histochemistry of glucose, glycogen, lactate, ATP, PCr, ADP, and total adenylates. The color slides were analyzed for neutral red wavelength specific absorption by projection onto the entrance slit of a rapid-scanning spectrophotometer. The ratio of the absorption by the acid form of neutral red at 560nm to that of the base form at 430nm was determined. Intracellular pH was then calculated from the equation relating this ratio to pH generated from a standard curve prepared from color slides of sections of frozen rat brain homogenates. Using the ratio of these two absorption peaks makes the method independent of dye concentration. Constructing a standard curve by this method was necessary to control for interference in pH measurements caused by temperature and dye binding influences. Current pH resolution using this method is better than 0.1 unit and spatial resolution is limited by the projector magnification and the size of the entrance slit of the monochromator. For these studies, we adjusted the size of the region from which pH was determined to match that of the samples taken for histochemistry, about 0.5mm x 2mm. This method allows regional comparisons of tissue metabolic state and corresponding acid-base status.

113.13 ACTIVITY-DEPENDENT ACID TRANSIENTS IN THE RAT OPTIC NERVE: A DEVELOPMENTAL STUDY. W.G. Carlini and B.R. Ransom. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Extracellular pH, pH_o, was measured in the isolated rat optic nerve (RON; Connors et al., Science 216:1341, 1982), a pure white matter tract of the CNS, using double-barreled H^+-sensitive microelectrodes with tip diameters of approximately 1-4 μm. Trains of supramaximal stimuli were delivered via suction electrodes to RONs of different postnatal ages (1 to 30 days). In RONs older than 14 days, stimulus trains produced an acid shift in pH_o which could be as large as 0.3 pH unit. The time course and magnitude of the pH_o decrease were positively related to stimulus frequency, duration and intensity. The time course of the neural activity-dependent acid transient was slower in its development and recovery than simultaneously measured increases in $[K^+]_o$; the $t_{1/2}$ recovery of pH_o was 3 to 4 times greater than the $t_{1/2}$ of $[K^+]_o$ recovery. No initial alkaline shift was seen, as was reported in the cerebellum (Kraig et al., J. Neurophys. 49:831, 1983) and this may relate to the absence of synaptic interactions in the RON. After very prolonged periods of stimulation (> 30 sec) an alkaline undershoot sometimes developed following the acid shift. Changes in pH_o (± 0.5 pH) produced by altering the CO_2 environment had little effect on the compound action potential, although brief exposure to an alkaline environment often produced a transient enhancement of the field potential.

Carbonic anhydrase, which may play an important role in pH_o buffering, is localized mainly in glia and, like gliogenesis, this enzyme's expression develops postnatally. Hence, it was anticipated that activity in RONs prior to gliogenesis would produce an acid shift larger than that produced in older nerves which contained mature glia. Contrary to expectation, acid transients were smaller in neonatal RONs, with nerves less than 4 days of age showing no acid shift whatsoever. Thereafter, the magnitude of the maximum activity-evoked acid shift increased progressively with age, reaching stable adult levels at about two weeks of age. In contrast, evoked increases in $[K^+]_o$ were much larger in neonatal, as opposed to adult, RONs. Exogenously applied K^+ (10 to 30 mM) produced rapid acid shifts by as much as 0.4 pH_o in adult RONs while similar applications in RONs less than five days of age produced much smaller acid shifts. The reduced acid shifts seen in neonatal nerves, relatively devoid of glia, could indicate a role for glia in producing these shifts. Alternatively, a metabolic system in optic nerve axons may be exclusively responsible for acidification of the extracellular space, and this system may be absent in neonatal nerves. Studies are in progress to answer these questions. The isolated RON preparation appears to be a useful model system in which to analyze activity-dependent changes in pH_o.

113.14 REGIONAL DISTRIBUTION OF CALCIUM IN THE RAT BRAIN. H.W. Sampson and M.E. Trulson. Department of Anatomy, College of Medicine, Texas A&M University, College Station, TX 77843.

The importance of calcium in physiological functions such as muscle contraction, gland secretion and nerve impulse conduction is becoming increasingly evident. Although large numbers of investigators have examined the activities of calcium at the cell level in nerve tissue, very little work has been directed toward the similarities and differences in calcium content of brain regions in toto. In this study, 11 male Sprague-Dawley and 3 Fisher rats were sacrificed by decapitation. Three of the Sprague-Dawley rats were six months old and averaged 174 g in weight. The remaining Sprague-Dawley rats were 1 year in age and averaged 450 g. The 3 Fisher rats were 2 years of age and averaged 410 g. The brain was rapidly removed and dissected over ice into 10 regions. The regions were cerebellum, hippocampus, caudate, frontal cortex, remaining cortex, thalamus, hypothalamus, tectum, tegmentum, and medulla. Total calcium was determined by atomic absorbtion spectrophotometry using a nitrous oxide-acetylene fuel mixture. One-way analysis of variance indicated that there is a significant difference in the experimental groups ($P<0.005$). Tukey's HSD test indicated a significant difference between cerebellum and the 5 other brain regions. In order to discern these variations more fully, the brain regions were grouped into forebrain, hindbrain, and cerebellum plus spinal cord. A two-tailed student's t-test indicated that there is a significant difference ($P<0.001$) between these regions when grouped in this manner. It is not clear as to why this variation exists since there is no major differences in cell population density. If the brain regions are ranked according to embryological derivation there is a Spearman rank order correlation coefficient of 1 ($P<0.01$). If the prosencephalon is further divided into diencephalon and telencephalon, this highly significant correlation coefficienct is retained. One surprising finding was that there was no significant difference in brain regions relative to advanced age of the animal. There was a large variation in calcium levels in the cerebellum among animals. It is not known if this variation is present in the "normal" state or a function of the behavior of the animal immediatley prior to death. Equally interesting is the extremly small variation between hippocampal regions, indicating possibly the need to keep the calcium level tightly controlled in this region of the brain. This is supported to some extent by reports that low and high calcium levels cause epileptiform activity in hippocampal neurons. Also, it has been suggested that calcium has a special role in long-term potentiation and cognitive memory which is located in certain areas of the hippocampus.

113.15 COPPER DISTRIBUTION IN THE NORMAL HUMAN BRAIN. E. Bonilla, E. Salazar*, J.J. Villasmil*, R. Villalobos*, M. Gonzalez*, and J.O. Davila*. FUNDACITE-ZULIA, Inst. Invest. Clinicas. LUZ. Apartado 376 Maracaibo, Venezuela.

Copper deficiency affects the central nervous system mainly during infancy. Menke's kinky hair syndrome is due to a genetically determined defect in copper absorption and is characterized, among other symptoms, by progressive mental deterioration. On the other hand, Wilson's disease is an inborn error of metabolism that affects copper homeostasis. The genetic abnormality leads to excessive copper accumulation in the liver, brain, kidney, and cornea. In order to get a better insight about the pathophysiology of the nervous system alterations produced by copper deficiency in humans, it is necessary to know the regional distribution of this metal in the brain. In the present work we include results from 38 areas of 7 normal human brains.

Samples weighing between 5 and 55 mg were taken from unfixed brain in which macroscopic examination showed no signs of disease. The autopsies took place from 2 to 4 hours after death. The copper content was determined by flameless atomic absorption spectrophotometry. Brain regions of seven males ranging in age from 11 to 75 years were analyzed. Two of them died from multiple traumata without brain lesions. Three died as a consequence of myocardial infarctions. Among the other two, one died by haemorrhage after a gun shot and the other by drowning. None of the persons had a previous disorder of the nervous system. The general linear model from Statistical Analysis System was used for the analysis of variance.

Copper was found to be unevenly distributed in the human brain. The gray matter yielded higher concentrations of copper than the white matter (16.73 $\pm$ 0.89 ug/g dry weight for gray matter; 10.74 $\pm$ 2.07 ug/g for white matter). The difference was statistically significant. The copper concentration ratio of cerebral gray matter to white matter was 1.56. Identical areas of the gray and white matter of the cerebral cortex showed significant difference between individuals. In the caudate nucleus, the highest concentration was found in the tail, followed by the body and the head, respectively of the same region. No difference was observed for the concentration of copper in the gray matter of the frontal lobe (18.80 $\pm$ 1.15 ug/g) when compared with the occipital (22.34 $\pm$ 1.61 ug/g), parietal (17.84 $\pm$ 1.59 ug/g) and temporal (16.30 $\pm$ 2.32) lobes, but when comparing the content of the occipital lobe with that of the parietal and temporal lobes the difference was significant at the 5% level. It was found a negative lineal regression between age and brain copper concentrations. With increasing age a decrease in brain copper content was observed.

113.16 PALMITATE UPTAKE INTO THE HYPOTHALAMIC-NEUROHYPOPHYSIAL REGIONS OF OSMOTICALLY STRESSED BRATTLEBORO (DIABETES INSIPIDUS) RATS. J.M. Gnaedinger* and S.I. Rapoport, Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20205.

Previous reports indicate increased glucose metabolism in certain hypothalamic-neurohypophysial regions of osmotically stressed and Brattleboro rats (Schwartz et al., Science 205:723, 1979; Kadekaro et al., Brain Res. 275:189, 1983; Sutherland et al., Brain Res. 271:101, 1983). This increased uptake of 2-deoxyglucose is presumably due to increased energy demands on this neural pathway due to stress or due to a genetically related abnormality (absence of vasopressin in Brattleboro animals). However, vasopressin treatment does not reverse this increased energy use in the pituitary of Brattleboro rats, suggesting that there may be structural changes associated with the pituitary. We therefore examined the turnover of stable membrane compartments in this neural pathway by assessing the incorporation of 14C labelled palmitate as described by the protocol of Kimes et al., Brain Res. 274:291, 1983.

Six groups of animals were examined which included Long-Evans controls, heterozygous Brattleboro, homozygous Brattleboro and their corresponding water-deprived groups. 14C-palmitate was injected IV, as a bolus, and animals were killed 4 hours later. Brains were frozen at -50°C, cut into 20 micron sections and autoradiographed. Films were densitometrically scanned and a ratio was calculated for each region which consisted of the optical density for the region/optical density for white matter. Results were analyzed using Bonferroni statistics for multiple groups.

Normally hydrated and water-deprived homozygous animals demonstrated significantly decreased ($p<.05$) palmitate uptake ratios, as compared to hydrated Long-Evans controls, into the following regions which are outside the blood-brain barrier: anterior and posterior pituitaries, subfornical organ, median eminence, and pineal gland. As in the 2-DG studies, there were few statistically significant differences in palmitate uptake in barrier-protected hypothalamic regions.

These decreases in palmitate uptake contrast with the increases seen in the 2-DG results, and may be due to several factors. The most likely explanation is that these non-barrier regions utilize palmitate for energy (Vanucci and Hawkins, J. Neurochem. 41:1718, 1983). Thus, an elevation in the quantity of palmitate used for energy purposes would result in smaller amounts available for uptake into stable membrane compartments. This competitive effect might mask any changes in palmitate uptake due to membrane alterations.

113.17 REGIONAL PALMITATE INCORPORATION INTO RAT BRAIN FOLLOWING UNILATERAL VISUAL DEPRIVATION, J.C. Miller*, O. Tone*, J.M. Bell*, and S.I. Rapoport, Laboratory of Neurosciences, National Institute on Aging, Bethesda, MD 20205, (spon: S.B. Waller).

Regional palmitate flux as determined by the quantitative autoradiographic technique of Kimes, et al.(Brain Res. 274,(1983) 291-301) has been positively correlated with the regional cerebral metabolic rate for glucose (rCMRglc) and is not limited by regional cerebral blood flow. Palmitate incorporation is increased from 15-25 days of age coincident with rapid brain growth and peaks at 20 days, when myelination is maximal, such that flux into white matter exceeds that into gray matter during this period (H. Tabata, et al., in preparation). In adult rats, incorporation into gray matter exceeds that into white matter and does not change with age from 3-34 months of age.

Because the visual system is 80-90% crossed at the optic chiasm, monoocular deprivation in the rat removes most of the visual sensory input to the contralateral cerebral hemisphere. Previous studies with 14C-2-deoxyglucose in rats and monkeys demonstrated marked decrements in rCMRglc in the contralateral superior colliculus, lateral geniculate, and visual cortex after enucleation (L. Sokoloff, J. Cereb. Blood Flow Metabol. 1,(1981) 7-36).

Regional incorporation of labelled palmitate was measured up to 12 weeks after unilateral deprivation of 11 day and 3 month old Fischer-344 rats. Enucleation and catheterization were done under halothane anesthesia followed by a 4 hour recovery period. 14C-palmitate was then injected into the femoral vein, timed arterial plasma samples collected to determine the integrated specific activity of plasma palmitate, and the animal killed after 4 hours by pentobarbitol overdose. The brain was then removed, frozen, sectioned, and exposed to x-ray film for autoradiography.

Preliminary results indicate that compared with the ipsilateral side small decrements in palmitate incorporation occur in the contralateral superior colliculus (3%, $p<0.02$) and the lateral geniculate (2%, $p<0.05$) 4-12 weeks after enucleation of 11 day old rats. No significant change in palmitate incorporation was observed in the visual cortex.

113.18 REGIONAL PALMITATE INCORPORATION INTO THE BRAIN FOLLOWING UNILATERAL AUDITORY DEPRIVATION IN RATS. O.Tone*, J.C.Miller*, J.M.Bell* and S.I.Rapoport. Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20205. (spon: N. Azzam)

The effects of acute and chronic unilateral auditory deprivation in immature and adult rats on the regional incorporation into the brain of plasma palmitate were studied, using the quantitative autoradiographic method of Kimes et al.(Brain Res. 274;291-301, 1983)

Two age groups were selected for this study to measure palmitate incorporation after cochlear destruction in immature (11 day old) and mature (3 month old) awake Fischer-344 rats. Palmitate incorporation into the brain is closely related to increased lipid synthesis during brain development (Tabata et al., in preparation). Cochlear function in rat increases quickly from 11-16 days after birth (Bosher,J.Physiol.212:739-761,1971). Incorporation of 14C-palmitate was measured 1 day, 1 week, and 6 weeks to 3 months after cochlear destruction in both age groups. The destruction of the left cochlea by the trans-meatal approach was done under halothane anesthesia. Catheters were inserted into the femoral artery and vein under halothane anesthesia, then allowed to recover for 4 hr. 14C-palmitate (450 uCi/kg) in 5 mM HEPES buffer, pH 7.4, containing 5 mg/ml BSA was injected into the femoral vein. Plasma samples were collected from the femoral artery for 240 min following injection to measure plasma palmitate radioactivity. The brains were removed 4 hr after isotope injection, following pentobarbital overdose and decapitation. The brains subsequently were frozen, sectioned, and exposed to film for quantitative autoradiography.

Palmitate incorporation into the left cochlear nucleus of the immature group, 6 weeks to 3 months after deprivation, was lower than that of right side by 7% ($p<0.01$). Right inferior colliculus and medial geniculate of individual animals had less incorporation than did the corresponding regions on the left side by 6% ($p<0.02$) and 5% ($p<0.02$) respectively. A similar pattern was observed in the adult group, but to lesser degree.

The present study indicates that chronic auditory deprivation reduces the palmitate incorporation into brain structures along the auditory pathway.

113.19 CHOLINERGIC INNERVATION OF THE CEREBRAL CIRCULATION:CHARACTERIZATION OF SPECIFIC UPTAKE AND RELEASE PROCESSES IN ISOLATED PIAL VESSELS.

E. Hamel, C. Assumel-Lurdin*, L. Edvinsson*§ and E.T. MacKenzie* Dept of Biology, Laboratoires d'Etudes et de Recherches Synthélabo, (L.E.R.S.), 92220-Bagneux, France and §Dept of Clinical Pharmacology, University of Lund, 221 85-Lund, Sweden.

Major cerebral arteries appear to be endowed with high affinity choline uptake and acetylcholine release mechanisms(1);however,very little is known about these specifically neuronal characteristics in small pial (arteriolar) vessels believed to be the most important vascular segment in the regulation of regional blood flow. In the present study, we have assessed the capacity of perfused, isolated rabbit pial vessels to accumulate ^{3}H-choline;furthermore,we examined the effects of potassium-induced depolarization on the spontaneous efflux of vessels pre-loaded with ^{3}H-choline. For comparison, these parameters were measured in the cerebral arteries of the circle of Willis and in the choroid plexus.

All preparations exhibited a high capacity to accumulate ^{3}H-choline at a low concentration ($5x10^{-8}$M). In pial vessels, the high affinity choline uptake was saturable, time- and temperature-dependent with the accumulation of choline at 4°C being less than 10% of that measured at 37°C (0.76 ± 0.14 vs 12.73 ± 1.4 pmol/mg protein/hr). Hemicholinium-3, a selective inhibitor of the high affinity choline uptake, induced a dose-dependent inhibition of ^{3}H-choline accumulation in pial vessels with maximal inhibition (> 90%) at 10^{-3}M.

Pial vessels and large arteries pre-incubated with ^{3}H-choline reached a stable spontaneous efflux of tritium after continuous superfusion of the tissues for 20 to 30 min. Addition of potassium to the medium induced a concentration-dependent increase in tritium outflow which, at 50 mM, was approximately double that of the basal release. The efflux returned to basal levels following 20 min superfusion with a normal potassium medium; after this period, the vessels were still responsive to stimulation of 50 mM potassium,though with a slight decrease in tritium outflow. After removal of calcium from the superfusion solution, addition of 50 mM potassium failed to evoke an increase in tritium efflux. The choroid plexus, preloaded with ^{3}H-choline, also exhibited a continuous efflux of tritium; however, this release was not stimulated by potassium, even in the presence of calcium.

These findings suggest that part of the choline accumulated in pial vessels is taken up by perivascular nerve terminals, transformed into acetylcholine which can be released upon depolarization. Also, the results confirm previous observations on the presence of functional mechanisms for the uptake and release of acetylcholine in large cerebral arteries but would argue against such an innervation in the choroid plexus.

113.20 HISTOCHEMISTRY AND EFFECT OF CHRONIC METHAMPHETAMINE ON MICROVESSELS OF RAT CAUDATE NUCLEUS, SUBSTANTIA NIGRA AND VENTRAL TEGMENTAL AREA. M.S. Cannon,* E.D. Kapes* and M.E. Trulson (SPON: J.B. Gelderd). Dept. of Anatomy, College of Medicine, Texas A&M Univ., College Station, TX 77843.

Young adult male Sprague-Dawley rats served as either saline-injected controls or as test animals receiving methampethamine HCl (20 mg/kg, i.p.) twice daily for ten consecutive days. All rats were then decapitated, brains removed and appropriate areas of forebrain and midbrain selected for histochemical examination of microvasculature. The histochemical reactions utilized represented a number of metabolic pathways, including; glycolysis, the hexose-monophosphate-shunt, Kreb's tricarboxcylic cycle, beta-oxidation of fats, and the respiratory chain. Enzymes were evaluated from fast, frozen material, while substrates such as glycogen, neutral fat and free fatty acids were examined from fixed and/or frozen tissue.

No differences in metabolic profiles of arterioles from rat caudate nucleus, ventral tegmental area and the zona compacta and zona reticulata of the substantia nigra were observed between control and amphetamine-treated animals. Arterioles from all three regions are metabolically active vessels with the capacity for aerobic and anaerobic metabolism. These arterioles, and in particular the larger microvessels of the caudate nucleus and ventral tegmental area, appear to possess a significant potential for nucleic acid and protein synthesis, while arterioles from these two regions and the substantia nigra demonstrate little intramural lipid storage; any fatty acids utilized by the arteriolar wall are provided by the blood supply. Furthermore, although arterioles of the rat ventral tegmental area and from both zones of the substantia nigra show similar metabolic profiles, when comparing the latter with the ventral tegmental area, a lower metabolic capacity is seen in the substantia nigra. In the ventral tegmental area and substantia nigra, it is not known if these metabolic differences are related to possible differential roles of dopamine neurons and the regulation of vascular tone. Also, this study indicates that metabolic differences do occur between microvessels of different calibers within the same vascular bed.

LEARNING AND MEMORY: PHARMACOLOGY I

114.1 A SPECIFIC DEFICIT IN SPATIAL LEARNING IS CAUSED BY REPEATED BUT NOT ACUTE TREATMENT WITH A CHOLINERGIC AGONIST. S. E. Wade* and S. F. Maier (SPON: M. L. Laudenslager). Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

The watermaze task (Morris, R. G. M., Learn. Motiv., 12:239, 1981) is used to assess spatial learning in rats: normal rats quickly learn to escape from a cool swimming pool onto a platform hidden at a fixed location just under the surface of the water, by reference to distal spatial cues. Hippocampal lesions severely impair performance on this task, without affecting performance on a task identical except in use of a visible rather than hidden escape platform (nonspatial task) (Morris, R. G. M. et al., Nature, 297:681, 1982). This disassociation is taken as evidence of a specific effect of hippocampal lesions on spatial learning, as opposed to motivational, reinforcement, or motor-performance factors. Cholinergic blockade given just before acquisition trials has also been shown to impair spatial watermaze performance (Sutherland, R. J. et al., J. Comp. Phys., Psych., 96:563, 1982). We demonstrate that while a single acute treatment with the cholinergic agonist, oxotremorine (OXO), has no effect upon acquisition of spatial watermaze performance, 2 treatments with OXO produce a profound and specific impairment of spatial learning that is observable 48-72 h after the last drug injection.

Male albino rats were removed from individual home cages, injected i.p. with OXO (2.5 µmole/kg), and returned to home cages. When given 9 acquisition trials in the spatial watermaze task 60-100 min later (the time of maximum drug effect upon body temperature), they showed normal performance, with mean escape latency on trials 7-9 (MEL) of 10-15 sec. Acute oxotremorine was similarly without effect on the nonspatial task, with normal MEL in the same range.

When identical OXO treatment was given on 2 successive days, and watermaze acquisition was tested 48 h after the last drug injection, performance on the spatial task was profoundly impaired (MEL 37 ± 5 sec) while latencies on the nonspatial task were normal. (MEL 14 ± 2.8 sec). Similar results were seen when OXO injections were alternated with saline injections over 4 days and testing was 72 h after the last injection. Saline injections alone were without effect.

These results suggest that a specific spatial learning deficit can be produced in the rat in response to repeated treatment with OXO, a cholinergic agonist. Both the absence of an acute drug effect and the observed time course of the impairment make a residual drug effect unlikely, and the impairment is therefore tentatively attributed to a regulatory change induced by repeated cholinergic insult. This change is similar in its effects on spatial learning to hippocampal lesions and cholinergic blockade.

114.2 EFFECTS OF SCOPOLAMINE ON PERFORMANCE OF RATS IN A 14-UNIT T-MAZE. E. Spangler*, P. Rigby*, and D. Ingram* (SPON: E. Bresnahan) Gerontology Research Center, NIA, NIH, Francis Scott Key Medical Center, Baltimore, MD 21224.

Relative to the performance of young adult rats, aged rats are impaired in many learning and memory tasks. Evidence has been presented that these age-related deficits are associated with declines in central cholinergic neurotransmitter systems. Previously, we had demonstrated age differences in both rats and mice in learning an automated, 14-unit T-maze task (Soc. Neurosci. Abstr., 10:452). By administering scopolamine, a muscarinic antagonist, to young animals, we sought to determine whether the cholinergic system was involved in learning this task. Male F-344 rats were given preliminary training in one-way active avoidance (US=1.0 mA) in a straight runway (1 m long). The criterion was 8/10 successful avoidances on the last of three consecutive 10-trial daily sessions. Testing in the automated maze task began 24 hr later. Animals were randomly assigned to one of six groups in which they received 30 min prior to testing an IP injection of either saline, scopolamine (0.1, 0.3, 1.0, or 3.0 mg/kg) or methylscopolamine (1.0 mg/kg). Each animal was provided with two 10-trial daily sessions in the maze task separated by 24 hr. The rat was required to traverse each of five maze segments within 10 sec to avoid footshock. All groups demonstrated learning in the maze task; however, the 1.0 and 3 mg/kg scopolamine groups learned at a slower rate and their asymptotic level of performance was higher. Based on a regression analysis, the variance accounted for by scopolamine dose was 62% - error scores; 42% - run time; and 38% - for the number of shocks. Scopolamine dose did not account for a significant amount of the variance for amount of shock. For the error score measure, one-way ANOVAs for each of four blocks of five trials revealed significant impairment for the 1.0 and 3.0 mg/kg scopolamine groups relative to the saline group (Dunnett's test; $p < .01$). For the run time measure, significance appeared in the final three blocks but not in the first block (p's < .01). Analyses of total shock time and number of shocks indicated no differences in block one for either measure. Differences were noted for the 1.0 mg/kg group only in block two of the number of shocks measure, while the 3.0 mg/kg group was impaired in blocks 2, 3, and 4 of this measure (ps < .01) and in blocks 2 and 4 for the amount of shock measure (ps < .01). These findings suggest that run time, amount of shock and number of shocks were influenced by error performance in this task. Thus, scopolamine had a deleterious effect on performance, particularly on error scores. These findings indicate that cholinergic neurotransmitter systems may influence learning of this complex maze task, but at doses higher than those previously observed to affect performance in a radial arm maze (Physiol. Behav., 26:845).

114.3 SCOPOLAMINE-DISRUPTION OF RADIAL ARM MAZE PERFORMANCE: MODIFICATION BY NORADRENERGIC DEPLETION. M. W. Decker and M. Gallagher. Curriculum in Neurobiology, University of North Carolina, Chapel Hill, NC 27514.

Cholinergic deficits characteristic of Alzheimer's disease (AD) are correlated with cognitive deficits, and experimental disruption of this system interferes with memory in both humans and laboratory animals. Cholinergic deficits in AD, however, typically occur in the context of depletions of other neurotransmitters such as norepinephrine (NE), so it is important to consider the possibility of interactions between the cholinergic system and other affected neurotransmitter systems.

We investigated the interaction of the ascending noradrenergic system and the cholinergic system in learning and memory by comparing the effects of the muscarinic antagonist, scopolamine, on radial arm maze performance of rats with 6-hydroxydopamine lesions of the dorsal noradrenergic bundle (n=7) with scopolamine's effects on the performance of operated control animals (n=6). Following training on both a continuous performance version of the 8-arm maze and on a version in which a 30 sec. delay was imposed between the 4th and 5th arm selections, surgery was performed. Two weeks post-operatively, rats were retrained on the no delay version of the task prior to beginning drug studies.

A pretraining injection of scopolamine (0.25 or 0.5 mg/kg) did not differentially disrupt performance in the continuous version of the task, but did impair the performance of lesioned animals more than control animals when a 45 min. delay between arms 4 and 5 was imposed. In both of these procedures, no differences were noted between the saline control performances of the two groups. In a post-training injection procedure, scopolamine was injected immediately after the 4th arm selection and a 5 hr. delay was imposed before the animal was allowed to complete the task. Here, NE-depleted animals performed significantly more poorly than control animals when 0.5 mg/kg scopolamine was administered, whereas no group differences were noted when saline or lower doses of scopolamine (0.25 or 0.125 mg/kg) were administered.

This study shows that NE depletion intereacts with blockade of the cholinergic system in a learning and memory task, and suggests that further consideration of the role of this interaction in the etiology of the cognitive deficits associated with Alzheimer's Disease may be worthwhile.

114.4 THE EFFECT OF PHYSOSTIGMINE AND/OR SCOPOLAMINE ON RADIAL ARM MAZE PERFORMANCE IN RATS. G. Vincent, R. Harney*, and E. Gamzu, Dept. of Pharmacology, Hoffmann-La Roche Inc., Nutley, NJ 07110

The effects of acute and/or repeated administration of cholinergic agonists and antagonists were evaluated on working memory of Wistar rats (4-8 months of age) in an eight-arm radial maze task. All drugs were administered intraperitoneally. Scopolamine (1 mg/kg), administered 30 minutes before testing, significantly decreased accuracy (i.e. more errors), but not rate (i.e. time to complete eight new choices) as compared to performance on non-drug control days. Methylscopolamine (1 mg/kg) had no effect on either accuracy or rate, suggesting that the effect produced by scopolamine is central rather than peripheral. The next study was undertaken to determine whether repeated exposure to scopolamine would produce a reliable deficit in working memory. Daily administration of scopolamine (1 mg/kg) for up to six days disrupted accuracy, but not rate, of performance compared to that observed on non-drug control days. However, the level of disruption decreased as a function of the number of days the drug was administered, suggesting an up-regulation of cholinergic receptors and/or an increased receptor sensitivity (Loullis, C.C. et al. Soc. for Neurosci. Abstr. 7:925, 1981).

Few studies have attempted to pharmacologically reverse drug-induced deficits in spatial memory performance. We administered physostigmine in an attempt to reverse the deficits in accuracy produced by scopolamine. In the first studies, a dose response curve for physostigmine was established by administering a constant dose of scopolamine (1 mg/kg) versus varying doses of physostigmine (0.03, 0.1, 0.3, and 1 mg/kg). Physostigmine, when administered 25 minutes before testing at doses of 0.3 and 1 mg/kg, reversed the scopolamine-induced deficit in accuracy of performance but had no effect on rate. The number of errors was not significantly different from control performance values. Doses of 0.03 and 0.1 mg/kg physostigmine did not reverse the scopolamine-induced deficit in accuracy of performance. When a constant dose of physostigmine was given (1 mg/kg) and the dose of scopolamine was varied (0.1 or 0.3 mg/kg), no effect on accuracy was observed at 0.1 mg/kg, but some disruption in accuracy was seen after the higher dose of scopolamine. These results support previous suggestions that the central cholinergic system is, directly or indirectly, involved in spatial memory, and that cholinergically induced deficits of this system are pharmacologically reversible.

114.5 EFFECTS OF SCOPOLAMINE AND KCL INJECTIONS INTO THE CAUDATE NUCLEUS ON THE PERFORMANCE OF CONTINUOUS AND FIXED RATIO REINFORCED BEHAVIORS. R.A. Prado-Alcalá and M. E. Archundia*. Dept. of Physiology, Faculty of Medicine, Natl. Univ. of México, P.O. Box 70250, México, D.F., México 04510.

Male Wistar rats were trained for 15 sessions to press a bar in order to obtain water. One group of animals was submitted to a continuous reinforcement schedule (CRF) and another to a fixed ratio-6 reinforcement schedule (FR-6). The sessions ended when the animals had pressed the bar 120 times or when 30 minutes had elapsed. Six minutes before sessions 10, 12 and 14 bilateral injections into the antero-dorsal aspect of the caudate-putamen were made (scopolamine (30 ug/3 ul), isotonic saline solution (3 ul) and 3M KCl (1 ul), respectively) to half the groups under each reinforcement condition. A significant impairment in performance was found only in the CRF animals injected with KCL.

The lack of effect of KCl injections to the FR-6 group and of scopolamine injections to the CRF anf FR-6 groups on learned performance is interpreted as being due to overtraining.

These results further support the hypotheses that: a) cholinergic activity of the caudate nucleus is not critically involved in the maintenance of overtrained tasks, and b) after overtraining the control of instrumentally conditioned tasks is transfered to a non-cholinergic system, within or outside the caudate nucleus.

114.6 EFFECTS OF CHOLINESTERASE INHIBITORS ON ONE-TRIAL PASSIVE AVOIDANCE RETENTION DEFICITS INDUCED BY IBOTENIC-ACID LESIONS OF THE NUCLEUS BASALIS OF MEYNERT. L.J. Thal[*1], C.P.J. Dokla[*1], E.L. Gardner[1], and M. Weinstock[2] (SPON: W.R. Salafia). [1]Departments of Neurology and Psychiatry, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, New York 10461 and [2]Department of Pharmacology, The Hebrew University-Hodassah Medical School, Jerusalem. Ibotenic acid (IBO) lesions of the nucleus basalis of Meynert (NBM) produce extensive loss of choline aceyltransferase (CAT) in cortex and currently serve as a primary animal model for Alzheimer's disease. NBM lesions impair retention on a number of behavioral tasks, particularly one-trial passive avoidance (PA) (e.g., Flicker et al., Pharm. Biochem. Behav. 18: 973-981, 1983). The present investigation examined the effects of IBO lesions on retention of PA, a reference-memory task, and sought to determine if the memory deficits could be eliminated or attenuated using two cholinesterase inhibitors: physostigmine and RA-6. RA-6 is a unique, potent, specific, and reversible cholinesterase inhibitor (Weinstock et al. 30th Oholo Biological Conference, Eilat, Israel, 1985) that may be useful in the treatment of Alzheimer's disease. Fischer 344 rats underwent bilateral stereotaxic NBM injections (two-stages) using 18 ug of IBO in 1 ul of buffered saline. Rats were trained on PA using a single 0.5 mA (0.5 sec.) footshock following two pretraining days. Retention of PA was assessed on the first two postshock days (600 sec. cutoff criterion), and dose-finding drug trials commenced on the next day and continued for 11 consecutive days. Independent IBO lesioned groups (n=9/group) were given physostigmine (in 0.04 mg/kg increments starting at 0.04 mg/kg); RA-6 (in 0.5 mg/kg increments starting with 0.5 mg/kg); or vehicle (distilled water). An additional group served as sham-operated controls (n=9). The IBO groups displayed the expected robust PA retention deficit on the first two postshock (no drug) days ($p<.001$) and the retention deficit persisted strongly for the first 8 days of dose-finding (p's <.01 to .05). While physostigmine failed to significantly attentuate the retention deficit (best dose 0.32 mg/kg), RA-6 produced significant recovery of PA at the 2.0 mg/kg dose ($p<.05$). The present results confirmed that IBO lesions of the NBM produce robust PA deficits and further suggest that the novel cholinesterase inhibitor, RA-6, may have potential value as a memory-enhancing agent following damage to the NBM (supported by the Westchester ADRDA).

114.7 ORAL TACRINE ADMINISTRATION IN MIDDLE AGED MONKEYS: EFFECT ON DISCRIMINATION LEARNING. A. Kling, L.J. Fitten*, K. Perryman* and K. Tachiki*. Departments of Psychiatry and Medicine, Sepulveda VA Medical Center, Sepulveda, CA 91343, and UCLA School of Medicine, Los Angeles, CA 90024

Animal studies testing the cholinergic hypothesis of age-related cognitive decline have usually employed acute, short-term parenteral administration of positive memory enhances. Our lab is developing a non-human primate model (macaca radiata) for assessing the effects of chronic, oral administration for tetrahydroaminoacridine (THA, Tacrine), a cholinomimetic with properties similar to physostigmine but with substantially more clinically desirable pharmacokinetic charasteristics.

All subjects (13-19) (N=4) were adapted for two weeks to the Wisconsin General Training Apparatus (WGTA). Each monkey then learned a series of five or seven different color pair discriminations. Learning criteria was reached when the subject scored 90% correct responses on three successive trials. Each trial consisted of 25 consecutive presentations of the discriminanda. The number of trials to criteria (TTC) were recorded. Two different dosing paradigms were used. In the first, a subject served as his own control (N=1). He received four successive THA dose regimens (2.5, 5.0, 7.5 and 10.0 mg/day). Each was preceded by placebo testing and followed by a five day drug-free interval before the next pair. A different color pair corresponded to each dose regimen or placebo trial. THA Serum levels 1 hour after ingestion were obtained for each dose and 24 to 48 hours after the beginning of the drug-free interval. In the second paradigm (n=3), subjects learned five discriminations on one dose and on placebo. Monkeys were either tested on 5.0 mg/day THA and then retested on placebo following a drug-free interval; or they were first tested on placebo and then on 5.0 mg/day THA. THA serum levels were monitored during the active (1 hour post injestion) and placebo periods.

Results in the first case indicate that 5.0 mg/day and 7.5 mg/day were particularly effective in reducing TTC (TTC=25, for THA vs 250, 200 for placebo) while 10.0 mg/day proved behaviorally toxic (TCC=175). In the second model, all subjects showed improvements on THA vs placebo but only one was statistically significant (p=.01). serum THA levels showed substantial variability throughout the dose range and from subject to subject. No signs of peripheral toxicity were noted.

We conclude that THA is well tolerated and possibly beneficial in enhancing discrimination learning. However, serum THA variability under our testing conditions may have significantly impacted on performance.

114.8 EFFECTS OF SCOPOLAMINE ON RECOGNITION MEMORY IN MONKEYS. D. Walker*, T. Aigner*, P. Cantor*, & M. Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205.

Previous work from our laboratory showed that the anticholinergic agent scopolamine (SCOP) impairs visual recognition in monkeys as measured by delayed nonmatching-to-sample (DNMS) with trial-unique objects. To test whether the drug has a retrograde effect equivalent to its anterograde effect, we administered SCOP to three rhesus monkeys either before (task 1) or after (task 2) the acquisition phase of DNMS. In the acquisition phase of both tasks, the animal was shown a series of 40 baited sample objects at the rate of 1 every 30 sec. In the test phase, the animal was given 40 choice trials in which each sample object, now unbaited, was paired with a novel baited object. During the test phase, the order of presentation of the sample objects was reversed (i.e. the last sample object in acquisition was the first to be paired with a novel object and vice versa). In task 1, the retention interval ranged from 1 to 40 min. In task 2, in order to allow for testing retrograde drug effects, a 20-min interval was imposed between acquisition and test, and, consequently, the retention interval ranged from 20 to 60 min. Drug testing on each task was preceded by 15 practice sessions on each. SCOP was injected 20 min before the start of acquisition in task 1 and immediately after acquisition in task 2. SCOP doses of 10 and 17.8 ug/kg were tested on task 1 and doses of 10, 17.8, and 32 ug/kg were tested on task 2. Each dose was tested 8 times and at least 1 nondrug session preceded each drug session. Equivalent doses of neostigmine were given just prior to SCOP to block adverse peripheral effects.

On both tasks, linear forgetting curves were obtained. In task 1, the average percent correct ranged from 98% for the shortest retention interval (1 min) to 70% for the longest (40 min), yielding a mean score of 80%. In task 2, the values ranged from 83% (20 min) to 65% (60 min), for a mean of 73%. In task 1, 10 ug/kg of SCOP produced a marginal impairment and 17.8 ug/kg produced a significant impairment. In task 2, in which SCOP was administered after acquisition, neither 10 nor 17.8 ug/kg produced an effect, impairment being observed only with the highest dose, 32 ug/kg. The results suggest that SCOP has mainly an anterograde effect on recognition and hence probably affects storage more than retrieval. Furthermore, in each task, the effective dose of SCOP produced a forgetting curve shifted downward but parallel to the control curve. The latter result suggests that the anterograde effect of SCOP is equivalent to reducing the strength of the memory trace by increasing the passage of time following acquisition.

114.9 EFFECTS OF DELTA-9-TETRAHYDROCANNABINOL (THC) ON RECOGNITION MEMORY AND HABIT FORMATION IN MONKEYS. T. Aigner*, R. Brown*, D. Walker*, & M. Mishkin (SPON: S. Mitchell). Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205 and Preclinical Research Branch, NIDA, Rockville, MD 20852.

Although the cognitive effects of marijuana, or its active metabolite THC, are still poorly understood, evidence from studies in animals suggests that THC may be exerting its effects through actions on the limbic system. To explore this possibility, we investigated the effects of orally administered THC in monkeys on two learning abilities, one known to be dependent on the limbic system, and the other known to be independent of it.

Six rhesus monkeys were divided into two groups of three each. Group I was trained in delayed nonmatching-to-sample (DNMS) with trial-unique objects, the limbic-dependent memory task. After receiving pretraining on easy versions of DNMS, the animals were tested for their ability to remember a series of 40 (baited) sample objects, presented at the rate of one every 15 sec. In the choice test, each sample object (now unbaited) was paired with a (baited) novel object, again once every 15 sec. Doses of THC (1, 2, & 4 mg/kg) were administered either 1 or 2 hrs prior to the session. Each dose was tested twice at each time point in a nonsystematic order. At least one nondrug control session preceded each session in which THC was given. Group II was trained in 24-hr concurrent discrimination learning (CDL), a task that monkeys with limbic lesions can perform normally. A set of 20 object pairs was presented once every 24 hrs, with the positive and negative objects in the pairs and the order of pair presentations remaining constant across sessions. Criterion was set at 90 correct responses in 100 trials. Three doses of THC (4, 8, & 16 mg/kg) and two nondrug control treatments were tested, each with a different set of 20 object pairs. THC was given 2 hrs prior to each daily session. Tests were conducted 7 days per week, with at least 1 week intervening between sets.

THC had a significant effect on the DNMS performance of Group I. The largest effect was seen 2 hrs after a 4 mg/kg dose, the highest dose tested on DNMS, with performance decreasing to 80% of control levels under this condition. No significant impairment was found on the CDL performance of Group II at any dose, though one of the three monkeys appeared to be slightly impaired at the dose of 16 mg/kg. The results suggest that THC interferes with memory more than with habit formation, and this in turn may reflect a selective action of THC on limbic structures.

114.10 A STUDY OF NICOTINE (NIC), DESGLYCINAMIDE ARGININE VASOPRESSIN (DGAVP), AND SCOPOLAMINE (SCOP) IN AN AUTOSHAPED LEVER-TOUCH MODEL OF "LEARNING" IN RATS. Edgar T. Iwamoto and William Mundy* (SPON:W.R.Martin) Dept. of Pharmacology and the Tobacco and Health Research Instit. Univ. of Kentucky, Lexington, KY 40536.

Nicotine reportedly increases or decreases "learning" and "memory" in animals and humans. Since nicotine is known to alter vasopressin plasma levels, and vasopressin purportedly modifies "learning" and/or "memory" as estimated by acquisition and resistance to extinction of conditioned avoidance behavior, the ruling hypothesis has evolved that "nicotine improves cognitive function because it releases vasopressin from the posterior pituitary". Messing and Sparber (EJP 89:43, 1983) reported that DGAVP improved acquisition and slowed extinction of a food-reinforced autoshaped lever touch response. Since most of the previous work with nicotine used avoidance paradigms, we decided to test the hypothesis that nicotine improves "learning" and "memory" using this positively reinforced task.

Methods: Adult male Sprague-Dawley rats, and heterozygous and homozygous male Brattleboro rats were food-deprived to 80% of original b.wt., 306±41g SD, N=150. Modular test cages held a retractable lever that was presented on a random interval 48s schedule. The lever retracted after 15s or until it was touched at which time one 45mg food pellet was delivered ("discrete trial"). In paradigm I, magazine trained rats were injected SC with saline, 5 or 10 µg/kg of DGAVP prior to each of two daily acquisition sessions. Three days after acquisition training, rats received saline or DGAVP prior to two daily extinction (feeder disabled) sessions. In paradigm II, the acquisition sessions consisted of 10 discrete trials/da for 5 or 10 da. Non-magazine trained rats were autoshaped to a criterion of 10 correct lever touches. The number of correct lever touches (lever extended), "nose-pokes" (touching retracted lever), and the time spent near the lever were recorded.

Results. Paradigm I: Five µg/kg (one experiment) and 10 µg/kg (2 experiments) of DGAVP did not alter the acquisition or the extinction of the lever touch response, the incidence of nose-pokes, nor the time spent near the lever. Paradigm II: Saline-trained rats acquired the 10 correct/10 trial criterion in 4 to 6 sessions. Ten µg/kg of DGAVP did not alter acquisition. NIC and SCOP, (0.1-0.8 mg/kg), given 15 min prior to each session caused significant dose-related depressions of acquisition compared to saline controls. Acquisition by homozygous Brattleboro rats was not different from heterozygous littermates (2 experiments). These data suggest that pharmacologic and physiologic manipulations of vasopressin do not affect, while both SCOP and NIC impair, the acquisition of a positively-reinforced, autoshaped lever touch response in rats. (Supported by the Kentucky Tobacco Research Board and BRSG).

114.11 ARGININE VASOPRESSIN (AVP) RETARDS THE ACQUISITION OF BEHAVIORAL TOLERANCE TO TWO EFFECTS OF ETHANOL IN RATS. D.L. Hjeresen, D. Brief, D.L. Amend, and S.C. Woods. (SPON: R.H. LOVELY.) Department of Psychology, University of Washington, Seattle, WA. 98195.

There is extensive evidence that AVP and related peptide fragments affect learning processes and increasing evidence that learning mechanisms contribute to the development of drug tolerance. The present study was conducted to determine the influence of AVP on the acquisition and extinction of tolerance to the ataxic and hypothermic effects of ethanol (EtOH).

Twenty-eight male Long-Evans rats were tested in 4 groups: 1) EtOH/NaCl, 2) EtOH/AVP, 3) NaCl/NaCl 4) NaCl/AVP. EtOH (2.0 g/kg, 15% v/v, i.p.) and/or AVP (6 ug/kg, s.c.) was administered after an initial rectal temperature was taken and 10 m prior to testing on a moving belt (10 cm/s) test for ataxia. Testing consisted of 3 1-m trials (30-s ITI) and a second rectal temperature. These procedures were repeated for 12 consecutive days (ACQUISITION). On day 13 all rats were injected with EtOH and NaCl to test for possible differences in tolerance development. On Days 14 to 20 (EXTINCTION) rats received the following treatments: Group 1) NaCl/NaCl, 2) NaCl/AVP, 3) NaCl/NaCl, 4) NaCl/AVP, and on Day 21 the procedures of Day 13 were repeated.

Results confirm that AVP is a hypothermic agent and that its effect is additive to the hypothermic effect of EtOH. AVP significantly retarded the acquisition of tolerance to both the ataxic (Grp 1 vs. Grp 2, $F=5.6$, $p<.01$) and hypothermic ($F=15.4$, $p<.01$) effects of EtOH, although the level of tolerance attained on Day 13 was not significantly different between Groups 1 and 2 (i.e., both groups were significantly more tolerant than rats in Groups 3 and 4 which did not differ from each other). During extinction Groups 2 and 4 were rendered significantly more hypothermic than Groups 1 and 3 while no significant differences were noted in treadmill performance. On Day 21 rats in Group 2 were significantly more tolerant to the hypothermic effect of EtOH than rats in any other group. Differences between groups on the treadmill task were not significant.

That AVP interferes with the acquisition of two different measures of EtOH tolerance suggests that this effect is due to a generalized interference with learning. However, results of the extinction phase indicate that AVP delays the extinction of tolerance once it has been acquired. Both results suggest a role for learning mechanisms in the development of ethanol tolerance.

114.12 EPINEPHRINE EFFECTS ON MEMORY STORAGE: INTERACTION WITH β-ENDORPHIN AND NALOXONE. I. Introini* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717.

There is extensive evidence that epinephrine modulates memory. Low doses facilitate memory and high doses induce amnesia in a variety of tasks. Opioid peptidergic systems also modulate memory: Retention is enhanced by naloxone and impaired by β-endorphin. The present study examines the interaction between peripheral epinephrine and opioid peptidergic systems on retention. Male CFW mice (60 days old) were trained on an inhibitory avoidance response (IAR) or a visual discrimination response (VDR), injected (IP) immediately posttraining and tested 24 hours later. No significant effects on retention were observed when a facilitatory dose of epinephrine (IAR: 10 µg/kg; VDR: 300 µg/kg) and an impairing dose of β-endorphin (IAR: 1.0 or 3.0 µg/kg; VDR: 1.0 µg/kg) were given together. Further, a subeffective dose of epinephrine (IAR: 3.0 µg/kg; VDR: 30 µg/kg) did not modify the dose-response curve of naloxone (0.3-3.0 mg/kg).

In contrast, a facilitatory dose of naloxone (IAR: 1.0 mg/kg; VDR: 3.0 mg/kg) completely reversed the impairing effect of epinephrine (IAR: 0.3 mg/kg; VDR: 1.0 mg/kg) on memory, suggesting that the amnestic action of epinephrine may be due to an increase release of an opioid peptide, possibly β-endorphin. In view of pharmacological evidence that a novel experience depletes brain β-endorphin (Izquierdo and McGaugh, unpublished), we also examined the effects of posttraining epinephrine (IAR: 0.3 mg/kg; VDR: 1.0 mg/kg) on mice given a novel experience one hour prior to training of both tasks. With these procedures, otherwise amnestic doses of epinephrine, significantly enhanced retention. These findings suggest that different mechanisms of action mediate the facilitatory and impairing effects of epinephrine on memory modulation.

114.13 ADRENAL DENERVATION ALTERS THE EFFECT OF MET-ENKEPHALIN AND NALOXONE ON MEMORY CONSOLIDATION. S. Zhang*, I. Introini*, R. Juler* and J.L. McGaugh (SPON: G. Novack). Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717 U.S.A.

Previous evidence indicated that endogenous opioid peptides are involved in modulation of memory. The site of action, however, is not yet clear. It is well known that enkephalins are released from adrenal medulla after stress, but the findings regarding enkephalins and memory are conflicting. The present study examined the effect of naloxone and Met-enkephalin (ME) on memory consolidation and assessed the involvement of adrenal medulla in such effect.

Two experiments were performed in male CFW mice (50-60 days old). In Experiment I, intact mice were trained in a one-trial inhibitory avoidance task (IA, 0.6 mA, 2sec footshock) and 10-14 days later in a Y-maze discrimination (YMD, 0.4 mA footshock). Immediately after training, animals received i.p. saline or one of the following drugs: naloxone, morphine, ME, naloxone + morphine or naloxone + enkephalin. Retention was tested 24 hr later. In both tasks, naloxone (0.3 mg/kg) enhanced retention while morphine (3 mg/kg) or ME (2 µg/kg in IA, 0.5 µg/kg in YMD) produced a retention deficit. For IA, morphine (3 mg/kg) or ME (2 µg/kg) attenuated the enhancement of naloxone on retention. For YMD, naloxone (0.3 mg/kg) antagonized the memory impairment caused by ME.

In Experiment II, mice were bilaterally adrenal denervated (ADXN) or sham-operated (SHAM). Two weeks after surgery the mice trained in IA and two weeks later in YMD. Approximately half the mice in each group immediately received posttraining injections of saline and the remainder were injected with naloxone (in IA) or ME (in YMD). Retention was tested 24 hr later. For IA, naloxone enhanced memory in SHAM, but did not enhance retention in ADXN. For YMD, ME significantly impaired retention in SHAM but did not significantly affect retention in ADXN.

The present data suggest that the effect of naloxone and ME on memory consolidation may be mediated in part by the release of ME from the adrenal medulla.

114.14 EFFECTS OF OPIATE ADMINISTRATION INTO THE MEDIAL SEPTAL AREA ON LATENT INHIBITION. M. Gallagher, E. Bostock, and M.W. Meagher.* Psychology Department and Neurobiology Program, University of North Carolina, Chapel Hill, NC 27514.

Studies using classical conditioning procedures have reported that opiates and some opioid peptides impair the performance of learned responses. In addition, opiates and opioid peptides administered after training disrupt retention of recent learning. The present investigation examined the effects of intracranial administration of an opiate agonist, levorphanol, on latent inhibition of classically conditioned heart rate responses in rabbits.

New Zealand albino rabbits in the latent inhibition (LI) groups received 15 tone (1KHz, 82dB, 5 sec) presentations per day for 2 consecutive days. On Day 3 all rabbits received a standard Pavlovian conditioning session in which 15 tone alone presentations were followed by 30 trials in which the tone was paired with eyelid shock (1.2 mA, 500 msec). Tone pre-exposure produces latent inhibition reflected in a decrement of subsequent conditioned responses. Compared to a normal conditioning group (Day 3 session only), both an unoperated LI group and a LI group receiving vehicle injections into the medial septal area (MSA) exhibited significant latent inhibition of classically conditioned heart rate responses ($ps<.002$). These LI control groups, however, did not differ from one another. Opiate administration into the MSA significantly reduced retention for tone pre-exposure. Two LI groups which received levorphanol (3 ug) administered into the MSA either prior to or immediately following each tone pre-exposure session on Days 1 and 2 differed significantly from the LI control groups ($ps<.01$).

The effect of post-training levorphanol injection into the MSA exhibited both pharmacological and neuroanatomical specificity. Administration of dextrorphan (3 ug), the inactive enantiomer of levorphanol into the MSA immediately following each tone pre-exposure session or administration of levorphanol (3 ug) 1.5 mm dorsal to the original injection site did not significantly alter subsequent latent inhibition of conditioned heart rate responses.

These results complement previous findings that systemic administration of opiate agonists and antagonists alter retention for exposure to non-reinforced presentation of stimuli. Morphine was found to impair long-term retention of habituation and post-training naloxone has been reported to enhance retention of habituation in rats and mice (Izquierdo, Psychopharmac., 66, 199, 1979; Rodgers et al., Psychopharmac., 82, 322, 1984) as well as latent inhibition of conditioned heart rate in rabbits (Bostock and Gallagher Soc. Neurosci. Abstr. 8, 148, 1982). The MSA appears to provide a brain site sensitive to the effect of opiates on retention of non-reinforced presentations of a tone as reflected in latent inhibition.

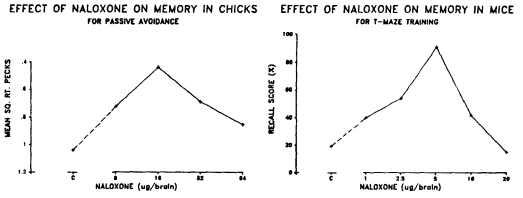
114.15 **INTRACEREBRAL NALOXONE ENHANCES MEMORY RETENTION IN CHICKS AND MICE.** **J.F. Flood, A. Cherkin and J.E. Morley. Psychobiology Res. Lab. and GRECC, VA Med. Center, Sepulveda, CA 91343.**

Naloxone, an opioid peptide antagonist, enhances memory retention in rodents after peripheral administration. Intravenous naloxone in human subjects produces conflicting effects on memory. One interpretation is the dose-dependence of memory-enhancing drugs, complicated by dose-dependent bidirectional effects, i.e., enhancement by moderate and impairment by high doses. The studies reported here examined the effect upon memory of central administration of naloxone over a wide dose range in two classes, Aves and Mammalia. All experiments were blind. Chicks (N = 30-38/gp) were trained in one 10-sec trial to suppress their spontaneous pecking at a normally attractive target (3-mm steel bead) by coating it with an aversive liquid, methyl anthranilate, in a passive avoidance paradigm (Physiol. Behav. 14:151, 1975). Naloxone hydrochloride (NAL) in 2 ul of saline was injected into each forebrain hemisphere 2 min after training, with the chick restrained in a head-holder. Moderate doses (16 or 32 ug per brain) enhanced 24-hr memory retention ($p < 0.05$, compared to saline, C in figure), as indexed by the reduced peck score (mean sq. root of pecks) during the 10-sec test presentation of the dry target. A lower dose (8 ug) or higher dose (64 ug) was ineffective (see figure; note inverted scale of ordinate and log scale of doses). In mice, a moderate dose (5 ug per brain) of NAL enhanced 168-hr memory retention ($p < 0.01$) when injected intracerebroventricularly 2 min after training in a T-maze active avoidance paradigm (Neurobiol. Aging 4:37, 1983). Lower and higher doses (1.0, 2.5, 10, 20 ug per brain) were not effective (see figure). We conclude that post-training central administration of NAL enhances memory retention in chicks and mice. The dose-response curve in each case is an inverted-U, i.e., low and high doses are ineffective. The "therapeutic window" is narrow from a pre-clinical point of view, suggesting that individual dose titration be considered in evaluating NAL for human memory enhancement.



114.16 OPIOID ANTAGONISTS ENHANCE AN ACQUIRED IMMOBILITY RESPONSE IN MICE. Gaila S. Opotowsky-Gulack*, Joe L. Martinez, Jr., and Marianne Leslie*. Psychology Department, University of California, Berkeley CA 94720

Naloxone (Nx) is known to enhance memory in several species. In contrast, Nx reportedly impairs learning of an acquired immobility task (the behavioral despair test) in rats and mice (Eur J Pharm 1984, [103] 205-210; Physio & Beh 1982, [28] 249-251). In the present study, mice were placed in a 1000 ml beaker containing 650 ml of 22 C water for 10 m. Nx or sal was administered either 5 m before training or immediately following training on Day 1. Retention was tested 24 h later (Day 2). Immobility was defined as floating, either upright or sideways, with no activity beyond that required to maintain balance. The number of s that a mouse remained immobile in each m was recorded. The number of s immobile in m 2-7 (posttrial administration) or m 1-10 (pretrial administration) was considered to be a measure of acquisition (Day 1) or retention (Day 2).

In the first experiment, Nx (1mg/kg, 10mg/kg) or sal was administered immediately posttrial on Day 1. Immobility in the Nx group (10mg/kg) was greater than that of the saline group [$t(76)=2.47, p<.01$]. The lower Nx dose was without effect. Nx (10mg/kg) or saline administered 5 m prior to training (Day 1) also enhanced Day 1 performance [$t(38)=2.88, p<.005$]. Further, Nx-treated animals showed an even greater immobility response than did animals in the sal group on Day 2 [$t(38)=6.88$, $p<.0005$].

Methylnaloxonium (MeNx) was administered to assess the contribution of peripheral opioid receptors. MeNx was given in doses equimolar to Nx (1.04mg/kg, 10.4mg/kg) immediately posttraining (Day 1). Neither MeNx dose produced a significant effect. Therefore, MeNx was administered at a dose three times the effective dose (30.12mg/kg) to compensate for the lower affinity of MeNx for opioid receptors. MeNx then produced a significantly greater immobility than sal [$t(36)=2.14, p<.05$].

These data demonstrate that Nx facilitates the retention of the immobility response, in general agreement with known actions of Nx in other tasks. Facilitation on Day 2 occurs whether Nx is administered before or after training on Day 1. Since MeNx also facilitates this response, it may be that Nx and MeNx affect learning by acting at the same peripheral receptor site. (Supported by ONR N00014-83-K-0385).

114.17 LEU-ENKEPHALIN: EFFECTS ON PLACE PREFERENCE CONDITIONING AND LACK OF EFFECT OF DES-TYR-LEU-ENKEPHALIN IN ACTIVE AVOIDANCE CONDITIONING. (SPON: M.R. Rosenzweig) Stephen Heinrichs,*Sandra Brown,*and Joe L. Martinez, Jr., Psychology Department, University of California, Berkeley, Ca 94720.

For place preference (PP) conditioning mice were injected (i.p.) with either Leu-enkephalin (LE) or sal and placed in a distinctive environment for 30 m. Drug and sal administration were alternated on consecutive days for 6 days. Before training the mice were allowed to freely explore the 2 environments for 10 m each day to determine preference scores. Following training the mice were given a 10 m testing session where they were allowed to choose between the 2 compartments. Mice were trained against and in the same direction as their initial preference. A dose of 300 ug/kg LE produced a positive PP [$t(56) = 2.1$, $p = .040$], if the mice were trained against their initial preference. Conversely, the opposite effect was observed with the 300 ug/kg dose, if the mice were trained towards their initial preference [$t(66) = 2.78$, $p = .007$]. The next experiment replicated the positive PP conditioning effect produced by 300 ug/kg LE [$t(21) = 1.91$, $p = .03$, one-tail]. This positive effect was partially attenuated by methylnaloxonium. Mice that received 10 mg/kg along with LE (300 ug/kg) were not different from the control group. These data extend the generality of enkephalin actions on conditioning to another non-shock motivated task. The partial attenuation by methylnaloxonium suggests that some aspect of the enkephalin effect is mediated by peripheral opioid receptors.

In the one-way active avoidance task mice were placed in the shock compartment of of a two-compartment alley and given 10 s to shuttle into the safe compartment. If no avoidance occurred in 10 s, a shock came on (800 uA), which was terminated when the mouse escaped. Four training trials were given on Day 1 and 14 trials were given on Day 2. The mice were injected with LE (saline 50 or 100 ug/kg, i.p.) or des-tyr-LE (saline 35.4 or 75.7 ug/kg) 5 min before training on Day 2. The number of avoidances the animal made on Day 2 was the measure of performance. LE at a dose of 100 ug/kg impaired acquisition of the avoidance response on Day 2 [$t(54) = 2.64$, $p = .019$]. Des-tyr-LE did not produce any significant effect [$ts < .98$]. This finding suggests that LE produces its effects through an action at opioid receptors, since des-tyr-LE is a non-opioid peptide. (Supported by ONR N00014-83-K-0408).

114.18 INTRASEPTAL β-ENDORPHIN IMPAIRS NOVEL SPATIAL MEMORY. E. Bostock and M. Gallagher, Neurobiology Program and Psychology Department, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514

Recent work from this lab has demonstrated that opiate antagonists facilitate acquisition of novel spatial information. The involvement of the hippocampal formation and it's connections in spatial behavior suggests that opiates may influence novel spatial memory by acting at sites within this neural system. These studies examine the effect of intraseptal β-endorphin (β-end) administration on performance of a previously acquired spatial task and on a task requiring the acquisition of novel spatial information.

In Experiment I male Long Evans rats were trained to visit each arm of a radial 8-arm maze once during a session to obtain food reward. Rats received 1 session/day of training until they achieved criterion performance of no more than 2 errors/session for 3 consecutive sessions. An error was a return visit to an arm that had been previously visited within a session. A within-subject design was used to test the effect of intraseptal injections of 1 μg β-end or vehicle solution on performance. Treatments were administered 10 min. prior to a maze session for 3 consecutive days. Following a 5-7 day interval the alternate treatment was administered. Treatment order was counterbalanced among animals. The total number of errors for each treatment condition was recorded for each rat. Intraseptal β-end injections had no effect on the number of errors made suggesting that intraseptal β-end does not influence performance of a previously acquired spatial task.

In Experiment II rats were trained on the maze as above. During further training a 5 hr. delay was inserted between the 4th and 5th arm choices within a session and training continued until rats achieved criterion performance. Experiments consisted of testing rats on the maze in novel spatial environments. Treatments were administered immediately following the 4th arm choice for the 1st 4 sessions in a new room. Using a within-subject design rats received 500 ng β-end in one room and vehicle treatment in another. Treatment order was counterbalanced among animals. The number of errors and sessions to acheive criterion performance was recorded for each animal in each new room. The results of this experiment reveal that animals commit more errors and require more sessions to acheive criterion performance when they receive β-end treatment. A further experiment revealed that intraventricular injections of β-end do not alter the aquisition of novel spatial information. These findings suggest that intraseptal β-end injections impair the acquisition of novel spatial information in rats and that the septal region may be a site sensitive to the memory altering properties of opiate substances.

114.19 PASSIVE AVOIDANCE CONDITIONING INHIBITED BY PRETRAINING INJECTION OF LEUPEPTIN. J.L. Davis and R.M. Pico. Aging and Behavioral Biology Res. Lab., VA Med. Ctr., Sepulveda, CA 91343; Dept. of Anatomy, College of Medicine, Univ. of California, Irvine, Irvine, CA 92717.

A one-trial passive avoidance paradigm using young cockerels has been employed in our laboratory to investigate the effects of certain amino acids and peptides (e.g., L-proline and vasopressin) on the avoidance response (Cherkin, A. & Van Harreveld, A., Br. Res., 156, 265-273, 1978; Pico, R.M. & Davis, J.L., IRCS Med. Sci., in press, 1985). Our work with neuroactive peptides has involved the assessment of L-leucyl-L-leucyl-L-arginyl (leupeptin); an inhibitor of proteases, including those known as calpain. Initial results indicated that it inhibited the avoidance response. A recent report described the performance of rats on several memory tasks after receiving leupeptin (Staubli, U., et.al., Behav. Neural Biol., 40, 58-69, 1984), and concluded that memory for delayed spatial alternation and not conditioned avoidance learning is disrupted by this peptide. We have therefore extended our investigation to determine the specificity of leupeptin in avoidance learning by testing it along with two analogues.

Male chicks received intraventricular injections of isotonic saline (N=29), leupeptin (N=30), L-leucyl-L-leucyl-L-leucine (LLL) (N=30) or L-leucyl-L-arginyl (LA) (N=28) 15 min prior to training (200 ug/chick). Each chick was presented with the stimulus probe (a 3-mm steel bead attached to a wire rod) which had been coated with an aversive liquid. After 1-4 pecks at the coated bead, chicks retreat and avoid the probe. Retention of this training is tested 24 hr later by presenting an uncoated test probe for a 10-sec period. The mean peck rate/10-sec (MPR) serves as an index of avoidance conditioning: Saline group MPR= 0.93, 72% pecked at the probe only 1 time or not at all (avoidance ratio: AR): LLL group MPR= 1.36, AR= 70%: LA group MPR= 2.21, AR= 46%: Leupeptin group MPR= 4.10, AR= 10%. These results indicate that leupeptin is the most effective inhibitor of the avoidance conditioning, although LA appears to have 50% of its potency. In light of these findings, we are currently examining the effects of leupeptin and analogues on avoidance conditioning in the rodent.

114.20 PHARMACOLOGICAL INVESTIGATIONS OF THE RELATIONSHIP BETWEEN LUMBAR SPINAL CORD CYCLIC AMP AND THE ACOUSTIC STARTLE REFLEX IN RATS. J.H. Kehne, D.I. Astrachan, J.F. Tallman, and M. Davis, Dept. Psychiat., Yale Univ. Sch. Med., 34 Park St. New Haven, CT 06508

Cyclic AMP has been widely implicated as an intracellular second messenger, though few experiments have shown a direct linkage between cAMP and behavior. In the present study, drugs which increase cAMP levels were infused intrathecally into the subarachnoid space of the lumbar spinal cord in behaving rats and the effects on the acoustic startle reflex were measured.

Dibutyryl cAMP (12.5 - 100 µg), a membrane-permeable and phosphodiesterase-resistant cAMP analog, markedly and dose-dependently increased startle following intrathecal infusion, with peak activation occurring at approximately one hour after infusion. Local infusions of dibutyryl cAMP at more rostral levels of the neuraxis failed to mimic the excitatory effect of lumbar infusion, indicating that the primary site of action was in the lumbar spinal cord. Furthermore, no activation was seen following intrathecal administration of dibutyryl cGMP (50-100 µg). Intrathecal infusions of the precursor ATP, the metabolite 5'-AMP, or cAMP itself, did not substantially alter startle, indicating that extracellular actions or non-specific changes in energy metabolism probably do not account for the observed activation by dibutyryl cAMP.

Forskolin has been shown to be a selective and reversible activator of adenylate cyclase. However, when infused intrathecally, forskolin (5.0 - 100 µg, dissolved in DMSO), had no consistent effect on startle amplitude. In contrast, a water-soluble forskolin derivative, 7-deacetyl-7-O-hemisuccinic acid (forskolin-DHA; 12.5-100 µg, dissolved in artificial CSF) increased startle following intrathecal infusion.

In summary, the excitatory effects of lumbar intrathecal infusions of dibutyryl cAMP and forskolin-DHA indicate a link between spinal cord cAMP and the acoustic startle response. Furthermore, the lack of effect of forskolin relative to forskolin-DHA indicates that the water-soluble derivative is a better pharmacological tool for investigating behavioral correlates of cAMP activation, at least in studies which involve drug administration directly into cerebrospinal fluid. Current studies are investigating the spinal cord receptor system(s) which are linked by cAMP to activation of the startle reflex.

BIOLOGICAL RHYTHMS I

115.1 CORTICAL GRAFTS IN III VENTRICLE OF SUPRACHIASMATIC LESIONED RATS INDUCES RECOVERY OF THE PHOTO PERIOD OF DRINKING RHYTHM+. R. Aguilar-Roblero*, F. García-Hernández*, R. Aguilar*, and R. Drucker-Colín. Departamento de Fisiología, Centro de Investigaciones en Fisiología Celular, UNAM, México 04510, D.F.

We have previously shown that fetal Suprachiasmatic Grafts can restore Diurnal Rhythms in Drinking behaviour in Suprachiasmatic Nucleus (SCN) lesioned adult rats. The present study attempts to establish whether the Drinking Rhythm of grafted animals is an endogenous Circadian Rhythm and also whether the recovery can only be induced by fetal SCN or whether grafts from other brain regions have similar effects.

Once complete abolishment of Drinking Rhythm was achieved by bilateral electrolitic lesions of the SCN of rats, the animals were divided in three groups. Group A, receiving fetal SCN grafts placed on the floor of the III ventricle, Group B, receiving fetal Occipital Cortex grafts placed on the floor of the III ventricle and, Group C receiving fetal Suprachiasmatic Nucleus in a cavity prepared on the Occipital Cortex. All the animals were placed in a room with a 12:12 L-D schedule. Six weeks later continuous recording of Drinking behaviour was carried out during 4 weeks. Illumination schedule was then changed to constant light (L-L), and the recording continued through the next 4 weeks. At the end of the experiment the animals were anestethized and the Brain removed and processed for Histological verification of lesion site and Graft characteristics.

With the L-D schedule both Group A and Group B showed restoration of the Drinking Rhythm, in phase with L-D cycle. Group C, however, did not show any diurnal periodicity in Drinking behaviour. During L-L schedule there was total desorganization of the Rhythm in both Group A and Group B animals, as if animals were SCN lesioned without grafts.

The results confirm previous observation that SCN fetal grafts can restore diurnal Rhythm of Drinking Behaviour in SCN lesioned animals and indicate that the rhythm is passively driven by the L-D schedule. Since Occipital Cortex grafts have similar effects as SCN grafts, the phenomenon seems to be unspecifically induced. This observation can be explained either by proposing that the graft functions merely as a bridge between the retina and other hypothalamic areas, or by proposing that the retinal fibers impinging upon grafter tissue, drives the rhythm either through direct or indirect outputs. The fact that SCN grafts to the Occipital Cortex cavity cannot restore the Diurnal Rhythm in Drinking behaviour suggests that direct Retinal inputs are needed to induce the photoperiod.

115.2 PERTURBATIONS OF CIRCADIAN RHYTHMICITY INDUCED BY MICROINJECTION OF αBUNGAROTOXIN INTO THE AREA OF THE SCN. J.R. Pauly* and N.D. Horseman* (SPON: R. Quock). Dept. of Biology, Marquette University, Milwaukee, WI 53233.

For skeletal muscle and fish electric organ acetylcholine (ACh) receptors, the binding of αbungarotoxin (αBT) is highly specific to nicotinic sites and is essentially irreversible. This ligand has also been used extensively to identify putative nicotinic cholinergic sites in the central nervous system and those sites have been proposed to be critical to the circadian timekeeping system of mammals. The highest concentrations of hypothalamic nicotinic receptors identified by αBT binding are in the suprachiasmatic nuclei (SCN), putative circadian pacemakers. However, the pharmacology of ACh transmission in the brain is proving to be quite different from more classically defined peripheral ACh systems. The identification of neuronal αBT binding sites and nicotinic receptors is still controversial because in most vertebrate preparations, αBT fails to inhibit neuronal nicotinic transmission. In the SCN, although there are a large number of αBT binding sites, the concentrations of choline acetyltransferase is very low. Therefore it is plausible that these αBT binding sites are important to the circadian system in ways not directly explained by ACH transmission. We have examined the effects of microinjection of αBT into the area of the SCN on circadian locomotor activity rhythms in the rat.

Animals were anesthetized with Chloropent and stainless steel guide cannula assemblies were implanted into the area just dorsal to the SCN. After surgeries, animals were entrained for a period of 2 weeks to LD12:12 and then blinded by bilateral orbital enucleation. Total locomotor activity rhythms were monitored through the use of plexiglass activity monitors. Infusions of αBT (10 µg in a volume of 1 µl) were given at either of two time points. Twelve animals were treated 2 hr after the onset, of the daily active interval. Phase delays were induced in 6 of these animals with a maximum phase shift of about 3 hr. Seven of 11 animals injected with αBT 2 hr prior to the offset of their daily active interval showed phase advances in their locomotor activity rhythms. Maximal response was again about 3 hr. In other cases the injections caused dramatic alterations of free-running period or caused dyschronism (loss of rhythmicity). These results indicate that αBT produces perturbations in circadian rhythmicity that in some cases are similar to those reported for light pulses. Recent studies in our lab have demonstrated that depletion of brain ACh stores does not alter the phase-shifting effects of light. This suggests that the previously hypothesized roles of ACh may not be correct. In light of the results presented here, it seems plausible that the effects of carbachol injections could be mediated through activation of αBT binding sites. These discrepancies may be resolved by comparing the effects of cholinergic agents of varying specificities.

115.3 THE DEVELOPMENT OF THE SUPRACHIASMATIC NUCLEUS IN AN EMBRYONIC EXPLANT SYSTEM. M. H. Roberts, M. F. Bernstein and R. Y. Moore, Depts. of Neurology and Neurobiology, SUNY, Stony Brook, NY 11794

The suprachiasmatic nucleus (SCN) of the hypothalamus has been implicated as a controlling pacemaker in the rodent circadian system. Anatomically, the nucleus can be divided into ventrolateral and dorsomedial portions based upon the area of termination of the direct retinohypothalamic tract (RHT), a secondary visual projection from the intergeniculate leaflet, the geniculohypothalamic tract (GHT), and upon the distribution of distinct, peptide containing neurons. Vasoactive intestinal polypeptide (VIP) immunoreactive cell bodies and fibers are found in the ventrolateral subdivision. Vasopressin (VP) immunoreactive cell bodies and fibers are found in the dorsomedial subdivision. The VP positive fibers also extend ventrally to form a capsule around the region of VIP immunoreactivity and the zone of RHT and CHT termination. The current study addressed the question of whether the SCN will develop when isolated from its normal environment.

Embryonic hypothalamic explants were placed in the anterior chamber of the eye of young adult rats. Embryonic day 13 explants allowed to develop for 14 or 30 days did not contain structures identifiable as SCN, but after 45 days, explants contained SCN-like cell groups, which appeared as dense, roughly elipsoid masses of tightly packed, small cells (10-15um) in Nissl stains. Immunohistochemistry showed a group of VIP positive cells and fibers that were in close apposition to a group of VP positive cells and fibers. The VP fibers extended in a cap around the region of VIP immunoreactivity in a pattern quite similar to that seen in the normal rat SCN. The SCN-like structure was closely apposed to a bud of cartilage. After 60 days of development, one explant also contained an SCN-like structure. In this case the VP staining was lighter and only partly surrounded the region of VIP immunoreactivity. In addition, there was no adjacent piece of cartilage.

Explants taken from E14 embryos also showed the development of an SCN-like structure. This was not evident at 45 days, but at 60 days, all explants contained SCN-like neuronal groups which contained dense VIP immunoreactivity adjacent to a region of VP immunoreactivity. Explants taken from older embryos (E15-16) demonstrated distinct fields of differentiated neurons which did not exhibit either VP, VIP or LHRH immunoreactivity and did not contain discrete identifiable nuclei.

These data can be summarized as follows: 1) the SCN will develop in an in vivo explant system; 2) the nuclei differentiate normally as expressed by the organization of VP and VIP containing neurons; 3) the cells of the germinal epithelium that give rise to the SCN are committed to form the nuclei as early as day 13 of embryonic development. Supported by USPHS Grant NS17600.

115.4 IN VITRO SUPRACHIASMATIC NUCLEUS RHYTHM FOR UPTAKE OF 14C-2-DEOXYGLUCOSE. G. Newman, P. Wu* and F. Hospod*. Department of Neurology, SUNY, Stony Brook, New York 11794.

The suprachiasmatic nucleus (SCN) appears to contain the endogenous circadian rhythm generator in mammals. In vivo and in vitro studies reveal high SCN neuronal firing rates during (subjective) day and low rates at night. 14C-2-deoxyglucose (2DG) uptake into the SCN in vivo also is high in the day and low at night. However, further insight into the biochemical mechanism of circadian rhythm generation is inhibited by the inaccessibility of the in vivo SCN and lack of an in vitro biochemical model.

Rats were maintained in a 12:12 light-dark cycle for 3 weeks. After decapitation, 400μ slices were prepared from hypothalamus and incubated in a chamber designed for biochemical and morphological studies of slice preparations (see Abstract by Hospod et al). After incubation the slices were exposed to 14C-2DG (0.5μCi/ml), rinsed, cryostat-sectioned to 20μ and developed 1 week on x-ray film. Sections with SCN were identified by Nissl staining. Densitometry measurements were made in a "blind" manner for 3 SCN regions and adjacent hypothalamus, 1mm from the SCN, (AHT) throughout the length of the SCN.

In the first experiment, slices were incubated for 1 hour and than exposed to 14C-2DG for 6 minutes. All middle-SCN sections from 3 rats were used for each time point. Slices exposed to 14C-2DG at CT0300 and CT0900 (lights on at CT0000) showed SCN radioactivity 75% greater than AHT. The SCN of slices exposed at CT1600 and CT2000 were less than 30% and those at CT2300 were 37% above AHT.

In the second experiment, 3 rats were sacrificed at CT1900 with exposure to 14C-2DG for 6 minutes at CT0300 and 3 were sacrificed at CT0800 with 14C-2DG exposure at CT1600. Thus radioactive exposure occurred in the phase opposite sacrifice. Slices exposed at CT0300 showed SCN radioactivity 75% above AHT and SCN of slices exposed at CT1600 were 18% of AHT. Microscopic results are presented in our companion abstract.

These results demonstrate that the SCN, in an in vitro hypothalamus slice preparation, continues to take up 2-deoxyglucose consistent with the circadian phase of the sacrificed animal even when incubation times cross phase transitions. Data is being analyzed to identify regional differences. Biochemical studies of protein synthesis and phosphorylation, ion concentrations and cyclic nucleotides are in progress.

115.5 CIRCADIAN PATTERNS OF VASOPRESSIN SECRETION AND SCN NEURONAL ACTIVITY IN VITRO. Steven M. Reppert and Martha U. Gillette Children's Service, Massachusetts General Hospital Boston, MA 02114 and Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61810.

The nonapeptide arginine vasopressin exhibits a prominent circadian rhythm in the cerebrospinal fluid (CSF) of numerous mammals. Brain lesion studies in rats show that the hypothalamic suprachiasmatic nuclei (SCN), the site of a circadian pacemaker, are necessary for the generation of the CSF rhythm. Since the SCN are capable of synthesizing vasopressin, the nuclei may be the actual source of the CSF vasopressin rhythm. We investigated this by examining the pattern of vasopressin release in vitro from perifused hypothalamic slices in which the SCN show a rhythm in single unit firing rate.

Adult male Long-Evans rats housed in diurnal lighting (12 hr light per day) were sacrificed, their brains were removed, and the hypothalami were blocked and cut into 400 um sections. Slices (n=3) containing only SCN (and not supraoptic and paraventricular nuclei) were put into a chamber that was perifused with Earl's balanced salts medium supplimented with Na_2CO_3 and glucose and bubbled with 95% O_2 and 5% CO_2. Single unit firing rates were recorded and analyzed over a 30-hr period (Gillette, this volume). The perifusate was collected as 4-hr fractions, and each fraction was acidified and passed through a C 18 Sep-Pak column. Vasopressin was eluted off the column, the effluent was dried, and the residue was reconstituted in assay buffer. Vasopression concentrations were determined by RIA.

Both vasopressin release and firing rates manifested clear daily rhythms. The rhythms expressed proper circadian timing based on the circadian time of the donor animal; that is the peak amplitude of both rhythms occurred during what would have been the daytime (subjective day) of the donor animal. The phase of the vasopressin rhythm was close to that expected in CSF with levels rising before lights on and peaking 4 to 8 hr into the subjective day. Interestingly, the peak in vasopressin secretion preceded the peak in single unit firing rate.

The results suggest that the SCN provide both the timekeeping information and secretory stores of vasopressin that appear in the CSF. The demonstration of two phase distinct oscillatory patterns raises interesting questions about possible interrelationships between neuronal electrical activity and vasopressin secretion.

115.6 CIRCADIAN RHYTHMS OF VASOPRESSIN RELEASE FROM PERIFUSED RAT SUPRACHIASMATIC EXPLANTS IN VITRO. D.J. Earnest and C.D. Sladek. Depts. of Anatomy and Neurology, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Numerous studies have established that the suprachiasmatic nucleus (SCN) of the anterior hypothalamus is an important component of the circadian system in mammals. Consistent with its role in the generation of a variety of physiological and behavioral rhythms, recent work suggests that intrinsic properties of the SCN oscillate on a circadian basis. In this regard, we have demonstrated that vasopressin (VP), which constitutes a major peptidergic component of the rat SCN, is released in a circadian fashion for at least four cycles from SCN explants in static organ culture. Using a perifusion culture technique, the present study was designed to extend these findings and to develop a system capable of providing better resolution of the waveform of the VP rhythm.

Suprachiasmatic explants were excised from the brains of decapitated male Sprague-Dawley rats (125-150g) that had been maintained on LD 12:12. The explants consisted of tissue blocks approximately 1mm on a side and included only the paired suprachiasmatic nuclei, their rostral projections to the organum vasculosum of the lamina terminalis and the underlying optic chiasm. Each of these preparations was cultured in a polysulfone chamber in constant darkness and perfused with medium at a constant flow rate (i.e., 0.25 or 0.4ml/hr). Following a period of equilibration, serial samples of the perfusate were collected at 2hr intervals for four days. VP concentration in the medium was determined by radioimmunoassay.

The total daily VP output from the SCN explants remained constant throughout the four-day sampling period; individual explants released an average of 120pg of VP per 24hr. However, VP concentration in the perfusate fluctuated rhythmically during the course of a day; the VP rhythm, which persisted for 2-3 cycles, was characterized by peak levels of release during the subjective day and minimal levels during the subjective night (3- to 5-fold difference). Importantly, the rhythmic pattern of vasopressin release was quite uniform among individual SCN explants; the daily increase in vasopressin release began late in the subjective night while the decrease occurred near the middle of the subjective day. These results indicate that the rhythm of vasopressin release from individual perifused rat SCN explants is similar to that observed with static organ cultures and thus provide a basis for utilizing the perifusion culture technique to examine the biochemistry and physiology of circadian oscillators in mammals.

115.7 OSCILLATION OF CYCLIC NUCLEOTIDE AND MELATONIN RELEASE IN THE DYNAMIC CULTURE OF AVIAN PINEAL. S.S. Nikaido* and J. S. Takahashi (SPON: D. Ferster). Department of Neurobiology and Physiology, Northwestern University, Evanston, Illinois 60201.

The avian pineal gland expresses a circadian oscillation of serotonin N-acetyltransferase activity and of melatonin release in vitro. In addition, light-dark cycles can entrain the rhythm of melatonin release in culture. Previous studies, in which drugs were applied and cyclic nucleotide and enzyme levels were measured in vitro, have suggested that cyclic nucleotides may be involved in the regulation of the enzyme, serotonin N-acetyltransferase. Measurement of cyclic AMP and cyclic GMP levels in cultured chick pineal glands has shown a reduction in the levels of both nucleotides with light exposure of the glands. The reduction of cyclic AMP and cyclic GMP levels by light preceded the reduction of serotonin N-acetyltransferase activity by light. Pharmacological experiments have strongly suggested that regulation of this enzyme occurs with changes in cyclic AMP rather than cyclic GMP.

To determine whether or not cyclic AMP levels oscillate in a light-dark cycle, chick pineal glands were cultured in a flow-through superfusion system. Both melatonin and cyclic AMP were measured by radioimmunoassay from samples collected every two hours over a 86-hour period. In this dynamic culture system, chick pineal glands expressed an oscillation of cyclic AMP release in a 12:12 LD cycle. The cyclic AMP oscillation is in phase with the entrained rhythm of melatonin release also seen in the organ culture. Levels of cyclic AMP release vary from 500 fmoles of cyclic AMP per hour during light to 2000 fmoles of cyclic AMP per hour during darkness. Addition of isobutylmethyl xanthine (IBMX) to the superfusion medium resulted in a loss of the rhythm of melatonin release. However, a rhythm of cyclic AMP release was sustained at levels which were approximately ten times the levels seen without IBMX. Preliminary experiments show that the oscillation of cyclic AMP release persists for up to three cycles in constant darkness.

Although a clear relationship between cyclic nucleotide levels and serotonin N-acetyltransferase activity has not been established, the concurrent oscillations of cyclic AMP and melatonin release suggests that cyclic AMP has a role in driving the circadian rhythm of melatonin release. The mechanisms governing the oscillation of cyclic AMP are not known, but they should be tractable to experimental analysis with currently available methods.

115.8 THE SUPRACHIASMATIC NUCLEI (SCN) OF THE CAT AND GUINEA PIG. J. Speh*, V.M. Cassone and R.Y. Moore (Spon. A. Rosen). Departments of Neurology and Neurobiology and Behavior, SUNY @ Stony Brook, Stony Brook, New York, 11794.

The SCN is a circadian pacemaker in the mammalian brain (Moore, '83). In the rat (Moore and Card, '85), hamster (Card and Moore, '84) and monkey (Moore and Card, '82), the SCN has a distinctive organization. Visual afferents from the retina, the retinohypothalamic tract (RHT), and from the intergeniculate leaflet of the thalamus (GHT), terminate in the ventrolateral subdivision of the SCN, an area that also contains a large population of vasoactive intestinal polypeptide (VIP)-immunoreactive neurons. In contrast, the dorsomedial division of the SCN receives no direct visual input and contains a large population of vasopressin (VP) immunoreactive neurons. Glutamic acid decarboxylase (GAD)-immunoreactive neurons are present throughout the SCN.

The present study was carried out to determine whether the organization of the SCN in two crepuscular mammals, the guinea pig and cat, is similar to that in the species noted above. The distribution of the RHT was shown by the autoradiographic tracing method following injection of tritiated proline into the eye. The distribution of the GHT, a neuropeptide Y (NPY)-containing pathway, was analyzed by the immunohistochemical demonstration of NPY. The distribution of VIP, VP and GAD-containing neurons was also shown by immunohistochemistry.

As in other mammals, the RHT and GHT in the guinea pig and cat terminate selectively within a subdivision of the SCN which is distinguished by a dense packing of neurons and the presence of a large population of VIP-immunoreactive cells. The VIP neurons are restricted to the portion of the nucleus receiving visual input and give rise to an axonal plexus which extends throughout the SCN and dorsally through the anterior hypothalamic nucleus to terminate at the ventral border of the paraventricular nucleus. Although there appear to be fewer VP-immunoreactive neurons in the guinea pig and cat SCN than are apparent in the rat or monkey, these cells are confined to the dorsomedial aspect of the SCN. Axons exhibiting VP-like immunoreactivity are similar to the VIP immunoreactive plexus in that fibers not only arborize throughout the SCN, but also project dorsally to terminate along the ventral border of the paraventricular nucleus. Neurons exhibiting GAD-like immunoreactivity occur in both SCN subdivisions and give rise to an extremely dense axonal plexus which is continuous into the immediately adjacent periventricular nucleus.

These data reiterate the consistency in organization of the SCN in divergent mammalian species and also provide evidence for two functionally distinct subdivisions of this nucleus. Supported by NIH grant NS-16304.

115.9 MAGNOCELLULAR NEURONS ADJACENT TO THE SCN ARE LABELLED BY INTRAVENOUS INJECTION OF HRP. T.G. Youngstrom and A.A. Nunez. Dept. of Psychology and Neuroscience Program, Michigan State University, E. Lansing, MI. 48824.

Studies of the retino-hypothalamic tract (RHT) in mammalian species utilizing horseradish peroxidase (HRP) have reported reaction product (RXP) in regions dorsal and lateral to the boundary of the suprachiasmatic nuclei (SCN). The SCN have, to date, been the only hypothalamic nuclei reliably reported as receiving RHT fibers. Intravenous (I.V.) application of HRP was used to determine the likelihood of HRP so transported, contributing RXP to that observed within or just outside the SCN after intraocular injections of the enzyme. Adult males of three species (house mouse-Mus musculus; deer mouse-Peromyscus maniculatus bairdi; white-footed-Peromyscus leucopus) were injected with 9 µl of 50% (w/v) HRP (Sigma Type VI) in physiological saline. Survival periods of 1 to 24 hr were used. Brains were prepared for histological examination using the chromogen 3,3',5,5'-tetramethylbenzidine. In all cases of 4 hours or greater survival, a large number of magnocellular neurons within the supraoptic and paraventricular nuclei were labelled with RXP, and RXP was also seen in a few magnocellular neurons immediately adjacent to the third ventricle. Compared to those of house mice, brains of deer and white-footed mice contained more labelled magnocellular units immediately dorsal-lateral to the SCN , and in lateral hypothalamus. These anatomical differences may be related to species differences in response to changes in photoperiod. The present results indicate that following intraocular injections, some of the RXP detected dorsal and lateral to the SCN previously interpreted as originating from the retinal ganglion cells may be the result of vascular transport of HRP. The presence of labelled cells near SCN after IV injections suggest a mechanism by which SCN neurons may affect or be affected by circulating blood constituents. 115.10 THE DEVELOPMENT OF CYTOCHROME OXIDASE ACTIVITY WITHIN THE SCN OF THE CAT. D. M. Murakami* and C. A. Fuller. Dept. of Animal Physiology, University of California, Davis, CA 95616.

Previously we have demonstrated the presence of a high metabolic region within the ventral suprachiasmatic nucleus (SCN) of the rat and cat (Fuller et al., Soc. Neurosci. Abstr. 10:503, 1984). This region of high activity in the cat was confined to those corinal sections containing the middle portion of the ventral SCN. Anterior and posterior portions of the SCN did not exhibit metabolic differences between dorsal and ventral regions. The dorsal region from the middle portion of the SCN and the anterior and posterior portions of the SCN exhibited significantly less metabolic activity than the surrounding medial and lateral hypothalamic (LH) areas.

In this study we have examined the development of metabolic activity within the SCN using the cytochrome oxidase (CyOX) method. Coronal sections through the SCN were taken from cats two weeks of age through adulthood. One series of sections was stained with thionin to reveal the nuclear boundaries. Alternate sections were stained for CyOX in order to reveal the metabolic activity within the SCN at the various stages of development. A microdensitometer was used to quantify the intensity of CyOX staining within the various regions of the SCN and for comparison in the lateral hypothalamus.

From 2 to 4 weeks of age there are no dorsal-ventral differences in CyOX staining within the SCN. However, between 4 and 6 weeks of age there is a dramatic increase in CyOX staining within the ventral SCN. This increase in metabolic activity is confined to the middle portion of the SCN, while anterior and posterior portions do not exhibit dorsal-ventral differences. From 2 to 6 weeks of age the anterior and posterior portions and the dorsal region from the middle portion of the SCN are equal in CyOX staining to the LH. However, after 6 weeks of age these areas of the SCN gradually decrease in CyOX staining until they stain significantly less intensely than the LH.

This study has shown that, within the middle portion of the SCN, the ventral region is a critical locus of high metabolic activity that matures dramatically between 4 and 6 weeks of age. This ventral SCN region is known to be the primary receiving area for afferent input, and the change in metabolic activity may reflect the maturation of these afferents. A decrease in metabolic activity in the other regions of the SCN appears to correlate with an extended period of neural development.

115.11 THE SUPRACHIASMATIC NUCLEUS OF THE ADULT MACAQUE: AN ULTRASTRUCTURAL ANALYSIS. S.L. Dewey, J.P. Card & R.Y. Moore. Departments of Neurology and Neurobiology and Behavior, SUNY @ Stony Brook, Stony Brook, New York, 11794.

The suprachiasmatic nucleus (SCN) of the rat and hamster (Moore, '83; Card and Moore, '84) is characterized by subdivisions which are distinguished by the differential termination of visual afferents and the location of immunohistochemically distinct neurons. Visual afferents arising from the retina and lateral geniculate nucleus terminate in the ventrolateral (VL) aspect of the nucleus, an area containing vasoactive intestinal polypeptide immunoreactive neurons. The dorsomedial (DM) SCN receives no direct visual input and contains vasopressin immunoreactive neurons. Ultrastructural studies of the rat SCN have shown that neurons in these subfields are also morphologically distinct.

The monkey SCN also contains subdivisions which can be distinguished using the same criteria established in rodents (Moore & Card, '82). In the present study the subdivisions of the macaque SCN were studied with transmission electron microscopy to determine if homologies also exist in the ultrastructural organization of the monkey and rodent SCN. As in the rat, this analysis revealed at least two morphologically distinct populations of neurons. The compact, retinal recipient portion of the SCN contains spherical to slightly oval neurons which exhibit multiple invaginations of the cell nucleus and an organelle rich cytoplasmic matrix. These cells have few axo-somatic synaptic contacts and are consistent in morphology with the neurons in the VL subdivision of the rat SCN. This portion of the nucleus is also distinguished by the presence of numerous axon terminals which contain lucent mitochondria, large numbers of lucent spherical vesicles and occasional dense core vesicles. These terminals synapse upon distal dendrites and spines and their morphology is consistent with that previously reported for retinal afferents in the monkey lateral geniculate nucleus and the SCN of other species. The second class of morphologically distinct neurons are confined primarily to the area of the SCN surrounding the compact cell mass. Cells in this subdivision are bipolar and are characterized by occasional fingerlike invaginations of the cell nucleus. Organelles are concentrated at the poles of the cell and are not nearly as numerous as in the first cell type. The morphology of this cell type is consistent with that reported for neurons in the DM aspect of the rat SCN.

Taken together, these data support previous conclusions regarding parcellation of the macaque SCN and emphasize the consistency in the organization of this nucleus in divergent mammalian species. Material was kindly provided by Dr. Anita Hendrickson, University of Washington Regional Primate Center. Supported by HIH grants NS-16304 and NS-19714.

115.12 MAGNOCELLULAR NEUROSECRETORY AXONS TERMINATING IN THE THIRD VENTRICLE OF THE GOLDEN HAMSTER BRAIN: ULTRASTRUCTURAL AND IMMUNOHISTOCHEMICAL CHARACTERIZATION. J.A. Mitchell and J.P. Card. Department of Anatomy, Wayne State University, Detroit, Michigan 48201 and Department of Neurology, SUNY @ Stony Brook, Stony Brook, NY.

Several investigations have established that vasopressin is present in the cerebrospinal fluid (CSF) and that levels of the peptide exhibit circadian fluctuations which are entrained to the light-dark cycle. In the present study we have utilized light microscopic immunohistochemistry and transmission electron microscopic analysis to determine the location of neurons in the golden hamster brain which secrete vasopressin into the CSF and to define the neural circuitry which modulates its circadian fluctuation in the CSF. Vasopressin-containing neurons are concentrated primarily within the suprachiasmatic (SCN), paraventricular (PVN) and supraoptic (SON) nuclei of the hypothalamus. Consequently, we employed immunohistochemical localization of vasopressin to determine if neurons in any of these nuclei gave rise to processes which penetrated the ependymal lining to terminate in the ventricular lumen. Since the SCN is known to be the primary neural locus responsible for the control of circadian rhythmicity our initial efforts were concentrated on this nucleus. Systematic analysis of closely spaced sections through the SCN demonstrated large numbers of parvocellular vasopressin neurons in the dorsomedial aspect of the SCN. These cells gave rise to an extensive plexus of thin, varicose axons which arborized within the SCN and also projected dorsally to terminate at the ventral limit of the PVN. However, immunoreactive fibers arising from the SCN neurons never entered the ventricular lumen. This was also true of the PVN and SON; large numbers of immunoreactive cells and fibers were present in both nuclei, but processes never entered the ventricle in the vicinity of either cell group. In contrast, magnocellular axons in the median eminence (ME), which arise from neurons in the PVN and SON, were routinely observed entering the CSF through the floor of the third ventricle. Ultrastructural analysis of the ME confirmed the immunohistochemical observations. Large magnocellular axons containing massive accumulations of large, dense core vesicles penetrated the ependymal lining of the ventricle floor and terminated within the CSF. The SCN is known to project to both the PVN and SON and we therefore suggest that while magnocellular axons arising from neurons in one or both of these nuclei account for secretion of vasopressin into the CSF, the circadian release of the peptide into the CSF is controlled via the projection of the SCN to these nuclei. Supported by RR-05387 (JAM) and NS-19714 (JPC).

OPIATES, ENDORPHINS AND ENKEPHALINS: BIOCHEMICAL CHARACTERIZATION

116.1 PURIFICATION OF ENKEPHALINS AND ENKEPHALIN-CONTAINING PEPTIDES ON BIO-REX 70. S.P. Wilson. Department of Pharmacology, Duke University Medical Center, Durham, NC 27710.

During studies on enkephalins and enkephalin-containing peptides (ECPs) in adrenal medullary chromaffin cells, a technique for partial purification of the peptides before further analysis was required because a number of endogenous and exogenous substances interfere with the enkephalin radioreceptor assay employed. In addition, removal of contaminating peptides and other small molecules before analysis by high performance liquid chromatography was desired. Chromatography on the acrylic ion-exchange resin Bio-Rex 70 proved to be a convenient technique for the partial purification of ECPs.

Bio-Rex 70 was prepared by washing the resin sequentially with 3 M HCl, 3 MNaOH, and 3 M acetic acid and was finally resuspended in 0.1 M acetic acid. Columns of the resin (0.25 cm^3 bed) were prepared in Pasteur pipets plugged with a small amount of glass wool and were washed with 0.1 M acetic acid. The sample was applied to the column in 0.1 M acetic acid (0.5-5 ml) and the column was washed with two 1-ml aliquots of 0.1 M acetic acid. The peptides were eluted from the resin with 2 ml of 1 M acetic acid in methanol. This peptide-containing solution was evaporated to dryness and resuspended in a small volume of 1 M acetic acid. Recoveries of peptide standards, including leu-enkephalin, met-enkephalin (ME), ME sulfoxide, ME-arg^6, ME-arg^6-phe^7, and ME-arg^6-gly^7-leu^8 and of both small and large molecular weight ECPs derived from the adrenal medulla were typically greater than 90%. Losses of ECPs when low amounts of the peptides were applied to the columns could be prevented by preadsorbing 0.5 mg of insulin to the resin bed. Catecholamines and other substances such as the gradient density media sucrose and Renografin were not retained by the resin under the conditions employed. A significant removal of protein and other material with absorbance at 280 nm was also obtained when adrenal medullary extracts were chromatographed. Bio-Rex 70 was superior to other chromatographic media that have been employed for enkephalin purification including Amberlite XAD-2, Porapak Q and Sep-Pak C_{18} cartridges. Columns of Bio-Rex 70 are relatively inexpensive, especially when compared to products such as Sep-Pak cartridges. Hence, this chromatographic technique should prove useful where preliminary purification of peptides derived from proenkephalin A is required and may be adaptable to other peptides as well.

This work was supported by a Grant-in Aid from the American Heart Association and with funds contributed in part by the North Carolina Affiliate.

116.2 METABOLIC PROFILING OF NEUROPEPTIDES BY USE OF RP-HPLC, RECEPTOR ASSAY, RIA, AND MASS SPECTROMETRY. D.M. Desiderio[1,2], F.S. Tanzer*[3], G. Eridland*[2], H. Onishi*[2], H. Takeshita*[2], C. Dass*[2], P. Tinsley*[2], J. Killmar*[2], and G. Wood*[4,5]. [1]Dept. of Neurology, [2]Charles B. Stout Neuroscience Mass Spectrometry Labortory, [3]Dept. of Biologic and Diagnostic Sciences, [4]Dept. of Orthopedics, Univ. Tenn. Center for the Health Sciences, Memphis, TN, 38163; [5]Campbell Clinic, Madison, Memphis, TN 38103.

This research aims towards developing a method to obtain the metabolic profile of endogenous peptides in a biologic matrix. This metabolic profile is used to determine in normal and stressed situations the relationship among several opioid peptidergic families (enkephalinergic, endorphinergic, dynorphinergic, and substance P-ergic) and the individual peptide constituents. These experimental techniques are used to examine peptide-rich fractions prepared from extracts of biologic tissues (brain, pituitary, tooth pulp) and fluids (CSF).

Gradient reversed phase-HPLC is used with acetonitrile as organic modifier and a volatile triethylamine formate buffer to separate individual peptides in a fast and facile manner with high resolution and high recovery. Ninety fractions are collected from the gradient. A canine limbic system (P_2 or synaptosome) preparation is used for the radioreceptor assay where several tritiated ligands are competitively displaced. Radiolabeled etorphin, dihydromorphine, ethylketoazocine, and substance P are used. Commercial RIA kits are used to measure met-enkephalin, leu-enkephalin, and substance P. Fast atom bombardment mass spectrometry is utilized as an objective analytical method because MS offers the highest level of molecular specificity. FAB-MS produces the protonated molecular ion of a peptide, a parameter useful for determining the presence of a particular peptide. However, because of the polymer problem (n amino acids could be linked into n! peptides), amino acid sequence-determining information must also be obtained by increasing the structural resolution of the MS method. Linked-field scanning in the B/E mode is useful to provide amino acid sequence-determining information and for use of quantification of the peptide utilizing an ^{18}O-peptide internal standard.

Results will be presented on the use of these methods for measuring the peptide content in brain regions, pituitary tumors, tooth pulp (controls and stressed), and cerebrospinal fluid (lower back pain patients) and for metabolic profiling of several peptidergic pathways. Work supported by NIH GM 26666.

116.3 RESERPINE-INDUCED ALTERATIONS IN PROENKEPHALIN PROCESSING: INCREASED AMIDATION. I. Lindberg, Dept. of Biochemistry, Louisiana State Univ. School of Medicine, 1100 Florida Ave., New Orleans, LA. 70119
