SOCIETY FOR NEUROSCIENCE

ABSTRACTS

VOLUME 11, PART 1

15th ANNUAL MEETING
DALLAS, TEXAS
OCTOBER 20–25, 1985

Made in the United States of America
International Standard Book Numbers
Part 1 0-916110-19-2
Part 2 0-916110-20-6
Both Parts 0-916110-21-4
Library of Congress Catalog Card Number 75-7761

Proper citation form for this volume:
Soc. Neurosci. Abstr., Vol. 11, Part 1, p. xxx, 1985.

Abstracts in Session Order*	
Monday, October 21 – Wednesday, October 23	1–752

***5086 volunteer abstracts, 18 symposium and workshop abstracts, 4 special lecture abstracts.**

1985 PROGRAM COMMITTEE

Perry B. Molinoff, M.D., *Chairperson*
University of Pennsylvania School of Medicine

Neal H. Barmack, Ph.D.
Neurological Sciences Institute, Portland

Ellen F. Barrett, Ph.D.
University of Miami Medical School

Monroe W. Cohen, Ph.D.
McGill University

David P. Corey, Ph.D.
Massachusetts General Hospital

Harold Gainer, Ph.D.
National Institutes of Health

Irving Kupfermann, Ph.D.
New York State Psychiatric Institute

Raymond J. Lasek, Ph.D.
Case Western Reserve University

Paul R. Lennard, Ph.D.
Emory University

Jennifer S. Lund, Ph.D.
University of Pittsburgh School of Medicine

Jeffrey F. McKelvy, Ph.D.
State University of New York, Stony Brook

Jose L. Ochoa, M.D., Ph.D.
University of Wisconsin Medical School

Maryann Ruda, Ph.D.
National Institutes of Health - National Institute of Dental Research

Lawrence P. Schramm, Ph.D.
Johns Hopkins University School of Medicine

Nicholas C. Spitzer, Ph.D.
University of California, San Diego

Ann E. Stuart, Ph.D.
University of North Carolina

Richard F. Thompson, Ph.D.
Stanford University

James W. Truman, Ph.D.
University of Washington

Joseph T. Coyle, M.D., *Consultant*
Johns Hopkins University School of Medicine

William D. Willis, Jr., M.D., Ph.D., *ex officio*
Marine Biomedical Institute

Bernice Grafstein, Ph.D., *ex officio*
Cornell University Medical College

Bruce S. McEwen, Ph.D., *ex officio*
Rockefeller University

CHRONOLOGICAL LIST OF SESSIONS

(see page ix for Thematic List of Sessions.)

Session Number and Title	Page
MONDAY thru FRIDAY	
388. History of the brain. L. MARSHALL	1326
SUNDAY	
Public Lecture — 8:00 PM	
1. Ion channels in neurobiology: an evolving molecular perspective. R. L. BARCHI	No abstract
MONDAY	
Symposia — 8:30 AM	
2. Actions of nerve growth factor in the central nervous system. *Chaired by:* I.B. BLACK	1
3. Cerebral processes and conscious functions. *Chaired by:* B. LIBET	1
Slide Sessions — 8:30 AM	
4. Cellular aspects of disease: CNS proteins	1
5. Monoamines and behavior I	5
6. GABA and benzodiazepines: cellular and behavioral effects	7
7. Peptides: receptors I	10
8. Development and plasticity: retina and optic nerve	13
9. Sensory systems: visual cortex I	16
10. Regulation of pituitary functions I	18
11. Subcortical somatosensory pathways I	21
12. Spinal cord and brainstem I	24
13. Presynaptic mechanisms I	27
14. Sensory systems: auditory pathways I	30
15. Cardiovascular regulation: ganglionic and spinal mechanisms	33
16. Feeding and drinking: CCK	36
17. Clinical neurophysiology: epilepsy	39
Poster Sessions — 8:30 AM	
18. Other biogenic amines I	42
19. Monoamines and behavior II	47
20. Feeding and drinking I	52
21. Feeding and drinking II	57
22. Specificity of synaptic connections I	62
23. Nutritional and prenatal factors	67
24. Control of posture and movement I	71
25. Oculomotor system I	77
26. Functions of glia I	84
27. Coexistence of transmitters	87
28. Characterization of cholinergic receptors I	91
29. Characterization of cholinergic receptors II	95
30. Synaptogenesis and synapse elimination I	98
31. Synapse elimination and competition	100
32. Excitatory amino acids: physiology and pharmacology	103
33. Excitatory amino acids: receptor characterization and localization	108
34. Psychotherapeutic drugs: neuroleptics	112
35. Somatic afferents: central pathways	117
36. Somatic afferents I	119
37. Somatic afferents II	121
38. Pain modulation: human studies	123
39. Pain modulation: peptides, monoamines	124
40. Pain modulation: stress analgesia	127
41. Pain modulation: central pathway mechanisms	129
42. Neurotransmitters and receptors in human disease	132
43. Neurotransmitters and receptors in disease	135
Symposium — 1:00 PM	
44. Behavioral functions of cholecystokinin in the central nervous system. *Chaired by:* J.N. CRAWLEY	140
Workshop — 1:00 PM	
45. Computer-assisted analysis of autoradiographs: applications to the 2-deoxyglucose method. *Chaired by:* D.L. MCEACHRON	140
Slide Sessions — 1:00 PM	
46. Molecular biology of gene expression and nucleic acids I	141
47. Peptides: anatomical localization I	144
48. Action potentials and ion channels I	147
49. Pharmacology of synaptic transmission I	150
50. Neurotoxicity I	153
51. Synaptogenesis and synapse elimination II	156
52. Endocrine effects on development and behavior	159

Session Number and Title	Page
53. Invertebrate sensory processing	163
54. Degenerative diseases: Parkinson's and Alzheimer's disease	166
55. Characterization of cholinergic receptors III	169
56. Pain: central pathways I	171
57. Process outgrowth: growth cones	174
58. Feeding and drinking III	177
59. Cerebellum: olivo-cerebellar circuitry	181
Poster Sessions — 1:00 PM	
60. Psychotherapeutic drugs: aminergic systems	184
61. Cardiovascular regulation	189
62. Basal ganglia: anatomical pathways	199
63. Basal ganglia: immunocytochemistry	203
64. Muscle I	209
65. Reflex function I	213
66. Spinal cord	217
67. Development and plasticity: normal and transplanted visual system	221
68. Sensory systems: visual cortex II	225
69. Sensory systems: subcortical visual pathways I	230
70. Retina and retinofugal projections	235
71. Retina I	238
72. Auditory sensory organs and transduction	243
73. Sensory systems: auditory pathways II	246
74. Regeneration: transplantation and modulatory factors	251
75. Neuronal death	256
76. Other biogenic amines II	262
77. Structure and function of identified cells I	264
78. Neuroethology I	267
79. GABA and benzodiazepines: pharmacology	272
80. GABA and benzodiazepines: receptor characterization and localization I	276
81. GABA and benzodiazepines: electrophysiology	281
82. GABA and benzodiazepines: release and localization	283
83. Pain modulation: intrathecal studies	285
84. Motor systems: motor and sensory integration	286
85. Neural basis of behavior: alcohol I	290
86. Neural basis of behavior: alcohol II	294
87. Neural basis of behavior: alcohol III	297
88. Synaptic structure and function I	302
Special Lecture — 4:00 PM	
89. Neurochemical specialization in the basal ganglia: the old motor system in a new light. A.M. GRAYBIEL	306
Presidential Symposium — 8:00 PM	
90. Neuroscience is good for your health. *Chaired by:* W. D. WILLIS, JR	No abstract

Session Number and Title	Page
TUESDAY	
Symposia — 8:30 AM	
91. Molecular synaptogenesis: transition from growth cone to synapse. *Chaired by:* M.C. FISHMAN	307
92. Coordination of respiratory and cardiovascular homeostasis. *Chaired by:* J.L. FELDMAN	307
Slide Sessions — 8:30 AM	
93. Opioid receptors I	307
94. Catecholamines: receptors I	310
95. Action potentials and ion channels II	313
96. Sensory systems: subcortical visual pathways II	316
97. Vestibular system I	319
98. Structure and function: cortical and subcortical organization I	322
99. Transmitters in invertebrates I	325
100. Control of movement: arm and wrist	328
101. Learning and memory: anatomy I	331
102. Process outgrowth: guidance mechanisms	334
103. Retina II	337
104. Interactions between neurotransmitters I	339
105. Feeding and drinking IV	342
106. Uptake storage and secretion I	346
Poster Sessions — 8:30 AM	
107. Peptides: anatomical localization II	349
108. Molecular biology of gene expression and nucleic acids II	353
109. Regulation of pituitary functions II	357
110. Basal ganglia: immunocytochemistry and physiology	362
111. Invertebrate learning and behavior I	366
112. Acetylcholine I	370
113. Brain metabolism I	374
114. Learning and memory: pharmacology I	379
115. Biological rhythms I	384
116. Opiates, endorphins and enkephalins: biochemical characterization	387
117. Limbic system: development and plasticity I	390
118. Metabolic studies	392
119. Functions of glia II	395
120. Developmental disorders I	398
121. Spinal cord and brainstem II	401
122. Muscle II	406
123. Pain: central pathways II	410
124. Peptides: receptors II	413
125. Regeneration: neuronal and glial responses	418
126. Psychotherapeutic drugs: anxiolytics	423
127. Catecholamines: effects of MPTP	427
128. Electroencephalography and evoked potentials	429

Session Number and Title	Page
129. Diseases of the nervous system: ischemia, trauma	432
130. Staining and tracing techniques	437
131. Metabolism of transmitters and modulators I	442
132. Diseases of the nervous system: genetic diseases, models	444
133. Development and plasticity: olfactory system	446
134. Development and plasticity: sensory system I	448
135. Development and plasticity: sensory system II	450
Special Lecture — 11:30 AM	
136. MPTP-induced Parkinsonism: mechanisms of toxicity and selective vulnerability. I.J. KOPIN	454
Symposia — 1:00 PM	
137. Physiological and biochemical basis of fatigue in the motor units of mammals. *Chaired by:* E. HENNEMAN	454
138. Molecular bases of the immune response to neural antigens. *Chaired by:* L.A. LAMPSON	454
Slide Sessions — 1:00 PM	
139. Catecholamines: dopamine receptors I	455
140. Learning and memory: anatomy II	458
141. Development and plasticity: visual pathways I	461
142. Postsynaptic mechanisms I	465
143. Opioids: physiological studies I	468
144. Oculomotor system II	471
145. Retina III	474
146. Circuitry and pattern generation I	477
147. Transmitters in invertebrates II	480
148. CNS neurons: vertebrate and invertebrate I	483
149. Peptides: biosynthesis and metabolism I	486
150. Cardiovascular regulation: bulbar mechanisms	489
151. Limbic system: development and plasticity II	492
152. Neuroethology II	495
Poster Sessions — 1:00 PM	
153. Catecholamines: release of dopamine	499
154. Structure and function: cortical and subcortical organization II	501
155. CNS neurons: vertebrate and invertebrate II	506
156. Invertebrate motor function	510
157. Presynaptic mechanisms II	514
158. Action potentials and ion channels III	516
159. Neurotoxicity II	521
160. Learning and memory: physiology I	525
161. Endocrine control of development I	528
162. Learning and memory: pharmacology II	533
163. Biological rhythms II	536
164. Endocrine control	541
165. Neuroethology III	546
166. Monoamines and behavior III	549
167. Feeding and drinking V	554
168. Subcortical somatosensory pathways II	559
169. Peptides: biosynthesis and metabolism II	563
170. Interactions between neurotransmitters II	568
171. Modulators I	572
172. Pain: central pathways III	577
173. Opioid receptors II	580
174. Process outgrowth: guidance mechanisms, growth cones	584
175. Regeneration: patterns and responses	588
176. Drug effects on receptors	594
177. Biochemical and pharmacological correlates of development I	598
178. Morphogenesis and pattern formation I	603
179. Uptake storage and secretion II	608
180. Neural plasticity in adult animals I	612
181. Neuropeptides and behavior I	617
182. Neuropeptides and behavior II	619
183. Neuropeptides and behavior: vasopressin	622
184. Structure and function of identified cells II	624
185. Effects of chronic drug administration I	628
186. Effects of chronic drug administration II	632
Grass Foundation Lecture — 8:00 PM	
187. Logistics of brain development. P. RAKIC	No abstract

WEDNESDAY

Session Number and Title	Page
Symposia — 8:30 AM	
188. Peptide-amine interactions in the neural regulation of cell function. *Chaired by:* A. NEGRO-VILAR and B. MCEWEN	637
189. Neural basis of lateralized behavior: from laboratory to clinic. *Chaired by:* R.G. ROBINSON	637
Slide Sessions — 8:30 AM	
190. Pain modulation: stimulation studies	637
191. Invertebrate learning and behavior II	641
192. Synaptic structure and function II	644
193. Cell lineage: differentiation and development I	647
194. Sensory systems: visual cortex III	650
195. Characterization of cholinergic receptors IV	653
196. Regulation of pituitary functions III	656
197. Trophic agents I	659
198. Neural control of immune system I	662
199. Regional localization of receptors and transmitters I	665
200. Transmitters: phenotypic plasticity	667
201. Behavioral pharmacology: aminergic systems	669
202. Blood brain barrier I	672
Poster Sessions — 8:30 AM	
203. Structure and function: cortical and subcortical organization III	675

Session Number and Title	Page
204. Peptides: anatomical localization III	679
205. Basal ganglia: electrophysiology and behavior	684
206. Cerebellum: anatomy, pharmacology and cellular physiology	688
207. Vestibular system II	693
208. Reflex function II	698
209. Control of posture and movement II	702
210. Physiological effects of peptides I	707
211. Catecholamines: dopamine receptors II	712
212. Monoamines and behavior IV	717
213. Aging: neural basis of behavior	721
214. Development and plasticity I: aging	727
215. Sensory systems: auditory pathways III	733
216. Hormonal control of behavior	736
217. Interactions between neurotransmitters III	742
218. Modulators II	746
219. Somatosensory cortex (con't. in Part 2)	750

CONTINUED IN SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 11 PART 2

THEMATIC LIST OF SESSIONS

(Includes slide and poster sessions, symposia, and workshops only.)

Theme A: Development and Plasticity

Session Number	Session Title	Type	Day and Time
2.	**Actions of nerve growth factor in the central nervous system**	**Symp.**	**Mon AM**
337.	Autonomic nervous system	Poster	Thu PM
177.	Biochemical and pharmacological correlates of development I	Poster	Tue PM
328.	Biochemical and pharmacological correlates of development II	Slide	Thu PM
354.	Biochemical and pharmacological correlates of development III	Poster	Thu PM
193.	Cell lineage: differentiation and development I	Slide	Wed AM
236.	Cell lineage: differentiation and development II	Slide	Wed PM
309.	Cell lineage: differentiation and development III	Poster	Thu AM
214.	Development and plasticity I: aging	Poster	Wed AM
261.	Development and plasticity II: aging	Poster	Wed PM
376.	Development and plasticity: motor systems	Poster	Fri AM
67.	Development and plasticity: normal and transplanted visual system	Poster	Mon PM
133.	Development and plasticity: olfactory system	Poster	Tue AM
8.	Development and plasticity: retina and optic nerve	Slide	Mon AM
134.	Development and plasticity: sensory system I	Poster	Tue AM
135.	Development and plasticity: sensory system II	Poster	Tue AM
141.	Development and plasticity: visual pathways I	Slide	Tue PM
235.	Development and plasticity: visual pathways II	Slide	Wed PM
298.	Development and plasticity: visual system plasticity	Poster	Thu AM
267.	Development of invertebrates I	Poster	Wed PM
282.	Development of invertebrates II	Slide	Thu AM
120.	Developmental disorders I	Poster	Tue AM
366.	Developmental disorders II	Slide	Fri AM
161.	Endocrine control of development I	Poster	Tue PM
262.	Endocrine control of development II	Poster	Wed PM
52.	Endocrine effects on development and behavior	Slide	Mon PM
388.	History of the brain	Poster	Mon AM
117.	Limbic system: development and plasticity I	Poster	Tue AM
151.	Limbic system: development and plasticity II	Slide	Tue PM
91.	**Molecular synaptogenesis: transition from growth cone to synapse**	**Symp.**	**Tue AM**
178.	Morphogenesis and pattern formation I	Poster	Tue PM
292.	Morphogenesis and pattern formation II	Poster	Thu AM
180.	Neural plasticity in adult animals I	Poster	Tue PM
225.	Neural plasticity in adult animals II	Poster	Wed AM
269.	Neural plasticity in adult animals III	Poster	Wed PM
284.	Neural plasticity in adult animals IV	Slide	Thu AM
318.	Neural plasticity in adult animals V	Poster	Thu AM
75.	Neuronal death	Poster	Mon PM
50.	Neurotoxicity I	Slide	Mon PM
159.	Neurotoxicity II	Poster	Tue PM
293.	Neurotoxicity III	Poster	Thu AM
350.	Neurotoxicity IV	Poster	Thu PM
333.	Neurotransmitters: phenotypic plasticity	Slide	Thu PM

23.	Nutritional and prenatal factors	Poster	Mon AM
57.	Process outgrowth: growth cones	Slide	Mon PM
102.	Process outgrowth: guidance mechanisms	Slide	Tue AM
174.	Process outgrowth: guidance mechanisms, growth cones	Poster	Tue PM
221.	Process outgrowth: molecular mechanisms	Poster	Wed AM
287.	Regeneration I	Slide	Thu AM
367.	Regeneration II	Slide	Fri AM
125.	Regeneration: neuronal and glial responses	Poster	Tue AM
175.	Regeneration: patterns and responses	Poster	Tue PM
74.	Regeneration: transplantation and modulatory factors	Poster	Mon PM
22.	Specificity of synaptic connections I	Poster	Mon AM
288.	Specificity of synaptic connections II	Slide	Thu AM
266.	Sprouting and sprouting mechanisms	Poster	Wed PM
31.	Synapse elimination and competition	Poster	Mon AM
30.	Synaptogenesis and synapse elimination I	Poster	Mon AM
51.	Synaptogenesis and synapse elimination II	Slide	Mon PM
200.	Transmitters: phenotypic plasticity	Slide	Wed AM
197.	Trophic agents I	Slide	Wed AM
271.	Trophic agents II	Poster	Wed PM
272.	Trophic agents: nerve growth factor	Poster	Wed PM
313.	Trophic agents: neurotrophic factors	Poster	Thu AM
279.	Trophic interactions I	Slide	Thu AM
335.	Trophic interactions II	Poster	Thu PM

Theme B: Cell Biology

Session Number	Session Title	Type	Day and Time
330.	Axonal transport I	Slide	Thu PM
381.	Axonal transport II	Poster	Fri AM
230.	**Biology of isolated brain capillary endothelia: an emerging field in neuroscience**	**Symp.**	**Wed PM**
202.	Blood brain barrier I	Slide	Wed AM
246.	Blood brain barrier II	Poster	Wed PM
319.	Cell surface macromolecules	Poster	Thu AM
4.	Cellular aspects of disease: CNS proteins	Slide	Mon AM
380.	Cellular aspects of disease: nerve, muscle	Poster	Fri AM
26.	Functions of glia I	Poster	Mon AM
119.	Functions of glia II	Poster	Tue AM
291.	Functions of glia III	Slide	Thu AM
224.	Glial and neuronal membrane composition I	Poster	Wed AM
331.	Glial and neuronal membrane composition II	Slide	Thu PM
118.	Metabolic studies	Poster	Tue AM
46.	Molecular biology of gene expression and nucleic acids I	Slide	Mon PM
108.	Molecular biology of gene expression and nucleic acids II	Poster	Tue AM
233.	Molecular biology of gene expression and nucleic acids III	Slide	Wed PM
316.	Molecular biology of gene expression and nucleic acids IV	Poster	Thu AM
324.	Molecular biology of gene expression and nucleic acids V	Slide	Thu PM
130.	Staining and tracing techniques	Poster	Tue AM
77.	Structure and function of identified cells I	Poster	Mon PM
184.	Structure and function of identified cells II	Poster	Tue PM

Theme C: Excitable Membranes, Transduction and Synaptic Transmission

Session Number	Session Title	Type	Day and Time
48.	Action potentials and ion channels I	Slide	Mon PM
95.	Action potentials and ion channels II	Slide	Tue AM
158.	Action potentials and ion channels III	Poster	Tue PM
226.	Action potentials and ion channels IV	Poster	Wed AM
227.	Action potentials and ion channels V	Poster	Wed AM
231.	Action potentials and ion channels VI	Slide	Wed PM
281.	Action potentials and ion channels VII	Slide	Thu AM
346.	Action potentials and ion channels VIII	Poster	Thu PM
148.	CNS neurons: vertebrate and invertebrate I	Slide	Tue PM
155.	CNS neurons: vertebrate and invertebrate II	Poster	Tue PM
176.	Drug effects on receptors	Poster	Tue PM
49.	Pharmacology of synaptic transmission I	Slide	Mon PM
247.	Pharmacology of synaptic transmission II	Poster	Wed PM
295.	Pharmacology of synaptic transmission III	Poster	Thu AM
142.	Postsynaptic mechanisms I	Slide	Tue PM
249.	Postsynaptic mechanisms II	Poster	Wed PM
250.	Postsynaptic mechanisms III	Poster	Wed PM
13.	Presynaptic mechanisms I	Slide	Mon AM
157.	Presynaptic mechanisms II	Poster	Tue PM
248.	Presynaptic mechanisms III	Poster	Wed PM
329.	Sensory transduction	Slide	Thu PM
88.	Synaptic structure and function I	Poster	Mon PM
192.	Synaptic structure and function II	Slide	Wed AM

Theme D: Neurotransmitters, Modulators, and Receptors

Session Number	Session Title	Type	Day and Time
112.	Acetylcholine I	Poster	Tue AM
289.	Acetylcholine II	Slide	Thu AM
360.	Acetylcholine III	Poster	Thu PM
317.	Acetylcholine: receptors	Poster	Thu AM
44.	**Behavioral functions of cholecystokinin in the central nervous system**	**Symp.**	**Mon PM**
348.	Behavioral pharmacology: adrenergic and histaminergic systems	Poster	Thu PM
201.	Behavioral pharmacology: aminergic systems	Slide	Wed AM
378.	Behavioral pharmacology: cholinergic systems	Poster	Fri AM
377.	Behavioral pharmacology: GABA and anxiolytics	Poster	Fri AM
349.	Behavioral pharmacology: neuroleptics and dopamine	Poster	Thu PM
374.	Behavioral pharmacology: phencyclidine and opiates	Poster	Fri AM
347.	Behavioral pharmacology: serotonin	Poster	Thu PM
243.	Catecholamines	Slide	Wed PM
139.	Catecholamines: dopamine receptors I	Slide	Tue PM
211.	Catecholamines: dopamine receptors II	Poster	Wed AM
260.	Catecholamines: dopamine receptors III	Poster	Wed PM
127.	Catecholamines: effects of MPTP	Poster	Tue AM
312.	Catecholamines: electrophysiology	Poster	Thu AM
311.	Catecholamines: morphology and electrophysiology	Poster	Thu AM
94.	Catecholamines: receptors I	Slide	Tue AM
305.	Catecholamines: receptors II	Poster	Thu AM

153.	Catecholamines: release of dopamine	Poster	Tue PM
353.	Catecholamines: synthesis and metabolism	Poster	Thu PM
352.	Catecholamines: tyrosine hydroxylase	Poster	Thu PM
28.	Characterization of cholinergic receptors I	Poster	Mon AM
29.	Characterization of cholinergic receptors II	Poster	Mon AM
55.	Characterization of cholinergic receptors III	Slide	Mon PM
195.	Characterization of cholinergic receptors IV	Slide	Wed AM
27.	Coexistence of transmitters	Poster	Mon AM
238.	Cyclic nucleotides I	Slide	Wed PM
315.	Cyclic nucleotides II	Poster	Thu AM
362.	**Estrogen and the nigrostriatal dopamine system**	**Wksh.**	**Fri AM**
241.	Excitatory amino acids: glutamate and glutamate analogs	Slide	Wed PM
32.	Excitatory amino acids: physiology and pharmacology	Poster	Mon AM
33.	Excitatory amino acids: receptor characterization and localization	Poster	Mon AM
6.	GABA and benzodiazepines: cellular and behavioral effects	Slide	Mon AM
81.	GABA and benzodiazepines: electrophysiology	Poster	Mon PM
79.	GABA and benzodiazepines: pharmacology	Poster	Mon PM
80.	GABA and benzodiazepines: receptor characterization and localization I	Poster	Mon PM
326.	GABA and benzodiazepines: receptor characterization and localization II	Slide	Thu PM
82.	GABA and benzodiazepines: release and localization	Poster	Mon PM
104.	Interactions between neurotransmitters I	Slide	Tue AM
170.	Interactions between neurotransmitters II	Poster	Tue PM
217.	Interactions between neurotransmitters III	Poster	Wed AM
131.	Metabolism of transmitters and modulators I	Poster	Tue AM
240.	Metabolism of transmitters and modulators II	Slide	Wed PM
171.	Modulators I	Poster	Tue PM
218.	Modulators II	Poster	Wed AM
277.	**Molecular insights into GABA-receptor function**	**Symp.**	**Thu AM**
43.	Neurotransmitters and receptors in disease	Poster	Mon AM

2 SYMPOSIUM. ACTIONS OF NERVE GROWTH FACTOR (NGF) IN THE CENTRAL NERVOUS SYSTEM. I.B. BLACK, Cornell University Medical College (Chairperson); H. Thoenen, Max-Planck Inst. for Psychiatry; L. Reichardt, Univ. of California School of Medicine; W.B. Mobley, WRFAIR, Walter Reed Army Medical Center; E. Johnson, Washington Univ. Medical School.

NGF is the prototypical neuronal trophic molecule: it was discovered over 30 years ago, it is the only neurotrophic molecule for which the amino acid sequence is defined, and it has been the molecular model for many concepts of ontogeny and trophic interactions. Until recently, the actions of NGF were thought to be restricted to peripheral neurons of neural crest origin, whereas brain trophic molecules, if any, were unknown. However, within the past 2 years increasing evidence has indicated that NGF regulates development and maintenance of subpopulations of brain neurons. This remarkable realization is the subject of the present symposium.

Hans Thoenen will begin by providing an overview of NGF research before discussing NGF transport in central systems, and the presence of mRNA coding for NGF in the brain. Lou Reichardt will review the central distribution of NGF mRNA, and discuss novel methods for message detection. Bill Mobley will discuss the effects of the trophic factor on developing populations of rat brain neurons in vivo. Ira Black will present work performed with brain neurons in culture, indicating that NGF specifically and selectively enchances growth of cholinergic neurons in rat caudate-putamen and the nucleus basalis complex. Eugene Johnson will discuss recent studies suggesting that the spinal cord dorsal horn contains NGF that regulates development of primary sensory neurons in dorsal root ganglia. The symposium, consequently, is designed to synthesize converging lines of evidence, indicating that NGF plays a critical role in brain development.

3 SYMPOSIUM. CEREBRAL PROCESSES AND CONSCIOUS FUNCTIONS. B. Libet, Univ. of California, San Francisco (Chairperson); J. C. Mazziotta, UCLA; S. A. Hillyard*, Univ. of California, San Diego; G. A. Ojemann, Univ. of Washington, Sch. of Med.; J. C. Eccles, Max Planck Institute, Göttingen.

Conscious, subjective phenomena can be studied directly via introspective reports but only in human subjects. The symposium provides current examples of significant developments in our understanding of this fundamental phenomenon.

Changes in neuronal activity patterns are accompanied by altered rates of metabolism. The latter can be mapped in cerebral cortex both spatially and temporally by the positron emission tomography (PET). Mazziotta will discuss PET findings that describe altered local metabolic patterns in association with conscious sensory responses and motor tasks, in normal and abnormal psychological states.

Certain long-latency event-related brain potentials are reliably associated with the focussing of attention on sensory input channels and the detection of relevant target signals. Hillyard will present evidence suggesting that these electrical waves are manifestations of different aspects of conscious perceptual processing. The P300 wave, in particular, appears to signify the conscious detection of a signal. This relationship can be used to investigate the role of conscious processing in the visually guided behavior of patients with cortical blindness (the "blindsight" phenomenon).

Different aspects of language functions, - in naming, reading, verbal memory, orofacial movements in expression, and phoneme identification -, have been experimentally analysed by Ojemann in cerebral studies on awake neurosurgical patients. Differential mapping of these cortical functions was achieved with electrical stimulation, while electrophysiological field and single neurone recordings enabled some functional analyses.

The initiation of a fully endogenous voluntary act has often been assumed to be a conscious process. Libet reports finding that onset of a cerebral process, the scalp-recorded "readiness-potential" (RP) precedes the appearance of conscious intent by about 400 msec. However, conscious intent precedes the motor act by about 200 msec, and some form of conscious control, for example a veto of actual movement, still remains possible.

The intervention by a non-material mental/conscious event in neural events of the brain can be envisaged within either a monist (e.g., Sperry) or a dualist (e.g., Popper and Eccles) view of mind-brain interaction. Eccles will present a theory of how such an interaction may occur. The theory proposes that a mental event can influence the probabilistic operations of synaptic boutons, by actions in conformity with the physics of probabilistic fields of quantum mechanics.

CELLULAR ASPECTS OF DISEASE: CNS PROTEINS

4.1 **NUCLEUS BASALIS MEYNERT NEURONS CONTAIN THE VITAMIN-D INDUCED CALCIUM BINDING PROTEIN: A CLUE TO ALZHEIMER DISEASE?** M.R. Celio, A.W. Norman*. Anatomisches Institut Universität Zürich, CH-8057 Zürich (Switzerland) and Biochemistry Dept. UCR, Riverside Ca 92521 (USA).

The basal nucleus of Meynert (NBM) comprises clusters of large multipolar neurons in the basal forebrain which are known to provide the major cholinergic input to the cerebral cortex. Central cholinergic pathways are thought to modulate behavioural states and a selective loss of cortical cholinergic markers has been recognized in Alzheimer's disease. We report on the immunohistochemical detection of the 28k Vitamin-D induced calcium-binding protein (CBP) in the neurons of the basal nucleus of Meynert in primates. For this study we perfused squirrel and rhesus monkeys with fixative and cut the brain with a vibrating microtome. The sections were incubated with diluted antisera against the 28k chicken intestinal CBP and processed by the unlabeled antibody method of Sternberger. In the monkey, the magnocellular components of the basal nucleus of Meynert displayed strong immunoreactivity with the antiserum against CBP. The cell bodies (25-30 um in diameter) and the thick diverging stem dendrites were homogeneously stained. In those cortical layers known to receive NBM projections, CBP immunoreactivity was indeed present. The NBM is not the only brain region which contains CBP and CBP is not restricted to cholinergic neurons in the brain. Interestingly, several of the systems containing CBP have been implicated in Alzheimer's disease pathology. For example NBM, Locus coerules, Nucl. Raphe dorsalis, somatostatin containing interneurons of the neocortex, all seem to be affected by the disease process. CBP, therefore, represent a "common denominator" underlying several diverse elements of the pathology of Alzheimer's disease. CBP may play a direct role in the pathogenesis of this neurodegenerative disorder, because it shuttles and buffer Ca^{++}-ions, thus regulating the intracellular calcium distribution and concentration. Malfunctioning or interference with the function of CBP in neurons may render these cells susceptible to intermittent calcium fluctuations and perhaps more prone to accumulate intolerable quantities of calcium. The uncontrolled elevation of the intracellular calcium concentration may lead to protein denaturation and cell death.

4.2 NEURON-SPECIFIC AND NON-NEURONAL ENOLASE (γ AND α SUBUNIT) ISOENZYME IMMUNOREACTIVITY IN CEREBRAL CORTEX OF PATIENTS WITH ALZHEIMER'S DISEASE. D.E. Schmechel (*), P.J. Marangos, B.J. Crain, G.M. Cook (*), A.D. Roses (SPONS: R.P. Erickson). Departments of Medicine, Anatomy and Pathology, Kathleen P. Bryan Alzheimer's Disease Research Laboratory, Duke University Medical Center; Durham VAMC; Durham, NC 27710; NIMH, Bethesda, MD 20205 (PJM).

The cellular localization of the neuron-specific (NSE or γ) and non-neuronal (NNE or α) subunits of the glycolytic enzyme enolase (EC 4.2.1.11) in primate cerebral cortex reveals that neurons are immunoreactive for NSE, but only weakly (+) or non-reactive for NNE. Especially in hippocampus, non-pyramidal neurons (NPN) are strikingly more NSE immunoreactive than most pyramidal neurons. We examined brain tissue from patients with Alzheimer's Disease (AD) to see whether this normal profile might be changed. We used formalin-fixed routine autopsy material (3 elderly controls and 4 patients with pathological diagnosis of AD). Two other patients with clinical AD had rapid autopsies (23 min and 1 hr to brain dissection); tissue from these cases was fixed for 24 hrs in a variety of fixatives in 5 mm slabs (both proved to have AD). Immunocytochemistry for NSE and NNE (human antigens) and somatostatin was carried out by peroxidase methods on 25-50 micron floating sections.

As in normal hippocampus, the hippocampus of all six cases of AD showed strong NSE staining of NPN compared to pyramidal neurons. This distinction is especially clear for NPN located in a loose reticular plate at the oriens-alveus border and in CA4. They remained strongly NSE(+) even in sectors containing pyramidal neurons with neurofibrillary tangles. Other evidence suggests that most of these 'reticular plate' NPN (see Schmechel et al. Neurosci Lett 47: 227, 1984) are somatostatin-containing GABAergic neurons.

The two rapid autopsy cases of AD showed better enolase immunoreactivity similar to surgical specimens of human brain. Both NSE and NNE localization was very consistent even in large sections resembling normal distribution in primates. However, in specific hippocampal subfields, many pyramidal neurons were very weakly NSE (+), but strongly NNE immunoreactive. Such a reversed profile was also seen in sectors of frontal, temporal and parietal lobe, but not in occipital lobe, cerebellum, or surgical samples of normal human temporal lobe.

In summary, the enolase profile of cortical neurons in regions affected by AD may range from normal (ex, preserved strong NSE(+) of 'reticular plate' NPN in hippocampus) to an abnormal pattern reminiscient of immature or axotomized neurons (ex, shift from NSE to NNE of selected hippocampal pyramidal neurons). Since NSE is involved in neuronal glycolysis, the NSE/NNE profile may allow detection of differences in the metabolic state of specific classes of neurons affected by the AD disease process. 4.3 A HYDROPHOBIC DOMAIN OF MICROTUBULE-ASSOCIATED PROTEIN 2 (MAP 2) SHARES ANTIGENS WITH ALZHEIMER NEUROFIBRILLARY TANGLES (NFT). K.S Kosik*, D.J. Selkoe and L.K. Duffy* (SPON: C.G. Rasool), Harvard Medical School, Brigham and Women's Hospital, Boston, MA 02115

NFT are one of the major neuronal structural changes in Alzheimer's disease. The exact molecular composition of the fibers comprising NFT is unknown. Ultrastructural and immunological observations have implicated neurofilament protein and, most recently, MAP 2 or MAP 2 fragments as possible constitutive elements of NFT. The latter finding (Kosik et al., PNAS, 1984) is based upon a monoclonal antibody, referred to as 5F9, which is highly specific for MAP 2 and also reacts with NFT. Characterization of the MAP 2 epitope with which this antibody reacts may provide information about one protein component of NFT. This report describes the isolation and characterization of a MAP 2 cyanogen bromide (CNBr) cleavage product that contains 5F9 immunoreactivity and has markedly different solution properties than the parent molecule. MAP 2 was obtained from calf brain using the taxol method (Vallee, J. Cell Biol., 1982) to prepare microtubules, followed by salt precipitation of tubulin and heat precipitation of MAP 1. Supernates highly enriched in MAP 2 were digested with CNBr for 48 h and resolved by SDS-PAGE. A Western blot of the CNBr cleavage products revealed a 5F9-immunoreactive protein doublet of M_r ~40,000. The CNBr cleavage products were also resolved by HPLC with an acetonitrile gradient over a Vydac C4 column. In the region of 40% acetonitrile, the elution profile showed the immunoreactive 40Kd doublet, a 65Kd doublet, and a 92Kd protein. The hydrophobicity of the immunoreactive 40Kd fragment was suggested by its relatively prolonged retention time, so that it co-eluted with CNBr fragments of considerably higher molecular weight. A portion of the total CNBr fragments of MAP 2 remains insoluble in aqueous buffers under both acidic and basic conditions. These relatively insoluble fragments were identified as the same three that showed prolonged retention time by HPLC; their insolubility contrasts with the properties of intact MAP 2, which is highly soluble under a wide range of salinities and pH's. A single HPLC fraction containing the 40Kd immunoreactive protein was rechromatographed under identical conditions as described above to purify further this fragment. A single amino acid analysis of a 40Kd-enriched fraction suggests an abundance of non-polar, hydrophobic residues, particularly glycine, in this fragment. Its composition is in contrast to that of the parent molecule, which is unusually low in non-polar residues. The other large molecular weight fragments of MAP 2 appear to be highly enriched in glutamic acid and thus bear some resemblance to the neurofilament carboxy-terminal tail pieces. We conclude that the portion of MAP 2 which contains an epitope shared with NFT is unusual in its hydrophobic nature in contrast to the highly charged domains which constitute the major portion of MAP 2. Supported by NIH grants 5KO7 NS00835 and RO1 AG05538 (KSK).

4.4 COMPARATIVE PROTEIN CHEMICAL STUDIES OF SENILE PLAQUE AMYLOID FIBERS AND PAIRED HELICAL FILAMENTS IN ALZHEIMER'S DISEASE. D. Selkoe, C. Abraham* and L. Duffy*. Harvard Medical School, Brigham and Women's Hospital, Boston, MA 02115

During aging of the human brain and particularly in Alzheimer's disease (AD), progressive neuronal loss is associated with the formation of highly stable intra- and extraneuronal protein fibers. Intraneuronally, paired helical filaments (~20 nm in diameter), together with some straight 10-20 nm filaments, accumulate in cell bodies (as neurofibrillary tangles) and in the dystrophic neurites that comprise senile plaques. Extraneuronally, deposits of unpaired ~8 nm filaments form the central cores of many senile plaques. Similar filaments also occur in the walls of some parenchymal and meningeal blood vessels in AD brain. These various fibers have physicochemical properties which allow their classification as amyloid proteins. Taking advantage of the size (5-22 μm) and dense spherical form of isolated senile plaque cores, we have developed a method to purify them to near homogeneity using fluorescence-activated cell sorting. The isolated, purified cores contain 70-130 pg protein each and contain abundant glycine and other non-polar amino acids and very little proline or cysteine. Their amino acid composition is similar to that of highly enriched fractions of PHF. Although both the amyloid cores and the PHF are insoluble in a variety of strong solvents, including SDS, urea and guanidine HCl, treatment with either saturated (7 M) guanidine SCN or concentrated (80%) formic acid causes disappearance of the fibers by light and electron microscopy and releases two major low M_r proteins at ~6,000 and ~12,000 daltons. The proteins released from PHF and from cores co-migrate by gel electrophoresis and by size-exclusion HPLC. These small polypeptides, which appear to be oligomerically related, react with PHF antibodies that do not recognize normal fibrous proteins. Intact, isolated amyloid cores also react with these antibodies, although in situ cores in brain tissue sections are not labeled. Both the purified amyloid core fibers and highly enriched PHF fractions produce an x-ray diffraction pattern consistent with the presence of considerable cross-ß-pleated sheet structure. Thus, intraneuronal PHF and extraneuronal amyloid fibers, although ultrastructurally distinct, share solubility properties, similar amino acid compositions, major constituent proteins, ß-pleated sheet conformation and specific antigenic determinants. Identification of the molecular origin of the proteins comprising these pathological fibers will now require sequence analysis. (Supported by NIH Grants AG01307 and NS20110.)

4.5 IMMUNOCYTOCHEMICAL STUDIES ON NEUROFILAMENT ANTIGENS IN THE NEUROFIBRILLARY PATHOLOGY INDUCED BY ALUMINUM. J. C. Troncoso*, L. A. Sternberger*†, N. H. Sternberger*†, P. N. Hoffman and D. L. Price (SPON: M. R. DeLong). Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205; †Center for Brain Research, University of Rochester Medical Center, Rochester, NY 14642.

Intrathecal administration of aluminum salts induces accumulation of neurofilaments in axons and perikarya of rabbit motor neurons. This pathology is associated with impaired axonal transport of neurofilaments. Phosphorylation of neurofilaments, in particular the 200-kd sidearm protein, seems to be important for interactions between neurofilaments and between neurofilaments and other cytoskeletal elements. Moreover, sidearms may play a role in axonal transport in the cytoskeleton. Therefore, it is possible that aluminum may produce its effects by altering phosphorylation of neurofilaments. To begin to test this hypothesis, we used antibodies directed against phosphorylated and nonphosphorylated epitopes of neurofilament proteins for immunocytochemical analysis of spinal cord sections from aluminum-injected rabbits. In control animals, phosphorylated neurofilaments were not conspicuous in perikarya of motor neurons. In experimental rabbits, two out of three phosphorylated epitopes were readily demonstrated in perikarya of affected motor neurons. The presence of phosphorylated epitopes of neurofilaments in perikarya of motor neurons is distinctly abnormal and may have important consequences for the organization and function of the cytoskeleton. This inappropriate location of phosphorylated neurofilaments may be associated with impairments in axonal transport. Finally, it is of interest that a similar, but not identical, pattern of neurofilament phosphorylation has recently been described in neurofibrillary tangles in Alzheimer's disease.

4.6 IN SITU DISTRIBUTION OF PHOSPHORYLATED AND NONPHOSPHORYLATED NEUROFILAMENT EPITOPES FOLLOWING AXOTOMY AND NEURECTOMY OF SENSORY NEURONS. J. Rosenfeld, M. E. Dorman*, N. H. Sternberger*†, L. A. Sternberger*†, P. N. Hoffman and D. L. Price. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205; †Center for Brain Research, University of Rochester Medical Center, Rochester, NY 14642.

Axonal transection results in an alteration of the metabolism of neurofilaments (NF). Evidence suggests that the 200-kd NF protein plays a role in crosslinking NF. Immunocytochemistry using monoclonal antibodies which recognize either phosphorylated or nonphosphorylated epitopes of the 200-kd NF protein demonstrate that NF epitopes have distinct distributions in the cell bodies/axons of normal neurons. We hypothesize that changes in NF metabolism, observed during regeneration, may be associated with altered distributions of NF epitopes within different regions of neurons. In the present study, the distributions of NF epitopes were examined in neurons of the dorsal root ganglia (DRG) using immunocytochemistry in the setting of effective and ineffective regeneration.

An altered pattern of immunoreactivity was observed following axotomy (nerve crush followed by regeneration) but was not observed following neurectomy (permanent axotomy) of sciatic nerve in adult rats. Three weeks following surgery, sections of DRG were stained using antibodies against phosphorylated and nonphosphorylated NF epitopes. In control animals, nonphosphorylated NF proteins were visualized predominantly in cell bodies, dendrites, and proximal axons, while phosphorylated NF proteins were localized primarily in axons and only rarely observed in cell bodies. Following axotomy, 50-90% of the total number of DRG cells showed phosphorylated epitopes in perikarya. Following neurectomy, phosphorylated NF proteins were not visualized in DRG cells. In both axotomy and neurectomy preparations, antibodies directed against nonphosphorylated NF proteins stained cell bodies of DRG.

This study demonstrated a change in staining patterns of NF epitopes in regenerating sensory neurons, i.e.., epitopes of phosphorylated NF proteins appear in the cell body. When regeneration does not occur, e.g., neurectomy, phosphorylated NF epitopes were observed only in axons. Mechanisms leading to abberant patterns of immunoreactivity are unknown. The abnormal distribution of epitopes could arise from increased amounts of phosphorylated NF proteins, altered regulatory mechanism for NF phosphorylation, etc. Abnormal patterns of phosphorylated NF also occur in cell bodies in a model of neurofibrillary pathology (aluminum intoxication) and in neurofibrillary tangles in individuals with Alzheimer's disease.

4.7 CYTOTOXIN I (NAJA NAJA OXIANA) INHIBITS SPECIFIC KINASES FROM SEIZURE SENSITIVE AND RESITANT STRAINS OF GERBILS AND MICE. J.G. Bajorek* and A.V. Delgado-Escueta. Dept. Neurology, Sch. of Med. Univ. Calif. Los Angeles , and V.A. Wadsworth Med. Ctr., Los Angeles, CA 90024.

Cytotoxin I (Naja naja oxiana) was used to evaluate the activity of phospholipid-calcium dependent kinase present in crude fractions (shocked P2) of mouse (C57/6J) and mongolian gerbil (meriones unguculatus) cerebral cortex. We have previously noted that in vitro phosphorylation assays of this fraction detect a difference between seizure sensitive and resistant strains of these mice and gerbils in the phosphorylation of several proteins separated by SDS polyacrylamide electrophoresis. Since the cytotoxin I polypeptide has been reported to be a relatively specific inhibitor of the phospholipid-calcium dependent kinase in purified enzyme preparations (Kuo et al FEBS Lett 153:183 1983), we hoped to use this property to identify substrates predominantly phosphorylated by the kinase and to expose possible alterations of the enzyme in seizure susceptible animals. In C57/6J mice proteins of 16K and 20K molecular weight were inhibited by 15-20% in an incubation mixture containing 25ug toxin, 5mM ATP32, 0.5mM Ca+2, 5mM Mg+2, 1ug/ul total protein in 0.1 ml of Iris buffer. Other proteins at 44K, 48K, 52K, 61K, and 74-79K were inhibited by only 6-8%. In the gerbils, the 16K and 20K proteins were not inhibited at 25ug but stimulated up to 8%. Using levels from 0-100ug, there was an inhibition noted of 20-25% after 100ug of toxin. This biphasic response was seen in three separate experiments. Seizure susceptible and resistant strains of gerbils showed similar biphasic patterns of toxin response, however seizure prone animals exibited a greater inhibition at the 100ug levels. Most other substrates were not inhibited but showed a slight stimulation. One protein at 48K which was stimulated by calmodulin had the calmodulin stimulation inhibited (30-35%) by the toxin. The complexity of this crude fraction was exposed by the addition of the toxin since the biphasic response may have been due to the phosphorylative activity of other kinases on the same substrates or to the presence of other cofactors or phospholipids which can modify the activity of the kinases. However, the toxin partially differentiated some of the substrates and provides a tool for studying these kinases/phosphatases in epileptic models.

4.8 VISUAL DYSFUNCTION ASSOCIATED WITH ANTINEUROFILAMENT ANTIBODIES. S. Kornguth, T. Kalinke*, G. Grunwald* and D. Dahl. University of Wisconsin, Madison, WI 53705; National Institutes of Health, Bethesda, MD 20205; VA Hospital, W. Roxbury, MA 02132.

This report describes the presence of antineurofilament antibodies in the sera of rabbits that were immunized against large ganglion cells from ox retinas. The intravitreal injection into cats, of these immunoglobulins, was shown to cause a selective reduction in the number of large retinal ganglion cells. The electrophysiological properties of Y-type neurons in the lateral geniculate nucleus were also affected. These immunoglobulins were also shown to react with large retinal ganglion cells by immunohistological methods.

Recent experiments on these polyclonal antibodies from rabbits indicate that they react strongly with a 210 kDa protein from bovine brain as shown by Western blot analysis. On 5% polyacrylamide gels, the 210 kDa antigen comigrates with the high molecular weight protein of the neurofilament triplet. This was determined using rabbit polyclonal antibodies that were produced against the 200 kDa neurofilament protein (from Dr. Doris Dahl).

In order to characterize further the relationship between the large ganglion cell antigens and the neurofilament proteins, our laboratory purified the neurofilament proteins. A crude neurofilament fraction was obtained from bovine brain by Triton X-100 extraction followed by centrifugation through sucrose according the method of Tokutake et al. Anal. Biochem. 135, 102-105, 1983. The pellets, which contained neurofilaments, were solubilized either in 8 M urea or 1.5 M sodium thiocyanate buffered with 10 mM sodium phosphate, pH 7.4, containing 1% 2-mercaptoethanol. Further purification of the 210 kDa protein was obtained by ethanol fractionation. The 210 kDa protein remained in solution at 50% saturation with ethanol. The solution was dialyzed against water and lyophilized to recover the 210 kDa protein.

These observations are of interest because our laboratory has shown that patients with small cell carcinoma of the lung who also have a visual paraneoplastic syndrome, contain a high titer of immunoglobulins in their sera that react selectively with a subset of the neurofilament triplet proteins. This suggests that visual dysfunction may be associated with exposure of the retina to antineurofilament (NF) antibodies in the patient with the small cell tumor and in the cat model. These immunoglobulins may be of etiologic significance in the development of retinal dysfunction.

4.9 PRION PROTEINS ACCUMULATE IN THE ROUGH ENDOPLASMIC RETICULUM OF SCRAPIE-INFECTED HAMSTER BRAINS. R. K. Meyer*, M. P. McKinley*, R. A. Barry* and S. B. Prusiner. Department of Neurology, University of California, San Francisco, CA 94143.

Scrapie is a transmissible, degenerative disease of sheep and goats which occurs after a prolonged incubation period. While the scrapie agent or prion is found in most tissues, the highest titers are found in brain. Animals with scrapie exhibit signs of neurologic dysfunction. Experimental studies have been facilitated by transmission to rodents. The scrapie prion contains a protein PrP and little or no nucleic acid. Scrapie PrP is a sialoglycoprotein, has a M_r of 27-30 kd in preparations purified by proteinase K digestion, and aggregates into amyloid rods and filaments. Immunoblots of unpurified fractions from infected and uninfected hamster brains demonstrated PrP proteins of higher M_r 33-35 kd. Similar results were obtained with rabbit antisera raised against PrP 27-30^{Sc} or against a synthetic peptide corresponding to the N-terminus of PrP 27-30^{Sc}. Proteinase K digestion of infected fractions converted PrP 33-35^{Sc} to PrP 27-30^{Sc}; whereas, the cellular protein PrP 33-35^{C} was completely degraded. After subcellular fractionation, both PrP 33-35^{Sc} and PrP 33-35^{C} were found in membrane fractions but not in 10^5 x g supernatant fluids. The protease sensitivity of PrP 33-35^{C} as well as the proteolytic conversion of PrP 33-35^{Sc} to PrP 27-30^{Sc} were unaltered by extracting the membranes with 2% sodium dodecyl sarcosinate (Sarkosyl). NaCl (0.1-0.5 M), 5 mM EDTA and osmotic shock failed to release the PrP proteins from microsomal membranes; in constrast 2% Sarkosyl did solubilize the PrP proteins since they were recovered in the supernatant fluid after centrifugation at 100,000 x g for 1 hr. Electron microscopy of these microsomal fractions showed membrane vesicles but not rod-shaped structures. The rods have been found in purified preparations of scrapie prions and are thought to be aggregates of the infectious particles. Sixty days after inoculation with ~10^7 ID_{50} units of prions, the concentration of PrP 33-35^{Sc} in scrapie-infected brain was increased ~10 times over that of PrP 33-35^{C} in uninfected brain. Fractionation of microsomal membranes on sucrose-CsCl gradients allowed separation of smooth endoplasmic reticulum (SER) from rough endoplasmic reticulum (RER) membranes. PrP 33-35^{C} was found primarily in RER fractions. Our observations suggest that PrP proteins are integral membrane proteins and that scrapie infection causes PrP 33-35^{Sc} to accumulate in RER. The transport and/or processing of PrP appears to be impaired during scrapie infection. How this alteration in cellular membranes relates to dysfunction of the central nervous system remains to be established.

4.10 SUSTAINED REACTIVE SPROUTING FOLLOWING MINOR HEAD INJURY. J.T. Povlishock, Dept. of Anatomy, Med. Coll. of Va., Virginia Commonwealth Univ., Richmond, VA 23298.

In previous communications we have observed that following minor head injury various forms of reactive axonal change occur. Typically such reactive change entails focal axonal swelling which over a 21 day post-traumatic course persists unchanged, degenerates or gives rise to multiple reactive [regenerative] sprouts. Since such sprout-containing swellings persist over a 21 day period in contrast to other reports of CNS regeneration which have characterized reactive sprouting as rapidly abortive, it seemed appropriate to better characterize this response and to follow it over a more prolonged post-trauamtic course. To this end, anesthetized cats were subjected to minor fluid-percussion brain injury. Following their complete and uneventful recovery from the traumatic insult , the animals were allowed to survive for periods ranging from 3 to 60 days. To aid in the recognition of the reactive axonal sprouting , the anterograde axonal transport of horseradish peroxidase [HRP] was utilized based upon our previous experience that such HRP passage was a sensitive probe for detecting focal reactive axonal change. At the designated survival times, the animals were anesthetized, perfused with aldehydes and prepared for LM and TEM analyses. Within 3 days of the traumatic episode multiple reactive sprouts were observed originating from the traumatically induced axonal swellings . These contained numerous lucent and dense core vesicles and such sprouts ranged from 0.5 to 2 μm in diameter and 5 to 20 μm in length . By the second post-traumatic week numerous sprout-containing swellings were recognized and in addition to these reactive sprouts , multiple robust processes, reminiscent of growth cones, were now also observed. With continued post-trauamtic survival both sprout and robust process-containing swellings were identified. Typically both the sprouts and robust processes had advanced beyond the swelling to parallel the distended myelin sheath and when the myelin sheath was either fragmented or totally lost, such processes could be observed coursing into the substance of the surrounding brain parenchyma which in the case of minor head injury was unaltered. Although with continued survival macrophages approximated such sprout and robust process-containing swellings, they did not appear to be related to the onset of any degenerative change. Such sprout and process extension was recognized to continue over a 60 day post-trauamtic course and , as such , appeared remarkable. As minor head injury causes only limited focal axonal change with sparing of the surrounding brain parenchyma and vasculature, it is conceivable that the retention of a realtively unaltered brain microenvironment contributed to such a dramatic and sustained regenerative response. Supported by NS-20193.

4.11 ECTOPIC AXON HILLOCK-ASSOCIATED NEURITE GROWTH IS MAINTAINED IN METABOLICALLY REVERSED SWAINSONINE-INDUCED NEURONAL STORAGE DISEASE. S.U.Walkley, S.Wurzelmann*, and D.A.Siegel*, Dept. Neuroscience, Rose F. Kennedy Center, Albert Einstein College of Medicine, Bronx, N.Y.10461.

Select populations of neurons in a variety of neuronal storage disorders have been shown to be characterized by growth of ectopic neurites at axon hillock regions. Ultrastructurally these neurites have been shown to resemble small dendrites and to possess spines and synapses. Axon hillock enlargements ("meganeurites") often occur on the same neurons and these unusual changes in neuronal geometry and connectivity have been hypothesized to be major contributors to neuronal dysfunction in such diseases.

Recently, a model of induced neuronal storage disease has been developed using the reversible α-mannosidase inhibitor, swainsonine, found in locoweed plants (Astragalus spp.). This model has been shown to be characterized by induced neuritogenesis and synaptogenesis qualitatively identical to that seen in inherited α-mannosidosis and other storage diseases. The goal of the present study was to use this model to determine the reversibility of axon hillock-associated neurite growth following metabolic correction (inhibitor withdrawal). Three littermate kittens were used. Two animals received identical, measured quantities of swainsonine per os daily, beginning at 1 mo. of age, while the third animal served as untreated control. Neurological deficits appeared in both treatment animals after 3 mos. Swainsonine administration was ended for one animal after 7 mos. and a cerebral biopsy was taken to confirm storage-induced morphological changes. This metabolically "reversed" animal showed slight clinical improvement following cessation of treatment, whereas the animal maintained on inhibitor displayed increased deficits. At 14 mos. of age all three animals were killed and tissues processed for LM and EM.

Combined Golgi-EM studies of pyramidal neurons in the cerebral biopsy taken at the time of swainsonine withdrawal revealed the development of characteristic cytoplasmic vacuolation, axon hillock neurite growth, and neurite-associated synapses. At autopsy, routine EM of cerebral cortex of this animal revealed that storage vacuoles had disappeared but Golgi studies demonstrated the persistence of axon hillock neurite growth which was indistinguishable from that of the continuously treated animal. Combined Golgi-EM studies of these neurite-bearing pyramidal cells in the corrected animal revealed the presence of large numbers of lipofuscin-like inclusions. These preliminary studies suggest that although storage vacuoles undergo modification and reduction in the metabolically corrected disease, ectopic axon hillock-associated neurites do not appear to undergo a similar process of reversal. (Supported by NS-18804 and NS-03356).

4.12 THROMBOXANE/PROSTACYLIN RATIO CHANGES FOLLOWING EXPERIMENTAL SPINAL CORD TRAUMA IN THE RABBIT. T.P. Jacobs, G. Feuerstein, A.I. Faden. Dept. of Neurology, Uniformed Services University of the Health Sciences, Bethesda, Md. 20814 and Neurology Service, San Francisco Veteran's Admisistration Medical Center, San Francisco, California 94121.

Morphologic damage caused by traumatic injuries to the spinal cord result in part from secondary changes developing over a period of several hours post trauma. These secondary alterations, which may contribute to paralysis, appear to be due to release of endogenous substances that may lead to a progressive reduction in spinal cord blood flow (ischemia). Prostaglandins (PGs), which have potent vasoactive properties have been found in increased concentrations in brain tissue after ischemic injury. Recent studies suggested that normal tissue perfusion may depend on a balanced interaction between thromboxane A2 (TXA2) and prostaglandin I2 (PGI2) at the blood-endothelial interface. The present study was designed to evaluate the rate of synthesis of TXB2 and 6-keto-PGF1α after traumatic lumbar spinal cord injury. Thirty-eight rabbits anesthetized with sodium pentobarbital were subjected to a 200g-cm impact injury in the lumbar spinal cord utilizing a modification of the Allen method. At 5 min, 30 min and 24 hrs post trauma, the spinal cord was removed and 1.0mm slices from the injury area were incubated in oxygenated Krebs solution for 45 min. Prostacyclin (measured as 6-keto-PGF1α) and thromboxane A2 (measured as TXB2) released from injured spinal cord slices and noninjured spinal cord were determined by radioimmunoassay (RIA). The rate of release of the PGs expressed as the TXB2/6-keto-PGF1α ratio were as follows: control=0.87; 5 min=1.52; 30 min=1.24 and 24 hrs=0.74. The change in TXA2/PGI2 ratio in the injured zone of the spinal cord was due only to an increase in TXB2 since the release of 6-keto-PGF1α was not changed by injury. These data suggest that there may be a preferential increase in TXB2 synthesis immediately following trauma. TXA2, which is a potent vasoconstrictor and platelet aggregator, may therefore contribute to the reduction of spinal cord blood flow and neurological dysfunction observed after trauma. The results of this study are consistent with previous findings that combined treatment of indomethacin, PGI2 and heparin improve neurological recovery in cats after spinal trauma. (Hallenbeck, J.M. et.al., J Neurosurg 58:749-54, 1983).

5.1 Alpha-2 Adrenergic Receptor Involvement in Adult Male Squirrel Monkey Vocal Behavior. James C. Harris, M.D.* & John D. Newman, M.D. Laboratory of Comparative Ethology, Bethesda, MD 20205.

The response to imipramine in children with separation anxiety disorder (Gittleman-Klein, R. and Klein, D.F. Arch. Gen. Psychiatry, 25:204-207, 1971) suggests the possible involvement of adrenergic mechanisms. Since a reliable indicator of separation distress in primates, including human infants, is the isolation call (IC) (Newman, J.D. In: Infant Crying: Theoretical and Research Perspectives, Lester, B.M. and Boubydis, C.F.Z. (eds.), Plenum, NY, 1985), we have investigated the mechanism mediating this behavior in the adult squirrel monkey, a species in which isolation calls are produced throughout adult life. Because the imipramine effect is thought to produce its anxiolytic effects via α-adrenergic receptors, clonidine, an agonist at α-adrenergic receptors and yohimbine, a specific α_2-antagonist were chosen to test the involvement of adrenergic mechanisms on isolation calls.

Previous studies indicate that adult male squirrel monkeys acoustically and physically separated from conspecifics reliably emit isolation calls for periods of up to one hour. We used this natural behavioral response to measure the effects of clonidine HCl and yohimbine HCl in changing IC rate over a 15 minute test period of separation from the conspecific group. Tests were performed no closer than at weekly intervals. Animals were administered 0.05 to 0.1 mgs. per kg. of clonidine IM 5 minutes prior to testing. The larger dose consistently reduced production of the IC. Subsequent administration of yohimbine (0.2mg/kg) reliably reversed the IC suppression. In addition, animals given this dose of yohimbine either after clonidine or alone, emitted significant numbers of another vocalization, the twitter, normally produced only rarely in isolation.

These findings support the original hypothesis of a role for α-adrenergic receptors in the vocal component of separation distress in the squirrel monkey. The reversal of clonidine suppression with yohimbine, a drug with high affinity for the α_2-adrenergic receptors, implicates this receptor population in this response. The unexpected production of twitters under yohimbine also suggests that adrenergic mechanisms are involved in other aspects of squirrel monkey vocal behavior.

5.2 COLD WATER STRESS ABOLISHES HYPERACTIVITY PRODUCED BY CORTICAL SUCTION LESIONS WITHOUT ALTERING NORADRENERGIC DEPLETIONS. Robert G. Robinson, Kristy A. Zern , Godfrey D. Pearlson, Timothy H. Moran, and Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Focal suction lesions of the right frontal cortex result in hyperactivity and cortical and subcortical norepinephrine (NE) depletions (Pearlson and Robinson, Brain Res., 218:233, 1981). Previous work from this laboratory has indicated that although the NE depletions are not necessary for the production of the behavioral hyperactivity, such depletions are sufficient to produce this behavioral outcome (Kubos, Moran, Saad, and Robinson, Phar. Biochem. and Behav., 21: 163, 1984). In an effort to further characterize the role of NE depletions in the mediation of post lesion hyperactivity, we examined the effect of postoperative forced cold water (15°C) swimming, a procedure demonstrated to increase NE turnover, on both the catecholamine depletions and behavioral hyperactivity produced by focal right hemispheric cortical suction lesions.

Throughout the thirty day postoperative period, lesion and sham operated control animals received swim tests either four times (i.e. once per week over four weeks), once during the first postoperative week or not at all. The effect of swimming stress was different for lesion and sham operated control groups. In the sham group, swimming stress at weekly intervals produced hyperactivity as measured by daily running wheel revolutions (approximately 135% of preoperative baseline). In the lesion group, either a single swimming stress or swimming at weekly intervals blocked the development of the post-lesion hyperactivity. Activity in the lesion, no swim group was 130% of preoperative baseline, significantly greater than the one swim lesion group activity which was 100% of preoperative baseline and the lesion four swim group activity which was 90% of preoperative baseline ($F_{8,171} = 3.69$, $p < .001$). Although altering the behavioral response to cortical lesions, swimming stress did not change the pattern or magnitude of NE depletions. NE was significantly depleted in the lesion as compared with control group in the frontal cortex ($F_{1,41} = 9.16$, $p < .01$), and posterior cortex ($F_{1,41} = 12.19$, $p < .01$).

These findings suggest that the central catecholaminergic effects of the forced swimming stress may have been interacting with different receptor states in lesion and control groups and support the hypothesis that receptor changes, secondary to the NE depletions may be important in mediating the behavioral hyperactivity following focal suction lesions of the right frontal cortex. This work was supported by NIH grant RSDA MH 00163, NS 15178, NS 18622 and NS 15330.

5.3 6-HYDROXYDOPAMINE (6-OHDA) LESIONS OF THE NUCLEUS ACCUMBENS, BUT NOT CAUDATE NUCLEUS, ATTENUATE ENHANCED RESPONDING FOR CONDITIONED REINFORCEMENT PRODUCED BY INFUSIONS OF INTRA-ACCUMBENS D-AMPHETAMINE. J.B. Taylor* and T.W. Robbins*, Dept. of Experimental Psychology, University of Cambridge, Cambridge, England. (SPON: B.J. Sahakian).

Intra-accumbens d-amphetamine has been shown to enhance responding for reward-related stimuli (conditioned reinforcers), whereas intra-caudate d-amphetamine has been found by comparison to produce weak and variable results (Taylor and Robbins, Psychopharm., 84:405, 1984). The present experiment was designed to examine further the involvement of the nucleus accumbens, and the role of dopamine (DA), in this behavioural effect using infusions of d-amphetamine in rats with 6-OHDA-induced depletion of DA in either the nucleus accumbens or the caudate nucleus, and sham-operated controls.

Thirsty rats were trained to associate a light (CR) with water. After this training, all the subjects were implanted with permanent guide cannulae aimed at the nucleus accumbens and assigned to one of four groups, which received either bilateral 6-OHDA (4 mg/ml free base in 2 ul of 0.9% saline) or sham (vehicle) infusions into the nucleus accumbens or caudate nucleus. In the test phase, water was no longer presented but responding on one of two novel levers produced the light (CR lever), whereas responding on the other lever (NCR lever) had no effect. All four groups of subjects received four counterbalanced intra-accumbens infusions of d-amphetamine (3, 10, 20 ug/2 ul) or vehicle over four test days. On a fifth test day, all subjects were pretreated with apomorphine (0.1 mg/kg).

Intra-accumbens d-amphetamine in both nucleus accumbens and caudate nucleus sham-lesioned groups produced a dose-dependent increase in responding on the CR lever, but no significant change in responding on the NCR lever. No selective dose-dependent increases in responding on either lever were found in animals with 6-OHDA-induced depletion of DA (>80%) in the nucleus accumbens following intra-accumbens d-amphetamine. However, intra-accumbens d-amphetamine in subjects with dopamine depletion of the posterior caudate nucleus (>80%) produced dose-related selective increases in responding on the CR lever, which were similar in magnitude to both the sham- lesioned groups except at the highest dose of d-amphetamine (20 ug). Following apomorphine, only the nucleus accumbens lesioned group continued to respond, preferring the CR lever, suggesting the involvement of 'supersensitive' DA receptors induced by 6-OHDA administration.

These results provide evidence to support the hypothesis that enhanced responding for CR found following psychomotor stimulant drugs is critically dependent upon activation of the nucleus accumbens, rather than the caudate nucleus, and is suggestive of a role for DA in mediating this behavioural effect.

5.4 THE TOPOGRAPHY OF LOCOMOTION: EFFECTS OF HALOPERIDOL. P.R. Sanberg, M.D. Bunsey*, S.H. Hagenmeyer, K.H. Russell*, and M.A. Henault. Behavioral Neuroscience Laboratory, Department of Psychology, Ohio University, Athens, Ohio 45701.

The process of screening neurolepics has long been hampered by inadequate methodology. Most behavioral studies on the effects of neuroleptics have involved measuring either catalepsy or the inhibition of stimulant-induced locomotion. However, tests such as catalepsy are plagued with methodological and procedural problems (e.g. inconsistent results, observer bias, learning effects, and dose insensitivity), while inhibition of stimulant-induced activity does not reveal any information on the spontaneous behavioral effects of neuroleptics. In an attempt to circumvent these problems, the present study examined the use of recently developed automated monitors on the behavioral effects of the neuroleptic, haloperidol.

Male Sprague-Dawley rats were placed into the activity monitors at 19:00 and allowed to habituate for one hr. At 20:00 rats were injected i.p. with haloperidol (HAL) in doses of 0.0, 0.1, 0.5, and 1.0 mg/kg and locomotor behavior was monitored for the next three hrs. The rats received each of the drug dosages over a period of two weeks. Dosages were counterbalanced among subjects and a two-day rest period was provided between injections.

Data analysis indicated a significant dose effect for every variable measured. At 0.1 mg horizontal activity (HA), distance travelled (TD), vertical activity (VA), no. of stereotypy (NS), stereotypy time (ST), and anticlockwise revolutions (AC) were significantly decreased from controls. The 0.5 mg group showed additional decreases from controls in movement time, number of movements (NM), av. distance per movement (AD), vertical time, vertical movements, clockwise revolutions (CL), and an increase in rest time (RT). Furthermore, there were significant decreases from 0.1 mg values in VA, NS, AC, and NM and a significant increase in RT. The 1.0 mg rats displayed the same decreases seen in the 0.5 mg rats with additional effects in HA, TD, ST, and CL from the 0.1 mg values. Average speed (SP) was significantly greater at 0.5 mg than at 1.0 mg HAL. In all locomotor categories the drug effect peaked during the second hour.

This study demonstrated the power of the automated monitor as a research tool. The monitor showed that a sub-cataleptogenic dose of HAL profoundly altered several aspects of nocturnal locomotion. The monitor also detected significant differences between the lower and higher dosages. Furthermore, the system revealed a second hour peak dose effect that was evident across all aspects of activity. Finally, SP was revealed to have a peculiar dose effect showing the least inhibition at 0.5 mg/kg.

5.5 LEARNING AND ATTENTIONAL IMPAIRMENTS IN HYPERACTIVE ADULT RATS TREATED NEONATALLY WITH 6-OHDA. G. K. Hodge and E. A. Reyes. Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM 87131.

Hyperactive children are impulsive and have difficulty sustaining attention. The sense that their inattention is cause for greater concern than their hyperactivity is reflected by the American Psychiatric Association's classification of their behavior as attention deficit disorder (ADD; *DSM-III*, 1980). Attentional problems persist into adulthood (Whalen & Henker, *Hyperactive Children*. NY: Academic, 1980). Animal models of ADD should therefore reveal early and persistent attentional problems.

In humans, Gordon (*J. Abnorm. Child Psychol.*, 7:317, 1979) has reported that hyperactive children do not perform as well as normal controls on a task involving differential reinforcement of low rates of responding (DRL). Hyperactive children made more errors of commission; i.e., they responded impulsively at inappropriate times. We report similar impairments in DRL performance of rats treated neonatally with 6-hydroxydopamine (6-OHDA).

Following desipramine pretreatment (20 mg/kg), cross-fostered male 5-day-old albino rats were injected intracisternally with either 100 µg/25 µl of 6-OHDA or 25 µl of the ascorbic acid/saline vehicle. Some pups received no treatment of any kind.

Beginning at postpartum Day 30, the animals were placed on an alternate-day 22-h food deprivation schedule. Rats were shaped to bar press for food pellets. Presses were eventually rewarded only when a target light was on. Initially, the target light alternated between being on 10 sec and off 10 sec. A distractor light later replaced the off period. On Day 40 and all subsequent days, presses to the distractor light further delayed onset of the target light by additional 10-sec periods. On Day 80, the target light duration was reduced to 7.5 sec; on Day 100, to 5 sec; and on Day 130, to 3 sec. Sessions ended after 50 successes or 20 min.

Analyses of variance revealed no differences between nontreatment and vehicle groups; they were combined (n = 13) and compared against the 6-OHDA group (n = 8). For all days, the 6-OHDA rats weighed less than controls ($p < .01$). During the two sessions that immediately followed shifts to shorter target light durations, the 6-OHDA animals made more commission errors than controls ($p < .05$). At 7.5 and 5 sec durations, the groups eventually attained comparable performance levels, but at the 3-sec duration, the 6-OHDA rats continued to make more errors through Day 170 ($p < .05$).

The results suggest that although both groups are capable of learning the DRL task, the 6-OHDA group has greater difficulty in detecting and making transitions to more stringent criteria, and at the most difficult criterion (3 sec), they continue to make more commission errors than controls. These errors may reflect attentional impairments and impulsivity.

5.6 DOPAMINE DEFICIENCY WITH CHRONIC COCAINE ABUSE. M.S. Gold, C.A. Dackis,* T.W. Estroff,* and A. Carter Pottash, Research Facilities, Fair Oaks Hospital, 19 Prospect St., Summit, NJ 07901.

Prolactin secretion is tonically inhibited by infundibular dopamine (DA) neurons. Cocaine increases DA neurotransmission acutely by blocking DA reuptake. The chronic effects of cocaine on DA neurons, however, may differ from acute effects. In order to assess the chronic effects of cocaine on DA neurons, we studied prolactin levels in 18 male cocaine abusers and 20 normal male controls, matched for age. Prolactin levels were determined in duplicate by radioimmunoassay on fasting blood drawn at 8 a.m., within 72 hours after the last cocaine use. Prolactin levels in the cocaine patients (mean ± SD; 35.4 ± 26.9 ng/ml) were significantly greater ($t=4.62$, $df=36$, $p<0.001$) than those of the controls (mean ± SD; 7.0 ± 5.0). Most of the prolactin levels of the cocaine patients (67%) were also greater than the established upper normal range (20 ng/ml) for prolactin in males.

The findings of this controlled study in male cocaine abusers are consistent with DA inhibition by chronic cocaine exposure. DA inhibition by cocaine is supported by reports in the literature of reduced DA levels and increased postsynaptic DA receptor density after the administration of cocaine to animals. DA depletion may result fron increased synaptic metabolism of DA after reuptake blockade. The functional inhibition of DA neurotransmission by cocaine could contribute to the abstinence symptoms seen after the abrupt cessation of chronic, severe cocaine abuse. DA depletion, as indicated by hyperprolactinemia, may also underly cocaine craving states. The duration of neuroendocrine and neurotransmitter disruptions by cocaine requires further study.

5.7 RATS TRAINED TO CIRCLE DO NOT EXHIBIT INCREASES IN DOPAMINE OR ITS METABOLITES IN THE CONTRALATERAL STRIATUM OR NUCLEUS ACCUMBENS. C. Szostak*, A. Jakubovic, A.G. Phillips and H.C. Fibiger, Div. Neurol. Sci., Dept. Psychiat., Univ. British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Yamamoto & Freed (Nature, 298, 1982) have reported that rats trained to circle have increased concentrations of dopamine (DA) and 3,4-dihydroxyphenylacetic acid (DOPAC) in the striatum (ST) and nucleus accumbens (nA) contralateral to their direction of turning. The reliability of this effect was tested in two experiments.

Rats were trained to circle for water according to a continuous schedule of reinforcement until stable performance was obtained. Following a 20-min test session, rats were decapitated and left and right ST and nA were dissected and prepared for analysis of DA, DOPAC and homovanillic acid (HVA) by HPLC. Circling did not influence levels of DA, DOPAC or HVA in the ST or nA contralateral to direction of turning. Moreover, the concentrations did not differ from non-circling, water-deprived control group values. Since the over-all response rates obtained were lower than those reported by Yamamoto & Freed, additional rats were trained to circle according to an intermittent schedule of reinforcement. Intermittent reinforcement resulted in much higher rates of circling. Despite the higher levels of responding, ST levels of DA, DOPAC and HVA were not influenced by circling. The rate of conversion of DA to HVA, as estimated by the HVA:DA ratios, was elevated bilaterally when compared with control ratios. Circling was found to decrease DA levels in the contralateral nA. However, between group differences were not observed. Relative to controls, HVA was increased bilaterally in the nA. This increase was smaller on the contralateral side.

To further assess the role of DA in circling, changes in DA activity resulting from stimulation-induced circling (SIC) were determined. Three groups were used: stimulated rotators, stimulated non-rotators and non-stimulated controls. Electrodes were implanted into the medial forebrain bundle, at the level of the lateral hypothalamus. Levels of DOPAC and HVA were selectively increased in the ipsilateral ST of stimulated rotators. However, this effect was not obtained in one animal that exhibited consistent rates of circling. Levels of DA, HVA and DOPAC were not influenced in the nA.

The present results indicate that high levels of circling produced by positive reinforcement or electrical stimulation can result in selective neurochemical changes. However, the present results failed to confirm that conditioned circling enhances DA utilization in the ST or nA contralateral to the direction of turning. Moreover, while SIC can produce asymmetrical changes in DOPAC and HVA, such effects are not always obtained.

5.8 MONOAMINES IN THE HIPPOCAMPUS OF RATS FED AN AMINO ACID-IMBALANCED DIET. D.W.Gietzen*,P.M.B.Leung* and Q.R.Rogers. Department of Physiological Sciences: School of Veterinary Medicine and Food Intake Laboratory, University of California, Davis, CA 95616.

Animals will decrease their food intake if prefed a low protein basal diet (BAS) and then offered a ration containing an imbalanced amino acid pattern (IMB). This behavioral response is characterized by a rapid decrease in food intake followed by gradual adaptation to IMB. Previous studies have demonstrated facilitation of the rat's adaptation to IMB feeding in animals bearing bilateral lesions of the hippocampus (Leung, P.M.B. and Rogers, Q.R., Physiol. and Behav.23:129,1979). Since the monoamine neurotransmitter systems may play a role in this behavioral response, we elected to measure the concentrations of several neuroactive amines in hippocampus from rats fed the IMB diet and in controls. Three groups of young male Sprague-Dawley rats were prefed a basal diet. On the day of the experiment they were offered either BAS, IMB or a corrected diet (COR) which differs from IMB only in the addition of 0.5% of the limiting amino acid, isoleucine, to correct the imbalance. The animals were killed after having access to the diet for 3.5 hr. Concentrations of norepinephrine, epinephrine, dopamine, serotonin (5HT) and the serotonin metabolite 5-hydroxyindoleacetic acid (5HIAA) were measured in bilateral sections of the hippocampus by HPLC with electrochemical detection. The concentrations of the monoamines were similar in all three diet-treatment groups. However, the turnover of 5HT, as indicated by the ratio of 5HIAA:5HT, was increased in the hippocampus from the IMB group when compared with either BAS or COR. Since increased turnover is thought to be representative of increased activity in neurons, these results suggest that acute diet-associated increases in the activity of the serotonergic system in the hippocampus may be involved in the animals' later adaptive responses to IMB. (Supported in part by NIH grants AM13252 and AM07355.)

5.9 BROMOCRIPTINE REVERSES COCAINE WITHDRAWAL. C.A. Dackis*and M.S. Gold, Research Facilities, Fair Oaks Hospital, 19 Prospect St., Summit, NJ 07901.

Dopamine (DA) neurons mediate cocaine reward and euphoria. Increased DA neurotransmission after reuptake blockade by cocaine presumably underlies its acute euphoric action. After cocaine abstinence, abusers often experience dysphoria, craving, and other withdrawal symptoms such as anergia, hypersomnia, and irritability. We have previously hypothesized that chronic cocaine abuse is associated with DA depletion, based on hyperprolactinemia in cocaine abusers, and DA disruptions in animals given cocaine. DA depletion may contribute to cocaine withdrawal.[1] In order to test this hypothesis, we administered the DA agonist bromocriptine to two female cocaine abusers (ages 18 & 20) after informed consent. Both patients had hyperprolactinemia (35.7 & 22.9 ng/ml) and intense cocaine craving. They quantified their degree of cocaine craving by marking a 100 mm line anywhere between the two poles, labelled "not at all" and "extremely." Fifteen minutes later, they blindly received either bromocriptine or placebo, and then rated their craving (see figure). The patients reported decreased subjective withdrawal complaints and objective decreases in self rated cocaine craving after bromocriptine but not placebo in all trials. One subject was given thioridazine, a DA antagonist in a similar design and rated a dramatic worsening of cocaine craving. These findings are consistent with DA depletion in chronic cocaine abusers, and indicate that bromocriptine may be an effective treatment for cocaine withdrawal.

5.10 *COMPARISON OF THERAPEUTIC EFFECTS OF RESERPINE AND ANIONS IN CATION-INDUCED ANXIETY. A.J. Giannini, W.A. Price, M.C. Giannini*, R.H. Loiselle. Dept. of Psychiatry, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Twenty four male volunteers received an exposure of ambient cations at a concentration of 2300 cations/cm^3 for 30 minutes. This was sufficient to induce anxiety in all volunteers as measured by BPRS. Half the volunteers were treated with one dose reserpine 0.2 mg po and the other with ambient anions. Both groups showed a significant reduction in anxiety within one hour. There were no significant differences between the anion- and reserpine-treated group. This indicates that the anxiogenic effects of cations may be mediated by biogenic amines.

GABA AND BENZODIAZEPINES: CELLULAR AND BEHAVIORAL EFFECTS

6.1 NEOCORTICAL PYRAMIDAL CELLS: $GABA_A$ AND $GABA_B$ MEDIATED RESPONSES AND TWO TYPES OF IPSP. B.W. Connors and R.C. Malenka. Depts. of Neurology and Psychiatry, Stanford Univ. Sch. of Med., Stanford, CA 94305.

We have compared the responses to activation of $GABA_A$ and $GABA_B$ receptors with the inhibitory synaptic potentials in neocortex. Experiments were performed on slices of rat sensorimotor cortex in vitro, and intracellular recordings were obtained from physiologically identified pyramidal cells of layer II/III.

Local stimulation elicited a short latency depolarization consisting of a brief EPSP and IPSP followed by a late hyperpolarizing potential (LHP). The early IPSP had a reversal potential of -75 ± 3.2 mV (n=7), which was slightly positive to the resting membrane potential. The reversal potential for the LHP was -91 ± 5.7 mV (n=7). At resting potential, focal application of GABA elicited a depolarization; at potentials positive to rest the response was bi- or triphasic, typically consisting of depolarizing ($GABA_d$) and hyperpolarizing ($GABA_h$) phases that reversed at -51 ± 4.7 mV and -70 ± 4.3 mV (n=11) respectively. We were unable to segregate the two response phases by selective application of GABA to dendritic or somatic regions, although the relative prominence of each phase varied with the application site. Bicuculline and picrotoxin are $GABA_A$ receptor antagonists. Either drug (10 μM) suppressed the early IPSP, and resulted in a large increase in the initial EPSP; the LHP was unchanged or increased slightly in amplitude. Concurrently the $GABA_d$ response was blocked, leaving the $GABA_h$ response unaffected or larger. In the presence of an antagonist the $GABA_h$ reversal potential increased significantly (to -87 ± 2.3 mV, n=5), approaching that of the LHP. When E_{Cl} was shifted positively by decreasing extracellular [Cl], the reversal potentials for both the $GABA_d$ response and the early IPSP also shifted positively, while the LHP and $GABA_h$ response were relatively unaltered. No selective antagonists of $GABA_B$ receptors exist. However baclofen is a selective $GABA_B$ agonist, and its focal application increased membrane conductance and elicited a small, long lasting hyperpolarization that reversed at -91 ± 6.2 mV (n=9). The response to baclofen was resistant to GABA antagonists and changes in E_{Cl}.

The results suggest that $GABA_A$ receptors mediate both the early IPSP and the major part of the neuron's response to exogenous GABA. Both are largely Cl^--dependent, although the complexity of the response to GABA suggests that E_{Cl} may vary on different parts of the same neuron. The similar properties of the LHP, the $GABA_h$ response (in the presence of $GABA_A$ antagonists) and the baclofen response suggest that the LHP may be a $GABA_B$ receptor-mediated IPSP, although its mediation by other transmitters is not ruled out.

6.2 PENICILLIN SHORTENS THE MEAN OPEN TIME OF GABA INDUCED MEMBRANE CHANNELS IN CULTURED SPINAL CORD NEURONS. D.A. Mathers* (SPON: E. Puil). Dept. of Physiol., Faculty of Medicine, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Penicillin (PCN) can cause epileptiform seizures when large doses are administered to patients and experimental animals. The convulsant effect of PCN is thought to involve a depression of inhibitory postsynaptic potentials mediated by the neurotransmitter γ-aminobutyric acid (GABA) (Avoli, M., Brain Res. 323: 154, 1984). In the present study, the extracellular patch clamp method was used to resolve currents flowing through single GABA sensitive channels in the membrane of cultured mouse spinal cord neurons. This approach has allowed direct examination of the influence of PCN on the gating of these channels.

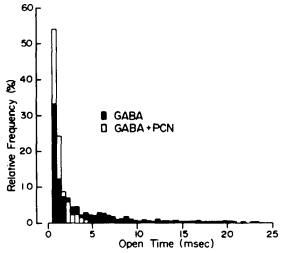

Fig. 1 shows the effect of 2 mM PCN on the open time distribution of GABA induced single channel currents recorded in an outside-out patch voltage-clamped to -60 mV (T=22°C). These distributions were normalized by expressing the number of observations in each time bin as a percentage of the total number of observed events. The first bin was not included in this analysis, since its event frequency was reduced by system bandwidth limitations. A Chi square test indicated tht PCN significantly altered the form of the open time distribution ($P<0.001$). During PCN action, the mean value of the plotted open times decreased from 3.6 msec (570 events) to 1.2 msec (538 events). PCN (2 mM) did not itself display significant agonist action on the GABA sensitive channels in these patches. These data indicate that PCN shortens the mean open time of GABA induced membrane channels, an effect consistent with the convulsant action of this drug.

6.3 ONSET AND SPONTANEOUS REVERSAL OF GABAERGIC SUBSENSITIVITY INDUCED BY CHRONIC DIAZEPAM. S.F. Gonsalves and D.W. Gallager, Dept. of Psychiatry and Neuroanatomy, Yale University School of Medicine and Abraham Ribicoff Research Facilities of the Connecticut Mental Health Center, New Haven, CT 06508

Recent electrophysiological studies have demonstrated that long-term exposure to benzodiazepines attenuates their ability to enhance postsynaptic GABAergic neurotransmission. These findings are consistent with clinical and behavioral evidence that tolerance develops to the pharmacological actions of benzodiazepines after chronic treatment. We have recently reported that slow continuous release of diazepam (DZ) from chronically ($\geq$ 3 weeks) implanted capsules selectively reduces sensitivity to microiontophoretically applied GABA in serotonergic dorsal raphe (DR) neurons (Gallager et al., Brain Res., in press). We now report the time course for the development of GABAergic subsensitivity following DZ capsule implantation and the time course for the reversal of GABAergic subsensitivity following removal of the capsules.

Two silastic capsules containing 90 mg of crystalline diazepam were implanted subcutaneously in male Sprague-Dawley rats under halothane anesthesia. This protocol has previously been shown to release the equivalent of 5 mg/kg of diazepam per day. Control rats received empty capsules. Microiontophoretic sensitivities to 5HT and GABA were determined in serotonergic DR neurons 1, 2 and 3 weeks after the capsules were implanted. Sensitivities were quantified as IxT_{50} values, i.e., the product of iontophoretic current (nA) and time (sec) required to reduce spontaneous firing rate of a recorded cell to 50% of its basal rate. Our results indicated that GABAergic subsensitivity was fully expressed after 2 weeks of exposure to the DZ implants (DZ 2 wk: IxT_{50} 43.0±4.1; DZ 3 wk: IxT_{50}= 46.7±3.1; VEH: IxT_{50}= 30.4 ±1.5, p<.05). GABAergic responsiveness at 1 week was not significantly different from control (DZ 1 wk: IxT_{50}= 29.0±2.8; VEH: IxT_{50}= 30.4 ±1.5, ns). Sensitivity to 5HT was not altered from control at any of the time points tested. In a second group of rats, the time course for spontaneous reversal of GABAergic subsensitivity was estimated after surgical removal of the implants (21 days minimum exposure). Responsiveness to GABA remained depressed for 5 days after the removal of the implants (DZ 5 day withdrawal: IxT_{50}= 44.0± 4.9; VEH: IxT_{50}= 29.4±1.2, p<.005) with control responsiveness returning by 8 days (DZ 8 day withdrawal: IxT_{50} = 33.5±2.9; VEH: IxT_{50}= 29.4±1.2, ns). In contrast, a single injection of the specific benzodiazepine antagonist, Ro15-1788, on the final day of chronic treatment restored GABAergic sensitivity to control levels within 24 hours. (Support: Klingenstein Fund, USPHS MH 14276 & NS 19655, Epilepsy Foundation and the State of Connecticut).

6.4 THE EFFECT OF BENZODIAZEPINES ON CHOLECYSTOKININ-INDUCED EXCITATION OF RAT HIPPOCAMPAL PYRAMIDAL NEURONS APPEARS NOT TO BE MEDIATED BY THE POTENTIATION OF GAMMA-AMINOBUTYRIC ACID. J. Bradwejn and C. de Montigny. Neuroscience Research Center, Université de Montréal, Montréal, Canada.

We have previously shown that benzodiazepine [BZD] receptor agonists, by activating BZD receptors, selectively suppress cholecystokinin (CCK)-induced excitation of rat hippocampal pyramidal neurons (Nature 312: 363, 1984). Since γ-aminobutyric acid (GABA) receptors coexist with BZD receptors, we undertook the present studies to determine whether GABA mediates the antagonism by BZD's of CCK-induced activation.

Male Sprague-Dawley rats (200-300 g) were anesthetized with urethane (1.25 g/kg, i.p.). Five-barrelled micropipettes were used for extracellular unitary recording of CA_3 dorsal hippocampus pyramidal neurons. The following substances were used for microiontophoresis: sulphated CCK octapeptide (10 μM in 200 mM NaCl, pH: 5; Squibb), acetylcholine.HCl [ACh] (20 mM in 200 mM NaCl, pH: 4; Calbiochem), flurazepam.HCl [FLU] (200 mM, pH: 4; Hoffman-Laroche), Met-enkephalin [mENK] (500 M in 200 mM NaCl with BSA 0.01%, pH: 4.6; Sigma), GABA (10 mM in 50 mM NaCl, pH: 4; Calbiochem) and bicuculline (10 mM in 100 mM NaCl, pH: 4; Sigma).

Microiontophoretic application of GABA during the activation of hippocampal pyramidal neurons by CCK, ACh or mENK reduced the firing activity of these neurons to the same extent for the three excitatory neurotransmitters. Activations induced by pulse applications of CCK, ACh or mENK were also reduced to the same extent by background microiontophoresis of GABA. The intravenous administration of picrotoxin (2.5 mg/kg), while completely blocking the effect of microiontophoretically-applied GABA, did not alter the suppression of CCK-induced activation by microiontophoretic application of FLU. Similarly, microiontophoretic application of bicuculline blocked the suppressing effect of GABA, but not that of FLU, on CCK-induced activation.

The results of the first two series of experiments show that, unlike BZD's, GABA does not have any selectivity for CCK-induced activation, as would be expected if a potentiation of GABA were underlying the effect of BZD on CCK-induced activation. The results obtained with picrotoxin and bicuculline show that the ability of FLU to antagonize CCK-induced activation is not affected by GABA receptor blockade. Hence, these results suggest that potentiation of GABA neurotransmission might not be the mechanism through which BZD's selectively suppress CCK-induced activation. This conclusion is consistent with the data of other investigators, suggesting that some of the clinical effects of BZD's, such as anxiolysis, might not be due to the potentiation of GABA neurotransmission.

6.5 INTERACTION OF t-BUTYLBICYCLOPHOSPHOROTHIONATE WITH GABA-GATED CHLORIDE CHANNELS IN CULTURED NEURONS FROM THE CHICK EMBRYO CEREBRUM. M. H. Jalilian Tehrani* and E. M. Barnes, Jr. Dept. of Biochemistry, Baylor Coll. of Med., Houston, TX 77030.

The specific, picrotoxinin-displaceable, binding of [^{35}S]t-butylbicyclophosphorothionate (TBPS) to isolated membranes of chick cerebral neurons, 8 days in culture, was examined by saturation studies at equilibrium. Scatchard plots of these data were curvilinear. Using non-linear regression analysis via a SCAFIT/LIGAND computer program, the best fit was obtained by a model based on two TBPS binding sites which differ in affinity and density: $K_{d(1)}$ = 3.1 nM, $B_{max(1)}$ = 0.031 pmol/mg; $K_{d(2)}$ = 270 nM, $B_{max(2)}$ = 3.9 pmol/mg. The dissociation constants for these two sites were similar to those found in membranes from adult rat and chicken cerebral hemispheres [Tehrani, M.H.J., et al. (1985) J. Neurochem., in press]. As in adult tissues, the specific binding of TBPS to membranes from cultured neurons was displaced by GABA (IC_{50} = 0.6 μM).

The effect of TBPS on $^{36}Cl^-$ uptake by intact cerebral neurons was studied in monolayers of cultured cells. The entry of $^{36}Cl^-$ was resolved into basal (GABA-independent, picrotoxinin-insensitive) and GABA-dependent (picrotoxinin-sensitive) permeabilities. The latter process exhibited a $K_{0.5}$ = 1.5 μM for GABA and an apparent V_{max} of 5.3 nmol Cl^-/sec/mg. This $K_{0.5}$ value was in reasonable agreement with the IC_{50} for GABA displacement of TBPS binding. Kinetic analysis of the GABA-gated Cl^- flux revealed that TBPS is an inhibitor (IC_{50} = 280 nM) whose action is non-competitive (K_i = 140 nM) with respect to GABA. TBPS also blocked the basal Cl^- flux observed in the absence of GABA, but higher concentrations were required (TBPS IC_{50} = 8 μM). Since no inhibition of Cl^- flux was observed at TBPS concentrations near its $K_{d(1)}$ for binding, the high affinity site may represent a physiologically inactive form of the receptor. The TBPS dissociation constant for the binding site of lower affinity, $K_{d(2)}$, agreed well with the IC_{50} and K_i values for inhibition of GABA-gated Cl^- flux, and thus is likely to represent an interaction with active Cl^- channels.

6.6 PHARMACOLOGICAL CHARACTERIZATION OF THE GABA/BENZODIAZEPINE RECEPTOR-CHLORIDE IONOPHORE COMPLEX USING A GABA-INDUCED ^{36}CI INFLUX ASSAY IN CULTURED SPINAL CORD NEURONS. P.F. Lehoullier* and M.K. Ticku (SPON: J. Maas) Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284.

GABA-mediated inhibition in the nervous system has been shown in electrophysiological experiments to be due to an increase in chloride ion conductance across the neuronal cell membrane. The present study describes a biochemical method of measuring GABA-stimulated ^{36}Cl influx in cultured mouse spinal cord neurons and the effects of various GABA-modulating drugs on this functional assay. The cultures were prepared according to methods described previously (Ransom, et al., J. Neurophysiol., 40:1132, 1977), with the exception that the cells were grown on poly-l-lysine coated plastic coverslips. Following 5 to 6 days in culture, the cells on coverslips were removed from tissue culture medium and incubated at 22°C for 20s in physiological buffer (136 mM NaCl, 5.4 mM KCl, 1.4 mM $MgCl_2$, 1.2 mM $CaCl_2$, 1 mM NaH_2PO_4, 20 mM HEPES, pH 7.4) containing ^{36}Cl in the absence and presence of GABA and/or other drugs. In the absence of any drug the time course of ^{36}Cl influx up to 30s was linear with time. For a 20s incubation, basal ^{36}Cl influx was 6.3 ± 0.9 nmol ^{36}Cl/mg protein and in the presence of 100 μM GABA the influx increased to 12.1 ± 0.9 nmol ^{36}Cl/mg protein. The half-maximal ^{36}Cl influx occurs at approximately 10 μM. GABA-induced ^{36}Cl influx was blocked by (+)bicuculline and picrotoxinin. (+)Bicuculline, in the absence of added GABA, had no effect on basal ^{36}Cl influx, indicating that basal influx is GABA-insensitive. Pentobarbital (25 to 100 μM) potentiated the effect of submaximal concentrations of GABA (20 μM) on ^{36}Cl influx. Pentobarbital in the absence of GABA, at concentrations greater than 100 μM, increased ^{36}Cl influx above basal values. Diazepam (100 nM to 10 μM) also caused a concentration-dependent potentiation of the GABA-induced ^{36}Cl influx. These results are consistent with the electrophysiological evidence and provide us with a functional assay for measuring the properties of the GABA receptor-chloride ionophore, and for characterizing the GABA synaptic pharmacology.

6.7 **IDENTIFICATION OF A DISCRETE SITE IN FOREBRAIN AS A SUBSTRATE FOR THE GENESIS OF CHEMICALLY-INDUCED SEIZURES.** S. Piredda* and K. Gale, (SPON: D. Stoff), Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

Although systemic injections of chemoconvulsive agents have been used to create experimental models of generalized epilepsy, to date there has been no identification of a specific locus at which these drugs act to initiate generalized seizures. By directly microinjecting varying doses of chemoconvulsant agents into several brain loci, we have discovered a discrete area in the forebrain from which bilateral motor seizures are elicited after unilateral application of pmol amounts of bicuculline, kainic acid or carbachol, nmol amounts of n-methyl-d-aspartate and physostigmine, and umol amounts of glutamate and aspartate; strychnine was ineffective at this site. This is, therefore, the first identification of a site in the brain from which bilateral motor seizures can be elicited by a single, unilateral and focal microinjection of chemoconvulsants in low doses. This site is located in the deep prepiriform cortex (DPC) and is less than 2.0 mm in diameter. When microinjections of the convulsants were placed in areas adjacent to this active site, no convulsant actions were obtained. The seizures were similar to those evoked by kindling of the limbic system. The bilateral manifestation was evident both behaviorally (forelimb clonus, rearing and falling) and electrographically.

It appears that GABA-mediated inhibition exerts a tonic control of the excitatory mechanisms identified as involved in the origin of these seizures: direct microinjection of muscimol (40 or 80 pmol) prevented seizures induced by the local application of all convulsants examined. In contrast, atropine (150 pmol) prevented only those seizures induced by carbachol, but not those induced by bicuculline and kainic acid. This suggests that the cholinergic system is not crucial for the genesis of seizures from this region. Some other excitatory input must therefore be responsible for the seizures initiated by the local removal of GABAergic inhibition. A specific n-methyl-d-aspartate receptor antagonist, 2-amino-7-phosphonoheptanoic acid (2APH) (100 pmol), was effective in preventing seizures induced by focal application of all convulsants examined, suggesting that excitatory amino acid transmission may be critical for evoking seizures from this locus.

Supported by HHS Grants NS 20576 and DA 02206.

6.8 **ANTICONVULSANT EFFECTS OF GABA AGONISTS AND AN EXCITATORY AMINO ACID ANTAGONIST MICROINJECTED IN THE DEEP PREPIRIFORM CORTEX.** K. Gale, M. Pavlick*, and S. Piredda*. Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

We have recently identified a discrete site in the rat deep prepiriform cortex (DPC) from which bilateral motor and electrographic seizures can be induced by the unilateral microapplication of pmol amounts of bicuculline (Piredda, Lim and Gale, Life Sci. 36:1295-1298, 1985). To determine whether this site plays a crucial role in the development of seizures induced by the systemic administration of bicuculline, we microinjected GABA agonists bilaterally into the deep prepiriform cortex via chronic indwelling cannulas and examined responses to intravenous bicuculline. Generalized seizures induced by bicuculline (.36 mg/kg i.v.) were prevented by direct microinjection of muscimol (5 ng) or gamma-vinyl-GABA (GVG, 5 ug) bilaterally into DPC. Muscimol was effective when microinjected 15 minutes prior to seizure testing; GVG was effective at six and 24 hour after microinjection, consistent with its irreversible inhibition of GABA-transaminase. In addition, 2-amino-7-phosphonoheptanoic acid (2APH, 225 ng), an antagonist of n-methyl-d-aspartate receptors, protected against seizures induced by i.v. bicuculline when the rats were tested 15 minutes following application of 2APH bilaterally into DPC. No obvious behavioral or neurological changes were associated with the drug injections into DPC. These results indicate that a change in the balance between GABA-mediated inhibition and excitatory amino acid transmission in DPC may be a critical mechanism for the initiation of seizures by systemic bicuculline.

In contrast, GVG (10 ug) bilaterally microinjected into DPC was completely ineffective against seizures induced by maximal electroshock (MES) when rats were tested at six or 24 hours after GVG microinjection. These results are consistent with previous studies (Iadarola and Gale, Science 218:1237-1240, 1982) showing that elevation of GABA in substantia nigra and not in any other brain region, confers protection against MES.

Thus enhanced GABA transmission in DPC is selectively effective against chemically-induced seizures. This, taken together with the ability of several chemoconvulsants to induce seizures upon direct application to DPC suggests that the DPC is a likely site of origin of chemically-induced seizures.

6.9 CHRONIC TREATMENT WITH FG 7142 POTENTIATES CONVULSIONS INDUCED BY ISONIAZID AND DMCM. G. Biggio, O. Giorgi, B. Longoni* and M.G. Corda. Institute of Biology, Chair of Pharmacology, University of Cagliari, Italy.

We have previously shown that repeated intraventricular administration of β-CCE (10 μg/twice a day) potentiates, three days after the last administration, the convulsive pattern elicited by isoniazid (1). Here we report that chronic (10 days) intraperitoneal administration of FG 7142 produces a long-lasting (25 days) potentiation of the convulsive effects of isoniazid and DMCM. Rats were treated with FG 7142 (15 mg/kg i.p. twice a day) for 10 consecutive days. Control groups received an equivalent volume of Tween 80 vehicle. A challenge dose of isoniazid (350 mg/kg s.c.) was administered 5,10 or 25 days after the end of the chronic treatment. Control rats showed clonic seizures starting 40 to 90 minutes after the administration of isoniazid. None of them showed more than one convulsive episode. The convulsive effects of isoniazid on FG 7142-treated rats had the same latency as compared with control animals but a two-three fold increase in the number of convulsive episodes per rat was observed. Moreover, the pattern of convulsions displayed by these rats was distinguished by the appearance of severe tonic hindlimb extension. The convulsive action of DMCM (0.33 mg/kg i.v.) was also potentiated by chronic FG 7142. In fact, clonic seizures were observed in 30 and 80% of control and FG 7142 treated rats respectively. The effect of FG 7142 persisted for at least 25 days after the last treatment. The behavioural effcts elicited by FG 7142 were paralleled by a marked decrease in the density of low affinity GABA receptors in different brain areas. The results indicate that chronic administration of β-carbolines induces in the rat brain a persistent down-regulation of GABA receptors which in turn potentiates the convulsive effect of isoniazid and DMCM.

6.10 CHRONIC FG 7142 ADMINISTRATION INDUCES LONG LASTING PROCONFLICT EFFECT AND GABA RECEPTOR DOWN-REGULATION. M.G. Corda and G. Biggio. Institute of Biology, Chair of Pharmacology, University of Cagliari, Italy

The recent finding that the "proconflict" effect of β-carboline derivatives is potentiated and mimicked by different GABA function inhibitors, suggests that β-carboline-induced anxiety may result from a decrease in the GABAergic activity at the level of the GABA/benzodiazepine receptor complex. To further verify this hypothesis we studied the effect of chronic administration of the β-carboline derivative FG 7142 on an animal model of anxiety and on the kinetic parameters of brain GABA receptors. Adult male rats were injected with FG 7142 (15 mg/kg /twice a day/i.p.) or its Tween 80 vehicle for 10 days. Four and fifteen days after the last injection rats were tested in a modified Vogel's conflict test (PNAS 80: 2072, 1983) to detect proconflict drug action. Punishment-suppressed behaviour was enhanced four days (Control: 24 ± 1.9; FG 7142: 11 ± 1.6 shocks, $P<0.02$) and fifteen days (Control: 27 ± 2.1; FG 7142: 16 ± 1.4 shocks, $P<0.05$) after the last injection. On the other hand the same treatment failed to affect unpunished behaviour. In a parallel series of experiments ^{3}H-GABA binding was measured in different brain areas. Four and fifteen days after the last FG 7142 administration a 25% decrease in the specific binding of ^{3}H-GABA was found in the cortex and cerebellum of FG 7142-treated rats. As revealed by the Scatchard plot analysis the decrease was due to a reduction in the maximum number of binding sites (Bmax) with no change in the apparent dissociation constant (K_D). The results suggest that the long-lasting proconflict effect induced by chronic FG 7142 administration is the consequence of a persistent down-regulation of GABA receptors. This finding may provide useful clues to elucidate the molecular mechanism involved in persistent anxiety states in humans.

6.11 ANTICONVULSANT BUT NOT THE HYPNOTIC EFFECT OF BARBITURATES APPEARS TO BE MEDIATED VIA GABAergic TRANSMISSION. M.K. Ticku and S.K. Rastogi*. Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284 and Lafayette Clinic, Detroit, MI.

To define if the anticonvulsant and/or hypnotic effect of barbiturates is mediated through the GABA system, we compared the behavioral profile of the optical isomers of 1-methyl-5-phenyl-5-propylbarbituric acid (MPPB). R(-)MPPB produced dose-related loss of righing reflex, whereas S(+)MPPB produced dose-related convulsions. Subconvulsive doses of R(+)MPPB were proconvulsant with a single subeffective dose of picrotoxin but not with subeffective dose of strychnine. The seizures induced by S(+)MPPB were blocked by R(-)MPPB and pentobarbital. The loss of righting reflex of R(-)MPPB or pentobarbital was not blocked by the convulsant S(+)MPPB. The radioligand binding studies demonstrated that S(+)MPPB interacts with the picrotoxinin site as studies with [^{35}S]t-butylbicyclophosphorothionate (TBPS) competitively, whereas R(-)MPPB inhibited it noncompetitively. These isomers also give a differential profile on the dissociation of [^{35}S]TBPS; R(-)MPPB accelerating the dissociation of TBPS the most and S(+)MPPB the least (J. Neurochem. 44:480-486, 1985). Pentobarbital also protected against maximal electroshock seizures in rats in a dose-related manner. This protective effect of pentobarbital was blocked by bicuculline. Subprotective doses of pentobarbital in combination with a single subprotective dose of ethanol or diazepam produced a potentiation of the loss of righting reflex and the anticonvulsant effect of pentobarbital. Bicuculline, picrotoxin and RO15-1788 did not block the loss of righting reflex produced by pentobarbital. These results indicate that a) the anticonvulsant but not the hypnotic effect of barbiturates is mediated via GABAergic transmission; and b) anticonvulsant and convulsant barbiturates bind to distinct and/or possibly overlapping sites on the GABA receptor complex.

PEPTIDES: RECEPTORS I

7.1 BRAIN-HEART PEPTIDES: VISUALIZATION OF ATRIOPEPTIN RECEPTORS IN MAMMALIAN BRAIN. M. Dalpe*, T.V. Dam* and R. Quirion. Douglas Hospital Research Centre and Dept. of Psychiatry, McGill Univ., Verdun, Quebec H4H 1R3 Canada

Recently, we reported on the autoradiographic distribution of [^{125}I]atrial natriuretic factor (ANF) 8-33 binding sites in rat brain (Quirion et al, Peptides, 5, 1167-1172, 1984). We have now further characterized these sites using [^{125}I] rat and human atriopeptin. Male guinea pigs (500 g) were killed by decapitation and brains were rapidly removed and processed for receptor autoradiography (Quirion et al, Peptides, 5, 1167-1172, 1984) or for membrane binding assays. Assays were performed as follows: cerebellum and thalamus-hypothalamus areas were homogenized separately and then centrifuged at 49,000 g for 20 min. Membranes preparations were subsequently incubated for 60 min in 50 mM Tris.HCl buffer, pH 7.4 at 25^{0}C plus 150 mM NaCl, 5 mM $MnCl_2$, .01 mM EDTA. Na_2, 0.5% BSA and various concentrations of either (3-[^{125}I]iodotyrosyl^{28}) rat atrial natriuretic peptide (ANP) or (3-[^{125}I]iodotyrosyl^{28}) human α-atrial natriuretic peptide (α-ANP). Incubations were terminated by rapid filtration under reduced pressure through glass fiber filters (GF/C) presoaked in 0.1% polyethyleneimine. Specific binding of both ligands was determined as the difference in radioactivity bound in presence and absence of 1 μM ANF (8-33). In vitro ANP receptor autoradiography was performed exactly as described for ANF (8-33) by Quirion et al, Peptides, 5, 1167-1172, 1984. Our results indicate that both ANP and α-ANP bind with high affinity (0.02 - 0.08 nM) to a single class of saturable binding sites in guinea pig cerebellum and thalamus-hypothalamus area. Ligand selectivity pattern demonstrates that human α-ANP > ANF (8-33) > atriopeptin II in both tissues. In vitro receptor autoradiography demonstrates that ANP binding sites (in either ANP or α-ANP) are very discretely distributed in guinea pig brain. Moderate to high densities of sites are found in the external plexiform layers of the olfactory bulb, subfornical organ, lateral-medial nucleus of the amygdala, amygdalo-hippocampal area, paraventricular, paratenial, rhomboid and reuniens nuclei of the thalamus, granular cell layers of the dentate gyrus, medial geniculate nucleus and lobules 9 and 10 of the cerebellum. Very low to low densities of ANP sites are present in remaining brain regions. Thus, this study demonstrates the existence of specific ANP binding sites in mammalian brain and suggests the existence of a new family of brain-heart peptides.

7.2 ONTOGENY OF SUBSTANCE P RECEPTORS IN RAT BRAIN. T.V. Dam* and R. Quirion (SPON: P. Gaudreau). Douglas Hospital Research Centre and Dept. of Psychiatry, McGill University, Verdun, Quebec H4H 1R3 Canada.

Recent data have demonstrated the existence of high affinity binding sites for substance P (SP) in mammalian brain, including man (Quirion and Dam, in press). SP binding sites are mainly concentrated in forebrain region such as the olfactory bulb, caudate-putamen, septum, nucleus accumbens and hippocampus. In the brainstem, very low to low densities of SP sites are found except in the locus coeruleus, parabrachial nucleus, nucleus ambiguus and inferior olive, all areas enriched in SP binding sites (Shults et al, Peptides, 5, 1097-1128, 1984). We now report on the ontogeny of SP binding sites in rat brain using membrane binding assays as well as in vitro receptor autoradiography. 15 days pregnant female Sprague-Dawley rats were individually housed and had free access to food and water. The development of brain SP binding sites has been studied both pre- and post-natally in -3, -1, +3, +7, +14, +21 days and 3 months old rats of either sexes. Brain membranes were prepared for [^{3}H]SP binding assay as described before (Park et al, Peptides, 5, 833-836, 1984). In vitro SP receptor autoradiography was performed as described by Shults et al (Peptides, 5, 1097-1128, 1984). Our data indicate that SP binding sites reach maximal value one day before birth (B_{max} = 177.0 fmol/mg protein) and then decreased 3 days after birth (88.8 fmol/mg protein) to finally stabilize at adult levels (54.6 fmol/mg protein) fourteen days after birth (59.4 fmol/mg protein). Interestingly, the autoradiographic distribution demonstrates that SP binding sites undergo important redistribution during development. Prenatally (-3 and -1) and early after birth, (+3 and +7), SP binding sites are heavily concentrated in the brainstem with low densities in the forebrain while the opposite is true in adult brain. These data demonstrate the plasticity of SP binding sites and suggest possible roles for SP during brain development.

7.3 RAT BRAIN AND GUINEA-PIG ILEUM TACHYKININ SP-P RECEPTORS ARE REGULATED BY DIVALENT CATIONS AND GUANINE NUCLEOTIDES.
Prem Mohini* and José M. Musacchio. Dept. of Pharmacology, New York Univ. Med. Ctr., New York, NY 10016.

[^{3}H]Physalaemin ([^{3}H]PHY) was used to label the tachykinin SP-P receptor in rat brain and in the guinea-pig ileum. The binding of [^{3}H]PHY is specific, saturable and reversible. In the rat brain, monovalent cations increase the binding of [^{3}H]PHY in an ionic strength dependent manner. Addition of 2.5 mM $MnCl_2$ results in a two fold increase in affinity and a 40 percent increase in B_{max}. Scatchard analysis demonstrates a single population of noninteracting sites with a K_D of 3.3 nM and a B_{max} of 81.3 fmol/mg protein. GTP and Gpp(NH)p decrease the B_{max} by 33-40 percent in the presence of either 125 mM Na_2SO4, 2.5 mM $MnCl_2$ or both. However, guanine nucleotides do not decrease the CNS SP-P receptor affinity for [^{3}H]PHY.

Divalent cations also markedly increase the affinity of Gpp(NH)p for its binding sites as indicated by the increased effectiveness of guanine nucleotides to inhibit binding to the SP-P receptors.

Preincubation of the membranes with N-ethylmaleimide (NEM) or p-chloromercuribenzoate for 30 min irreversibly inhibited the binding of [^{3}H]PHY with an IC_{50} of 1.0 and 0.15 mM respectively. If the SP-P receptors were protected with 10 μM PHY, 3 mM NEM did not inactivate binding, but inhibited the effect of both, divalent cations and guanine nucleotides. These effects could be prevented by reduced glutathione or DTT.

Similar experiments in the guinea-pig ileum also demonstrated that manganese increases the binding of [^{3}H]PHY and that Gpp(NH)p inhibits it. Likewise, if the membranes are pretreated with NEM while the receptors are protected with 10 μM PHY, the effects of divalent cations and guanine nucleotides are blocked.

Since NEM has also been found to inhibit the regulatory effects of guanine nucleotides on adenylate cyclase coupled receptors, our findings indicate that even though the SP-P receptors are not linked to adenylate cyclase, the binding of SP-P agonists may be regulated by a GTP-binding regulatory protein.

7.4 ANGIOTENSIN II RECEPTOR BINDING IN THE BRAIN OF SPONTANEOUSLY HYPERTENSIVE RATS: AN AUTORADIOGRAPHIC QUANTITATIVE STUDY.
B.H. Hwang, J.-Y. Wu and J.W. Harding. Depts. of Anatomy and Physiology, College of Medicine, The Pennsylvania State University, Hershey, PA 17033, and Dept. of Vet. and Comp. Anat. Pharmacol. and Physiol., College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Angiotensin II (AII) is known to participate in several brain functions including the cardiovascular regulation. We used ^{125}I-[Sar^1,Ile^8]-AII (^{125}I-SI-AII), an AII antagonist, as radioactive ligand, and localized AII receptors in many parts of the central nervous system of the spontaneously hypertensive (SHR) and Wistar-Kyoto (WKY) rats.

The K_d values for ^{125}I-SI-AII binding to AII receptors in the membrane preparation from the septum/anteriorventral part of the third ventricle, dorsal medial brain stem, olfactory bulb and thalamus were around 0.1 nM. The B_{max} values were between 6.95 ± 1.60 to 15.52 ± 4.99 fmol/mg protein. Heavy labelling for AII receptors was recorded in nucleus tractus solitarius (NTS), paraventricular hypothalamic nucleus (PVN), subfornical organ (SFO), suprachiasmatic nucleus (SCN), area postrema, the dorsal motor nucleus of the vagus (DMV), and the nucleus of spinal tract of the trigeminal system (NST).

Among five areas assessed by using quantitative receptor autoradiography in conjunction with ^{125}I-standards, the NTS possesses the highest AII receptor binding. For example, there were 0.85 ± 0.05 fmol/mg protein AII binding in the NTS of 4-week old SHR rats, whereas there were 0.80 ± 0.17 fmol/mg protein AII binding in the NTS of age-matched WKY rats after incubation of 20-μ sections with 90 pM ^{125}I-SI-AII for 60 min. Non-specific binding was determined in the presence of 1 μM non-labeled SI-AII in the above ^{125}I-SI-AII. The heavy labelling of AII antagonist in the PVN, SFO, NTS, DMV, and NST indicates that there are high densities of AII receptors in these areas. One of the most interesting findings of this study is that SHR rats at early hypertensive (7 weeks) and established hypertensive (16 weeks) stages contained significantly higher AII receptor binding in the NST, as compared to age-matched WKY rats. Furthermore, AII receptor binding was significantly higher in the DMV of SHR rats at 16 week established hypertensive stage, but not at 7-week stage. It has been documented that the NST and DMV also contain high densities of opiate receptors. The literature and the present study are therefore collectively in favor of a notion that AII in association with the opiate system in the DMV and NST may play important roles in the development of hypertension in SHR rats. (Supported in part by AHA851334.)

7.5 COMPARISON OF NEUROTENSIN ANALOGS FOR SPECIFIC BINDING TO NEUROBLASTOMA CLONE N1E-115 AND INTRACELLULAR STIMULATION OF CYCLIC GMP.
J.A. Gilbert*, C.J. Moses*, M.A. Pfenning*, and E. Richelson. Mayo Foundation, Rochester, MN 55905.

Neuroblastoma clone N1E-115 possesses receptors specific for neurotensin (NT), an endogenous tridecapeptide (pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu). Neurotensin bound to receptors on N1E-115 cells cultured in growth medium containing fetal bovine serum with an equilibrium dissociation constant (K_D) of 11 nM, stimulating the intracellular production of cyclic GMP with a potency (EC_{50}) of 1.5 nM. A number of neurotensin analogs and fragments were compared for their ability to inhibit [^{3}H]neurotensin binding and induce intracellular cyclic GMP formation with intact N1E-115 cells. A direct correlation was found between the EC_{50} for each of these peptides in stimulating cyclic GMP production and its K_D for binding to neurotensin receptors.

The carboxyl-terminal half of neurotensin, NT(8-13), proved to be fifty times as potent as intact neurotensin in stimulating intracellular cyclic GMP formation and 17 fold more active in competing with [^{3}H]neurotensin binding. In contrast, NT(1-6) and NT(1-8) displayed no binding or biochemical activities, and substitutions of amino acids in the amino-terminal half of neurotensin did not significantly alter the biochemical activity of those analogs (e.g., [Gln^4]NT and [D-Pro^7]NT). Modifications in the carboxyl-terminal half of neurotensin produced drastic changes in activity. NT(1-11), NT(1-10), and NT-NHMe were inactive. NT(9-13) had 5 fold less biochemical activity than did native neurotensin and a K_D twenty times larger. [D-Arg^8]NT had the same biochemical potency as did neurotensin with half the binding activity, while substitution of a D-phe in position 11 and a D-pro in position 10 of neurotensin almost completely destroyed the biochemical and binding activities. [D-Trp^{11}]NT and [D-Tyr^{11}]NT retained some functional capabilities at very high concentrations. Replacement of the Tyr^{11} of neurotensin with Phe^{11} had no significant effect on the EC_{50} for stimulating cyclic GMP formation but it increased the K_D almost 7 fold.

All of the neurotensin peptides which were active in stimulating intracellular cyclic GMP production induced maximal responses similar to that of neurotensin itself except for those analogs with D-amino acids in positions 10 or 11, which produced maximal cyclic GMP levels that were routinely lower than that for neurotensin. In addition, [D-Trp^{11}]NT, a reported antagonist for the neurotensin receptor, displayed no ability in the concentration range of 0.01 to 1000 nM to inhibit the stimulation by neurotensin of intracellular cyclic GMP formation. (Supported by Mayo Foundation and USPHS Grant MH 27692).

7.6 NEURONAL CHOLECYSTOKININ RECEPTORS: BINDING CHARACTERISTICS AND EFFECTS ON SECOND MESSENGER SYSTEMS.
B. Petrack, D.J. Steel* and L.P. Wennogle, Neuroscience Research, Research Department, Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, N.J. 07901

It has previously been reported that cholecystokinin (CCK) recognition sites in the brain differ from those in the pancreas (Science, 208: 1155, 1980). CCK binding sites in membrane preparations from mouse and guinea pig cerebral cortex recognize carboxyl terminal fragments of CCK-8, CCK-4 being the smallest peptide with nanomolar potency. In the pancreas, the IC_{50} of CCK-4 is 1000-fold greater.

To determine further the structural requirements for binding to neuronal CCK receptors, some tetrapeptide analogs were evaluated on ^{125}I-(BH)-CCK-8 binding to mouse cortical membranes, according to published procedures. (Life Sciences 36: 1485, 1985). The results indicated that to retain nanomolar potency:

- The carboxyl terminus must be amidated. (The IC_{50} of CCK-4 was 5.9 nM, whereas the free acid was inactive up to 1.3 μM; Gly extension of the C-terminus reduced activity).
- The amino terminus may be free, but its blockade by t-BOC increased potency more than 20-fold.
- The β-carboxyl of Asp-32 should be free; esterification or amidation of Asp-32 markedly reduced activity.
- Replacement by Gly of each substituent amino acid residue in CCK-4 reduced potency 1000-fold.
- Ser or Gly insertion between Met and Asp abolished activity.

Despite the marked differences between brain and pancreas recognition sites, CCK receptors in both tissues have been reported to be coupled to phosphatidylinositol (PI) hydrolysis (J.B.C., 259: 4346, 1984; Cell Calcium, 3: 413, 1982). However, the effect was not confirmed in brain slices; CCK-8 did not induce inositol phosphate accumulation in ^{3}H-inositol-prelabeled mouse cortical slices under conditions where acetylcholine increased PI hydrolysis 500-600%. Furthermore, although CCK-8 modulates cerebellar cGMP (Steel,Wood and Petrack, this volume), the peptide did not affect basal or dopamine-activated adenylate cyclase in rat brain P_2 membranes or bovine retina.

We conclude that the differences between central and peripheral CCK recognition sites are reflected also in differences in effector coupling mechanisms.

7.7 AUTORADIOGRAPHIC LOCALIZATION OF CHOLECYSTOKININ RECEPTORS IN PRIMATE CORTEX. M.F. Kritzer, R.B. Innis, and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT. 06510.

Cholecystokinin (CCK), a putative peptide neurotransmitter, is found in high concentrations in the cerebral cortex of many species. Although CCK binding sites have been described in several of these species, the highly differentiated primate cerebrum allows a more fine-grained analysis of regional variation in the distribution of cortical receptors. We report here in vitro autoradiographic localization of CCK binding in the cerebral cortex of three macaque monkeys labeled with ^{125}I-Bolton-Hunter CCK-33. Briefly, thaw-mounted cryostat sections (20μ) of unfixed tissue were incubated in 50pM ^{125}I-CCK-33, dried, and placed against LKB Ultrofilm. The addition of 10^{-6}M CCK-8 to the incubation media was used to determine non-specific binding. Binding studies in tissue homogenates and slide-mounted sections showed that ^{125}I-CCK-33 labels a high affinity, saturable site in primate cortex, similar to that of rodent brain.

The laminar organization of CCK binding sites varies among cortical lobes and major cytoarchitectonic fields. In the frontal lobe, the distribution of binding sites is discontinuous: dense radiolabel is seen in the principal and cingulate sulci, while the interposed dorsomedial cortex is only lightly and diffusely labeled. Within all areas of the frontal cortex, radiolabel is distributed with highest concentration in layer IV. The parietal lobe has a similar laminar distribution, and also shows marked regional variation. For example, label is pronounced in layer IV in the rostral somatosensory cortex, but is very light in the intraparietal cortex. In the temporal lobe, from posterior amygdaloid to mid-hippocampal levels, high concentrations of putative CCK receptors are found in layer IV throughout the superior and inferior temporal cortex. A novel finding is the emergence of a bilaminar pattern in the inferior temporal cortex, with dense binding in layer II as well as layer IV. The occipital lobe displays a unique laminar distribution of binding sites which is uniform throughout primary visual striate cortex. In this region, radiolabel is heavy in layers I, V and VI, and, in contrast to other areas, layer IV is more lightly labeled.

Thus, CCK binding is unevenly distributed in primate cerebral cortex. Variations in density of putative CCK receptors across cytoarchitectonic regions and specific laminae in macaque monkey indicate that this peptide may have selective rather than diffuse influences on cortical functioning in primates.

7.8 THE PEARL MUTATION INDUCES HYPERSENSITIVITY OF THE RETINA TO SOMATOSTATIN-14. H. Suzuki* and L. H. Pinto. Department of Biological Sciences, Purdue University, West Lafayette, IN 47907.

We recorded action potentials from retinal ganglion cells, in the isolated superfused retinas of wild-type (C57BL/6J), pearl mutant (*pe*/*pe*) and pearl revertant (*pe*$^+$/*pe*$^+$) mice. Somatostatin of either 14 (SS-14) or 28 (SS-28) amino acid composition was introduced into the superfusate while the response of an on-center cell to an optimally-positioned light spot was recorded. The effects of SS-28 upon all genotypes were similar. 10-100 pM of SS-28 enhanced the on-discharge and increased the maintained discharge; 100 pM - 1 nM caused further enhancement of the response in some cells and suppression of the response and maintained discharge in other cells; over 1 nM suppressed in the response and maintained discharge in all cells; and over 10 nM caused long-lived suppression. The effects of SS-14 were similar to the effects of SS-28 in pearl mutants. However, no effect was observed in wild-type or pearl revertant animals for concentrations less than 10 nM. Higher concentrations produced the long-lived suppression seen with high concentrations of SS-28. We conclude that the pearl gene causes hypersensitivity to SS-14. The mechanism might be (a) expression of a normally unexpressed, high-affinity receptor molecule, (b) suppression of an endogenous endopeptidase for SS-14, and (c) mutation of a somatostatin receptor. If the free concentration of SS-14 in pearl mutant retinas were sufficiently high, then this compound might cause the night-blind phenotype observed in intact pearl mutants.

7.9 **ARE ANGIOTENSIN II AND SAR^1, ILE^8-AII BINDING SITES IDENTICAL?** **J.B. Erickson, and J.W. Harding. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520**

Angiotensin derivatives with a sarcosine substitution at the carboxy terminus and an aliphatic amino acid substitution at the amino terminus have been shown to be competitive ligands for the angiotensin "receptor". We have substantiated that data with competition experiments and by analyzing the data using double reciprocal plots. The results show that Angiotensin II and Sar^1,Ile^8-AII are clearly competitive inhibitors in the binding assay. However, a number of observations concerning the binding properties of these two ligands suggest a more complex story. (1) Scatchard plots derived from saturation isotherm data in rat brain membranes and rat and bovine adrenal particulates consistently demonstrate three to five times the number of binding sites for ^{125}I-Sar^1,Ile^8-AII than for ^{125}I-AII in experiments in which the two ligands are run side-by-side in the same tissue preparation. (2) Time course experiments in which dissociation was performed at equilibrium (60 minutes) reveals a very slow off-rate for both ligands, whereas dissociation at a time well before equilibrium (5 minutes) leads to complete dissociation in about 15 minutes. (3) Brain distribution data show binding sites for Sar^1,Ile^8-AII in areas where AII binding is not detectable. The paradox is that two ligands which interact competitively in vivo and in receptor binding studies have distinctly different B_{max} values. An explanation consistent with the above observations is that there are two populations of binding sites, one with fast on-fast off kinetics and a second with slow on-slow off kinetics. The slow on-slow off site may represent a modulatory protein such as a membrane bound angiotensinase associated with the angiotensin receptor. Both ligands competitively interact, but only the degradation resistant ^{125}I-Sar^1, Ile^8-AII analog may be detected at the putative enzyme site since ^{125}I-angiotensin II would be rapidly cleaved and lost. Thus, Sar^1, Ile^8-AII appears to interact with multiple binding sites which include, but are not limited, to the angiotensin receptor.

7.10 INTERACTION BETWEEN CENTRAL ASCENDING DOPAMINERGIC PATHWAYS AND NEUROTENSIN BINDING SITES IN THE RAT BRAIN. W.H. Rostène*, D. Hervé*, J.M. Studler*, P. Kitabgi*, C. Dana*, J.P. Vincent*, J. Glowinski* and J.P. Tassin*. *INSERM U.55, Hôpital Saint-Antoine, 75012 Paris; *INSERM U.114, Collège de France, 75005 Paris, and Centre de Biochimie CNRS, Faculté des Sciences, Parc Valrose, 06030 Nice, France

Several morphological, biochemical and behavioral data suggest an interaction between dopamine (DA) and neurotensin (NT) in both rat and human brains. We thus tested the possibility of NT binding sites regulation by DA pathways. Quantitative autoradiography was used to study the effect of 6OHDA lesion in the ventral mesencephalic tegmentum (VMT) on monoiodo ^{125}I-Tyr$_3$-NT binding on slide-mounted sections from adult male rats. Incubations were carried out with 0.1 nM monoiodo ^{125}I-Tyr$_3$-NT (2000 Ci/mm) for 60 min at 4°C in 50 mM Tris-HCl buffer (pH 7.6) containing 5 mM $MgCl_2$, 0.2% BSA and 20 μM bacitracin. The sections were washed, dried and apposed for 3 weeks on ^{3}H-Ultrofilm. Quantitation of the autoradiograms was carried out by means of ^{125}I-standards.

Correlated to endogenous DA depletions after 6OHDA, ^{125}I-NT binding was decreased in the VMT (-70%), central substantia nigra (-76%) and in the medial and lateral caudate nucleus (-23% and -41%, respectively). In contrast, no decrease was found in the nucleus accumbens and even a significant increase (+45%) of NT binding sites was observed in the prefrontal cortex (PFC) dorsal to the forceps minor, related to a change in the topographical distribution of the binding sites, suggesting a differential DA control of NT binding sites sensitivity in various brain regions.

In order to confirm this hypothesis, DA neurotransmission was chronically blocked by means of administrations (40, 20 and 5 days before sacrifice) of a long-acting neuroleptic, pipotiazine palmitate. This treatment elicited important increases of ^{125}I-NT binding sites in the PFC, nucleus accumbens, entorhinal cortex and medial caudate nucleus (+54%; +34%; +30%; +25%, respectively). No significant change was found in the lateral caudate nucleus, the VMT and in the substantia nigra. Our results confirm the presence of NT binding sites on DA cell bodies and strongly suggest that NT receptors on DA nerve-terminals are localized on two types of sites, one of which, located postsynaptically in limbic and cortical areas, is regulated by DA innervation.

7.11 CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTORS IN RAT BRAIN. April V. Applegate*, Michael J. Kuhar and Errol B. De Souza (SPON: K. Dismukes). Dept. of Neuroscience, Johns Hopkins Univ. Sch. Med. and Lab of Neuroscience, Addiction Res. Center, NIDA, Baltimore, MD

CRF, a 41-amino acid peptide originally isolated from ovine hypothalamus, stimulates the release of proopiomelanocortin-derived peptides from the anterior and intermediate lobes of pituitary. In addition, numerous pharmacological and immunohistochemical studies suggest a role for CRF as a neurotransmitter or neuromodulator in the CNS. Further evidence for such a role was provided by our autoradiographic identification and localization of high-affinity binding sites for a radioiodinated analog of ovine CRF (oCRF) in discrete areas of rat brain (De Souza et al., Science 224:1449, 1984). More recently, rat CRF (rCRF) has been isolated and sequenced, and this peptide differs from oCRF by seven amino acid residues. In the present study, we have used a stable iodine-125 labeled ligand (^{125}I-rCRF; New England Nuclear) which is homologous to the endogenous peptide to define the pharmacological characteristics and regional distribution of CRF receptors in rat brain homogenates. The kinetics and pharmacological specificity of ^{125}I-rCRF binding were characterized in membrane preparations of rat cerebral cortex and olfactory bulb. The binding of ^{125}I-rCRF was saturable and of high affinity with an apparent K_d of 1.9 nM and a B_{max} of 129 fmoles/mg protein in the cerebral cortex. Rat CRF, oCRF and the weak receptor antagonist α-helical CRF(9-41)NH_2 inhibited ^{125}I-rCRF binding with IC_{50} values of 1.4, 2.2 and 68 nM, respectively. The relative potencies of various peptides in displacing ^{125}I-rCRF binding were examined; at a 1 uM concentration, the CRF-related peptides oCRF, α-helical CRF, α-helical CRF(9-41)NH_2 and AcoCRF(4-41)NH_2 were equipotent with rCRF, the biological weaker fragment oCRF(1-39)NH_2 displaced 40% of the specific binding, rCRF(1-20)OH, rCRF(21-41) and rCRF(6-33)OH were minimally effective, and the unrelated peptides arginine vasopressin, angiotensin II, vasoactive intestinal peptide and growth hormone releasing factor did not affect ^{125}I-rCRF binding. Regional analysis indicated a heterogenous distribution of ^{125}I-rCRF binding sites within the rat brain and pituitary with highest densities of receptors present in the anterior pituitary and progressively lower concentrations present in the olfactory bulb and cerebral cortex; low but detectable levels of binding were found in the striatum, cerebellum, hippocampus, brain stem and hypothalamus. In summary, these studies using a ligand homologous to endogenous rCRF confirm the presence of specific, high-affinity receptors for CRF in discrete areas of rat brain. These data provide further evidence in support of a role endogenous CRF in regulating CNS function. Supported by NSF Graduate Fellowship and NIMH grants T32MH18030, MH25951 and MH00053.

7.12 COMPARISON OF THE AUTORADIOGRAPHIC DISTRIBUTION OF SUBSTANCE P, SUBSTANCE K, ELEDOISIN, AND NEUROMEDIN K BINDING SITES IN THE RAT CENTRAL NERVOUS SYSTEM. S.H. Buck, E. Burcher*, C.J. Helke, and T.L. O'Donohue. Sect. Biochem. Pharmacol., NHLBI; Exper. Ther. Br., NINCDS; Dept. Pharmacol., USUHS Sch. Medicine, Bethesda, MD; Div. Biol. & Hlth. Sci., Deakin University, Victoria, Australia.

In addition to the putative neurotransmitter, substance P (SP), two novel tachykinin peptides have been identified in the mammalian CNS. These are substance K (SK) (neurokinin α, neurokinin A) and neuromedin K (NK) (neurokinin β, neurokinin B), both similar in structure to the amphibian tachykinin, kassinin (KAS). SP and SK coexist in some neurons since a precursor, β-preprotachykinin, containing one copy of each peptide has been identified. Three distinct tachykinin receptors have been postulated in the CNS and periphery based on bioassay and ligand binding studies: P-type where SP and physalaemin (PHYS) are most potent, E-type where NK, KAS, and eledoisin (E) are most potent, and K-type where SK is most potent. Autoradiographic examination of the binding of ^{125}I-Bolton-Hunter labeled (BH) tachykinins has revealed that BHE, BHSK, and BHKAS binding sites have a different distribution from those for BHSP. However, it is not clear if the former three ligands all label one type (E) of site or E- and K-type sites in the CNS. We have investigated this question by directly comparing the autoradiographic distribution of BHSK, BHE, BHNK, and BHSP binding sites in the rat CNS.

The distribution of BHSK, BHE, and BHNK binding sites was strikingly similar but clearly distinct from sites labeled by BHSP. BHSK, BHE, and BHNK labeled cortical layers 4 and 5, the supraoptic n., paraventricular n., habenula, interpeduncular n., and the periaqueductal gray. Binding sites for BHSP were located in other regions including striatum, septum, dentate gyrus, superior colliculus, certain cerebellar vermi, n. ambiguus, hypoglossal n., and dorsal motor n. of X. Some CNS regions, such as the nucleus of the solitary tract and the dorsal horn of the spinal cord, contained binding sites for all four ligands. In general, BHSP binding sites have a more widespread distribution than those for BHSK, BHE, and BHNK. In the brainstem, BHSP appears to label both sensory and motor nuclei whereas BHSK, BHE, and BHNK label only sensory nuclei.

In crude membrane suspensions from rat cerebral cortex, the high-affinity binding of BHE and of BHNK was inhibited by the tachykinins in the potency rank order of KAS = E ≥ NK > PHYS > SK > SP indicating that both ligands bound to the recently characterized E-type cortical sites.

In conclusion, the results of these studies indicate that BHSP labels the P-type tachykinin receptor while BHSK, BHE, and BHNK all appear to label a distinct type of site, presumably the E-type tachykinin receptor, in the rat CNS.

DEVELOPMENT AND PLASTICITY: RETINA AND OPTIC NERVE

8.1 OCULAR PIGMENTATION AND THE BOUNDARIES OF DORSAL AND VENTRAL RETINA IN GOLDFISH. A.D. Springer and A.S. Mednick. Department of Anatomy, New York Medical College, Valhalla, NY 10595.

One operational definition used to distinguish dorsal from ventral retinal ganglion cells (RGCs) is to define them in terms of which optic tract their axons enter. Ventral RGC axons enter the dorsal optic tract and dorsal RGC axons enter the ventral optic tract. Dorsal and ventral retina have also been distinguished in terms of a horizontal meridian that passes through the optic disc and is perpendicular to a line that extends from the choroid fissure through the optic disc (vertical meridian). Cobaltous-lysine was applied to retinal slits that were centered on either end of the horizontal meridian and were parallel to the ora serrata. Such slits filled RGC axons in the dorsal optic tract. Thus, the present study found that the horizontal meridian does not accurately predict which optic tract RGC axons enter and it is, therefore, not a reliable indicator as to the boundaries of dorsal and ventral retina. Instead, the goldfish iris contains nasal and temporal pigmentation marks (PMs) that are correlated with the pathways that adjacent RGC axons enter. The PMs varied from fish to fish, but were located approximately 21° above the horizontal meridian. When cobalt was applied to retinal slits above the PMs, RGC axons were filled in the ventral optic tract. When cobalt was applied to retinal slits below the PMs, RGC axons were filled in the dorsal optic tract. In order to obtain converging evidence to prove that the PMs were indicators of the retinal poles, we severed nasal RGC axons along the dorsomedial edge of the optic tectum and retrogradely labeled the RGCs that corresponded to these severed axons. Cobalt-filled RGCs were found ventral to the nasal PM. The present findings indicate that these PMs are useful landmarks in that they reliably predict the nasal and temporal retinal poles. Thus, they could be a means by which to standardize electrophysiological retinotectal maps across studies. In addition, these landmarks would allow reliable intraretinal labeling of RGC axons from defined retinal sectors. Therefore, the PMs will be useful for elucidating the topographical transformations of the RGC axons within the visual pathways. Supported by Grant EY-03552.

8.2 **PHOTORECEPTOR DIFFERENTIATION IN VITRO: DEVELOPMENT AND POLARIZATION OF OPSIN IMMUNOREACTIVE MATERIALS.** R. Adler. Wynn Center, Wilmer Institute, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Retinal photoreceptors are highly polarized cells showing several discrete compartments. Opsin-containing visual pigments, for example, are synthesized in the inner segment and vectorially transported to and selectively accumulated in the outer segment. The mechanisms controlling the development and maintenance of this organization pattern are poorly understood. This laboratory is investigating some of these issues using a recently developed monolayer culture system in which embryonic retinal cells express typical photoreceptor phenotypic traits.

Photoreceptor-containing cultures were prepared as described (Adler et al., J. Cell Biol. 99:1173-1178, 1984) and fixed in paraformaldehyde. Opsin-immunoreactive materials were identified by indirect immunofluorescence using an anti-rhodopsin antibody (courtesy of Dr. D. Papermaster). F-actin was localized with fluorescent phalloidin. These studies showed that opsin-immunoreactive materials: i) are not detectable during the first 2-3 days in vitro; ii) appear first in an apparently random pattern; iii) become selectively concentrated in the photoreceptor apical region including the small outer segment-like process; iv) co-localize with an apical accumulation of phalloidin-stained materials; v) can be detected without plasma membrane permeation; and vi) are not present in neurons. In vivo studies carried out using cryostat sections of chick embryo retinas showed that opsin immunoreactivity is negative through ED15, and becomes detectable in photoreceptor outer segments by ED-16. Phalloidin-positive materials are also abundant in this photoreceptor region.

In summary, these studies show that cells isolated from the embryonic retina before overt differentiation are programmed to express characteristic photoreceptor phenotypic traits such as the polarized distribution of opsin. The co-localization of phalloidin-stained and opsin-immunoreactive materials is compatible with a possible involvement of the cytoskeleton in this phenomenon.

Supported by USPHS Grant EY04859.

8.3 **CALCIUM BINDING IN PIGMENTED AND ALBINO EYES.** Ursula C. Dräger. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Pigment defect mutations in mammals are associated with a diverse complex of neurological abnormalities which point to functions of melanin beyond photoprotection. Possible functions discussed include an involvement in redox reactions and scavenger roles for free radicals and potentially harmful heavy metals. The mechanism by which absence of these functions could lead to the defects in hypopigmentation mutants is not clear, however. Here the localization of Ca^{++} binding sites in eyes was determined autoradiographically by extracting endogenous Ca^{++} from tissue sections with EDTA and replacing it with $^{45}Ca^{++}$. The strongest labeling by far was associated with pigmented tissues, due to high concentration of melanin, which was shown to bind Ca^{++} very effectively and in a pH-dependent fashion. The second strongest binding was over the tapetum lucidum of the cat eye, and moderate labeling was associated with eye muscles and inner and outer epithelia of the cornea. The neural retina was generally more lightly labeled than the surrounding tissues of the eye; here the plexiform layers stood out in comparison to the nuclear layers, as did a band located internal to the photoreceptor outer segments.

The Ca^{++} binding to pigmented tissue was not influenced by the presence of Na^{+} or K^{+}; it was relatively insensitive to Mg^{++}, but it was reduced by high concentrations of Ba^{++}, Mn^{++} or Zn^{++}. Ca^{++} and Mg^{++} are probably the major natural ligands of melanin, since they are the only metals with melanin affinity present in more than trace amounts under normal physiological conditions. As binding of an ion of such biological relevance as Ca^{++} is not likely to represent a scavenger function of melanin, the possibility arises that melanin contributes to Ca^{++} regulation and that a defect in Ca^{++} buffering capacity may represent the common denominator of the various neurological defects found in hypopigmentation mutants. Melanin starts to appear in the embryonic eye around the time when the retina is presumably undergoing irreversible specification. At this stage the retinal pigment epithelium may represent a temporary Ca^{++} sink, causing a lowering of Ca^{++} in cells of the adjoining neural retina with which it is transiently connected via gap junctions; this in turn might influence the timing sequence of other processes by slightly delaying the closure of gap junctions; in such case the aberrant optic crossing in albinos may reflect a defect in temporal coordination. In the adult eye the massive Ca^{++} buffering capacity of pigmented tissues behind the retina may influence the Ca^{++} regulation in photoreceptors, and the light sensitivity defect found under scotopic conditions in the hypopigmented mouse pearl (Balkema et al. '81) may reflect a defect in Ca^{++} regulation, which is consistent with a role of Ca^{++} in dark adaptation. Supported by EY 01938 and the American Federation for Aging Research.

8.4 Development of the Outer Plexiform Layer (OPL) of the Cat Retina. Edward H. Polley, Roger P. Zimmerman, and Richard L. Fortney*. University of Illinois, College of Medicine, Department of Anatomy and Ophthalmology, Chicago, IL 60680 and Rush Medical College, Chicago, IL 60612.

The appearance and development of cells contributing processes to the OPL was studied in the fetal and neonate kitten retina. By using techniques of autoradiography after isotope labelling, combined with Lucifer Yellow staining to give a Golgi-like fluorescent representation of single cells, we were able to identify cell "birthdays" and/or classify cells on the basis of their cytoplasmic morphology. In an earlier study of neurogenesis in the inner nuclear layer (INL) (Polley, Walsh, and Hickey, 1982) we had shown that A-type horizontal cell neurogenesis was virtually complete while amacrine cell labelling was just starting at E28. No other cells in the INL are isotope labelled in adult animals injected in utero at E28, although cone photoreceptors are labelled in the outer nuclear layer (ONL).

Serial sacrifice at approximately weekly intervals of single individuals from litters of kittens receiving intravitreal injections clearly demonstrated the development, maturation, and distribution of pulse labelled cells in the neuroretina.

After intravitreal injection of tritiated thymidine in the neonate (postnatal Day 2) the principal population of labelled cells in the INL are the B-type horizontal cell and bipolar cells. Amacrine and Muller cells are rarely labelled although rod photoreceptors in the ONL are frequently labelled. A-type horizontal cells are completely unlabelled.

The differing time course for the production and development of A- and B-type horizontal cells in the INL of the retina is unique to our concepts of the development of laminar organization in the nervous system. There is however, a parallel in the early development of the A-type horizontal cell and associated cone photoreceptors in contrast to the later development of the B-type cell and associated rod photoreceptors. Indeed, the significant increase in the vertical dimension of the OPL after B-type cell birth is probably due to, 1) the developing dendritic processes of B-type horizontal cells in relation to cone pedicles, 2) the developing axonal processes of B-type horizontal cells to rod spherules, 3) the greater than 2:1 ratio of B- to A-type horizontal cells, and 4) the developing processes of newly formed bipolar and rod photoreceptor cells.

The differing time periods of neurogenesis during which these two cell types are produced and their insertion into the changing morphology of the developing retina could account for the reported differences in cell density and position in the adult retina. (Wassle, et al., 1978).

8.5 STAGES IN THE DEVELOPMENT OF THE INNER PLEXIFORM LAYER OF THE CAT RETINA. Roger P. Zimmerman, Edward H. Polley, and Richard L. Fortney*, Rush Medical College and University of Illinois College of Medicine, Chicago, Illinois 60612

The sequence of development of the inner plexiform layer (IPL) of the cat retina was studied over the two month period centered on the day of birth (E35 to P37) in experiments in which *in vitro* staining with Lucifer Yellow was combined with tritiated thymidine autoradiography or with electron microscopy. *In vitro* staining with Lucifer Yellow yields reliable and consistent Golgi-like staining of individual cells.

Early Fetal Retina (E35): The retina appears to consist primarily of ventricular cells, with a few amacrine and ganglion cells. Cones and horizontal cells have undergone their final mitosis, but are not yet morphologically differentiated. A distinct, unistratified, IPL is made up of the dendrites of several sizes of ganglion cells and processes of amacrine cells with somata lying on both sides of the IPL. Postmitotic cells can be observed crossing the IPL, indicating that the IPL is not a barrier to cell migration at this stage.

Late Fetal Retina (E51): The processes contributing to the IPL are clearly multistratified. Although differentiated cones and horizontal cells, and the beginnings of the outer plexiform layer, are present, no bipolar cell terminals are observed in the IPL.

Neonate Retina (P0 - P37): Bipolar cells are being produced during the first week after birth; their terminals enter the IPL within seven days after the final mitosis. By the end of the first postnatal month, ganglion cell dendrites are stratified in either sublamina a or sublamina b of the IPL, and receive both ribbon and conventional synapses. By P37 the pattern of branching of amacrine and ganglion processes is similar to that found in the adult retina. The laminar distribution of bipolar cell terminals is similar to that of the adult.

8.6 RELATIONSHIPS BETWEEN GANGLION CELL DENDRITIC FIELD STRUCTURE AND RETINAL TOPOGRAPHY IN THE CAT. J.D. Schall, S.J. Ault* and A.G. Leventhal. Dept. Anat., Univ. Utah Sch. Med., Salt Lake City, UT 84132.

The morphology of retinal ganglion cell dendritic fields varies with distance from the area centralis (Boycott, B.B. & H. Wässle, J. Physiol., 240:397, 1974) and with angle off of the horizontal meridian (Leventhal, A.G. & J.D. Schall, J. Comp. Neurol., 220:465, 1983). The center of the dendritic field of many ganglion cells is displaced laterally from the center of the cell body (Honrubia, F.M. & J.H. Elliott, Arch. Ophtholmol., 84:221, 1970; Wässle, H., L. Peichl & B.B. Boycott, Proc. R. Soc. Lond., B 212:157, 1981). We related the direction of displacement and the orientation of horseradish peroxidase filled retinal ganglion cell dendritic fields to the topography of the adult and developing retina. In our analysis the ganglion cell's principle dendrites primarily determine the displacement of the dendritic field from the cell body, and the orientation of a dendritic field is determined by the spatial distribution of higher order dendritic branches in the inner plexiform layer.

We find that the direction of displacement of the dendritic fields in any spot of retina can be predicted from the direction in which the ganglion cell density falls off most steeply in that spot of retina, i.e., ganglion cell dendritic fields are displaced from their cell bodies down the ganglion cell density gradient.

From approximately embryonic day 50 (of the 65 day gestation) to postnatal day 10 the kitten retina undergoes a period of maturation (reviewed by Rapaport, D.H. & J. Stone, Neurosci., 11:289, 1984). This process begins at the area centralis and spreads over the retina in a horizontally elongated wave. We find that the mean orientation of the dendritic fields in any spot of retina is predicted by the angle through which the wave of maturation passes in that spot of retina; the orientation of a dendritic field does not correlate with the direction of its displacement.

These findings indicate that the displacement of a ganglion cell's dendritic field from its cell body results from mechanisms different from those which are responsible for the orientation of higher order dendrites in the inner plexiform layer.

8.7 EXPERIMENTAL ALTERATION OF CAT RETINAL GANGLION CELL DENDRITIC FIELD STRUCTURE. S.J. Ault*, J.D. Schall and A.G. Leventhal. Dept. Anat., Univ. Utah Sch. Med., Salt Lake City, UT 84132.

Interactions among retinal ganglion cell dendrites (Wässle, H., L. Peichl & B.B. Boycott, Nature, 292:344, 1981; Perry & Linden, Nature, 297:683, 1982) may be responsible for many aspects of dendritic field structure. We have investigated these interactions by studying the effects of reduced ganglion cell density on dendritic field structure.

Areas of retina were depleted of ganglion cells following lesions of the optic tract or pinpoint lesions of the retina near the optic disc in two day old kittens. The dendritic fields of horseradish peroxidase filled ganglion cells which survived within or on the border of the depleted areas were compared with those of their normal counterparts.

While the somas of beta cells which survived within an area of reduced ganglion cell density were not significantly larger than normal, their dendritic fields covered an abnormally large area. To see how this was accomplished, we first related the amount of dendritic material supported by a cell to the size of its cell body. The resulting dendrite/soma ratios were compared for cells in normal and depleted regions of retina. This analysis indicated that the dendrite/soma ratios of beta cells in the depleted areas were not significantly different from normal. Moreover, all types of retinal ganglion cells exhibited similar dendrite/soma ratios; dendrite/soma ratios did not change with retinal eccentricity. A quantitative analysis of dendritic branching indicated that the dendritic fields of cells in depleted regions are abnormally large because their dendrites are distributed more diffusely, branching less than normal.

In agreement with the observations of Perry and Linden (1982) and Eysel, Peichl and Wässle (Soc. Neurosci. Abstr., 9:26, 1983), we have found that the dendritic fields of the alpha and beta cells on the border between normal and depleted regions extend preferentially into the depleted area. This is not accomplished by the growth of an abnormally large amount of dendrite since the dendrite/soma ratios of these cells were normal. Also, the orientations of these dendritic fields were often not the same as the direction of displacement. This provides support for the hypothesis that dendritic field displacement and orientation are determined by different mechanisms.

Based upon our results, we suggest that the size of a ganglion cell's soma determines the amount of dendritic material produced; the local ganglion cell density gradient determines the direction in which the dendritic field grows, and the density of neighboring ganglion cells of the same class determines branching frequency and the area which the dendritic field covers.

8.8 DEVELOPMENTAL CHANGES IN CELL DEATH AND RETINAL GANGLION CELL DISTRIBUTION IN THE POSTNATAL FERRET RETINA Z. Henderson, K. C. Wikler and B. L. Finlay Physiology Laboratory, University of Oxford, Oxford, England and Department of Psychology, Cornell University, Ithaca, NY 14853

The ferret is a highly altricial mammal with large eyes and a marked specialization for central vision which makes it particularly advantageous for studies of the process of formation of retinal specializations. For postnatal days 1 (the day of birth), 2, 3, 6, 10, 24 and adulthood, the spatial distribution of retinal ganglion cells was reconstructed from both paraffin embedded, horizontally sectioned eyes stained with cresylecht violet, and from similarly sectioned material in animals that had received multiple injections of horseradish peroxidase in the thalamus and superior colliculus on postnatal days 1, 2, 5, 9 and at adulthood. Retinae were reacted in the eyecup with cobalt-intensified diaminobenzidine. All retinae were examined for the incidence and spatial distribution of degenerating cells.

The adult ferret retina has an 8 to 1 ratio of cell density from the area of maximum density in the area centralis to the extreme periphery, and a 4 to 1 difference between central temporal retina overall and the remaining retina. On postnatal days 1 through 6, the distribution of all cells and HRP labeled cells is only slightly elevated in superior temporal retina (1.3 to 1). At all days, HRP labelled at maximum a third to half of the cells in the ganglion cell layer, which were always the largest cells. The remaining cells presumably are displaced amacrine cells and glia.

The period of cell degeneration in the retinal ganglion cell layer is quite protracted in the ferret, with large numbers of degenerating cells in evidence at birth, and many still visible by postnatal day 24. In the HRP labeled retinae, HRP reaction product could often be seen in the residual cytoplasm of degenerating cells. Numbers of degenerating cells were at maximum on postnatal day 1. On this day, their spatial distribution was distinctly inhomogeneous. Cell death rates were lowest in the superior temporal retina and temporal margin (15.7 ± 1.48), intermediate in the nasal margin, and highest in the remaining retina (21.5 ± 1.5). The incidence of degenerating cells was particularly high in the inferior retina and in the area immediately surrounding the optic disc in the nasal retina. If the retina is divided into the areas corresponding to the prospective area centralis and the periphery, there is no difference in rates (a.c. = 17.9 ± 1.8; periphery = 19.4 ± 1.6). On later postnatal days, the distribution of degenerating cells appears more uniform, with a suggestion of elevation in the periphery in the latest postnatal days. We suggest that the early inhomogeneity in cell death rates is related to the establishment of projection laterality; specifically, that the elevation of cell death in nasal retina reflects the removal of cells with inappropriate ipsilateral connections. The later cell death may reflect the mechanisms of creation of the area centralis or numerical matching of the retina to its targets.

8.9 RETINAL TRANSPLANTS INTO NORMAL AND DAMAGED ADULT RETINAS. M. del Cerro, D.M. Gash, G.N. Rao*, M.F. Notter, S.J. Wiegand and C. del Cerro*, Depts. of Anatomy and Ophthalmology and Center for Brain Research, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

We performed transplants of embryonic (E 13-16) and postnatal (PN 2) retina, neural portion, and pigment epithelium, into the anterior chamber and vitreal cavity of adult rats of the same (Long-Evans) and different strain (Lewis) than that of the donor. The hosts either had normal retinas or retinas selectively damaged by 15 days of continuous exposure to low levels (0.47 mw/cm^2) of fluorescent light. We report herein the successful outcome of these experiments. The fate of the grafts was followed by ophthalmoscopic examination for a period up to 5 weeks. Two to 3 days after transplantation, the grafts became vascularized; light and electron microscopic observations, therefrom, showed histotypical differentiation of the grafts. Although there was variability within different areas, those regions that developed more fully showed formation of all the nuclear and plexiform layers, which were populated by the usual neuronal and glial cell types; the retinal pigment grew and differentiated in the transplants. These results suggest that intraocular retinal transplants may become a valuable tool in determining the extent of neural repair and plasticity possible in the adult retina.

Supported by Supported by National Eye Institute grant #EY 05262 and by the Rochester Eye Bank.

8.10 GLIAL STRUCTURE IN RELATION TO FIBER ORDER IN THE FERRET'S OPTIC STALK. C. Walsh, S. Price*, & R.W. Guillery. Dept. of Human Anatomy, Univ. of Oxford, Oxford, OX1 3QX, England, and Dept. of Pharmacological & Physiological Sciences, Univ. of Chicago, Chicago, IL 60637, USA.

Retinal fibers in the ferret's optic nerve undergo a systematic sorting in terms of age during their course from the retina to the optic chiasm. Preferential labelling of the oldest retinal fibers shows that older and newer fibers intermingle in the nerve near the eye, but become segregated as the optic nerve leaves the orbit and passes through the optic foramen (Walsh, C., unpublished). In order to determine whether this fiber reordering occurs where the environment of the fibers shows a morphological change, we have studied the developing eye stalk in fetal ferrets from the twenty-first to the thirty-ninth days of gestation (E21-E39) with the light and electron microscope.

In its intraorbital segment, the fetal optic nerve is subdivided into fasicles by early glial cells. Bundles of unmyelinated axons are invaginated into the cytoplasm of these cells rather as fine axon bundles relate to Schwann cells in the peripheral nervous system. The axons lie close to the glial nuclei, and growth cones show no preferential localization within the cross-section of the nerve. In contrast, in the prenatal tract there are few glial cell nuclei, and instead optic axons grow in relation to the peripheral processes and end-feet of radially oriented neuroepithelial cells. This radial glial organization, typical of developing central tracts, is associated in the optic tract with the preferential growth of newer axons near the pial surface (Walsh, C. & Guillery, R.W., J. Neurosci., in press).

The transition from the "peripheral" glial structure to the radial glial, "central" structure occurs near the optic chiasm in the older animals (E30 and on), but the younger animals (E24-E26) show a radial glial structure in the eye stalk between the optic foramen and the optic chiasm, with the point of transition moving progressively nearer the chiasm at later stages. The youngest animals (E21-E24) show a transient pigmentation of the stalk, described previously (Strongin, A.C., & Guillery, R.W., J. Neurosci., 1:1193, 1981; Silver, J. & Sapiro, J., J. Comp. Neurol., 202:521, 1981), which extends from the eye to the optic foramen, the same region that shows the "peripheral" glial structure at slightly later stages. These data suggest that the systematic fiber reordering that occurs near the optic foramen reflects a change in the glial structure in this region.

Supported by funds from the MRC of the U.K., and by the Medical Scientist Training Program, NIH grant 5T32 GM07281.

9.1 MODULATION OF GABA, SUBSTANCE P AND PROTEIN KINASE IMMUNOREACTIVITIES IN MONKEY STRIATE CORTEX FOLLOWING EYE REMOVAL S.H.C. Hendry, E.G. Jones and M.B. Kennedy
Dept. of Anat., U. Cal. Irvine, Irvine, CA 92717 and Div. of Biol. Cal. Inst. of Tech. Pasadena, CA 91125

Neurons displaying immunoreactivity for the inhibitory neurotransmitter, GABA, for the neuropeptide, substance P (SP), or for a calcium/calmodulin-dependent protein kinase (type II CaM kinase) were examined in the striate cortex (area 17) of normal monkeys and of monkeys from which an eye had been removed one to three weeks before sacrifice. In normal monkeys, large numbers of GABA immunoreactive non-pyramidal neurons and punctate profiles are found in area 17. The stained cell bodies and profiles are densest in layers IVA, IVC and VI. SP-positive cells in area 17 are all non-pyramidal and are found mainly in layers II-III and VI. Others in layers IVA and IVC lie among a dense population of stained punctate profiles. These SP positive cell bodies and profiles are found to be also GABA positive in immunofluorescent double-labeling experiments. The CaM kinase immunoreactive neurons are present in all layers of area 17 and include a subpopulation of both pyramidal and non-pyramidal cells. They are densely packed in layers II and IVB and to a lesser extent in layer IVCB and VI. Within each subdivision of layer IV, staining for all three substances is uniform in normal monkeys. By contrast, three weeks following removal of one eye, GABA and SP staining in layers IVA and IVC becomes patchy. Patches of darkly stained cell bodies and terminals in layer IVC alternate with lightly stained patches. Comparison with adjacent sections stained for cytochrome oxidase shows that the patches coincide with ocular dominance columns; darkly stained patches correspond to columns driven by the intact eye and lightly stained patches by the removed eye. One or two weeks following eye removal, the protein kinase stained neurons in layer IVCB also form lightly and darkly stained patches. However, the darkly stained patches here correspond to columns related to the removed eye. Thus, eye removal leads to decreases in GABA and SP immunoreactivities and an increase in kinase immunoreactivity in neurons of removed-eye dominanace columns. The altered immunoreactivities may occur through changes in the concentration of each substance, brought about by a reduction in synaptic activity.

9.2 COMPARATIVE EFFECTS OF IMPULSE BLOCKAGE ON CYTOCHROME OXIDASE ACTIVITY IN THE VISUAL SYSTEMS OF MACACA MULATTA, FASCICULARIS AND SAIMIRI SCIUREUS. E.W. Carroll* and M. Wong-Riley. (SPON: D.A. Riley). Dept. of Anatomy, Med. Coll. of Wis., Milwaukee, WI 53226.

Intravitreal injections of tetrodotoxin (TTX) can reversibly alter the levels of cytochrome oxidase (C.O.) in the visual system (Wong-Riley and Riley, '83; Wong-Riley and Carroll, '84). We sought to compare our previous results in Macaca mulatta (Mm) with M. fascicularis (Mf) and Saimiri sciureus (Ss). In Mf, C.O. activity was also contrasted with monocularly enucleated (ME) animals. 19ug TTX in 10ul sterile saline were injected monocularly every 3-4 days, and survival times were 2, 4, 8, and 12 wks for Ss and 2 wks for Mf (both TTX and enucleation). Perfused tissues were then processed for C.O. histochemistry. Areal measurements of the C.O. rich "puffs" in laminae 2-3 were made using computer-assisted digitization. In the normal retina of each species, similar patterns of C.O. activity were observed: the large ganglion cells tended to be more reactive for C.O. than the smaller ones, and sublamina b of the inner plexiform layer (IPL) was more reactive than sublamina a. In both Mf and Ss, the difference between sublamina a and b was not as pronounced as in Mm. Horizontal cells, cone pedicles, photoreceptor inner segments and the outer plexiform layer were highly reactive. In all three species, slight decreases in C.O. activity (due to TTX) were observed in the ganglion cell layer and in the IPL. The pattern of C.O. activity in the normal dLGN (dorsal lateral geniculate) of Mf and Ss was similar to that of Mm (Wong-Riley and Carroll, '84). Magnocellular layers (1 and 2) were more reactive than the parvocellular layers, layer 6 was more reactive than 5, which in turn was more reactive than layers 3 and 4. In all three species, dramatic decreases in C.O. activity were observed after TTX treatment, the ipsilateral side being more affected than the contralateral. Both ME and TTX were equally effective in decreasing the amount of C.O. activity. In the visual cortex of Ss, TTX injections had little effect on the level of C.O. activity; however, one animal (4 wks) exhibited a slight banding pattern in lamina 4C in a limited region of area 17. In Mf (both TTX and ME), the decrease in C.O. activity produced the typical banding pattern (ocular dominance columns, ODC) in lam 4C, and shrinkage of the puffs overlying the affected ODC. On the average, there was no significant difference in areal decreases of affected puffs between Mm and Mf, and no difference between TTX injections and ME in Mf. However, in both Mm and Mf it appeared that lam 4Cα (normally 4.7% higher in optical density than 4Cβ) decreased by 9.7%, while lam 4Cβ decreased by 21.9%. These results indicate that even in the adult monkey, neurons in the retina, dorsal lateral geniculate nucleus and cortex (primarily in the Macaque) remain sensitive to impulse blockage at the retinal level. [Supported by NIH EY05439 (MWR) and IF32NS07664 (EWC)].

9.3 DEOXYGLUCOSE LABELING OF MACAQUES WITH MONOCULAR ENUCLEATION SHOWS STRIPES, NOT SPOTS, OUTSIDE OF LAYER 4 OF STRIATE CORTEX. S.J.Schein#, F.M.de Monasterio#, C.Kennedy+ & L.Sokoloff+
#Section on Visual Processing, National Eye Institute, NIH and +Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD. 20205.

Activity labeling with deoxglucose of macaques visually stimulated by normal viewing of the room produces a pattern in striate cortex of rows of dense spots in layers 2, 3 and less prominently, 5 and 6 (Kennedy et al. PNAS 1976). Layer 4, which is most heavily labeled, is uniform. Cytochrome oxidase (CO) histochemistry replicates this pattern.

If one eye is occluded, the pattern of 2DG in the ocular dominance "slabs" corresponding to the open eye is apparently unchanged, including the presence of rows of spots outside of layer 4. In the alternating slabs, no spots can be seen. Due to uniform reduction of label in layer 4 of the occluded eye's slabs, stripes appear in this layer. Others have reported this result, and we have observed it in 10 animals (including one with occlusion for 3 months) with only one exception.

Change in CO activity occurs slowly, so the CO pattern just after occlusion is normal. However, 2 months after enucleation of one eye, the CO pattern shows rows of dense spots outside of layer 4 and dense stripes in layer 4, alternating with rows of light spots and light stripes. The only difference between this pattern and the 2DG pattern found in animals with occlusion of one eye is the presence of the light spots in the former, perhaps due to insufficient passage of time. It would thus seem that (1) CO activity regulates according to chronic levels of metabolic activity, in parallel with the acute picture afforded by labeling with 2DG; (2) Removal of the input from one eye has little or no effect on the activity in the ocular dominance slabs corresponding to the other eye.

We report here, however, that the 2DG pattern after enucleation of one eye is quite different from that described above, in that all layers show stripes. Since activity of the interspot zones of the dense (seeing) slabs increases, no spots are found. This result has been obtained in 3 out of 3 unilaterally enucleated animals (and in the above-noted unilaterally occluded animal). In 2 animals, enucleation was performed on the morning of the 2DG procedure; in 1 animal, enucleation was performed several weeks earlier. We speculate that in normal macaques, activity in the interspot zones is reduced by binocular inhibition, which is released by removal of the other eye. We also suggest that the two conclusions listed above should be reexamined.

9.4 2DG EVIDENCE FOR A BINOCULAR BORDER ENHANCEMENT IN LAYERS 2+3 OF MACAQUE STRIATE CORTEX. +Tootell, R.B.H., +Hamilton, S.L.* and #Switkes, E.* +Dept. Psychol., U. Calif., Berkeley, CA and the #Dept. Psychobiology, U. Calif., Santa Cruz, CA

In the course of an extensive series of 2DG experiments in anesthesized, paralyzed macaques, we have discovered (quite serendipidously) a significant 2DG effect which appears to indicate a striate mechanism for extracting binocular object borders from more complex images in the monocular striate inputs. This 2DG "border enhancement" is a diffuse swath of obviously higher 2DG uptake (about 2 mm wide) which appears at the striate representation of certain stimulus borders (described below). Two aspects of the border enhancement are especially significant. First, it occurs only in striate layers 1-3: it is completely absent from the geniculate input layers 4A, 4C and 6, as well as from 4B and 5. Secondly, it appears only following binocular (but not monocular) viewing conditions.

An enhancement is produced at the striate border between the representations of: 1) two (or more) adjacent patterned stimulus fields which differ from each other in orientation, spatial frequency, or texture; or 2) one such patterned field and an adjacent unpatterned (diffuse) grey field of the same mean luminance. An enhancement does not appear at the representation of borders between two unpatterned grey fields of different mean luminance: this and other evidence indicate that the border enhancement is not an artifact of mean luminance per se. The enhancement is robust at the borders of regions of high (but not low) spatial frequency gratings. When the binocular convergence of the border is slightly misaligned, the border enhancement occurs between the diverged border representations, as well as on the border representations themselves. Surprisingly, binocular misalignment of up to a degree has no obvious effect on 2DG results within the representation of a given screen region, in any layer.

It is conceivable that the 2DG border enhancement is the result of feedback interaction from extrastriate areas, perhaps from V2. However, this seems unlikely because: 1) certain aspects of the striate border enhancement are retinotopically more discrete than any known extrastriate 2DG pattern, and 2) the border enhancement is faint in striate layer 1, where much of the projection from extrastriate cortex terminates.

Since the border enhancement appears to be computed de novo within striate layers which are largely binocular, this 2DG mechanism may provide a significant insight into the striate disparity architecture. Because the 2DG border enhancement occurs in layers 2+3 (which project to V2) but not in layers 4B and 6 (which project to MT and perhaps V3), it appears that at least some aspects of binocular coding are completely segregated within the V1-V2 (rather than the V1-MT) stream of visual information processing. 9.5 BINOCULAR CORRELATION SYSTEM IN MONKEY VISUAL CORTEX. G.F.Poggio, F.Gonzalez* and F.Krause*. Bard Laboratories of Neurophysiology, Department of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

The activity of cortical visual neurons during binocular vision reflects the interaction between the inputs from the two eyes and its characteristics are greatly influenced by the spatial and temporal correlation of the afferent signals. In order to investigate the neural substrate for binocular correlation, we have studied the effects of dynamic random dot patterns with different dot correspondence on the activity of single neurons.

Rhesus monkeys were trained on a fixation/detection task under conditions of normal binocular vision. Visual patterns irrelevant to the behavioral task were presented during the periods of eye fixation and the associated neural response observed. The response properties of the neuron, including its disparity sensitivity to contour stereograms and to dynamic random-dot stereograms, were first assessed. Subsequently, correlation sensitivity was tested with dynamic random-dot correlograms (RDC) generated on a square field (5^0 or 10^0) of random dots and displayed over the neuron's receptive field. All neurons were tested with fields of 1^0-4^0 50% dot density in which the dot pattern of a smaller (1^0-4^0) central region alternated from binocularly identical (correlation) to binocularly complementary (uncorrelation or negative correlation).

Whereas a majority of cortical neurons do not signal binocular correlation, others respond in opposite ways to correlated and uncorrelated patterns. One third of the neurons we studied in V1 (297) responded to uncorrelation either with an increase of their discharge (60) or with suppression (46); for both types the reciprocal effect was evoked by correlation which reduced the discharge of the former and increases that of the latter. Similar effects were found for smaller samples from areas V2 and V3.

A majority of neurons activated by binocular uncorrelation also responded to dynamic random-dot stereograms. Nearly all these neurons had complex receptive field properties, whereas complex and simple neurons occured in nearly equal proportion among the neurons suppressed by or insensitive to binocular correlation.

Although no relation was found between the neuron's disparity sensitivity for 'local' features and its sensitivity to binocular correlation, a particular association was observed for neurons whose activity was suppressed by decorrelation for, if disparity sensitive, they all had tuned excitatory response profiles.

These observations provide some support to the conjecture that binocular correlation and binocular disparity are processed by separate neural system, and that both modes of processing may be part of the functional repertoire of the neuron. (Research supported by USPHS, EY02966).

9.6 INTRINSICALLY PROJECTING PYRAMIDAL NEURONS OF MONKEY STRIATE CORTEX: AN EM-HRP STUDY. K.S. Rockland. E.K. Shriver Center, Waltham, MA. 02154

Periodic intrinsic connections have been reported in primate visual cortex within layers 2-3 and 4B (Rockland and Lund,'83). In layers 2-3, HRP injections show these connections to originate from pyramidal neurons, mainly small and medium in size (8.0 - 15.0um at soma base). These neurons have long horizontal axon collaterals that intracellular HRP injections (Gilbert and Wiesel, '83) show to branch at regular intervals. Still unknown from these light microscopic studies, however, is the type of synaptic contact made by these neurons. To address this issue, extracellular HRP injections were made in macaque striate cortex. After a 3 day postoperative survival, animals were perfused with a brief saline prewash, followed by 1.0% paraformaldehyde and 1.5% glutaraldehyde. Tissue blocks were vibratome sectioned at 50-60um, reacted with DAB, postosmicated, and plastic embedded. After light microscopic inspection to identify labelled areas, relevant portions were trimmed, reembedded for 1.0um sectioning, then reinspected and trimmed for electron microscopy (EM). Initial inspection has been restricted to layer 3. In this layer, EM reveals many HRP-filled axons, which can be clearly identified in longitudinal section as myelinated and of small caliber (commonly <0.75um in diameter). HRP reaction product is localized in large terminals (typically 1.0 x 1.5um), usually containing numerous mitochondria and a conspicuously high density of round vescicles. These terminals consistently form asymmetric synapses (about 0.25um in length) with dendritic spines. There are occasional examples of terminals synapsing with two adjacent spines. En passant synapses are also observed between large HRP-filled terminals (5.0um long in one ultrathin section) and two spines spaced 2.0um apart. These data are consistent with earlier lesion-degeneration studies on intrinsic cortical connections (Fisken et al.,'75), which reported a large population of degenerating terminals making asymmetric synapses with spinous profiles. The degeneration technique also labelled asymmetric synapses with dendritic shafts and stellate cell bodies, as well as a smaller proportion of symmetric synapses. Examples of these contacts have not yet been found in EM-HRP material. The present work indicates that intrinsically projecting pyramidal neurons in primate layer 3 form asymmetric, presumably excitatory synapses onto dendritic spines. Further experiments are necessary to determine whether these spines belong to other layer 3 pyramidal neurons, to sparsely spinous stellate neurons, or to other elements passing through layer 3.

9.7 ULTRASTRUCTURAL CHARACTERIZATION OF LONG-RANGE CLUSTERED HORIZONTAL CONNECTIONS IN MONKEY STRIATE CORTEX. B.A. McGuire, C.D. Gilbert and T.N. Wiesel, The Rockefeller University, New York, NY 10021.

Most pyramidal cells in the striate cortex form long-range clustered horizontal connections (Gilbert and Wiesel, J. Neurosci., 3: 1116-1133, 1983). To learn more about the functional role of these connections in monkey visual cortex, we are studying them using electron microscopy of cells which have been injected intracellularly with horseradish peroxidase (HRP). Cortical neurons were impaled with a micropipette, their receptive fields mapped, and the HRP injected iontophoretically. After fixation by perfusion, the cortex was sectioned, reacted with diaminobenzidine, and processed for electron microscopy. The first cell we have examined ultrastructurally had a well-oriented complex receptive field located a few degrees from the fovea. It was a pyramidal cell with the soma located in layer IIIB of area 17. Light microscope reconstruction revealed that the axon arborized extensively within the superficial layers and also projected into the white matter. In surface view, the axonal field of this cell was long and narrow, projecting antero-posteriorly, perpendicular to the 17/18 border, and extending for 2 mm along its long axis. The axon collaterals branched in 4 distinct clusters within layers II-III, separated from one another at regularly spaced intervals. One cluster, located 300 μm lateral to the apical dendritic tree, was chosen for analysis and serially sectioned for electron microscopy.

The HRP-labeled collaterals were followed through consecutive sections and photographed with the electron microscope. Labeled terminals were found to make asymmetric synapses. From an initial sample of HRP-labeled synaptic contacts, 80% were axo-spinous, the remainder being axo-dendritic. No labeled contacts were found on cell bodies. Serial reconstruction of the postsynaptic dendrites suggests that almost all of the postsynaptic cells were spiny. Furthermore, our preliminary evidence is that a disproportionate number of the postsynaptic processes were apical dendrites belonging to pyramidal neurons. Taken together, our results indicate that the long-range lateral interactions are excitatory, and exist between clusters of pyramidal cells. These results are consistent with the results of Ts'o et al. (Abstr. Soc. Neurosci. 9: 476, 1983) who have found excitatory long-range interactions in striate cortex on the basis of cross-correlation analysis. We speculate that the apical dendrites of pyramidal cells may represent a specialization for receiving the long-range horizontal connections within the cortex.

9.8 RELATIONSHIPS BETWEEN HORIZONTAL CONNECTIONS AND FUNCTIONAL ARCHITECTURE IN STRIATE CORTEX AS REVEALED BY CROSS-CORRELATION ANALYSIS. D.Y. Ts'o, C.D. Gilbert, and T.N. Wiesel. Laboratory of Neurobiology, The Rockefeller University, NY, NY 10021

We have been investigating the functional relationships between cells participating in horizontal interactions in striate cortex which may be mediated by intrinsic horizontal connections that have been demonstrated anatomically. We have previously reported experiments in cat and monkey striate cortex using cross-correlation analysis of pairs of superficial layer cells recorded from two independently manipulated extracellular electrodes. These experiments revealed excitatory horizontal connections that spanned distances in the millimeter range. The observed interactions were found in pockets suggestive of the clustered nature of long range horizontal connections. The horizontal interactions were found between cells with matched receptive field properties such as orientation specificity. The dependence of the horizontal interactions on matching orientation specificity was strong evidence that these connections were intrinsic.

Further experiments in the cat have shown that these horizontal interactions extend over several millimeters and at the longest distances the cells had non-overlapping receptive fields. The cytochrome oxidase-rich patches (blobs) in the monkey visual cortex offer another opportunity to study the relationship between intrinsic connections and functional architecture. Experiments show a tendency for unoriented monocular cells in the blobs to be connected to unoriented monocular cells in other blobs and not to oriented non-blob cells. These blob-to-blob interactions are excitatory. Correlated firing between blob cells with the same eye preference is more prevalent than between blob cells with a different eye preference.

We have found that a large proportion of the observed correlated firing between cell pairs is due to common input from an intrinsic source. In some cases, the orientation tuning of the cells providing the common input could be established. Several experiments used local iontophoresis of a glutamate analogue (DLH) at each recording site to raise the firing rates of the cells under study instead of light stimuli. In these experiments DLH stimulation usually did not reveal a direct connection between the cells. The prevalence of common input is likely to be due to interconnections between large numbers of cells in columns of like functional specificity.

9.9 VOLTAGE SENSITIVE DYES IN MACAQUE STRIATE CORTEX. G. G. Blasdel and G. Salama*. Departments of Ophthalmology, Physiology, and the Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

Recent successes in the application of voltage sensitive dyes to mammalian cortex (Orbach, Cohen, and Grinvald, 1983) have encouraged us to explore the use of optical probes in monkey striate cortex. Macaque monkeys were anaesthetized and prepared in a manner suitable for physiological studies. We then imaged a small (1x1mm) patch of cortex on 4 photodiodes and stained the cortex with an absorbence dye (NK2367). While the cortex was illuminated with light at 720nm, currents from the photodiodes were amplified and fed into a computer where they were averaged as the monkey viewed 20-40 presentations of visual stimuli - blank screen, vertical, or horizontal gratings (0.5 cy/deg, moving 8 deg/sec). In order to control for movement artifacts, we randomly interleaved sham presentations, where the animal saw only a blank screen, and synchronized each sequence to the animals respiration and its EKG (as first suggested by Orbach et al., 1983). Visually driven responses consisted usually of a reduction (by 0.1%) in the light reflected from a specific region of stained cortex. They appeared believable because they: (1) coincided with the onset of visual stimulation (either Horizontal or Vertical) and returned to baseline with its cessation, (2) showed different responses at different sites, (3) were repeatable from one sequence to the next, (4) were of large amplitude - twice that of anything produced by respiration or heartbeat, and (5) because their strength depended upon the focal plane - the optimal plane lying some 100-200 micra beneath the cortical surface. Due to their relatively slow time course - 1-2 sec to develop or decay - these changes seem unlikely to derive directly from membranes yielding action potentials. They could develop, however, from the depolarization of glial cell membranes or from the invasion (with repeated depolarizations) of small dendritic processes.

Preliminary experiments, using a TV camera and frame averager (together capable of detecting 0.02% changes in reflected light), have revealed stripe-like patterns of activity in 1.5x2mm patches of cortex. These patterns develop in response to visual stimulation and are specific for orientation. Those resulting from stimulation with vertical are approximately 0.2 to 0.4 mm in width and, for the most part, separate from those resulting from stimulation with horizontal. The sets of patches seen with vertical and horizontal do not form simple complements of one another, however, since there are regions where the cortex appears to respond to both vertical and horizontal, as well as regions where it appears not to respond to either orientation. Supported by EY05403, AHA18253, and in part by EY05282.

9.10 REAL TIME OPTICAL MAPPING OF NEURONAL ACTIVITY IN THE MAMMALIAN VISUAL CORTEX IN VITRO AND IN VIVO. A.Grinvald, C.D.Gilbert, R.Hildesheim*, E. Lieke* and T.N.Wiesel. Laboratory of Neurobiology, Rockefeller Univ., New York, N.Y. 10021 and Dept. of Neurobiology, The Weizmann Institute, Rehovot, Israel.

The use of voltage-sensitive dyes and optical recording of neuronal activity (Cohen, et al; Grinvald, Ann. Rev. Neurosci., 1978, 1985) is a potentially powerful technique for the evaluation of local circuits using in vitro brain slices (Grinvald, et al., J. Physiol., 1982) and for studying the functional organization of exposed brain structures in vivo (Orbach, et al., J. Neurosci., 1983, 1985; Grinvald, et al., Nature, 1984). However, past attempts to use optical mapping for the investigation of the cat visual cortex in vivo and in vitro were not fruitful due to the lack of penetration by the dyes into the cortex and to the inadequate signal-to-noise ratio (S/N).

To overcome these difficulties we have evaluated the performance of 57 dyes, including 29 which were newly synthetized, with a hippocampal slice preparation. We were able to improve the S/N considerably by finding a better dye (giving a 3 to 5 fold improvement over the best dye available previously, RH-414), by making fluorescence rather than transmission measurements and by using a brighter light source. This yielded a total improvement in S/N by a factor of 10 to 20, thus facilitating the recording of a pattern of population acitivity in hippocampal slices with a S/N of 20 to 30 without signal averaging (the fractional change in fluorescence was 0.5%). Several dyes were then tested on slices of visual cortex from cats and monkeys, where the electrically evoked activity is much smaller than that in the hippocampal slice. We therefore averaged over 20 to 30 trials when using the dimmer tungsten light source. Optical mapping of local circuits in the visual cortex confirmed many features of the known microcircuitry of the visual cortex.

Some of the newly designed probes were then used in in vivo experiments. Following topical application for 1-1.5 hours on cat and monkey visual cortex, the full cortical thickness was stained. When we used a flashing grating on a monitor screen, we obtained large optical signals, with a fractional change in fluorescence of 0.07%. The S/N was 10 to 15 when averaged over 20 trials, and 6 to 8 such measurements could be repeated on the same cortical area. For other visual stimuli, however, the signals were smaller and the heartbeat associated movement artifact interfered with reliable interpretation of the different patterns that were observed for different visual stimuli.

REGULATION OF PITUITARY FUNCTIONS I

10.1 THE PLASMA GROWTH HORMONE RHYTHM DRIVES THE RHYTHM OF EPISODIC SOMATOSTATIN RELEASE. M. Zorzaf A. Williams*, T. Hughes*, and L.C. Terry. University of Michigan and VA Hospitals, Ann Arbor, MI 48105.

In the rat, growth hormone (GH) is released episodically with a period of about 3 h between bursts. To account for the reduced responsiveness to iv injections of growth hormone-releasing factor (GRF) during the trough compared to the peak phase of GH release, Tannenbaum (Endocrinology, 115:1952, 1984) has proposed that hypothalamic somatostatin (SS) is also released episodically, about 180 degrees out of phase with the GH rhythm. This study was undertaken to determine if the GH rhythm induces the SS rhythm.

Chronically cannulated, unanesthetized, male rats were administered 500 ul antiserum to rat GRF (1-43) iv at 0930 h, which inhibited endogenous GH release to undetectable levels until at least 1600 h. GH release was stimulated by iv injection of 1 ug hpGRF (1-44) to which the antiserum to rat GRF showed no cross reactivity. Animals received two hpGRF injections either in phase (3 h apart) at 1245 and 1545 h or out of phase (4.5 h apart) at 1245 and 1715 h. No significant difference in pituitary GH responsiveness to hpGRF was found between the two injections whether delivered in phase or out of phase. Mean plasma GH (ng/ml) 5 min after the first and second injections was 1810 ± 288 and 1999 ± 438, respectively, in the in phase group (N=8) and 1610 ± 256 and 1730 ± 355 in the out of phase group (N=7). If SS continues to be released episodically at 3 h intervals even though the endogenous GH rhythm is suppressed, a significant difference in responsiveness to hpGRF injections delivered out of phase would have been anticipated. SS rhythmic release is apparently absent in GH suppressed rats.

A second experiment was designed to determine if an iv pulse of exogenous rat GH could induce SS release, again in rats treated with 500 ul antiserum to rat GRF at 0930 h. In rats given 1 ml normal sheep serum (NSS) at 1000 h, 20 ug rat GH in 250 ul saline was administered 1.75 h prior to a 1 ug hpGRF injection at 1245 h and 250 ul saline was administered 1.75 h before a 1 ug hpGRF injection at 1545 h. GH pretreatment significantly diminished the pituitary response to hpGRF at 1245 h. Mean plasma GH (ng/ml) 5 min after the first hpGRF injection was 500 ± 130 compared to 2180 ± 421 after the second (N=8). Administration of 1 ml antiserum to SS at 1000 h, instead of NSS, reversed the GH induced reduction of hpGRF responsiveness. In this group (N=6), mean plasma GH (ng/ml) 5 min after the first hpGRF injection was 1332 ± 362 and 1068 ± 220 after the second.

These results suggest that the GH rhythm drives the rhythm of episodic SS release. The hypothalamic somatostatinergic neurons constitute a GH dependent, passive oscillatory element in the control of the GH rhythm.

10.2 SOMATOSTATIN (SS) AUTOIMMUNIZATION INCREASED GROWTH RATE (GR) BUT REDUCED GROWTH HORMONE (GH) SECRETORY RESPONSIVENESS TO GROWTH HORMONE RELEASING FACTOR (GRF) IN LAMBS. M.A. Della-Fera, F.C. Buonomo*, C.A. Baile and M.J. Sabacky*. Nutr. Chem. Div. Monsanto, St. Louis, MO 63167

GH secretion is regulated primarily by two hypothalamic hormones: the inhibitory factor SS, and the releasing factor GRF. The balance between these two is thought to determine the frequency and amplitude of GH secretory episodes. Because of the inhibitory effect of SS on GH secretion, immunoneutralization should lead to increased GH secretion and thus increased GR. Lambs immunized with ovalbumin-SS developed high anti-SS titers and increased GH levels, but grew slower than controls (Varner et al, 1980). In contrast, lambs immunized with human a-globulin-SS (hg-SS) had increased GR compared to controls (Spencer & Garsen, 1983). We have tested two SS-antigens: 1) lambs (N=4/treatment) were immunized with thyroglobulin-SS (TG-SS) or TG (control); 2) lambs (N=7/treatment) were immunized with HG-SS or HG (control). In both cases GR, measured over a 16 wk period, was significantly greater in the SS-immunized sheep than in controls (TG-SS vs TG: .29 vs .24 Kg/day, $p<.01$; HG-SS vs HG: .31 vs .27 Kg/day, $p<.01$). Although there was no significant difference between TG-SS and TG sheep in plasma Somatomedin (SmC) levels, sheep immunized with HG-SS had increased plasma SmC levels compared to controls (0-16wk mean plasma SmC: 5.1 vs 4.2 U/ml, $p<.001$). To determine whether increased SS secretion was responsible for decreasing GH secretory responsiveness with multiple injections of GRF, SS-autoimmunized and control sheep were injected IV with GRF (.016 and .065 nmol/Kg doses in separate tests) hourly for three hours. In both TG-SS and HG-SS sheep plasma GH levels after each GRF injection (either dose) were significantly lower compared to controls. Thus, refractoriness to GRF may result from depletion of GH, changes in GRF receptor affinity or number and/or changes in post-receptor functions, but increased SS secretion does not appear to play a major role. Increased GR of SS-autoimmunized sheep, however, does suggest that SS-antibodies decreased the amount of SS reaching the somatotrophs, thereby resulting in greater GH secretion (as evidenced by increased SmC in one study), and increased GR.

10.3 SOMATOSTATIN IMMUNOCYTOCHEMISTRY IN GROWTH HORMONE-DEFICIENT SNELL DWARF AND "LITTLE" MICE. G.E. Hoffman and C.J. Phelps. Department of Anatomy, University of Rochester Medical Center, Rochester, NY 14642

Snell dwarf mice manifest a recessive genetic disorder which, when present in the homozygous condition, results in a pan-hypopituitarism; the condition includes failure to transcribe GH mRNA (Cheng et al., Endocrinology 113:1669, 1983). Mice possessing the unrelated "little" mutation exhibit an isolated GH deficiency, to 10% of normal levels (Ibid). GH has been shown to stimulate hypothalamic somatostatin (SS) levels, including restoration after SS depletion by hypophysectomy (Kanatsuka et al., Neuroendo. 29:186, 1979). Two recent reports have noted a significant decrease in radioimmunoassayed SS in median eminence, but not in pineal or stomach (Webb et al., Life Sci 36:1239, 1985), and in hypothalamus, but not other CNS sites (Fuhrmann et al., Brain Res. 328:161, 1985) among Snell dwarfs. The present study was undertaken to determine the anatomical distribution of SS in the brains of dwarf (dw/dw) and little (lit/lit) mice, and in their phenotypically normal counterparts, DW/? and LIT/?.

Brains of young adult (2-3 months old) male and female mice (Jackson Labs) were prepared by vascular perfusion with Zamboni's fixative; coronal sections were cut at 30 um and processed for immunocytochemistry using SS antiserum (Immunonuclear 1:1000), and the avidin-biotin technique. Specific staining was eliminated by substitution of non-immune serum, or by preabsorption of SS antiserum with 5-10 uM SS. In dw/dw mice, distribution of SS fibers and perikarya was comparable to the pattern observed in DW/? brains, except for immunoreactivity in hypothalamus. In dwarf median eminence (ME), there was a marked loss of SS terminals in the external zone; immunoreactive SS cells of the periventricular hypothalamus (PE) were extremely sparse and numbered less than 10% of normal. Despite the reduction in the PE-ME pathway, other hypothalamic SS cells and fiber projections appeared normal. In the brains of lit/lit mice, SS distribution was similar to LIT/? patterns in the PE-ME pathway, as well as in other regions.

These observations indicate that the SS abnormality in the hypothalamus of dwarf mice, detected by others biochemically, represents a specific defect in hypophysiotropic neurons. This defect maybe a primary manifestation of the Snell mutation, or be secondary to the pituitary disorder. The presence of normal SS patterns in the lit/lit mouse suggests that SS expression is independent of GH in that strain or that the small amounts of GH present in the little mice are sufficient to maintain SS expression.

Little mice were provided courtesy of the research facilities of Dr. W.G. Beamer. The study was supported by NIH grants HD18243 (CJP) and HD 18418 (GEH).

10.4 α-MELANOCYTE STIMULATING HORMONE EVOKES A STIMULATORY EFFECT OF β ENDORPHIN ON SOMATOSTATIN RELEASE. M.C. Aguila,* O. Khorram* and S.M. McCann. Dept. of Physiology, Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235

The influence of α-melanocyte stimulating hormone (α-MSH) and β-endorphin on the secretion of somatostatin (SRIF) from the median eminence (ME) was studied using an in vitro incubation system. Adult male rats were used as tissue donors. The ME's were first preincubated in 0.4 ml of Krebs-Ringer bicarbonate-glucose buffer with bacitracin, pH 7.4 at 37 C, in an atmosphere of 95% O_2, 5% CO_2 with constant shaking for 30 minutes. Medium was discarded and replaced by medium containing different doses of α-MSH, β-endorphin, or a fixed dose of α-MSH (10^{-7} M or 10^{-9} M) plus β-endorphin at various concentrations. By themselves α-MSH and β-endorphin were unable to affect basal SRIF release, but a 10^{-7} M concentration of α-MSH evoked a stimulatory effect of β-endorphin on somatostatin release. This effect was significant at 10^{-8} M and higher doses of β-endorphin. The permissive effect of α-MSH was observed at a dose as low as 10^{-9} M, but in this case the stimulatory effect of β-endorphin became evident only at higher doses tested (10^{-7} M). It is suggested that α-MSH and β-endorphin participate in the modulation of SRIF release. By themselves β-endorphin and α-MSH did not affect basal release of SRIF but in the presence of α-MSH, β-endorphin had a stimulatory effect on SRIF release. The mechanism for this interaction is unknown. The results are consistent with the possibility that β-endorphin neurons have stimulatory and inhibitory effects on SRIF release and that α-MSH by blocking the inhibitory components, discloses the stimulatory effect of β-endorphin on SRIF release. Experiments are being performed to test the validity of this hypothesis. (Supported by AM10073-19)

10.5 VENTRAL MEDIAL PREOPTIC NUCLEUS (vMPN) OR SUPRACHIASMATIC NUCLEUS (SCN) LESIONS COMBINED WITH ESTROGEN, PROGESTERONE TREATMENT; EFFECTS ON PROLACTIN (PRL) AND LUTEINIZING HORMONE (LH) IN THE CYCLING FEMALE RAT. M.A. Dykshoorn*, M.J. Kelly and O.K. Rønnekleiv. Department of Physiology, Oregon Health Science University, Portland, OR 97201 and Oregon Regional Primate Research Center, Beaverton, OR 97006.

The hypothalamic site of action of progesterone to induce an LH surge has been found to reside in the ventral medial preoptic nucleus (vMPN). Although SCN lesions abolish the proestrus and estrogen-induced PRL surge, the site of action of progesterone to induce a PRL surge has not been determined. In the present study bilateral electrolytic lesions were performed in the SCN (N=10) and/or the vMPN (N=6) of 4-day cycling female rats. The lesions were produced by passing 1-5 μA of anodal current for 3 min through a glass micropipette filled with Wood's metal, with a tip diameter of 60-75 μm and resistance of 2-10 MΩ. Vaginal smears were monitored before and 5-10 weeks after the lesions were made. Serial blood samples (0.4 ml) were obtained every 30-45 min for 6 1/2 hr on the afternoon of various stages post lesion. The plasma was retained for hormone determinations, the blood cells were resuspended in Plasmanate and reinjected. Lastly, partially (N=4) and complete (N=4) SCN-lesioned animals were injected subcutaneously with estrogen (25 μg) and then progesterone (2 mg) 48 h later. Control animals (N=4) received progesterone only on the morning of estrus.

Control lesioned animals cycled normally and exhibited low levels of LH and PRL during diestrus and estrus (3-50 ng/ml). PRL showed occasional spikes during the afternoon of estrus (100-250 ng/ml), and on proestrus PRL and LH surges occurred precisely on successive afternoons. Progesterone treatment on the morning of estrus induced PRL surges in all control animals. Discrete lesions in the SCN or the vMPN caused persistent estrus, interrupted occasionally with 1-2 days of diestrus-type smears. Animals with vMPN lesion or SCN lesions extending rostrally showed an estrus-type pattern of LH and PRL. Estrogen and progesterone treatment of vMPN or partial SCN-lesioned animals caused elevation of plasma PRL, whereas LH remained low. SCN-lesioned animals showed no significant change of plasma PRL or LH in response to estrogen and progesterone. Therefore, these findings indicate that the vMPN and the SCN both control the proestrus surge of PRL and that the SCN is necessary for the estrogen/ progesterone-induced surge of PRL.

10.6 ACUTE EFFECTS OF PROPRANOLOL IN UNILATERAL DECORTICATED ANIMALS DURING LH AND FSH PULSATILE RELEASE. J.C. Bedran de Castro*, S.L. Petrovic*, S.M. McCann (SPON: S. Speciale). Dept. of Physiology, Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235.

Previous studies indicate the involvement of the cortico-rhinencephalic pathways in pulsatile LH and FSH release since unilateral removal of these structures shortened the cycle period for LH and had the opposite effects for FSH. At the same time there was a significant increase in β-adrenoreceptor binding density probably due to a decrease in firing rate of the noradrenergic neurons projecting to the remaining cerebral cortical structures. Recently a possible inhibitory influence on gonadotropin secretion emanating from the cortex via a β-adrenergic pathway was suggested. To assess the physiological significance of these observations during the pulsatile cycle, female Sprague-Dawley control (C) and hemidecorticated (HD) rats (180-200 g) maintained under controlled lighting conditions (14 h light/10 h dark) were used 21 days after ovariectomy. In freely moving rats blood samples (250 μl) were withdrawn every 10 min over a period of 3 1/2 h and LH and FSH were measured. After 1 1/2 h d,l propranolol (PROP) (3 mg/kg) was administered i.v. in C and HD. The analysis of hormonal profiles indicated changes in number of LH cycles and cycle period after PROP. The LH and FSH overall means before PROP were higher in HD ($p<0.05$) compared with C. After PROP a decrease in LH overall mean occurred at 60 min ($p<0.05$) and at 120 min ($p<0.05$) in the HD group. The lower overall LH mean suggests a β-adrenergic blockade induced by PROP in the unilateral decorticate animals. A cortico-rhinenecephalic β-adrenergic mechanism inducing modulations in LH release in ovariectomized rats may be due to the increase in β-adrenergic binding capacity in HD animals as previously demonstrated. The lack of acute modulation in FSH levels suggests once more a differential LH and FSH pulsatile modulation. (Supported by FAPESP and HD09988).

10.7 WHICH LHRH NEURONS PROJECT TO THE MEDIAN EMINENCE? A COMBINED RETROGRADE TRACING AND IMMUNOCYTOCHEMICAL ANALYSIS. Ann-Judith Silverman and Leo Renaud. Dept. Anatomy & Cell Biology, Columbia Univ., P&S, New York, N.Y. 10032 and Neuroscience Unit, Montreal General Hospital, McGill Univ., Montreal, Canada, H3G 1A4.

LHRH neurons in the rat CNS are not concentrated into a single nuclear group but are widely distributed in preoptic, hypothalamic, septal and olfactory regions. The major, if not sole, neurosecretory terminus where neurohormone is released is in the median eminence (ME). Since it is not known which specific LHRH neurons innervate this structure, we used a modification of the procedure of Wiegand and Price (J. Comp. Neurol. 1980 192:1) to answer this question. A 10% wheat germ agglutinin solution (WGA: EY Labs) was administered by pressure injection in nanoliter quantities via a micropipette (20-40 um tip) directly into the ME via a transpharyngeal approach in pentobarbital anesthesized male Sprague Dawley rats. 10-12 hrs later, animals were perfused (Zamboni's fixative) and the lectin localized immunocytochemically in 50-75 um vibratome sections (antibody: EY Labs) using an avidin-biotin-HRP procedure (Vecastain) with DAB as the chromagen. The reaction product was seen as discrete brown dots within neuronal cytoplasm corresponding to the vesicular structures within which WGA was transported. Sections were washed and then incubated in an antibody to LHRH (Benoit, LR-1) which was localized with an avidin-fluorescein procedure (Vecastain). Sections were analyzed to determine which LHRH neurons were retrogradely labeled, i.e., projected to the ME. Approximately 50% of the LHRH neurons found in the diagonal band of Broca, the medial and triangular septal nuclei, the medial and lateral preoptic area and the lateral hypothalamus just dorsal to the supraoptic nucleus also contained WGA. The doubly and singly labeled cells showed no obvious preferential distribution in any of these regions. Both smooth contoured and thorny or spiny LHRH cells were observed; both types were also doubly labeled. These data suggest that the neurosecretory cells that directly influence gonadotropin secretion are widely distributed in the rat CNS and that neighboring cells containing the same peptide may have different efferent projections.

10.8 CORRELATIVE STIMULATION OF SUPRAOPTIC NEURONS AND VASOPRESSIN RELEASE TO NORADRENERGIC STIMULATION IN VITRO W.E. Armstrong, M.J. Gallagher* and C.D.Sladek. Dept.of Anatomy, Univ. of Tenn. Ctr. for Health Sci., Memphis, TN 38163 and Depts. of Neurology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

When a neuroactive substance is implicated in the control of neurohypophysial hormone release, seldom does an investigator have the opportunity to directly measure the substance's action on both hormone release and on the electrical activity of the neurons synthesizing the hormone in question. Such an experiment can be accomplished in vitro using the isolated hypothalamo-neurohypophysial system, which retains intact a substantial number of supraoptic neurons and their projection to the neurohypophysis. In the present study, explants prepared from male albino rats were used to assess the action of noradrenergic agonists on the electrical activity of supraoptic neurons and vasopressin released into the perifusate.

Following their excision explants were perifused in a balanced salt solution at 2 ml/min. After a 2-3 hr recuperative period, extracellular recordings were made in the retrochiasmatic portion of the supraoptic nucleus, which contains a majority of neurons immunoreactive for vasopressin. Potentials identified antidromically from neural stalk stimulation were held for a 2 hr period during which drug applications were made and samples of the effluent collected every minute for radioimmunoassay.

Basal vasopressin release ranged from being undectable to approximately 5 pg/min. Transient injection of the α_1-agonist, phenylephrine (0.1 µm-1 mM) into the perifusate resulted in a dose-dependent release of vasopressin and a burst of action potentials in the recorded supraoptic neuron. Within an explant the mean within-burst firing rate for the first 30 sec of the burst was positively correlated with the peak rate of vasopressin release, which usually occured during the second minute of collection following drug application. In equimolar amounts, noradrenaline was associated with a greater rate of vasopressin release than was phenylephrine and also excited supraoptic neurons. Neither the β-agonist isoprenaline (100 mM) nor the α_2-agonist clonidine (100 mM) stimulated vasopressin release or supraoptic neurons.

The consistent ability of phenylephrine to release vasopressin is predictable considering that in additional electrophysiological experiments 88% of all retrochiasmatic supraoptic neurons were excited by this compound, including 48 of 56 slow/silent neurons and 16 of 17 phasic neurons. Since the great majority of these neurons synthesize vasopressin, the results indicate vasopressin release and excitation of vasopressin secreting neurons are directly associated during noradrenergic stimulation.

10.9 ANTIDIURESIS PRODUCED BY α-ADRENERGIC AND DOPAMINERGIC STIMULATION OF THE RAT SUPRAOPTIC NUCLEUS. Sarah F. Leibowitz and Kenneth F. Garay.* The Rockefeller University, New York, N.Y. 10021.

To examine the role of central catecholamine (CA) systems in the control of urine formation, CA agonists were injected through a chronic cannula directly into the supraoptic nucleus (SON), and their effects on the urine output of freely-moving, hydrated rats was measured. l-Norepinephrine (NE) and l-epinephrine (EPI), in contrast to their d-isomers or various control solutions with adjusted pH, osmolarity or bitartrate concentrations, produced a clear state of antidiuresis, characterized by a strong suppression of urine flow (30-70%), an increase in urine osmolality and Na^+ and K^+ concentrations, but no change in the ratio of Na^+/K^+, nor in the clearance of creatinine. This antidiuretic effect was dose-dependent (0.05-100 nmoles), lasting 15-120 min and, in particularly responsive animals, could be observed at a dose at least as low as 1.0 pmole (170 pg free base). A 25 ng dose induced a similar response, comparable in magnitude and duration, to that induced by sc injection of 300 µU lysine vasopressin. A somewhat less robust antidiuretic effect was obtained with SON administration of dopamine (DA).

SON injections of the α-adrenergic antagonists, phentolamine, phenoxybenzamine and tolazoline, were effective in blocking the action of NE or EPI, whereas other receptor antagonists, including β-adrenergic, DA, cholinergic (muscarinic and nicotinic), and serotonergic blockers were,without effect. The DA antagonists, haloperidol and pimozide, in addition to the α-adrenergic blockers, antagonized DA-induced antidiuresis. At higher doses, both phentolamine and haloperidol, and also the CA synthesis inhibitor α-methyl-p-tyrosine, each acted in the opposite direction to the agonists, producing increased diuresis after SON injection.

Cannula mapping studies with NE (0.1-20 nmoles) showed that the hypothalamic paraventricular nucleus (PVN) can exhibit a similar, although somewhat less robust, antidiuretic response to α-noradrenergic stimulation. The sensitivity of this nucleus contrasted with that of the ventromedial nucleus, which responded only to a high dose (10 nmoles) of NE, and with that of the caudal lateral hypothalamus, the rostral perifornical hypothalamus just lateral to the PVN, the nucleus accumbens and caudate nucleus, which were generally unresponsive to NE.

From these results, it is concluded that NE (α) and DA, in the SON and PVN, act to induce a state of antidiuresis. Based on a variety of evidence, including measurements of cardiovascular changes, it is suggested that this antidiuretic effect may result from the release of vasopressin from magnocellular neurons in these hypothalamic nuclei.

10.10 OPIOID PEPTIDES MEDIATE THE WATER-INDUCED REDUCTION IN PLASMA VASOPRESSIN AND OXYTOCIN CONCENTRATIONS OF HYPOVOLEMIC RATS. L.M. Rosella-Dampman*, R.D. Hartman*, and J.Y. Summy-Long (SPON: W.B. Severs), Dept. of Pharm., Penn St. Univ., Hershey, PA 17033.

Overhydration inhibits release of vasopressin (VP) and oxytocin (OT) from the hypothalamo-neurohypophysial system (HNS) stimulated by hypovolemia (Stricker and Verbalis, Soc. Neurosci. Abstr. 10:90, 1984). We proposed that endogenous opioid peptides (EOP) mediate inhibition of the HNS by H_2O during hypovolemia. The effect of naloxone (NAL), an opiate receptor antagonist, on plasma [VP] and [OT] was studied in normal and overhydrated male rats made hypovolemic by either hemorrhage (HEM) of 35% blood volume (B.V.; 65 ml/kg) or injection of polyethylene glycol (PEG; 20-M). B.V. was reduced by removing blood at a rate of 0.51 ml/min from catheters placed in the femoral artery 2 days earlier or by s.c. injection of 30% PEG (w/v, 35 ml/kg). When 10% of the B.V. was removed (HEM) or 6.75 hr after PEG, rats were intubated (no H_2O) or given H_2O (40 ml/kg, p.o.), which lowered plasma osmolality 8-18 mOsm/kg. Saline (SAL, 1 ml/kg) or NAL was injected 4 min before HEM (2 mg/kg, i.v.) was ended or 6.83 hr after PEG (5 mg/kg, s.c.). Rats were decapitated 5 min (HEM) or 10 min (PEG) later. Control animals were treated similarly but not HEM or were injected with SAL without PEG. Plasma VP and OT (pg/ml ± SE; n4-14) were quantified by RIA, and analyzed by ANOVA. HEM increased ($p < 0.05$) plasma [VP] (5±1 vs 334±92) and [OT] (83±10 to 329±72). Water reduced ($p < 0.05$) the rise in [VP] (127±27) and [OT] (146±27) after HEM, but not in controls (VP: 6 ± 1; OT: 78 ± 10). NAL elevated [OT] in HEM rats that were intubated (508±83) or overhydrated (469±86) without affecting [VP]. In control rats that were not HEM, plasma [OT] but not [VP] was increased by NAL after intubation (OT: 127±11) or overhydration (OT: 181±28). Since surgery (vs unoperated controls) in the HEM study altered basal levels of OT (83 ± 10 vs 6 ± 0.2 pg/ml), we examined NAL effects during hypovolemia produced by PEG, a less invasive protocol. PEG increased [VP] (2±0.2 vs 41±6) and [OT] (6±0.2 vs 77±17). Water suppressed ($p<0.05$) the PEG-induced rise in [VP] (13±1) and [OT] (22±4) without altering levels in controls (VP: 2 ± 0.3; OT: 6 ± 0.8). As during HEM, NAL augmented the rise in [OT] (395±75) but not [VP] (42±6) after PEG. However, in overhydrated animals, NAL partially reversed ($p<0.05$) the water-induced reduction in both [VP] (21±3) and [OT] (118±33) after PEG. Neither NAL nor H_2O affected [VP] or [OT] in controls. Similar results were obtained in the PEG study when data were expressed as pg hormone per mg plasma protein. Thus, H_2O attenuated release of hormones during hypovolemia rather than only diluting their concentrations. We conclude that EOP: a) inhibit release of OT after surgery and hypovolemia, and b) mediate, in part, the inhibitory effects of water on release of VP and OT during hypovolemia. (Supported by NIH HL 32826).

10.11 OXYTOCIN ANTISERUM BLOCKS STEROID-INDUCED PROLACTIN RELEASE AND ATTENUATES THE PROLACTIN RESPONSE TO SUCKLING. WK Samson, MD Lumpkin & SM McCann (SPON: A. Rupert). Physiol, Southwestern Med Sch, Dallas, Tex 75235.

We have reported previously that synthetic oxytocin (OT) possesses powerful and specific prolactin (PRL) releasing activity in vitro (Endo. 112:1711, 1983; Fed. Proc. 43:503, 1984) at doses similar to those found in hypophysial portal blood in vivo (Endo. 114:1216, 1984). Additionally, we have reported that OT surges in peripheral plasma preceed those of PRL following a suckling stimulus and after steroid treatment in the rat. Steroid treatment: Injection of estradiol benzoate (5µg, sc) in ovariectomized rats results two days later in a significant release of OT at 1200 and 1300h and PRL at 1300h. When 1ml normal rabbit serum was infused i.v. at 1000hr, the PRL peak at 1300h was still present (1100h:9.23±1.30; 1200h:17.64±5.84; 1300h:40.88±13.15; 1400h:23.20±12.60ngm PRL/ml plasma). However, infusion of 1ml antiserum specific to OT completely abolished the PRL surge (1100h:13.23±7.63; 1200h:10.28±3.91; 1300h:10.68±3.22; 1400h:13.53±3.36). These preliminary data suggest a possible physiological PRL releasing factor (PRF) role for endogenous OT released into hypophysial portal blood on the afternoon of proestrus (Sarker and Gibbs, Neuroendo. 39:481, 1984) just prior to the proestrous PRL surge. Lactation: Both OT and PRL are released in response to a suckling stimulus; however, if suckling is maintained, levels of PRL remain elevated, while those of OT return within 30 min to presuckling baseline (Soc. Neurosci. 136:12, 1983). When mothers were denied their pups for 4hr and 1ml normal rabbit serum (NRS) was infused (n=6) i.v. just prior to pup reinstatement, suckling induced PRL release occured as expected, however following infusion of 1ml antiserum to OT (n=9) the surge was significantly attenuated (prior to pup reinstatement:NRS 18.3±8.1, anti OT 21.0±2.9 ngm PRL/ml plasma; 45 min later:NRS 300.1±76.8, anti OT 113.8±40.4, $p<.05$; 60 min later:NRS 399.0±89.1, anti OT 115.2±25.6, $p<.005$). Infusion of a lower titer anti OT serum was without effect. Thus while some investigators feel that the initial PRL response to suckling is dependent upon dopamine withdrawal (Grosvenor and Mena, Neuroendo. Persp., Vol. 1, 1982) the initial release of PRL appears to be in part due to OT. The ability of OT antiserum to completely block this initial PRL surge is similar to results obtained by Abe et al. (Endo. 116:1383, 1985) using antiserum to VIP suggesting a multiplicity of peptidergic PRFs during this phase of PRL release. In summary, the ability of OT to stimulate PRL release in vitro coupled with our present data on passive immunoneutralization of endogenous OT strongly suggests a role for OT in the physiological control of PRL release.

10.12 HIGH GLUCOSE UTILIZATION IN THE PITUITARY NEURAL LOBE OF BRATTLEBORO RATS IS DECREASED BY DESMOPRESSIN. M. Kadekaro and P.M. Gross. Lab. of Cerebral Metabolism, NIMH, Bethesda, MD 20205, Div. of Neurosurgery, UTMB, Galveston, TX 77550* and Dept. Neurological Surgery, SUNY, Stony Brook, NY 11794. *Present addresses.

Our previous studies showed that high glucose utilization in the pituitary neural lobe of Brattleboro (DI) rats persisted after chronic treatment with arginine vasopressin (AVP), while other brain structures exhibited normal rates of glucose utilization (Brain Res. 275:189, 1983). This finding conflicted with the semi-quantitative studies of another group (Sutherland et al., Brain Res. 271:101, 1983) who found an apparent normal level of glucose utilization in the neural lobe of DI rats after acute treatment with desmopressin (dDAVP, 1-desamino-8-D-arginine vasopressin), a synthetic analogue of AVP with a more potent and prolonged antidiuretic effect. Using the quantitative autoradiographic deoxyglucose method we have reexamined the local rates of glucose utilization in the brain and neural lobe of DI rats given dDAVP. Four month-old DI rats were injected either with dDAVP (100µg/kg ip) once a day for two days (n=4) or with vehicle (n=4). Water intake was measured daily for five days before treatment with dDAVP and for two days afterwards. Local rates of glucose utilization were determined and compared to our previous results from rats receiving AVP for one week (reference above).

	Long-Evans (n=10)	DI (n=10)	DI+AVP (n=7)	DI (n=4)	DI+dDAVP (n=4)
Water intake (ml/100g/24hr)	11±1	84±5	22±4*	66±10	15±1***
Glucose utilization (µmols/100g/min)					
Subfornical organ	48±2	69±3	53±4*	60±3	45±2**
Paraventricular nuclei	59±3	58±2	57±3	58±1	47±3**
Supraoptic nuclei	58±2	61±3	55±2	52±2	51±3*
Neural lobe	41±2	83±5	84±6	69±5	45±6

Values are means+SEM; *p<.05, **p<.01, ***p<.001, compared to respective control

The results demonstrate that dDAVP has a potent inhibitory effect on water intake and on glucose utilization in the neural lobe and other brain structures. We suggest that the ineffectiveness of chronic AVP treatment in decreasing glucose utilization in the neural lobe of DI rats may be due to the reported phenomenon of physiological adaptation which leads to diminished response to the hormone.

SUBCORTICAL SOMATOSENSORY PATHWAYS I

11.1 CHARACTERIZATION OF CAT NASAL RECEPTORS PROJECTING TO TRIGEMINAL SUBNUCLEUS INTERPOLARIS. G. E. Lucier and R. Egizii*. Department of Medical Physiology, University of Calgary, Calgary, Alberta T2N 4N1, Canada.

The ethmoidal nerve innervates the anterior portion of the nasal mucosa and constitutes the afferent limb of several upper respiratory tract protective reflexes. Previous anatomical studies (Lucier and Egizii, Proc. IUPS, 25:123.30, 1983) have shown that ethmoidal afferents project to all regions of the spinal trigeminal nucleus. The purpose of this study was to characterize the nature of the ethmoidal inputs onto cells in the subnucleus interpolaris.

Adult cats were anaesthetized with alpha chloralose. Two tracheal cannulae were inserted, one to provide access to the lungs for ventilation and a second to allow air and test odorants to be pulled through the upper airway. Arterial blood pressure and end tidal CO_2 were monitored. Bi-polar stimulating electrodes were placed on the ethmoidal, vagus, hypoglossal, glossopharyngeal and superior laryngeal as well as the ipsilateral, maxillary and mandibular canine tooth pulp. During recording, all animals were paralyzed with gallamine triethiodide and artificially ventilated. The activity of functionally identified single neurons in subnucleus interpolaris was recorded using tungsten microelectrodes.

The inputs to over 100 interpolaris neurons which had a discrete trigeminal receptive field were studied. Neurons which received short latency ($\leq$10 msec) input from the ethmoidal nerve also responded to non-noxious tactile stimuli either applied to the nasal region or facial receptive fields. A much smaller group of neurons were encountered which resembled neurons previously described in subnucleus caudalis which receive an ethmoidal projection. These neurons, in addition to having a long latency input from ethmoidal ($\geq$10 msec) also receive input of a nociceptive nature from other trigeminal divisions (i.e. tooth pulp stimulation, noxious radiant heat applied to the face). These cells could also be stimulated by non-electrical noxious ethmoidal input (i.e. ammonia vapour). Supported by the Canadian MRC.

11.2 STRUCTURE-FUNCTION-CONNECTIVITY RELATIONSHIPS FOR NEURONS IN SUBNUCLEUS INTERPOLARIS (SpVi). M.F. Jacquin, D. Woerner*, R.D. Mooney & R.W. Rhoades. Dept. of Anatomy, UMDNJ-School of Osteopathic Medicine & Rutgers Medical School, Piscataway, NJ 08854

Intracellular recording, antidromic stimulation, and HRP injection techniques were used to compare the morphological and physiological properties of 56 neurons in rat SpVi. In most experiments, stimulating electrodes were inserted in the trigeminal ganglion, cerebellum (CB), and subnucleus principalis (PrV) ipsilateral, and the ventral posteromedial thalamus (VPM) and deep layers of the superior colliculus (SC) contralateral, to the recording electrode. 20 cells projected to VPM and, of those tested, 91% also projected via axon collaterals to SC, 64% to PrV, 64% to adjacent parvicellular reticular formation, and 73% to SpVi itself. 6 of these cells projected to all of these targets, while none were driven from CB. VPM-projecting cells had medium or large sized multipolar perikarya (range of average diameters=20-48um) with widespread, transversely oriented dendrites. All but 2 were responsive to deflection of any 1 of a # of vibrissae (4-19). Significant correlations were noted between VPM conduction latency and axon diameter, and # of targets innervated and axon diameter. 9 other cells projected to CB with small or medium sized (16-31um) multipolar somata. None of these had multiple projections and all but 1 had a small receptive field (1 or 2 vibrissae). 2 cells projected to SC, but not VPM, and 1 of these projected to PrV as well. Each had multipolar perikarya (15 & 41um) and they responded to 4 and 6 vibrissae, respectively. 4 medium sized multipolar cells (20-24um) were backfired from PrV only and had dense compact local axon arbors; each responded to 1 vibrissa. For all of the above projection neurons, receptive field size was correlated with dendritic area in the transverse plane.

The 21 remaining cells did not have an identifiable long range projection and, in most cases, their axons terminated locally. 11 of these responded to 1 vibrissa and had small or medium sized (12-25um) round, fusiform or multipolar somata; all had similar, longitudinally oriented, compact dendritic and axon arbors. 5 responded only to guard hair deflection. These had small or medium sized (15-27um) fusiform or multipolar perikarya and widespread dendrites. 5 responded only to noxious pinch or pressure and their morphology ranged from small (18um) and round with compact dendrites, to medium sized (30um) and multipolar with widespread dendrites. Nociceptors were located along the medial border of SpVi. Other cells were topographically organized in a manner consistent with prior mapping studies in SpVi. We conclude that strong structure-function-connectivity relationships exist for individual neurons in SpVi. 11.3 INTRINSIC AND EXTRINSIC CONNECTIONS OF THE SPINAL TRIGEMINAL NUCLEUS IN CATS: SUBNUCLEUS ORALIS. N.F. Capra and J.M. Bailey*. Dept. of Anatomy, U. Miss. Med. Ctr., Jackson, MS 39216.

The subnucleus oralis (Vo) of the spinal trigeminal nucleus receives primary afferent input from the face, temporomandibular joint, teeth, and periodontium. The diversity of its peripheral inputs suggests a complex role for Vo in orofacial mechanisms. Central connections which may serve to modulate activities in Vo are the subject of this report.

Discrete electrophoretic injections of wheat germ agglutinin-conjugated horseradish peroxidase (WGA-HRP; 2-4%) were made into physiologically identified regions of Vo. The animals were euthanized 12-24 hours later and perfused transcardially with saline followed by a mixed aldehyde fixative. Serial sections (40-60 μm) made through the brain stem, upper spinal cord, and portions of the cerebral cortex were processed for histochemical demonstration of HRP using TMB as a chromagen.

Eight cats selected for this study had discrete injection sites restricted to the rostral part of Vo. Labeled perikarya were identified throughout trigeminal sensory nuclei, dorsolateral reticular formation, nucleus cuneatus, and the orbital gyrus of the cerebral cortex. Of these, the largest number of neurons projecting to Vo originated in laminae IV and V of the ipsilateral medullary dorsal horn (MDH) and layer V of the contralateral orbital gyrus. Contributions from laminae I-III of the ipsilateral MDH, contralateral trigeminal nuclei, ventrolateral region of nucleus cuneatus, though sparse, were reliably observed. Anterogradely filled axons from Vo projected caudally to terminate on cells in trigeminal subnucleus interpolaris and the MDH. Rostrally directed axons either crossed exiting fibers of the facial nerve and terminated in the region of the trigeminal motor nucleus or decussated and ascended in the pontine tegmentum.

These results are consistent with electrophysiologic data suggesting that MDH neuron project rostrally and modulate the activity of neurons in Vo which receive primary afferent input from the tooth pulp (Hu et al., '84). These connections may provide an indirect avenue for the periaqueductal gray (PAG) and the nucleus raphe magnus (NRM) to exert inhibitory effects on primary afferent transmission from Vo. Both PAG and NRM project to MDH but not to Vo. Corticofugal fibers from the orbital gyrus, participate in modulation of orofacial reflexes and mastication. Efferent projections from Vo to trigeminal motor neurons complete the masticatory reflex pathways. Other extrinsic and intrinsic projections that originate in Vo may be involved in mechanisms which underlie the conscious appreciation of jaw position and oral stereognosis since many of the neurons in this region are activated by passive jaw movements and by pressure applied to the teeth (Capra and Anderson, J. Dent. Res., '85). Supported by DE06027

11.4 MECHANICAL RESPONSE PROPERTIES OF TRIGEMINAL THALAMIC NEURONS IN THE ALERT MONKEY. G.H. Duncan* and M.C. Bushnell. Fac. Medecine dentaire, Univ. de Montreal, Montreal, Que. CANADA H2V 3B5

Previous studies of trigeminal thalamic neurons have not yielded a consensus regarding the neurophysiological properties of the ventroposterior medial nucleus (VPM). Most investigators have observed an overwhelming majority of rapidly adapting low threshold (RA) neurons. Recently, however, some studies have documented smaller populations of slowly adapting (SA) low threshold, wide dynamic range (WDR), and nociceptive specific neurons. Most reports of VPM in monkeys are incorporated within larger surveys of the ventrobasal complex, so that frequently VPM is not systematically explored. In addition, most studies have been conducted in either anesthetized or paralyzed animals. The present study explores the properties of trigeminal cutaneous thalamic neurons in an alert monkey to determine receptive field and response properties in neurons unaltered by pharmacological agents.

One macaque monkey received juice reward for sitting quietly while an investigator probed the monkey's face with mechanical stimuli. Extracellular single-unit recordings were made from VPM neurons, and mechanical response properties were evaluated for each cell having an extraoral cutaneous receptive field.

Sixty-four VPM neurons with receptive fields on the face were characterized. Fifty-two (81%) of these neurons responded maximally to gentle touch of hair or skin. Twenty-nine (56%) of the low threshold cells adapted rapidly to sustained touch (RA), but 23 (44%) continued to respond throughout the stimulus presentation (SA). Most low threshold neurons had receptive fields on the contralateral side, but 7% showed fields confined to the ipsilateral face. Both RA and SA neurons were found throughout VPM. Six neurons (9%), classified as WDR, showed a graded response to increasingly intense stimuli, with a maximum discharge to noxious pinch. Receptive fields of WDR neurons were smaller than those previously observed in trigeminothalamic neurons of the medullary dorsal horn, and no larger than those of low threshold VPM cells in the current study. WDR cells were located primarily in the caudal third of VPM. Finally, the activity of six neurons (9%) was inhibited during innocuous mechanical stimulation. These cells had small contralateral receptive fields and were located in the caudal third of VPM.

In summary, response characteristics of VPM neurons show more diversity in the alert monkey than has been reported in paralyzed and/or anesthetized animals. In addition to the large proportion of RA neurons, there exists a similar population of SA neurons, and smaller populations of inhibitory and WDR cells. Thus, VPM contains neurons capable of coding both static and dynamic mechanical properties of noxious and innocuous cutaneous stimuli.

11.5 AROUSAL-RELATED RESPONSE MODULATION OF VP THALAMIC NEURONS TO SOMATIC AND SPINAL LEMNISCAL STIMULATION IN THE AWAKE MONKEY. T.J. Morrow and K.L. Casey, Neurology Research Laboratories, V.A. Medical Center, Ann Arbor, MI 48105.

RATIONALE: Our sensory systems are continually bombarded by inputs from which we select information as a basis for action, ignoring all the rest. It is reasonable to hypothesize that certain properties of a neuron's response to a specific sensory stimulus should covary with changes in behavioral state. Accordingly, the somatosensory responses of ventral posterior (VP) thalamic neurons would be expected to vary with the level of arousal in unanesthetized, behaving animals. Previous studies have failed to demonstrate this relationship, and have shown changes in only the spontaneous discharge of VP somatosensory neurons (Baker, 1971; Hayward, 1975).
METHODS: The responses of single neurons in the ventral posterior thalamus to a variety of controlled, calibrated, somatic stimuli and to electrical stimulation of the midbrain spinal lemniscus (SL) were recorded in four awake squirrel monkeys. Movements of the animal and EEG changes were continually monitored, and used to identify periods of drowsiness, quiet waking and waking with movement. Neural responses to stimuli delivered during these periods were separately analyzed by computer for changes which correlated with changes in the state of arousal.
RESULTS: Many VP thalamic neurons (29/51) exhibited changes in somatosensory responsiveness which correlated with shifts in arousal. Arousal-related changes were not selective for neurons responding to any specific stimulus type (ie. hair movement, touch, tap, etc.) and included modulation of 3 neurons in the wide dynamic range class (WDR). Most neurons discharged maximally during quiet waking. Responses were significantly reduced during drowsiness and either unchanged or reduced during periods of waking with movement. Similar arousal-related changes were seen in 13 of 30 neurons driven by SL stimulation. The spontaneous discharge of many somatically driven neurons also varied as a function of the state of arousal. All changes in stimulus evoked responses were, however, independent of the pre-stimulus background discharge frequency since reduced responses to somatic and spinal lemniscal stimulation were seen during increased or decreased background activity.
CONCLUSIONS: The somatosensory responses and the spontaneous discharge of VP thalamic neurons are significantly modulated during concurrent changes in the state of arousal. One modulating mechanism includes inhibition (possibly presynaptic) at the level of the VP thalamus.

11.6 CEREBELLAR RELATIONSHIPS WITH SOMATIC SENSORY PORTIONS OF THE PRETECTUM AND ZONA INCERTA IN THE CAT. M.S. Bull and K.J. Berkley. Dept. of Psychology, Florida St. Univ., Tallahassee, FL 32306.

Considerable evidence has accumulated showing that neurons in the dorsal column nuclei (DCN) project not only to the ventroposterolateral nucleus of the thalamus (VPL), but also to a number of other structures throughout the neuroaxis (e.g. Hand and Liu, 1966; Berkley and Hand, 1978). Recent evidence from several laboratories suggests that the group of DCN neurons projecting to VPL differs both anatomically and functionally from the groups projecting to these other targets (see Berkley, 1985).

One common feature of some of the extra-VPL-projecting groups of DCN neurons is that they project to the cerebellum and to precerebellar nuclei such as the inferior olive (IO) and PONS. In addition, another group of DCN neurons projects to the anterior pretectal nucleus (PTA) whose neurons in turn project to the DCN-recipient portions of the IO and PONS (Bull and Berkley, 1983).

In the course of studying these cerebellar-related pathways, it became apparent that the neurons in the DCN-recipient portion of the pretectum, (i.e. PTA), had reciprocal connections with the DCN-recipient portion of the zona incerta (ZI). It is difficult to speculate, however, what role the ZI might have in the context of a cerebellar-related system involving DCN and PTA. This difficulty may be due in part to ZI's diverse nature as a structure with putative motor as well as sensory (nociceptive) functions (Kaelber and Smith, 1979).

In an effort to understand what role, if any, the ZI inputs might play in a cerebellar-related system, the DCN inputs to ZI and PTA were compared with those from the cerebellum using a double orthograde labeling strategy. The results showed that the DCN and cerebellar terminations overlapped in PTA but did not share the same domain in ZI. (The DCN terminations were ventral, lateral and caudal to those from the cerebellum.)

That the DCN and cerebellar terminations converge in PTA, a structure which projects to the cerebellum through the PONS and IO, but do not converge in ZI, is consistent with the suggestion that the pretectum and its afferent DCN input is involved in somatic-motor feedback functions associated with the cerebellum. The separation of the DCN and cerebellar inputs in ZI, on the other hand, suggest that the afferent DCN input contributes to a different, perhaps more sensory (i.e. nociceptive) role for ZI.

11.7 SYNAPSES UPON PHYSIOLOGICALLY CHARACTERIZED THALAMIC NEURONS WHICH RESPOND TO HAIR FOLLICLE STIMULATION: AN ELECTRON MICROSCOPE STUDY. P.T. Ohara, D.D. Ralston*, and H.J. Ralston, III. Department of Anatomy, University of California, San Francisco, CA 94143

The morphological features of the synaptic populations contacting single, physiologically characterized thalamic neurons which were iontophoretically labeled by the intracellular injection of HRP have been studied in the cat by the electron microscopic analysis of serial thin sections. The purpose of the study was to determine whether the populations of synapses contacting various regions of the cells, (soma, primary, secondary or tertiary dendrites) varied, and whether cells which responded to movements of hairs had different synaptic inputs than those upon thalamic neurons which responded to other nonnoxious or noxious peripheral stimuli. Cats were anesthetized with IM ketamine followed by intravenous pentobarbital, placed in a stereotaxic headholder and the cortex overlying VB removed by suction. A glass guide tube was placed on top of the thalamus, and a metal electrode used to search for receptive fields. Once the stereotaxic coordinates had been determined, a glass micropipette containing 4% HRP with a resistance of 100 MΩ was advanced into the thalamus and the receptive fields and response properties of neurons recorded. In this study, we report on 3 neurons with small receptive fields on the contralateral forepaw which responded to deflection of small clusters of hairs and which adapted rapidly to the stimuli. The cells were held intracellularly from 5-10 minutes, during which time 0.5 nA of positive current was injected. One to 4 hours later the animal was perfused with aldehydes and the thalamus serially sectioned at 50μm, reacted with DAB, and sections containing labeled neurons osmicated and embedded in epoxy resins. Drawings were made of labeled cells and the 50μm section cut serially for EM, with frequent drawings and photographs being made for the identification of various neuronal elements. In this way, most of the synaptic input to a single neuron can be examined. Examination of 425 consecutive sections of the first 40um of a dendrite, from cell body to the initial portion of a tertiary branch, has revealed 27 contacts made by large synaptic profiles with round vesicles (RL), 7 by presynaptic dendrites (PSD), 10 by flat-vesicle axonal profiles (F-1), 7 by F profiles of unknown origin, and 8 by profiles which could not be classified. No contacts by small profiles with round vesicles (RS) were seen on this protion of the dendritic tree. The serial sections permitted a determination of the dendritic character of several PSD's, as well as the synaptic input to these PSD's. In addition, PSD's could be found to follow a tortuous course, forming multiple contacts with the labeled dendritic shaft. These contacts were not involved in triadic synaptic relationships with RL profiles. An extensive description of the synaptic input to all regions of this physiological class of neurons will be presented. (Supported by NS-11614 from NIH).

11.8 THE CUNEATE NUCLEUS OF THE MONKEY: ANATOMICAL AND ELECTROPHYSIOLOGICAL EVIDENCE FOR SUBMODALITY SEGREGATION.

M. Wiesendanger, H.Hummelsheim*, R. Wiesendanger* and M. Bianchetti*.
Institut de Physiologie, Université de Fribourg, CH-1700 FRIBOURG, Switzerland.

The main cuneate nucleus (MCN) and the external cuneate nucleus (ECN) were investigated by means of transganglionic labeling with WGA-HRP, field potential mapping, and extracellular unit recordings in the anesthetized monkey. It was found that labeling following incubation of the deep radial nerve occurred in the pars triangularis of the MCN and in the ventromedial segment of the ECN. Field potentials evoked by electrical stimulation of low-threshold muscle afferents were likewise focused on these subdivisions of the ECN and MCN. By contrast, the pars rotunda of the MCN is projected upon by cutaneous afferents: loading of the superficial radial nerve or cutaneous infiltration of a single digit with WGA-HRP produced dense patches in this 'core' region of the MCN. After having established the territory of the 'proprioceptive' bulbar relay of the forelimb, single neurons were studied with respect to their sensitivity to small sinusoidal and ramp stretches of the extensor digitorum communis (EDC) muscle, to their convergence pattern, and to their projection to the thalamus and the cerebellum. In the MCN 27 neurons and in the ECN 8 neurons were found to project to the thalamus. In each nucleus two additional cells were found to project to both targets. With controlled longitudinal displacements of the EDC muscle, neurons in both ECN and MCN discharged phasically, often with partial entrainment in response to 100-200 Hz sinusoidal stretches. Many neurons were activated with minimal step amplitudes of 50 μm or less. The majority of neurons appeared to react specifically to one muscle. Our electrophysiological results corroborate previous suggestions that a subpopulation of ECN neurons contribute to a proprioceptive transmission system, via the thalamus, to the cerebral cortex (Boivie and Boman, 1981). The electrophysiological properties of the 'proprioceptive' bulbar neurons were very similar to those recorded in the thalamus and in cortical area 3a with the same experimental protocol. The transmission system thus functions with high synaptic efficacy, providing the cortex with precise musculotopic information about small changes of muscle length.

11.9 THE SOURCES OF PEPTIDERGIC INPUT TO THE LATERAL SPINAL NUCLEUS IN THE RAT. K.D. Cliffer, G. Urca,* R. Elde and G.J. Giesler, Jr. Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455 and Dept. of Physiology and Pharmacology, Tel Aviv Univ., Ramat Aviv, Israel.

The lateral spinal nucleus (LSn) of rats is rich in fibers that are immunoreactive for met-enkephalin (ENK), substance P (SP), somatostatin (SOM), dynorphin (DYN) and FMRF-amide (FMRF-NH_2). In this study we examined the sources of these peptidergic fibers.

In rats with unilateral dorsal rhizotomies of at least three lumbar segments ten days prior to sacrifice, no difference was seen between sides in staining for any of the five peptides in the LSn, even though the staining for SP was greatly reduced in superficial laminae of the dorsal horn on the side of the rhizotomy. Thus, little, if any, of the peptidergic input to the LSn appears to come from primary afferents.

In spinal cords transected at low thoracic levels nine days before sacrifice, no loss of immunoreactivity was apparent for any of the peptides in the LSn below the transection. In addition, unilateral transections of the lateral funiculi resulted in no consistent difference between sides in the amount of immunoreactivity to any of the substances in the LSn. These results demonstrate that few, if any, of the peptide-containing fibers afferent to the LSn in lumbar cord originate in the brain or in upper levels of the spinal cord.

Since these experiments indicated that the peptidergic input to the LSn originates locally, we examined cells in the lumbar spinal cord of colchicine-treated rats for immunoreactivity for the five peptides. Immunoreactivity for ENK was found in cells in the marginal zone (MZ), substantia gelatinosa (SG), nucleus proprius (NP), lateral reticulated area (LRA) and near the central canal (CC). Cells were labeled by antibody to SP in MZ, NP, LRA and the dorsal lateral funiculus (DLf). Cells immunoreactive for SOM were found only in NP. Staining for DYN occured in cells in MZ, NP, SG and LRA. Cells had immunoreactivity for FMRF-NH_2 in MZ and NP. Following injections of fast blue into the LSn, retrogradely labeled cells were found ipsilaterally in all areas in which immunocytochemically stained cells had been seen. Contralaterally, cells were retrogradely labeled in SG and NP. While some label may have been picked up through axons of passage or from spread of the injection to the lateral dorsal horn, the cells afferent to the LSn should be among those labeled. These results, in conjunction with the results from transections and rhizotomies, indicate that virtually all peptidergic fibers afferent to the LSn originate locally in cells among those in the MZ, SG, NP, LRA, DLf or near the CC.

11.10 SOMATOSENSORY EVOKED POTENTIALS RECORDED FROM HUMAN THALAMUS C.D.Yingling, Y.Hosobuchi* and J.E.Adams*, Dept. of Neurological Surgery, University of California, San Francisco, CA 94143

Somatosensory evoked potentials (SEPs) have been recorded from the thalamic somatosensory nucleus (VPL) in over 30 patients permanently implanted with multi-contact electrodes (Medtronics) for relief of chronic deafferentation pain. Electrical stimulation of the median nerve at the wrist elicits a P17-N20-P24 complex with a limited spatial distribution (often seen at only 1 or 2 of the contacts, which are spaced 2 mm apart). In surface recordings of SEPs, P/N14 is thought to be generated by dorsal column nuclei or medial lemniscus, and N20 by the primary somatosensory cortex; it is thus likely that P17 represents the initial activation of the somatosensory thalamus. Recordings a few mm anterior to VPL during thalamotomy for movement disorders show a polarity reversal of P17 to N17. P24 is more variable and not recorded in all patients.

Of particular interest is the presence of fast oscillatory wavelets riding on the P17-N20 waves, with a frequency of 1 kHz or faster. These components are highly reproducible within each subject (see figure below) and may correspond to the scalp recorded high frequency waves reported by Eisen et al (EEGJ 59:388-395,1984) and others using 250 Hz high-pass digital or analog filtering.

The limited subcortical distribution of thalamic SEPs suggests that they are generated by relatively closed dipole fields, and are thus unlikely to contribute substantially to the major SEP components recorded from the scalp. On the other hand, this gives them clinical utility in guiding precise placement of thalamic electrodes in VPL. Finally, it is tempting to speculate that the fast oscillatory activity reflects a recurrent intrathalamic mechanism which may play a role in encoding the thalamocortical representation of sensory events.

12.1 EXCITATORY EFFECTS OF NORADRENALINE ON BURSTING PACEMAKER NEURONS IN CULTURED SPINAL CORD CELLS. J.D. Vincent and P. Legendre . INSERM U.176 Rue Camille Saint-Saëns 33077 BORDEAUX-Cedex France.

Intracellular recordings were made from dissociated mouse spinal cord cells in primary culture (Legendre, P. et al., Brain Research 297 : 287, 1984). One type of neuron with a large cell body and several short thick neurites was found to fire rhythmic bursts of action potentials with a phase duration of approximately 1 sec when the membrane potential was depolarized to -55 mV. These cells remained generally silent at resting potential (-65 mV). Bursts did not arise from spontaneous synaptic input but appeared to result from endogenous ionic conductance properties of the membrane ressembling those observed in molluscan bursting pacemaker (BP) neurons. Pharmacological application of ionic conductance blockers and of modified ionic media suggested that Ca^{2+} is involved in burst generation and controls the burst duration by activating a K^+ conductance. Na^+ appeared principally involved in pacemaker potential generation and partially involved in spike generation.

Since Noradrenaline (NA) seems to be involved in the activation of spinal cord rhythmic generators, we looked at the effects of NA application on the electrophysiological properties of our cultured spinal cord BP neurons. Application of NA (Sigma 1 µM in the delivery pipette) onto the surface of BP neurons evoked, in a dosedependent manner, an increase in the input resistance (Ri) associated with a progressive depolarization of the membrane potential.

This response was potential dependent. The maximum change in Ri was observed at membrane potential values between -60 to -45 mV. No response was observed at membrane potential less than -80 mV. The extrapolated reversal potential (Rp) of the NA effect was close to -90 mV. The Rp value was not altered by increasing the intracellular Cl^- concentration whereas it was modified by increasing extracellular K^+ concentration. This excitatory effect was not blocked by extracellular application of tetraethylamonium but it was reversibly suppressed by Ba^{2+} and Cd^{2+} application. Ours results demonstrate that NA has an excitatory effect on pacemaker SC neurons in culture by decreasing a Ca^{2+} and potential dependent K^+ conductance. Alpha 1 receptors seem to be involved in this response since Phentolamine, an α 1 antagonist, prevent the effect of application whereas Clonidine, an α 2 agonist, did not mimick the NA response and since the β antagonist, L-Aprenolol, had no effect.

12.2 AN ISOLATED IN VITRO PREPARATION OF THE NEONATAL RAT BRAINSTEM AND SPINAL CORD. K. Walton and R. Llinás. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

We have developed a preparation suitable for the study of the development of supraspinal inputs to spinal motoneurons in rats during the first postnatal week. The preparation consists of the brainstem posterior to the inferior colliculus and the entire spinal cord (SC) with the dorsal roots (DR) and ventral (VR) roots attached; the cerebellum may also be included. Cranial nerves V, VIII, XI and XII are long enough to be stimulated individually via suction electrodes. The dissection was caried out under ether anesthesia. The preparation was pinned in a Sylgard-lined chamber and continually superfused with a modified Ringer's solution bubbled with O_2/CO_2 (95%/5%); oxgenation was supplemented with 0.004% H_2O_2. Recordings were made from the SC at the lumbar level using suction electrodes placed on the VR; glass micropipettes were used to record field potentials and intracellular responses. Stimulation was accomplished using suction electrodes on the DR and selected crainal nerves; a twisted pair of silver wires was used for stimulating the spinal column and brainstem areas. Typical spinal reflexes were recorded from the ipsilateral VR following DR stimulation and bilaterally following ventral column stimulation. The response consisted of a sharp monosynaptic component followed by a low amplitude polysynaptic component. Stimulation of the trigeminal nerve elicited responses in the lumbar ventral roots bilaterally. These comprised long latency, prolonged (about 50 ms) responses. Stimulation of the pyramidal tracts at the posterior margin of the pons, the nuclei gracilis and cuneatus, the posterior and the anterior funiculus at the cervical level also elicited ventral root potentials. Intracellular recordings indicated both excitatory and inhibitory responses to DR and ventral column stimulation. The preparation can be maintained in good condition for 8 hours at room temperature as indicated by VR potentials recorded following brainstem activation. These preliminary results indicate that this preparation should prove to be a valuable tool in studying the development of the descending synaptic inputs to spinal motoneurons and their interaction with DR inputs during the first week of postnatal life. Supported by USPHS grant NS-13742 from NINCDS.

12.3 AN INTRACELLULAR STUDY OF THE EFFECTS OF ACETYLCHOLINE ON MOTONEURONS IN A NEONATAL RAT SPINAL CORD SLICE PREPARATION. N. J. Dun and Z. G. Jiang* (SPON: R. S. Schmidt). Dept. of Pharmacol. Loyola Univ. Med. Ctr., Maywood, IL 60153

Intracellular recordings stable for many hours were made from motoneurons situated in thin (400-500µm) transverse slices in vitro of rat thoracolumbar spinal cord removed from neonatal rats aged 8-15 days old. Spinal cord slices were superfused with a Krebs solution saturated with 95% O_2 & 5% CO_2; the temperature of the solution was maintained at 34 ± 0.5°C. Motoneurons were identified by the appearance of an all-or-none action potential following stimulation of the ventral rootlets that remained attached to the spinal cord slices. Two types of motoneurons could be categorized on the basis of their electrical membrane properties. The first group of motoneurons, constituting the majority of motoneurons sampled here, had conduction velocities between 20-50 m/s, lower input resistance (5-40 MΩ) and shorter time constant (2-5 ms). The conduction velocity of the second group of motoneurons was below 10 m/s. These motoneurons exhibited higher input resistance (50-150 MΩ) and slower time constant (10-15 ms). These two groups of motoneurons observed here may correspond to the alpha and gamma motoneurons that have been extensively studied in the adult spinal cord. Acetylcholine (ACh) applied by either pressure ejection or by bath superfusion in known concentrations (10-100 µM) depolarized nearly all the motoneurons tested. In the majority of motoneurons the depolarization induced by ACh was slow in onset and lasted seconds to minutes. The slow ACh depolarization was accompanied by an increase in input resistance and the response was made smaller upon membrane hyperpolarization. Atropine (≤ 1 µM) completely and readily abolished the slow ACh depolarization. Tetrodotoxin (TTX, 0.1-1 µM) or low Ca (0.12 mM)/high Mg (12 mM) solution did not appreciably affect the slow depolarization induced by ACh. These findings collectively suggest that the slow depolarization evoked by ACh was probably due to a direct action of ACh on motoneuron muscarinic receptors. ACh evoked a biphasic depolarization in a small number of motoneurons tested; an initial brisk depolarization was followed by a slow depolarization. The fast and slow component was reversibly depressed by d-tubocurarine and atropine, indicating that the respective response may be due to an activation of nicotinic and muscarinic receptors. The effect of eserine (≤ 1 µM) on muscarinic depolarizations induced by ACh on motoneurons was biphasic; an initial enhancement was followed by a long lasting depression. The high incidence of ACh sensitive motoneurons observed here in conjunction of the report of the presence of nerve fibers exhibiting immunoreactivity to choline acetyltransferase near the motoneurons by others may suggest a transmitter/modulator role of ACh in the ventral horn. (Supported by NIH Grant NS18710).

12.4 MOTOR PATTERNS FOR RESPIRATION AND LOCOMOTION GENERATED BY AN IN VITRO BRAINSTEM-SPINAL CORD FROM NEONATAL RAT. J. C. Smith* and J. L. Feldman. Department of Physiology, Northwestern University, Chicago,IL. 60611

In vitro brainstem-spinal cord preparations of lower vertebrates are commonly used to investigate properties of central pattern generators (CPG's) for respiration and locomotion, but a suitable in vitro preparation for routine study of these CPG's in a mammalian system has not yet been developed. We have found spontaneous rhythmic respiratory motor activity, and locomotor patterns elicited by excitatory amino acids, in an in vitro preparation of the brainstem-spinal cord of the neonatal rat. The finding of spontaneous respiratory motor activity confirms the observations by Suzue (J. Physiol.,354:173,1984). The preparation consists of the brainstem and spinal cord up to the lumbar level from 0-4 day old rats placed in modified oxygenated Krebs solution (pH 7.4) at 27-30° C. Preparations including portions of the body wall (rib cage with intercostal musculature) with dorsal and ventral thoracic roots intact, preserving mechanosensory afferent input, have also been used. The respiratory pattern consists of a synchronous periodic discharge on the hypoglossal nerve, 4th and 5th cervical and thoracic ventral roots. The brainstem origin of the pattern was verified by transection experiments. Following spinomedullary transection, the periodic discharge persists on the hypoglossal nerve but is absent on ventral roots of the spinal cord. The spontaneous discharge frequency is increased by bath applied N-methyl D-aspartic acid (NMDA;1-10 uM), acetylcholine (ACH;0.01-1 mM) and reduced pH; preliminary observations indicate that the discharge frequency is reduced in a dose-dependent manner by GABA (0.01-1 mM) and atropine (1-10 uM). The respiratory burst pattern is altered by mechanical perturbation of the rib cage musculature indicating the presence of functional afferent circuitry. The locomotor patterns recorded on ventral roots are elicited by ACH (0.1-1 mM), NMDA (1-10uM) and D-glutamate (0.1-1 mM) in a manner similar to the induction of locomotor patterns in lower vertebrates (Grillner & Wallén, Ann. Rev. Neurosci.,8:233,1985; McClellan & Farel, Brain Res.,332:119,1985). These motor patterns range from alternation to synchrony in bursting between contralateral ventral roots in a given segment with burst frequencies varying with the excitatory neurotransmitter concentration. The results indicate that this preparation should be suitable for study of mammalian respiratory and locomotor CPG function. It may also provide data for a comparative analysis of CPG mechanisms among lower and higher vertebrates. The induction of locomotor patterns by similar amino acids in this and lower vertebrate preparations may suggest a phylogenetic conservation of mechanisms controlling the locomotor circuitry. Supported by NIH Grant HL-23820.

12.5 CONTROL OF ABDOMINAL MUSCLE ACTIVITY DURING VOMITING: ROLE OF VENTRAL RESPIRATORY GROUP EXPIRATORY NEURONS. A.D. Miller, I. Suzuki* and L.K. Tan. Lab. of Neurophysiology, The Rockefeller University, New York, NY 10021.

Vomiting is produced primarily by the synchronous contraction of the diaphragm and abdominal muscles (2,5). The brainstem mechanism controlling these muscles during vomiting is unknown. In an attempt to identify these neurons, we examined the firing patterns of ventral respiratory group (VRG) expiratory (E) neurons during fictive vomiting in decerebrate, paralyzed cats. VRG E neurons project to the region of abdominal motoneurons and are probably the main source of expiratory modulation of abdominal muscle activity (3,4). However, since VRG E neurons are inhibited during inspiration (6), it is uncertain what their firing patterns will be during co-contraction of the diaphragm and abdominal muscles.

Fictive vomiting was defined by co-activation of phrenic and upper lumbar abdominal nerves in response to sub-diaphragmatic vagal stimulation (1) or emetic drugs. We find that vagal stimulation (pulse trains) readily produces vomiting in non-paralyzed, decerebrate cats but does not elicit other expulsive acts in which the abdominal muscles and diaphragm are knownto be co-active, such as coughing, eructation, or defecation. Latencies from onset of vagal stimulation to onset of nerve co-activation average about 30 sec. Each episode of fictive vomiting consists of an average of 8 bursts of nerve co-activation. Abdominal nerve activity increases an average of about 10 times during fictive vomiting, as compared to respiration, while phrenic discharge increases about 3 fold.

Data have been obtained from 21 VRC E neurons,located 1.6-5.2mm caudal to the obex, that were antidromically identified as projecting to the lumbar cord. Eighteen cells were studied during 1-3 episodes of vagal-induced fictive vomiting while 4 cells were studied during drug-induced nerve co-activation. The activity of two-thirds of these neurons (14/21) was greatly reduced or abolished during nerve co-activation. These neurons typically fired between bursts of co-activation. The maximum firing rates of the 7 remaining neurons were either unchanged (N=3) or increased 2-4 times (N=4).

Thus, it would appear that abdominal muscle activity during vomiting is mainly controlled not by VRG E neurons but by some other as yet unknown descending input.

This study was supported by grants from NSF (BNS8317651), NASA (NAG2164, NSG2380), and NIH (NSO2619, RR07065).

12.6 LONG LASTING HYPERPOLARIZATION OF SOLEUS ALPHA MOTONEURON ELICITED BY PONTINE STIMULATION IN DECEREBRATE STANDING CAT. T. Sakamoto*, Y. Ohta*, S. Mori (SPON: H. Asanuma),Dept. of Physiol.,Asahikawa Med. Col., Asahikawa, JAPAN 078-11.

Stimulation of the dorsal part of the caudal tegmental field (DTF) along the midline of the pons (P5 to P6, H -4.5 to H -5.5) suppresses the postural muscle tone of hindlimb in the decerebrate cat. Such a suppression continues for more than several minutes after termination of stimulation.

To understand the neuronal mechanisms underlying such a long lasting suppression, we attempted intracellular recording of soleus alpha motoneurons with glass micropipettes filled with 2M potassium citrate. While the animal was maintaining the standing posture, soleus motoneurons were identified by antidromically stimulating the nerve endings within soleus muscle. DTF stimulation (10-50 uA, 0.2msec, 50 cps) which lasted 5-10 sec always produced hyperpolarization in soleus motoneurons with amplitude ranging between 1 to 16 mV and these hyperpolarizations continued several minutes after termination of DTF stimulation.

To examine whether there were differences in the mechanisms for producing hyperpolarizations which were observed during and after DTF stimulation, following measurements were made. 1) Characteristics of Ia EPSPs which were evoked at stimulus strengths subthreshold for antidromic invasion of identified motoneurons before, during and 10 sec after DTF stimulation. 2) Delay of antidromic spike potentials which were evoked at a frequency of 1-2 Hz. 3) Differences in input resistance. These were determined by delivering depolarizing and hyperpolarizing current pulses through the impaling microelectrode and dividing the elicited voltage changes by the amount of injected current. 4) Reversal of hyperpolarization by injecting Cl^-ion through 3M potassium chloride microelectrode.

The results obtained were: During DTF stimulation, 1) there were reductions in amplitude and in the time of decay of the averaged EPSPs, 2) there was a suppression of antidromic impulse propagation,i.e., increased IS-SD delay or IS-SD block, 3) there was a reduction of the input resistance and 4) there was a reversal of the membrane hyperpolarization. None of such modifications were evident during the hyperpolarization which outlasted beyond the termination of DTF stimulation.

These results indicated that there were differences between different parts of long lasting hyperpolarizations, i.e., during and after DTF stimulation. It was concluded that postsynaptic inhibition played a major role during the DTF stimulation but disfacilitation or other mechanisms played a major role after termination of DTF stimulation.

12.7 A RETICULOSPINAL TRACT THAT PREVENTS SYNCHRONY OF DISCHARGE BETWEEN GAMMA MOTONEURONES IN THE CAT. P.H.Ellaway and N.J.Davey* (SPON: D.G. Stuart). Department of Physiology, University College London, London WC1E 6BT, England.

Neurones that share presynaptic stem fibres may show a tendency to synchrony in their discharges as a result of near simultaneous synaptic potentials. Background and reflex discharges of gamma motoneurones in the spinal cat show such synchrony of discharge (Ellaway & Murthy. Quart.J.Exp.Physiol., 70: 1985). In motor control the consequence of synchronized discharges of gamma efferents to muscle spindles would be a state of tremor. We show here that this undesirable tendency is prevented by activity in fibres of the descending dorsolateral funiculus.

The discharges of individual gamma motoneurones in the decerebrated cat are regular and show no tendency to synchrony. After complete spinal section, discharges of gamma motoneurones below the cut became irregular and a tendency to synchronized firing appeared. Synchrony was evident as a peak (half-width 3-5 ms) in the cross correlogram between the discharges of two efferents. Discrete lesions of the spinal cord were made, in the region T8-10, by section with a fine blade. The site and extent of the lesions were verified by histological preparation. The degree of synchrony between pairs of gastrocnemius gamma motoneurones, and the regularity of firing of the individual efferents, were assessed before and after each lesion. We found that discrete lesions of the dorsolateral funiculus needed to be made on both sides of the spinal cord to produce synchronous and irregular firing at the level observed after total spinal cord section. Large lesions of the cord that spared either the ipsilateral or contralateral, dorsolateral funiculus did not produce any marked change in regularity of firing or tendency to synchrony.

Reticulospinal neurones descend in the dorsolateral funiculus. They are known to control the flexion reflex by release of catecholamines (Anden, Jukes & Lundberg. Acta Physiol.Scand. 67: 387, 1966). In the spinal cat intravenous injection of 75mg/kg of L-Dopa, a precursor of catecholamines, caused a pronounced reduction in the degree of synchronized firing and an increase in regularity of gamma motoneurone discharge. This effect was antagonized by intravenous injection of chlorpromazine (1 mg/kg).

We conclude that the prevention of synchronized gamma efferent discharge is exercised through a bilateral reticulospinal tract that involves catecholaminergic transmission in the spinal cord.

12.8 VESTIBULOSPINAL AND RETICULOSPINAL INTERACTIONS IN ACTIVATING AXIAL MUSCLE EMG IN THE RAT. S.L. Cottingham*, P.A. Femano, and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

Lesion and electrical stimulation studies show that vestibulospinal and reticulospinal systems are necessary for lordosis, an hormonally-dependent female rat sex behavior (Modianos and Pfaff, 1976). Electrical stimulation of the medullary reticular formation (MRF) activates the axial muscles medial longissimus (ML) and lateral longissimus (LL) essential for the vertebral dorsiflexion of the lordosis reflex (Femano et al, 1984). The present study examines activation of ML and LL muscles by electrical stimulation of the lateral vestibular nucleus (LVN), and interactions between vestibulospinal and reticulospinal stimulation of these muscles.

Female rats were anesthetized with urethane, and two multistranded stainless steel EMG recording electrodes were placed in ML and LL at spinal level L4-L5. EMG units were amplified and displayed on an oscilloscope, and PST histograms were constructed. Electrical stimulation to MRF and LVN consisted of neg-pos biphasic pulses (0.2 msec/phase) at 200 Hz delivered in trains (30-100 pulses/train, one train/sec). Effective current range: 20-100 µA; 40-50 µA was typical. Data reported were from nucleus gigantocellularis in RF, and medial, central, and lateral placements in LVN. Electrical stimulation of LVN activated ML (threshold range 20-50 µA) and LL (thr 20-50 µA). Similarly, electrical stimulation of MRF activated ML (thr 20-40 µA) and LL (thr 20-50 µA). With repetitive delivery of trains to LVN or MRF, each successive train was more effective; that is, the tenth train elicited more units, at shorter latency than the first. LVN-evoked activity in the axial muscles can be facilitated by electrical stimulation of MRF. Facilitation was observed as a lowering of threshold to elicit muscle activity; for LVN stimulation already above threshold, an increase in number of units firing for a given LVN current was seen. MRF sites that produced facilitation of an LVN response were sites that evoked firing in axial muscles. LVN stimulation also facilitated MRF-evoked axial muscle activity. Trains using currents subthreshold for both MRF and LVN (the lower being 10-50% of threshold), delivered simultaneously to MRF and LVN, could lead to activity in axial muscles. Inhibitory MRF sites did not activate ML or LL, but ventroflexion of the animal was sometimes observed. Such inhibitory interactions were accompanied by rebound facilitation.

Ventral and medial motor control systems long have been suspected to be important for axial motor control (Lawrence and Kuypers, 1968). These EMG data in the rat show some ways in which lateral vestibulospinal and medullary reticulospinal neurons could cooperate in activating deep back muscles important for reproductive and other behaviors. (Supported by NIMH grant MH38273).

12.9 LOCUS COERULEUS FACILITATION OF LUMBAR MONOSYNAPTIC REFLEXES IN THE RAT. Julie Y.H. Chan, Simon J. Fung, Samuel H.H. Chan and Charles D. Barnes. Washington State University, College of Veterinary Med., Pullman, WA 99164-6520.

Stimulation of the locus coeruleus (LC) in the cat has been demonstrated in our laboratory to unequivocally produce facilitation of both extensor and flexor monosynaptic reflexes (MSRs) of the hindlimb. Since the majority of work on coerulospinal projections was performed on rodents, and there are known structural differences in the LC of cats and rats, the possibility arises for a specific difference in LC influences on spinal motoneurons. The present study was initiated to examine this possibility, by extending our previous investigations on cats to the rat.

MSRs were evoked in chloral hydrate-anesthetized male Sprague-Dawley rats by stimulating either the L5 dorsal root or the posterior tibial (TIB)/common peroneal (CP) nerves, respective representative of extensor/flexor muscle nerves. They were quantified by the amplitude of the compound action potential recorded from the L5 ventral root. Electrical activation of the LC, using a train of four 100- or 500-μs rectangular pulses at a train pulse frequency of 770 Hz, consistently promoted facilitation of these MSRs regardless of their origins. Such LC-evoked potentiations may vary in degree (37.5-147.4%), duration (70.6-72.9 ms) and latency (3.0-5.5 ms) among different animals. Further experiments, using the tracking technique, ascertained that our observations were specifically the result of activating LC neurons locally and not due to current spread to neighboring tissues.

While affecting minimally the control MSRs, intravenous administration of prazosin (20 μg/kg) significantly antagonized the enhancing effects of LC on MSRs. It is also interesting to note that the ventral root discharges elicited by LC stimulation were also depressed by this alpha$_1$-adrenoceptor blocker. These data confirmed the involvement of noradrenergic neurotransmission in the LC-promoted facilitation of MSRs.

Since the results obtained in the present study are in general agreement with previous observations from this laboratory on the cat, we conclude that the LC exerts similar actions on the spinal motoneurons in at least two animal species, cat and rat. We postulate that this pontine nucleus may directly or indirectly excite the motoneuron pool, allowing more neurons to be included in the discharge zone upon the arrival of afferent volleys, in a process that involves noradrenergic neurotransmission.

12.10 STUDIES ON INPUT-OUTPUT ORGANIZATION OF MEDIAL PONTINE RETICULAR FORMATION. R.W. McCarley and K. Ito. Neuroscience Lab., Harvard Medical School and VAMC, Brockton, MA 02401.

Considerable data indicate the importance of mPRF for a number of behaviors, including saccadic eye movements, somatic motor activity and REM sleep, but there have been few physiological studies of mPRF organization and none explicitly addressing the question of whether some mPRF neurons are specialized to receive input ("input neurons") and others are specialized as "output neurons". We have recently examined this question with intracellular mPRF recordings and microstimulation (<85 uA) of reticular areas, using undrugged cats so as not to introduce anaesthetic confounds. Monosynaptic responses were defined as PSPs of <1.2 ms latency and antidromic (AD) responses by the usual intracellular criteria.

In 40 mPRF neurons antidromically activated from ipsilateral bulbar magnocellular tegmental field (FTM) we varied stimulation current to below AD threshold; in 38/40 neurons (95%) monosynaptic PSPs were seen, with 87% EPSPs and 13% IPSPs; these were the same proportions as seen in a larger sample (N=470) of mPRF neurons showing no AD activation (chi square test, p=0.5). Furthermore, the histograms of monosynaptic latencies for the AD and non-AD groups were not different (Kolmogoroff-Smirnoff test, $p > .4$) and the mean latency was identical (0.73 ms). Thus there was no evidence for any distinction on any of the input parameters between the population of "output neurons" (AD) and the total sample population, and thus no evidence for the presence of a specialized "input neuron". We simularly found no differences in the proportion of monosynaptic PSPs in mPRF neurons that were and were not AD activated by microstimulation of ipsilateral bulbar lateral and gigantocellular fields and contralateral gigantocellular PRF, although the small Ns (10) made detailed statistical comparisons impossible.

The apparent identity of input and output elements in mPRF suggests that a great deal of integration of input for response is done in individual mPRF neurons rather than having a "cascade" of information flow from one neuronal type to another as in cerebral cortex. The large size of mPRF soma and of dendritic fields and the absence of anatomical evidence for Golgi II neurons among mPRF neurons is also compatible with this concept. If there are no "interneurons" in mPRF, this raises the interesting question of the origin of relatively short latency IPSPs which follow EPSPs. On the ventral and lateral borders of mPRF we have recorded neurons with a burst discharge that occurs just after the time of EPSPs in mPRF neurons. While further data are necessary, these burst neurons are possible candidates for neurons inhibitory to mPRF.

12.11 **RETROGRADE LABELING OF SPINAL NEURONS FOLLOWING INJECTION OF HRP INTO THE FLEXOR DIGITORUM LONGUS MOTOR NUCLEUS IN THE CAT.** **D. Meyers*, J.W. Fleshman and B.J. Schmidt* (SPON: J.S. McIntosh). Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205.**

It has been known for some time that EPSPs can be evoked in motoneurons following electrical stimulation of cutaneous nerves. Previous results from this laboratory (Fleshman et al., Exp. Brain Res. 54: 133, 1984 and Fleshman et al., this meeting) have shown that, following electrical stimulation of the superficial peroneal nerve, short latency EPSPs are generated in flexor digitorum longus (FDL) motoneurons. The segmental onset latency of these EPSPs is so short (1.3-2.0 ms) as to suggest the existence of a disynaptic pathway from the skin to the FDL motoneurons. If this pathway exists, the intercalated neuron should be located in the deeper laminae of the medial dorsal horn (the termination region of cutaneous afferents innervating the distal hindlimb). At present there is no evidence that this region of the grey matter contains neurons that are both presynaptic to motoneurons and monosynaptically driven by cutaneous afferents.

In the present work we are attempting to determine whether there are last-order premotor interneurons in the dorsal horn by making small pressure injections of lectin-conjugated HRP through a micropipette (tip size 5-10 μm) at a number of sites in the FDL motor nucleus. The pipette tip was positioned by recording the antidromic field potential elicited from the FDL nerve. Animals were perfused after a survival period of 24 hr. The cord was then sectioned and reacted with tetramethyl benzidene.

Of three experiments, one with effective injection sites about 1 mm in diameter is presented below. Retrogradely labeled neurons were found on both sides of the cord in the L6-L7 segments. Cells labeled contralateral to the injection site were restricted to lamina VIII. These cells may be the last order neurons in the crossed extension reflex pathway. As expected, most cells labeled ipsilateral to the injection site were located in laminae VII and IX with a few cells in lateral lamina VIII. There was, however, another group of labeled cells located in ventral lamina V and lamina VI. These data are consistent with the hypothesis of a disynaptic cutaneous pathway to FDL motoneurons. Further experiments are in progress using smaller injection volumes and techniques to minimize problems associated with uptake from damaged axons.

12.12 CYTOCHEMICAL LOCALIZATION OF CYTOCHROME OXIDASE IN THE SPINAL CORD AND DORSAL ROOT GANGLIA, WITH QUANTITATIVE ANALYSIS OF VENTRAL HORN CELLS IN THE MONKEY. M. Wong-Riley and D.A. Hoppe*. Dept. of Anatomy, Med. Coll. of Wisconsin, Milwaukee, WI 53226.

At the 1984 Neuroscience meeting, we (Wong-Riley and Kageyama) reported the histochemical pattern for cytochrome oxidase (C.O.) in the spinal cord and dorsal root ganglia of several mammalian species. The present report represents an extension of that study to the ultrastructural level in the macaque. The spinal cord exhibited a heterogeneous but consistent pattern of C.O. staining, which could be correlated positively with known levels of activity in various nuclear groups. We have selected the substantia gelatinosa, dorsal nucleus of Clarke, ventral horn and dorsal root ganglia for further EM analysis. In the lightly reactive substantia gelatinosa layer, there were relatively few mitochondria in both neurons and neuropil. Most of the neurons were small, spindle-shaped, and contained very few and lightly-reactive mitochondria. In the dorsal nucleus of Clarke, medium to large neurons contained numerous darkly reactive mitochondria intermixed with a rich array of other organelles. Some of the smaller neurons were much less reactive. In the ventral horn, many of the large motoneurons had lightly-reactive mitochondria, while small and medium-sized neurons often contained moderate to darkly-reactive mitochondria. Axon terminals in the ventral horn had varying degrees of C.O. reactivity. Medium-sized "F" terminals with flattened synaptic vesicles typically had darkly-reactive mitochondria, while small "S" terminals with spherical vesicles often had light to moderately-reactive ones. The largest "C" type terminals were richly supplied with lightly-reactive mitochondria. "M" terminals with Taxi bodies were rarely encountered. Quantitative analysis of 1770 ventral horn neurons from 3 macaque monkeys indicated that the distribution of cell sizes as well as optical densities (for C.O. activity) at every level of the cord fell on a continuum. There was a negative regression coefficient such that a greater proportion of large neurons tended to be less reactive than the small ones. However, neurons of all size categories had representations in the dark, moderate, and light ranges of C.O. reactivity. Dorsal root ganglion neurons likewise exhibited a heterogeneous distribution of C.O. reactivity in every size category. The darkly reactive ones had a large number of reactive mitochondria, while others with equivalent volume of cytoplasm had fewer mitochondria, most of which were only lightly reactive. Satellite cells were not reactive for C.O.

Thus, our analyses indicate that the oxidative enzymatic activity of neurons in the spinal cord and dorsal root ganglia cannot be correlated strictly with size, but it is likely to reflect their total functional demand which, in turn, is strongly governed by their cumulative levels of synaptic and spontaneous activities. (Supported by NIH NS18122.)

12.13 ANATOMICAL AND PHYSIOLOGICAL ASPECTS OF THE ELECTROGENIC SYSTEM IN THE SPINAL CORD OF GYMNOTUS CARAPO. E. Decima, J. A. Echague*, D. Lorenzo* and O. Trujillo-Cenoz*. Dept. of Anatomy, UCLA School of Medicine, Los Angeles, CA 90024, U.S.A., and Neurobiology, Inst. C. Estable, Montevideo, Uruguay.

The electrogenic system of the so-called "weakly electric fish" consists of a muscle-derived electrogenic organ (EO) and a complex neural command determining the characteristics of the EO discharge (EOD). The main components of the command network are located in the fish medulla and spinal cord. This report concerns the spinal cord portion of the system, particularly the electrogenic neurons. These represent the final output of the EO command system and they were unambiguously identified by means of the somatopetal transport of HRP previously injected in the EO. The HRP-labelled cells are located medially, close to and dorsal to the ependyma. They form a long slender column along the spinal cord. When silver-impregnated, each neuron appears as a monopolar pear-shaped cell (about 25 μm in diameter), whose axon runs perpendicular to the main axis of the fish. Under the EM the electromotor neurons show synaptic knobs apposed to the somatic plasma membrane. Most of these synaptic terminals exhibit the characteristics of both chemical and electrical synapses.

Electrophysiological recordings of extracellular activity (field potentials and unitary responses) were obtained from the spinal cord with glass micropipettes while the EOD was simultaneously monitored. In the first type of experiment a high spinal cord section was made and stimulating electrodes were implanted in the caudal stump. Their aim was to activate the descending tract. In a second design, the animal was immobilized with gallamine and artificially oxygenated. Under this condition the normal activation of spinal electrogenic cells was maintained. In both experiments, field potentials and unitary responses were recorded preceding the EOD by 0.6 to 0.8 ms.

It remains to be elucidated whether these electrical events correspond to the activity of the electrogenic neurons themselves or to their driving pre-synaptic elements (i.e., those axons from the medullary command centers).

PRESYNAPTIC MECHANISMS I

13.1 MESOLIMBIC AND NIGROSTRIATAL DOPAMINERGIC AUTORECEPTOR PROPERTIES OF (-)-APOMORPHINE: SEROTONERGIC INTERACTIONS. P.A. Broderick, Department of Psychiatry, Albert Einstein College of Medicine, Bronx, New York, 10461 and Department of Biology and Medical Technology, Bronx Community College, The City University of New York, Bronx, New York 10453.

(-)-Apomorphine's presently suggested role as prototypic dopamine autoreceptor agonist is intriguing. Small doses of (-)-apomorphine selectively stimulate presynaptic autoreceptors on dopaminergic nigrostriatal neurons and may serve as the mechanism for the suppression of firing rate and possibly release in dopamine neurons. This is in keeping with behavioral effects of (-)-apomorphine which show that administration of small doses of (-)-apomorphine decrease locomotor activity, similar to the effects of dopamine receptor blockers; nonetheless, larger doses of (-)-apomorphine produce an increase in locomotor activity (Strombom, U., Acta Physiol. Scand. suppl., 431:1-103, 1975). In vivo electrochemical procedures are particularly suited to further investigate autoreceptor hypotheses because they measure the ongoing dynamics of neurotransmitter release in the synaptic cleft. A previous paper using in vivo electrochemistry (Broderick, P.A., Annals of N.Y. Acad. Sci., 1985, in press) demonstrates evidence for a significant suppression ($p<0.05$) of dopamine release after intraperitoneal administration of small doses of (-)-apomorphine to male, Sprague-Dawley rats, stereotaxically implanted with stearate indicator electrodes in anterior striatum (for methodological details, cf. Broderick, P.A., Life Sci., 36(24):2269-2275, 1985). The data further show a reversal of this (-)-apomorphine effect at larger doses, possibly stimulating postsynaptic dopaminergic receptors and perhaps explaining unexpected, behavioral responses (Strombom, U., Naunyn-Schmiedeberg's Arch. Pharmacol., 292:167-176, 1976). The present paper further shows that the sensitivity of mesolimbic dopaminergic autoreceptors, as shown by dopamine release from tuberculum olfactorium, after systemic (-)-apomorphine administration, may be greater than that of striatum, in agreement with electrophysiological studies (Roth, R.H., Comm. Psychopharmacol., 3:429-445, 1979). Preliminary data showed that serotonin release from rat striatum after (-)-apomorphine appeared inconsistent; serotonin release from rat tuberculum olfactorium, after (-)-apomorphine, decreased 30-40% below basal levels. These data support previous data (Lee, E.H. and Geyer, M.A., Eur. J. Pharmacol., 94(3-4):297-303, 1983) which showed differential effects of dopaminergic autoreceptor agonist activity in striatal and mesolimbic serotonergic systems in rat brain.

13.2 ASSOCIATIVE PRESYNAPTIC INTERACTIONS IN THE CA_1 AREA OF RAT HIPPOCAMPUS. B. R. Sastry and J. W. Goh*. Neuroscience Research Laboratory, Department of Pharmacology and Therapeutics, Faculty of Medicine, The University of British Columbia, Vancouver, B. C., Canada, V6T 1W5.

A tetanic stimulation of stratum radiatum in the hippocampus results in a post-tetanic long-lasting potentiation (LLP) of the CA_1 neuronal population spike evoked by the same input. Some investigators reported that a coactivation of several input fibres is needed to induce LLP and suggested that the necessity for a coactivation of several input fibres and the associative nature of the induction of LLP could be explained if LLP is postsynaptic. In the present studies on rat hippocampal slices, we examined whether Schaffer collateral terminals interact with each other.

Individual CA_3 neurones were antidromically activated with an electrode in the CA_{1b} area to determine the threshold for the generation of an action potential in the terminal region of the fibre. The threshold was usually decreased (by about 15% at 50 ms delay) for about 300 ms following the activation (with a separate electrode in the CA_1 area) of other nearby fibres in stratum radiatum (5 conditioning pulses at 100 Hz, n = 14). The decrease in the threshold was less intense if the conditioning was given in Ca^{++}-free (substituted with Mn^{++}) medium (n = 8). Exposure of slices for 1 min to a medium containing 4.5 mM K^+ (control medium had 3.1 mM K^+) also decreased the threshold (by 11-36%, 5/6). When the number of conditioning pulses was increased to 10 (at 100 Hz), the threshold was increased (by 88-294% at 50 ms delay, 3/7; by 83-278% at 300 ms delay, 5/7). Exposure for 1 min of slices to a medium containing 6 mM K^+ resulted in an increase in the threshold (by 22-215%, 5/7) while an exposure to a 12 mM K^+ containing medium caused even a larger increase in the threshold (by 55-300%, 7/7). Subsequent to the exposure of the slices to 12 mM K^+, the threshold was maintained at higher than control for a long period of time (increase in threshold 20 min post 12 mM K^+: 25-76%, 5/7) as was seen during LLP of the population spike.

These results indicate that presynaptic terminals in the hippocampal CA_1 area interact with each other to alter their excitability. The interaction may be a consequence of a build-up of extracellular K^+ or secondary to the release of transmitters. In view of these results, future studies should examine if such interactions play a role in associative induction of LLP.

13.3 PROPERTIES OF EXCITATORY POSTSYNAPTIC POTENTIALS MEDIATED BY LARGE MYELINATED CLUB ENDINGS ON THE GOLDFISH MAUTHNER CELL.
J.-W. Lin and D.S. Faber. Div. Neurobiology, Dept. Physiology, SUNY at Buffalo, Buffalo,NY 14214.

The major excitatory inputs to the goldfish Mauthner (M-)cell are the large myelinated club endings (LMCE) which arise from the saccular nerve and terminate on the lateral dendrite. Ultrastructural studies demonstrated that all the endings established morphologically mixed synapses on the M-cell (Nakajima,Y., J.Comp.Neurol. 156:375,1974). In contrast, our electrophysiological investigations, utilizing simultaneous pre- and postsynaptic intracellular recordings, show that impulses in most of the saccular fibers sampled (>80%) produce only electrotonic coupling potentials in the M-cell, i.e. they are chemically 'silent'. In the remaining cases, chemical excitatory postsynaptic potentials (EPSPs) are recorded as well. Presynaptic HRP injections demonstrate that the individual afferents send one process to the M-cell which terminate as LMCEs. Thus EPSP fluctuations could be studied under conditions where branch point failure does not occur and presynaptic spike variations can be monitored directly.

The average unitary EPSP amplitude was 137±77μV (n=15) and was significantly less than the electrotonic coupling potential (826±410μV) produced by impulses in the same fibers. When individual saccular fibers were activated repetitively at intervals of 1.5 to 3 msec., the EPSPs showed pronounced facilitation; the second and third EPSPs averaged 91% (n=6) and 102% (n=5) larger than the first, respectively. The coefficient of variation of the second EPSP was always smaller than that of the first, which is expected if transmitter release is quantal and probabilistic. Furthermore, fluctuations in the amplitudes of the first and second EPSPs were uncorrelated. This independence strongly suggests a presynaptic origin for the facilitation and is consistent with the notion that it occurred at any active site regardless of whether or not it had undergone exocytosis.

Repetitive stimulation of the 'silent' junctions failed to evoke any detectable EPSPs following the second or third spikes. Similarly, while 4-aminopyridine increased EPSP amplitude and duration, it had no detectable effect on the silent junctions. The contrast between facilitation of functioning chemical synapses and the inability to evoke EPSPs at silent synapses suggests that in the latter case either: (1) the postsynaptic receptors, if present, did not respond to the released transmitter, or (2) there is an overriding mechanism in presynaptic terminals which block release at all active sites and is insensitive to the facilitatory mechanisms described here. Supported by NIH Grant #NS-15335.

13.4 QUANTAL ANALYSES DURING PRESYNAPTIC INHIBITION AND CORRELATED MORPHOLOGY OF CRAB MOTOR AXON SYNAPSES. F.W. Tse* and H.L. Atwood, Dept. of Physiology, University of Toronto, Toronto, Ontario, Canada M5S 1A8

The crab limb stretcher muscle is innervated by one excitor (E) axon. In Pachygrapsus crassipes, this single axon provides individual muscle fibers with synapses that show diverse synaptic performance. At low frequencies of stimulation, low-output and high-output synapses are apparent. Low-output synapses (1 mV EPSPs at 1 Hz stimulation) show strong facilitation at higher frequencies of stimulataion and high-output synapses (20 mV EPSPs at 1 Hz stimulation) show depression or poor facilitation. The E axon receives diverse strength of presynaptic inhibition (PI) from a specific inhibitor (SI) axon that is known to form axo-axonal synapses with the E axon. The distribution of synaptic terminals and the branching patterns of both axons can be observed with fluoresence microscopy using rhodamine 123 to stain the nerve endings. Such staining has no significant effect on synaptic transmission or on the muscle fibers' resting membrane potential. Focal extracellular ("loose patch") recordings of synaptic currents from morphologically identified neuromuscular synaptic sites show that PI is stronger at sites with high-output synapses. Quantal output of the E axon at identified sites was analysed statistically with a computer programme. Binomial statistical parameters (n and p) were calculated before and during PI. Without PI, the output of the E axon can be described by binomial statistics which assume that a focal electrode records from a fixed number (n) of equivalent synapses, each with a uniform and stationary probability (p) of releasing one quantum of transmitter. With PI, the reduction in probability of output at a group of synapses is seldom uniform and sometimes non-stationary. Usually, the probability of quantal release at some synapses in a site is reduced to almost zero, while that of adjacent synapses in the same site is still appreciable. In some cases, PI is strong and stationary; the output of the E axon can be described by binomial statistics with a reduced number (n) of detectable synapses. Fluorescence microscopy shows that high-output synapses with strong PI occur on compact, end-plate like clusters of boutons, while low-output synapses with weaker PI occur on more diffuse axonal branches with sequential boutons. In electron microscopy, active synapses can be distinguished from inactive ones by an uptake of extracellular markers (e.g. HRP) after stimulation. This method is being applied to verify whether there are inhibited synapses adjacent to active ones during presynaptic inhibition.

13.5 DIFFERENTIAL MODULATION OF ENDPLATE POTENTIALS IN SLOW AND FAST MAMMALIAN MUSCLES.
A. Lev-Tov, The Department of Anatomy, The Hebrew University Medical School, Jerusalem, Israel.

The modulation of endplate potentials during double pulse stimulation and repetitive stimulus trains was studied in the fast twitch extensor digitorum longus (EDL) versus the slow-twitch soleus (Sol) muscles of the rat. Nerve-muscle preparations were isolated from 8 rats and the muscular contraction was abolished by decreasing the calcium level of the perfusate. The muscle nerve was stimulated by a suction electrode and the synaptic potentials were recorded using surface-extracellular and conventional intracellular recording methods. Twin-pulse facilitation (F) was measured from 32-sweep computer averages. Tetanic potentiation (TP) and posttetanic potentiation (PTP) were evaluated from computer averages of endplate potentials at the end and immediately following stimulus trains of 200 pulses. The data revealed that F, TP and PTP were substantially higher in EDL versus Sol synapses (see the table below).

Interpulse interval		F 100(V2/V1-1)	P(max) (% p o t e n t i a t i o n)	PTP
25ms	EDL	*30.3±2.0 (5)	*251.1±17.7 (11)	*44.0±5.7 (11)
	Sol	25.6±2.0 (5)	169.4±12.7 (14)	22.6±10.7(14)
100ms	EDL	13.6±2.0 (4)		
	Sol	11.7±3.0 (4)		
200ms	EDL	*10.5±1.0 (5)	*41.3±6.5 (9)	*12.5±2.9 (9)
	Sol	3.1±1.0 (5)	16.4±2.2 (10)	7.2±3.7 (10)

These data are based on surface recordings from populations of synapses. The number of recording sessions (each from a different recording site) are in parentheses. Sig- nificant differences between the respective means of EDL and Sol (two tail t-test P<0.001) are denoted by asterics (*).

The results thus demonstrate that the synaptic potentials generated in neuromuscular synapses of slow twitch mammalian muscles are modulated differently from those generated in fast twitch muscles. Further studies regarding the basis for these differences are now in progress.

13.6 SEROTONIN PRODUCES A DECREASED CONDUCTANCE EPSP AND BROADENING OF THE ACTION POTENTIAL IN GROWTH CONES OF APLYSIA SENSORY NEURONS. F. Belardetti*, S. Schacher, E. R. Kandel, and S. A. Siegelbaum. Howard Hughes Medical Institute and Center for Neurobiology & Behavior, Dept. of Pharmacology, Columbia Univ., College of P & S, and N. Y. State Psychiat. Instit., New York, NY 10032.

Serotonin (5-HT) facilitates transmitter release from sensory neuron terminals in Aplysia abdominal ganglia, and produces a slow EPSP and broadening of the action potential (AP) due to closure of a specific class of K^+ channels (S channels). In the past, exploration of the relation of the S channel modulation to presynaptic facilitation was restricted to studies of the cell body membrane. To explore whether K^+ channel closure also occurs in presynaptic terminals, we have used the whole cell patch clamp and studied the action of 5-HT on both intact and isolated growth cones (g.c.), the precursors to the mature synaptic terminal of Aplysia sensory neurons in culture.

Using patch pipettes filled with an "intracellular" solution (containing KCl, EGTA, MgATP, GTP, and HEPES at pH 7.3) we recorded resting potentials of -50 to -60 mV. Recordings from cell bodies (n=8) show that a brief puff of 5-HT (100 uM serotonin creatinine sulfate) produces a slow depolarization of 4-10 mV, a 15-20% increase in input resistance, and a 14-30% increase in the action potential duration. Recordings from intact growth cones (n=4) show that before application of 5-HT, the growth cones are either inexcitable or fire only a small AP. After application of 5-HT either on the growth cones or the cell bodies, the growth cones show a slow depolarization of 2-7 mV and a 3-14% increase in input resistance. In addition, all growth cones now display action potentials, and in those that had action potentials prior to 5-HT, there is an increase in duration (25%).

To determine whether these effects of 5-HT result from a modulation of ionic conductances within the growth cone itself, we have begun to record from growth cones that had been mechanically isolated from their axons with a glass needle. Most of the growth cones remained morphologically and electrically intact and depolarizing current pulses elicit an action potential. In preliminary experiments, we have found that 5-HT (n=2) induces a 22% broadening in action potential duration, a slow 2-5 mV depolarization of the resting potential, and a 12-24% increase in input resistance. Application of a control solution (n=2) (creatinine sulfate) had no effect. These findings indicate that 5-HT induces a slow EPSP in sensory neuron growth cones that is similar ot the EPSP produced in the cell body, and suggest that an increase in excitability and in the broadening of the AP at the terminals contributes to presynaptic facilitation.

13.7 PRESYNAPTIC FACILITATION IN APLYSIA SENSORY NEURONS: A PROCESS INDEPENDENT OF K^+ CURRENT MODULATION BECOMES IMPORTANT WHEN TRANSMITTER RELEASE IS DEPRESSED. B. Hochner*, S. Schacher, M. Klein*, and E. R. Kandel. H. Hughes Medical Institute and Center for Neurobiology and Behavior, Columbia P & S.

Sensitization in Aplysia involves cAMP-mediated presynaptic facilitation of transmitter release from sensory neurons. This process is accompanied by reduction in a K^+ current (S-current). Closure of these channels can produce spike broadening which increases Ca^{++} influx and enhances transmitter release. Two recent findings raised the possibility that another process might also contribute to facilitation: 1) 5-HT increases the Ca^{++} transient (measured with arsenazo III) caused by long depolarizing commands under voltage clamp (Boyle et al., 1984); 2) Blockade of 5HT-induced facilitation using K^+ channel blockers reduces not only the S current but also the increase in Ca^{++} transient (Hochner et al., 1984).

To reveal additional processes in facilitation we prevented the voltage changes produced by 5-HT-induced closure of the S-channel using voltage clamp. To achieve optimal control of the terminals, we isolated sensory neurons and their followers and plated them in close proximity in dissociated cell culture. The synaptic connections formed are similar to those in vivo and in some cases we could control transmitter release from the cell body in normal sea water using a two-electrode voltage clamp. The dependence of PSP amplitude on voltage step duration is steep. Release starts with a duration of 1.5 msec and asymptotes at 10 to 20 msec. In the range of 1.5 msec to 3 msec, a 0.5 msec increase in duration causes a 2 to 3 fold increase in transmitter release, suggesting that in the normal range of release spike broadening plays an important role in facilitation. This input-output relationship is not mantained, however, when this synapse undergoes homosynaptic depression with repeated stimulation as in vivo. In the depressed state, the increase in release caused by increasing step duration is greatly reduced. This suggests that now the amount of transmitter available for release is limiting; this is also supported by the fact that the PSPs produced by short pulses are more refractory to depression. When 5-HT is applied to depressed synapses, there is only little or no facilitation of the PSPs produced by short duration pulses, but large facilitation for PSPs elicited with longer duration pulses. In addition, 5-HT restores the steepness of the input-output relation. TEA does not mimic this effect.

These data suggest that 5-HT induces presynaptic facilitation by two mechanisms: 1) By closure of S-channels. This predominates for short duration pulses (comparable in duration to the action potentials) and for normal (nondepressed) levels of release. Here release is strongly dependent on pulse duration. 2) By mobilization of transmitter or other steps in the release mechanism. This predominates when the synapse is in a depressed state and might be related to 5-HT modulation of Ca^{++} handling. In the intermediate range of release, duration and mobilization both regulate transmitter release, and here, 5-HT-induced facilitation presumably involves synergistic interaction of the two processes.

13.8 RELEASE OF TRANSMITTER FROM APLYSIA SYNAPTOSOMES. G.J. Chin, E. Shapiro & J.H. Schwartz. Howard Hughes Med. Inst., Columbia Univ. Coll. of Physicians & Surgeons, New York, NY 10032.

We have developed a preparation of isolated nerve endings from Aplysia to examine the biochemistry and physiology of transmitter release. We find that this synaptosomal preparation releases neurotransmitter in a Ca^{2+}-dependent manner and displays a Co^{2+}-inhibitable Ca^{2+} influx. To prepare synaptosomes, central ganglia from 8-10 Aplysia (trimmed of all extraneous connective tissue, but not desheathed) were homogenized in buffered 0.8 or 1.1M sucrose using a ground-glass tissue grinder. Connective tissue debris was removed manually, and the remaining suspension (10 mg protein in 1.0 -1.5 ml) was centrifuged for 10 min at 1000 x g on a two-step density gradient (0.8M/1.1M sucrose). We isolated three fractions: P1, the pellet below the 1.1M sucrose layer; P2, the material suspended in the 1.1M layer and the 0.8M/1.1M interface; and P3, the 0.8M layer and floating material. The two lighter fractions were diluted with several vol of Ca^{2+}-free seawater and centrifuged for 10 min at 10,000 x g to obtain membrane pellets P2 (2 mg protein) and P3 (1 mg protein).

For electron microscopy, the pellets were fixed and sectioned and then compared stereometrically (n=4). Profiles containing synaptic vesicles enclosed by external membrane were called synaptosomes. The % area occupied by synaptosomes in the unfractionated homogenate was 7.1, P1 contained 4.2% synaptosomes, P2 14.4% synaptosomes, and P3 22.1%. The average diameter of an Aplysia synaptosome is 1 um, with many profiles as large as 3 um.

To measure Ca^{2+} uptake, the membranes were resuspended and incubated for 30 sec at room temperature in normal or high K^+ solutions containing ^{45}Ca. Uptake assayed on glass fiber filters was greatest in the P3 fraction; it was stimulated by high K^+, and inhibited by 5 mM Co^{2+}. Transmitter release was assayed similarly. Membrane fractions were labeled with ^3H-choline for 30 min at 15°C, then washed and suspended in Ca^{2+}-free seawater at 4°C. Aliquots were exposed for 30 sec to normal or high K^+ seawater at room temperature, then rapidly filtered. Release of radioactivity from the P3 membrane was stimulated by high K^+ only in the presence of external Ca^{2+}.

We are currently extending these investigations in two directions: First, we are prelabeling identified Aplysia neurons with radioactive transmitter by intracellular injection before homogenization to study modulation of release from identified, isolated presynaptic terminals. Second, we have begun to characterize these fractions biochemically by examining protein phosphorylation.

13.9 EXPRESSION, PACKAGING, AND REGULATED RELEASE OF HUMAN GROWTH HORMONE IN PC-12 CELLS. E.S. Schweitzer and R.B. Kelly. Univ. Cal. Sch. of Med., San Francisco, CA 94143.

We have transfected the gene coding for human growth hormone into the rat pheochomocytoma-derived cell line, PC-12, in order to study the processing and secretion of a foreign peptide by a cell with neuronal characteristics. The genomic DNA coding for hGH was introduced in a plasmid containing the selectable marker for neomycin resistance, permiting the selection of stably transformed cell lines. The hGH gene is expressed in these cells, and immunoreactive growth hormone that co-migrates with authentic hGH is secreted into the medium. In addition to the major form of the hormone (MW=22,000), a smaller form of Mr=20,000 is secreted. This peptide is also found in normal human (but not rat) pituitary, and is thought to be the result of alternative RNA splicing.

Human growth hormone is stored within the cells in a compartment that appears to correspond to the endogenous catecholaminergic vesicles. These vesicles can be specifically immunoprecipitated by either of two vesicle-specific monoclonal antibodies. On sub-cellular fractionation, hGH co-purifies with the norepinephrine-containing vesicles. Treatment of the cells with NGF causes a 2-3 fold increase in the storage of hGH.

Stimulation of the transfected PC-12 cells either by elevated external K or 5 mM carbachol causes a large, rapid increase in the release of hGH. This release peaks in less than 2 min; approximately 40% of the total stored hGH is released in 10 min. The kinetics of the hGH release parallel those of norepinephrine, supporting the suggestion that they are packaged into the same vesicles. Differentiation of the cells with NGF causes an increase in the stimulated secretion of hGH. In these cells, stimulated release is 25-fold higher than the basal release.

The packaging and release of hGH from synaptic vesicles involves segregation of secretory proteins, since not all proteins seem to be packaged into these same vesicles. For example, laminin, a soluble protein that is a component of extracelluar matrix, is secreted by PC-12 cells independently of stimulation. Carbachol causes no increase in the rate of its release. PC-12 cells therefore possess at least two pathways for protein secretion, and are capable of selectively packaging a foreign hormone into one of the two paths.

13.10 ECTO-PROTEIN KINASE ACTIVITY AT THE SURFACE OF INTACT NEURAL CELLS. Y.H. Ehrlich, T.B. Davis*, E. Kornecki and R.H. Lenox. Neurosci. Res. Unit, Dept. of Psychiatry, Univ. of VT, Burlington, VT 05405

Extracellular adenosine triphosphate (ATP) exerts potent effects on the activity of excitable cells, neurons and muscle. Furthermore it is known that ATP is released in association with neurotransmitters at synapses and neuromuscular junctions. The molecular mechanisms underlying the modulation of neuronal function by extracellular ATP may involve the phosphorylation of surface proteins by ecto-protein kinase activity. Conclusive evidence for the existance of an ecto-kinase and the identification of its specific protein substrates requires that studies be carried out with a homogenous population of intact, viable cells. In the present study, this was done by incubating intact, viable cells of neuronal origin, the neuroblastoma x glioma hybrid clone NG108-15, with extracellular radiolabeled ATP. ^{32}P-incorporation into specific protein components was measured by autoradiography of SDS-solubilized proteins separated in slab polyacrylamide gels. To exclude the possibility that the measured activity arises from serum proteins or resides in membrane fragments formed when some cells break during harvest, NG108-15 cells were grown and differentiated for 6-8 days in a chemically defined (serum-free) medium supplemented with insulin, transferrin and linoleic acid. Cells were grown and assayed while attached to individual wells of 96 well plates. Prior to the assay, the cells were rinsed with a modified Krebs-Ringer buffer (containing 145mM NaCl, 6mM KCl, 0.8mM $MgCl_2$ and 1.8mM $CaCl_2$) and the reactions were carried out in this physiological medium. Intact cells utilized extracellular ATP to phosphorylate surface proteins within 30 seconds. The labeling of intracellular proteins with equivalent amounts of inorganic ^{32}Pi proceeded with a much slower time-course, and produced a different pattern of protein phosphorylation. Evidence for the ecto-enzymatic nature of the measured activity includes the ability of intact NG108-15 cells to phosphorylate an exogenous protein (casein), and the elimination of the activity by mild treatment of intact cells with 0.01% trypsin. The major protein substrates of ecto-kinase activity in NG108-15 cells have apparent M.W.'s of 190K, 120K, 97K and 44K. When NG108-15 cells are treated with 1mM dibutyryl cyclic AMP for 4-6 days they differentiate morphologically, biochemically and physiologically, and acquire many properties characteristic of mature neurons. In such differentiated NG108-15 cells the phosphorylation of endogenous proteins by extracellular ATP was increased compared to nontreated cells, suggesting that ecto-protein kinase activity is associated with the neuronal properties of these cells. A possible function for this activity was indicated by our finding that extracellular ATP induced an increase in the uptake of Ca^{++}-ions by intact NG108-15 cells.

13.11 ATP RELEASED POSTSYNAPTICALLY CONTRIBUTES TO PRESYNAPTIC NEURONAL ATP POOL AND MODULATES NEURONAL CALCIUM UPTAKE. C.A. Lindgren and D.O. Smith. Department of Physiology, University of Wisconsin, Madison, WI 53706.

Stimulation of the excitor axon to the opener muscle in the crayfish walking leg causes bath levels of ATP, ADP, AMP and adenosine to increase significantly. Addition of the postsynaptic antagonist, γ-methyl-glutamate, prevented the increase in ATP and reduced the levels of ADP, AMP, and adenosine below their limit of detection (1 pmol). This suggests that activation of the muscle causes it to release ATP and possibly also its products of hydrolysis.

The released ATP may contribute to the neuronal intracellular ATP pool. Addition of ATP to the bath solution increased ATP levels in the nerve. Moreover, addition of 2-deoxy-D-glucose and [γ-^{32}P]-ATP to the bath resulted in the formation of [^{32}P]-2-deoxy-D-glucose-6-P by the nerve. This implies that the extracellular ATP must have entered the neuron chemically intact because these results cannot be explained by extracellular hydrolysis of the ^{32}P-ATP to ADP and ^{32}P-orthophosphate. We conclude that ATP released by the muscle is capable of contributing to the neuronal ATP pool.

The released ATP may also modulate transmitter release from excitor nerve terminals. In cells with normal intracellular ATP levels, exogenous ATP was found to inhibit evoked transmitter release by 43%; neither ADP, AMP nor adenosine had any effect. Omission of glucose from the bathing solution caused nerve ATP levels to decrease by 40% within 80 minutes and an additional 10% over the next two hours. Under these conditions, 5 mM exogenous ATP increased release by 26%. This latter effect did not result from changes in intracellular ATP levels induced by the extracellular ATP since low intracellular ATP levels per se do not significantly alter average quantal content, synaptic delay nor interquantal latency.

These effects may be related to changes in the cell's Ca^{2+} permeability. Stimulation-induced ^{45}Ca uptake was reduced by exogenous ATP. However, 5 mM ATP increased resting ^{45}Ca uptake. These results are interpreted as follows. Exogenous ATP normally inhibits evoked transmitter release by reducing stimulation-induced Ca^{2+} influx into the synaptic terminal. In the absence of glucose, however, 5 mM ATP increases transmitter release because under these conditions the nerve has insufficient intracellular ATP levels to buffer the increased resting Ca^{2+} influx. Supported by NIH grant NS13600.

13.12 CYCLIC AMP REGULATES CALCIUM UPTAKE IN CORTICAL SYNAPTOSOMES OF THE RAT. J. A. Wagner, I.J. Reynolds and S.H. Snyder. Department of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Electrophysiological evidence suggests that an adenylate cyclase system in heart cells regulates calcium conductance through voltage-sensitive calcium channels. No such evidence exists for calcium channels in the brain, but modulatory agents such as enkephalins and adenosine, which influence adenylate cyclase, regulate release of neurotransmitters through their effects on calcium flux in nerve terminals.

Calcium flux into nerve terminals was measured as $^{45}Ca^{++}$ uptake into rat brain synaptosomes. Synaptosomal fractions were prepared according to Hajos (Brain Res. 93:485-489, 1975). Synaptosomal fractions were preincubated with or without drugs at 30°C for 30 min and incubated with $^{45}Ca^{++}$ for 45 sec. Undepolarized (3 mM KCl) and depolarized (57.5 mM KCl iso-osmotically substituted for NaCl) $^{45}Ca^{++}$uptake was measured. Uptake was stopped by rapid filtration and assessed as radioactivity trapped on filters.

Agents that enhance the adenylate cyclase systems, dibutyryl cyclic AMP, forskolin, and fluoride, enhance depolarized but not undepolarized synaptosomal $^{45}Ca^{++}$ uptake in a dose-dependent fashion. At 100 μM dibutyryl cyclic AMP maximally enhances $^{45}Ca^{++}$ uptake by 33°/°. Forskolin increases uptake maximally at 10 μM by 33°/°. Fluoride enhances uptake by 100°/° at 20 mM. These effects are all pharmacologically specific to adenylate cyclase because inactive analogs of these agents do not affect $^{45}Ca^{++}$ uptake. In addition, agonists at adenosine A_1, $GABA_B$ and opiate receptors, which block neurotransmitter release and inhibit adenylate cyclase, block depolarization-induced $^{45}Ca^{++}$ uptake. These findings suggest that adenylate cyclase is a major regulator of calcium uptake into nerve terminals in the brain and thereby modulates neurotransmitter release. (J.A.W. was supported by an NSF graduate fellowship.)

SENSORY SYSTEMS: AUDITORY PATHWAYS I

14.1 Representation of Envelope Information in Cochlear Microphonic Responses to Sinusoidal Amplitude Modulation

Susan E. Shore and Ben M. Clopton*
Kresge Hearing Research Institute
The University of Michigan
1301 E. Ann Street
Ann Arbor, Michigan 48109

Amplitude modulated sinusoids produce responses in VIII nerve fibers synchronized to the carrier (C), upper and lower sideband (U and L) and envelope (E) frequencies (Javel, E. J. Acoust. Soc. Amer. 68:133-146, 1980). For this to occur, the signal components (C, U and L) must fall within the unit's response area. The neuron's response to the modulation envelope is presumed to occur as a result of the relative response amplitudes and phases of these components. The amplitude of the VIII nerve response to the envelope varies with modulation frequency (Fm). The function describing this variation (the modulation transfer function or MTF) is low pass with a cutoff frequency which increases as the characteristic frequency of the fiber increases, reflecting a decrease in discharge modulation as the width of C, U and L exceed the width of the fiber response area (Palmer, A. R. Arch. Otorhinolaryngol. 236:197-202, 1982).

However, there are instances in which MTFs may not be directly predictable from single fiber filter functions. At high intensities, low CF fibers show synchronized responses to envelopes at their CFs, although the C, U and L frequencies do not fall within their response areas (Javel, 1980). The responses therefore arise from distortion products propagated to low frequency regions.

In this study, round window cochlear microphonic (CM) responses from guinea pigs were obtained to amplitude modulated sinusoids of different frequencies. Modulation frequency was varied from 25-800 Hz. Fourier Transforms (FFTs) of the CM waveforms revealed major frequency components at E and C with minor components at U and L. The magnitude of E, now expressed as a ratio of E/C, varied as a function of Fm. The MTF was bandpass with a maximum around 100 Hz.

These findings suggest that a distortion component at Fm is generated within the cochlea in response to sinusoidal amplitude modulation. Our data supports the hypothesis that this could partly determine those aspects as the response modulation observed in VIII nerve fibers which are not attributable to filter bandwidth. This work was supported by grant NS #21769.

14.2 Single-Unit Responses at Cochlear Nuclei to Group Delay in Noise

B. M. Clopton*, Y. N. Au* and S. S. Shore
[SPON. Sandord C. Bledsoe]
Kresge Hearing Research Institute
The University of Michigan
1301 E. Ann Street
Ann Arbor, Michigan 48109

The cochlea analyzes sounds with multiple frequency components into narrowband frequency channels. The outputs of these channels have amplitude envelopes which slowly vary in time. We modified the phase spectrum of a wideband noise to produce a second noise with envelopes delayed relative to those in the first by an amount proportional to frequency. A comparison of unit responses in the cochlear nuclei to the two noises show temporal delays which are predictable from a unit's characteristic frequency and the envelope or group delay appropriate to that frequency. In addition to providing a rapid technique for estimating characteristic frequency using complex sounds, this experiment illustrates that the envelope waveform resulting from narrowband filtering is a major determinant of the temporal pattern of responding for units in the cochlear nuclei.

This work was supported by Grant NS #21769.

14.3 CAT COCHLEA DENDRITE RESPONSES FOR DIFFERENT Rm VALUES AND SYNAPTIC PULSE TRAINS. J.L. Winslow*, Faculty of Dentistry, U. of Toronto, Toronto, Ont. M5G1G6

The responses of cat cochlea inner and outer afferent dendrites to synaptic input were investigated by solving an electrical compartment model based on their geometry. There is still no clear identification of the role played by outer afferent dendrites in the peripheral auditory system. The response potential V(x,t) at location x, time t, was described by a system of ordinary differential equations, which is the compartmental version of the cable equation for dendrites. The synapses were driven by the nonlinear boundary condition $D_x V(x,t)|_{x=0} = -(\rho/\pi r^2) * G(t) * [V(0,t) - Vr - Ena]$, where Vr is resting potential, Ena is sodium equilibrium potential, ρ is axoplasm resistivity, r is radius, and input is post-synaptic conductance G(t). For inner dendrites of diameter 1 muM, length 25 muM, followed by a constricture of diameter 0.3 muM, length 20 uM, and axon of diameter 2 muM, a system of ordinary differential equations was obtained and solved using fast numerical stiff integration techniques. The responses were as expected with membrane capacitance 1.3 muF and membrane resistance 4000 ohm*sqcm, giving potential pulses that followed synaptic conductance pulses. The dendrite showed temporal summation for pulse trains of 1 KHz. Using the same model with only the different geometry for outer dendrites (shaped like a long handled comb with 10 to 100 synapses over 1 mm), response were similarly calculated. These responses exhibit spatial summation. However, their response potential at the spike generating site is too small to generate spikes at the start of the myelin. When the membrane resistivity is increased to 20 K ohm*sgcm, the space constant and hence response at the AP generating site increases, but still not sufficient to trigger spikes. When input for the synapses was taken to be conductance pulse trains, the responses showed temporal summation.

14.4 S^{35}-CYSTEINE UPTAKE LABELS NEURONS AND SYNAPTIC TERMINALS IN THE GERBIL COCHLEAR NUCLEUS. I.R. Schwartz, Division of Head & Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024

Autoradiographic studies of localization of label following H^3-GABA uptake in synaptic terminals (Schwartz, I.R. 1985, in Auditory Biochemistry, D. Drescher, ed.) and histochemical studies of glutamic acid decarboxylase (GAD) immunoreactivity localization in synaptic terminals and cell bodies (Adams, J.C., Neurosci. Absts. 10:393, 1984; Moore, J.K. & Moore, R.Y., Neurosci. Absts. 10:843, 1984) provide data which suggests the presence of several populations of GABAergic neurons and synaptic terminals in the cochlear nucleus (CN) and superior olivary complex (SOC). However, Oertel et al (Neurosci. 6:2701-2714, 1981) have shown that GAD from rat liver and brain is indistinguishable from the protein of cystein sulfinic acid decarboxylase (CSD). Further, Iwata et al (J. Neurochem. 38:1268-1274, 1982) have demonstrated transmitter-like properties of uptake and release of cysteine sulfinic acid (CSA) by a rat brain preparation. To investigate the possibility that some of the data suggesting a transmitter role for GABA in the CN and SOC might be related instead to CSA, or some other closely related compound, we used light microscopic autoradiography to examine the distribution of label localization following incubation of fresh gerbil brain slices with S^{35}-cysteine (CYS).

At the light microscopic level CYS incubations produced labeling of neuronal somata, in contrast to the absence of neuronal somatic labeling observed in the cat after incubation with D- or L-aspartic acid, glutamic acid, glycine, GABA, taurine or alanine. In the gerbil CN labeled small neurons were found sparsely distributed in the molecular layer of the dorsal and anterior ventral CN (DCN & AVCN). Neither fusiform cell bodies in the DCN, nor spherical or globular cell bodies in the AVCN were labeled, although a few small labeled cells were found within the AVCN. Granule cells appeared generally unlabeled. The heaviest labeling was observed in terminals and small processes in the outer molecular layer of both DCN and VCN, the regions where both radioactive label following GABA uptake and GAD immunoreactivity are greatest. No labeled neurons were observed in the SOC.

These observations emphasize the need for additional data, especially on the "identity of action criteria", before it can be concluded whether GABA, CYS or some other compound is a transmitter of the labeled or immunoreactive neural elements.

Supported by grants NS09823 & NS14503 from the NIH/NINCDS and a grant from the Hope for Hearing Foundation.

14.5 AGE-DEPENDENT EFFECTS OF COCHLEA REMOVAL ON THE COCHLEAR NUCLEI OF MICE. D.B. Webster. Kresge Hearing Research Laboratory of the South, Departments of Otorhinolaryngology and Anatomy, Louisiana State Univ. Med. Center, New Orleans, LA 70119.

The left cochlea was surgically removed in four groups of mice with seven mice in each group. Group 1 mice had the cochlea removed at 12 days after birth (DAB) and were sacrificed at 90 DAB; group 2 mice had their cochlea removed at 24 DAB and were sacrificed at 90 DAB; group 3 mice had their cochlea removed at 45 DAB and were sacrificed at 90 DAB; and group 4 mice had their cochlea removed at 45 DAB and were sacrificed at 123 DAB. All ears and brains were prepared for serial section, light microscopic analyses. All right ears were normal and the cochlea, including spiral ganglion, was totally destroyed in all left ears. In the ventral cochlear nuclei volumes and numbers of neurons were determined for the anterior ventral cochlear nuclei, intermediate ventral cochlear nuclei, and posterior ventral cochlear nuclei. The volumes of the dorsal cochlear nuclei were measured. The cross-sectional areas of spherical cells, octopus cells, and globular cells were measured in the ventral cochlear nuclei.

There were no differences ($p > 0.05$) in dorsal cochlear nuclear volumes between left and right sides in any of the 4 groups. In the ventral cochlear nuclei, the volume of each subdivision and the cross-sectional area of each cell type were significantly smaller ($p < 0.01$) in the left (operated) side than on the right in all four groups. The number of neurons in the ventral cochlear nuclei was significantly less ($p < 0.01$) on the left side than the right in all four groups. Analyses by subdivisions showed that all significant cell death occurred in the anterior ventral cochlear nuclei. Age-dependence of these results were found only for the volume of ventral cochlear nucleus, the cross-sectional area of octopus cells, and the number of neurons in the anterior ventral cochlear nucleus. For these three measurements, the effects were significantly ($p < 0.01$) more profound in the mice with earlier cochlear removals. Cell death in the anterior ventral cochlear nucleus continued between 90 and 123 days after birth: i.e. there were fewer neurons in the anterior ventral cochlear nucleus group 4 mice than in group 3 mice.

14.6 SELECTIVE RETROGRADE LABELING OF LATERAL OLIVOCOCHLEAR NEURONS IN BRAINSTEM BASED ON PREFERENTIAL UPTAKE OF 3H-D-ASPARTIC ACID IN THE COCHLEA. A.F. Ryan* and I.R. Schwartz (SPON: D. Strelioff). Division of Otolaryngology, VA Medical Center & UCSD School of Medicine, La Jolla, CA 92093 and Division of Head & Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024.

Cochlear perfusion with probe concentrations of 3H-D-aspartic acid (D-ASP) results in preferential labeling of 60% of the efferent terminals under the inner hair cells (IHCs), based on EM autoradiographic reconstruction, while efferents beneath the outer hair cells (OHCs) are not labeled. Perfusion with 3H-GABA results in labeling of all efferents under the OHCs, and 40% of the efferent terminals under the IHCs. Cochlear afferents are not labeled with either amino acid (Schwartz and Ryan, Hearing Res. 9:185, 1983; unpubl. obs.). To identify the central neurons whose projections give rise to D-ASP-labeled fibers and terminals, gerbils were perfused perilymphatically with D-ASP in artificial perilymph and allowed to survive for 24 or 48 hours. The brains were then prepared for light microscopic autoradiography.

At 24 hours after D-ASP perfusion, densely-labeled cells and neural processes were observed in the ipsilateral lateral superior olivary nucleus (LSO). The cells were primarily fusiform in shape and were found throughout the LSO, although with a tendency to be located at the margins of the nucleus and in the medial and middle limbs. Labeled cells and processes were observed in the contralateral LSO, but they represented only 5-10% of the number observed ipsilaterally. At 48 hours after D-ASP perfusion, a smaller number of similarly distributed cells and axons in the LSO were labeled.

At both 24 and 48 hours after D-ASP perfusion, densely-labeled, scattered fibers could be traced dorsally from the ipsilateral LSO. After passing on the medial side of the trigeminal nucleus, the fibers turned laterally and aggregated to form bundles. Labeled fibers from the contralateral LSO passed under the floor of the fourth ventricle to join the ipsilateral fibers at this point. The fibers could be traced along the ventromedial edge of the vestibular portion of the VIIIth nerve root to the nerve stump. Adjacent to the cochlear nucleus (CN), densely-labeled collateral fibers left the bundles and crossed the VIIIth nerve root to enter the CN. Labeled fibers and apparent terminals were prominent throughout the central region of the ventral CN.

The D-ASP-labeled cells and fibers clearly belong to the lateral olivocochlear system identified by Warr and Guinan (Brain Res. 173: 152, 1979) in the cat. Neither retrograde transport of D-ASP by medial olivocochlear neurons, nor anterograde transport by afferent VIIIth nerve fibers, were observed. Retrograde transport of D-ASP thus allows the cells, axons and collaterals of the lateral olivocochlear system to be studied in isolation.

14.7 REPRESENTATION OF A SINGLE LOW FREQUENCY TONE BY THE AVERAGE DRIVEN RATE OF AUDITORY-NERVE FIBERS. W.P. Shofner and M.B. Sachs. Dept. of Biomed. Eng., Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

At low sound pressure levels, the profile of discharge rate vs. best frequency (BF) of the population of auditory-nerve fibers in response to a single pure tone shows a peak at the frequency of the tone. The peak is maintained over a wide range of sound pressure levels for high frequency tones (Evans, in Neuronal Mechanisms of Hearing, pp. 69-85, 1981), but not for low frequency tones (Kim and Molnar, J. Neurophysiol., 42:16, 1979). One interpretation of this result is that a place mechanism is used for encoding high frequencies, while low frequencies are encoded by temporal information such as phase-locking. On the other hand, studies using more complex stimuli such as vowels (Sachs and Young, JASA, 66:470, 1979) and tones in noise (Costalupes and Helstrom, Soc. Neurosci. Abs., 10:392, 1984) have shown that a rate-place representation of the acoustic stimulus is preserved over a wide range of levels by the low spontaneous rate (SR) auditory-nerve fibers. Because of the different functional and morphological characteristics of low SR fibers, we have re-examined the rate representation of a single low frequency tone in the population of auditory-nerve fibers.

Single auditory-nerve fibers were recorded from anesthetized cats, and average discharge rate during a 400 msec 1.5 KHz tone burst was determined at 4 sound pressure levels. The profiles of rate as a function of BF for high SR fibers (SR $>$ 19 spikes/sec), medium SR fibers (SR= 1 to 19 spikes/sec) and low SR fibers (SR $<$ 1 spike/sec) were plotted separately.

At the lowest sound pressure levels studied, all 3 populations of auditory-nerve fibers show a peak in the average rate profile around 1.5 KHz. At intermediate sound levels, this peak is lost in the rate profile of the high SR population, but is present in the rate profile of the low and medium populations. At the highest levels studied (87 dB SPL), the driven rates in both high and medium SR populations are saturated across a wide range of BFs. However, even at high sound pressure levels there is a peak around 1.5 KHz in the average rate profile for the low SR auditory-nerve fibers. The peak in the rate profile of the low SR population at high levels is undoubtedly the result of their higher thresholds (Liberman, JASA, 63:442, 1978) and wider dynamic ranges (Sachs and Abbas, JASA, 56:1835, 1974; Schalk and Sachs, JASA, 67:903, 1980; Evans and Palmer, Exp. Brain Res. 40:115, 1980). These results show that a rate-place representation of a single low frequency tone exists in the auditory-nerve over a wide range of sound pressure levels.

14.8 CHANGES IN EXTERNAL EAR POSITION SHIFT THE SPATIAL TUNING OF AUDITORY UNITS IN THE CAT'S SUPERIOR COLLICULUS. J.C. Middlebrooks and E.I. Knudsen. Dept. of Neurobiology, Stanford University, Stanford, CA 94305

A neural map of auditory space has been demonstrated previously in the cat's superior colliculus in a preparation in which the highly mobile external ears are fixed in place. However, one might predict that movements of the ears would modify that map, since the acoustical properties of the ears largely determine the auditory cues from which the nervous system must derive the locations of sound sources. We have confirmed this prediction, at least for anesthetized cats, by measuring the influence of external ear position on the auditory responses of units in the superior colliculus. We recorded the responses of single units to noise burst stimuli presented in a free sound field. All units were selective for the horizontal and vertical location of the sound source. We represent the spatial tuning of a unit by its "best area", which is the area within which a given stimulus activated the unit to within 75% of its maximum firing level. Best areas were measured first with both external ears in a forward, symmetrical position, then with one ear turned approximately 50^{o} to the side. We refer to the ears as contra- or ipsilateral with respect to the side of the recording site.

The spatial tuning of units was influenced by changes in the position of either external ear. Whenever we turned the contralateral ear to the side, the best areas of units shifted contralaterally. The best areas of most units shifted ipsilaterally when we turned the ipsilateral ear to the side; this effect was greatest for best areas that were centered away from the area of greatest sensitivity of the contralateral ear. For a standard change in position of the contra- or ipsilateral ear, the variability in the directions and magnitudes of best area shifts was substantially greater between units than was the variability due to errors in positioning the ears.

The influence of external ear position on auditory spatial tuning has several consequences for the map of auditory space in the superior colliculus of the anesthetized cat. First, the shifts in best areas associated with changes in ear position imply that the portion of auditory space that is represented in the colliculus by best areas also can change. Second, the variability in best area shifts observed among different units implies that changes in the position of one ear can change the internal order of the auditory map on both sides of the brain. Finally, the portion of the auditory map that is least affected by a change in the position of one ear is the portion that represents the region of greatest sensitivity of the ear that is not moved. This suggests that the representation of locations in front of each external ear is relatively unaffected by changes in the position of the other ear.

14.9 PATTERNS OF IMMUNOSTAINING WITH ANTISERA TO PEPTIDES IN THE AUDITORY BRAINSTEM OF CAT. J.C. Adams[1] and E. Mugnaini[2]. [1]Depts. of Otolaryngology and Anatomy, Medical University of South Carolina, Charleston, SC 29425, [2]Dept. of Biobehavioral Sciences, University of Connecticut, Storrs, CT 06268

Antisera against a variety of neuropeptides produce similar staining patterns of fibers and terminals in the auditory brainstem. In the inferior colliculus, particularly extracentral portions, antisera to cholecystokinin-8 (CCK-8), substance P, neurostensin, and met-enkephalin show a dense network of immunoreactive fibers and boutons. Following local injections of colchicine all four antisera show immunoreactive cell bodies in the colliculus as well. Far more cells and fibers are shown by antisera to CCK-8 and substance P and these antisera show cells and fibers within the central portions of the colliculus. All immunoreactive fibers may not be of intrinsic origin, however, because all antisera also show cells in the adjacent central grey, within and near the brachium of the inferior colliculus, and in the posterior medial geniculate body. Previous work has shown that cells in these areas are labelled following HRP injections of the inferior colliculus. More caudally, there are also similarities of staining patterns in the superior olive and the cochlear nucleus. The ventral nucleus of the trapezoid body and the cochlear nucleus contain fibers that are immunoreactive to all antisera. It is known that cells in the inferior colliculus send projections to these nuclei so it is possible that the subcollicular terminals shown by the immunostaining have origins in the inferior colliculus. This interpretation is complicated by the presense of cells in the ventral nucleus of the trapezoid body that are stained with antisera to met-enkephalin and to neurotensin. Also, in the cochlear nucleus there are cells that are CCK-8 and enkephalin immunoreactive. It seems likely that some of the subcollicular immunoreactive terminals arise from these subcollicular cell bodies. The present preliminary data serve as guide for experiments to determine the origins of these various fiber systems.

14.10 THE ULTRASTRUCTURE OF THE CENTRAL NUCLEUS OF THE INFERIOR COLLICULUS OF THE RAT. C. E. Ribak and R. C. Roberts*. Dept. of Anatomy, Univ. of Calif., Irvine, CA 92717.

A few descriptions of the ultrastructure of the inferior colliculus have been made but none have described this structure in rats. Our analysis of the inferior colliculus in a normal strain of rat would serve as a baseline for future studies of the genetically epilepsy prone rat that displays a 100-200% increase in the number of GABAergic neurons specifically in this brain region. Therefore, Sprague-Dawley rats were perfused with either saline followed by 4% paraformaldehyde, 1% gluteraldehyde and 0.0002% CaCl in phosphate buffer or ringers solution followed by 1% paraformaldehyde and 1.25% gluteraldehyde in phosphate buffer followed by 3% gluteraldehyde in phosphate buffer. Tissue from the ventral lateral portion of the central nucleus was dehydrated, embedded in plastic, thin sectioned and examined under the electron microscope.

Three sizes of neurons were observed in the central nucleus. All somata contained the usual organelles but had varied amounts of perikaryal cytoplasm depending on somal size. Many small neurons (10-15 um in diameter) were spherical in shape and usually contained infolded nuclei. Occasionally two nucleoli were observed in the same nucleus. Only a few symmetric axosomatic synapses were found for this size neuron. Medium sized neuronal somata (15-20 um in diameter) were often ovoid in shape with highly infolded nuclei. Synapses were sparsely located on their somata. Large neurons were observed only occasionally, and their somata were elongated or round in shape. Their nuclei were occasionally infolded, but not to the extent of the medium sized neurons. In contrast to the medium and small cell types, many synapses occurred on the somata of the large neurons.

Many myelinated axons as well as unmyelinated axons were observed in the central nucleus some of which were observed to be in continuity with axon terminals that had three basic types of characteristics: 1) dark matrix and densely packed with round vesicles, 2)lucid matrix with flattened or pleomorphic vesicles and 3)lucid matrix with round vesicles. In addition to neuronal elements, the inferior colliculus contained many glial elements including astrocytes and oligodendrocytes.

14.11 RECIPROCITY OF AUDITORY CORTICOTHALAMIC AND THALAMOCORTICAL PROJECTIONS: STUDY WITH AUTORADIOGRAPHIC AND HORSERADISH PEROXIDASE METHODS IN RAT MEDIAL GENICULATE BODY. D.T. Larue* and J.A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

We analyzed the overlap of corticothalamic axon terminal fields and of thalamocortical cells of origin in the rat medial geniculate body (MGB). Our goal was to assess whether the distribution of auditory cortical axons projecting upon the ipsilateral MGB is coextensive with retrogradely labeled thalamocortical somata. Anesthetized adult Sprague-Dawley rats received unilateral injections of mixtures of [^{3}H]leucine (100 µCi/µl; 0.01-.2 µl total volume) and horseradish peroxidase (HRP; 20-30%). After 24-96 hours, the animals were reanesthetized and perfused transcardially with saline and mixed aldehydes, and the brains were blocked stereotaxically and then frozen-sectioned in a series of one 30 µm thick autoradiograph and two 60 µm thick TMB-reacted sections. Other experiments in which leucine or HRP alone were injected were also available. Using brightfield and darkfield microscopy, the numbers of silver grains and the disposition of labeled somata were plotted onto adjacent, independently studied sections and the separate results superimposed. The subdivisions of the MGB were defined in Nissl and Golgi stained preparations and were related to previous studies in the cat (Winer, J.A., Adv. Anat. Embryol. Cell Biol., 1985, 86:1-98).

Our primary finding was that zones of silver grains and HRP-labeled cells were not in complete continuity, although there was substantial overlap between them. Often, patches of silver grains 3-20 times above background (as assessed in the contralateral MGB) occurred, while the adjoining HRP section had few or no labeled cells; conversely, labeled cells were present in zones without corresponding levels of anterograde labeling. Such patterns of discontinuity occur in the nuclei of both the ventral and dorsal divisions of the MGB. The silver grains in both divisions were concentrated primarily in the neuropil. However, in experiments in which most somata in the adjoining, HRP-reacted section were labeled, the number of silver grains in the ventral division was consistently many times greater than in the dorsal division. We conclude that, besides zones of anterograde-retrograde continuity and discontinuity in the MGB, there are also regional variations in the distribution of corticogeniculate terminal fields which are independent of reciprocity. This research was supported by USPHS grant RO1 NS16832.

14.12 CONNECTIONS OF AUDITORY CORTEX IN SQUIRRELS. L. E. Luethke,* L. Krubitzer, and J. H. Kaas (Spon.: R. B. Langdon). Department of Hearing and Speech Sciences and Deparatment of Psychology, Vanderbilt University, Nashville, Tennessee 37240.

The connections of auditory cortex were investigated in grey squirrels, which have a larger brain and architectonically more distinct cortical subdivisions than commonly used laboratory rodents. Microelectrode multiunit recordings were used to determine the best frequencies for recording sites in auditory cortex. In each case, the borders of AI were estimated from the recordings, and lesions were placed to mark known physiological borders for later correlation with cortical architecture. Following mapping, single injections of approximately 0.06 microliters of 1% wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) were placed in AI of adult squirrels. Cortex was separated from the brainstem, flattened, and cut parallel to the surface. The brainstem was cut separately in the frontal plane. Alternate sections were reacted with tetramethylbenzidine or stained for fibers or cells. Reciprocal connections were found between AI and at least two adjoining subdivisions of auditory cortex, one immediately ventral and one rostroventral to AI. Other ipsilateral connections were with a newly discovered somatosensory representation, the parietal ventral area (PV), which is immediately ventral to the second somatosensory area, contains a systematic representation of the body surface, and is also responsive to auditory stimuli. Injections placed in AI, but extending slightly posterior to the caudal border of AI, resulted in additional connections with more caudal cortex in the temporal lobe. Callosal connections of AI were with AI and adjoining auditory fields. Subcortical connections of AI were with the principal division of the medial geniculate nucleus and the external nucleus of the inferior colliculus. These results confirm subcortical connections of auditory cortex in other mammals and reveal the convergence of somatosensory and auditory information within a specific cortical field, PV, along the lateral margin of the cerebral hemisphere.

CARDIOVASCULAR REGULATION I: GANGLIONIC AND SPINAL MECHANISMS

15.1 **VENOUS DISTENSION LEADS TO EXCITATION OF NEURONS IN THE GUINEA-PIG INFERIOR MESENTERIC GANGLION.** K.D. Keef* and D.L. Kreulen. Department of Pharmacology, Health Sciences Center, University of Arizona, Tucson, Az. 85724.

The mesenteric sheath of the distal colon containing the inferior mesenteric artery and vein and the inferior mesenteric ganglion (IMG) was dissected free and pinned in an experimental chamber. Intracellular recordings were made in ganglionic neurons and nerve fibers were stimulated with bipolar electrodes. The colon was removed and the vein cannulated with a glass micropipette attached to a gravity-driven pressure head. To distend the vein the pressure was rapidly raised from 0 mmHg to 40 mmHg, maintained for 2 minutes, then lowered back to 0 mmHg. In 37% of cells (145 cells, 23 preparations) continuous excitatory post-synaptic potentials (EPSPs) were observed in the absence of distension. The frequency of this activity ranged from 1 to 100 EPSPs per minute with a mean maximum amplitude of 4.1 ± 2.5 mV. The activity was blocked by TTX (3×10^{-7} M) and hexamethonium (1×10^{-4} M). Three different types of responses to venous distension were observed: 1) In 5 of 46 cells exhibiting continuous activity venous distension was associated with an increase in the frequency of EPSPs. 2) In 17 of 48 cells venous distension gave rise to depolarization and an increase in membrane resistance. The mean depolarization for these cells was 3 ± 2 mV and the mean increase in membrane resistance was 20 ± 8%. Depolarization began within 15 seconds of distension and usually persisted for the duration of distension. When pressure was returned to 0 mmHg the cells repolarized. 3) When presynaptic nerve fibers were stimulated at intensities that produced subthreshold EPSPs (9 to 12 mV), venous distension was associated with conversion of EPSPs to action potentials in 16 of 49 cells. Conversion to action potential generation was associated with depolarization in 63% of cells. In conclusion we have demonstrated that venous distension increases the excitability of a population of neurons in the guinea-pig IMG. Since each type of response can occur independent of the others, the possibility exists that venous distension may involve several different neural pathways to the IMG. (Support: HL27781)

15.2 AN ELECTROPHYSIOLOGICAL DESCRIPTION OF RENAL AFFERENT FIBERS. Mark M. Knuepfer and Lawrence P. Schramm. Department of Biomedical Engineering, The Johns Hopkins University School of Medicine 21205.

Afferent renal nerves have been implicated in control of arterial pressure. Neuroanatomical and histological studies have described a predominance of unmyelinated fibers and a small population of myelinated fibers which project to the lower thoracic and upper lumbar spinal cord. This study was designed to characterize renal afferent fibers and their spinal projections using electrophysiological techniques.

Sprague-Dawley rats were anesthetized with chloralose and cannulated for arterial pressure measurement and venous drug administration. Rats were paralyzed, artificially respired and placed in a stereotaxic frame. The lower thoracic and upper lumbar spinal cord was exposed and covered with mineral oil. Each exposed dorsal root (DR) was cut at its entry into the spinal cord, and the peripheral end was electrically stimulated through a bipolar hook electrode. The left kidney and renal nerve were exposed by a lateral laparotomy and kept under mineral oil. A branch of the renal nerve was placed on a bipolar stainless steel hook electrode and cut or crushed distal to the electrode. Rats were treated with atropine (0.3 mg/kg) and hexamethonium (20 mg/kg) to prevent collateral activation in sympathetic ganglia and to reduce sympathetic postganglionic activity. Antidromic evoked responses were elicited in the renal nerve by stimulation of DR. Averaging of 10-100 responses was used to determine the number of fibers activated with fixed latency.

Of 284 antidromically activated fibers recorded in 22 renal nerve branches, 80% had conduction velocities under 2 m/s and 5% had conduction velocities over 10 m/s (range = 12-32 m/s). Thresholds for activation of these fibers, ranging from 1.5 to 50 µA, were inversely related to conduction velocities. Single fibers followed twin pulses at 1.1 to 22 ms interpulse intervals. Although DR from T8 to L3 were stimulated, antidromic responses in renal nerves were observed only during stimulation of DR T9 to L1. Seventy-five percent of responses occurred during stimulation of DR T11 to T13. Histological examination of renal nerves after recording verified the existence of the larger myelinated fibers.

These data corroborate anatomical evidence for a predominantly unmyelinated population of renal afferents. In addition, we have demonstrated that myelinated and unmyelinated fibers are evenly distributed over these roots. We have electrophysiologically identified a group of fibers of intermediate conduction velocity for which we have not observed anatomical correlates.

Supported by NIH Grant HL16315.

15.3 **RESPONSES OF THORACOLUMBAR SPINORETICULAR NEURONS TO RENAL MECHANORECEPTOR STIMULATION.** **W. Steve Ammons. Dept. of Physiology, University of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK 73190.**

Renal afferent fibers are activated by mechanical stimuli applied to the kidney, particularly renal venous or ureteral occlusion. These mechanoreceptor stimuli may also elicit cardiovascular and renorenal reflexes. However, the central substrates for such reflexes are unknown. The goal of the present study was to test the hypothesis that neurons in the thoracolumbar spinal cord that project to the reticular formation respond to activation of renal mechanoreceptors. Experiments were performed on 17 α-chloralose anesthetized cats. Spinoreticular neurons were located by antidromic activation of neurons from the medial medullary reticular formation in or near nucleus reticularus gigantocellularis (15 cells) or the ventrolateral reticular formation near the lateral reticular nucleus (17 cells). After location of a spinoreticular neuron its response to electrical stimulation of the renal nerves was characterized and the type of renal afferent input (Aδ or C) determined. Responses to somatic stimuli were also examined. Twelve cells were tested for responses to renal vein occlusion. Eight responded with an increase in activity from 4 ± 2 to 15 ± 5 spikes/s. Renal vein occlusion also caused an increase in blood pressure (10 ± 4 mmHg); however, cell activity was not secondary to blood pressure changes as injection of phenylephrine caused pressor responses but no change in cell activity. Twenty-two cells were tested for responses to ureteral occlusion and 15 increased their activity from 6 ± 3 to a peak of 19 ± 6 spikes/s. Ureteral occlusion caused presser responses that averaged 6 ± 2 mmHg. Responses to either stimulus were rapid in onset (1-2 s) and often were maintained through the period of the occlusion. Seven responses to ureteral occlusion were of the slowly adapting type while 3 completely adapted. Almost all cells with responses to occlusion of the ureter or renal vein received both Aδ - and C-fiber input whereas many of the non-responding cells had Aδ -renal input only. All cells responded to somatic stimuli. Somatic receptive fields were usually in the left flank region. These experiments show that spinoreticular neurons receive renal mechanoreceptor input. These cells may participate in reflexes initiated by renal mechanoreceptors. Such reflexes could be part of the affective component of renal pain. (Supported by NIH Grant HL 30985).

15.4 **CONVERGENT INPUTS ONTO SYMPATHETIC PREGANGLIONIC NEURONS IN THE THORACIC SPINAL CORD OF THE CAT.** **Roger Thies and Robert Bourlier*. Dept. of Physiology & Biophysics, Univ. of Okla. Health Sci. Ctr., Oklahoma City, OK 73190.**

This study examined the responses of sympathetic preganglionic neurons (SPNs) on the left and right sides of the spinal cord to electrical stimulation of various nerves. We recorded with tungsten extracellular microelectrodes the activity of 16 SPNs in the intermediolateral cell column of the T2 and T3 segments of nine chloralose-anesthetized cats, relaxed with i.v. pancuronium (7 ug/kg/min). Neurons were identified as SPNs by antidromic stimulation of white rami that could be blocked by collision in the axon from orthodromic activation.

SPNs were found at depths of 1910 ± 210 (S.D.) from the surface, with ten on the left side and six on the right. Eight SPNs at T2 had axons with conduction velocities of 3.4 ± 0.4 (S.E.) m/sec, while eight SPNs at T3 had axons with conduction velocities of 6.2 ± 0.6 m/sec, a significant difference. Mininum afferent conduction velocity (MACV) for activation of T2 SPNs by stimulation of the T3 root was 7.6 ± 0.7 m/sec, and for activation of T3 SPNs by stimulation of the T2 root was 5.1 ± 0.4 m/sec. SPNs could be activated from stellate ganglia with a MACV of 8.2 ± 1.2 m/sec from the same side of the cord, and of 8.7 ± 1.3 m/sec from the opposite side of the cord.

Thoracic SPNs did not respond to electrical stimulation of either radial nerve, but they did fire to stimulation of the left or right third intercostal nerve. In addition, 90 V. stimuli to thoracic vagal afferents 50 msec before stimuli of 1.1x threshold across the stellate ganglion completely inhibited the response of SPNs to 6-9 of 10 stimuli on the left side, and to 4-8 of 10 stimuli on the right side in two of four SPNs tested. This suggests a descending inhibitory input onto SPNs from brain stem centers that relay vagal afferent information.

These studies show that SPNs in the thoracic spinal cord of the cat have visceral and somatic inputs from both sides of the body. In addition, the descending inhibitory input from vagal afferent excitation might suppress sympathetic input at the spinal level, similarly to the input to thoracic spinothalamic (1) and spinoreticular (2) neurons.

15.5 MORPHOLOGY OF SYMPATHETIC PREGANGLIONIC NEURONS IN THE RAT SPINAL CORD REVEALED BY INTRACELLULAR STAINING WITH HORSERADISH PEROXIDASE. C.J. Forehand. Dept. Anat. and Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Understanding the central neural control of autonomic functions requires a knowledge of the morphology of the preganglionic neurons; for example, the dendritic arborizations of preganglionic neurons should indicate which central pathways have access to these cells. To this end, individual preganglionic neurons in the thoracic spinal cord of the rat have been examined by intracellular injection of horseradish peroxidase (HRP).

Rats (1-2 weeks postnatal) were anesthetized with pentobarbitol, cooled on ice, and decapitated. The vertebral column was removed and placed in ice-cold saline. The spinal cord was dissected free, hemi-sected longitudinally, and placed with the lateral surface uppermost in a recording chamber continuously superfused with oxygenated saline at room temperature. Individual preganglionic neurons in the vicinity of the intermediolateral cell column (IML) were impaled with HRP-filled microelectrodes while stimulating the appropriate ventral root. Cells exhibiting an antidromic action potential in response to ventral root stimulation were filled with HRP by iontophoresis. The HRP reaction product was visualized in transverse sections of the cords.

Most of the injected cells were located within the IML; others lay in the lateral funiculus (LF) adjacent to IML or in the intercalated nucleus (IC) medial to IML. The average cell body diameter was 22 um and total dendritic length averaged 2021 um. Dendritic arborizations were quite different depending on cell soma location. Dendrites of IML cells traversed the full mediolateral extent of the ipsilateral cord; typically, 2-3 dendrites extended from the cell body to the pia and 2-3 others extended from the cell body to the vicinity of the central canal. These cells also had dendrites that extended 300-500 um in the rostrocaudal dimension within the IML. Preganglionic neurons that lay in the LF or IC had strikingly different morphologies in that they lacked transversely oriented dendrites that spanned the mediolateral extent of the cord. Rather, these cells had dendritic arbors that extended into the IML and into the dorsal and ventral horns, traversing a rostro-caudal distance of about 400 um.

The different dendritic arborizations of preganglionic neurons in these spinal nuclei implies that the connectivity of preganglionic neurons varies according to cell body location. A further implication is that these groups may represent functionally different classes of preganglionic cells.

15.6 SOMATIC AND DENDRITIC MORPHOLOGY OF INTRACELLULARLY LABELLED SYMPATHETIC PREGANGLIONIC NEURONS. J.B.Cabot, N.Bogan* and L.J.Reid*. Dept. of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, New York 11794.

Recently there has been an impressive accumulation of anatomical data documenting both the subnuclear organization within the vertebrate spinal cord of sympathetic preganglionic neurons(SPN's), as well as the spinal and supraspinal localization of cells providing afferents to the SPN neuropil. Despite the seminal nature of such findings, there still remains a critical need for certain types of anatomical data on single SPN's. For example, information correlating (a) location, (b) somatic structure, (c) proximal dendritic size and number, and (d) distal dendritic shape, orientation, and arborization are not currently available. Within this context, the following observations are presented.

Experiments were performed in pigeons (Columba livia). Extracellular recordings from 51 antidromically activated and collided SPN's were obtained. Eleven of these cells were successfully labelled intracellularly with HRP. The mean latency for antidromic activation of the 11 SPN's was 6.6 ± 3.7 msec (±SD); median latency was 5 msec. Statistically there is not a significant difference between the antidromic latencies of the population of unlabelled SPN's and those intracellularly filled.

Nine of the 11 HRP-labelled SPN's were located within the principal SPN cell column. Two cells were located laterally in the nucleus intercalatus(IC). Four different somatic shapes were observed. Three were fusiform with major x minor axis diameters ranging from 35-43 x 16-28 um. Three were pear-shaped with major and minor diameters being approximately equal (22-31 x 21-28 um). Three were elongated and multipolar. One of these was quite large (61x33 um) and the other two were medium sized (30x22 um). The remaining SPN was small (21x12 um) and stellate-shaped.

The dendritic trees of 9 labelled SPN's exhibited simple planar organizations restricted to the longitudinal axis of spinal cord. The other 2 SPN's, both located in IC, had their principal dendritic processes oriented dorsoventrally. For one of these, a terminal arbor extended to the dorsolateral funiculus, ending adjacent to the lateral margin of the dorsal horn.

The first-order, and proximal portions of the major secondary dendrites were smooth. The number of primary dendrites/SPN varied from 4-8 and ranged widely in diameter (<1.0 to 5.3 um). Ten cells had at least one dendrite extending laterally into the intermediate spinal laminae. Moreover, 7 had processes reaching out into the lateral funiculus. The terminal portions of secondary and higher-order processes were "beaded or varicose" in appearance. Dendritic spines in the classical sense were not observed. (Supported by HL24103 to JBC).

15.7 LIGHT AND ELECTRON MICROSCOPIC OBSERVATIONS ON AXON COLLATERALS OF SYMPATHETIC PREGANGLIONIC NEURONS. N. Bogan* and J. Cabot (SPON: S. Yazulla). Department of Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, New York 11794.

There is a longstanding debate as to whether sympathetic preganglionic neurons(SPN's) give rise to axons that have intraspinal collateral branches. All available light and electron microscopic data indicate that SPN axons do not branch, whereas some physiological observations support their presence. This report provides definitive evidence showing the existence of SPN axon collaterals.

Experiments were performed in pigeons (Columba livia). SPN's in T1 were identified electrophysiologically using antidromic activation and collision techniques. Eleven cells were intracellularly labelled with HRP. The axons of 5 SPN's could be traced to the ventral rootlets. The main axon of two cells branched intraspinally and none of these collaterals were recurrent onto the SPN of origin. While these two cells were similar in that the latencies of antidromic activation were among the shortest observed (2 and 5 msec, estimated conduction velocity: 4.7 and 1.9 m/sec), they differed significantly in spinal location, somatic structure, and dendritic organization. The cell with the slower conducting axon was pear-shaped, located in the principal SPN cell column (column of Terni), and had dendrites oriented horizontally; the other SPN was elongated and multipolar, localized in the nucleus intercalatus (IC), and had dendrites oriented dorsoventrally.

The parent axon of the SPN in IC branched twice. The first branch originated and terminated laterally within spinal lamina VII; the other arose at the intermediate spinal gray/funicular border and continued on into the white matter. Both collaterals (a) were significantly smaller in diameter than the parent axon; (b) travelled and ramified in the longitudinal spinal axis; and (c) exhibited bulbous terminal endings.

The SPN within the column of Terni gave rise to a single axon collateral 280 um from the soma. The collateral projected medially, and terminated in a restricted region at the lateral edge of the column of Terni. This branch, its endings, and the parent axon have been examined electron microscopically. A serial section analysis has revealed that the main axon was myelinated and of a caliber consistent with the estimated conduction velocity. The collateral tapered rapidly in diameter, became unmyelinated and branched. Each branched process was extremely small in diameter and periodically expanded to form varicose regions which were the exclusive sites of synaptic contact. These boutons contained small round electron-lucent vesicles and made only asymmetric, axo-dendritic synapses. (Supported by HL24103. The authors thank S.Van Horn for her aid).

15.8 REFLEX RESPONSES OF SINGLE SPLENIC NEURONS ELICITED BY STIMULATION OF INTESTINAL RECEPTORS AND BARORECEPTORS. R. Meckler and L. Weaver. Dept. Physiol., Mich. State Univ., E. Lansing, MI 48824.

Stimulation of visceral afferent nerves can produce unequal magnitudes of excitation or inhibition in multifiber recordings of splenic and renal nerve activity. Splenic nerve excitation is greater than renal nerve excitation in response to stimulation of splenic or intestinal receptors. Activation of arterial and cardiopulmonary pressoreceptors often results in less inhibition of splenic than renal nerve discharge. Is a greater response of one nerve caused by general excitation or inhibition of all neurons or by particular responses of only some neurons? This study was done to assess responses of individual splenic neurons to stimulation of intestinal receptors and baroreceptors. Experiments were done in chloralose-anesthetized cats that were artificially ventilated. Femoral arteries and veins were cannulated for monitoring arterial pressure and for infusions of drugs and solutions. The intestine was exteriorized through a laparotomy and placed in a small plastic bag filled with physiological saline. Splenic nerve bundles were identified close to the spleen, carefully dissected from surrounding tissue, and severed. Small fibers were teased from the central end and were placed on bipolar platinum electrodes for recording electrical activity. The nerves were immersed in a pool of warmed mineral oil. Pressoreceptors were stimulated by intravenous injections of 1 to 5 µg norepinephrine. Pressoreceptors were "unloaded" by small hemorrhages of blood that was subsequently returned. Intestinal receptors were stimulated by superfusion of the small intestine with 1 to 25 ml of physiological saline containing 1 µg/ml bradykinin triacetate. Between periods of drug application, the serosa was thoroughly rinsed with warmed normal saline. Discharge rates of spontaneously active neurons ranged from 0.6 to 7.5 spikes/s under resting conditions (average = 3.2 ± 0.5 spikes/s). Most neurons were baroreceptor sensitive: activity of 50% of the cells tested tended to be excited (from 3.1 ± 0.4 to 4.0 ± 0.4 spikes/s) by decreasing arterial pressure from 132 ± 3 to 110 ± 3 mmHg, activity of 70% of the neurons was excited (from 3.1 ± 0.5 to 5.0 ± 0.5 spikes/s) by decreasing arterial pressure from 132 ± 3 to 95 ± 3 mmHg, and activity of 82% of the cells was inhibited (from 3.2 ± 0.4 to 1.6 ± 0.4 spikes/s) by increasing arterial pressure from 127 ± 4 to 166 ± 4 mmHg. Serosal application of bradykinin caused excitatory responses (from 3.1 ± 0.7 to 6.7 ± 0.7 spikes/s) in 86% of the cells tested despite the concomitant blood pressure increases that ranged from 2 to 67 mmHg. Recruitment of previously inactive neurons was rarely observed during the excitatory responses. It appears that most of these efferent cells react similarly, although responses of splenic neurons are not homogeneous to stimulation of visceral afferent nerves. Support: NIH, HL21436.

15.9 SPLENIC AFFERENT NERVE RESPONSES TO STIMULATION OF SPLENIC RECEPTORS. J. Tobey and L. Weaver. Dept. of Physiol., Mich. St. Univ., E. Lansing, MI 48824.

Non-noxious stimulation of splenic receptors produces patterns of neural responses that differ from those produced by noxious stimuli. Non-noxious stimuli, such as congestion, produce equal magnitudes of splenic and renal excitation, whereas noxious stimuli, such as capsaicin, produce greater splenic than renal nerve excitation. Previous experiments employing two different levels of splenic congestion indicate different patterns of neural responses can be produced. Increase in splenic venous pressure (SVP) to 40 mmHg produces equivalent splenic and renal neural responses (18% increase and 11% increase, respectively). In contrast, increase in SVP to 50 mmHg produces greater splenic (51% increase) than renal (23% increase) excitation. The present study investigated responses of splenic afferent nerves that initiate the reflex responses. Two possible hypotheses are: 1) Unequal reflex responses are mediated by a different afferent population than the equal reflex responses, or 2) Intensity of afferent stimulation determines the pattern of reflex response. Experiments were done in anesthetized, vagotomized, sinoaortic denervated cats with vascularly isolated spleens. Splenic nerve bundles were identified next to the splenic artery and severed. Small fibers were teased from the distal cut end and prepared for recording afferent electrical activity. Nerve bundles with spontaneous activity of one or two units were tested. Splenic efferent nerve activity was monitored simultaneously to evaluate the reflex responses. Receptors of the vascularly-isolated spleen were stimulated by capsaicin (CAPS) or congestion with isotonic saline. Discharge rates of spontaneously active units ranged from 0.2 to 10.7 spikes/s (average = 2.7 ± 1.0 spikes/s). Two patterns of afferent response to stimulation of splenic receptors were found. One group of units responded to congestion only. Increase in SVP to 40 mmHg increased unit activity from 3.4 ± 2.3 spikes/s to 9.6 ± 5.3 spikes/s. The other group of units responded to non-noxious and noxious stimuli. Congestion increased activity in these units, from 2.9 ± 1.5 spikes/s to 4.8 ± 1.6 spikes/s. 5 µg CAPS increased unit activity from 2.0 ± 0.8 spikes/s to 8.4 ± 2.8 spikes/s. These results suggest the pattern of reflex responses is determined both by the intensity of afferent stimulation and by different afferent populations. Unequal reflex responses of splenic and renal nerves appear to be due to more intense activation of receptors responsive to mechanical and chemical stimulation, while equal reflex responses appear to be produced by less intense activation of these receptors and mechano-receptors. 15.10 SPINAL TRANSECTION ELEVATES RENAL NERVE SYMPATHETIC ACTIVITY IN ANESTHETIZED RATS. L.P. Schramm, R.H. Livingstone, and M.M. Knuepfer. Department of Biomedical Engineering, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Tonic sympathetic activity is generally thought to be driven by supraspinal systems. However, we have observed substantial sympathetic activity in the renal nerves of anesthetized rats after spinal transection. The present studies are determining the effect of spinal cord transection on the magnitude and sources of renal sympathetic activity.

Male Sprague-Dawley rats weighing 250 to 490 g were anesthetized with ether followed by 100 mg/kg alpha-chloralose, and they were kept deeply anesthetized throughout experiments with supplemental doses of chloralose. Arterial blood pressure was measured through a carotid arterial cannula. Drugs were delivered via a femoral venous cannula. Rats were paralyzed with gallamine triethiodide, artificially respired, and mounted in a stereotaxic apparatus. The cervical spinal cord was exposed through a dorsal laminectomy and covered with mineral oil. A left renal nerve bundle was approached through a laparotomy and placed on bipolar stainless steel electrodes. Sympathetic activity was amplified, rectified, integrated, and stored on magnetic disc or tape.

Spinal transection between C1 and C2 slightly reduced mean arterial pressure from 90 +/- 19 to 83 +/- 9 mmHg. However, renal sympathetic activity rose, on the average to 230 +/- 70% of control ($P < 0.001$, $N = 14$, paired t-test). We hypothesized that supraspinal drive for renal sympathetic activity was replaced, within 5-15 minutes after spinal transection, by drive from spinal primary afferents. Two observations were consistent with this hypothesis. First, analgesic doses of morphine (4-40 mg/kg) dramatically reduced renal sympathetic activity after spinal cord transection. Naloxone restored the activity. Second, electrical stimulation (20 Hz, 25-250 µA, 0.3 ms pulse duration) in the cervical dorsolateral funiculus, after spinal cord transection, reduced or abolished the spontaneous and sensory-evoked firing of dorsal horn neurons, and it simultaneously reduced renal sympathetic activity by approximately 60%. The system responsible for the evoked sympathoinhibition did not descend from the brainstem since renal sympathetic activity could still be inhibited by stimulation caudal to chronic lesions of the dorsolateral funiculus made several weeks prior to the acute experiments.

We conclude that spinal afferents may be disinhibited by spinal cord transection in the rat. The resulting afferent drive, which may be particularly great in our surgically prepared animals, is more than sufficient to overcome the loss of supraspinal drive to the sympathetic preganglionic neurons, and it elicits elevated renal sympathetic activity.

15.11 LONG-TERM POTENTIATION (LTP) IN DESCENDING SPINAL SYMPATHETIC PATHWAYS. Ralph L. Myers* and Donald N. Franz. Department of Pharmacology, Univ. of Utah School of Medicine, Salt Lake City, Utah, 84132.

LTP is readily produced in the bulbospinal sympathetic pathways of cats. Brief tetanic stimulation of the ipsilateral cervical dorsolateral funiculus in unanesthetized spinal cats produces a 20-30 minute enhancement of subsequent transmission to sympathetic preganglionic neurons (SPGNs). Stimulation within the range of physiological frequencies can produce 50-300% increases in intraspinal transmission (measured from thoracic white rami at 0.1 Hz) which decays along a single-exponential time course with a time constant of 9.5 minutes. This study investigated the ability of polysynaptic sympathetic reflex pathways and contralateral descending excitatory sympathetic pathways to produce LTP of transmission to SPGNs.

Tetanic stimulation (50 Hz for 10 sec) of intercostal nerve T4 in intact alpha-chloralose anesthetized cats did not induce LTP in the spinal-bulbospinal reflex pathway, nor did spinal sympathetic reflexes alone exhibit LTP or PTP. A modest LTP was induced in the polysynaptic spinal reflex pathway of spinal cats by tetanization (50 Hz/10 sec) of the intraspinal (descending) pathways, suggesting that some component of this LTP may be postsynaptic on the SPGNs.

Tetanization of ipsilateral pathways induced LTP of transmission through both ipsilateral and contralateral pathways, and vice versa. The maximun LTP in a given pathway was nearly identical whether the contralateral or ipsilateral pathways were tetanized, even though singly evoked contralateral evoked responses were much smaller than ipsilaterally evoked responses.

That LTP can be induced in contralateral and ipsilateral pathways by stimulating either pathway, suggests a convergence of these pathways at some level. The interaction may be presynaptic, postsynaptic, or both, and may involve mediation by an interneuron. The properties of LTP in spinal sympathetic pathways suggest a role for LTP in central regulation of cardiovascular function and, by virtue of its long duration, a possible role in the pathogenesis of primary hypertension. (Supported by HL-24085, GM-07579, and Utah Heart Association.)

15.12 ROLE OF SPINAL VASOPRESSINERGIC MECHANISMS IN THE CARDIOVASCULAR EFFECTS PRODUCED BY STIMULATION OF THE PARAVENTRICULAR NUCLEUS. J.P. Porter* and M.J. Brody. Dept. of Pharmacology and the Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Vasopressin-containing neurons extend monosynaptically from the paraventricular nucleus (PVN) to the spinal cord. In the present investigation we sought to determine if vasopressin released from these spinal nerve terminals could alter sympathetic outflow to the peripheral vasculature.

In initial experiments, we compared the hemodynamic responses produced by stimulating the PVN in Long Evans rats (LE) and Brattleboro rats (BRAT) which lack hypothalamic and spinal vasopressin. Rats were anesthetized with urethane and instrumented with pulsed Doppler flow probes on the mesenteric and renal arteries and the lower abdominal aorta. Posterior parvocellular PVN was then stimulated with 25-200 µA before and after acute sinoaortic deaferentation (SAD). Stimulation of PVN in baroreceptor-intact BRAT produced responses which were not significantly different from LE controls. The response was characterized by an increase in arterial pressure and vasoconstriction in the mesenteric and renal vascular beds and vasodilation in the hindquarters. Following acute SAD, the pressor and vasoconstrictor responses were significantly enhanced in both groups except for mesenteric vasoconstriction which was not augmented in BRAT. In both groups the hindquarter vasodilation was reversed to a vasoconstriction.

In separate experiments, we sought to determine if vasopressin could specifically activate V1 receptors within the subarachnoid space of the spinal cord to produce hemodynamic effects similar to those produced by stimulating PVN. In conscious Sprague-Dawley rats with indwelling intrathecal catheters 1-17 pmoles of vasopressin (AVP) was injected into the area of the thoracic spinal cord. Within 1 min after AVP, arterial pressure increased 47 ± 8 mmHg accompanied by bradycardia and vasoconstriction in all three vascular beds. This effect appeared to be produced by an action of AVP within the spinal cord since prior blockade of peripheral V1 receptors did not prevent the increase in pressure. Intrathecal injections of oxytocin (30-1500 pmoles) had no effect. Pretreatment intrathecally with 0.5 nmoles of a V1 vasopressin receptor antagonist completely prevented the hemodynamic effects of subsequent intrathecal injection of AVP. However, intrathecal administration of the antagonist had no effect on the increase in pressure produced by stimulating PVN.

Taken together, these data suggest that AVP can act specifically on V1 receptors within the spinal subarachnoid space to produce pressor and vasoconstrictor responses. However, these receptors do not appear to be functionally involved in mediating the hemodynamic effects produced by stimulation of the PVN.

FEEDING AND DRINKING: CCK

16.1 EFFECT OF BOMBESIN, CHOLECYSTOKININ, CALCITONIN AND GLUCAGON ON CONSUMMATORY BEHAVIORS IN WOLF PUPS. J.E. Morley, A.S. Levine, T. Tandeski, H. Hertel, U.S. Seal. Neuroendocrine Research Laboratory and Geriatric Res Education and Clinical Center, VA Medical Center, Minneapolis, MN, 55417 and Sepulveda, CA, 91343.

We have previously examined the effect of a variety of satiety factors on food intake in the dog and the effect of opioid blockade on food intake in the wolf. In the present study we evaluated the effect of various satiety factors on 1 hour food intake in 24 hour deprived wolf pups (n = 5) weighing between 15 - 28 kg. Baseline food intake was measured following administration of 4 different vehicles used to dissolve the peptides. Intramuscular administration of bombesin (BB) (5 and 1 µg/kg) and cholecystokinin (CCK) (5 µg/kg) depressed food intake ($p < 0.05$) in 5/5 pups (Table). Calcitonin (CT) (5 and 1 U/kg) decreased food intake in 3/5 pups and 4/5 pups, respectively. Glucagon (G) (0.5 mg/kg) only decreased food intake in 2/5 pups.

	Food Intake (g)	
Vehicles	622 ± 75	
BB (5 µg/kg)	319 ± 84*	$p < 0.05$
BB (1 µg/kg)	489 ± 95*	$p < 0.05$
CCK (5 µg/kg)	418 ± 61*	$p < 0.05$
CT (5 U/kg)	531 ± 95	
CT (1 U/kg)	589 ± 82	
G (0.5 mg/kg)	575 ± 98	

Eating, drinking, moving and grooming behaviors were observed each minute and scored as the number of behavioral bouts which occurred in a 1 hour period. Although BB and CCK suppressed food intake, the number of eating bouts in one minute was not decreased (vehicle: 22 ± 3; BB - 5 µg/kg: 18 ± 5; BB - 1 µg/kg: 21 ± 6; CCK - 5 µg/kg: 20 ± 3 bouts/h). In contrast, CT at the 5 U/kg dose (14 ± 3 bouts/h) and 1 U/kg dose (15 ± 2 bouts/h) resulted in a significant decrease in observed eating behavior. Drinking behavior was decreased following administration of BB (1 µg/kg: 1.4 ± 0.4 bouts/h) and CCK (5 µg/kg: 1.8 ± 0.4 bouts/h) compared to the vehicle controls (3.4 bouts/h). Resting, moving and grooming behaviors were unaffected by any of the drug treatments. Of interest is the fact that the effect of these peptides on food intake does not necessarily correspond to the number of bouts of eating in a one hour period. These data indicate that food intake in wolf pups is decreased following intramuscular administration of CCK and BB, but not following CT or G. In other species, including the dog, CT is generally a potent anorectic agent. Thus, we have observed again that various species respond differently to the effects of peptides on consummatory behaviors.

16.2 HYPERPHAGIA AND OBESITY INDUCED BY NEUROPEPTIDE Y INJECTED CHRONICALLY INTO THE PARAVENTRICULAR HYPOTHALAMUS OF THE RAT. B.G. Stanley, S.E. Kyrkouli*, S. Lampert* and S.F. Leibowitz. The Rockefeller Univ., New York, NY 10021.

Neuropeptide Y (NPY), a 36 amino acid peptide which coexists with norepinephrine and is found in great abundance in the brain, has recently been shown to stimulate feeding behavior following intracerebroventricular or hypothalamic injection in satiated rats. NPY is the most powerful chemical stimulant of feeding behavior tested to date, with a single injection into the paraventricular nucleus of the hypothalamus (PVN) eliciting, in 4 hr, the equivalent of what rats normally eat in 24 hr. NPY acts within min after injection and is behaviorally specific.

The present experiment tested the effect of chronic PVN injection of NPY on 24 hr food intake and body weight gain of adult female Sprague-Dawley rats with bilateral 26-gauge cannulas aimed at PVN. After 5 days of preinjection baseline measurements, testing was initiated by injecting NPY (1 ug/0.3 ul saline, n=14) or vehicle (0.3 µl saline, n=6) bilaterally into the PVN every 8 hr (8:00, 16:00 and 24:00 hr) for 6 days. Body weight and food intake (67% Purina rat chow, 33% vegetable oil) were measured every 24 hr, and food intake was also measured 3 hr after each of the injections. NPY chronically injected into the PVN dramatically increased daily food intake and body weight gain. Food intake increased from a control baseline of 17 g/day, to 25 g the first day, 28 g the second day and not less than 36 g/day on days 3-6. With animals weighting 318 g when the injections were initiated, body weight gain increased from a control average of 2 g/day to 15 g/day during the 6 days of testing. The weight gain of individual subjects ranged from 8 to 24 g/day during this period. NPY was equally effective in increasing food intake in the light and in the dark phases.

This peptide-induced hyperphagia and weight gain demonstrates that chronic stimulation by exogenous NPY injected into the PVN can override mechanisms of satiety, as well as short- and long-term mechanisms of body weight regulation. It remains to be determined whether endogenous NPY mediates normal feeding, and whether it is involved in the hyperphagia and obesity produced by other experimental manipulations.

(Supported by NIH grant MH 22879).

16.3 CAPSAICIN PRETREATMENT ATTENUATES CCK-INDUCED SUPPRESSION OF SUCROSE INTAKE DURING SHAM FEEDING AND REAL FEEDING. D. Yox and R.C. Ritter. Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164, and WOI Regional Program in Veterinary Medical Education, University of Idaho, Moscow, ID 83843.

Cholecystokinin (CCK) is a peptide which is localized in gut endocrine cells and in some neurons. Administration of exogenous CCK or its biologically active octapeptide (CCK-8) reduces consumption of solid and liquid foods. Recently, we demonstrated that pretreatment of adult rats with capsaicin, a neurotoxin that destroys small-diameter primary sensory neurons, markedly attenuates CCK-induced suppression of food intake (Ritter and Ladenheim, 1985). Consequently, we hypothesized that capsaicin destroys a population of neurons that directly mediates CCK-induced satiety. It is also possible, however, that capsaicin destroys neurons that mediate changes in gastric emptying produced by CCK, or impairs some interaction between CCK and receptors for gastric distension, thereby indirectly attenuating CCK's satietogenic effects. If this latter hypothesis were correct, then CCK-induced satiety in capsaicin-pretreated rats should not be attenuated when ingesta is allowed to drain from their stomachs via open gastric fistulae (sham feeding). Therefore, we have examined the effect of CCK injection on sham feeding and real feeding of 15% sucrose in capsaicin- and vehicle-pretreated rats. CCK-8-induced suppression of real feeding was significantly attenuated in capsaicin-pretreated rats. Vehicle-pretreated control rats suppressed their intake by 66.7±15.6%, 79.3±5.8%, and 86.1±4.1% in response to CCK-8 doses of 1, 2, and 8µg/kg respectively, whereas capsaicin-pretreated rats suppressed their intakes by 38.1±12.0%, 26.0±9.4% and 58.8±7.5% in response to the same doses of CCK-8. During sham feeding, suppression of sucrose intake by capsaicin-pretreated rats was significantly attenuated relative to suppression produced in vehicle-pretreated rats. In sham feeding vehicle-pretreated rats, CCK-8 (1, 2, or 4µg/kg) suppressed intake by 47.4±7.4%, 71.5±8.8% and 70.8±3.2% respectively. Capsaicin-pretreated rats, however, exhibited suppressions of only 1.7±8.9%, 29.4±9.2% and 21.6±17.0% respectively in response to the same three doses of CCK-8. These results confirm the previous findings of Gibbs et al. (1973) that CCK-induced satiety in the rat does not require accumulation of ingesta in the stomach. Furthermore, our results demonstrate that attenuation of CCK-induced satiety by capsaicin is due to the toxin's direct action on CCK-sensitive afferents and not to secondary impairment of gastric mechanoreception or gastric emptying.

This work was supported by NIH grant RO1 NS20561 to R.C. Ritter.

16.4 ATTENUATION OF CCK-INDUCED SATIETY BY SYSTEMIC, INTRAVENTRICULAR OR PERIVAGAL CAPSAICIN ADMINISTRATION. E.H. South and R.C. Ritter. WOI Regional Program in Veterinary Medical Education, University of Idaho, Moscow, ID 83843, and Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Capsaicin is a neurotoxin which destroys small-diameter primary sensory neurons. Previous work from our laboratory has demonstrated that CCK-induced satiety is attenuated in rats pretreated with intraperitoneal injections of capsaicin (Ladenheim and Ritter, 1984). Localization of the capsaicin-sensitive neurons which participate in CCK-induced suppression of food intake has not yet been accomplished. However, Smith et al. have demonstrated that CCK-induced satiety is abolished by section of the gastric vagal branches. Furthermore, capsaicin causes degeneration of vagal primary sensory terminals in the commissural and medial subnuclei of the nucleus of the solitary tract (Dinh and S. Ritter, 1985), where most gastric vagal sensory fibers terminate (Leslie et al., 1982). Therefore, the available data are consistent with the hypothesis that capsaicin destroys a population of vagal sensory neurons which participate in the mediation of CCK-induced satiety. In an initial test of this hypothesis we have examined CCK-induced satiety in rats treated with capsaicin via several different routes of administration. In confirmation of Ladenheim and Ritter, we found that intraperitoneal (IP) capsaicin (3 x 50mg/kg) attenuates CCK-induced satiety. Percent suppression of intake by IP vehicle treated rats was 80±2%, while in IP capsaicin treated rats percent suppression by CCK was only 27±4%. Capsaicin (225µg/3 doses) treatment via the fourth cerebral ventricle virtually abolished CCK-induced satiety, while administration of the same capsaicin dose IP did not significantly attenuate CCK-induced satiety. In rats treated with capsaicin applied directly to the vagal trunks, CCK suppressed food intake by 44±12%, whereas in vehicle treated rats CCK suppressed intake by 73±10%. Capsaicin applied intrapylorically failed to attenuate CCK-induced satiety. In contrast to CCK-induced satiety, suppression of food intake by bombesin was not significantly attenuated by fourth ventricular or perivagal capsaicin application. However, IP capsaicin caused a small but significant attenuation of bombesin-induced suppression of food intake. These data suggest that capsaicin attenuates CCK-induced satiety by damaging vagal sensory neurons. The data further suggest that bombesin's effects on feeding are mediated in part by capsaicin-sensitive neurons which are not of vagal origin.

This work was supported in part by NIH grant RO1 NS20561 to R.C. Ritter.

16.5 DORSAL HINDBRAIN PARTICIPATION IN CHOLECYSTOKININ-INDUCED SATIETY. G.L. Edwards, E.E. Ladenheim and R.C. Ritter. Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164, and WOI Regional Program in Veterinary Medical Education, University of Idaho , Moscow, ID 83843.

The satietogenic effect of exogenous CCK appears to depend upon the integrity of the gastric vagus (Smith et al., 1981). However, the area postrema (AP) has also been proposed as a central CCK receptor, necessary for suppression of feeding by CCK (Van der Kooy, 1984). Our previous work indicates that the AP is not essential for expression of CCK's satietogenic effect (Edwards and Ritter, 1981). Nevertheless, the gastric vagus projects densely to both the medial subnucleus of the NST, just rostral to the AP, as well as to the commissural subnucleus of the NST immediately subjacent to the AP. Therefore, it is probable that these areas are involved in the mediation of CCK-induced satiety as has been previously suggested by Crawley and Kiss (1984). In order to resolve the current uncertainty regarding the participation of dorsal hindbrain structures in CCK-induced satiety, we have compared the satietogenic action of CCK-8 in rats with lesions aimed to destroy the following structures: 1) the AP and adjacent commissural subnucleus of the NST [AP-lesion], 2) the medial subnucleus of the NST [mNST-lesion], and 3) all three structures mentioned above [AP/mNST-lesion]. We have found that lesions aimed to destroy only the AP and adjacent commissural nucleus do not attenuate CCK-induced satiety. Likewise, lesions directed to destroy only the medial subnucleus of the NST do not attenuate CCK-induced satiety. However, lesions which were aimed to destroy the AP, the commissural subnucleus, and the medial subnucleus of the NST strongly attenuated CCK-induced satiety. The completeness of AP-lesions was verified antemortem utilizing a conditioned food aversion (CFA) to paraquat. Paraquat-induced CFA has been shown to be mediated by the AP (Dey et al., 1984). Subcutaneous injection of paraquat (48 µmoles/kg) did produce CFA in all rats with an intact AP. Rats with complete lesions did not develop paraquat-induced CFA. We conclude 1) that the AP is not necessary for expression of CCK-induced satiety, and 2) both the commissural and medial subnuclei of the NST probably contain vagal terminals which participate in CCK-induced satiety.

Table I. PERCENT SUPPRESSION OF FOOD INTAKE BY CCK-8 IN BRAIN-LESIONED RATS

	CCK-8 Dose (µg/kg)			
	1	2	4	8
Controls	45.4±8.6	56.6± 7.5	70.3±5.8	76.3± 9.4
AP-lesions	36.1±9.2	53.7±10.1	56.4±5.5	73.0± 6.6
mNST-lesions	38.4±7.3*	52.3± 9.2*	76.3±4.8*	77.8± 9.2

16.6 INFUSION OF CCK-8 BETWEEN MEALS INTO FREE-FEEDING RATS FAILS TO PROLONG THE INTERMEAL INTERVAL. D.B. West, L. Prescod*, and J. Triscari*. Vassar College, Poughkeepsie, NY 12601, and Hoffmann-La Roche Inc., Nutley, NJ 07110.

We have previously demonstrated that meal-contingent infusion of the octapeptide of cholecystokinin (CCK-8) into free-feeding rats persistently suppressed meal size, but total food intake recovered due to an increased feeding frequency (Am. J. Physiol. 246: R776-787, 1984). The failure to prolong the intermeal interval (IMI) in this previous study may be due to the relatively short half-life of the peptide in the circulation.

We have further evaluated the role of CCK-8 in regulating the IMI by infusing the peptide into 4 adult, male, Sprague Dawley rats during the intermeal interval. The rats were first habituated to computer-monitored enclosures where 45 mg food pellets were provided ad libitum. After 1 week of habituation, intraperitoneal catheters were implanted and the rats were infused with saline at the end of each free-feeding meal and every 5 minutes between meals. When stable growth rates were observed, 5 days of control data were collected. The rats were then infused for 6 days with a CCK-8 solution at a dose of 1.87 µg/meal per rat at the end of each free-feeding meal. The rats also received a CCK-8 infusion every 5 minutes between meals. The dose of the intermeal infusion was increased gradually over the 6 days of drug infusion. On the last day of CCK-8 infusion, the rats received a 20 second infusion containing 0.63 µg of CCK-8 every 5 minutes during the IMI.

At no time during the 6 days of drug infusion was the total daily food intake suppressed relative to control days when no drug was infused. Average control daily intake was 28.0 ± 1.5 g while mean intake during CCK-8 infusion was 25.8 ± 1.0 g. The CCK-8 infusion at the end of each meal persistently suppressed meal size by an average of 27.3% over the 6 day period. Meal number also increased from an average of 11.9 ± 0.9 meals/day during the control period to an average of 15.2 ± 1.4 meals/day over the 6 drug days. Average IMI decreased with CCK-8 administration from 81.1 ± 3.5 minutes to 64.4 ± 3.4 minutes. Intermeal infusion of CCK-8 clearly did not prolong the IMI in this study. These findings suggest that CCK-8 may be involved in the termination of a meal and the initiation of postprandial behaviors; but it does not regulate the intermeal interval.

16.7 COMPARATIVE EFFECTS OF CAERULEIN ON FOOD INTAKE AND PANCREATIC SECRETION IN DOGS. R. D. Reidelberger*, T. J. Kalogeris*, and T. E. Solomon* (SPON: R. C. McClure). Depts. of Medicine and Physiology, Univ. of Missouri Med. Sch. and Truman V.A. Hosp., Columbia, MO 65201.

Cholecystokinin (CCK) inhibits food intake in several species when large doses are administered peripherally. Whether physiologic doses of CCK produce satiety is not established. Since the primary role of CCK is thought to be regulation of exocrine pancreatic secretion, we compared dose-response effects of the CCK analog caerulein on food intake and exocrine pancreatic secretion in dogs adapted to one meal per day. Nine fasted mongrel dogs with gastric and pancreatic fistulas received intravenous scalar doses of caerulein (0, 6.25, 12.5, 25, 50, 100, 200, 400 pmol/kg-h, each for 30 min); pancreatic secretion was measured at 10 min intervals. Maximal stimulation of pancreatic enzyme secretion occurred at 50 pmol/kg-h. A similar maximal pancreatic secretory response occurred when five dogs received a single caerulein dose of 100 pmol/kg-h for 4 h. In feeding studies, eight pure-bred beagle dogs received intravenous infusions of caerulein (0, 200, 400, or 800 pmol/kg-h, one dose per day) for 15 min before presentation of canned dog food and during the 45 min feeding period. Food intake was inhibited significantly only at 400 and 800 pmol/kg-h (49 % and 98 % inhibition, respectively). These results do not support a role for CCK as a satiety hormone, since the minimal effective dose for inhibition of food intake was 4 to 8 times larger than the maximal dose for stimulation of pancreatic enzyme secretion.

16.8 PANCREATIC GLUCAGON IN COMBINATION WITH CHOLECYSTOKININ INHIBITS SHAM FEEDING IN THE RAT. J. LeSauter*, J. Arle*, T. Cornacchia* & N. Geary. Dept. of Psychology, Columbia University, New York, NY 10027.

Pancreatic glucagon (PG) elicits a behaviorally specific inhibition of meal size when injected before meals. PG does not, however, inhibit intake in rats sham feeding with open gastric cannulas (Geary & Smith, Peptides 3: 163, 1982). This suggests that some gastric or postgastric food stimulus that is absent during sham feeding is necessary for PG's satiety effect. Therefore, we tested whether PG regains its potency to inhibit sham feeding when it is administered in combination with injections of bombesin (BBS) or cholecystokinin (CCK), two peptides that may mediate the satiety effect of food in the stomach and small intestine (Gibbs & Smith, Peptides 3: 553, 1982). Ten rats were equiped with chronic gastric cannulas and maintained on Purina chow. Sham feeding of evaporated milk was tested in non-deprived rats after i.p. injection of PG, two doses of BBS, or two doses of CCK either singly or in combination. None of the single doses, except the higher CCK dose, inhibited sham feeding in comparison to control injections. Combinations of PG + BBS also failed to inhibit sham feeding. Combinations of PG + CCK, however, significantly potentiated the effect of CCK alone. The lower BBS + CCK dose failed to inhibit sham feeding, but in combination with PG, BBS + CCK did inhibit sham feeding. Mean ± SEM 30 min sham intakes were:

	Peptide (mcg/kg)					
	CON	CCK.15	CCK.30	BBS.25	BBS.50	CCK.15+BBS.25
without PG	50.5 ±3.6	47.5 ±3.5	37.8* ±4.9	46.1 ±3.7	48.7 ±4.3	43.8 ±5.1
with PG (200)	53.4 ±3.8	30.8##** ±5.1	21.0##** ±4.7	48.9 ±3.7	46.6 ±3.2	27.0##** ±4.1

*p < .05 vs. control, Dunnett's test; **p < .01.
##p < .01 vs. without PG, Tukey's test.

These data indicate that PG synergizes with CCK to inhibit sham feeding. Further, PG can inhibit sham feeding in combination with doses of CCK or CCK + BBS that alone have no effect on sham feeding. This demonstration of potentiation extends Hinton & Geary's (FPA Proc: 56: 30, 1985) report of similar synergistic effects of satiety peptides on real feeding.

16.9 NEUROMEDIN C INHIBITS FOOD INTAKE IN RATS. J.A. DiPoala* and J. Gibbs (SPON: C. Shamoian). Dept. of Psychiatry, Cornell Univ. Med. Coll., and Eating Disorders Institute and E.W. Bourne Behav. Res. Lab., The New York Hosp., White Plains, NY 10605.

Bombesin (BBS) and BBS-like peptides produce large, dose-related and specific inhibitions of food intake. A new BBS-like decapeptide, neuromedin C (NMC), has been isolated from rodent brain and porcine spinal cord and shown to have BBS-like smooth muscle bioactivity (Roth et al, 1983; Minamino et al, 1984). We tested NMC to determine if it, like BBS, inhibited food intake.

METHODS: Adult male Sprague-Dawley rats (n=8) on a 12:12h light:dark cycle (lights on at 0700) were maintained on food pellets and tap water. At 1000, pellets were removed and a predeprivation 30-min access to liquid food (BioServ, 40%) was provided. Rats were deprived of all food from 1030-1330. At 1330, they were injected intraperitoneally with 0.15M NaCl (vehicle control), or 2,4,8, or 16 $\mu g\text{-}kg^{-1}$ NMC or BBS. Liquid food was presented immediately and consumption was measured during the 30-min test meal.

RESULTS: Neuromedin C and BBS inhibited feeding:

	Dose ($\mu g\text{-}kg^{-1}$)				
Peptide	0	2	4	8	16
BBS	19.1±1.1	10.6±1.3** (-41)	9.5±0.9** (-48)	9.0±0.9** (-51)	
NMC	19.7±0.8	19.0±2.0 (-1)	13.9±0.9* (-28)	14.4±2.1* (-30)	9.8±1.2** (-49)

Values are mean food intakes in ml±SEM. Values in parentheses are mean % change from control. *p<0.05, **p<0.01; Tukey's test following ANOVA.

Both peptides produced large inhibitions of food intake. On a weight basis, BBS was more potent than NMC: threshold doses were 2 $\mu g\text{-}kg^{-1}$ (BBS) and 4 $\mu g\text{-}kg^{-1}$ (NMC); 50% inhibition was seen at 8 $\mu g\text{-}kg^{-1}$ (BBS) and 16 $\mu g\text{-}kg^{-1}$ (NMC). On a molar basis, NMC was approximately 40% as potent as BBS; this is similar to the relative potencies of these peptides for contraction of smooth muscle. All rats showed behaviors typical of normal satiety and no abnormal behaviors were noted.

CONCLUSION: Neuromedin C inhibits food intake in a potent, dose-related fashion. This inhibition may represent a satiety action of exogenous NMC.

16.10 BOMBESIN INCREASES POSTPRANDIAL INTERMEAL INTERVAL. S. Mindell*, J.A. DiPoala*, S. Wiener*, J. Gibbs, and G.P. Smith. Dept. of Psychiatry, Cornell Univ. Med. Coll., and Eating Disorders Institute and E.W. Bourne Behav. Res. Lab., The New York Hospital, White Plains 10605.

Bombesin (BBS) decreases meal size (MS) and increases the length of the postprandial intermeal interval (IMI) when it is injected intraperitoneally before a test meal (Wiener et al, 1984). We determined the effect of BBS on postprandial IMI by administering it at the end of the meal.

METHOD: Adult male Sprague-Dawley rats (n=16) were maintained on a condensed milk (50% v/v) diet. After an 18h overnight food deprivation, a high carbohydrate liquid diet (BioServ, 40% v/v) was provided for a daily 140 min test. At the end of the initial meal, a single injection was given of a 0.15M NaCl vehicle control or of tetradecapeptide BBS (2,4, or 8 $\mu g\text{-}kg^{-1}$). For comparison, the synthetic C-terminal octapeptide of cholecystokinin (CCK-8, 8 $\mu g\text{-}kg^{-1}$) was also administered. IMI length was determined by observing rats once each min throughout the test.

RESULTS: (1) All doses of BBS and CCK-8 produced large, highly significant increases in IMI length. (2) The effect of BBS was dose related: 8 $\mu g\text{-}kg^{-1}$ BBS increased IMI 60%; this was significantly more than the effect of 2 $\mu g\text{-}kg^{-1}$ (48% increase) or of 4 $\mu g\text{-}kg^{-1}$ (47% increase). (3) BBS was more potent than CCK-8: 8 $\mu g\text{-}kg^{-1}$ of BBS increased IMI 60%, while 8 $\mu g\text{-}kg^{-1}$ of CCK-8 increased IMI 42%.

CONCLUSION: Exogenous BBS prolongs the postprandial IMI. This effect is dose-related. BBS is apparently more potent for increasing IMI than CCK-8, while previous work (Gibbs et al, 1979) showed that BBS was less potent than CCK-8 for decreasing meal size.

16.11 SUPPRESSION OF FOOD INTAKE IN RATS BY MICROINJECTION OF CHOLECYSTOKININ (CCK) TO THE PARAVENTRICULAR NUCLEUS (PVN). P.L. Faris* and J.W. Olney, Dept Psychiatry, Washington U. St. Louis, MO 63110.

The presence of CCK fiber terminals in the ventromedial hypothalamic nucleus (VMN) (Zaborsky et al, Br Res 303,225,'84) and fiber varicosities in the PVN indicates that these areas are sites of endogenous CCK action. Since both regions are classically implicated in food intake control, the VMN and PVN are candidate regions where CCK may act to produce satiety. We have examined the effect on food intake of CCK microinjection to these areas. Adult male rats were implanted stereotaxically with chronic indwelling unilateral guide cannulae terminating 1.5 mm dorsal to either the PVN or the VMN. Following recovery, each rat (n=7 for both PVN and VMN) received saline, 4.4 pmoles of desulfated CCK-8 (DES-CCK), 4.4 pmoles CCK and 22 pmoles CCK on alternate days in a counterbalanced fashion. The injection cannulae extended the guides by 1 mm. Following injection, dry food pellets were removed and replaced with a pre-weighed cup of wet food mash. Food cups and spillage were weighed 30,60 and 120 min following the injection. Cannulae placements were histologically verified.

Microinjections of both doses of CCK to the PVN significantly decreased food intake. The suppression appears to be both dose and time dependent. The low dose (4.4 pmoles) reduced food intake by 27% during the first 30 min. Food intake was reduced by 47% at 30 min and by 66% during the second half hour interval as a result of treatment with 22 pmoles CCK. DES-CCK did not significantly affect food intake (Table I).

Direct injections of CCK to the VMN did not have a significant effect on food intake (Table II). Thus, it is likely that the suppression of food intake by CCK administered to the PVN is a regionally specific effect, implicating the PVN as a central site for CCK-mediated control of food intake.

Table I. Mean Food Intake (grams ± SEM) Following CCK to the PVN

	Saline	4.4 pmoles DES-CCK	4.4 pmoles CCK	22 pmoles CCK
30 min	8.8 (±1.1)	7.6 (±1.2)	6.5^{A} (±1.7)	4.7^{B} (±1.2)
60 min	2.6 (±0.8)	2.5 (±0.7)	1.7 (±0.7)	0.9^{A} (±0.5)
120 min	2.3 (±1.3)	3.0 (±0.9)	3.6 (±0.8)	2.7 (±1.0)

^{A} $p < 0.05$; ^{B} $p < 0.01$

Table II. Mean Food Intake (grams ± SEM) Following CCK to the VMN

	Saline	4.4 pmoles DES-CCK	4.4 pmoles CCK	22 pmoles CCK
30 min	7.5 (±2.7)	5.6 (±2.0)	5.5 (±1.6)	8.7 (±2.8)

16.12 CCK-8 INTERACTS WITH PREFEEDING TO IMPAIR RUNWAY PERFORMANCE. J. E. Cox. Dept. Psychology, Univ. Alabama at Birmingham, Birmingham, AL 35294.

We previously reported that doses of cholecystokinin octapeptide up to 4 μg/kg did not produce decrements in runway performance of food deprived rats (Cox et al., Behav. Brain Res., 14: 41, 1984. These results suggested that this substance does not reduce feeding motivation prior to contact with food, consistent with the hypothesis that CCK injections reduce food intake by acting late in the meal to prematurely trigger satiety. To further examine this hypothesis, runway performance was assessed after CCK-8 administration in combination with prefeeding. After 21 hr food deprivation, male Sprague-Dawley rats (N=7) received i.p. injections of 1.0 μg/kg CCK-8 (Sincalide, Squibb) or saline immediately following 0, 1, 2, or 5 min access to 30% sucrose. Beginning 10 min after injections, rats ran 6 runway trials for 0.3 ml of 30% sucrose. Mean running speeds (cm/s ± S.E.) were as follows:

	0'	1'	2'	5'
Saline	56.4±1.8	57.0±1.8	45.1±3.7	49.1±5.2
CCK-8	53.6±2.7	53.9±2.4	35.7±7.6	14.9±4.3
Prefed (ml)	0	2.0	4.6	9.7

After 5 min prefeeding (mean intake = 9.7 ml), CCK-8 produced a 70% decrease in running speed compared to tests on which rats were prefed the same amount but received saline injections ($P<.01$). Following shorter intervals of prefeeding or no prefeding, CCK-8 did not significantly affect runway performance. Mean 20 min consumption of 30% sucrose after runway trials with no prefeeding was 15.4±1.0 ml after saline and 12.6±1.4 ml after 1.0 μg/kg CCK-8 ($P<.01$).

Subsequent tests showed that after 5 min prefeeding. 0.50 μg/kg CCK-8 produced a 59% decrease in running speed compared to saline tests ($P<.01$). A dose of 0.25 μg/kg produced a marginally significant 16% decrease ($P<.10$).

Thus, in conjunction with prefeeding, low doses of CCK-8 produced substantial decrements in runway performance. These results contrast with the lack of effect without prefeeding of the same doses and the previously reported ineffectiveness of much larger doses. Inhibitory effects of CCK administration arise, therefore, though interaction with other signals generated by ingestion of food. The nature of these signals is not known, but after 1.0 μg/kg CCK-8 they apparently reach threshold after consumption of between approximately one-third and two-thirds (2 and 5 min prefeeding) of a full meal of 30% sucrose. (Supported by NIH grant AM31805).

CLINICAL NEUROPHYSIOLOGY: EPILEPSY

17.1 AGE RELATED SEIZURE FACILITATION. E.S.Sperber, R. Okada, B. Wong*, S.L. Moshe, Dept. of Neurology and Pediatrics, Albert Einstein College of Medicine, Bronx, NY 10461 and Dept. of Psychiatry, Juntendo University School of Medicine, Tokyo, Japan.

Recent evidence indicates that bilateral muscimol infusions in the substantia nigra (SN) protect adult rats from a variety of experimentally induced seizures. In the present study we report the effects of muscimol infusions into the SN on seizures in developing rats.

Two week old rat pups were implanted with bilateral chronic cannulae in or above the SN. After a two day recovery period, the pups were injected with muscimol (in a volume of .25 ul per site) and their susceptibility to the development of flurothyl induced seizures was compared to that of saline infused rats. The latency to the onset of a generalized clonic seizure was considered as the convulsive threshold.

Rats injected intranigrally with 100 ng of muscimol per site and tested 30 min later, developed flurothyl seizures significantly faster than saline controls or rats whose cannula tips were 1-1.5 mm above the SN ($p<.001$). A time response curve was also generated. The proconvulsant effect of 100 ng of muscimol was already present at 15 min post infusion, became maximal at 30 min and decreased somewhat at 60 min. At all 3 times the muscimol infused rats differed from the two control groups ($p<.001$).

To evaluate the possibility that nigral muscimol infusions may have a biphasic effect on seizures in rat pups, a dose response curve was created, 30 min after the completion of the infusions. Rat pups infused with 12.5 ng/.25 ul/per site of muscimol into the SN had similar latencies to the onset of a flurothyl induced seizures as controls. However, doses of muscimol ranging from 50-200 ng/per site facilitated the development of flurothyl seizures.

These results indicate that the effects of nigral muscimol infusions on seizures are age dependent. The altered responsivity of the nigral GABA sensitive system may account for the increased seizure susceptibility of the immature CNS.
(Supported by grant RO1 NS 20253 from the NINCDS and a grant from the EFA).

17.2 RESERPINE REVERSES THE ANTICONVULSANT EFFECT OF GAMMA-VINYL GABA MICROINJECTED INTO THE SUBSTANTIA NIGRA OF KINDLED RATS. R.L. Gellman & J.O. McNamara. Duke & VA Med. Ctr., Durham, NC.

Microinjection of GABA agonists bilaterally into the substantia nigra (SN) suppresses both clonic motor and limbic seizures produced by kindling of olfactory structures, amygdala or entorhinal cortex. The suppression of limbic seizures behaviorally is paralleled by suppression of focal afterdischarge at the site of stimulation, thereby indicating that the SN can regulate intrinsic neuronal excitability of multiple forebrain sites. The anatomic pathways mediating this regulation are unknown. Direct connections from the SN to all three structures have not been elucidated. The widespread influence of SN on forebrain excitability raised the possiblity that this action was mediated by a population of neurons with diffuse projections. We considered monoaminergic neurons to be likely candidates both because of their diffuse projections and because of their profound influence on seizure susceptibility in the kindling model. To begin to test the hypothesis that the anticonvulsant effect of intranigral γ-vinyl GABA (GVG) is mediated by one or more of the monoamines, we determined whether reserpine, a monoamine-depleting drug, would reverse the anticonvulsant effect.

Sprague Dawley rats were stereotactically implanted with a bipolar electrode in the right amygdala and bilateral guide cannulas overlying the SN. They were stimulated 2x/day until 7 class 5 seizures were evoked. Following determination of the generalized seizure threshold, GVG (5 ug/0.5 ul saline in 2.5 min) was microinjected into the SN bilaterally and the response to a test stimulation was determined at 16 and 36 hrs thereafter. Either reserpine (2.5 mg/kg) or vehicle was administered subcutaneously to the animals 24 hours after GVG treatment. The afterdischarge duration (ADD) in seconds was recorded on EEG. All electrode and injection placements were histologically verified. Preliminary experiments indicated that reserpine produced >90% depletion of monoamines in multiple brain regions.

Reserpine, but not vehicle, reversed the anticonvulsant effect of intranigral GVG. Prior to GVG, both groups had similar baseline ADDs (86 ± 10 and 89 ± 10 secs respectively, mean ± SEM). GVG shortened ADD in both groups at 16 hrs (39 ± 11 and 50 ± 19, $p<0.05$, student's t-test). Reserpine (n=9) returned ADD to baseline (80 ± 10), while vehicle (n=8) left the GVG effect intact at 36 hrs (54 ±12, $p<0.05$ vs. baseline). Additional experiments demonstrated that reserpine alone did not lengthen the ADD in animals receiving intranigral injections of saline.

We conclude that reserpine, but not vehicle, reverses the anticonvulsant effects of intranigral GVG. This suggests that one or more of the monoamines may mediate nigral influence on intrinsic neuronal excitability in forebrain structures.

17.3 ELECTROPHYSIOLOGICAL EVIDENCE THAT SUBSTANTIA NIGRA TRANSMITS SEIZURE ACTIVITY IN KINDLED RATS. D.W. Bonhaus, J.R. Walters and J.O. McNamara. Depts. Med. (Neurology) and Pharm. Duke Univ. and V.A. Medical Centers, Durham, NC and NINCDS, Bethesda, Md.

Kindling, an animal model of limbic epilepsy, is achieved by repeatedly administering initially subconvulsive electrical stimuli to specific brain areas until generalized clonic seizures are evoked. Previous work in our laboratory has demonstrated that intranigral injection of muscimol or destruction of the substantia nigra (SN), treatments which presumably decrease the neuronal output of the SN, suppress both clonic motor and limbic seizures in kindled rats. These findings indicate that the SN is involved in the propagation of seizures in kindled rats, but they do not specify a mechanism. We proposed two hypotheses regarding the role of the SN in the propagation of kindled seizures: 1) the SN directly transmits seizure activity from rostral sites of origin to target structures; and/or 2) the SN produces a tonic seizure facilitating action on other structures which themselves directly transmit the seizure activity.

To begin testing these hypotheses we recorded single unit activity of both dopamine and pars reticulata neurons in the SN during electrical seizures induced by stimulation of amygdala in paralyzed ventilated rats. We recorded electroencephalographic (EEG) activity with electrodes in amygdala and caudate.

The most striking finding was that SN neurons in the kindled animals exhibited a dramatic change in firing pattern during the electrical seizure. This pattern consisted of the cells firing in bursts; moreover the bursts were temporally correlated to specific components of the EEG recorded in the caudate or amygdala during the evoked seizure. This firing pattern was found in the majority of both dopamine and pars reticulata neurons of kindled animals, but was found uncommonly in SN neurons of naive animals. In kindled rats 88% of the SN pars reticulata and 88% of the SN dopamine neurons fired in bursts time-locked to the EEG waveform during seizures while in naive rats only 18% of the SN pars reticulata and none of the SN dopamine neurons fired in this pattern. The firing of neurons in bursts temporally correlated to components of the the EEG waveform in kindled animals is not a global phenomenon since only one of 30 cells recorded in the pontine tegmentum of kindled animals exhibited any clear change in firing pattern during seizure.

This change in firing pattern, to firing time-locked to specific components of the EEG, indicates that the SN is directly transmitting seizure activity. Although these results do not exclude the possibility that the SN exerts a tonic seizure facilitating action to promote seizure propagation, the observed change in firing pattern of nigral neurons during the seizure seems sufficient to account for its role in seizure propagation.

17.4 ALPHA$_2$, BUT NOT ALPHA$_1$, ADRENERGIC RECEPTOR ANTAGONISTS FACILITATE KINDLING DEVELOPMENT. J.A. Kallianos*, R.L. Gellman and J.O. McNamara (SPON: S. Schiffman). Depts. of Medicine (Neurology) and Pharmacology, Duke and VA Medical Centers, Durham, NC 27710.

Kindling, an animal model of epilepsy, is a phenomenon in which periodic administration of an initially subconvulsive stimulus eventually results in prolonged limbic and motor seizures. Selective depletion of forebrain norepinephrine (NE) markedly facilitates kindling development; this suggests that endogenous NE normally mediates an anticonvulsant action. The receptor subtype with which endogenous NE interacts to produce this anticonvulsant action is unknown. The anticonvulsant effects of an alpha$_2$ agonist against audiogenic and pentylenetetrazol (PTZ) seizures together with the proconvulsant effects of alpha$_2$ antagonists in the PTZ model led us to hypothesize that the anticonvulsant effects of NE in the kindling model are mediated through alpha$_2$ receptors. To test this hypothesis, we examined the effects of three different compounds on the rate of kindling development: yohimbine and idazoxan (RX 781094), two structurally dissimilar alpha$_2$ antagonists and corynanthine, a stereoisomer of yohimbine with selective alpha$_1$ antagonist properties.

Male Sprague Dawley rats implanted with a bipolar electrode in the right amygdala were pretreated daily with antagonist or vehicle and stimulated until 3 class 5 seizures were elicited.

TREATMENT	DOSE	# STIMS 3 CL 5 SZ (mean ± SE)	P value
Control		19.6 ± 1.6	
Yohimbine	1 mg/kg	9.5 ± 1.9	P<0.05
Idazoxan	1 mg/kg	7.8 ± 0.5	P<0.001
Corynanthine	1 mg/kg	18.0 ± 2.1	NS

The facilitatory effects of yohimbine and idazoxan were dose dependent over a range of 0.1 - 10 mg/kg and 0.05 - 10 mg/kg respectively. Corynanthine had no effect on kindling development at 0.1 mg/kg or 1 mg/kg. No difference was observed between drug and vehicle treated animals in terms of the behavioral or electroencephalographic patterns of seizures. The drugs did not produce any overt behavioral effects nor did the drugs alone produce seizures.

We propose that alpha$_2$ adrenergic receptors mediate the anticonvulsant action of NE since: 1) antagonists of these receptors facilitate kindling development; 2) the degree of facilitation is equivalent to that observed after elimination of NE. The proconvulsant effect of alpha$_2$ receptor antagonists seems paradoxical in view of the historical perspective that alpha$_2$ receptors are located on presynaptic terminals and that alpha$_2$ antagonism results in increased NE release. Hence, our results suggest that the alpha$_2$ receptors mediating the endogenous anticonvulsant effects of NE are located on targets of NE neurons, not on NE neurons themselves.

17.5 THE ROLE OF SUBSTANTIA NIGRA IN THE DEVELOPMENT OF KINDLING. C. Shin, J.M. Silver*, D.W. Bonhaus and J.O. McNamara. Depts. Med. (Neur.) and Pharm. VA and Duke Univ. Med. Ctrs. Durham, NC 27710.

Kindling, an animal model of temporal lobe epilepsy, refers to the phenomenon whereby repeated administration of an initially subconvulsive electrical stimulus eventually results in intense limbic and generalized motor seizures. Previous work from our laboratory has demonstrated that both intranigral injection of γ-vinyl-GABA (GVG), a GABA transaminase inhibitor, and lesioning of substantia nigra (SN) with the neurotoxin N-methyl-DL-Aspartate (NMDA) can block motor and limbic seizures in previously kindled rats. This led us to hypothesize that the same manipulations in SN would retard the development of kindling. We tested this hypothesis using both intranigral GVG and NMDA and thermocoagulative lesions of SN.

SN of male Sprague-Dawley rats were lesioned bilaterally by either microinjection of NMDA or thermocoagulation. Stimulating electrodes were stereotaxically implanted in the right amygdala. After 1 week, both lesioned and sham-operated control rats were stimulated 4 times a day at 100 μA above their afterdischarge threshold (ADT) until kindled (3 clonic motor seizures). Another group of animals was implanted with amygdala electrodes and guide cannulae overlying SN. After 1 week, GVG (5μg/side) was injected into the SN bilaterally. These rats and their respective controls were stimulated 7 times per day at 100 μA above their ADT until kindled. Nissl stained frozen sections were examined to determine electrode and cannula placements and extent of lesion.

Animals with SN lesioned by either method were found to kindle significantly faster than sham-operated controls: NMDA lesioned animals were kindled after 15.0 ± 1.7 (mean ± SEM) stimulations compared to 22.5 ± 2.2 for controls ($p<0.05$). Thermocoagulative lesioned animals were kindled after 13.5 ± 2.0 stimulations versus 22.2 ± 1.6 in the controls ($p<0.05$). Conversely, animals receiving GVG required 77% more stimulations (28.8 ± 3.8) to kindle than those receiving intranigral saline (16.3 ± 1.7) ($p<0.05$, 2-tailed Student's t test). GVG 2 mm dorsal to the SN did not delay kindling development (17.3 ± 2.0 stimulations).

Thus kindling development is retarded by intranigral GVG and facilitated in animals with lesions of SN. One explanation for these findings is that an intact SN is part of the network of kindling development and GVG, by presumably inhibiting SN output, retards kindling. However, in the absence of SN, kindling may take place through an alternate network. Kindling through this alternate network is apparently faster than that which exists in the unlesioned brain. Once kindling is established through an intact SN, the SN becomes an important structure in seizure propagation; thus do both SN lesions and intranigral GVG suppress kindled seizures.

17.6 METHOD OF BRAIN LESIONING DETERMINES LIKELIHOOD OF SEIZURES. J. M. Silver*, D.W. Bonhaus and J. O. McNamara. Departments of Medicine (Neurology) and Pharmacology, Duke University and VA Medical Centers, Durham, N.C. 27710.

Lesions of brain structures are used extensively to elucidate the anatomical substrates of brain function. Little is known, however, about the physiologic consequences of different lesioning techniques. Previous observations from our laboratory demonstrated that electrolytic lesions caused seizures. Since lesion-induced seizures are a serious confounding variable in our attempts to understand the functional anatomy of kindled seizures, we examined several lesioning techniques in order to find one that did not evoke seizures.

Brainstem structures were lesioned in male Sprague-Dawley rats using one of three different techniques. Lesions of similar size and location were obtained with the excitotoxin N-methyl-DL-aspartate (NMDA), electrolysis or thermocoagulation. All animals were monitored for electroencephalographic and behavioral seizures for a period of four to five hours following lesioning. Sham-operated animals served as controls.

Four of six animals receiving NMDA lesions and three of six animals receiving electrolytic lesions demonstrated seizure activity, whereas zero of six animals receiving thermocoagulative lesions did so. In a group of pooled controls, one of eighteen animals demonstrated seizure activity. Significant differences in the fraction of animals seizing were found between both the NMDA and electrolytic groups and controls ($p=.01$ and $p=.03$, respectively), but no significant difference was found between the thermocoagulative group and controls. The average NMDA treated animal had 4.8 seizures during the 4 hour monitoring period ($p<0.001$ compared to controls by Student's t-test) and the average electrolytic animal had 3.3 seizures ($p<0.02$ compared to controls). Again, thermocoagulative animals showed no seizures and these were not different from controls in average number of seizures.

These results demonstrate that of the three methods examined, thermocoagulation is least likely to produce seizures and is therefore the lesioning method of choice when lesion-induced seizures are a potential confounding variable. Recognition that seizures occur following brain lesions is crucial since seizures may alter brain function in a manner unrelated to the simple destruction of a specific anatomical structure.

17.7 Unilateral Chronic Foci in deep prepiriform cortex in Rat. G.G.Smith*, R.G. Fariello, G.T.Golden and P. F. Reyes. Neurology & Research, VAMC, Coatesville PA 19320 and Neurology & Psychiatry, Thomas Jeff. Med. College, Phil. PA 19107.

Recently a site deep in the forebrain of the rat has been identified from which generalized convulsions can be elicited by focal injection of a number of different epileptogenic agents including bicuculline, picrotoxin, carbacol, kainic acid and acetylcarnitine at doses many magnitudes lower than the convulsant threshold dose for other cerebral structures (Piredda, Lim & Gale, Life Sciences, 1985. 36 (13):1295).

In the present study we have examined the electrographic and behavioral results of unilateral placement of cobalt chloride ($CoCl_3$) or ferric chloride ($FeCl_3$) in deep prepiriform cortex in adult Long Evans hooded male rats. Placement of either $CoCl_3$ or $FeCl_3$ into left deep prepiriform cortex was accomplished by a micropipette and a nanoliter pump. $CoCl_3$ 25 µg to 150 µg or $FeCl_3$ 135 µg was injected over a period of 15 to 30 minutes. Coordinates for placement of foci were 4 mm anterior to bregma, 2.5 mm lateral to midline and 6.5 mm below the dura, with the incisor bar 5 mm above the interaural line. EEG recording electrodes were placed within 1 mm of the focus i.e. left prepiriform area, in the right mirror prepiriform area, in left and right frontal cortex and left and right parietal cortex. Animals had EEG activity recorded for 4 - 6 hours each day for over 80 days.

Early epileptiform activity consisted of interictal spikes in the right mirror prepiriform area. Several days later the EEG pattern consisted of electrographic seizures with onset from the focal area in left deep prepiriform area often with spread to the ipsilateral frontal and parietal cortex. Occasionally this spread to cortex was accompanied by mild behavioral manifestation of seizure activity e.g. facial myoclonus and or forepaw twitches. At no time were generalized electrographic or behavioral seizures observed.

Large injections of $CoCl_3$ produced extensive necrosis in prepiriform and adjacent areas. In $CoCl_3$ animals with large injections (150 µg) interictal and ictal discharges were very transient. $CoCl_3$ animals with small injections (25 µg) showed more consistent and longer lasting electrographic discharges. Interictal spikes and ictal electrographic discharges were observed up to 80 days post focus in some animals.

17.8 MPTP protects against picrotoxin induced seizures. M.DeMattei*, R.G. Fariello, G.T. Golden. (Spon: L.A. Marco). Neurology & Research VAMC, Coatesville PA 19320 and Thomas Jeff. Med. College, Phil. PA 19107

The substantia nigra has been implicated as the site of anticonvulsant activity mediated by GABA (Iadarola & Gale, Science, 1982,218:1237) and as a site crucial to the generation of seizures (McNamara et al., Epilepsia, 1983, 24:522). In addition, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine has been shown to produce nerve cell destruction in the substantia nigra (SN).

In the present study we have investigated the effect of destruction of SN cells, by the selective neurotoxin MPTP, on picrotoxin induced seizures. Albino male swiss mice were injected ip with either 30 mg/kg of MPTP or injection vehicle for ten days. On the eleventh day all mice were given sc injections of picrotoxin 7.0 mg/kg and observed and rated on behavioral seizure activity. A four point seizure scale was used, 0 indicating no seizure activity and a score of 4 indicating maximal seizure activity with tonic forelimb extension.

Ninety percent of the control vehicle injected mice experienced convulsions and death following a 7.0 mg/kg dose of picrotoxin whereas only 25% of the MPTP mice died following picrotoxin injection.

The mean latency to first seizure after picrotoxin injection was 8 min 32 sec for the control vehicle mice whereas MPTP treated mice had a mean latency of 16 min 32 sec MPTP treated mice had fewer seizures ($\bar{x}$ = 1.75), than control animals ($\bar{x}$ = 4.25). The mean seizure score for the control group was 14.8. The MPTP group had a mean seizure scores of 5.8. These results will be discussed with regards to the histopathological findings.

These preliminary results suggest that the substantia nigra is an essential area for picrotoxin induced seizures, and provides further evidence for the substantia nigra in GABA mediated seizure mechanisms.

17.9 **TRANSIENT EXPOSURE TO NOREPINEPHRINE INCREASES NEURONAL EXCITABILITY IN HIPPOCAMPAL AREA CA3.** D.M. Taylor*, A.C. Bragdon and W.A. Wilson. Depts. of Pharmacology and Medicine (Neurology), Duke University and VA Medical Centers, Durham, NC 27705.

Norepinephrine (NE) is recognized as having an anticonvulsant effect in a variety of in vivo and in vitro models of epilepsy. We observed that in addition to an acute inhibition of epileptiform activity in area CA_3 of the hippocampal slice, transient exposure to NE had the effect of increasing neuronal excitability in CA_3 following NE removal.

Male Sprague-Dawley rats, 270-380 g, were decapitated, and the hippocampi rapidly dissected into chilled (15 C), oxygenated ACSF. ACSF contained (mM): NaCl 120, $NaHCO_3$ 25, dextrose 10, KCl 3.3, NaH_2PO_4 1.23, $MgSO_4$ 1.2, and CaCl 1.8. 625 micron slices were cut perpendicular to the hippocampal long axis at the temporal end using a McIlwain chopper. Slices from temporal hippocampus were chosen (the second through fifth slices cut, starting at the temporal pole). After incubation for at least an hour, slices were placed in an immersion chamber with a continuous flow of warmed (32 C), oxygenated ACSF. Stimulating electrodes were placed in stratum radiatum of area CA_3, adjacent to the fimbria--extracellular recording electrodes in stratum pyramidale of CA_3b. Slices were stimulated every 100 seconds at the current intensity found to yield a maximum orthodromic population spike, in order to evaluate the slice response. After a given slice produced stable, healthy evoked potentials for 15 min., ACSF containing 100 uM NE was bath applied for 15 min.,followed by 15 minutes of washout. If the slice was not spontaneously bursting after this regimen, stimulus trains of a type previously shown to induce bursting (60 Hz, 0.01 ms duration, 2 s train; Stasheff et al., Brain Research, 1985, in press) were applied every 10 minutes until spontaneous bursting occurred. Control slices were treated identically, except that no NE was applied.

Evoked responses in the presence of NE were similar to those in control slices. Following NE washout, responses became more "epileptic"; a single stimulus resulted in multiple orthodromic population spikes. Following NE aplication and washout, 1.0 $\pm$0.3 SEM stimulus trains were required to obtain spontaneous population bursting in CA_3; in controls 2.3 $\pm$0.4 SEM were needed to reach the same criterion (significant @ $p<.025$, Student's t-test).

NE modulates population firing of CA_3 pyramidal cells. The excitatory component of this modulation is not seen during drug aplication, perhaps due to simultaneous activation of alpha and beta recptors. Thus NE acutely may be inhibitory, but the long term effect of NE is to increase neuronal activity in hippocampal area CA_3. This suggests that NE may modulate the development and expression of epilepsy in the whole animal.

17.10 EFFECTS OF ANTICONVULSANT DRUGS ON SINGLE UNIT ACTIVITY OF SUBSTANTIA NIGRA (SN) PARS RETICULATA NEURONS. B.L. Waszczak, E.K. Lee* and J.R. Walters. Pharmacology Section, Northeastern Univ., Boston, MA 02115 and NINCDS, Bethesda, MD 20205.

Recent reports have suggested that enhancement of GABAergic transmission within the SN prevents the motor manifestations of both chemically-induced and kindled seizures. Thus, it has been proposed that inhibition of SN pars reticulata output function specifically suppresses the propagation of seizure activity to motor effector sites. The current studies were undertaken to evaluate the effects of a diverse group of anticonvulsant drugs on the firing rates of SN pars reticulata neurons, and to correlate these effects with the drugs' anticonvulsant profiles and/or presumed mechanisms of action.

Extracellular, single unit activity of pars reticulata neurons was monitored in male rats which were paralyzed and locally anesthetized. Drugs were administered i.v. at 2 min intervals over a range of logarithmically-increasing doses which included doses effective in suppressing experimentally-induced seizures in rats. Phenytoin (1.25-160 mg/kg; n=9) and carbamazepine (1.25-40 mg/kg; n=13) produced no changes in reticulata cell firing at any dose. Conversely, diazepam (31.25-8000 µg/kg; n=10) and clonazepam (2-500 µg/kg; n=10) consistently produced partial inhibitions of cell firing. Both drugs had similar efficacies, with diazepam producing an average maximal inhibition to 45.6$\pm$10.6% of the baseline rate, and clonazepam producing a maximal inhibition to 59.3$\pm$5.9% of baseline. Clonazepam, however, was approximately 16 times more potent in eliciting equivalent degrees of inhibition. Two other anticonvulsant drugs, phenobarbital (1.25-80 mg/kg; n=10) and valproic acid (5-640 mg/kg; n=9), also partially inhibited cell firing, but only at doses several time greater than those required to block seizure activity in experimental models. In fact, for phenobarbital doses up to 20 mg/kg produced slight increases in firing (ranging from about 10-25% above baseline), whereas only at the highest dose administered (80 mg/kg) was firing inhibited (to 64.9$\pm$9.3% of the baseline rate). Similarly, valproic acid caused no significant changes in firing until administration of the highest dose (640 mg/kg) whereupon firing was slowed to 69.5$\pm$5.8% of the baseline rate. Finally, ethosuximide (12.5-800 mg/kg; n=11) differed from all of the above drugs in its ability to markedly stimulate firing of pars reticulata neurons. The average change in firing was 27.2$\pm$7.7% over baseline after 50 mg/kg and increased to 92.0$\pm$29.7% over baseline after a dose of 200 mg/kg.

These results reveal that the effects of anticonvulsant drugs on the firing rates of SN pars reticulata neurons in normal rats does not correlate closely with either their clinical profiles or effectiveness in inhibiting seizures in various experimental models. However, the ability of some drugs to partially inhibit reticulata cell firing does correlate with the known or proposed ability of those drugs to potentiate inhibitory responses to GABA, a transmitter these cells are sensitive to and physiologically influenced by. 17.11 EFFECT OF NOREPINEPHRINE DEPLETION ON KINDLING-BASED STATUS EPILEPTICUS. D.C. McIntyre and N. Edson.* Department of Psychology, Carleton Univ., Ottawa, Ont., Canada K1S 5B6

The progressive development of kindled seizure activity, resulting from the low intensity stimulation of discrete forebrain sites, is suppressed by norepinephrine (NE). This suppression is inferred by the dramatic rapid genesis of kindling following NE depletion with the neurotoxin 6-hydroxydopamine (6-OHDA) (e.g., Arnold, et al., Exp. Neurol., 40: 457, 1973).

We have described previously a model of status epilepticus (SE), based on antecedent kindling of the amygdala, which results in convulsive behavior lasting 24 h or more and which is associated with extensive pathology in the pyriform cortex, its projections and CA_1 hippocampus (McIntyre et al., Brain Res., 250: 53, 1982). The SE develops from continuous stimulation of the kindled amygdala, for 60 min, with the original kindling stimulus. The sustained activity precipitated by this procedure consists largely of partial motor seizures with afterdischarges at 2-3 Hz.

In the present experiments, we examined NE involvement in SE development by continuous stimulation of the amygdala in NE-depleted or control rats having either (a) no previous kindling, (b) one kindled amygdala, or (c) two kindled amygdalae. The NE depletions were achieved by bilateral intraventricular 6-OHDA infusions (125 µg x2) three weeks before kindling or stimulation per se.

Good depletion of NE was observed in all the 6-OHDA pretreated rats compared to controls. As previously reported, NE depletion resulted in a significant facilitation in the rate of kindling, prior to the SE treatment. In none of the SE experiments, however, did NE depletion affect the probability of developing SE, its severity, duration or the extent of associated brain pathology compared to controls. Clearly NE has little obvious involvement in the etiology or offset of kindling-based SE from an amygdala focus.

OTHER BIOGENIC AMINES I

18.1 SEROTONIN MIGRATION IN BRAIN CELL MICROENVIRONMENT. M. E. Rice* and C. Nicholson. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Serotonin (5-HT) is implicated in a vast range of neuronal functions ranging from control of neuronal development to modulation of brain arousal. Some of these functions are thought to be mediated by local release of serotonin into the brain cell microenvironment. To understand such functional modes it is essential to clarify how serotonin migrates when released into the extracellular space. Using quantitative methods based on iontophoresis and ion-selective microelectrodes (ISMs) sensitive to serotonin and electrochemical microsensors (ECMs) we showed that this indolamine can migrate readily within the extracellular space, but that its behavior deviates from that associated with small non-neuroactive cations.

Methods were based on those described by Nicholson & Phillips (J. Physiol. 321:225, 1981) in the rat cerebellum and consisted of the iontophoretic release of serotonin from a micropipette in the isolated turtle cerebellum and subsequent monitoring of extracellular concentrations of serotonin at distances of 75-250 µm using ISMs and ECMs. Diffusion properties were analyzed using an on-line microcomputer. Tetramethylammonium (TMA) was used as a control cation in a similar experimental paradigm with ISMs and all measurements were compared to diffusion in an adjacent agar substrate.

Measurements with TMA indicated that this ion diffused normally in the turtle cerebellum and revealed volume fraction and tortuosity values similar to those reported in the rat cerebellum. In contrast, serotonin showed small but consistent deviations from ideal diffusion: during iontophoresis $[5\text{-}HT^+]_o$ increased more slowly than TMA but at the cessation of the pulse $[5\text{-}HT^+]_o$ decayed more rapidly.

These results may indicate uptake of serotonin from the extracellular space, despite the fact that classical serotonin uptake mechanisms (Km <10 µM) (Shaskan & Snyder: J. Pharmacol. Exp. Therap., 175:404, 1970) are likely to be saturated at the extracellular concentrations achieved in our experiments (0.02 - 2mM at the ISM). Moreover, the cerebellum has only a sparse serotonergic afferent system. The putative uptake revealed by our studies is thus likely to be relatively non-specific. [Supported by USPHS Grants NS-13742 and NS-07745 (MER).]

18.2 TWO POPULATIONS OF SEROTONERGIC AXONS IN CAT CEREBRAL CORTEX. K.A. Mulligan* and I. Tork* (SPON: P. Huttenlocher). School of Anatomy, University of New South Wales, Kensington, Sydney, Australia

Recent studies of the serotonergic (5-HT) innervation of the mammalian cortex reveal regional and laminar variations in the density of 5-HT axons. However, little information is available on the morphology of cortical 5-HT axons in any species. In the present study, quantitative analysis and serial reconstructions at the light microscopic level provide the first detailed characterization of 5-HT axons in the cat cerebral cortex.

Three types of 5-HT axon segments can be distinguished in immunohistochemical preparations of cat visual cortex (area 17) on the basis of the presence and nature of varicosities.

(1) Axons with small, fusiform varicosities (< 1 um in diameter) constitute the largest population (90%) of cortical 5-HT fibres. They are distributed throughout all layers, but are most abundant in layer I. They branch frequently, giving rise to daughter fibres of similar morphology, and end as single terminal boutons in the upper layers of cortex.

(2) Non-varicose axons (7% of the cortical 5-HT fibres) are usually about 1 um in diameter and course parallel to the pial surface in layers I, V, VI and the white matter. They branch infrequently.

(3) Fine axons bearing large (one or more microns in diameter), round varicosities constitute only 3% of the population and are located predominantly in layer I, where they form dense, basket-like arrays around single neurons. In Nissl-counterstained preparations the varicosities of these axons contact somata and appear to extend along the unstained dendrites of the neurons.

It was found in partial serial reconstructions that the fine, basket-forming fibres (3) arise as branches of non-varicose 5-HT axons (2), and that a single non-varicose axon can give rise to fibres forming several baskets. 5-HT axons with small, fusiform varicosities (1) do not appear to be related to the latter two types of 5-HT axon. Hence, it appears that the 5-HT innervation of the cat cortex is organized into two parallel subsystems. One system, distributed widely through the cortex, is composed of fibres with small varicosities and may play a role in the diffuse function normally associated with the 5-HT system. The second system, represented by the non-varicose axons and their basket-forming branches, has a more restricted distribution and may exert a strong influence over a particular population of cortical neurons.

18.3 A COMPARISON OF BIOCHEMICAL INDICES OF 5-HYDROXYTRYPTAMINERGIC NEURONAL ACTIVITY FOLLOWING ELECTRICAL STIMULATION OF THE DORSAL RAPHE NUCLEUS. N.J. Shannon , J.W. Gunnet* and K.E. Moore. Dept. of Pharmacol./Toxicol., Michigan State Univ., East Lansing, MI 48824.

The activity of 5-hydroxytryptaminergic (5HT) neurons has been estimated from measurements of: 1) concentrations of 5-hydroxyindoleacetic acid (5HIAA), 2) 5HIAA/5HT concentration ratios, 3) rate of accumulation of 5-hydroxytryptophan (5HTP) following the administration of an aromatic L-amino acid decarboxylase inhibitor such as NSD 1015 and 4) rate of accumulation of 5HT and decline of 5HIAA after administration of a monoamine oxidase inhibitor such as pargyline. There has been no systematic comparison of these techniques under conditions of elevated 5HT neuronal activity, although electrical stimulation of 5HT neurons has been reported to increase 5HIAA concentrations (Aghajanian et al., 1967) and 5HTP accumulation following NSD 1015 (Duda and Moore, 1985). The purpose of the present study was to compare these different methods with changes in neuronal impulse traffic produced by electrical stimulation of these neurons and, to determine which of these methods is the most appropriate for use in selected brain and pituitary regions.

Male Long-Evans rats anesthetized with chloral hydrate (400 mg/kg, i.p.) were sacrificed following 0, 15 or 30 minutes of electrical stimulation of the dorsal raphe nucleus (monophasic pulses; 0.3 mA; 1 msec duration; 0, 5 or 10 Hz). Concurrent with the onset of stimulation, the appropriate groups of animals received either saline (1 ml/kg, i.v.), a supramaximal dose of NSD 1015 (25 mg/kg, i.v.) or a supramaximal dose of pargyline (30 mg/kg, i.v.). HPLC with electrochemical detection was used to quantify concentrations of 5HTP, 5HT and 5HIAA in selected brain regions (e.g., amygdala, nucleus accumbens, suprachiasmatic nucleus). Because the content of 5HIAA in the intermediate lobe of the pituitary gland was below the sensitivity of the assay (30 pg), only the 5HTP accumulation method could be applied to this region. In each brain region, electrical stimulation elicited an increase in the concentration of 5HIAA and the 5HIAA/5HT concentration ratio in saline-treated animals and an increase in 5HTP accumulation in NSD 1015-treated rats. The magnitude of response to stimulation varied among these methods. In the amygdala, for example, 30 minutes of stimulation at 5 Hz produced increases in 5HIAA, 5HIAA/5HT and 5HTP concentrations that were 125%, 150% and 170% of sham-stimulated (0 Hz) values, respectively. However, in pargyline-treated animals, electrical stimulation failed to alter the concentrations of 5HT or 5HIAA. The results of this study indicate that while the concentrations of 5HIAA, 5HIAA/5HT and 5HTP each increase in response to accelerations in 5HT nerve firing, and thus serve as valid biochemical indices of 5HT neuronal activity, the sensitivities of the various methods and their applicability to specific brain and pituitary regions differ. In contrast, increases in 5HT and decreases in 5HIAA concentrations following administration of pargyline were not significantly altered following stimulation of 5HT neurons. (Supported by USPHS grant NS15911.)

18.4 EFFECTS OF TRYPTOPHAN ADMINISTRATION ON THE SYNTHESIS, STORAGE AND METABOLISM OF 5-HYDROXYTRYPTAMINE IN THE HYPOTHALAMUS AND THE POSTERIOR PITUITARY GLAND OF THE MALE RAT. K.J. Lookingland*, N.J. Shannon, D.S. Chapin and K.E. Moore. Dept. of Pharmacology/Toxicology, Michigan State Univ., East Lansing, MI 48824.

The effects of tryptophan administration on neurochemical estimates of synthesis (5HTP accumulation following NSD 1015), storage (5HT concentrations) and metabolism (5HIAA concentrations) of 5HT in selected regions of the hypothalamus and in the intermediate and neural lobes of the pituitary gland were determined using HPLC coupled to an electrochemical detector. Tryptophan (30-300 mg/kg, i.p.) produced a dose-dependent increase in 5HTP accumulation throughout the hypothalamus and in the intermediate but not the neural lobe of the pituitary. Peak 5HTP levels were attained by 30 min following tryptophan administration (100 mg/kg) and were maintained for an additional 60 min. Tryptophan also produced concomitant dose-dependent increases in 5HT and 5HIAA concentrations in these same regions without change in the ratio of 5HIAA/5HT. These results indicate that exogenous tryptophan administration increases the synthesis, storage and metabolism of 5HT in the hypothalamus and intermediate lobe of the pituitary. Since an increase in release of 5HT is typically accompanied by an increase in the ratio of 5HIAA/5HT, the lack of change in this ratio following tryptophan suggests that this precursor does not alter 5HT release.

5HIAA measured in brain tissue for the most part represents a combination of 1) newly synthesized 5HT that is directly metabolized within the neuron, and 2) 5HT that has been released, recaptured and subsequently metabolized by intraneuronal MAO. To determine the effects of precursor loading on the metabolism of newly synthesized 5HT, the effects of chlorimipramine (5 mg/kg, s.c.), an inhibitor of 5HT uptake, on 5HIAA concentrations were examined in control and tryptophan-treated rats. Chlorimipramine caused only a modest (10-35%) reduction in 5HIAA concentrations throughout the hypothalamus of control and tryptophan-treated animals indicating that only a minor portion of 5HIAA is derived from released 5HIAA while the major portion of this metabolite may reflect direct intraneuronal metabolism of unreleased 5HT. In chlorimipramine-treated rats 5HIAA concentrations were significantly increased by tryptophan administration suggesting that the increase in synthesis of 5HT following precursor loading is accompanied by an increase in the intraneuronal metabolism of 5HT. (Supported by USPHS grant NS15911).

18.5 5-HYDROXYTRYPTAMINE SYNTHESIS IN DISCRETE RAT BRAIN NUCLEI IS AFFECTED BY 5-HYDROXYTRYPTAMINE AGONISTS AND ANTAGONISTS. J.A. Nielsen. Department of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

A procedure for studying 5-hydroxytryptamine (5-HT) synthesis by determining the rate of accumulation of 5-hydroxytryptophan (5-HTP) after administering m-hydroxybenzylhydrazine (NSD 1015), an inhibitor of aromatic-L-amino acid decarboxylase (LAAD), and large doses of L-tryptophan (L-trp) was characterized. The utility of this method as an index of 5-HT neuronal activity was studied by determining the effects on 5-HTP accumulation after administering 5-HT agonists (viz., quipazine, chlorimipramine and fenfluramine) and 5-HT antagonists (viz., metergoline, pirenperone and pizotifen). The effects of these drugs on the accumulation of the dopamine (DA) precursor dihydroxyphenylalanine (DOPA) and L-trp were also studied.

The in vivo rate of 5-HT and DA synthesis was determined in the nuclei caudatus putamen, accumbens, amygdaloideus centralis and septi lateralis of male rats (175-300 g) by measuring the concentration of 5-HTP and DOPA after the administration of NSD 1015 (100 mg/kg, i.p.). 5-HTP, DOPA and L-trp were analyzed by high pressure liquid chromatography coupled to an electrochemical detector.

In the absence of NSD 1015 pretreatment, 5-HTP and DOPA were not readily detectable in any brain region studied. However, both of these neurochemicals accumulated after NSD 1015 treatment in a time-dependent manner. Administration of L-trp 60 minutes before sacrifice increased 5-HTP, but not DOPA, in a dose-related manner. Chlorimipramine, fenfluramine and quipazine all decreased 5-HTP, but had no effect upon DOPA in NSD 1015 and L-trp-treated animals. Chlorimipramine produced these effects in a dose-related manner only after L-trp loading and without affecting brain concentrations of L-trp. The three 5-HT antagonists each had a unique effect. Pizotifen increased 5-HTP in a dose-related and time-dependent manner, but did not alter DOPA or L-trp. Metergoline increased 5HTP and DOPA, and decreased L-trp in a dose- and time-dependent manner. Pirenperone increased 5-HTP and DOPA, and had no effect on L-trp. These effects were also time- and dose-related.

These results suggest that: 1) the measurement of 5-HTP after L-trp administration and LAAD inhibition might serve as a useful index of 5-HT synthesis; 2) three 5-HT agonists all decreased 5-HTP, but neither DOPA accumulation nor L-trp concentrations; and 3) three 5-HT antagonists affected 5-HTP, DOPA and/or L-trp. (This work was supported in part by USPHS Grant NS 15911).

18.6 IMMUNOCYTOCHEMICAL AND BIOCHEMICAL ANALYSIS OF THE BULBOSPINAL SEROTONINERGIC PATHWAY AFTER NEONATAL 5,7-DHT LESION. EFFECTS OF MONOSIALOGANGLIOSIDE GM_1. G. Vantini*, M. Fusco*, B. Figliomeni*, R. Zanoni*, H. Hallman*[1], G. Jonsson [1] and A. Gorio (SPON: A. Cangiano). Fidia Research Laboratories, 35031 Abano Terme, (PD), Italy and [1]Dept. of Histology, Karolinska Institutet, Stockholm, Sweden.

The potential role of the monosialoganglioside GM_1 in promoting regeneration and restoration of functions following lesions to the nervous system has derived recent impetus from positive results obtained in many laboratories. In this study, the effect of GM1 on the alterations of the bulbospinal serotoninergic system induced by 5,7-dihydroxytryptamine (5,7-DHT) was investigated. 5,7-DHT (50 mg free base/Kg s.c.) was administered within 4-8 h after birth, thereafter the rat pups received four injections of saline or GM_1 (30 mg/Kg s.c.) daily from postnatal day 1 to 4. All the analysis were performed in two month old rats. Neonatal administration of 5,7-DHT caused a marked decrease of 5-HT and 5-HIAA contents in the thoracic and lumbar spinal cord (-40%), conversely, in the medulla-pons, 5-HT and 5-HIAA were increased (+30%; "pruning effect"). These alterations detected by HPLC-ED were reflected by decreases and increases respectively of the number of 5-HT nerve terminals as demonstrated by quantitative immunocytochemical analysis using antibodies against 5-HT. Moreover, in thoracic and lumbar cord sections of lesioned animals 5-HT fibers showed swollen varicosities and their general organization seemed disrupted. Neonatal administration of GM1 did not have significant effects on 5-HT neurons. However, GM_1 showed a pronounced counteracting effect on the alterations induced by 5,7-DHT. In thoracic and lumbar segments, the levels of 5-HT and 5-HIAA were almost normal as if regeneration of 5-HT fibers was stimulated by GM_1 treatment. Preliminary data indicate that 5,7-DHT lesion produce apparent changes in binding parameters of the high affinity component of $5\text{-}HT_1$ binding sites in the lumbar spinal cord. GM1 administration was still effective in reducing such alterations. These data indicate that GM_1 may have normalizing and/or regenerative effects and further support the hypothesis that GM_1 may play a role in CNS repair processes after injury.

18.7 IMMUNOCYTOCHEMICAL ANALYSIS OF SEROTONINERGIC REINNERVATION IN THE VENTRAL HORN OF THE RAT SPINAL CORD, AFTER NEONATAL 5,7-DIHYDROXYTRYPTAMINE LESIONING. EFFECT OF GM_1 GANGLIOSIDE TREATMENT. M.G. Nunzi, D. Guidolin*, P. Polato*, M. Fusco* and A. Gorio. Lab. Of Neurobiology, Fidia Research Labs., 35031 Abano Terme, Italy.

The capability of GM_1 monosialoganglioside to enhance regenerative growth of the bulbospinal serotoninergic system was evaluated, at various times after birth, following neonatally degeneration induced by 5,7-dihydroxytryptamine (5,7-DHT, 50 mg/kg s.c.). In particular, morphometric changes in serotonin (5-HT)-positive varicosities were quantified, via computerized image analysis, in the laminae VIII and IX of the spinal cord, following immunocytochemical staining with monoclonal antibody to 5-HT and PAP tecnique. The mean areas of 5-HT varicosities in non-lesioned control and 5,7-DHT lesioned animals, either treated with saline or GM_1 (30 mg/kg s.c. from postnatal day 1 to 4) are reported in the Table. Results indicate that the post-natal development, from day 17 to day 60, of 5-HT fibers is characterized by a 60% increase in the size of the 5HT varicosities. However, in the animals injected with 5,7-DHT no varicosities were detectable at postnatal day 17. In addition, at longer post-natal times, these animals displayed a statistically significant reduction in the size of the 5-HT varicosities. Treatment with GM_1 did not interfere with the primary degenerative action of 5,7-DHT. However, at postnatal day 30 and 60, a significant increase in the size of 5-HT varicosities occurred in GM_1 treated animals.

Electron microscopy analysis of the 5-HT varicosities, in adult rats, indicated that the above varicosities were mainly presynaptic terminals associated with motoneurons. As such, the decreased size of 5-HT varicosities observed in the lesioned saline-treated animals may represent a structural immaturity of the regrowing 5-HT-fibers. This immaturity is not present in 60 day old animals treated with GM_1, thereby indicating a facilitatory effect of GM_1 treatment on synaptic maturation of the regrowing 5HT axons.

	CONTROL	LESIONED	TREATED
17 days	1.20 ± .04 μm^2	------	------
30 days	1.24 ± .04 μm^2	.90 ± .03 μm^2	1.11 ± .04 μm^2
60 days	1.87 ± .08 μm^2	1.20 ± .05 μm^2	1.80 ± .04 μm^2

18.8 CHARACTERIZATION OF [3H]KETANSERIN (SEROTONIN-2) BINDING SITES IN CHICK EMBRYO BRAIN. J.S. Soblosky, G.D. DuMontier* and I. Jeng. Neurochemistry Unit, Missouri Institute of Psychiatry and Department of Biochemistry, University of Missouri-Columbia, School of Medicine, St. Louis, MO 63139.

Utilizing [3H]ketanserin and 2 µM cinanserin to define nonspecific binding, saturable, specific high affinity binding sites were detected in the chick embryo brain. When measured at three different times (days of incubation) during embryonic development the binding sites were found to develop linearally: 13 days: B_{max} = 1.57 pmol/g., K_D = 3.7 nM; 16 days: B_{max} = 2.30 pmol/g, K_D = 4.4 nM; 20 days: B_{max} = 4.50 pmol/g, K_D = 5.2 nM. In the "20 day old" chick embryo, regional investigations revealed the following proportions in the number of specific binding sites - cerebellum:optic lobes:cerebral cortex:remainder = 1:2:2.4:3.

The specificity of various displacing ligands, in terms of IC_{50} values, suggested that [3H]ketanserin binding sites in the chick embryo brain may be similar, but not identical, to the serotonin-2 receptors reported in the rat frontal cortex (Leysen et al. (1982) Mol. Pharm. 21: 301). IC_{50} values: ketanserin = .9 nM, spiperone=.2 nM, pizotifen (BC-105) = 30 nM, cinanserin = 100 nM, methysergide = 100 nM, 5-HT = 1 µM.

When compared to our previous results regarding [3H]5-HT binding site development (Soblosky & Jeng (1985) J. Neurochem. 44: 544), the present results suggest that there are also serotonin-2 binding sites in the chick embryo brain, which are present in a smaller number and appear later in embryonic development than the [3H]5-HT binding sites.

18.9 **INNERVATION OF EMBRYONIC CEREBRAL CORTEX BY SEROTONERGIC NEURONS IN VITRO.** A. R. Aitken* and I. Törk* (SPON: C. Straznicky), School of Anatomy, University of New South Wales, Kensington 2033, Sydney, Australia.

The serotonergic system is one of the earliest developing neurotransmitter systems in the mammalian brain. The axons of brainstem serotonergic neurons reach the cerebral cortex a few days after the establishment of neurotransmitter identity. In the present study some of the guidance mechanisms by which serotonergic fibres find their way to cerebral cortex were examined.

Explants of embryonic serotonergic neurons from the dorsal raphe were cultured separately and co-cultured with embryonic cerebral cortex on a substratum of poly-L-lysine. The interactions of serotonergic neurons with cerebral cortex were observed using early to late embryonic material (E12-19) that was maintained for 7 days in vitro. Serotonergic neurons were identified using a monoclonal antibody against 5-hydroxytryptamine in conjunction with the avidin-biotin peroxidase procedure.

Serotonin immunoreactive fibres displayed spontaneous radial outgrowth from explants of dorsal raphe, forming a vast anastomotic plexus of varicose fibres in the explant and within the outgrowth zone. The outgrowth of serotonergic fibres was accompanied by a concomitant migration of non-immunoreactive neurons and glia from the perimeter of the explant which formed a carpet of cells beneath the serotonergic fibres. Within the outgrowth zone serotonergic fibres maintained preferential contact with these migrating cells avoiding direct contact with the culture substratum. Finally, many non-immunoreactive cells within the outgrowth zone appeared surrounded by a dense plexus of serotonergic fibres and varicosities.

When embryonic dorsal raphe and cerebral cortical explants were co-cultured the outgrowing serotonergic fibres did not show preferential growth towards the cortical explant. Instead, they continued their radial outgrowth observed in single cultures of dorsal raphe, growing in all directions including into the cortical explant. After reaching explants of embryonic cerebral cortex, serotonergic fibres were observed to colonize the surface of the explant before growing further inwards. No special enhancement of serotonergic fibre proliferation was noticed after contact with the cortical explant.

These observations indicate that embryonic serotonergic neurons possess an intrinsic capacity for spontaneous neurite extension and elongation. This urge for outgrowth is not influenced by soluble target factors produced by cerebral cortex. In contrast the evidence suggests that the guidance of serotonergic fibres depends on local recognition of specific membrane constituents apposing the serotonergic growth cone.

18.10 EVIDENCE FOR A 5-HT INVOLVEMENT IN VASOPRESSIN RELEASE FROM NEUROHYPOPHYSIS OF RATS. L. Steardo*[1,2,3] M. Iovino*[1], E. Hunnicutt[3], Dept. Neurology, 2nd Medical School, Naples, Italy[1], Dept. of Neurology, Harvard Medical School[2], and Dept. of Neurology, Mass. General Hospital, Boston, MA 02114[3]

There is evidence that serotonin (5-HT) may play a role in the mechanisms controlling thirst and water balance. In fact electrolytic lesions of the dorsal raphe nucleus (DR), in rats an important site of 5-HT neuronal cell bodies in the brain, produce significant increases of daily urine output and water intake, whereas electrical stimulation of DR results in a diminished diuresis. The present experiments were designed to pharmacologically investigate whether brain 5-HT participates in the regulation of vasopressin (ADH) secretion. For this purpose plasma ADH levels were measured in rats treated with drugs enhancing 5-HT transmission, such as d-fenfluramine and quipazine, and with 5-HT depleting drugs, p-chlorophenylalanine (PCPA) and 5,7-dihydroxytryptamine (5,7-DHT). Forebrain 5-HT, noradrenaline (NA) and dopamine (DA) were also measured.

1. In a first group of rats, plasma ADH concentrations were measured after quipazine maleate (5,10 or 20 mg/kg) or d-fenfluramine hydrochloride (5,10 or 20 mg/kg) administration. Controls received saline injections alone.
2. In a second group of animals, plasma ADH concentrations were determined 60 min after quipazine (10 mg/kg) or 30 min after d-fenfluramine (10 mg/kg) administration in rats pretreated with PCPA (300 mg/kg), or saline.
3. In a third group of rats, plasma ADH concentration and forebrain catecholamines and 5-HT were determined 14 days after i.c.v. administration of 150 ug of 5,7-DHT. Controls received desipramine (25 mg/kg i.p.) and an equal volume of vehicle i.c.v.
4. In a fourth group of rats, plasma ADH levels, forebrain catecholamines and 5-HT were measured 60 and 40 min after PCPA (300 mg/kg) administration. Controls received saline. The rats of the third and fourth groups were also water-deprived 24 h before sacrifice to induce ADH release.

Quipazine and d-fenfluramine induced dose-related increases in plasma ADH levels in normally hydrated rats. The stimulatory effect of both quipazine (10 mg/kg i.p.) and d-fenfluramine (10 mg/kg i.p.) on ADH release was completely prevented in normally hydrated rats by pretreatment with PCPA. In water-deprived rats receiving PCPA or 5,7-DHT, 5-HT forebrain levels decreased while NA and DA were unchanged. Both these treatments blocked the elevation of plasma ADH normally induced by water deprivation. The results summarized imply that serotonin is a part of the apparatus for the physiological release of ADH from neurohypophysis.

18.11 SEROTONERGIC DORSAL RAPHE NEURONS: REDUCED SENSITIVITY TO AMPHETAMINE WITH LONG-TERM TREATMENT. B.A. Heidenreich*, A.E. Basse and G.V. Rebec (SPON:R.M. Wightman). Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Dopamine (DA)-containing neurons in the substantia nigra and ventral tegmental area respond to amphetamine with a dose-dependent inhibition of firing rate. This response is attenuated during long-term treatment. In fact, multiple amphetamine injections produce a clear shift to the right of the inhibitory dose-response curve and, in some cases, shift the neuronal response to an excitation. This change in responsiveness, which appears to be mediated in part by a subsensitivity of DA autoreceptors, has been implicated in the behavioral alterations associated with chronic amphetamine treatment (Rebec, G.V., Monogr. Neural Sci.,10:207, 1984). Serotonin (5-HT) also has been implicated in these behavioral changes although relatively little information is available concerning the effects of this drug on the activity of 5-HT neurons. In the present series of experiments, therefore, we characterized the actions of both acute and long-term amphetamine administration on the firing rate of 5-HT neurons in the dorsal raphe nucleus (DRN).

Adult, male rats received twice daily injections of saline, 1.0 or 5.0 mg/kg d-amphetamine sulfate for 6 consecutive days. On the following day, the animals were prepared for single-unit recording and 5-HT neurons were identified according to previously described electrophysiological and histological criteria (e.g., Wang, R.Y. & Aghajanian, G.K., Brain Res.,132:186, 1977). Following the isolation of single-unit discharges, d-amphetamine was administered intravenously in increasing incremental doses beginning with 0.125 mg/kg until unit activity was inhibited by more than 50%. In control rats, this degree of inhibition was achieved with a mean cumulative dose of 1.6 mg/kg. Rats pretreated with amphetamine, on the other hand, were progressively less responsive. In fact, the mean cumulative dose required to suppress DRN activity in rats pretreated with the high dose of amphetamine was 3.0 mg/kg. These results indicate that, like midbrain DA cells, 5-HT neurons in the DRN lose their sensitivity to amphetamine with long-term treatment. To the extent that this drug facilitates the local release of 5-HT and that this effect is responsible for the amphetamine-induced inhibition in the DRN, the decreased responsiveness to amphetamine may reflect, at least in part, a reduction in the sensitivity of 5-HT autoreceptors. This effect would have important implications for understanding the role of 5-HT in the behavioral alterations produced by long-term amphetamine treatment.

This research was supported, in part, by USPHS Grants DA 02451 and RR 7031.

18.12 THE CENTRAL ACTIVITY OF TR2515 A QUINAZOLINEDIONE DERIVATIVE. *Barragán,LA.;*Galindo-Morales, J.A.;and *Hong,E.-(Spon:*Pacheco Carrasco, M.).- Centro Universitario de Investigaciones Biomédicas, Universidad de Colima, Apdo.Postal No.199, Colima,Col.,México;Depto de Farmacología,Fac.de Medicina,U.N.A.M.,México; Unidad de Terapéutica Experimental, Depto.de Farmacología y Toxicología, CINVESTAV, I.P.N., México.

It was previously reported (Barragán, etal., Proc.West.Pharmacol. Soc.27:329,1984) that the 2,4(1H,3H) quinazolinedione, 3-3-4(phenyl -1-piperazinyl)-propyl hidrochloride (TR2515) was highly effective in antagonizing the so called serotonin (5-HT) behavioural syndrome. Sveral lines of evidence had relate this 5HT syndrome with the specific activation of S_2 subtype of 5HT receptors (Peroutka et al, Science 212:827,1981). With the aim to evaluate the antagonist activity of TR2515 at different functional levels, experiments were undertaken on well established 5-HT agonist effects in several parallel series: 1)Behavioural open field observations of rats under harmaline (20mg/Kg) or quipazine (20 mg/Kg) effects and its interaction with methysergide (0.5 mg/Kg) or TR2515 (0.1mg/Kg); 2)Rat EEG analysis of the wake sleep cycle under same experimental conditions was carried out; and 3) At the neuronal cell level by means of microiontophoretic application of 5HT, quipazine, or harmaline as agonists and their interactions with methysergide and TR2515. Sites explored for unit neuronal activity were: the 5HT containing neurons of the dorsal raphe nucleus (DRN), 5HT target cells of the cerebral cortex, and the medial and dorsal subnucleai of the inferior olive (dION, mION) of the rat. We followed conventional techniques for each manipulation serie and animal care as established.(NIH Guide for Grants and Contracts, Vol.7,No.17,Nov.1978, App.1). The results confirm the antagonism exerted by TR2515 to the behavioural effects induced by quipazine and harmaline, in addition, this drug led to a significant diminution of the spontaneous activity not presented with methysergide. The sleep suppressive effects of quipazine and harmaline were prevented by TR2515 being of a higher effectiveness on the quipazine interaction although REM sleep was delayed on its onset, total REM time was not modified. DRN total inhibition of the cell firing induced by 5-HT (20nA) and quipazine (20nA) was prevented and reverted by continuously ejection of TR2515 (5nA). dION and mION cell rhythmic activation by harmaline and quipazine were also antagonized by TR 2515. This drug effectively antagonized cortical cell excitation elicited by 5-HT or quipazine, however, it was ineffective over inhibitory cell responses. In contrast, methysergide exerted its antagonism in both cell response types, but inconsistently. This results led us to assume that the quinazolinedione derivative antagonizes 5HT by a possible specific interaction with the S_2 5HT receptor subtype.

18.13 **SIMILARITIES IN THE STIMULUS EFFECTS OF 8-HYDROXY-2-(DI-N-PROPYLAMINO)TETRALIN (8-OHDPAT), BUSPIRONE, AND TVX Q 7821: IMPLICATIONS FOR UNDERSTANDING THE ACTIONS OF NOVEL ANXIOLYTICS?** K. A. CUNNINGHAM, P. M. CALLAHAN and J. B. APPEL. Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, SC 29208.

The "partial ergoline" 8-OHDPAT has effects characteristic of a serotonin agonist: that is, it decreases serotonin turnover, produces the "serotonin syndrome" and is a potent inhibitor of serotonin-1, especially serotonin-1A, binding. In contrast to other serotonin agonists, however, 8-OHDPAT releases punished responding, stimulates male sexual behavior and, in animals trained to discriminate either d-lysergic acid diethylamide (LSD), trifluoromethylphenylpiperazine (TFMPP) or MK 212 from saline, elicits saline-lever responding. To further clarify the mechanism(s) of action of 8-OHDPAT, rats (N=24) were trained to discriminate this agent (0.4 mg/kg, i.p.) from saline and were given various neuroactive compounds during substitution (generalization) test sessions. Of the serotonin agonists tested, neither LSD (0.08-0.24 mg/kg), 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) (0.5-4.0 mg/kg), MK 212 (0.25, 0.5 mg/kg), quipazine (0.5-2.0 mg/kg), Ru 24969 (0.5, 1.0 mg/kg) nor TFMPP (0.25-1.0 mg/kg) substituted for the training drug; the dopamine agonist apomorphine (0.0625-0.25 mg/kg) and the alpha-2 noradrenergic agonist clonidine (0.2, 0.4 mg/kg) also engendered saline-lever responding. However, the atypical anxiolytics buspirone (0.5-4.0 mg/kg) and TVX Q 7821 (1.0-4.0 mg/kg) completely mimicked the 8-OHDPAT cue. In combination tests, the serotonin antagonists metergoline (0.5-2.0 mg/kg), methiothepin (0.125-0.5 mg/kg) and pirenperone (0.02-0.08 mg/kg) as well as the dopamine antagonist haloperidol (0.25 mg/kg) failed to attenuate responding on the drug-appropriate lever.

Since the similar stimulus properties of 8-OHDPAT, buspirone and TVX Q 7821 are mirrored by the common abilities of these agents to potently inhibit serotonin-1 but not serotonin-2 binding, to produce the serotonin syndrome and to release punished responding, modulation of serotonin-1 (serotonin-1A?) neuronal systems may account for the similar behavioral effects of novel anxiolytics. However, such a conclusion must be tempered by the lack of sufficient antagonism data and the fact that possible interactions of all of these agents with other neuronal systems have not yet been investigated extensively.

18.14 SEROTONIN AUTORECEPTORS: BIOCHEMICAL CHARACTERIZATION AND EFFECTS OF ANTIDEPRESSANTS, M.P. Galloway, and technical assistance from E.A. Novak* & R.A. Lodhi*, Neurochemical Pharmacology Research Unit, Lafayette Clinic, and Dept. of Psychiatry, Wayne State University, Detroit, MI 48207

To understand those factors that influence presynaptic activity of serotonin (5HT)-containing neurons, the neurochemical pharmacology of 5HT synthesis and metabolism has been studied in the rat CNS by determining the acute effects of 5HT agonists,antagonists, and uptake blockers on 5HTP accumulation and 5HIAA levels in different 5HT terminal fields. To measure the effect of agonists on 5HTP synthesis, animals were treated with the decarboxylase inhibitor NSD-1015 and different doses of 8-OHDPAT (8-hydroxy-2-(di-n-propylamino)tetralin), MDMT (5-methoxy-dimethyl-tryptamine), or TFPP (1-(m-trifluoromethyl-phenyl) piperazine) and levels of 5HTP, 5HT, and 5HIAA then determined by HPLC-EC. It was found that each agonist produced a dose-dependent (10-1000 ug/kg) decrease in 5HTP levels in the striatum, hippocampus, brain stem, medial prefrontal, piriform, and temporal cortices. In terms of regional responses to the synthesis-suppressant effect of 8-OHDPAT (100 ug/kg), the most sensitive area was the prefrontal cortex (-62%) whereas the least sensitive area tested was the brain stem (-19%). Acute administration of zimelidine (ZIM, 5 mg/kg), an antidepressant preferentially blocking 5HT reuptake, uniformly decreased 5HTP synthesis by 40-50%. Striatal, but not hippocampal, DOPA was increased (64%) after ZIM, a phenomena that was reversed by coadministration of 8-OHDPAT (500 ug/kg). Depletion of monoamines with reserpine pretreatment did not substantially alter basal 5HTP synthesis. These findings suggest that 5HTP synthesis in vivo is subject to modulation after stimulation of somatic or terminal 5HT autoreceptors and that regional differences in sensitivity may exist.

Chronic administration of 5HT uptake inhibitors has been reported to decrease the rate suppressant effects of LSD on dorsal raphe 5HT neurons (de Montigney et al 1984). To assess the biochemical correlate of this phenomenon, the effect of 8-OHDPAT on 5HTP synthesis was determined after ZIM treatment (13 days, 5 mg/kg/day ip). In preliminary studies, basal rates of synthesis were increased in the cortex (20%) and hippocampus (36%) after ZIM, however the inhibitory effects of 8-OHDPAT (10 or 100 ug/kg) on 5HTP, expressed as percent of relative control, was not significantly different in these areas. The decrease in 5HIAA levels after 8-OHDPAT, however, was less in subjects treated with ZIM. Thus, basal synthesis rates and the 5HIAA response indicate a decreased responsivity whereas the similar 5HTP response to agonist may indicate differences between LSD and 8-OHDPAT or between autoregulation of firing rate and 5HTP synthesis. Supported by Dept. of Mental Health, State of Michigan.

18.15 A PARTIAL CHARACTERIZATION OF THE RAT SPINAL CORD SEROTONIN (5HT) AUTORECEPTOR. L.M. Brown and D.J. Smith. Dept. of Pharmacology/Toxicology and Anesthesiology. WVU Med. Cent., Morgantown, WV 26506

Serotonergic compounds capable of interacting with the multiple subtypes of the 5HT-1 receptor were examined for their ability to directly alter ^{3}H-5HT release or to effect depolarization-induced (K^+-evoked) release from rat spinal cord synaptosomes. The compounds included the 5HT-1B preferring drugs 1-(m-trifluoromethylphenyl) piperazine (TFMPP) and 1-(m-chlorophenyl) piperazine (mCPP) (Sills et al. JPET 231:480, 1984) and the 5HT-1A preferring drug 8-hydroxy-2 (di-n-propylamino) tetralin (8-OH-DPAT)(Middlemiss and Fozard EJP 90:151, 1983). Two nondiscriminative compounds serotonin and lysergic acid diethylamide (LSD) were also studied.

A preparation of isolated nerve terminals (synaptosomes) from rat spinal cord tissue was used. The synaptosomes were suspended in Tris-buffered Krebs medium at 37°C and the tissue serotonin was labelled by incubation with 100 nM 3H-5HT for 10 minutes. Aliquots were then transferred to columns containing Sephadex G-15 as a solid support and were continuously superfused with oxygenated buffer containing fluoxetine (1μM). After 50 min, the tissue was exposed to buffer containing various concentrations of drugs for 20 min. This exposure allowed an assessment of the ability of the drugs to directly induce serotonin release. Then the tissue was superfused with buffer containing elevated K^+ (15 mM) as well as the drugs to determine if depolarization induced transmitter release might be modified.

None of the drugs tested were found to directly induce ^{3}H-5HT release. However, several of the compounds did alter depolarization induced release. For example, LSD, in a manner similar to that previously observed for 5HT (Monroe & Smith, Abs. Soc. Neurosciences 10:419, 1984), produced a dependent depression of K^+ stimulated 5-HT release that was reversed by quipazine, a putative 5 HT-1B antagonist (LSD at 0.1 and 1μM reduced ^{3}H-5HT release to 77.8 ± 6.9 and 70 ± 5.8% of control, no drug; while in the presence of quipazine the values were 93 ± 8.1 and 78 ± 4.1% respectively. The ability of a 1B antagonist to reverse autoreceptor effects supports the proposal that the 1B site may function as the autoreceptor.

Additional support comes from preliminary studies with the drugs that preferentially interact with specific receptor subtypes. For example, mCPP and TFMPP, 1B preferring drugs, depress K^+-evoked 5-HT release to about 76 & 80% respectively at 1μM drug. The 5HT-1A preferring drug, 8-OH-DPAT, did not alter evoked release except in concentrations that non-specifically altered serotonergic nerve function, as indicated by a drug-induced increase in both ^{3}H-5HT and ^{3}H-5HIAA effluxes.

18.16 BIOCHEMICAL CHARACTERIZATION OF SEROTONIN (5HT) STIMULATED PHOSPHOINOSITIDE (PI) HYDROLYSIS. P.J. Conn and E. Sanders-Bush. Dept. of Pharmacology, Vanderbilt University Sch. of Medicine and Tennessee Neuropsychiatric Institute, Nashville, TN 37232.

Neurotransmitter induced hydrolysis of phosphoinositides has been proposed to be a multifunctional transducing mechanism for generating several important intracellular signals including calcium fluxes, increased arachidonate metabolism, increased cyclic GMP, and protein kinase C activation. 5HT stimulates PI hydrolysis in blowfly salivary gland, rat cerebral cortex, and rat aorta. This response is apparently mediated by the S_2 binding site in rat cerebral cortex and aorta. While it is generally assumed that stimulus induced increases in PI hydrolysis are the result of direct receptor mediated activation of phospholipiase C, there are a number of other mechanisms by which an agent could indirectly increase PI hydrolysis. These include: 1) Stimulus induced increases in arachidonate metabolism resulting in production of an arachidonate metabolite which stimulates PI turnover. 2) Stimulus induced release of another neurotransmitter which stimulates PI hydrolysis. 3) Stimulus induced increase in de novo synthesis of phospholipids resulting in a mass action increase in PI hydrolysis. We have initiated a series of studies aimed at elucidating the biochemical mechanism of 5HT's effect.

The accumulation of ^{3}H-inositol phosphate (IP) was measured in rat aorta and cerebral cortex in the presence of lithium. The cyclooxygenase inhibitor, indomethacin, did not inhibit the response to 5HT suggesting that this effect is not dependent upon formation of a cyclooxygenase product of arachidonate. Selective muscarinic, alpha-adrenergic, and H_1-histaminergic antagonists did not block 5HT induced increases in PI turnover. The presence of a cocktail of protease inhibitors consisting of phenylmethylsulfonyl fluoride (0.2 mM), leupeptin (1 μg/ml), and pepstatin (1 μM) did not potentiate the response to 5HT, suggesting that 5HT does not exert its effect by stimulating the release of a peptide neurotransmitter. Furthermore, the addition of 1 μM tetrodotoxin, a sodium channel blocker, did not inhibit 5HT induced PI hydrolysis, therefore, it is likely that this effect is independent of neurotransmitter release. These data suggest that 5HT does not exert its effect on PI hydrolysis by stimulating production of a cycloxygenase product or by stimulating release of another transmitter. It has yet to be determined if 5HT's effect upon PI turnover is dependent upon production of a lipoxygenase product of arachidonate or stimulation of de novo phospholipid synthesis. If these mechanisms are excluded, it can be concluded that 5HT elicits direct receptor mediated activation of phospholipase C.

18.17 AFFINITY OF INDOLE AND PIPERAZINE AGONISTS FOR 5-HT_{1A} RECEPTORS IN FRONTAL CORTEX OF THE RAT. L.S.Y. Tyau* and A. Frazer, Departments of Psychiatry and Pharmacology and VA Medical Center, Philadelphia, PA 19104.

Recent studies of the 5-hydroxytryptamine$_1$ (5-HT_1) receptor indicate that multiple subtypes, termed 5-HT_{1A} and 5-HT_{1B}, exist. Structurally dissimilar serotonin agonists, namely indole-and piperazine-type drugs, were found to have different selectivity for these subtypes; indole-agonists were either non-selective or showed selectivity for the 5-HT_{1A} subtype whereas piperazine-type agonists showed selectivity for the 5-HT_{1B} subtype (J. Pharmacol. Exp. Therap. 231:480, 1984). In the study cited, the subtype selectivity of these drugs was determined by measuring the inhibition they produced of the binding of the non-selective ligand ^{3}H-5-HT in the presence of both GTP and drugs that preferentially inhibited one of the subtypes.

An alternative way to evaluate the selectivity of these serotonin agonists would be to measure their inhibition of selective ligands. Recently, evidence was presented that ^{3}H-8-hydroxy-2-(di-n-propylamino) tetralin (^{3}H-DPAT) is selective for the 5-HT_{1A} receptor (Nature 305:140, 1983). Consequently, competition experiments using indole- and piperazine-agonists were conducted using this ligand. Saturation experiments indicated that the binding of ^{3}H-DPAT in the frontal cortex was to a single population of sites having an affinity for ^{3}H-DPAT of about 1nM. GTP produced a dose-dependent inhibition of ^{3}H-DPAT binding (IC_{50}, 20uM) such that specific binding was non-existent at concentrations of GTP greater than 0.5 mM. Because of this, competition experiments (15 concentrations) with the indole- and piperazine-agonists for ^{3}H-DPAT binding were done in the absence of GTP. The indole compounds, 5-HT, lysergic acid diethylamide (LSD), N,N-dimethyltryptamine (DMT), and 5-methoxy-N-N-dimethyltryptamine (5-MeODMT) inhibited ^{3}H-DPAT binding with IC_{50} values ranging from 1-100nM. The piperazine-agonists, quipazine, 1-(m-chlorophenyl) piperazine (mCPP) and 1-(m-trifluoromethylphenyl) piperazine (TFMPP), had IC_{50} values ranging from 150 to 5000nM. The order of potency of these drugs for inhibiting ^{3}H-DPAT binding - LSD = 5-HT > 5-MeODMT > DMT > TFMPP > mCPP > quipazine - is identical to their order of potency for the 5-HT_{1A} receptor as assessed previously by their inhibition of ^{3}H-5-HT binding. This separate study confirms that indole-agonists do have greater affinity for the 5-HT_{1A} subtype than piperazine-agonists do. (Supported by Research Funds from the VA and USPHS Grant MH29094).

18.18 IN VIVO AND IN VITRO INVESTIGATION OF NEWLY SYNTHESIZED DRUGS FOR 5-HT_1 AND 5-HT_2 RECEPTORS. R.A. Lyon*, M. Titeler, J.D. McKenney*, and R. Glennon* (SPON: D. POULOS). Dept. Pharmacol.Toxicol., Albany Medical College, Albany, New York 12208; Dept. Pharmaceutical Chem., Virginia Commonwealth University, Richmond, Va. 23298.

Brain serotonin receptors have been subdivided into 5-HT_1 and 5-HT_2 receptors based on their differing pharmacological properties (1). Recent data have revealed that the potencies of a series of phenylisopropylamine hallucinogens are strongly correlated with their potencies in animal drug discrimination tests; also there is a very strong correlation between hallucinogenic potency and affinity for the radiolabeled 5-HT_2 receptor(2). In order to design compounds with selectivity for 5-HT_2 and 5-HT_1 receptors, derivatives of phenylispropylamines and phenylpiperazines, which have been implicated as having a potential serotonergic structure, have been synthesized. These compounds are being screened for their ability to interact with brain 5-HT_1 and 5-HT_2 receptors labeled in vitro with ^{3}H-serotonin and ^{3}H-ketanserin respectively (table one).

Drug	K_i (nM) ^{3}H-serotonin	K_i (nM) ^{3}H-ketanserin
DM-4-72 (phenylisopropyl.)	1,710+/-249	207+/-34
DM-4-61 (phenylpiperazine)	148+/-7	17,170+/-1189
DM-1-50 (phenylpiperazine)	6+/-3	18+/-2

In general, it appears that phenylisopropylamines have higher affinity for 5-HT_2 than 5-HT_1 receptors. One of these, DOB(3), is currently being radiolabeled to be used as an agonist probe of the 5-HT_2 receptors. Among the phenylpiperazines there appear to be compounds with higher affinity for 5-HT_1 receptors than 5-HT_2 receptors. Animals are being trained to discriminate selective 5-HT_1 receptor and 5-HT_2 receptor drugs as they are developed. The results of further in vivo and in vitro screening of new compounds will be presented. It is anticipated that the functional roles of 5-HT_1 receptors (and possibly 5-HT_{1A} and 5-HT_{1B}, ref.4) and 5-HT_2 receptors will be revealed through the development of such selective drugs. 18.19 SEROTONERGIC DORSAL RAPHE NEURONS: ELECTROPHYSIOLOGICAL RESPONSES IN RATS TO 5-HT_{1A} AND 5-HT_{1B} RECEPTOR SUBTYPE LIGANDS. J.S. Sprouse* and G.K. Aghajanian. Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06508.

Radioligand binding studies have suggested the presence of multiple 5-HT_1 recognition sites termed 5-HT_{1A} and 5-HT_{1B} (Pedigo et al., J. Neurochem., 36: 220, 1981). Compounds selective for these "receptor subtypes" have been identified (Sills et al., J. Pharmacol. Exp. Ther., 231: 480, 1984). Autoradiographic localization of subtypes has disclosed high receptor densities within the septal area, the prefrontal and frontal cortex, the hippocampus and certain areas of the midbrain including the raphe nuclei (Deshmukh et al., Brain Res., 288: 338, 1983). However, little is known about the physiological significance of the multiple 5-HT_1 binding sites and the pharmacology of subtype-selective ligands.

Two long-chain substituted piperazines, TVX Q 7821 (Dompert et al., Naunyn. Schmied. Arch. Pharmacol., 328: 462, 1985) and LY 165163 (Asarch et al., Life Sci., 36: 1265, 1985) were chosen for use in the present study for their selective 5-HT_{1A} binding activities; two short-chain substituted piperazines, trifluoromethylphenyl piperazine (TFMPP) and m-chlorophenylpiperazine (mCPP) were chosen for their selective 5-HT_{1B} binding activities (Sills et al., 1984). Extracellular recordings were made from spontaneously active 5-HT neurons in the dorsal raphe nucleus of chloral hydrate anesthetized rats. Compounds were administered intravenously and the effect on firing rate observed.

The 5-HT_{1A} ligands uniformly inhibited raphe cell firing in a dose-dependent manner. For TVX Q 7821, the dose which reduced spontaneous activity by 50% was 9 ± 3 µg/kg (N = 5); for LY 165163, 42 ± 12 µg/kg (N = 5). In contrast, the 5-HT_{1B} ligands displayed weak or irregular actions: TFMPP in repeated doses ranging 25 - 400 µg/kg either had no effect on raphe cell firing, partially suppressed activity or occasionally caused a facilitation (N = 6). Similar responses were observed following repeated 250 µg/kg doses of mCPP (N = 7).

The efficacy of 5-HT_{1A} ligands was further demonstrated by intracellular recordings of dorsal raphe neurons in coronal brain slices maintained in vitro. TVX Q 7821 and LY 165163 mimicked the effects of 5-HT in hyperpolarizing cell membrane potential and decreasing input resistance (cf., Aghajanian and Lakoski, Brain Res., 305: 181, 1984).

Taken together, these data suggest that (1) dorsal raphe 5-HT neurons are highly responsive to 5-HT_{1A} ("autoreceptor agonists") but not 5-HT_{1B} ligands and (2) the biochemical, physiological and behavioral effects of the 5-HT_{1A} compounds may stem in part from their inhibitory action on raphe neurons.

18.20 SPIPERONE ALTERS THE EFFECT OF 5-HT ON POPULATION SPIKE AMPLITUDE IN RAT HIPPOCAMPAL SLICES. S. G. Beck, W. P. Clarke, and J. Goldfarb. Department of Pharmacology, Mount Sinai School of Medicine, New York, N. Y. 10029

Superfusion of rat dorsal hippocampal slices in vitro with serotonin (5-HT) reversibly decreases the amplitude of CA1 population spikes evoked by stratum radiatum stimulation. The magnitude of the 5-HT effect is stimulus-dependent and concentration-dependent with an EC_{50} of 3.2uM. In some experiments the decrease in population spike amplitude is preceded by a transient increase within the first 5 min of drug perfusion (Beck & Goldfarb, Life Sciences, 36, 1985, 557). In order to characterize the effects elicited by 5-HT we have been testing the actions of 5-HT antagonists in this system.

The 5-HT elicited changes in population spike amplitude were altered in the presence of 0.1 and 1.0 uM spiperone, although the effect of 0.1uM spiperone was not as pronounced. At either concentration, spiperone antagonized the 5-HT induced decrease in population spike amplitude, and it was possible to surmount at least partially the antagonism by increasing the 5-HT concentration (10-100uM). In addition, 10uM 5-HT invariably caused a transient increase in the population spike amplitude that lasted from 5-8 min, even when no increase was observed before perfusion with the antagonist. When the increase was present in control 5-HT responses, it was augmented during spiperone superfusion. The transient increase in population spike amplitude decreased as the concentration of 5-HT was increased (10-100uM). In the absence of 5-HT, spiperone did not affect the population spike amplitude.

The ability of spiperone to block differentially the 5-HT elicited decrease but not the increase in population spike amplitude is consistent with the hypothesis that these effects of 5-HT may be mediated by a heterogenous population of 5-HT receptors. In preliminary experiments 1.0uM ketanserin did not alter the 5-HT induced decrease in population spike amplitude. Therefore, we suggest that the decrease in population spike amplitude may be mediated by the 5-HT_{1A} receptor.

MONOAMINES AND BEHAVIOR II

19.1 SPONTANEOUS ACTIVITY OF STRIATAL NEURONS IS CORRELATED WITH RECOVERY OF BEHAVIORAL FUNCTION AFTER DOPAMINE-DEPLETING BRAIN LESIONS. E.S. Nisenbaum*, M.J. Zigmond, E.M. Stricker, and T.W. Berger. Psychobiology Program and Center for Neuroscience, University of Pittsburgh, Pgh, PA 15260. (SPON: A.R. Caggiula).

Near-total depletions of striatal dopamine (DA) in rats produced by intraventricular (ivt) administration of the neurotoxin 6-hydroxydopamine (6-HDA) result in profound behavioral deficits from which animals can gradually recover. Such lesions also induce presynaptic compensatory mechanisms, including increased DA synthesis and release, which may underlie the observed behavioral recovery (Zigmond, et al., Arch. Neurol., 41, 1984). The nigrostriatal DA system is inhibitory in nature, and electrophysiological studies have revealed increases in the spontaneous firing rate of striatal cells shortly after 6-HDA treatment (e.g., Orr, et al., Soc. Neurosci. Abstr., 8, 1982). Schultz and Ungerstedt (Exp. Brain Res., 33, 1978) also have demonstrated that striatal spontaneous activity in DA-depleted animals returns to normal more than 1-year later. The present study investigated two hypotheses: 1) that recovery of striatal activity is correlated with behavioral recovery, and 2) that striatal cell recovery is dependent on DA neurons remaining after the 6-HDA lesion.

Rats were injected ivt. with 200 ug of 6-HDA, dissolved in 0.9% NaCl and 0.1% ascorbic acid and extracellular single unit activity of Type II neurons was recorded from the striatum of these animals either 4-8 days or 27-38 days post-lesion. A control group of animals was injected ivt. with the vehicle solution and striatal activity was recorded 4-8 days later.

The spontaneous firing rates of striatal neurons recorded 4-8 days post-lesion from animals exhibiting behavioral deficits were significantly increased relative to neurons recorded from control animals. In contrast, striatal activity was not increased when recorded from animals that had recovered behaviorally by 27-38 days after the lesion. However, the spontaneous activity of striatal cells recorded from non-recovered animals 27-38 days post-lesion was significantly higher than levels seen in recovered and control animals, but not different than striatal activity recorded 4-8 days post-lesion. These results indicate that the recovery of striatal activity is positively correlated with behavioral recovery, and can occur much earlier than one year after the lesion. Finally, in an additional group of animals that had recovered from an earlier 6-HDA injection, a second injection of 6-HDA (100 ug) was administered. Firing rates of striatal neurons recorded from these animals were increased significantly relative to control levels, in association with marked behavioral deficits. The latter demonstrates that neural recovery is dependent on residual, intact elements of the DA system. Supported by NS19608.

19.2 DIFFERENT EFFECTS OF D-1 AND D-2 AGONISTS IN RATS WITH UNILATERAL STRIATAL LESIONS. P. Barone*, T.A. Davis*, A.R. Braun*, T.N. Chase. Experimental Therapeutics Branch, National Institute of Neurological and Communicative Disorders and Stroke, Bethesda, MD 20205.

The injection of excitotoxins into rat striatum may provide a behavioral, histological and biochemical model of Huntington's disease (HD) (Coyle J.T., Schwarcz, R., Nature 263: 244-246, 1976). Two weeks after the administration of kainic or quinolinic acid into one striatum, ipsilateral rotation can be induced by systemically administered dopamine agonists (L-dopa, apomorphine, pergolide). Here we report the characterization of this turning behavior through the use of relatively selective D-1 and D-2 agonists, SK&F 38393 and LY 171555, respectively.

Sprague-Dawley rats (200 gm) were placed in stereotaxic apparatus and lesioned with quinolinic acid (300 nM in 1 µl) injected into the left striatum (coordinates: 8.2 A, 2.6 L, 4.8 V). Two weeks later they were tested with apomorphine (0.5 mg/kg s.c.). Rats performing 200-230 turns/hr were selected for further experiments allowing one week intervals between treatments for wash-out.

The D-1 agonist, SK&F 38393 failed to induce rotation even at doses which produce behavioral effects such as grooming, sniffing, rearing, locomotor activity, non-object chewing. The D-2 agonist, LY 171555, induced only rotation, whose duration was dose-dependent, but none of the behavioral effects, characteristic of the D-1 agonist. After completion of the behavioral observations, acetyltransferase activities in the striatal tissues were measured to evaluate the amount of lesioning.

The present observations indicate a clear distinction between the behavioral effects of D-1 and D-2 stimulation in rats with intact DA receptors. In a different model where supersensitivity of DA receptors is produced by 6 OH-DA lesion of the median forebrain bundle, both D-1 and D-2 agonists induce rotation (Gerhanik, O. et al., Neurology 33, 1489-92, 1983).

SK&F 38393 seems to require supersensitivity of DA receptors to produce effects that do not occur in intact preparations. This observation is supported by neurophysiological evidences: SK&F has no significant effect on pallidal firing rates in normal animal. However, in the supersensitive rat, SK&F induces changes in pallidal firing comparable to those observed with apomorphine (Carlson, J.H., et al., Soc. for Neuroscience Abstract # 124.8, 1984).

19.3 DOPAMINE-INDUCED CONTRALATERAL CIRCLING FROM RAT OLFACTORY TUBERCLE. M.R.Szewczak*, M.Cornfeldt* and S.Fielding. Pharmacology Dept., Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ 08876.

Postural asymmetry and circling commonly result from manipulation of the nigrostriatal dopamine tract; the same has not been reported for the mesolimbic dopamine system. Unilateral lesions of the ventral tegmental area or the nucleus accumbens, as well as direct injections of dopamine agonists into the nucleus accumbens have all failed to cause postural asymmetry or circling.

In addition to the nuc. accumbens, the olfactory tubercles serve as terminal areas for mesolimbic dopamine neurons. We are now reporting that unilateral injection of dopamine (50 and 25 μg in 1 μl) into the olfactory tubercles of nialamide pretreated rats results in contralateral circling. A dose of 12.5 μg was ineffective. Circling developed gradually over a 2 hour period and then persisted for 3-4 hours. Norepinephrine (50 μg) was without effect. Systemic treatment with haloperidol (0.2 mg/kg,ip) and clozapine (20 mg/kg,ip) but not phentolamine (2 mg/kg,ip) or propranolol (5 mg/kg,ip) blocked the circling. These results suggest that the mesolimbic dopamine system shares control with the nigrostriatal system over the direction of locomotion. Circling induced from this area may also provide a valuable method for the evaluation of site specificity of antipsychotic agents.

19.4 LATERALIZED BEHAVIORAL AND BIOCHEMICAL EFFECTS OF UNILATERAL LESIONS OF DOPAMINE AND SEROTONIN NEURONS. R. J. Carey, Department of Psychiatry, SUNY and VA Medical Centers, Syracuse, NY 13210.

In an effort to determine the functional inter-relationship between dopaminergic and serotonergic innervation of the striatum, separate and combined denervations of these two neurotransmitter systems were performed. In adult male sprague-dawley rats unilateral injections of the neurotoxins 6-hydroxydopamine HBr (2µl of 3 µg/µl, base) and 5-7 dihydroxytryptamine creatnine sulfate (2 µl of 3 µg/µl, base) were made separately or together in animals pretreated with 25 mg/kg desmethylimipramine. Tests for lateralized sensory-motor disturbances included tests of responsivity to nociceptive stimulation applied to the ipsilateral versus contralateral body surface and measurements of turning tendencies. Also, measures of global behavior were evaluated by measurement of spontaneous motor activity. Unilateral lesions of dopamine neurons produced lateralized deficits in responsivity to nociceptive stimulation, persistent turning tendencies and decreased spontaneous motor activity. Combined lesions of dopamine and serotonin lesions attenuated the lateralized deficit in responsivity to nociceptive stimulation produced by the dopamine lesion alone but the motor asymmetry and decreased spontaneous motor activity was not affected. The unilateral serotonin lesions generally were without effect on the behavioral tests. The serotonin lesions both separately and in combination with the dopamine lesions produced marked effects on dopamine metabolism in the contralateral non-lesional hemisphere. Striatal dopamine and dopamine metabolites HVA and DOPAC were substantially increased by the destruction of serotonergic neurons in the contralateral hemisphere. These studies indicate both behavioral and biochemical influences of serotonin on dopaminergic systems in the brain.

19.5 A FOREBRAIN MAP OF DOPAMINE'S RELEVANCE TO LATERAL HYPOTHALAMIC STIMULATION REWARD AS BASED ON INTRACRANIAL NEUROLEPTIC INJECTION. J.R. Stellar, D. Corbett and A.L. Hamilton*. Department of Psychology and Social Relations, Harvard University, Cambridge, MA, 02138.

A great deal of evidence now exists to implicate dopamine in the reward effect generated by lateral hypothalamic (LH) brain stimulation. For example, sophisticated behavioral measurement techniques have revealed that systemic neuroleptic treatment degrades LH stimulation reward, apart from any motor/performance effects. As a refinement of the systemic treatment technique, brain injections of neuroleptic drugs into some discrete brain areas have been shown to disrupt self-stimulation behavior. However, in many of these brain injection studies reward degradation and general performance impairment effects of brain injection are confused due to the use of behavioral measures which do not separate these factors.

In this study, a high quality behavioral measure, the runway-based reward summation function (RSF) technique, was employed to quantitatively assess shifts in reward pulse effectiveness independently of impairments in performance capacity. (Stellar, Kelley, and Corbett, Pharmac., Biochem., Behav. 18: 433-442, 1983). The neuroleptic cis-flupenthixol was injected bilaterally into specific brain sites through chronic guide cannulae in conscious animals which were then immediately tested with the RSF technique. Two doses were employed: 0.5 ug/0.5 ul and 1.0 ug/0.5 ul dissolved in isotonic saline. Trans-flupenthixol (0.5 ug/0.5 ul saline), an inactive isomer, served as a control. As of this writing, 47 sites have been investigated in the caudate, putamen, the nucleus accumbens, the amygdala, and the frontal cortex.

By far the largest reward impairing effects were obtained from injections into the accumbens and surrounding ventral forebrain (N = 20). No effect was found from dorsal caudate injections (N = 5). The central caudate-putamen (N = 6), amygdala (N = 3), and frontal cortex (N = 6) injections produced small changes in reward pulse effectiveness. Very few motor impairments were seen following brain injection from any region, perhaps due to the small quantities of drug injected. Other brain sites of neuroleptic injection and the effects of selective 6OHDA lesions of dopamine in some animals cited above will also be presented.

Supported by NIH grant NS 17612.

19.6 EFFECTS OF LY163502, A SELECTIVE D_2-DOPAMINERGIC RECEPTOR AGONIST, ON COPULATORY BEHAVIOR OF MALE RATS. M. M. Foreman and J. L. Hall*. The Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN. 46285.

LY163502, trans(-)5,5a,6,7,8,9,9a,10 octahydro-6-propyl-pyrimido (4,5g) quinolin-2-amine dihydrochloride, is a potent and selective D_2-type dopaminergic receptor agonist that we have used to study the effects of dopaminergic receptor stimulation on sexual behavior. The male rats used in these studies were either sexually inactive (noncopulators), unable to achieve ejaculation (nonejaculators) or capable of ejaculation in a 30 min exposure to a receptive female rat. Subcutaneous injections of solutions containing various concentrations of LY163502 were made 30 min prior to behavioral evaluation. At doses of 0.25-25 µg/kg, 75% or more of the noncopulators displayed mounting behavior and at doses of 0.025-25 µg/kg, 50% or more of the nonejaculators were able to achieve ejaculation. In both cases, the effects of LY163502 were dose related. At doses of 0.025-25 µg/kg, statistically significant reductions in ejaculatory latency were observed in rats capable of ejaculation. At doses of 0.10 - 25 µg/kg, significant reductions in the number of mounts required for ejaculation were observed. The minimum effective doses for potentiation of sexual behavior in each of these experiments were at least 10 X lower than any other detectable response. At doses lower (2.5 ng/kg) or higher (25 mg/kg) than this dose range, inhibition of sexual behavior was observed. The inhibiton of sexual behavior observed at the low doses of LY163502 are characteristic of behavioral changes associated with autoreceptor activation. Dopaminergic autoreceptor activation is thought to be linked with the inhibition of endogenous dopamine secretion and thereby a suppression of dopamine-mediated behaviors. The inhibition of sexual behavior observed at 25 mg/kg was accompanied by profound stereotypic behavior, which was assumed to have disrupted sexual behavior by a nonselective overstimulation of CNS dopaminergic receptors. These data are supportive of the view that within a defined dose range D_2 dopaminergic receptor stimulation can induce the expression of sexual behavior and lower the response thresholds for erectile and ejaculatory reflexes.

19.7 DOPAMINE VARIATIONS ASSOCIATED WITH ACUTE AND CHRONIC STRESSORS. P. Ahluwalia*, R. M. Zacharko and H. Anisman. Dept. Psychology, Carleton University, Ottawa, Ontario, K1S 5B6, Canada.

Several experiments assessed the consequences of stressors of varying severity on norepinephrine (NE) and dopamine (DA) neuronal activity in several brain regions. Consistent with other reports, alterations of DA activity associated with stressors varied considerably across brain regions. In frontal cortex footshock appreciably increased the accumulation of the DA metabolite, DOPAC, and markedly reduced DA concentrations. Likewise, in the ventral tegmentum reductions of DA concentrations were readily provoked by stressors. In the nucleus accumbens DA utilization was increased, but a greater amount of aversive stimulation was necessary to provoke reductions in DA concentrations. In other DA rich regions, such as the caudate and substantia nigra, DA utilization and concentrations were unaffected by the stressor. The most pronounced stressor induced NE variations occurred in hypothalamus and locus coeruleus. As in the case of stressor provoked NE variations, controllability over the aversive stimulation appeared to influence DA activity; however, this effect appeared to vary with the brain region examined. While escapable shock provoked a small decline of DA in frontal cortex, a more pronounced DA reduction was evident after inescapable shock. In contrast, both escapable and inescapable shock were equally effective in altering DA concentrations in the nucleus accumbens. Thus, it appeared that the psychological dimension of coping contributed to the DA variations in the frontal cortex, while the stressor per se played a greater role in affecting the DA variations in the nucleus accumbens. Finally, adaptation was evident after repeated application of a stressor such that the reductions of DA and NE concentrations were absent in mice that had received 15 footshock sessions applied on successive days. These data paralleled several of the behavioral changes associated with stressors, thus provisionally supporting a role for DA variations in accounting for the stressor induced behavioral alterations.

19.8 PERIPHERAL ADMINISTRATION OF NOREPINEPHRINE FACILITATES RECOVERY FROM BRAIN DAMAGE. J.P. Ryan, C. Hardy,* J. Johnston,* J. Thomas,* and R.L. Isaacson. Dept. of Psychology and Center for Neurobehavioral Sciences, SUNY-Binghamton, Binghamton, NY 13901

A role for catecholamines in neural plasticity and behavioral recovery have been proposed by several researchers (Feeney, Gonzalez, & Law, Science 217: 855, 1982; Kasamatsu, Pettigrew, & Ary, J. Comp. Neurol. 185: 163, 1979). The various catecholaminergic treatments in these studies have involved intracerebral injections or drugs that readily cross the blood-brain barrier. Others, using nonlesioned animals, have demonstrated behavioral alterations following peripherally administered catecholamines that appear to have limited access to the brain (McCarty & Gold, Horm. & Beh 15: 168, 1981; Gold & van Buskirk, Horm. & Beh. 7: 509, 1976). The present study examined the effects of intraperitoneal injections of norepinephrine (NE) on the behavioral anomalies of hippocampally lesioned animals both before and after the induction of adrenergic supersensitivity.

Male Long-Evans Hooded rats were prepared with sham, neocortical, or hippocampal lesions by aspiration. Pharmacological treatments and behavioral testing began 21 days after surgery. The T-maze and open field apparati were used to measure spontaneous alternation and activity/exploratory behavior, respectively. Bretylium tosylate, a drug that inhibits the release of peripheral NE, was administered in order to induce a condition of adrenergic supersensitivity. NE (4 μg/kg) and a solution of tartaric acid/distilled water were injected on separate days prior to and after bretylium treatment. At the completion of testing clonidine (.1 mg/kg) was administered and colonic temperatures checked at 40, 60 and 80 min intervals. An enhancement of the clonidine-induced decrease in body temperature has been interpreted as an indicator of α-adrenergic supersensitivity (Isaacson, Youngue, & Carrera, Physiol. Psych 6: 236, 1978).

Animals with hippocampal lesions exhibited hyperactiviy in the open field as well as impaired ability to alternate between arms in the T-maze. The administration of NE following 4 days of Bretylium treatment significantly increased the amount of spontaneous alternation of these lesioned animals, however, NE was ineffective in normalizing the lesioned-induced hyperactivity. Both the activity level and the alternation were not affected by the initial NE administration prior to bretylium treatment. A condition of supersensitivity was established as indicated by the significant decrease in colonic temperature of the bretylium-treated animals in comparison to control animals. The results indicate that the rigid, perseverative behavior of hippocampally lesioned animals can be ameliorated by the peripheral administration of NE following the induction of supersensitivity.

19.9 EFFECTS OF DESIPRAMINE ON LOCUS COERULEUS NEURONS IN THE FREELY MOVING CAT. R.J. Ross,* G.L. Mann,* S. Yang,* J.H. Indik,* and A. R. Morrison (SPON: C.P. O'Brien). Dept. of Psychiatry, Vet. Admin. Med. Ctr. and Sch. of Veterinary Medicine, University of Penna., Philadelphia, PA 19104 U.S.A.

Effects of tricyclic antidepressant drugs on diverse forms of behavior, including paradoxical sleep (PS) architecture and the course of depressive illness, are often ascribed to noradrenergic (NA) mechanisms. With electrophysiological techniques, it has previously been demonstrated that the repeated administration of imipramine inhibits NA neurons in the locus coeruleus (LC) of the anesthetized rat (Svensson, T.H. and Usdin, T., Science, 202:1089-1091, 1978). While these results could have been influenced by the presence of anesthesia, use of the technique of single unit recording in the unrestrained, unanesthetized animal should eliminate such a source of variance. We have therefore begun a series of experiments in the unanesthetized cat, designed to compare the properties of LC neurons recorded following repeated desipramine (DMI) administration with those recorded under control conditions. The feline LC has been recognized as pharmacologically heterogeneous, but criteria have been suggested for identifying particular cells as NA on the basis of their prominent deceleration during PS (PS-off cells) (Parsons, T.D., et al., Soc. Neurosci. Abst., 9:560, 1983).

A microdrive assembly, for recording single cell activity, and EEG, EOG, EMG, and hippocampal electrodes, were implanted in 4 female cats under halothane anesthesia. Microwires were aimed at the region of the LC (P2.5, L3.0, V-3.0). The rate of discharge of each isolated neuron was studied over the entire sleep-wake cycle. Four PS-off cells, which were presumed to be NA, were recorded in 2 cats after the repeated administration of DMI (1 mg/kg p.o., b.i.d.) for periods of time ranging from 1 to 30 days (av. 18). Their average frequencies of discharge ranged from 0.51-1.39s^{-1} (mean 0.79s^{-1}) during the state of quiet waking (QW); from 0.41-0.77s^{-1} (mean 0.55s^{-1}) during slow wave sleep (SWS); and from 0.00-0.15s^{-1} (mean 0.05s^{-1}) during PS. These values compared with mean firing rates of 1.36, 0.60, and 0.08s^{-1}, respectively, of a control population of PS-off cells (Reiner, P.B., Ph.D. Thesis).

The activity of 1 neuron was recorded in both the undrugged and drugged states. Approximately 2 hours after the first dose of DMI, its frequency of firing was reduced by 10% of baseline during SWS. By the following day, the decrements in firing rate were 68% and 69% during QW and SWS, respectively.

These results, suggesting that chronic DMI administration may slow the firing of at least some norepinephrine-containing LC neurons, are consistent with earlier observations in the anesthetized rat.

19.10 DIETARY MANIPULATION OF D-AMPHETAMINE SELF-ADMINISTRATION IN RATS L.S. Geis*, D.G. Smith* and W.H. Lyness. Dept. of Pharmacology, Texas Tech Univ. Health Sciences Center, Lubbock, TX 79430.

It has been well documented that the addition or omission of the large neutral amino acids in a diet can alter human and animal behavior as well as the neurochemistry of brain monoamines. Of the monoamines, serotonin (5-HT) and dopamine (DA) have been shown to be of import in the maintenance of stimulant self-administration. DA appears to be crucial to the subjective experience of euphoria (reward), while the role of 5-HT is unknown. Lesions of ascending 5-HT neurons increase self-administration while i.p. injection of L-tryptophan (TRY), the 5-HT precursor, decreases drug intake. With this in mind, experiments were designed to test the hypothesis that a diet high in TRY might attenuate drug self-administration.

Rats were implanted with i.v. cannulae and allowed access to a device which delivered 0.125 mg/kg d-amphetamine with each lever press. After achievement of a steady daily response rate (55-98 inj./8 hr. (0900-1700 hr), the rats were divided into 2 groups; normal rat chow and identical chow supplemented to 4.0% TRY. Access to food was from 1700 to 0900 hr. Animals on the supplemented diet, when allowed access to the self-administration apparatus, exhibited a profound decrease in drug intake. When the diet was continued for 3 days, on each successive day amphetamine self-injection was reduced (range; 0-40 injections/ 8 hr). With the reinstatement of the normal rat diet, the recovery to pre-diet drug intake appeared slow to return to normal (3 days) although whole brain 5-HT concentrations appeared normal much sooner (1 day post-diet). One animal which disconnected its i.v. line exhibited an increased rate of lever pressing while on the diet which is characteristic of an extinction response. This suggests that the diet does not produce sedation or decrements in motor performance which could lead to decreased responding. Experiments will be performed to: 1) establish a minimal TRY supplementation that reduces drug intake, 2) determine whether tolerance develops with long term dietary changes and 3) to determine possible mechanisms for the phenomenon.

Further experimentation includes dietary manipulation of L-tyrosine, precursor to both norepinephrine (NE) and DA, and the examination of both behavior and neurochemistry. In preliminary experiments, i.p. injection of tyrosine restores brain NE concentrations which were reduced by prior amphetamine injections. It remains to be determined whether dietary supplements will alter drug intake.

19.11 LOCUS COERULEUS UNIT ACTIVITY IN BEHAVING CATS: HABITUATION OF RESPONSES EVOKED BY SIMPLE SENSORY STIMULI. B.L. Jacobs and K. Rasmussen. Prog. in Neurosci., Princeton Univ., Princeton, NJ.

Brain noradrenergic (NE) neurons in the area of the locus coeruleus (LC) are responsive to a variety of afferent inputs. In the course of studying NE-LC neurons in freely moving cats, we noted that their single unit response to repetitive presentation of clicks or flashes appeared to show rapid habituation. The present study examined this relationship in greater detail. For comparison, we also examined the response of serotonergic (5HT) neurons in the dorsal raphe nucleus and dopaminergic (DA) neurons in the pars compacta of the substantia nigra. Single unit activity was recorded by means of bundles of movable 32 and 64 μm dia, wires implanted in the LC. Neurons in the area of the LC were initially identified as NE by their long duration action potentials, slow and somewhat regular discharge pattern, excitation-inhibition response to pinch, and complete cessation of activity during REM sleep. This identity was confirmed further by the complete suppression of neuronal activity following injection of the α_2 agonist clonidine. Finally, all neurons displaying such characteristics were histologically localized within the LC (this characteristic activity was not encountered on penetrations outside of the LC). Cats were exposed to a series of 64 auditory or visual stimuli presented once every two sec. Auditory stimulation consisted of a 1 msec duration 113dB pulse. Visual stimulation consisted of flashes of approximately 1.5 x 10^6 candle power, 1.9 x 10^7 lumens peak intensity. Data were analyzed both with computer generated peristimulus time histograms and with raster outputs on an oscilloscope. Neurons in all three areas displayed similar latencies and durations of excitation in response to both the flash and the click. (The duration of excitation in NE cells appears to be slightly longer.) In contrast to the similarities

	STIMULUS TYPE			
	AUDITORY		VISUAL	
CELL TYPE	latency	duration	latency	duration
NE	61	130	69	120
5HT	40	64	53	76
DA	51	86	63	82

in response latency and duration across these three cell types, the NE neurons differed dramatically from the 5HT and DA neurons in terms of habituation. Neurons in the latter two groups displayed no evidence of habituation, whereas, the response strength of NE neurons often would begin to diminish within a few trials and often would show a complete abolition of response within 10-20 stimulus repetitions. We are currently attempting to determine whether this response decrement in NE neurons is attributable to shifts in behavioral state or attention. (Supported by grants MH-23433 and AFOSR 85-0034.)

19.12 LOCUS COERULEUS UNIT ACTIVITY IN BEHAVING CATS: RESPONSE TO AVERSIVE AND APPETITIVE CONDITIONING. K. Rasmussen and B.L. Jacobs, Prog. Neurosci., Princeton Univ., Princeton, NJ.

Noradrenergic (NE) neurons in the area of the locus coeruleus (LC) have been implicated in stress and anxiety responses. This is supported by a variety of studies including reports that in rats brain NE turnover increases in response both to acute stress and to environmental stimuli previously paired with acute stress. NE units in the LC have also been implicated in some aspects of learning. This is supported by a variety of studies including reports that transient posttraining decreases in brain NE concentration predict later retention performance of an avoidance response. In an attempt to shed light on both of these issues, we employed paradigms that involve anxiety and/or learning. Thus, we have examined LC unit activity in response to conditioned emotional response (CER) and conditioned food reward (CFR) training. The general methodology and the criteria for identifying neurons as NE are described in the preceding abstract. During CER training cats were exposed to 10 pairings, with a 3 min inter-trial interval, of a 5 sec tone (CS+, 2900 Hz, 74 dB) and a 1 sec duration air puff to the face (US). During the inter-trial-interval a CS- (5 sec lights off) was randomly delivered. During CFR training a separate group of cats was exposed to repeated pairings, with a 3 min inter-trial-interval, of a 5 sec tone (the same tone used in CER training) with the delivery of a highly preferred food. All animals rapidly learned the stimulus contingencies in both paradigms. Presentation of the CS+ prior to CER training resulted in a modest but significant increase in NE unit activity above a baseline level of activity of ∿1-2 spikes/sec. However following CER training, NE units showed a dramatic increase in activity upon presentation of the CS+. The increase in activity in response to the CS+ during CER training (173%) was significantly greater than the increase in response to the CS+ before CER training (54%). Conversely, the increase in activity in response to the CS- during CER training (53%) was not significantly different from the increase in activity in response to the CS- before training (33%). Contrary to this, the increase in activity in response to the CS+ during CFR training (76%) was not significantly different from the increase in activity in response to the CS+ before training (54%). Therefore NE units in the LC dramatically increase their activity in response to a tone that predicts the occurrence of a noxious event, but not to a tone that predicts the occurrence of a rewarding event. These data support the hypothesis that NE neurons in the LC play a role in stress or anxiety responses and also support the hypothesis that NE units play a role in aversive but not appetitive conditioning. (Supported by grants MH-23433 and AFOSR 85-0034)

19.13 INCREASES IN STRIATAL SEROTONIN ARE NOT NECESSARY FOR WEANING IN DOPAMINE-DEPLETED RAT PUPS. J.P. Bruno, D. Jackson*, M.J. Zigmond, and E.M. Stricker. Department of Psychology, Center for Neurosciences, University of Pittsburgh, Pittsburgh, PA 15260

Unlike adult rats given large dopamine (DA)-depleting brain lesions, neonatal animals given comparable lesions are spared from the initial deficits in ingestive and motor behavior. Moreover, there is a sprouting of striatal serotonin (5-HT) neurons only in response to the neonatal lesion. Two experiments were done to determine whether the 5-HT hyperinnervation is necessary for the sparing phenomenon seen in rats given brain lesions as neonates. First, three-day-old rat pups were injected ivt either with 6-hydroxydopamine (6-HDA; 150 ug in 10 ul, n=11), 6-HDA and 5,7-dihydroxytryptamine (5,7-DHT; 150 ug of each drug in 5 ul, n=18), or the vehicle solution (.1% ascorbic acid in .9% NaCl, n=7) 30-45 min after pretreatment with the norepinephrine uptake blocker desmethylimipramine (DMI; 25 mg/kg, s.c.). Despite >98% depletions of striatal DA (control, 12.77 ± 1.35 ug/g) and 5-HT (control, .60 ± .05 ug/g), 87% of these pups continued to suckle and grew at a rate that was slower than controls but comparable to that of pups with 99% DA depletions. Moreoever, they had no difficulty ingesting food and water when weaned on Day 27. In the second experiment, 15-day-old rat pups were injected ivt with 6-HDA (150 ug in 10 ul, n=14) or its vehicle solution (n=9) 30-45 min after pretreatment with DMI (25 mg/kg, s.c.) and the MAO inhibitor pargyline (45 mg/kg, s.c.). Despite 97% depletions of striatal DA (control, 10.42 ± 1.80 ug/g), the brain-damaged pups continued to suckle and could be weaned on Day 27. Unlike the younger pups, however, there were no significant lesion-induced increases in striatal 5-HT levels when measured 1-2 mo later (control, .36 ± .03 ug/g; 6-HDA-treated, .47 ± .08 ug/g).

These results suggest that increases in striatal 5-HT are not necessary for maintaining ingestive and motor behavior in rats sustaining near-total DA-depleting brain lesions as neonates. We are currently investigating the neural mechanisms underlying this age-dependent sparing phenomenon.

19.14 ANALGESIA INDUCED BY INTRATHECALLY INJECTED CLONIDINE IN THE INFANT RAT. Harry E. Hughes* and Gordon A. Barr* (SPON: Wagner H. Bridger). Biopsychology Program, Hunter College, City University of New York, and Dept. Psychiatry, Albert Einstein College of Medicine, Bronx, New York 10461.

Various lines of evidence suggest that inhibition of dorsal horn afferents and consequent analgesia are under the control of descending noradrenergic (NE) pathways in the spinal cord of adult animals. Furthermore, pharmacological studies have suggested that it is the alpha receptor, rather than the beta receptor, that is involved. Recent developmental studies from several laboratories have shown that opiate-induced analgesia in the spinally mediated tail flick test develops largely during the second week of life and that kappa opioid receptors are functionally active prior to mu opioid receptors However, there are no data on the development of spinally mediated non-opiate induced analgesia. Because NE-stimulated cyclic AMP activity, the number and size of spinal NE terminals, and the concentration of NE in rat spinal cord increase postnatally, to peak near the end of the second week of life, it might be expected that NE induced analgesia would appear at that time. The present study addressed the contribution of the developing spinal alpha NE receptors in producing analgesia in the infant rat.

Long-Evans hooded rats were implanted with chronic intrathecal catheters at 9 days of age. Anesthesized pups were incised just above the thoracic and lumbar vertebrae and the underlying muscle and fascia gently scraped away. A laminectomy was performed at level T8 - T11 with care taken not to injure the underlying dura. The dura was then gently lifted and punctured with a needle and a five mm length of dialysis tubing (250 μm in diameter) was inserted under the dura. The dialysis tubing was fit to polyethylene tubing (PE-10) external to the entry into the dura, the PE tubing was anchored to the vertebrae and musculature, and the wound was closed. The entire procedure required approximately 15 minutes and there was no damage to the underlying spinal cord when examined histologically and no obvious impairment of motor function. Twenty-four hours later, at 10 days of age, pups were injected with 0, 25, 50, or 100 μg in 4 μl of diluent of the alpha NE agonist clonidine HCl. This volume of fluid perfused the cord from the lumbar/sacral segments rostral to the caudal cervical region. Spread was verified in each pup by injection of dye following testing. Following a 15 minute postinjection period, the forepaw, hindpaw, and tail were sequentially submerged in 47 ° C water and the latency to withdraw each appendage was recorded. The order of testing of each limb and the tail was randomly determined.

Clonidine produced significant dose dependent analgesia as evidenced by increased tail flick latencies. It had no effect on withdrawal of either the forepaw or hindpaw. Thus, the physiological organization of NE induced analgesia appears different for the limbs and the tail. This is consistent with other data that demonstrate developmental differences in the ability of opiates to produced analgesia in the paws compared to the tail. These data further suggest that, in response to a thermal stimulus, in the tail flick test, spinal NE circuitry associated with antinociception is functional by at least 10 days of age.

19.15 REPEATED STRESSOR OR DESMETHYLIMIPRAMINE EFFECTS ON FOOTSHOCK INDUCED DEPRESSION OF SELF-STIMULATION. W.J. Bowers*, R.M. Zacharko and H. Anisman, Psychology Dept., Carleton University, Ottawa, Ontario, K1S 5B6, Canada

It has been observed that acute exposure to inescapable footshock induces marked and long lasting reductions in responding for intracranial self-stimulation (ICSS). Such effects were noted in dopamine (DA) containing brain regions where stressors reliably influenced DA turnover and concentrations. In particular, inescapable shock disrupted ICSS responding from the nucleus accumbens, ventral tegmental area and the medial forebrain bundle in both rate dependent and independent paradigms. In contrast, inescapable footshock did not affect DA turnover in the substantia nigra, and likewise this treatment did not influence responding for ICSS. Contrary to the reduction of ICSS elicited by acute stressors, adaptation occurred with repeated exposure to footshock, such that high levels of responding for brain stimulation were maintained. Moreover the extent of the adapatation was directly related to the number of shock sessions mice received. Paralleling these findings, it was observed that the depressed response rate from the nucleus accumbens ordinarily elicited by acute footshock was prevented by repeated administration with the tricyclic agent, desmethylimipramine (DMI). It was observed that in animals where adaptation had occurred, withdrawal from the DMI treatment or termination of the chronic shock regimen resulted in a marked and relatively protracted depression of responding. These data were taken to support the contention that chronic stressor application results in the induction of adaptive neurochemical changes. Behavioral depression occurs when the adaptive variations do not occur. Under such conditions, antidepressants are necessary to engender the course of neurochemical changes that would ordinarily occur. However, since such effects persist only so long as the treatment is maintained, it is suggested that the antidepressants either provoke compensatory adaptive changes or mask the symptoms associated with the stressor, rather than affecting the etiology for the depressed behavior.

19.16 PERTURBATIONS OF SLEEP CYCLE PERIOD LENGTH PRODUCE PARALLEL INCREASES IN THE FREQUENCY OF DESYNCHRONIZED (D) SLEEP AND DORSAL RAPHE (DRN) DISCHARGE PROFILES. R. Lydic, R.W. McCarley, and J.A. Hobson. Harvard Medical School, Boston, Ma 02115

Studies of intact, undrugged, adult mammals uniformly report regular DRN firing which is positively correlated with behavioral arousal and a cessation of DRN discharge (D-off) during D sleep. The present experiment characterized the DRN and D sleep response to alterations in the period length of the sleep cycle. If DRN discharge is causally involved in generating the ultradian sleep cycle, then the relationship between DRN activity and behavioral state should not be easily dissociable by forced locomotor activity.

Adult, male cats were chronically implanted with electrodes for recording sleep and wakefulness (EEG, EOG, EMG, and PGO waves) and with moveable microwire electrodes aimed for the DRN. These polygraphic variables and DRN discharge potentials were recorded after: 1) 16 hrs. of forced locomotor activity; and 2) a similar interval during which sleep could occur ad libitum.

The results were derived from 177 sleep cycles, with each cycle operationally defined: from the end of one D sleep epoch thru the end of the subsequent D sleep epoch. For cycles ranging in period length (Tau) from 10 to 80 mins., DRN discharge profiles were phase-locked to the temporal organization of sleep. Although forced activity shortened the sleep cycle (control Tau=34.7 $\pm$ 13.1 mins., n=86; forced activity Tau=28.7 $\pm$ 11.3 mins., n=91; $p<0.0001$) it was not possible to dissociate the sleep cycle from the DRN discharge profiles. DRN discharge rate in each behavioral state was partly a function of sleep cycle Tau. Forced activity produced statistically significant reductions in the duration of wakefulness (W) and synchronized (S) sleep and increases in the duration of transition (T) and D sleep. There were no significant differences in DRN discharge rate during W, S, or T, but an enhanced DRN discharge rate during D epochs which followed forced activity. There was a significant increase in the number of D sleep epochs but not in D sleep duration after forced activity. The D-off DRN discharge profiles exactly paralleled the changes in D sleep.

These results are consistent with the hypothesis that the DRN is involved in sleep cycle regulation. Furthermore, they suggest that the homeostatic response to perturbations of the ultradian sleep cycle is mediated by an increase in the frequency rather than the period length of putative D sleep generating mechanisms.

19.17 SIMILAR EFFECTS OF CLONIDINE AND HISTAMINE ON THE CENTRAL NERVOUS SYSTEM. B. Delbarre and G. Delbarre. Faculté de Médecine, 37000 TOURS, FRANCE.

The action of clonidine and histamine have been investigated in several animal species. In young chickens, mice and rats, clonidine (0.25 - 0.75 mg.kg-1 I.M.) and histamine (20 - 50 mg.kg-1 I.M. - 0.250 ug I.C.V.) induce behavior and E.E.G. sedation (a pattern of high slow waves appeared on the E.E.G.) This sedative effect is blocked by mepyramine (5 mg.kg-1 s.c) atropine (5 - 10 mg.kg-1 s.c) and alpha 2 adrenergic blocking agent : yohimbine (1 - 3 mg.kg-1 I.P.) and piperoxan (2 - 5 mg.kg-1 I.P.) but not by alpha 1 : dibenamine (15 - 20 mg.kg-1 I.P.) and prazosin (2 - 5 mg.kg-1 I.P.).

In rats, clonidine (0,15 mg.kg-1 s.c) and histamine (30 mg.kg-1 s.c) depress avoidance conditionned reflexes. Atropine (10 - 15 mg.kg-1 s.c) antagonizes the depression of conditionned avoidance response.

Clonidine (0,1 - 0,5 mg.kg-1 I.M.) and histamine (10 - 40 mg.kg-1 I.M.) induce hypothermia in mice, rats and chickens.

Sedative effect of chlorpromazine (4 mg.kg-1 I.M.) (N-Methyl transferase inhibitor) is blocked by atropine (10 mg.kg-1 s.c) and mepyramine (2 mg.kg-1 I.P.)

These data suggest the central action of histamine may be explained by release of catecholamines.

19.18 RADIOENZYMATIC DETERMINATION OF PHENYLPROPANOLAMINE IN PLASMA. A.A.Reid*, P.J.Fleming* and C.R.Lake* (SPON:H.Holloway). Dept. of Psychiatry, USUHS, Sch. of Med., Bethesda, MD 20814.

Phenylpropanolamine (PPA) is a drug which is widely used in over-the-counter diet aids and cold remedies and as an abusive substance. In recent years an increasing number of articles in the literature have reported mild to severe neuropsychiatric side effects associated with the use of PPA containing products. To date only a few controlled PPA studies aimed at understanding its effects, metabolism and mechanism of action have been conducted. Current methodologies capable of detecting plasma PPA concentrations from 5 ng/ml to 240 ng/ml include one gas chromatography (GC) and two high pressure liquid chromatography (HPLC) techniques.

We have developed a new radioenzymatic method for plasma PPA analyses with a 17 fold increase in sensitivity. In principle the assay involves conversion of PPA to tritium radiolabelled ephedrine ([3H]EPD) by the enzyme phenylethanolamine - N - methyltransferase (PNMT) and tritium radiolabelled S-adenosylmethionine ([3H]SAM). The product, [3H]EPD, is isolated from unreacted [3H]SAM and labelled side products by an organic extraction and a thin layer chromatography procedure. In addition, a pre-incubation organic extraction procedure is included to remove inhibitors of PNMT from plasma and to concentrate the sample for enhanced enzymatic conversion.

Each of the steps within the radioenzymatic assay has been optimized for PPA and the assay has been characterized in terms of sensitivity, linearity, reproducibility, recovery, accuracy and specificity. In order to accurately quantitate PPA across the wide range of possible physiological concentrations, the assay is conducted at two plasma volumes. PPA concentrations between 0.3 - 50 ng/ml can be detected with 1 ml of plasma, while concentrations between 4 - 1500 ng/ml can be detected with 0.1 ml of plasma. The intra (within) assay coefficients of variation (CV), which represent the reproducibility of the assay, are 9.3 % and 5.7 % at 0.5 ng/ml and 1500 ng/ml respectively, while the inter (across) assay CV is 9.7 %. Although the overall recovery of PPA as EPD (1 %) appears low, it is predictable because the enzymatic reaction is conducted at initial velocity conditions, which results in only 3 % conversion of PPA. Further, the accuracy of the assay was confirmed by a GC technique and the specificity analysis revealed that none of the compounds tested interferred with PPA determinations.

The new radioenzymatic assay is currently the method of choice for plasma PPA analyses, because it is superior to the HPLC and GC techniques in terms of sensitivity, range of linearity, and volume of plasma required.

19.19 INTERACTION BETWEEN HARMANE AND ADRENOCEPTORS IN THE MODULATION OF ANXIETY. G. Delbarre, B. Delbarre and A. Ferger*. Faculté de Médecine, 37000 TOURS, FRANCE.

Harmane is a potent endogenous inhibitor of benzodiazepine receptor binding (Rommelspacher, H., et al., Naunyn-Schmiedeberg's Arch. Pharmacol., 314 : 97, 1980).

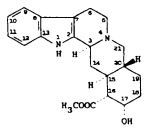
Harmane (50 mg.kg-1 I.P.) induced convulsions are antagonized by diazepam (ED 50 : 1,20 mg.kg-1 I.P.) and delorazepam (ED 50 1,09 mg.kg-1 I.P.).

Similarity of structure between harmane, yohimbine and raubasine prompted us to investigate anticonvulsive activity of these compoumds.

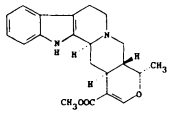
Yohimbine (2 - 5 mg.kg-1 I.P.) known to have anxiogenic activity (Goldberg et al., Pharma. Rev., 35 : 143, 1983) potentiates convulsive activity of harmane (50 mg.kg-1 I.P.). Raubasine (5 - 10 - 20 µg.I.C.V) alpha 1 blocking agent, known to have benzodiazepine agonist type activity (Charveron, M., et al., Eur. J. Pharmacol., 106 : 313, 1985) antagonizes convulsive activity of harmane. Moreover this effect is antagonized by yohimbine (5 mg.kg-1 I.P.).

These results suggest that alpha 1 and alpha 2 may be involved in the modulation of anxiety.

HARMANE



YOHIMBINE



RAUBASINE

19.20 HALOPERIDOL, THIAZIDES AND SOME ANTIHYPERTENSIVES SLOW RECOVERY FROM APHASIA. B. Porch*, J. Wyckes* and D.M. Feeney. Depts. of Communicative Disorders, Psychology and Physiology, University of New Mexico, Albuquerque, NM 87131.

This study was prompted by the report of haloperidol slowing recovery from hemiplegia in the rat (Feeney et al., Science, 217, 815-817, 1982). Since catecholamine antagonists are often given to stroke patients to lower blood pressure or reduce agitation they may slow recovery of function in man. Aphasia, despite its complexity, can be objectively scored and spontaneous recovery can be estimated using a mathematical model (Porch, Clin. Aphasiology Proc., 187-200, 1981). In this model untreated patients, based on the 1 month poststroke test with the Porch Index of Communicative Ability, have a predicted score for a second evaluation six months later. Scores reported here represent deviations from the predicted scores, and so a 0.0 indicates spontaneous recovery to the predicted test result. On the second test some patients receive scores markedly different from the predicted value and some of this variability may be due to medications. There were 32 patients who received speech therapy and aphasia testing at the Albuquerque VA hospital (between 1980-1984) and all cases with complete records were examined. There were 13 cases that received no drugs and their deviation score was +9.1. For patients in speech therapy the math model applies a correction factor of +10.0 above untreated cases, so this group had the expected recovery. The 19 patients on various drugs, mostly thiazides and antihypertensive medication, had a mean of -7.4 below the predicted value for spontaneous recovery (17.4 below the score expected for patients in therapy). The difference between the drug and no drug groups was significant (p less than .01). This result is likely due to medications rather than differences in hypertension, since 4 patients given propranolol, which does not slow recovery in the rat hemiplegia model (Harrington et al., MBRS Abst., 411, p.103, 1984), had a mean score of +15.5. There were 3 patients given haloperidol and they had a mean score of -16.0. We tentativly conclude that some drugs are contraindicated in patients with brain damage.

FEEDING AND DRINKING I

20.1 NALOXONE ATTENUATES DEPRIVATION-INDUCED DRINKING AND FEEDING IN A DESERT-DWELLING RODENT. D.A. Czech and C. McCrimmon* (SPON: K.A. Vaughn). Dept. of Psychology, Marquette Univ, Milwaukee, WI 53233.

Considerable evidence has accumulated suggesting that endogenous opioid mechanisms play a modulatory role in the regulation of consummatory behavior. Opioid antagonists, e.g., reliably attenuate both drinking and feeding in a number of animal species, and in a variety of experimental situations. Recently, pronounced species differences in opioid-linked consummatory behaviors have been reported. It was reported that the prototypic opioid antagonist, naloxone, attenuates food, but not water, intake in domestic pigeon (Deviche & Schepers. Psychopharm. 82:122, 1984) and that the longer acting antagonist, naltrexone, depresses drinking but appears to be without effect on feeding in male golden hamsters(Lowy & Yim. Life Sci.30:1639, 1982). In the present study, we investigated a potential effect of naloxone on deprivation-induced feeding and drinking in a desert-dwelling, murid rodent - the spiny mouse (Acomys cahirinus). In a first experiment, male mice were adapted to a 23-hr water-deprivation schedule with food available ad lib. Following stabilized drinking, mice were injected SC with 4 doses of naloxone hydrochloride (NX) (0.3, 1.0, 3.0 & 10.0 mg/kg as the salt) and normal saline vehicle, approximately 30 min prior to scheduled drinking, in a within-subject design. Injections were given at 3-4 day intervals, approximately 4 hours into the light period. Deionized water intake was automatically monitored at 1-min intervals throughout the hour drinking period in the home cage. Food was not available during tests. Intakes were converted to percent of intake on saline(control) day and these data were evaluated at 5, 15, 30 & 60 min into the drinking period with ANOVAs and Dunnett's procedures. Significance level was set at $p < .05$. All dosage levels used resulted in significantly attenuated drinking, as compared to the control condition, for all cumulative periods. Mice characteristically consumed all of their water within the first 5 min of access. In a second experiment, food intake was measured in the same group of mice, using the same doses of NX. This time, however, they were food-deprived for 20 hr prior to feeding tests, again at 3-4 day intervals. These animals do not adjust well to a feeding schedule, seeming unable to ingest adequate food during limited access. Water was not available during feeding tests. One-hour intakes were converted, again to percent of control, and analyzed with ANOVA and Dunnett's procedures. As with drinking, food intake was significantly attenuated at all dosage levels of NX. The spiny mouse appears to possess an opioid-sensitive mechanism for both feeding and drinking. Results are discussed.

20.2 FOOD HOARDING AND INGESTION IN THE DEER MOUSE: SELECTIVE MU AND KAPPA OPIATE INFLUENCES. M. Hirst* and M. Kavaliers. Depts. Pharmacology and Toxicology and Zoology, University of Western Ontario, London, Ontario, Canada N6A 5B7.

Many studies have suggested that endogenous opiates participate in the mediation of feeding. Little is known, however, about the influences of endogenous opioid systems on the components of natural feeding activity. The deer mouse, Peromyscus maniculatus, displays in the field and in the laboratory several behaviours associated with feeding. These include searching for food, transporting of food, hoarding or caching of food and ingestion. Since both mu and kappa agonists have been implicated in feeding behaviour in rodents, their influences on food hoarding and ingestion by deer mice were evaluated.

Male deer mice (22-25 g) were maintained at 20°C under LD 10:14 for several days. After being housed individually for three days, with powdered food available ad lib, determinations were made of food acquired by licking each hour in three hour blocks of time in the light period after injections (i.p.) of U-50,488H, morphine or saline. Uninjected mice were used as an additional control. Other mice were acclimated in cages which had a black polyethylene U-shaped tunnel attached from which they could remove food pellets and hoard them in a second polyethylene tube in the home cage. After five days determinations were made of food hoarded each hour in three hour blocks of time in the light period after animals received morphine, U-50,488H or saline. Uninjected mice were used as a second control.

The results of this study demonstrated that the kappa agonist, U-50,488H, caused a significant dose-dependent increase in food ingestion over three hours, whereas the mu agonist, morphine, had little impact. In contrast, morphine induced a dose-dependent increase in food hoarding while U-50,488H decreased hoarding, the animals ingesting the pelleted food. Morphine-treated animals did not hoard similar pellets of a non-food item.

These findings imply that endogenous opiate systems can selectively influence different components of food acquisition in this species.

20.3 EFFECTS OF NALMEFENE, AN OPIATE ANTAGONIST, ON ENERGY BALANCE AND GLUCOSE METABOLISM IN ZUCKER OBESE RATS. C.L. McLaughlin, C.A. Baile, R.L. Gingerich* and M.E. Michel. Washington Univ. Med. Sch., St. Louis, MO 63110 and Keys Pharmaceuticals, Miami, FL 33269.

Evidence suggests that opioid peptides are involved in the control of food intake and glucose metabolism. Since Zucker obese rats are hyperphagic and hyperinsulinemic, we investigated their responses to nalmefene, an opiate antagonist. SC administration of 2 mg/kg nalmefene twice daily to Zucker obese and lean rats for 21 days decreased food intake (20.8 vs 21.9 and 17.2 vs 19.6 g/day, respectively $p \leq .001$) and body weight (1.3 vs 1.5 and .4 vs .9 g/day, respectively, $p < .02$). On day 1 glucose concentrations were decreased 60 min after the first injection in obese (110 vs 124 mg/dl, $p < .002$) but not lean (118 vs 119 mg/dl rats). In addition, insulin concentration was decreased only in obese rats (15.0 vs 17.7, $p < .03$ and .67 vs .74 ng/ml, NS for lean rats). On the last day of injection glucose concentration was also increased only in obese rats (124 vs 114 mg/dl, $p < .001$ and 112 vs 106, NS for lean rats) and insulin was again decreased only in obese rats (17.5 vs 21.7, $p < .03$ and 1.11 vs 1.16, NS for lean rats). In nalmefene-treated compared with saline-treated rats B-endorphin content of the pituitary was increased (1341 vs 1178, $p < .07$) while concentration in the plasma was unaffected (49 vs 43 pmol/l). In a second experiment addition of nalmefene to food (100 mg/kg food) for 21 days also decreased food intake (19.3 vs 21.2 g/day $p < .01$) and body weight gain (.03 vs .59 g/day $p < .01$) in obese but not lean rats (18.0 vs 18.5 and .13 vs .42 g/day for food intake and weight gain respectively). In the same experiment addition of tolbutamide to food (670 mg/kg) did not influence food intake (19.4 vs 19.9 g/day) or body weight gain (.22 vs .50 g/day) in obese or lean rats; thus effects of nalmefene were greater than those of tolbutamide. Glucose and insulin concentrations were measured weekly after a 2-hr fast and only glucose concentrations were decreased in nalmefene-treated compared with saline-treated rats on day 7 (127 vs 136 mg/dl, $p < .03$). In a third experiment Zucker obese and lean rats were administered saline or nalmefene (2 mg/kg) orally with 2.0 ml/kg water or 50% dextrose. Nalmefene produced a smaller change in insulin concentration after 30 (11.5 vs 18 ng/ml, $p < .002$) and 60 (-12.7 vs -18.7 ng/ml, $p < .01$) min in obese but not lean rats (1.8 vs .9 and -1.4 vs -.1 ng/ml respectively, NS) and only after oral glucose, which increased blood glucose 66 and 33% respectively for obese and lean rats ($p < .001$) and which was not influenced by nalmefene. Thus, while nalmefene affected food intake and body weight in obese rats whether administered IV or in the food, and the effect was stronger than that of tolbutamide, effects on glucose metabolism occurred only after a glucose challange. (Supported by Keys Pharmaceuticals)

20.4 EFFECTS OF AMPHETAMINE MICROINJECTIONS INTO DOPAMINE TERMINAL AREAS ON FEEDING, DRINKING AND OPEN FIELD BEHAVIOR. G.D. Carr and N.M. White. Department of Psychology, McGill University, Montreal, Canada, H3A 1B1.

Systemic injections of amphetamine produce anorexia and adipsia but at lower doses have been shown to stimulate eating. In the open field amphetamine injections result in increased activity and stereotyped repetition of certain species-typical behaviors. All of these effects have been shown to depend to some extent on the ability of the drug to stimulate dopaminergic neurotransmission. The present study further examined these behavioral effects by microinjecting amphetamine into one of six dopaminergic regions and observing how the injections affected eating, drinking and open field behavior in rats. The drug was injected (10 ug in 0.5 ul, bilaterally) into the medial prefrontal cortex, nucleus accumbens, anteromedial caudate nucleus, lateroventral caudate nucleus, amygdala or the region subjacent to the area postrema. The rats were mildly food or water deprived, injected with the drug and allowed access to food or water respectively. Animals that had received injections into the nucleus accumbens or amygdala showed both anorexia and adipsia relative to saline control injections but no effects were observed from the other sites. It is suggested that amphetamine's actions on the accumbens and amygdala contribute to the anorexia and adipsia that are produced by systemic injections.

A detailed analysis of 12 behavioral categories in the open field showed that the amphetamine injections caused a slight increase in locomotion from the medial frontal cortex and anteromedial caudate. There was a large increase in the amount and speed of locomotion and amount of rearing produced by intra-accumbens injections accompanied by complementary decreases in lying down, standing still, grooming and sniffing of the floor. The amygdala-injected rats spent more time standing still and the sub-area postrema region group initially spent more time lying down. The stereotyped repetition of behaviors that is observed after systemic injections was not elicited from any of the intra-cranial injection sites suggesting that this component of amphetamine's effects may depend on simultaneous stimulation of more than one dopaminergic region.

20.5 CORTICOTROPIN-RELEASING FACTOR (CRF) INCREASES GROOMING IN THE PARAVENTRICULAR NUCLEUS (PVN). D.D. Krahn*, B.A. Gosnell, J.E. Morley, A.S. Levine (SPON: M.W. Dysken). Neuroendocrine Research Laboratory, VA Medical Center, Minneapolis, MN, 55417 and Geriatric Research Education and Clinical Care Center, VA Medical Center, Sepulveda, CA, 91343.

CRF decreases food intake and increases grooming and locomotor activity when administered intracerebroventricularly (icv) to rats. CRF also decreases feeding when administered locally in the PVN of the hypothalamus but does not decrease feeding when administered in the lateral or ventromedial nuclei of the hypothalamus, the striatum, or the globus pallidus. We decided to test whether CRF administered in the PVN of rats elicits the rest of the syndrome caused by CRF (icv) (i.e., increased grooming and movement).

Twenty-one male, Sprague-Dawley rats housed in a 12 hour light/12 hour dark environment in single cages were implanted with 23 gauge, indwelling cannulae directed at the PVN. Following a 5 day recovery period, the animals were treated with .5 µl of normal saline or CRF (1 µg/µl) in their home cages at 1600 hours in each of the following conditions: previous 24 hour deprivation, food available; 24 hour deprivation, no food available; no deprivation, food available. Each animal was observed once per minute by a rater blind to treatment and behavior was classified into one of six categories (grooming, resting, moving, eating, drinking or rearing). Food was collected and weighed after 1 and 2 hours.

ANOVA's showed that CRF increased grooming in the PVN ($F(1,20) = 43.93$, $p = .000$) but that neither deprivation ($F(1,20) = 2.68$, $p < .12$) or food availability ($F(1,20) = .04$, $p = .84$) significantly influenced grooming. CRF in the PVN also increased locomotion significantly ($F(1,20) = 37.26$, $p = .000$). CRF in the PVN did decrease food intake at these doses as well (mean 2 hour intakes; CRF = 4.86 g, NS = 2.45, $F(1,20) = 22.23$, $p = .0001$).

Thus, CRF in the PVN not only causes the decrease in feeding previously reported but also causes the increased grooming and locomotion seen with CRF (icv). Although these behaviors are linked following CRF injection into the PVN, injections into other areas of the brain may result in the dissociation of these behaviors. In the present study, we also observed that CRF-induced grooming is not influenced by either the presence of food or the degree of hunger, both of which obviously affect feeding.

20.6 GLUCOPRIVIC FEEDING AND VASOPRESSIN. P.F. Aravich* and C.D. Sladek (SPON: M. Blair). Departments of Anatomy and Neurology, University of Rochester Medical Center, Rochester, NY 14642.

One of the most popular theories of feeding behavior is the glucostatic theory. Major support for this hypothesis has come from the orexigenic effects of 2-deoxy-D-glucose (2DG) and insulin. However, the phenomenon of delayed glucoprivic feeding reveals that ongoing glucoprivation is not necessary for the feeding response, suggesting the contribution of other factors. One neuroendocrine consequence of glucoprivation is the release of vasopressin (VP) (Endoc. 107:1970, 1980), which has metabolic as well as pressor and antidiuretic actions. We now report that the acute release of VP may play a role in 2DG feeding.

Female Brattleboro rats (DI) lacking VP (n=6) and body-weight matched Long-Evans (LE) rats (n=6) served as subjects. The animals were maintained and tested with access to both a high-sucrose diet and a high-fat diet. Four-hour caloric intakes were determined following counterbalanced i.p. injections of varying doses of 2DG. The DI rats were found to have a substantially attenuated dose-response function relative to LE rats, which was particularly evident at higher doses. The DI rats were then given chronic VP replacement therapy (0.1 µg/hr). Such therapy corrects many of their abnormalities, including those related to diabetes insipidus. Replacement therapy failed to facilitate 2DG feeding in DI rats. Thus, their feeding deficit is not due to the complications of diabetes insipidus.

VP may contribute to 2DG feeding by promoting endogenous energy mobilization. This could occur via routes that include a direct action on liver glycogenolysis (V1 receptors) or by a direct action on glucagon release (V2 receptors) (Peptides 5:871, 1984). A specific V1 antagonist was selected for evaluation using the diets and normal LE rats noted above. Rather than reducing 2DG feeding specifically, the V1 blocker increased overall food intake (main effect) and was not associated with a glucoprivic-by-antagonist interaction effect. Thus, V1 VP receptors do not mediate 2DG feeding.

It is concluded that VP release from the hypothalamo-neurohypophysial system participates in 2DG feeding by affecting VP receptors related to glucagon release. This would in turn promote lipolysis and VP-insensitive glycogenolysis. Alternatively, VP within the suprachiasmatic nucleus may alter circadian rhythms of catobolism and anabolism, which influence 2DG feeding. It should be noted, however, that circadian ingestive rhythms in the DI rat are reported to be normal. Regardless, the contribution of VP to 2DG feeding suggests one mechanism by which glucoprivation induces secondary changes, which then elicit feeding.

20.7 ENVIRONMENTAL CONTROL OF LIPOPROTEIN LIPASE ACTIVITY. J. A. Stidham*, S. M. Mena*, and A. W. Knehans*, (SPON: J.P. Farber). Departments of Psychology and Human Development, University of Oklahoma, Norman, OK 73019.

Continuous feed-starve cycles sometimes promote adiposity (Hollifield & Parson, 1962). Several lines of reasoning have led us to suspect that the phenomenon depends upon classical conditioning. This possibility was investigated by cyclicly feeding rats in a context distinctly different from the one in which they were deprived. Later, when the rats had been refed for a week, the ability of the separate environmental contexts to modify some indices of metabolism was assessed.

Sixteen male rats were placed on a variable time deprivation-feed schedule that prescribed daily 2 hr food access that was separated from the previous day's feeding by an average of 22 hr. The 2 hr feeding period, which occurred in a different context from deprivation (F vs. NF), was thus unpredictable on the basis of time alone. This assured that only the physical context could exert stimulus control and that circadian rhythms were not entrained. Following 35 conditioning days, the rats were allowed to feed freely. This took place in a separate context and lasted 7 days.

The test trial consisted of a 60 min exposure to the F or NF context and was followed by immediate decapitation. Blood was collected for blood urea nitrogen (BUN), free fatty acids (FFAs), and blood glucose (BG) determinations. The epididymal fat pads were removed and prepared for lipoprotein lipase (LPL) assay.

Rats exposed to the F context displayed a significant depression of FFAs and a significant elevation of LPL activity relative to the NF controls. BUNs and BGs were undifferentiated across groups. The results indicate that certain aspects of metabolism can be brought under external stimulus control. Under ordinary circumstances this anticipatory response would help to dispose of a forthcoming flood of nutrients and inhibit mobilization. That the conditioned responses were restricted to fat metabolism suggests that insulin was probably not the mediating hormone. The rise in aldosterone titers with repeated deprivation (Wright & Schultz, 1982), their role in the promotion of lipogenesis (Devenport, et al, in press), and inhibition of energy mobilization (Devenport, et al, 1983) suggest these steroids as possible candidates.

20.8 Neurotoxic Hypothalamic Lesions Alter the Content of Cholecystokinin in Anterodorsal Hypothalamus and Pituitary. A.C. Scallet, P.L. Faris, M.C. Beinfeld* and J.W. Olney. National Center for Toxicological Research, Jefferson, AR 72079 and Washington and St. Louis University Schools of Medicine, St. Louis, MO 63110.

Both monosodium glutamate (MSG) and bipiperidyl mustard (BPM) produce partially overlapping basomedial hypothalamic lesions that interact to alter the subsequent feeding behavior and/or insulin levels of treated animals. Administration of exogenous cholecystokinin also has been shown to effect feeding behavior and plasma insulin. To study the possible role of endogenous cholecystokinin in the effects of neurotoxic hypothalamic lesions, cholecystokinin content of the regionally dissected hypothalami and pituitaries of rats treated with MSG alone, BPM alone or with both toxins was measured by radioimmunoassay. BPM alone produced a 147% increase in posterior pituitary concentrations of cholecystokinin ($p<.01$) compared to controls. MSG treatment by itself had no effect on pituitary cholecystokinin, but prior MSG lesioning prevented the BPM effect. Preliminary data on cholecystokinin levels in regionally dissected portions of the hypothalamus suggest that either MSG or BPM alone produced a non-significant increase (20%) in the anterodorsal area ($p<.10$). Combined MSG/BPM treatment increased cholecystokinin by more than 60% ($p<.01$). There were no effects on cholecystokinin of other hypothalamic regions. Since the paraventricular nucleus (contained in the anterodorsal sample) has many cholecystokinin containing cell bodies, and axonal projections from these cells are the source of cholecystokinin in the pituitary, it is not surprising that changes associated with neurotoxic hypothalamic lesions were localized to the anterodorsal hypothalamus and posterior pituitary. It is difficult to interpret our cholecystokinin findings, however, in terms of the known effects of these neurotoxic lesions. The striking increase in pituitary cholecystokinin occurred only in rats lesioned with BPM alone, a group that displays no significant disturbance in food intake or plasma insulin. Our preliminary results suggest that the greatest change in paraventricular nucleus content of cholecystokinin occurred in MSG/BPM rats, a group that does display hyperphagic obesity and hyperinsulinemia. How these functional disturbances may relate to the increased cholecystokinin concentrations in paraventricular nucleus of these rats, however, awaits further study. Supported by NS1818335 and NS18667 (MCB) and ES07066.

20.9 INSULIN BINDING SITES ARE WIDELY DISTRIBUTED IN RAT BRAIN: IN VITRO QUANTITATIVE RECEPTOR AUTORADIOGRAPHY. E.S. Corp*, D.A. Davidson*, D.P. Figlewicz*, D.M. Dorsa, S.C. Woods, D. Porte, Jr.*, D.G. Baskin. Depts. of Psychology, Medicine, Pharmacology and Biological Structure, Univ. of Washington and VA Medical Center, Seattle, WA 98108.

Recent evidence suggests that insulin is widely distributed throughout the brain and may be involved in feeding and metabolism. However, the anatomical location of insulin's action is not completely understood. Our approach to this problem was to localize insulin specific binding (SB) sites by in vitro receptor autoradiography. Therefore, frozen-dried coronal sections of rat brain were labeled with ^{125}I-monoiodinated human insulin (0.5nM; S.A.=336 μCi/μg). The location of binding was determined by apposing radiolabeled sections to LKB Ultrofilm (5 days exposure). Concentrations of bound insulin in small anatomical regions were determined by computerized densitometry, using a standard curve of optical density (OD) vs. fmol/mm^2 of tissue slice which had been calibrated with tissue standards of known radioactivity. The results showed that low levels of SB (radioactivity displaced by 0.1μM unlabeled porcine insulin) were widespread throughout the brain (e.g., SB=5x10^{-3} fmol/mm^2 in septohippocampal region and ventromedial hypothalamus). However, high concentrations of insulin SB sites were present in the following regions:

Region	SB (fmol/mm^2)
Raphe nucleus	13.0 x 10-3
Arcuate nucleus*	7.5 x 10-3
Dorsomedial nucleus*	7.5 x 10-3
Inferior olivary nucleus	7.5 x 10-3
Nucleus of the solitary tract*	6.1 x 10-3
Paraventricular nucleus*	5.7 x 10-3
Tract of the trigeminal nerve	5.7 x 10-3

These results show the presence of insulin SB sites in brain regions known to be involved in feeding and metabolism (*), some of which have been shown to be uptake sites for blood-borne insulin. Our new findings are: (1) insulin SB occurs in the dorsomedial nucleus and paraventricular nucleus, both of which have been implicated in the regulation of feeding and metabolism; (2) insulin SB occurs in the raphe nucleus, tract of the trigeminal nerve and inferior olivary nucleus. This suggests either that these structures participate in energy homeostasis, or that insulin has broader responsibility in the CNS than has previously been suspected.

20.10 MEAL PATTERN ANALYSIS AND THE HOMEOSTATIC MODEL OF FEEDING. Thomas W. Castonguay*, and Judith S. Stern* (Spon: M. McGinn). Food Intake Laboratory and Nutrition Department, University of California - Davis, Davis CA 95616

The meal patterns of 8 week old male Sprague-Dawley rats (n=12) were studied over a two week period. All animals were individually housed in custom made modules, and given ad libitum access to Purina rat chow and water. Each module was equipped with a food cup placed on a Mettler balance that was capable of measuring 0.01 g. Output from the balance was monitored once per second by an LSI 11/02 minicomputer. The data were then repeatedly analyzed using five end-of-the-meal (traditionally referred to as the intermeal interval or IMI) definitions: 2, 5, 10, 20, and 40 minute definitions were used. Minimum meal size was defined as 0.05 grams. Thus, in order for a meal to be recorded, a rat had to eat at least 0.05 g and stop eating for a minimum of 2 or a maximum of 40 minutes. Intervals that did not meet the required definition were scored as pauses within a meal, and food intake from bouts both preceding and subsequent to the pause were scored together as part of the same meal. The resulting meal patterns from each of the animals were then characterized with respect to daytime and nighttime meal frequency, size, and duration. Further, the relationships between these variables were examined using a correlational analysis. Finally, the intervals between meals were correlated with both meal size and meal duration.

These analyses showed that variations in IMI definition had an effect upon meal size, duration and frequency. Shorter IMI's promoted the observation of more frequent but smaller meals, that were also shorter in duration. The relationship between meal size and meal duration was surprisingly weak. Further, variations in IMI definitions strengthened the observed correlation between the size and duration of nighttime meals but weakened the same correlation within daytime meals.

Of note, too, was the observation that the correlation between meal size and either the interval preceding the meal (the premeal interval) or the interval subsequent to the meal (the postmeal interval) was not reliably correlated. Increasing the IMI definition promoted weaker correlations between premeal interval and meal size, but strengthened the correlation between postmeal interval and meal size. At best, the postmeal interval/meal size correlation was r=0.288 with the use of a 40 minute IMI, and at worst, r=-0.047, with the use of a 2 minute IMI.

These results are in marked contrast to those reported by LeMagnen and coworkers. Their implications on LeMagnen's homeostatic model of feeding behavior will be discussed.

20.11 OPIOID REGULATION OF NUTRIENT SELECTION AND INTAKE. B.A. Gosnell, D.R. Romsos*, J.E. Morley, A.S. Levine, Neuroendocrine Res Lab, Minneapolis, MN, 55417, Dept of Food Sci and Human Nutr, Michigan State University, East Lansing, MI, 48824, and Geriatric Res Educ and Clinical Care Center, VA Medical Center, Sepulveda, CA, 91343.

Several experiments were performed to evaluate the effects of opioid agonists and the antagonist naloxone on the intakes of diets of varying carbohydrate and fat composition. In the first experiment, rats were maintained on either a high carbohydrate (CHO) diet (69% CHO, 20% protein, 12% fat), an intermediate (INT) diet (40% CHO, 20% protein, 40% fat), or a high fat (FAT) diet (3% CHO, 20% protein, 77% fat). After a 20 hour fast, naloxone injections (s.c.) caused a greater reduction in caloric intake in rats fed the FAT diet than in rats fed the INT or CHO diets. Naloxone (10 mg/kg) reduced 1 hour mean caloric intakes by 53, 61 and 71% in the CHO, INT and FAT groups, respectively. These differences, however, are complicated by the fact that the baseline intakes in the three diet groups were different; 18, 23 and 30 Kcal, respectively, for the CHO, INT and FAT groups. When nocturnal intake was measured in the non-deprived state, naloxone reduced caloric intake to an approximately equal degree in all 3 diet groups. The feeding effects of the opioid agonists ketocyclazocine (KC) and butorphanol tartrate (BT) were also tested in rats maintained on either the CHO, INT or FAT diet. Both KC and BT were generally more effective in rats fed the FAT diet than in those fed the CHO diet.

In a second set of experiments, rats were given access to both CHO and FAT diets. After a 20 hour fast, naloxone (s.c.) reduced total caloric intake. A 10 mg/kg naloxone dose reduced 1 hour total intake by 52%; calories derived from the FAT diet were reduced by 72%, whereas calories derived from the CHO diet were reduced only 29%. This preferential reduction of fat intake was not found when nocturnal intake was measured in non-deprived rats. When daytime intake was measured after the administration of butorphanol tartrate (BT) to rats offered a CHO and FAT diet choice, overall caloric intake was increased by doses from 0.5 to 10 mg/kg. This increase was due primarily, though not exclusively, to an increased intake of the FAT diet. Six hours after injection, mean total caloric intake was increased from 2 Kcal in the control condition to 20 Kcal in the 10 mg/kg condition; 63% of this intake was derived from the FAT diet.

These studies generally support the work of Marks-Kaufman and Kanarek (Pharmacol. Biochem. Behav. 12:427, 1980; Psychopharmacol. 74:321, 1981) which suggests that opioids may partially regulate both the amount and the type of nutrients ingested.

20.12 EFFECT OF CHRONIC ADMINISTRATION OF MORPHINE AND NALMEFENE ON FOOD INTAKE AND BODY WEIGHT IN DIABETIC AND CONTROL RATS. A.S. Levine, M. Grace*, C. Billington*, B.A. Gosnell, D.M. Brown*, J.E. Morley. Neuroendocrine Res Lab and Geriatric Res Education and Clinical Center, VA Medical Center, Minneapolis, MN and Sepulveda, CA.

Diabetic animals respond differently than non-diabetic animals to various effects of opiates, including analgesia and food intake. We investigated the effect of chronic administration of morphine (10 mg/kg bid) and nalmefene (10 mg/kg bid), a long acting opioid antagonist, on food intake and body weight in diabetic rats (DB) and their non-diabetic (ND) controls. Food intake was also measured 2, 4 and 6 h following administration of morphine on days 1, 2 and 7. Morphine (2.3 $\pm$ 0.5 g/4h) failed to increase 4 h food intake above saline baseline (2.0 $\pm$ 1.0 g/4h) on day 1 in the DB rats, whereas morphine (1.9 $\pm$ 0.3 g/4h) did stimulate 4 h food intake above saline baseline (0.4 $\pm$ 0.2 g/4h, $p < 0.05$) in the ND rats. By day 7 morphine caused a significant increase of 4 h food intake compared to baseline in both ND and DB animals (ND: 0.3 $\pm$ 0.1 g vs 2.5 $\pm$ 0.4 g, $p < 0.05$; DB 1.8 $\pm$ 1.2 g vs 5.8 $\pm$ 0.7 g, $p < 0.05$). However, cumulative food intakes for 24 and 48 h were decreased on days 1 and 7. Changes in body weight and food intake were also measured over a 21 day period. Diabetic animals receiving either morphine or nalmefene gained significantly less weight than the saline injected DB rats (morphine: 8.4 $\pm$ 3.3 g, $p < 0.05$; nalmefene: 20.1 $\pm$ 4.5 g, $p < 0.05$; saline: 31.2 $\pm$ 3.1 g). The ND animals receiving nalmefene gained slightly less weight than the ND rats injected with saline (18.0 $\pm$ 4.2 g vs 24.1 $\pm$ 7.7 g). Morphine resulted in a marked weight loss in the ND animals by day 21 (-13.2 $\pm$ 7.5 g). In the DB rats 21 day cumulative food intake was decreased following morphine administration (920.0 $\pm$ 38.4 g) or nalmefene administration (976.4 $\pm$ 23.3 g) compared to saline administration (1087.2 $\pm$ 18.6 g). In contrast, neither morphine (385.8 $\pm$ 13.2 g) nor nalmefene (464.0 $\pm$ 17.1g) effected food intake compared with saline injected (429.6 $\pm$ 22.1 g) in ND controls. Thus chronic administration of morphine and nalmefene to DB animals decreased both body weight gain and food intake, whereas ND rats were only sensitive to the morphine-induced reduction in body weight gain. The maximum weight loss for the animals receiving morphine was much greater in the ND controls (-56 $\pm$ 8 g) compared to the DB rats (-14 $\pm$ 2 g). These data demonstrate a differential effect of morphine and nalmefene on food intake and body weight change in DB and ND rats.

20.13 NEUROCHEMICAL CORRELATES OF FEEDING BEHAVIOR IN HYPEROSMOTIC WESTERN TOAD (BUFA BOREAS). K. H. Tachiki*, C. F. Baxter, J. W. Dole* and B. B. Rose*. V.A. Medical Center, Sepulveda, CA 91343, UCLA Sch. Med., Los Angeles, CA 90024, Dept. Biology, California State Univ., Northridge, CA 91330.

In western toads, acclimation to a hyperosmotic (HOA) environment (400mOs) alters prey-capture response. HOA acclimation also results in a change of many amino acid levels in brain tissue, including the levels of some putative neurotransmitters. This suggests that changes in behavioral responses may be related to these biochemical changes in the brain.

Feeding responses to mealworms by HOA toads were monitored and the following parameters quantitated: 1) time elapsed before feeding began (LT), 2) food consumption rate (FCR), and 3) the strike accuracy (SA), i.e. the consistency with which the toad's tongue hit targeted mealworms.

For amino acid analysis, toads were sacrificed following a behavioral test session. Brains were removed, divided into cerebral hemispheres (CH), optic lobs (OL), and olfactory bulbs (OB), and tissue extracts prepared of each brain area. Amino acids were quantitated employing an automated amino acid analyzer.

Pearson Correlation Analysis was used to assess the strength of association between the three behavioral measures and the levels of each of 22 amino acids in the three brain areas of responding toads. Of these, the levels of ten amino acids (GABA, ASP, PHE, GLU, GLY, SER, ASN, ALA, GLN, 3-METHYL-HIS) in one or more of the brain areas were significantly correlated ($p<0.05$ with at least one behavioral parameter. The levels of the first five amino acids were similar in the same brain areas of both normally-behaving HOA-acclimated toads and normally-behaving freshwater-acclimated toads. They were used for further analysis of neurochemical correlation with feeding behavior.

CORRELATIONS BETWEEN BEHAVIOR AND AMINO ACIDS IN BRAIN AREAS

BEHAVIOR	GABA	ASP	PHE	GLY	GLU
LT	CH*		OL* OB*	CH***	--
FCR	CH* OL*	CH* OL* OB*	OL** OB**	CH**	CH*
SA	--	CH* OL* OB*	OL** OB**	CH*	CH**

* $p<0.05$ ** $p<0.01$ *** $p<0.001$

These five amino acids, in one or more brain regions, were directly correlated with one or more of the measured parameters of feeding behavior. Supported in part by the Medical Research Service of the Veterans Administration.

20.14 NEURAL TRANSPLANTS AND FEEDING BEHAVIOR. T.J. Collier, P.F. Aravich*, and J.R. Sladek, Jr. Department of Anatomy, University of Rochester Medical Center, Rochester, NY 14642.

The development of techniques for neural transplantation has stimulated interest on the impact such grafts may have on the behavior of the host organism. Neural transplantation may be particularly useful in determining the roles specific transmitter-containing cells play in the elaboration of specific behaviors. One behavior that appears to be especially amenable to transplantation techniques is feeding behavior, which is influenced by a wide variety of established neurochemical systems. The feeding effect produced by central norepinephrine (NE) injections has been one of the most thoroughly studied responses, and can be obtained by intrahypothalamic or intraventricular NE infusion. Fetal locus coeruleus (LC) neurons were transplanted into the third ventricles of adult rats to determine if transplanted NE-containing neurons can mimic the feeding effect of intraventricular NE infusion.

Eight male Sprague-Dawley rats completed the experiment. Five subjects received intra-third ventricular implants of fetal (15 d. gestation) pontine tissue, including the LC, and three subjects received control implants of cerebellar tissue. The effects of the transplants on food intake (Purina chow) and body weight were determined across a 9-mo. period. The diet was then switched to a 0.1% quinine HCl (QHCL) diet, since NE infusions are associated with finickiness to bitter diets. Following testing, the rats were sacrificed and the presence of catecholamine-containing neurons in the pontine tissue verified utilizing the ALFA histofluorescence technique.

It was found that the LC rats were not hyperphagic on the chow diet, nor did they gain excess body weight. Epididymal fat-pad weights also indicated that the LC rats were not obese relative to controls. The LC rats were, however, abnormally reactive to the QHCL diet compared to controls (-59.7$\pm$5.8% vs. -43.6$\pm$3.0% reductions from baselines, respectively).

These data indicate that transplanted NE-containing neurons can induce finickiness to a bitter QHCL diet, but not hyperphagia and excess body-weight gain on a standard diet. This suggests either that the sensitivity of the finickiness effect is greater than that of the hyperphagic effect, or that different substrates mediate the two phenomenon. Transplantation of greater numbers of NE-containing neurons may be required to demonstrate an effect of LC implants on hyperphagia and body weight gain. Nonetheless, this investigation reveals that neural transplants can influence at least certain aspects of feeding behavior, and may be useful in lesion/replacement studies examining the role of transmitter-identified neurons in the neurobiology of feeding behavior.

20.15 HEPATIC VAGOTOMY BLOCKS DIETARY OBESITY BUT NOT DEXAMETHASONE ANOREXIA. C.M. Woodbury*, F. Rodman* and R.M. Gold (SPON: A. Trehub). Department of Psychology, Univ. of Mass., Amherst, MA 01003.

Hepatic vagotomy has been shown to block glucagon anorexia. This suggests that glucagon anorexia is mediated by hepatoreceptors which send a satiety signal to the brain via the vagus nerve. The liver is known to contain glucocorticoid receptors. The present report examined the effect of hepatic vagotomy on another anorexic agent, the potent synthetic glucocorticoid Dexamethasone. We incidentally examined the effect of hepatic vagotomy on dietary obesity.

Prior to surgery, five days of a diet of 10% sugar water and Purina Mouse Chow increased the weight gain of female rats from 0.5 g/day to 6.2 g/day. Over the first 14 days following hepatic vagotomy the weight gain fell to only 0.6 g/day, whereas sham vagotomized controls continued to gain 2.5 g/day on the palatable diet. Thus, despite previous reports, hepatic vagotomy blocks dietary obesity when the rats are tested immediately after surgery. Perhaps the orosensory properties of good tasting food activate efferents to the liver which block hepatically mediated satiety in response to absorbed nutrients.

In contrast, despite the highly palatable diet, 100 ug/Kg of Dexamethasone, delivered for three days via the drinking water, produced rapid weight loss in both the hepatic vagotomized and sham vagotomized groups (12.3 and 19.1 g/day weight losses, respectively). The anorexic effect of dexamethasone must therefore be mediated via other glucocorticoid receptors such as those in brain, pituitary, and thymus.

20.16 ADRENAL SUPPRESSION FOLLOWING HYPOTHALAMIC KNIFE-CUTS THAT PRODUCE OBESITY. A. Sylvan*, J. Fecko*, R.M. Gold and J. McElroy*, Division of Neuroscience and Behavior, Psychology Department, University of Massachusetts, Amherst, MA 01003.

The hypothalamic knife cuts that elicit hyperphagia and obesity in rats are located alongside the paraventricular nucleus. The PVN has also been identified as the primary source to the pituitary of a 41AA corticotropin releasing factor. This suggests that knife cut obesity is produced via insult to the hypothalamo-pituitary-adrenal axis.

Ether stress tests were conducted prior to and 4 days after unilateral adrenalectomy and/or knife cuts. As compared with double sham-operated controls, the serum corticosterone response to ether stress after unilateral adrenalectomy was reduced by 39.2%. Hypothalamic knife cuts alone reduced the ether stress response 64.5%. Combined surgeries (knife cuts plus unilateral adrenalectomy) increased the suppression to 74.4%. Knife-cuts, but not unilateral adrenalectomy, also reduced basal (pre-stress) corticosterone levels.

Fifteen days after the initial surgery, all remaining adrenals were removed. In the previously double sham-operated rats, adrenal weights at 15 days were 37.9% greater than at initial surgery (vs. an 18.4% growth of body weight). Hypothalamic knife cuts without unilateral adrenalectomy completely suppressed this maturational adrenal growth (vs. a 71.5% increase in body weight). Using the same paradigm, sham knife cuts with unilateral adrenalectomy incerased the weight of the remaining adrenal by 90.5%. Hypothalamic knife cuts blocked 73% of this compensatory hypertrophy.

Adrenocortical secretions and adrenal weights were consistently suppressed by obesifying hypothalamic knife cuts. This supports the notion that hypothalamic knife cut obesity is mediated via interruption of the adreno-regulatory axis.

20.17 POTASSIUM-INDUCED NOREPINEPHRINE RELEASE FROM HYPOTHALAMUS OF RATS: MODULATION BY INSULIN. B.J. Mullen* and R.J.Martin(SPON: L.M.Proenza).Dept. of Foods & Nutrition, University of Georgia, Athens, GA 30602

Postprandial insulin release is associated with a satiated or anabolic state while preprandially the converse is true. Although insulin plays a major role in glucose metabolism, its influence on central feeding mechanisms is unclear. Since the activity of hypothalamic neurons has been shown to reflect feeding behavior, we investigated the possibility that insulin's effect on food intake was mediated by direct action at this brain site. The effect of insulin on in vitro hypothalamic norepinephrine (NE) release was measured. Ad libitum chow fed male Sprague Dawley rats were decapitated and brains were removed. The hypothalamus was dissected into a lateral (LH) portion and a ventral medial (VMH) portion. Control tissues were preincubated for 60 minutes in Krebs-Ringer buffer containing 10 mM glucose, 10 mg% sodium metabisulfite and 1 uM pargyline. Experimental tissues were preincubated in the same buffer containing 50 uU/ml insulin. In order to induce NE release, tissues were then depolarized for 10 minutes with buffer containing 100 mM potassium. Media were collected, concentrated over an alumina column, and assayed for NE using HPLC with electrochemical detection. In the VMH, insulin depressed release of NE while in the LH, a slight elevation of NE was noted. Considering NE's putative inhibitory role in the hypothalamus, a depression of NE in the VMH should result in satiety, while an elevation of NE in the LH should result in an inhibition of feeding. These data are in agreement with Porte et al. who has demonstrated a satiating effect of insulin when infused into lateral cerebral ventricles. Thus, these results suggest that that the peripheral effect of physiological levels of insulin are reflected in central mechanisms, however further research in this area is needed to confirm these findings.

20.18 EFFECTS OF ALTERING FATTY ACID OXIDATION RATES IN THE HYPOTHALAMUS OF RATS ON FOOD INTAKE. J. L. Beverly* and R. J. Martin, Dept. of Foods and Nutrition, Univ. of Georgia, Athens, GA 30602

Metabolic profiles of the ventral hypothalamus are related to feeding status in rats (Kasser et al., Am. J. Physiol. 1985, in press) such that the rate of fatty acid oxidation (FAO) in the ventral lateral hypothalamus (VLH) is reciprocally related to level of food intake. The objective of this research is to determine if induced changes of the metabolic pattern in the VLH will influence the amount of food eaten. A two step approach has been undertaken, an in vitro evaluation of pharmacologic compounds followed by in vivo central infusions.

in vitro: Compounds which increase (HL-0654, clofibrate and L-carnitine) or decrease (4-pentenoic acid) hepatic FAO were evaluated at concentrations of .01 mM to 1 mM (except clofibrate, .1 mM to 10 mM). Compounds were added to incubation media (Krebs bicarb., 2% BSA, 1 mM palmitate) and $^{14}CO_2$ from ^{14}C-1-palmitate (1 uCi/umole) collected after 3 hr incubations with hypothalamic, cortical or hepatic tissue (collected at incubation from 200 g rats fed chow fed lib). Clofibrate stimulated hepatic FAO at 2 mM but had no effect on (.01 mM to 2 mM) or inhibited (2 mM to 10 mM) FAO in hypothalamic tissue. HL-0654 inhibited FAO in hypothalamic tissue at 1 mM but had no effect on hepatic FAO rates. 4-pentenoic acid and L-carnitine reduced or increased FAO, respectively at all concentrations measured.

in vivo: L-carnitine (1 mM) and 4-pentenoic acid (.1 mM) were compared to sCSF in rats with chronic 3rd ventricle cannulae. Compounds were administered dissolved in sCSF via osmotic pump (.5 ul/hr) for 14 d, after which rats were sacrificed. No differences in food intake or body weights during infusions were observed. In vitro evaluation indicated limited diffusion of compounds as, of tissues evaluated, only the ventral medial hypothalamus exhibited expected alterations in FAO. Evaluations with bilateral cannulae immediately dorsal to the VLH are presently in progress.

20.19 THE EFFECT OF SIX-HYDROXYDOPAMINE ON FOOD INTAKE AND BRAIN BIOGENIC AMINES IN CHICKS. W. J. Kuenzel. Dept. of Poultry Sci., Univ. of Maryland, College Park, Md. 20742.

Six-Hydroxydopamine (6-OHDA) was administered to chicks intracerebroventricularly (ICV) to study the effect of the neurotoxin on food intake and motor activity. The experimental design consisted of six groups in which two levels of pargyline (50 mg/Kg and 100 mg/Kg) and three concentrations of 6-OHDA (0, 200 and 300 µg) were examined. Six chicks were included in each of the experimental groups and pargyline (P) was injected intraperitoneally 15 min. prior to the ICV injection when two weeks of age. Food intake and body weight were monitored daily for 14 days and a subjective scoring of motor activity and behavior were determined daily. When four weeks of age all chicks were sacrificed and brains were dissected rapidly. While freezing, each brain was dissected into three pieces: striatum, hypothalamus and brainstem. All brain pieces were frozen in liquid nitrogen for later determination of dopamine, norepinephrine, epinephrine, 5-Hydroxyindole 3-acetic acid, and serotonin. Reverse phase high pressure liquid chromatography with electrochemical detection was used to quantitate biogenic amines in brain tissue. A dose-response effect was found; the greatest reduction in food intake and body weight loss occurred in the group injected with 100 mg/kg P followed by 300 µg 6-OHDA. The aphagic response, however, was transient and lasted only an average of 4 days in the highest drug treatment group. Several behavioral abnormalities were observed particularly in the two 300 µg 6-OHDA groups. The most commonly observed abnormalities included: hyperactivity, imbalance, head orientation problems, head shakes and pecking the air while attempting to feed. The largest differences in brain concentrations of biogenic amines occurred in the striatum. Striatal dopamine concentrations were found significantly depressed ($P < 0.05$) in the 6-OHDA treatment groups compared to controls. Similar to the response in chicks following large bilateral lesions made throughout the lateral hypothalamic-thalamic brain regions, aphagia persisted for only a few days in experimental groups. These data are in contrast to mammalian findings in which aphagia and adipsia last for several days and tube feeding is required to maintain rats subjected to bilateral hypothalamic lesions or ICV administration of 6-OHDA.

FEEDING AND DRINKING II

21.1 IMPACT OF FOOD DEPRIVATION ON HYPOTHALAMIC AND CORTICAL α1 AND α2-NORADRENERGIC RECEPTORS. M. Jhanwar-Uniyal*, M. Darwish*, G. Beitmirza* and S.F. Leibowitz. (SPON: L-M. Kow) The Rockefeller University, New York NY 10021.

Norepinephrine (NE) alters feeding behavior when injected directly into specific hypothalamic areas. The medial paraventricular nucleus (PVN) has been identified as the most sensitive brain site to NE, which stimulates food intake through α2-noradrenergic receptors. NE turnover has been found to be increased specifically in this nucleus in response to food deprivation. The present biochemical study was undertaken to investigate the impact of short- and long-term food deprivation on α1 and α2-noradrenergic receptors, in large brain areas and discrete hypothalamic nuclei.

Male albino rats, maintained on a 12:12 light/dark cycle, were deprived of food (water was provided ad lib) for either 0h, 3h (18.00h-21.00h), 6h (00.00h-06.00h) or 48h. The rats were sacrificed by decapitation, and 3 large hypothalamic areas (medial, lateral, and basal) and frontal cortex were microdissected. In other animals, 8 discrete hypothalamic nuclei were micropunched. Standard radioligand binding techniques were employed with the α2-noradrenergic agonist [^{3}H]p-aminoclonidine ([^{3}H]PAC, 0.05-1.0 nmoles; 3.0 nmoles for discrete hypothalamic areas), and the α1-noradrenergic receptor antagonist [^{3}H]prazosin (0.05-1.0 nmoles). Nonspecific binding was determined in the presence of phentolamine (50 µM). The specific binding was expressed in fmoles/mg protein.

The results demonstrated that, of the 3 large hypothalamic regions examined via Scatchard analysis, only the medial hypothalamus showed a significant down-regulation of its α2-noradrenergic receptors in response to 48h food deprivation. A 52% decrease ($P < 0.02$) in Bmax was demonstrated by the high affinity binding sites, in contrast to no change in low affinity sites. The K_D for both high and low affinity sites was unaffected. The α1-noradrenergic receptors did not exhibit a change as a result of food deprivation in any of the areas examined. Short-term food deprivation (3h), specifically during the onset of the dark period, also resulted in a down-regulation (-65%, $P < 0.001$) of the α2-noradrenergic receptor sites specifically in the PVN. However, 6h food deprivation during the second half of the dark period resulted in an up-regulation (+54%, $P < 0.05$) of PVN [^{3}H]PAC binding. These results indicate that food deprivation produces site-specific changes in α2-noradrenergic receptors in the medial hypothalamus, particularly in the PVN. Together with other biochemical evidence revealing deprivation-induced changes in PVN NE turnover, they support pharmacological results indicating a specific role for a PVN α2-noradrenergic system in the regulation of feeding behavior.

21.2 DO INTESTINAL CALORIES DETERMINE THE INTERMEAL INTERVAL (IMI)? V. E. Mendel, J. Kobayashi and T. J. Kalogeris. Depts. of An. Physiol. and An. Science and, Food Intake Lab, Univ. of Calif., Davis, CA 95616.

Six rats, each with gastric and duodenal cannulas were individually housed and maintained on semi-purified diet and tap water. All were trained to sham-feed Vivonex™-high nitrogen (VHN) or 20% sucrose. During experimental periods the animals sham-fed liquid VHN with a caloric concentration of 1 Kcal/ml. Rats were fasted 13 to 16 hr, the gastric cannula were then opened and the stomach flushed 2-4 times with 0.9% saline. In experiment 1, ten ml of 20% sucrose at 0.25, 0.5 and, 1.0 Kcal/ml was duodenally infused at a rate of 0.42 ml/min beginning 10 min after sham-feeding was well established; thus, caloric loads of 2.5, 5.0 and, 10 Kcal were delivered in about 24 min. In experiment 2, 5 ml VHN was duodenally infused at 0, 1, 2, 3 and 4 Kcal/ml for total caloric loads of 0, 5, 10, 15 and 20 Kcal over 12 min. The results are shown in the table.

Caloric load	n	Vol. (ml)	IMI (min)
0.0	5	5	9.28 ± 5.19
* 2.5	4	10	16.35 ± 6.53
5.0	3	5	24.42 ± 4.12
* 5.0	4	10	52.47 ± 8.44
10.0	8	5	51.36 ± 10.18
*10.0	4	10	>120
15.0	2	5	>120
20.0	3	5	>180

*20% sucrose.

We conclude that IMI increases exponentially with increasing caloric load, however, 20% sucrose produces a significantly more rapidly rising curve than does VHN. It is not yet clear whether the volume infused or the duration of infusion interacts with IMI to influence its duration. It appears that the small intestine is capable of producing a signal in response to caloric load that results in satiety, although factors other than calories may be involved.

21.3 HEPATIC VAGOTOMY OR TOTAL LIVER DENERVATION CAN BLOCK PANCREATIC GLUCAGON'S SATIETY EFFECT. L. MacIsaac*& N. Geary (SPON: D. Hood). Dept. of Psychology, Columbia University, New York, NY 10027.

The inhibitory effect of pancreatic glucagon (PG) on meal size in rats has been blocked by selective hepatic vagotomy (HV) in some experiments[1,2], but survived HV or total liver denervation (TLD) in others[3,4]. We therefore reinvestigated the effects of liver denervations on the inhibitory actions of PG and of epinephrine (EPI), another hormone that may inhibit feeding via an hepatic neural mechanism[5]. First, either HV, selective hepatic denervations that spare only the hepatic branch of the vagus (PLD), or sham operations (SH) were done, and evaporated milk meal sizes compared after after i.p. injection of vehicle (VEH), PG, or EPI. PG's satiety effect was blocked by HV, but not by PLD. EPI inhibited meal size potently in both HV and PLD rats. Mean +SEM meal sizes:

		PG(mcg/kg)		EPI(mcg/kg)	
	VEH	100	400	12.5	50
SH	18.1	14.7**	12.3**	13.4**	9.3**
(n=20)	±0.7	±0.9	±1.0	±1.1	±1.2
HV	13.9	12.8	13.9	9.8**	8.5**
(n=14)	±0.9	±1.3	±1.3	±1.4	±1.4
PLD	14.9	9.8**	9.5**	11.7*	6.6**
(n=12)	±1.3	±1.2	±1.3	±2.0	±1.1

*p<.05 vs VEH, Dunnett's test after ANOVA; **p<.01.

The same rats were then reoperated to produce TLD; i.e. HV was done on PLD rats, PLD on HV rats, and SH on SH rats. TLD rats did not respond to PG, but EPI still inhibited meal size:

		PG(mcg/kg)			EPI(mcg/kg)	
	VEH	100	200	400	12.5	50
SH	14.7	12.3*	11.5**	11.4**	13.1	11.3*
(n=14)	±2.6	±1.3	±0.8	±0.9	±1.0	±1.1
TLD	12.3	11.2	12.0	11.7	7.8**	8.4**
(n=11)	±0.6	±1.2	±1.4	±1.4	±0.8	±1.2

These data indicate that the hepatic branch of the vagus is necessary for PG's satiety effect and fail to suggest a role for any other component of hepatic innervation in this effect. Further work is needed to determine the generality of this conclusion, however, because PG has continued to inhibit meal size after HV or TLD under apparently similar test conditions[3,4]. Finally, these data extend previous indications [2,3] that EPI's inhibitory effect on meal size is not mediated by hepatic innervation.

REFS: [1]PhysiolBehav31:391,1982. [2]SocNeurosciAbstr10:1109, 1985. [3]PhysiolBehav31:391,1983. [4]FedProc44:1164,1985. [5]JCCPsychol96:361,1982.

21.4 **SEROTONIN-INDUCED DRINKING IN RATS: FURTHER ANALYSIS** **N.E. Rowland and M.J. Fregly*. Depts. Psychology and Physiology, Univ. of Florida, Gainesville FL 32611.**

We have previously shown that serotonin(5HT) induces drinking in rats after peripheral (sc) administration. This drink may be inhibited by methysergide. Drinking is also induced by 5-hydroxytryptophan (5HTP), the precursor of 5HT, and this response is blocked by decarboxylase inhibitors as well as by methysergide. 5HT and 5HTP also induce the release of renin from the kidney, and it appears that the consequent formation of angiotensin II (AII) may mediate the drinking response.

To investigate this possibility, 5HT (4 mg/kg) and 5HTP (25 mg/kg) were administered sc to rats that were acutely nephrectomized, or laparotomized controls. The drinking response to 5HT was abolished by nephrectomy, but that to 5HTP was largely unaffected. Lower doses of 5HT also failed to induce drinking in nephrectomized rats. This suggests that the absence of drinking to 5HT in nephrectomized rats is not due to debilitating hypotension, and thus the peraistence of 5HTP drinking after nephrectomy is puzzling. We next showed that 5HTP drinking could be abolished by either peripheral or cerebroventricular (ic) injection of the 5HT antagonist metergoline. The role of angiotensin II in brain seems to be nonessential because ic saralasin had no effect on drinking induced by peripheral 5HT or 5HTP, but the same dose (250ng, ic) antagonized the dipsogenic action of AII (200 ug/kg, sc). It thus appears that no single theory can account for drinking induced by 5HT (which cannot cross the blood brain barrier) or 5HTP (which can enter the brain and be decarboxylated to 5HT).

In related experiments we measured water intake following peripheral administration of the 5HT agoniat, quipazine, and the 5HT- releasing drugs, fenfluramine and p-chloroamphetamine. In two studies, quipazine (10-20 mg/kg, ip) induced significant drinking, mostly in the 2nd hour after injection. The amount consumed also increased up to 5x with repeated daily administration. However, in two other studies quipazine produced no drinking; the reasons for this discrepancy are not clear to us. Quipazine has been reported to produce a short-lived rise in plasma renin activity, but we found no increases at the time (1-2 hr) at which any drinking normally would occur. P-chloroamphetamine, in doses which release renin, did not cause drinking and all of the rats were severely debilitated. Fenfluramine also failed to stimulate drinking. **Support: NIH AM31837-03.**

21.5 EFFECTS OF HYPOPHYSECTOMY ON HYPOTHALAMIC OBESITY IN RATS: ROLE OF CORTICOSTERONE. R. L. Smith* and B. M. King. Dept. of Psychology, University of New Orleans, New Orleans, LA 70148.

Recent studies have found that obesity induced by lesions of the ventromedial hypothalamus (VMH) in rats and mice is both reversed and prevented by complete adrenalectomy (ADX)(i.e., plasma corticosterone levels < 1.0 µg/dl) and restored by administration of glucocorticoid hormones (Debons et al., Endocrinology, 112: 1847-1851, 1983; King et al., Am. J. Physiol., 245: E194-E199, 1983). Similar results have been reported for the effects of complete hypophysectomy (HYPOX) in mice (i.e., plasma corticosterone < 1.0 µg/dl)(Debons et al., Physiol. Behav., 29: 695-699, 1982), but of the many older studies that have investigated the effects of hypophysectomy in VMH-lesioned rats, none have reported any substantial suppression of weight gain or body fat content. Most of these studies, however, failed to include a sham hypophysectomized (SHYPOX)-VMH lesioned control group and none measured plasma levels of corticosterone. The present study therefore directly compared the effects of hypophysectomy and adrenalectomy in female rats given VMH lesions.

Commercially prepared HYPOX, ADX, and SHYPOX-SADX rats (Charles River Breeding Labs) received sham or bilateral VMH lesions approximately two weeks after the initial surgery. Body weight was measured daily for 20 days after the lesions. The SHYPOX-SADX-VMH rats (n=8) displayed a mean weight gain of nearly 200 g over this time period, but the abnormal weight gain was totally absent in VMH rats with complete adrenalectomy (n=8). Adrenalectomy did not significantly affect intracranial self-stimulation and thus the absence of hyperphagia was probably not due to fatigue or a general loss of motivation. Six rats with incomplete adrenalectomies displayed a moderate obesity (97 g/20 days) even though stress-induced corticosterone levels were very low (mean=2.7 µg/dl). Hypophysectomy partially suppressed weight gain in VMH animals, but as reported by others, the HYPOX-VMH rats (n=8) gained more weight than HYPOX rats with sham lesions (n=10)(83.9 g vs. -12.3 g/20 days). The HYPOX animals were found, however, to have low levels of plasma corticosterone (from residual pituitary tissue or of diencephalic origin) similar to that found in incompletely ADX rats. It was concluded that hypophysectomy and adrenalectomy have similar effects on hypothalamic obesity and that glucocorticoid hormones play a permissive role in the obesity syndrome, i.e., obesity is prevented in their absence, but even small concentrations allow for some abnormal weight gain.

21.6 CIRCADIAN VARIATION OF HEPATIC GLYCOGEN: EFFECT OF GLUCAGON ON FOOD INTAKE AND GLYCOGEN CONCENTRATION. L.J. Stein*, L. O'Farrell, and D. Novin. Dept. of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

The mechanism by which peripheral glucagon reduces food intake is unknown. One possibility is that glucagon (GCN) may decrease intake by activating hepatic glycogenolysis. To test this hypothesis, GCN's ability to reduce meal size and to deplete hepatic glycogen were compared. Each of 4 groups of adult male rats was maintained on ad lib chow pellets and trained to eat a chow mash meal at a different time of the (12/12) light cycle: beginning light (BL, n=12), mid-light (ML, n=15), beginning dark (BD, n=13), and mid-dark (MD, n=13). Thirty-min food intakes were recorded following i.p. saline or GCN (600 µg/kg) and are expressed as % of baseline. Glucagon reliably reduced 30-min food intake only at ML.

Group	Saline	GCN	p
BL	-4.3 ± 17.7%	-12.8 ± 23.3%	n.s.
ML	+25.8 ± 11.7%	-46.8 ± 13.1%	<.005
BD	-13.3 ± 17.9%	-11.7 ± 5.4%	n.s.
MD	+19.6 ± 16.5%	+25.2 ± 30.2%	n.s.

One week later, rats were again injected with saline or GCN and food was removed. After 30 min, rats were decapitated, truncal blood collected, and liver samples removed for glycogen assay. Glycogen was influenced by time of cycle ($F(3,45)=10.5$, $p=.008$) and by GCN administration ($F(1,45)=10.5$, $p=.003$). The interaction was not significant ($F(3,45)=0.2$, $p=0.9$). Glycogen of saline rats was highest at BL and lowest at BD. At ML, glycogen did not reliably differ between saline (37.3 ± 1.2 mg/gm) and GCN (31.3 ± 4.1 mg/gm), even though food intake was significantly reduced by GCN. Conversely, at BD, glycogen was reliably reduced in GCN-injected rats (saline: 26.0 ± 2.3 mg/gm vs GCN; 16.8 ± 1.6 mg/gm, $p<.05$), while food intake was not affected. Plasma glucose levels did not differ as a function of either time of cycle or GCN administration. These data demonstrate that the ability of GCN to reduce food intake can be dissociated from its action to reduce hepatic glycogen, and suggest that glycogenolysis, systemic hyperglycemia, and reduction of total hepatic glycogen are not sufficient to explain GCN-induced reduction of meal size.

21.7 Effects of the Narcotic Antagonist, Nalmefene, on Spontaneous and Insulin - Induced Food Intake and Body Weight Gain in Male Rats. J.W. Simpkins, M.E. Michel and R. Tuttle,* Department of Pharmacodynamics, College of Pharmacy, University of Florida, Gainesville, FL 32610 and Key Pharmaceuticals, Miami, FL 33269.

Narcotic antagonists have been shown to acutely block the hyperphagic response to a variety of stimuli. However, their efficacy in chronically reducing food intake is less well defined. We undertook studies to determine the acute and chronic effects of the narcotic antagonist nalmefene, insulin, and their combination, on food and water intake and on the rate of body weight gain in male rats. Rats, at an initial body weight of 290±2.5 gm were treated twice daily (0800 to 0900h and 2000 to 2100h) with protamine zinc insulin (5 IU/KgBW), nalmefene HCl (10 mg/KgBW), nalmefene followed 30 min later by insulin, or the vehicle for both compounds. Body weights were determined daily and food and water intake was quantitated for a 24h period, beginning on the 1st, 4th and 8th days of drug treatment. Insulin increased mean daily body weight gain by 33%; increased food intake on the 1st and 4th but not the 8th day of treatment; and increased water intake at each of the observation times. Nalmefene decreased spontaneous mean daily body weight gain by 30% but this effect was diminished late in the 8-day treatment period. Nalmefene reduced food and water intake on the 1st, but not 4th and 8th, day of treatment. However, nalmefene antagonized the insulin-induced increase in mean daily body weight gain and antagonized the hyperphagic and dipsogenic effects of insulin treatment. In a second experiment, these treatments were initiated when the male rats weighed 181±2.0 gm. Nalmefene reduced food intake on 1st, 9th and 16th days of treatment and mean daily body weight gain was reduced throughout the treatment period. When nalmefene was administered 2-times daily for 8 days prior to the initiation of twice-daily insulin treatments, nalmefene antagonized the insulin-induced increase in food and water intake on the 1st but not the 8th day of insulin treatment. After 8 days of nalmefene pretreatment, narcotic antagonist was less effective in antagonizing the insulin-induced increase in mean body weight gain. These studies indicate that (i) nalmefene can transiently reduce weight gain in larger animals (BW = 290 gm) and can persistently reduce weight gain in lighter rats (BW = 181 gm), (ii) nalmefene can antagonize insulin-induced food and water intake and body weight gain for 8 days and (iii) the ability of nalmefene to antagonize these effects of insulin dissipates with increasing length of pretreatment with the narcotic antagonist.

21.8 SATIETY IN 6-DAY-OLD RAT PUPS: IS GASTRIC DISTENSION THE ONLY CUE? C.B. Phifer, C.R. Sikes and W.G. Hall. Dept. of Psychology, Duke University, Durham, NC 27706.

The relative roles of pregastric, gastric and intestinal food cues as mediators of satiety were investigated in 6-day-old rat pups using a non-suckling model ingestive system (Hall, W.G., J. Comp. Physiol. Psychol., 93:977, 1979).

Sham-feeding pups (i.e. animals with stomach contents spilling through open gastric fistulas), experiencing only pregastric and non-distension related gastric cues, ingested over twice as much milk as pups with closed fistulas (18.3±2.4 vs. 9.1±1.2% body weight, $p<0.01$). This difference in intake was not due to the absence of intestinal food cues. In a second experiment, pups whose pylorus was occluded by a noose, and therefore receiving no intestinal food cues, ingested less than pups with an open pylorus [$F(1,21)=28.7$, $p<0.01$]. Furthermore, when a 5% body weight gastric preload of milk (or a non-nutritive preload of saline) was given to pups with an open or closed pylorus, the two groups exhibited equivalent degrees of intake inhibition. The amount of suppression in each group was equal to the volume of the preload. Gastric distension appeared to be the critical factor for inhibition of feeding; intake was terminated when stomach content volume reached approximately 6.5% of body weight, regardless of pyloric noose or preload condition.

In a third experiment, two groups of pups, i.e. one group with open pyloric nooses and one group with closed nooses, were allowed to load their own stomachs by orally ingesting milk until they terminated intake. Subsequently, gastric fistulas were opened in half the pups from each group, allowing ingested milk to spill from the stomachs. All pups were then given a second opportunity to feed. Pups whose stomach contents had been emptied resumed ingestion and consumed over 12% of their body weight in milk, regardless of whether they had milk in their intestines or not. Pups whose stomachs had not been emptied ceased feeding after consuming only 3% of their body weight [$F(1,28)=56.1$, $p<0.01$].

We conclude that intake termination in 6-day-old rat pups ingesting independently is a function of gastric cues, specifically gastric distension. Pregastric cues, acting in the absence of gastric cues, are not sufficient to suppress intake. Intestinal cues, both pre- and postabsorptive, appear to be unnecessary. Only at later ages do intestinal signals become important.

21.9 **PERIPHERAL ACTIONS OF FENFLURAMINE IN ANOREXIA AND TOLERANCE.** **J.Carlton and N.E.Rowland. Department of Psychology, Univ. of Florida, Gainesville FL 32611.**

The actions of fenfluramine (FEN) on central serotonin (5HT) systems have been well-established, but the relationship between these actions and the anorectic effect of the drug have been questioned. FEN has several peripheral actions including thermogenesis, metabolism (including futile cycles), and gastric clearance. We report a series of experiments investigating the role of peripheral factors in the production of anorexia and tolerance to FEN. 1. SHAM FEEDING. Rats with gastric fistulas were trained to sham feed a liquid diet. When intakes were stable, d,l-FEN (5 mg/kg) was given 30 min prior to daily sessions. FEN suppressed sham feeding on the first day by a % comparable to the inhibition of real feeding by this dose. Tolerance to the suppression of sham feeding developed within 5 days. Thus, anorexia and tolerance to FEN develop in the absence of normal accumulation of food in the upper digestive tract. 2. PRELOADS. Rats with indwelling gastric catheters were adapted to a deprivation schedule, and on test days were infused with loads of 0, 25 or 50% of the calories normally consumed. These preloads produced a graded suppression of the subsequent meal. FEN (0, 1 or 2.5 mg/kg) produced effects that were additive, but not interactive, with the preload. Thus, FEN does not seem to potentiate natural satiety signals. 3. CCK. The CCK antagonist, proglumide (200 mg/kg) reversed CCK (20 ug/kg) anorexia, but had no effect on FEN (5 mg/kg) anorexia. Thus, FEN does not appear to produce satiety indirectly by releasing CCK. 4. GUT 5HT. The concentrations of 5HT and 5HIAA were measured in rats given FEN (5 or 15 mg/kg) acutely or chronically (8 days). Brain, but not gut 5HT and 5HIAA were reduced in all treated groups. This suggests that FEN may not work via release of gut 5HT, although more sensitive measurements of release should be made. 5. EXERCISE. Syrian hamsters with free access to running wheels did not decrease their running (15 km/night) to FEN (20 mg/kg/day x 8 days). Both exercise and sedentary groups showed small but nonsignificant decreases in overall food intake and body weight gain, relative to vehicle-treated groups, but there was no selective enhancement of drug effect in the exercise group. FEN does not seem to affect muscular efficiency in this species. **Support: NSF BNS 82-16528.**

21.10 LESIONS IN THE VENTROMEDIAL HYPOTHALAMUS OR THE AMYGDALA DO NOT AFFECT NALOXONE'S SUPPRESSION OF WATER CONSUMPTION. G. A. Olson, M. F. Pignatiello*, A. J. Kastin, B. F. Geiger* and R. D. Olson. Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70148.

Previous work has indicated that opiate receptors of the ventromedial hypothalamus (VMH) do not mediate the suppression of feeding behavior produced by naloxone, since naloxone reduced eating in both VMH-lesioned and normal rats in deprivation-induced and appetitively-motivated feeding. One purpose of the present study was to determine if this finding also occurs with water consumption. A second purpose of this experiment was to test the effect of naloxone in rats with lesions in the amygdala. Previous studies had found that basolateral amygdala (BA) lesions produce either hypodipsia, hyperdipsia or no effect depending on their exact location. The effect of naloxone on water intake in these rats was not studied.

MIF-1 has been found to act like naloxone in some situations, including the suppression of fluid consumption by naloxone. Thus, both MIF-1 and naloxone were used here to evaluate their effects on drinking in these lesioned rats.

Four VMH-lesioned, six BA-lesioned, and five sham-operated adult female Long-Evans hooded rats were fed ad lib for several months after the operations, thus allowing ample recovery time. All animals were deprived of water for 12 hours before testing began and were deprived of food during testing. Amount of water intake was recorded every 30 min. for two hours starting immediately after the injections, which were given ip and consisted of either 2 mg/kg of naloxone, 2, 4 or 8 mg/kg of MIF-1, or diluent. Each rat received all five injections, one per day, every other day, over a nine day period.

There was a significant drug effect, with naloxone suppressing water intake relative to the diluent control group and to the 8 mg/kg dose of MIF-1. No other comparisons were reliable, and there were no interactions associated with the drug conditions. Although MIF-1 tended to reduce drinking, the effect was not statistically significant. There was no significant main effect for lesions. A significant lesion x time interaction occurred, however, with the BA-lesioned rats showing the greatest drinking for the first 30 min but slowed consumption in the 30-60 min interval relative to the other two groups, which continued high intake levels through 60 min. The VMH-lesioned rats also drank significantly more than the sham animals for the second interval. There were no differences between groups in consumption rate after 60 min.

These findings are in agreement with previous work on the suppression by naloxone of consumption in VMH-lesioned rats. Apparently the intact basolateral amygdala, like the VMH, is unnecessary for naloxone's effect on water consumption.

21.11 HYPERPHAGIA-INDUCING HYPOTHALAMIC AND PONTINE KNIFE-CUTS INTERRUPT OXYTOCIN PATHWAYS IN THE RAT BRAIN. A.L. Kirchgessner*, A. Sclafani and G. Nilaver. Downstate Medical Center of SUNY, Brooklyn Coll. of CUNY, Columbia Univ. Coll. Phys. & Surg., NY.

Bilateral parasagittal knife-cuts in the medial hypothalamus (MH) adjacent to the paraventricular nucleus (PVN) produce hyperphagia and extreme obesity in rats. A unilateral MH cut combined with a contralateral coronal cut in the caudal ventro- lateral pontine tegmentum also produces overeating. This indicates that fibers critical to hypothalamic hyperphagia extend into the hindbrain. At least some of these fibers may be PVN efferents as evidenced by retrograde labeling of PVN neurons following injection of HRP tracer into a pontine knife-cut (Kirchgessner and Sclafani, 1983). Since the axons which constitute the caudal projections from the PVN are predominantly oxytocinergic (Nilaver et al., 1980), we studied the effects of hyperphagia- inducing MH and pontine knife-cuts on oxytocin (OT) immunoreactivity.

Adult female rats received either (1) a unilateral parasagittal MH cut, (2) a unilateral coronal ventral pontine cut, or (3) a MH cut combined with a contralateral pontine cut. After 3 to 8 days of survival, the brains (100 um; coronal) were immunoreacted with specific rabbit antiserum to OT, employing the avidin-biotinylated peroxidase complex (ABC) method.

The results revealed that parasagittal MH and coronal pontine knife-cuts interrupt, although at different levels of the neuroaxis, OT fibers that course from the PVN in a caudo-lateral direction to reach the hindbrain. Distal to the unilateral MH cut, at the level of the midbrain, descending OT fibers that course dorsal to the substantia nigra were sparse compared to the contralateral unoperated side. In the medulla, OT immunoreactivity was also significantly reduced, on the cut side, in the ventrolateral tegmentum where fibers normally emanate from the main descending bundle to terminate in the nucleus of the solitary tract and dorsal motor nucleus of the vagus. Similar reductions in medullary OT were observed following unilateral ventral pontine cuts. However, although the unilateral MH and pontine knife-cuts clearly interrupted the ventro-laterally descending OT fiber bundle on the operated side, they did not affect the OT innervation of the vagus-solitarius complex. This suggests that OT fibers from the PVN to the hindbrain are crossed. Also, since a high density of OT fibers was seen in the vagus- solitarius complex following combined MH and contralateral pontine transections, bilateral innervation may be supplied by the periventricular bundle.

The present study demonstrates that hyperphagia-inducing knife-cuts interrupt PVN-hindbrain OT fibers, and suggest a role for OT in the hypothalamic hyperphagia syndrome. In addition, our findings indicate that the precise course of the descending PVN OT system is still only partially understood.

21.12 EFFECTS OF FOOD DEPRIVATION AND FOOD RESTRICTION ON PLASMA AND CEREBRAL TRYPTOPHAN AND TYROSINE CONTENT, ON PLASMA DBH ACTIVITY AND ON CEREBRAL BIOGENIC AMINES IN RATS. L. Thibault* and A.G. Roberge. Centre de Recherche en Nutrition et Département de Nutrition, F.S.A.A., Université Laval, Ste-Foy, Québec, G1K 7P4.

Adult rats were submitted to 4 days food deprivation or to 7 consecutive days on a 60% restricted energy intake, to obtain a weight loss of about 20%. Plasma and brain tryptophan and tyrosine content were measured, as well as brain biogenic amines in five different structures using a fluorimetric technique. Plasma tryptophan and tyrosine concentrations were lowered in starved and food restricted rats whereas plasma DBH activity was significantly increased in either group. Brain tryptophan and tyrosine content was decreased in starved rats whereas in food restricted rats to a significant increase in tryptophan content corresponds a significant decrease in tyrosine level. In food restricted rats, a significant increased DA level was observed in the brainstem, raphe nuclei and hypothalamus whereas a corresponding decrease was noted in the striatum. In starved rats brain, similar changes were observed in DA level except a normal value noted in the brainstem. In food restricted rats, the NA content was increased in the brainstem and decreased in the raphe nuclei whereas in starved rats brain, a decrease was observed in the raphe nuclei and thalamus but a significant increase was noted in the striatum. In starved rats brain, the 5-HT content did not change whereas in food restricted rats, a significant increase was observed in the brainstem and raphe nuclei and a significant decrease noted in the striatum. In the present study, starvation and food restriction induced similar effects in the plasma thus suggesting a common response to stressfull situations. In the CNS, the DA to NA ratio has revealed a DA mobilization in all structures studied except the brainstem in either group whereas the 5-HT to 5-HIAA ratio has demonstrated either a low 5-HT degradation or a high 5-HT utilization according to the situation and the neuroanatomic system. (Supported by NSERC of Canada and Fonds FCAR, Québec).

21.13 SINGLE-UNIT RESPONSES IN THE ROSTRAL ZONA INCERTA TO OSMOTIC STIMULATION OF THE ANTEROVENTRAL THIRD VENTRICULAR AREA (AV3V). D. Mok* and G.J. Mogenson (SPON: M.M. Robinson). Department of Physiology, University of Western Ontario, London, Canada N6A 5C1.

Previous studies in the rat have shown that electrical stimulation of the zona incerta (ZI) elicits drinking (Huang and Mogenson, Exp. Neurol., 37:269, 1972) and that bilateral electrolytic lesions of this region produce water intake deficits in response to an osmotic stimulus (Walsh and Grossman, Physiol. Behav., 16:211, 1976). To further investigate the role of the ZI in the neural regulation of osmotic thirst, we made extracellular single-unit recordings from neurons in the rostral ZI of the rat while injecting hyper- and hypo-osmotic solutions into the anteroventral third ventricular area (AV3V), a region thought to contain osmoreceptive elements for thirst (Buggy et al., Am. J. Physiol., 236:R75, 1979).

Experiments were performed on urethane-anesthetized male Wistar rats. AV3V injections of hyper-osmotic solutions (1- or 2-µl of NaCl solutions having osmolarities of 1.2 or 0.6 osmol/l, respectively) and hypo-osmotic solutions (1- or 2-µl of distilled water) elicited 2 types of responses from ZI neurons. Cells which changed their firing rate relative to the baseline in response to either the hyper- or hypo-osmotic solution and whose firing rate remained unchanged in response to the alternate solution were designated Type I. The response patterns of Type I cells included an increase or a decrease in firing rate to a hyper-osmotic injection with no response to a hypo-osmotic injection and an increased or decreased firing rate to a hypo-osmotic injection with no response to a hyper-osmotic injection. Cells with firing rates that increased to one solution and decreased to the other, relative to the baseline, were designated Type II. Some Type II cells had firing rates that increased in response to a hyper-osmotic injection and decreased in response to a hypo-osmotic injection. Other Type II cells showed the reverse pattern. In a series of 16 animals we have been able to identify 13 Type I cells and 12 Type II cells in the ZI.

These results indicate that osmotic stimulation of the AV3V changes activity of neurons in the ZI and suggest that they have connections with osmo-receptive structures located near the AV3V. In addition, the findings provide further evidence that the ZI has a role in the central regulation of osmotic thirst.

Supported by the National Science and Engineering Research Council (NSERC) of Canada.

21.14 INTERACTION BETWEEN OVARIECTOMY-INDUCED OBESITY AND AREA-POSTREMA-ABLATION-INDUCED WEIGHT LOSS. Anita J. Bhatia*, Amina Bhatia*, Linda Stankovic*, Jon N. Kott and Nancy J. Kenney. Department of Psychology, University of Washington, Seattle, WA 98195.

Following ovariectomy (OVX), body weights of rats increase. In most cases, this is due to elevated food intakes although weights of OVX rats also increase when daily intakes are mildly restricted. Ablation of the area postrema and subjacent aspects of the caudomedial nucleus of the solitary tract (APX) results in transient hypophagia and weight loss. Although intakes of the lesioned rats do return to control levels, no compensation for the intial weight loss ensues.

To determine whether OVX would reverse, prevent and/or attenuate the weight loss due to APX, body weights and food intakes of rats which underwent OVX 2 or 5 wks before or 2 wks after APX were monitored. When OVX was performed 2 wks after APX, rate of weight gain of APX/OVX rats did not increase immediately. During the 2 wks following OVX, APX/OVX rats gained 20.1 ± 7.8 g and the APX/sham OVX rats, 20.1 ± 3.1 g. Sham APX/OVX rats gained 50.1 ± 4.1 g during that time ($F(1,14)=11.7$, $p<.01$ compared to APX/OVX). However, over the following 10 wks, APX/OVX rats gained more weight (42.6 ± 5.9 g) than did the APX/sham OVX rats (24.5 ± 5.6 g; $F(1,14)=5.0$, $p<.05$). By 12 wks after lesioning, weights of the APX/OVX rats (290 ± 19.2 g) did not differ from those of the sham APX/sham OVX rats (306 ± 10.4 g). Weights of the APX/sham OVX rats (267 ± 10.3 g) remained below those of the sham APX/sham OVX rats ($F(1,14)=7.1$, $p<.05$).

When OVX preceded APX by 2 wks, weight loss due to the APX was not attenuated. During the 2 wks following APX, the OVX/APX rats lost 42.4 ± 5.2 g and sham OVX/APX rats lost 33.9 ± 12.2 g. Weight changes of the OVX/APX rats remained indistinguishable from those of the sham OVX/APX rats for the next 10 wks. When OVX preceded APX by 5 wks, the OVX/APX rats lost 56.2 ± 5.1 g during the 2 wks following the ablation. At the end of that time interval, the OVX/APX rats did not differ in weight from the neurologically and ovarian intact controls.

Thus, ovariectomy, performed before or after area-postrema ablation has little effect on the weight loss due to the ablation. Ovariectomy may affect the weights of lesioned rats over the long-term such that APX rats without ovaries may weigh as much as neurologically and ovarian intact female rats. In no case, however, is the weight gain of the APX, ovariectomized rat as great as that of the non-lesioned, ovariectomized rat.

21.15 MICROINJECTED OPIOIDS INTO VTA OR PAG INDUCE OPPOSITE EFFECTS ON LH STIMULATION-INDUCED FEEDING. F. Jenck*, R. Quirion and R.A. Wise (SPON: A. Giovino). Center for Stud. in Behav. Neurobiol.,Dept. Psychology, Concordia University, Montreal, Quebec, Canada H3G 1M8.

Morphine was microinjected at the level of ventral tegmental area (VTA) or dorsal periaqueductal gray matter (PAG) and its effect recorded on latency for feeding in response to lateral hypothalamic (LH) electrical stimulation. Stimulation intensity was held constant and rats were stimulated at a range of different frequencies: for each stimulation frequency, latency to eat three 45 mg pellets was measured.

Morphine (0.8, 1.6, 3.2 and 8 nmoles) injected in 0.25 µl into the VTA was found to induce a dose-dependent facilitation of stimulation-induced feeding. Latency to feed as well as frequency threshold at which feeding started to appear, decreased; this facilitatory effect lasted for the 60-70 min duration of the test and was suppressed by an IP injection of 1.0 mg/kg naloxone. Conversely, morphine (1.6, 3.2, 8 and 16 nmoles) microinjected in a volume of 0.25 µl into the PAG induced a dose-dependent attenuation of stimulation-induced feeding. Increase in latency to feed as well as in feeding threshold has been found to last for the duration of the test; this effect was blocked by an IP injection of 2.0 mg/kg naloxone.

Morphine appears therefore to induce opposite and anatomically differentiated effects on stimulation-induced eating. Given the known differential distribution of the various subclasses of opioid receptors throughout the brain, these opposite effects of morphine might well be due to the activation of different opioid receptors at the level of two different brain regions. In order to test this hypothesis, the effects of microinjected U-50,488, a selective kappa opioid receptor agonist were compared to those of morphine. Equimolecular doses of morphine and U-50,488 were injected in a volume of 0.25 µl into the VTA and the PAG.

When microinjected into the VTA, the kappa-agonist U-50,488 induced a facilitation of LH-induced feeding; this facilitatory effect appeared even slightly more marked than the effect of morphine. Conversely, when microinjected into the PAG, U-50,488 did not produce any of the suppressive effects shown by morphine microinjected into this region.

These data indicate that the differential effects of morphine on LH stimulation-induced feeding are not only anatomically distinct but also pharmacologically distinct. Indeed, it is suggested that the facilitatory activity of morphine at the level of the VTA is subserved by kappa and perhaps also mu opioid receptors; at the level of the PAG however, mu and perhaps delta opioid receptors mediate the suppressive effect on LH-induced feeding exhibited by morphine.

21.16 GLUCAGON (GLG) AND EPINEPHRINE (EPI) EFFECTS ON MILK INTAKE (MI) AND PLASMA GLUCOSE (GLU) IN LIVER DENERVATED (LD) AND SHAM OPERATED (SHAM) RATS. L.L. Bellinger and F.E. Williams. Dept. Physiol., Baylor Coll. Dent., Dallas, TX 75246.

GLG and EPI injections suppress food intake in rats, however, it is unknown if this is a normal physiologic control. Where these hormones act to reduce food intake is uncertain, but the liver is a proposed site. It has been postulated that these hormones affect liver glycemia, which in turn influences neural afferents to the brain. In the present study male S.D. rats (260-270g BW) were SHAM (n=9) or totally LD (n=13) see Bellinger and Williams, Physiol. Behav. 30:463, 1983. Rats were kept on a L:D 12:12 (lights out at 1330h) and fed Purina chow ad lib. After operation chow intakes and BW of the groups did not vary significantly. Seven days after surgery chow was removed at 0830h and the rats injected I.P. with 0.5 cc of vehicle (VEH) at 0900h. Within one min. sweetened condensed milk (Eagle Brand), diluted 50% with water was given in Wahmann calibrated bottles. MI was recorded after 30 min. and then removed. After 8 daily VEH injections the rats were then injected with GLG, 400 ug/kg BW. Daily VEH injections were resumed. At 5-7 day intervals the rats were injected with GLG at 100 ug/kg (2 trials) and 50 ug/kg (2 trials) and EPI 30 ug/kg free base (2 trials). At weekly intervals, in a counter balanced design, the rats under ether anesthesia were bled (0.5cc) by heart puncture within 60 sec. of removal from their cages. Blood samples were obtained just prior to injection and at 10 min. after GLG (400 ug/kg)or VEH. At weekly intervals the rats were bled 10 min. after injection of 50 and 100 ug/kg GLG and 30 ug/kg EPI. Compared to VEH, GLG suppressed (pair T-test one tail, multiple trials averaged) MI (mls) of both SHAM and LD rats at 400 ug/kg (LD, 7.8±0.6 vs 6.5±0.6, P<0.04; SHAM, 8.5± 0.7 vs 6.4±0.8, P<0.05); 100 ug/kg (LD, 8.7±0.7 vs 7.7±0.7,P<0.05; SHAM 8.6±0.7 vs 6.4±0.9, P<0.01) but not at 50 ug/kg. Compared to VEH, EPI also reduced MI (mls) of both groups (LD, 8.3±0.3 vs 5.9±0.3, P<0.01; SHAM, 7.5±0.8 vs 4.9±0.6, P<0.01). Compared to VEH, GLG at 50-400 ug/kg raised (P<0.01) plasma GLU in both groups to a similar degree. Thus GLG at 50 ug/kg while not suppressing MI caused marked liver glycogenolysis. EPI increased GLU to a lesser degree than 50 ug/kg GLG, yet produced MI suppression. The data indicate that liver innervation is not necessary for GLG or EPI suppression of MI nor is MI reduction correlated to changes in liver glycogenolysis or plasma glucose. Concern is expressed since ug quantities of both hormones are required to suppress MI when they are normally found in only pg/ml concentrations.

21.17 ELEVATION OF PLASMA AND BRAIN CATECHOLAMINES FOLLOWING MAJOR BURN TRAUMA. J.L. Nelson, W.T. Chance, M.W. Kim*, T. Foley-Nelson and J.E. Fischer*. Dept. of Surgery, Univ. of Cincinnati Medical School, Cincinnati, OH 45267.

Hypermetabolism is a characteristic of burn trauma, with the degree of hypermetabolism being directly related to the extent of the burn injury. A result of this hypermetabolic state is catabolism of lean body tissue. However, we have observed that major burn trauma induces anorexia for several days in experimental animals. This anorectic response in the presence of hypermetabolism suggests a dysfunction of CNS hunger and satiety mechanisms. Alterations in brain norepinephrine (NE) have been suggested to mediate the hypermetabolism following burn trauma. The present experiment was designed to evaluate changes in NE and other neurotransmitters associated with burn-induced anorexia and hypermetabolism. Nineteen rats were anesthetized and subjected to a 30% body surface area open-flame burn (25 sec). This treatment produces a full-thickness burn, destroying the free nerve endings that mediate pain from cutaneous sources. Thus, the animals experienced minimal pain after the burn trauma. An additional 9 rats served as nonburned controls. The burned (B) rats exhibited significantly reduced food intake for 4 days. Six of these animals were sacrificed at this time in order to assess, by HPLC, neurochemical alterations associated with the anorexia. The remaining B rats developed hyperphagia by day 10 and were eating 178% of the control intake values at sacrifice (day 28). However, these rats did not gain body weight, weighing 86% of control values at time of sacrifice. The assessment of metabolic rates on day 18 revealed that the B rats were experiencing hypermetabolism during this period. Plasma catecholamines were elevated in both B groups and catabolism was indicated by reduced gastrocnemius muscle weight. Plasma levels of glucagon were also elevated in the B anorectic rats, suggesting an increase in gluconeogenesis during the anorectic phase of burn trauma.

In the brains of the hyperphagic B rats NE levels were significantly elevated in the hypothalamus (21±3%) and nucleus accumbens (42±7%). Dopamine (DA) levels were significantly elevated in the amygdala of the anorectic B rats (56±13%). Concentrations of the DA metabolite, homovanillic acid, were significantly increased in the corpus striatum (49±11%), nucleus accumbens (26±6%) and amygdala (88±18%) of the anorectic B rats. Levels of the serotonin metabolite, 5-HIAA, were significantly elevated in the amygdala in both the B anorectic and hyperphagic rats, suggesting an increase in serotonin metabolism due to burn trauma. Together, these data suggest that there is an increase in DA turnover and gluconeogenesis during the anorectic phase of major burn trauma and elevated synthesis of NE when the rats are hyperphagic and hypermetabolic.

21.18 CHANGES IN NEUROTRANSMITTER LEVELS ASSOCIATED WITH FEEDING AND SATIETY. W.T. Chance, T. Foley-Nelson, J.L. Nelson, M.W. Kim* and J.E. Fischer*. Dept. of Surgery, Univ. of Cincinnati Medical Center, Cincinnati, OH 45267

Although previous reports have suggested that increased dopamine (DA) turnover in several brain areas is associated with feeding, the relationship of these changes to satiety is unclear. In order to investigate the role of DA and other neurotransmitters to food deprivation, the act of feeding and satiety, 21 adult male SD rats were deprived of food across an 18 day period. The amount of food allowed each rat was decreased by 25% of that consumed by ad lib. fed controls (n=8) across the first 6 days, 50% across the next 6 days and 75% during the last 6 days of the experiment. This gradual reduction was employed to mimic the weight loss that we have observed in anorectic tumor-bearing rats and resulted in a 31% reduction in body weight on day 18 as compared to the ad lib. fed controls. Seven of these rats were sacrificed while they were still food-deprived and 7 rats were presented with 2 grams of food (refed) and sacrificed 60 minutes later. The remaining 7 rats (satiated) were presented with 20 grams of food, allowed to feed to satiation (one meal $\bar{X}$ consumption = 5.2±0.5 g) and were sacrificed 60 minutes thereafter. The brains were dissected over ice into 8 regions (nucleus accumbens, amygdala, cortex, corpus striatum, hypothalamus, diencephalon, septal area, brainstem) and frozen in liquid nitrogen prior to analysis of neurotransmitter concentrations by HPLC. In the nucleus accumbens and corpus striatum, levels of the DA metabolites, homovanillic acid and 3,4-dihydroxyphenylacetic acid, were elevated significantly in the satiated rats as compared to the ad lib. fed or the food deprived groups. However, levels of these compounds were not significantly different from the deprived group in the rats that were fed 2 grams of chow. Therefore, only the rats that fed to satiation exhibited apparent increases in DA turnover. Concentrations of the serotonin (5-HT) metabolite, 5-hydroxyindoleacetic acid (5-HIAA), were increased in the satiated rats in all brain areas and in the deprived and refed groups in all areas except the nucleus accumbens. These apparent changes in 5-HT turnover are probably due to increased precursor availability.

Therefore, these data suggest that increased DA turnover in the nucleus accumbens and corpus striatum may be associated with the termination of feeding within a single meal. The ubiquitous increases in brain 5-HT metabolism are probably reflective of overall nutritional status, being caused by malnutrition-induced decreases in blood concentrations of neutral amino acids that compete with tryptophan for transport into the brain.

21.19 INSULIN AND SATIETY. D. A. VanderWeele. Dept. of Psychology, Occidental College, Los Angeles, CA 90041.

While it is well known that the acute and repeated administration of large, aphysiologic dosages of insulin can lead to obesity through increased eating, recent studies have suggested that more prolonged and physiological amounts of this hormone, given to rats that are feeding ad libitum, can result in decreased food ingestion and body weight gain. Furthermore, insulin has been shown to reduce sham food intake (these meetings, last year). The present study evaluated and reports the effects of small dosages of insulin upon meals when the insulin administration begins conincident with the initiation of the meal.

Rats were trained to press a bar for food pellets in a standard operant chamber. When taking all of their daily meals at a stable baseline rate (required 5 to 8 days of testing), subjects were anesthetized and received a hepatic-portal catheter threaded into a mesenteric collecting vein of the small intestine and terminating approximately 2 cm from the liver. Once recovered from surgery and eating normally (approximately 25 g per day), animals were returned to the operant chamber for the experimental phase.

Upon return to the operant chamber, all rats received 3 days of free feeding with each pellet contingent upon a single bar press and no infusions made; during this period, complete meal pattern analysis was carried out with a minimum meal definition used of 10 pellets (0.45 g) and minimum intermeal interval defined as 10 minutes of no feeding. After the 3 days, each meal during the daylight hours initiated an infusion pump which delivered injections of 1 or 0 mU of insulin. The insulin was regular Iletin insulin in diluting fluid provided by Lilly Co. The infusions of insulin or vehicle were delivered in 0.15 ml aliquots over 1 min which began 10 pellets into each meal.

Uninfused meals in the rats observed to date with this procedure averaged just over 2 g. Infusion of vehicle reduced this meal size by approximately 10%, not reliably different from no-infusion condition. Infusion of 1 mU of insulin, however, reduced the size of spontaneously ingested meals by 45%, $p < .005$. Most animals show an increase in meal frequency when being infused with insulin (compared to vehicle and no-infusion condition), but this effect has not reached statistical significance in the number of subjects evaluated to date.

The present findings are consistent with the hypothesis that insulin's effects on nutrient substrate utilization are part of the total complex of stimuli arising from the ingestion of food which produce satiety.

SPECIFICITY OF SYNAPTIC CONNECTIONS I

22.1 CELLULAR BASIS OF THE RETURN OF FUNCTION OF REGENERATED GIANT AXONS OF LUMBRICUS TERRESTRIS. A.W. Lyckman and G.D. Bittner, Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Earthworms exhibit an escape response to novel, potentially threatening tactile stimuli. This response is mediated by the electrical activity of the three (one medial and two lateral) dorsal giant axons of the ventral nerve cord, and consists of a rapid contraction of longitudinal muscles which pulls the animal away from the stimulus. The transection of the nerve cord results in a blockade of the escape response at the site of the lesion. Both halves of a severed giant axon survive for weeks or months, and continue to conduct APs up to the lesion site. Return of the propagation of the escape response across the lesion site can be correlated with the appearance of APs in the giant axons which cross the lesion site. Furthermore, APs originating in the medial giant axon on one side of the lesion appear only in the medial giant axon on the other side of the lesion. Likewise, APs originating in the lateral giant axons on one side of the lesion appear only in the lateral giant axons on the other side. Through-conduction is initially slow and labile and often unidirectional, i.e., an AP may cross the lesion in one direction but not the other. Over time, through-conduction becomes more rapid and reliable, and unidirectional through-conduction becomes bidirectional (Birse and Bittner, 1981, J. Neurophys. 45: 724). Additionally, some APs approaching the lesion site may rebound from the lesion site (Balter, Drewes and McFall, 1980, J. Exp. Zool., 211: 395).

In order to determine the cellular basis for the apparent specific reconnection of the severed giant axons and the changing properties of through-conduction, we have examined longitudinal and transverse section of lesioned giant axons using light and electron microscopy. Severed giant axons in varying stages of recovery after lesioning (24h, 2d, 1wk, 2wk, 4wk, 8wk, 10wk, 3mo) were filled with horseradish peroxidase or lucifer yellow-CH by in situ intracellular iontophoresis in order to identify neuronal processes in the site of reconnection and the intercellular contacts made by these processes. We are correlating the appearance of various intercellular junctions with physiological records of giant fiber activity at the lesion site. Thus, we expect to provide a morphological description of junctions responsible for the initially labile one-way conduction through the lesion, two-way conduction, spike-rebounding, and the strengthening of conduction across the lesion which is seen in animals which have had longer recovery times. We expect to show that processes of medial (lateral) giant axons on one side of the lesion do not form electrical or chemical junctions with the processes of lateral (medial) giant axons on the other side of the lesion, explaining the electrophysiological evidence for specific reconnection.

22.2 TARGET-REGULATED PROTEINS IN DORSAL ROOT GANGLION NEURONS. L. Baizer, M.C. Fishman. Neuroscience Group of the Howard Hughes Medical Institute, and the Department of Medicine, Harvard Medical School and Massachusetts General Hospital.

The set of macromolecules within presynaptic neurons whose level of expression is regulated by their interaction with target cells presumably includes those related to the transition between growth cone and nerve terminal. In order to identify such "target-regulated" proteins we have analyzed by two-dimensional electrophoresis the axonally transported proteins of rat dorsal root ganglion (DRG) neurons. DRG neurons were cultured in a compartmentalized system, with their somas restricted to the center chamber where they can be labelled metabolically, and their axons growing through to the side chambers where they can be exposed to particular target cells. Axonal proteins constituted a subset of total cellular proteins. They included a group of rapidly transported, glycosylated proteins, most prominent of which was a family of proteins with Mw about 68 kilodaltons and pI from 6.1 to 6.6. The next wave of transported proteins included actin, and the slowest, α and β tubulins.

The effect of contact between growing axons and target cells upon expression and transport of particular proteins was examined. Since such target cells were cultured outside of the labelling chamber, labelling was restricted to axonal proteins of the presynaptic (DRG) neurons. Contact with target tissue caused the decreased expression of several high molecular weight, rapidly transported proteins. One of the most prominent of these was a protein with Mw about 210 kilodaltons and an isoelectric point that ranged from 6.2 to 6.7. Non-neuronal cells when presented as targets did not affect expression of this protein.

The exact target-specificity and chemical identity of these target-regulated proteins are under investigation.

22.3 CONNECTIONS FORMED BY SENSORY NEURONS TRANSPLANTED TO A NOVEL ENVIRONMENT C.L. Smith and E. Frank, Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60201.

During development, sensory neurons form highly specific connections between structures in the periphery and neurons in the central nervous system. One hypothesis proposed to account for this specificity is that developing sensory neurons acquire chemical labels from their peripheral targets that cause their central axons to establish synaptic connections with the appropriate neurons. To test this hypothesis, we are examining the connections formed by sensory neurons transplanted to novel positions along the neuraxis in bullfrog tadpoles.

Dorsal root ganglia (DRGs) are transplanted in tadpoles at stages coinciding with the innervation of the forelimb (stages V-VIII). The DRG that would normally supply the forelimb is removed and replaced with two thoracic DRGs. These thoracic DRGs would normally innervate skin of the trunk. The tadpole is allowed to metamorphose and then both the peripheral and central projections from the transplanted sensory neurons are examined.

Sensory neurons in the transplanted DRGs innervate the arm. Anatomically, their central projection resembles that from the DRG that normally supplies the arm in that it consists of two distinct neuropils, one located in the dorsal horn and the second, more ventrally, in the vicinity of motoneurons. In normal frogs, thoracic sensory neurons project exclusively to the dorsal horn; the ventral neuropil, composed of muscle spindle afferents, is not present at thoracic levels. The finding that neurons in the transplanted ganglia form a ventral neuropil suggests they are muscle spindle afferents. Electrophysiological recordings from muscle nerves have confirmed that some of the transplanted sensory neurons are activated by stretching muscles. The patterns of connections between these muscle afferents and motoneurons have been examined by electrophysiological methods. Just as in normal frogs, sensory afferents from the medial triceps muscle have direct, monosynaptic connections with triceps motoneurons while projections to functionally unrelated motoneurons are much less strong.

The thoracic ganglia that were transplanted to the brachial level never innervate limbs in normal frogs. The finding that neurons in these ganglia will innervate the arm shows that sensory neurons can innervate novel peripheral targets. The observation that transplanted neurons form central connections appropriate to their novel peripheral targets supports the hypothesis that developing sensory neurons are influenced in their choices of central targets by their interactions with peripheral tissues. 22.4 PROPERTIES AND DISTRIBUTION OF MUSCLE AFFERENT PROJECTIONS TO LUMBOSACRAL MOTONEURONS IN THE SPINAL CORD OF THE CHICK EMBRYO. M. Koebbe* and M.J. O'Donovan. (Spon: C. Gisolfi) Dept. of Physiology and Biophysics, Univ. of Iowa, Iowa City, IA 52242.

The synaptic connections of anterior thigh muscle afferents with lumbosacral motoneurons were examined electrophysiologically in St.36-39 chick embryos using an isolated spinal cord preparation. Motoneuron synaptic potentials were recorded electrotonically from cut ventral roots or individual muscle nerves in response to muscle afferent stimulation. Synaptic potentials recorded in this manner were small (10-100μV), slow and fatigued rapidly following a few impulses at 1 Hz. The amplitude of synaptic potentials recorded from individual muscle nerves could be significantly enhanced by superfusion of the parent ventral root with isotonic sucrose. A small triphasic presynaptic potential was observed to preceed the onset of the ventral root synaptic potential by approximately 5 msec. Synaptic potentials were completely abolished when the cord was bathed in a low calcium, high magnesium solution indicating that they were predominantly chemical at this developmental stage. The afferents from individual muscles projected widely to various motoneuron pools and to different segments of the spinal cord (see Fig. 1). The largest ventral root potentials were recorded from those segments containing the largest number of homonymous motoneurons. Activation of muscle afferents projecting to both synergist and antagonist motoneuron pools prouced excitatory synaptic potentials, although it is likely that such potentials are composed of both excitatory and inhibitory components.

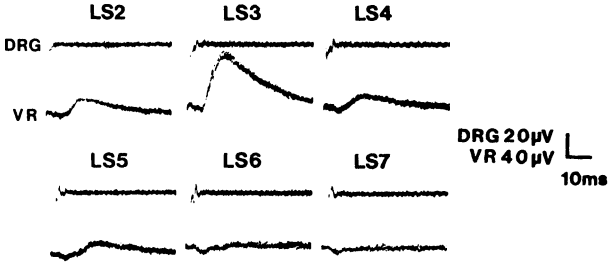

FIG. 1. Variation in the amplitude of potentials recorded from the lumbosacral ventral roots in response to a single supramaximal stimulus to the femorotibialis muscle nerve. The upper traces (DRG) show the afferent volley recorded in the dorsal root ganglion (LS1 for VR LS2 and LS2 for VR LS3-LS7).

22.5 ORGANIZATION OF MOTOR UNITS IN A SIMPLE MUSCLE. R.S. Wilkinson and J.W. Lichtman, Departments of Cell Biology & Physiology and Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The transversus abdominis of the garter snake is a thin (one fiber thick) segmental muscle containing ~80 muscle fibers. Three distinct muscle fiber types (faster twitch, slower twitch, and tonic) may be identified by morphological, electrophysiological, contractile, or biochemical criteria; these 3 fiber types are arranged within the flat muscle sheet as a repeating sequence. Because of its geometric simplicity and accessibility, innervation patterns in this muscle can be characterized precisely.

Motor unit "maps" were obtained by activating individual motor axons and identifying their targets using either activity-induced uptake of extracellular markers to label presynaptic terminals (J.W. Lichtman et al., Nature 314, 357-359, 1985) or systematic intracellular recording to identify activated muscle fibers. Each muscle contained 4-5 twitch and 3-4 tonic motor units. Fibers belonging to a given motor unit were strictly homogeneous in type, but were distributed randomly (among fibers of the proper type) throughout the muscle.

Twitch motor axons of either type innervated 5-15 muscle fibers and constituted the sole source of innervation to those fibers. In contrast, tonic axons innervated more fibers (20-40) but generally each fiber was multiply innervated. The larger size and overlap of tonic motor units evidentally stems from the ability of tonic muscle fibers to sustain polyneuronal innervation, both by providing multiple endplate sites (~7 endplates/fiber) and by allowing terminal boutons from different axons to co-innervate the same endplate.

In studies where several motor units were mapped in the same muscle, one axon's innervation was not only randomly distributed within the muscle as a whole, but also randomly distributed with respect to the innervation supplied by other axons. Thus all the motor units were intermingled throughout this small muscle. The random distribution of motor units argues 1) that the repeating fiber type pattern in this muscle is of intrinsic rather than neural origin, and consequently, 2) that highly selective recognition between axons and particular muscle fibers operates to generate homogeneous motor units. (Supported by the NIH, MDA, and McKnight Foundation).

22.6 TOPOGRAPHIC MAPPING OF MOTOR POOLS ONTO MUSCLES. M.B. Laskowski[1] and J.R. Sanes.[2] Depts. of Physiology, St. Louis Univ.[1] and Washington Univ.[2] Medical Centers, St. Louis, MO 63110

The selective reinnervation of muscles transplanted from different segmental levels to a common site has suggested the existence of positional labels that bias synapse formation between axons and muscles: rostral muscles are preferentially reinnervated by axons from rostral levels of the spinal cord, while caudal axons preferentially reinnervate caudal muscles (Wigston and Sanes, Nature 299, 464, 1982; J. Neurosci., 1985). If such a system operates during development, one might expect motor pools to "map" onto the rostrocaudal axis of normal adult muscles, much as the retina "maps" onto the tectum. To test this idea, we sought trunk muscles that (1) span several segments, but (2) have single fibers associated with individual segments; we also required that they (3) be innervated through a single nerve (4) by axons that arise in several spinal segments. Two muscles that meet these criteria are the serratus anterior and the diaphragm. The serratus anterior inserts on ribs 1-7 and is innervated through the long thoracic nerve from cervical (C) segments 6-8; the diaphragm inserts on ribs 7-13 and is innervated through the phrenic nerve from C3-6. For each muscle, we assessed the topography of innervation by recording intracellularly from muscle fibers while stimulating motor axons in individual bundles of ventral rootlets. In both muscles, we found a consistent and significant tendency for axons from rostral portions of the motor pool to innervate rostral portions of the muscle; progressively more caudally-derived axon groups innervated more caudally disposed muscle fibers. Histological confirmation of this pattern exploited the finding that N-CAM accumulates in denervated muscle fibers (Covault and Sanes, PNAS, 1985); transection of individual ventral roots led to topographically restricted partial denervation that was detected by immunofluorescent staining. Thus, the rostrocaudal axes of motor pools and muscles are matched; topographically ordered innervation also occurs in limb muscles (e.g., Bennett and Lavidis, J. Neurosci. 4, 2204, 1984), and may be a general feature of neuromuscular connectivity. The preparations we have used should be well suited for learning how this order arises during development and whether it can be re-established during regeneration.

22.7 MORPHOLOGICAL CORRELATES OF TRANSIENT RETINA-MUSCLE SYNAPSES. J.M. Thompson and S.W. Norby. Dept. of Anatomical Sciences and Dept. of Physiology, University of Illinois, Urbana, IL 61801.

Retinal neurons have been shown to form cholinergic synapses on myotubes in culture as detected by electrophysiological recording of muscle synaptic responses. These mismatched synapses form quickly, but are transient. The maximum number of innervated muscle cells occurs at 1 day of coculture with muscle. By 7 days of culture, retina-muscle synapses are no longer detected. (Puro et al., Proc. Natl. Acad. Sci. USA, 74:4977, 1977; Ruffolo et al., Proc. Natl. Acad. Sci. USA, 75:2281, 1978; Thompson et al., Int. J. Devel. Neurosci., 1:25, 1983.)

To determine the nature of the loss of connections, we have examined the retinal neuron - muscle contacts at the ultrastructural level. The hypothesis which we are testing is that retina-muscle synapses are lost due to competition between target cells (other retinal neurons versus muscle cells). This should be seen as a decrease in retina-muscle contacts with a concomitant increase in retina-retina contacts during the time of coculture. At one day after coculture, retinal neurons adhered to the myotubes, to each other to form small clumps, and to the substrate or underlying fibroblasts. Neural processes can be seen to run longitudinally along the myotube, thus, making contact on the muscle for the entire length of the neurite. At three days of coculture, the number and length of neurites increased greatly. Neurites reached over 100 microns in length, and most terminate on myotubes. The retinal neurons are still observed to often adhere to myotubes and send processes along their length. Many of the neural processes ramify into many fine processes which contact the myotube. At five days of coculture, little change is observed compared to three day cultures. Neurons often adhere to myotubes, and neurites, often very long, will terminate on myotubes. At seven days after coculture, the number of neurites contacting the myotubes was greatly reduced. In this later stage of coculture, although the retinal neurons still have extensive networks of processes, few processes make contact on the muscle cells. The neurites usually pass over or under the myotube without terminating. Most neurons associate only with other neurons either in small clusters or by process extension. These initial studies demonstrate that at early times of coculture, retinal neurons will contact myotubes directly or by extending their processes along the myotubes. At further times in culture, the number and length of neurites increases, as do the number of contacts on the myotubes. At later stages of culture, the number of contacts on myotubes decreases dramatically. Thus, there is an apparent decrease in retinal-muscle contacts with a maintenance of retina-retina contacts during the time of loss of retina-muscle synapses detected physiologically.

22.8 PROJECTION PATTERNS OF SYMPATHETIC PREGANGLIONIC AXONS IN CHICK EMBRYOS. Joseph W. Yip. Department of Physiology, School of Medicine, University of Pittsburgh, Pittsburgh, PA 15261.

The projection patterns of sympathetic preganglionic neurons arising from different spinal cord segments were studied in stages 24-35 (4½-9 days) chick embryos using orthograde and retrograde horseradish peroxidase (HRP) labelling techniques. An HRP solution was injected into individual spinal cord segments or sympathetic ganglia of an isolated spinal cord-sympathetic chain preparation. The tissues were fixed, serially sectioned and reacted according to a DAB-cobalt method.

The adult patterns of preganglionic axon projection are apparent after the first week of embryonic life. Preganglionic axons arising from individual spinal cord segments exit via the adjacent ventral root and consistently innervate the same ganglia of the sympathetic chain. These ganglia are contiguous. However, the number of ganglia innervated by preganglionic axons arising from different spinal cord levels is variable. For instance, T1 preganglionic axons innervate considerably more ganglia than T4 preganglionic axons. Individual preganglionic axons, moreover, will branch to innervate multiple ganglia. A striking feature in the projection patterns of preganglionic axons is the stereotyped rostro-caudal distribution of preganglionic axons arising from different levels of the spinal cord. For example, T1 preganglionic axons project predominantly in the rostral direction whereas T4 preganglionic axons project predominantly in the caudal direction. Axons from the T2 spinal level assume an intermediate type of distribution, with many axons projecting in both rostral and caudal directions.

The characteristic rostro-caudal distribution of preganglionic axons is evident as soon as they enter the sympathetic chain at stage 27 (5-5½ days). The pathways taken by preganglionic axons towards their targets are therefore correct from the onset.

These results indicate that the outgrowth of sympathetic preganglionic axons is precise and suggest that there are specific cues for the guidance of these axons.

Supported by BNS 82-10028 and by a Basil O'Connor Starter Research grant from the March of Dimes Birth Defects Foundation.

22.9 IDENTIFIED SUBCLASSES OF BULLFROG SYMPATHETIC NEURONS PROJECT TO DIFFERENT TYPES OF PERIPHERAL TARGETS. J.P. Horn, W.D. Stofer* and S. Fatherazi* Department of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261

In the ninth and tenth paravertebral sympathetic ganglia of the bullfrog, three subclasses of neurons (fast B, slow B and C cells) can be identified on the basis of their axonal conduction velocities (Dodd & Horn, J. Physiol. 334, 255 (1983)). In addition, the two B cell groups are innervated selectively by preganglionic axons that enter the sympathetic chain via spinal nerves four to six while C cells receive their input via spinal nerves 7 and 8. However, the functional significance of multiple ganglionic cell types is obscure. One possibility is that subclasses of sympathetic neurons modulate different types of targets. To test this hypothesis we have measured the sympathetic fiber spectrum of nerves innervating visceral* smooth muscle, striated muscle and the skin.

All experiments were done on isolated preparations of sympathetic chain ganglia 7 through 10 with attached peripheral nerves. At the start of each dissection, after double pithing the animal, targets of interest (eg. the sartorius muscle) were identified. The nerve entering the target was located, marked, dissected back to the sciatic nerve and then removed in continuity with the sympathetic chain. Suction electrodes were placed on spinal nerves 7 and 8 for stimulating preganglionic C fibers and on the sympathetic chain rostral to ganglion seven for stimulating preganglionic B fibers. Two pairs of recording suction electrodes were used in each experiment. One pair was used to record a control response from the sciatic nerve. The sciatic nerve contains all three groups of sympathetic axons and enabled us to adjust the stimulating eletrodes for supermaximal responses while maintaining selective stimulation of the B and C inputs. The second pair of recording electrodes was applied to the identified target nerve.

By recording compound extracellular action potentials in this manner we have found that the visceral branch of the pelvic nerve innervating the bladder and motor nerves innervating the adductor magnus, gracilis, iliofibularis, sartorius, gastrocnemius and semitendinosis muscles all contain only C sympathetic axons. Even with signal averaging, no B inputs to these muscle were detected. By contrast, the cutaneous branch of the gracilis nerve and the cutaneous lateral and posterior crural nerves each contain fast B, slow B and C axons. Thus it appears that subclasses of sympathetic axons segregate as they project through peripheral nerves and that B axons selectively innervate targets in the skin. The precise cellular targets of the different sympathetic cell groups remain to be determined.

This work was supported by NIH grants NS21065 and MH30915.

22.10 **THE ONTOGENIC DEVELOPMENT OF SEROTONERGIC FIBERS IN THE RAT OLFACTORY BULB.** J.H. McLean, M. Lazoff, E.B. Sieloff, W.T. Nickell, and M.T. Shipley. (University of Cincinnati College of Medicine).

We have shown that serotonergic (5-HT) raphe neurons project heavily to the glomeruli of the rat main olfactory bulb (Schumacher et al., 1984). This suggests that raphe neurons may have a marked influence on olfactory information processing at the level of the first synaptic relay. Recently, it has been proposed that 5-HT fibers have trophic effects on target neurons during neural development (Lauder et al, 1982). Here we have examined the ontogenic development of serotonergic fibers in the main olfactory bulb (MOB) of the postnatal rat using immunocytochemistry and image analysis.

The distribution and density of 5-HT fibers in the MOB undergo a dramatic transition from the neonate to the adult rat. In the first week of life 5-HT fibers are located in all layers of the MOB including the proliferative ependymal zone. Beginning with day 8, there is a progressive redistribution of fibers to the glomerular and internal part of the external plexiform layer (epl). In addition, there is a steep overall increase in the number of 5-HT fibers in all layers. From day 14 - 37 the fibers become progressively concentrated in the glomerular layer; a sparce innervation remains in epl. With increasing age the density of serotonin fibers appeared to diminish slightly in the glomeruli. We have four possible explanations for this observation: 1) There may be an initial over proliferation of 5-HT fiber in the glomeruli followed by a modest reduction to adult levels; 2) the proliferation of glomerular 5-HT fibers may stop at ca. 6 weeks while the size of the glomeruli continues to increase. 3) The 5-HT in the mature glomeruli may be less accessible to the antisera. 4) 5-HT levels in glomeruli may undergo circadian fluctuations. We are currently investigating these possibilities.

The dramatic laminar redistribution of developing 5-HT fibers suggests that there is transition from non-specific to specific 5-HT fiber deployment during the first weeks of life. The mechanism of this redistribution is unknown. One possibility is that fibers die off in the deep layers. The initial presence of 5-HT fibers in the deep, proliferative layers of the bulb could mean that 5-HT plays a trophic role during neurogenesis and migration. Alternatively, early arriving 5-HT fibers may contact their definitive target cells from the outset; accordingly the redistribution of 5-HT terminal arbors would represent the co-migration of terminals and target neurons from proliferative zones to their definitive loci in the glomeruli.

22.11 **ORGANIZATION OF TRANSIENT CEREBROCEREBELLAR PROJECTIONS FROM THE PRIMARY SOMATOSENSORY CORTEX.** T. Donnigan*, D.L. Tolbert*, and W.M. Panneton. (SPON: L.C. Massopust) Francis and Doris Murphy Neuroanatomy Res. Lab., Depts. of Anatomy and Surgery (Neurosurgery), St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

There are transient bilateral projections from the primary sensorimotor cortex to the cerebellum in neonatal cats. Most ipsilateral cerebrocerebellar projections course through the superior cerebellar peduncle and end in the deep nuclei on that side, whereas most contralateral cerebrocerebellar projections enter through the inferior cerebellar peduncle and end in the internal granule cell layer in the cortex. Previous findings suggested that cerebrocerebellar projections were somatotopically organized in the cerebellar cortex (J. Comp. Neurol. 221:216, 1983).

In the present study, the organization of cerebrocerebellar projections from forelimb, hindlimb, and face areas of the primary somatosensory cortex (S-I) was examined in two-week-old cats. Labeled cerebrocerebellar projections were in the folial white matter and internal granule cell layer in different areas of the cerebellar cortex after tritiated amino-acid injections into forelimb and hindlimb areas of S-I. Injections into the forelimb S-I area labeled mostly contralateral cerebrocerebellar projections to lobules IV and V in the anterior lobe and to the dorsal sublobule and dorsal folia of the intermediate sublobule of the paramedian lobule in the posterior lobe. Fewer labeled projections were to similar lobules and folia in the ipsilateral anterior lobe and paramedian lobule. After injections into the hindlimb area of S-I, most labeled projections to the contralateral cerebrocerebellar cortex were in lobules I-III in the anterior lobe and in the ventral sublobule of the paramedian lobule. Fewer hindlimb cerebrocerebellar projections were directed ipsilaterally to the rostral anterior lobe and to the ventral paramedian sublobule. Forelimb and hindlimb cerebrocerebellar projections to the anterior lobe were more dense in intermediate and lateral parasagittal zones than in medial zones. Ongoing studies are examining the distribution of cerebrocerebellar projections from the face area of S-I.

These findings indicate that the transient cerebrocerebellar pathway from S-I is somatotopically organized. Furthermore, the organization of forelimb and hindlimb S-I projections to the cerebellar anterior lobe and paramedian lobule is very similar to the topography of precerebellar afferent projections relaying fore- and hindlimb somatosensory input from the periphery. It is unlikely, however, that cerebrocerebellar projections organize other cerebellar afferent systems.

Supported by NIH grant 20227 and NIH Training Grant HL 7486.

22.12 AN ULTRASTRUCTURAL STUDY OF THE SPECIFICITY OF ABERRANT RUBRAL AFFERENTS FOLLOWING NEONATAL CEREBELLAR OR SENSORIMOTOR CORTICAL LESIONS IN THE RAT. C.C. Naus, A.W. Hrycyshyn* and B.A. Flumerfelt. Department of Anatomy, The University of Western Ontario, London, Canada.

The afferent projections to the rat red nucleus are topographically organized, with the nucleus interpositus and the nucleus lateralis projecting to the contralateral magnocellular and parvocellular areas, respectively, and the sensorimotor cortex projecting to the ipsilateral parvocellular region. To this topographic specificity is added a specificity of synaptic localization at the ultrastructural level. The interpositorubral projection synapses on somatic and proximal dendritic membrane of magnocellular neurons, while the projection from the nucleus lateralis synapses on small to medium-sized dendrites of parvocellular neurons. In addition, the afferents from the sensorimotor cortex synapse on distal dendrites of parvocellular neurons. Following neonatal hemicerebellectomy, an aberrant ipsilateral cerebellorubral projection develops which maintains the topographic specificity of the normal contralateral projection. Similarly, neonatal lesions of the sensorimotor cortex lead to the appearance of an aberrant contralateral corticorubral projection which mirrors the topographic specificity of the normal ipsilateral input. The specificity of synaptic localization in these aberrant projections was studied using ultrastructural visualization of anterogradely transported HRP-WGA. Neonatally lesioned adults received HRP-WGA injections in the unablated deep cerebellar nuclei or sensorimotor cortex. After 48 hours, animals were sacrificed and processed for ultrastructural localization of anterogradely transported HRP-WGA. In hemicerebellectomized animals, both the contralateral and ipsilateral interpositorubral projections synapsed on somatic and proximal dendritic membrane of magnocellular neurons. Some of these labeled synaptic terminals were located on somatic or dendritic spines. Following HRP-WGA injection into the unablated nucleus lateralis, anterogradely labeled synaptic terminals were located on small to medium-sized dendrites of parvocellular neurons bilaterally. Injection of HRP-WGA into the remaining sensorimotor cortex of animals which had undergone neonatal unilateral ablation of the sensorimotor cortex resulted in anterogradely labeled corticorubral terminals which synapsed on distal dendrites of ipsilateral and contralateral parvocellular neurons. These results demonstrate that, following neonatal deafferentation of the rat red nucleus, the topographic specificity of the aberrant rubral afferents is accompanied by a specificity of synaptic localization on discrete membrane areas of rubral neurons.

22.13 THALAMIC AFFERENTS TO FETAL CORTICAL TISSUE TRANSPLANTED TO THE CEREBRAL CORTEX OF NEONATAL RATS. N.Aa. Sunde*, A.J. Castro, J. Zimmer*, E.L. Bold and M.M. Molinari*. (SPON: D. Anderson) Instit. of Anat. B., Aarhus Univ., Aarhus, Denmark; Dept. of Anat., Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153 and Instit. of Neurol., Catholic Univ., Rome, Italy.

Several reports demonstrate that fetal cerebral cortical tissue will survive and grow when transplanted into the brain of newborn rats. In the present study, host thalamic projections to cortical grafts were examined using retrograde fluorescent tracers.

Neocortical tissue was dissected from rat fetuses (E 15-17) that were removed from pentobarbital-anesthetized dams and placed in sterile saline. Plates of fetal cortical tissue (2-3 mm) were layered using a small glass "shovel" into host (0-1 day old) sensorimotor cortical lesions made by gentle aspiration. The transplant was then sealed with a bone flap. At maturity (6-10 wks) and under pentobarbital anesthesia, the cranium was carefully reopened and the transplant identified using an operating microscope. Using Hamilton syringes mounted to a micromanipulator, separate injections (0.2-0.3 ul) of diamidino yellow (DY) and fast blue (FB) were placed into the transplant. Animals were sacrificed 5-8 days later by vascular perfusion with buffered formalin in sucrose. Brains were cryostat-sectioned at 30 um, mounted and coverslipped. Alternate sections were stained with thionin.

Analysis by epifluorescent microscopy demonstrated that at least one of the dyes appeared confined to the transplant in 6 of 7 animals, and in 2 of these cases both dyes appeared confined to the transplant and with little overlap between them. Numerous single-labeled DY and FB neurons were observed within several thalamic nuclei, including the ventral, intralaminar and midline groups. Furthermore, an apparent medial to lateral topography of labeled cells was observed particularly in the 2 cases with both injections confined to the transplant. Double-labeled cells were rarely found.

These findings demonstrate that host thalamic neurons can innervate cortical transplants. Additionally, the lack of double labeling and the topographic distribution of labeled cells suggests a selective growth of host fibers into the transplant. (Supported by funds from the Danish MRC and NIH Grant NS13230.)

22.14 THALAMIC AND CORTICAL PROJECTIONS ARISING FROM FETAL CORTEX TRANSPLANTED TO THE CEREBRAL CORTEX OF NEONATAL RATS. A.J. Castro, J.Zimmer*, N.Aa. Sunde* and E.L. Bold. Dept. of Anat., Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153 and Instit. of Anat. B, Aarhus Univ., Aarhus, Denmark.

Several reports demonstrate that fetal cerebral cortical tissue will survive and grow when transplanted into the brain of newborn rats. In the present study, neural projections from transplant to host were were examined using retrograde fluorescent tracers.

Neocortical tissue was dissected from rat fetuses (E15-17) that were removed from pentobarbital anesthetized dams and placed in sterile saline. Grafts were placed at bregma in the cortex of 0-1 day old pups according to two basic protocols. In one group (n=7), plates of fetal cortical tissue (2-3mm) were layered using a small glass "shovel" into host sensorimotor cortical lesions made by gentle aspiration. The transplant was then sealed with a bone flap. In other animals, smaller blocks of donor tissue were aspirated into a glass cannula fitted to a Hamilton syringe and then injected into the host cortex of normal animals (n=6) or animals with small cortical lesions (n=6). At maturity, separate injections of 0.8 to 1.2 ul of diamidino yellow (DY) and fast blue (FB) were stereotaxically placed into the host thalamus ipsilateral to the transplant and into the host cortex on the side opposite the transplant. Animals were sacrificed 5-8 days later by vascular perfusion with buffered formalin in sucrose. Brains were cryostat-sectioned at 30 um, mounted and coverslipped. Alternate sections were stained with thionin.

Transplanted tissue consistently survived and grew within the host brain in all groups. Grafts were easily identified by characteristic whorls of cell bands separated by fibrous septae. Transplant to host neural connections were demonstrated by numerous single-labeled DY and FB cells observed within the transplant. No double-labeled neurons were found. In cases where areas of the transplant demonstrated apparent lamination, labelled cells showed a distribution pattern that resembled the normal pattern in which neurons projecting to the contralateral cerebral cortex are located superficial to those projecting to the thalamus. These findings suggest that fetal cortical transplants may establish normal connections with the newborn host brain. (Supported by funds from the Danish MRC and NIH Grant NS13230.)

22.15 SPECIFICITY OF INNERVATION OF VASOPRESSIN NEURONS IS MAINTAINED FOLLOWING TRANSPLANTATION INTO ADULT HOSTS. J.R. Sladek, Jr., T.J. Collier and P.F. Aravich. Department of Anatomy, University of Rochester, Rochester, NY 14642.

Norepinephrine (NE) neurons of the caudal brainstem heavily innervate magnocellular vasopressin (VP) neurons of the supraoptic nucleus (SON) of the hypothalamus. Another hypothalamic nucleus, the suprachiasmatic nucleus (SCN), also contains a population of vasopressin neurons. However, these parvicellular neurons receive a very light NE innervation. These different vasopressin target nuclei present a useful model for studying the ability of transplanted tissue to become "reinnervated" in a specific manner by adult host brain systems. In order to test this specificity, we have transplanted fetal hypothalamic tissue containing SON and SCN VP neurons into the region of the medial forebrain bundle (MFB), bilaterally, in adult male Sprague-Dawley rats. Animals were allowed to survive 1-2 months after implantation and were examined with the ALFA histochemical fluorescence technique coupled with immunohistochemistry for vasopressin-specific neurophysin. Adjacent section analysis was performed in a comparator bridge microscope which allowed direct superimposition of catecholamine (CA) histofluorescence patterns and neurophysin-positive perikarya. Clusters of transplanted parvicellular VP neurons were identified in the region of the MFB immediately adjacent to a dense plexus of catecholamine fibers. Evidence for reorganization of these fluorescent fibers included the presence of 1) swollen varicose profiles reminiscent of regenerative fibers, 2) dense islands of CA fluorescence adjacent ot the MFB, and 3) numerous fine-sized fluorescent fibers. In spite of the close proximity of SCN-like neurons, the NE fibers did not form axosomatic juxtapositions with these parivcellular VP neurons. However, an occasional linear fluorescent profile was seen within the outline of the SCN-like group. In contrast, transplanted magnocellular VP-positive neurons seen adjacent to the MFB were characterized by NE varicosities in close apposition to the outlines of their cell bodies. These NE-VP relationships are reminiscent of those found in the intact hypothalamus, suggesting the retention of a high order of specificity in the relationship of NE fibers to neurons. Thus, transplantation of VP neurons appears to stimulate the establishment of "anatomically appropriate" connections with the host NE system. These findings encourage the view that some degree of integration reminiscent of that seen in the intact brain may be possible in neural transplantation.

22.16 ONTOGENY OF PEPTIDE-MONOAMINE INTERACTIONS IN THE BRATTLEBORO RAT: EFFECTS OF SYSTEMIC VASOPRESSIN REPLACEMENT. B.C. Blanchard*, P.F. Aravich* and J.R. Sladek, Jr. (SPON: I. Shoulson). Department of Anatomy, University of Rochester Medical Center, Rochester, NY 14642.

There is an intimate and relatively specific morphometric relationship between vasopressin (VP) perikarya and afferent noradrenergic varicosities within the supraoptic nucleus (SON) of the hypothalamus. It has been suggested that the VP target neuron is necessary for the maintenance of this interaction. This hypothesis is based, in part, upon the observation that the catecholamine (CA) innervation of the SON of VP-deficient Brattleboro rats is relatively normal during the initial phases of postnatal development, but diminishes dramatically during later stages. The current investigation determined the effects of systemic VP replacement on the CA innervation of the SON of the developing Brattleboro rat. The V2 agonist, 1-deamino-8-D-arginine vasopressin (DDAVP), also was evaluated.

Male Brattleboro rats suffering from diabetes insipidus (DI) and normal Long-Evans rats served as subjects. Three postnatal ages were examined: 24, 42, and 90 days. Within each age group there were three groups of DI rats (Saline replaced, VP replaced, and DDAVP replaced) and one group of LE rats (Saline replaced). VP replacement (13 days) was achieved using a subcutaneous osmotic minipump, VP (322.58 ng/hr x kg), and DDAVP (6.45 ng/hr x kg).

VP and DDAVP replacement enhanced the SON CA histofluorescence of DI rats relative to saline-treated controls across all age groups, though the DDAVP effect was less than the VP effect. However, despite these drug-related increases, CA fluorescence patterns were not equivalent to those in LE rats. The enhancement effect of replacement also was age dependent: 24- and 42- day old animals were more affected than 90- day old animals. Both VP and DDAVP reduced water intake and urine output to near normal levels across groups, with the DDAVP effect slightly greater than the VP effect in the 24- and 90-day old DI rats.

Thus, VP replacement appears to exert an indirect maintenance effect on the CA innervation of the SON via a peripheral route of action. (The dose of VP employed in this study does not cross the blood-CSF barrier.) Systemic VP administration can affect hemodynamic, water balance, and metabolic factors. The substantial increase in SON CA fluorescence produced by systemic DDAVP treatment excludes the contribution of hemodynamic factors, but does not distinguish between water balance and metabolic factors. The greater susceptability of young DI rats to the replacement effects is consistent with our earlier observations indicating that, with age, the DI rat gradually loses CA terminals within the SON. Finally, the inability of systemic replacement to increase CA fluorescence to LE levels is consistent with the view that VP may also exert a direct CA maintenance action within the SON.

22.17 AN ULTRASTRUCTURAL STUDY OF DOPAMINE (DA) NEURONS IN REAGGREGATE CELL CULTURE. L. Won*, S. Price*, B. Wainer, A. Heller, P. Hoffmann and J.P. Bolam[a] The University of Chicago, Chicago, IL 60637 and [a]The University Department of Pharmacology, Oxford, U.K.

DA neurons mature biochemically and morphologically when cocultured for 21 days with striatal target cells in reaggregate cell culture. In particular, the presence of target cells (striatum) but not nontarget cells (tectum) results in a dense proliferation of varicose dopamine-containing fibers suggestive of axons and boutons. In the present study immunocytochemical localization of tyrosine hydroxylase (TH) immunoreactivity was examined at the light and electron microscopic level to determine: 1) whether TH-positive neurons are morphologically similar to mesencephalic DA neurons in vivo; 2) if TH-immunoreactive neurons form and receive synaptic connections which resemble those observed in the nigrostriatal system. Dissociated fetal mesencephalic cells containing DA neurons were coaggregated with dissociated striatal cells in rotatory culture for 21 days (Kotake et al., J. Neurosci. 2:1307-1315, 1982). Perikarya positiyely labelled for TH were approximately 20 micrometers in diameter and either multipolar or fusiform in shape. The nucleus was slightly indented and eccentrically located within the neuron. The cytoplasm contained a moderate amount of organelles and appeared granular perhaps due to the peroxidase-anti-peroxidase reaction. These labelled neurons morphologically correspond with the description of DA neurons in the substantia nigra and ventral tegmental area. Unlabelled boutons containing pleomorphic vesicles synaptically contacted TH-immunoreactive cell bodies. Symmetric and asymmetric axosomatic synapses were identified. Several labelled perikarya closely abutted unlabelled cells within the aggregate; however, membrane specializations were rarely observed between the opposed plasma membranes. TH-positive dendrites generally had a smooth contour and were contacted by unlabelled boutons along their length. Both symmetric and asymmetric axodendritic synapses were observed. In adult animals symmetric synapses predominate. A few proximal dendrites projected between 1-3 spinous processes which were synaptically contacted by unlabelled boutons near their base. Spines are rarely observed on dopaminergic dendrites of adult animals but may occur during neuron development. TH immunoreactive boutons were usually found in a region away from positively labelled cell bodies. Label in these boutons was dark and granular which frequently obscured the shape of the synaptic vesicles. These bouton profiles were among the smaller of the bouton profiles within the reaggregates. Dendrites were the most common post-synaptic targets of TH-positive boutons although a few axosomatic synapses were evident. The majority of these synapses had symmetric membrane specializations which have been described in the adult corpus striatum. Thus, DA neurons in reaggregate cell culture form and receive synaptic connections which resemble those seen in vivo. (Supported by MH-28942 and L.W. was supported by GM-07151.)

22.18 SELECTIVE ASSOCIATION OF DOPAMINERGIC (DA) AXONS WITH THEIR STRIATAL TARGETS IN VITRO. A. Heller and L. Won* Department of Pharmacol. and Physiol. Sciences, The Univ. of Chicago, Chicago, Il 60637

Proliferation and/or maintenance of DA axons in aggregate cultures occurs only in the presence of target cells (Hemmendinger et al., PNAS 78(2):1264-1268, 1981). The purpose of the present study was to determine whether the outgrowth of such DA axons would be restricted to areas containing target cells in aggregates composed of both target and non-target cells. We examined the distribution of DA axons after simultaneously confronting DA cells with both target cells of the corpus striatum (CS) and with non-target cells of the tectum (T). Dissociated fetal cells of the rostral mesencephalic tegmentum (RMT) containing DA neurons and dissociated non-target T cells were exposed to wheat germ agglutinin conjugated to the fluorescent dye, rhodamine, prior to reaggregation in rotary culture in order to allow one to distinguish these cells from non-dyed CS cells in the resulting aggregates. After 9 days in culture the RMT-T-CS aggregates were exposed to 10^{-6} M DA and processed for DA histofluorescent development. Single aggregates were serially sectioned and color photomicrographs prepared from each section. It was found that non-target cells (red fluorescence) segregated from the undyed target cells forming discrete areas consisting of the 2 cell types. DA neurons and their processes could be distinguished by their green fluorescence. Since it is not possible to distinguish axonal from dendritic processes in a single section, the extent of the dendritic fields was estimated from aggregates prepared from cells of the RMT and non-target T cells, in which there is no extensive proliferation of DA axons and DA fluorescent processes are confined to the area near the cell body. DA neurons were identified in the photos of RMT-T-CS aggregates and the dendritic fields surrounding the cell bodies were subtracted. A 0.5 cm^2 transparent grid was placed over the photomicrographs and the squares containing either green (DA) or red (rhodamine) fluorescence marked on separate grids. By comparison of superimposed grids the extent of overlap of green DA fluorescence into areas of non-target cells (red rhodamine dye) could be determined. Following the exclusion of DA dendritic fluorescence it was found that 85.2% of the presumed axonal fibers were present in the non-dyed areas containing striatal target cells. This finding suggests that DA axons either do not invade, or do not persist, in non-target areas when given the opportunity afforded by the presence of adjacent target cells. Moreover, the target cell factor(s) responsible for the proliferation and/or maintenance of DA axons does not appear to be diffusable into adjacent non-target cell-containing areas. (Supported by MH-28942 and L.W. was supported by GM-07151.)

23.1 INCREASED BODY WEIGHT PRODUCED BY GESTATIONAL UNDERNUTRITION. A. P. Jones & L. S. Crnic, Depts. of Psychiatry & Pediatrics, Univ. Colorado School of Medicine., Denver, CO. 80262.

Previous work by Jones and colleagues demonstrated that male offspring of rats restricted to 50% of pre-pregnancy intake during the first 2 trimesters of pregnancy and then refed normally during the 3rd trimester develop hyperphagia and obesity as adults. This obesity is characterized by increased adipocyte size but not number, and is not a function of altered lipoprotein lipase activity, triglyceride levels nor locomotor activity. In the current study we assessed the status of several metabolic systems which are important in the etiology of obesity. Hepatic lipogenesis was assessed by measuring glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, isocitrate dehydrogenase, and fatty acid synthetase. The function of brown adipose tissue (a major thermogenic organ) was determined by monitoring core temperature in a 4°C room for 24 hours. Intrascapular brown adipose tissue (IBAT) depots were weighed. Activity of hepatic cytochrome P-450 monooxygenase, (a pathway associated with the exothermic oxidation of NADPH) was determined. Body composition (lipid, protein, water and ash) was determined at birth.

Initial attempts to continue this work in Denver (1600m) were unsuccessful because litters were resorbed at levels of food restriction (50% of pre-pregnancy baseline) successfully used at sea level: 68% of baseline intake was the minimum requirement for the litter to be carried to parturition. Rats were either fed ad libitum throughout gestation or 68% of baseline intake for the first two weeks of pregnancy and then refed either ad libitum (DA), or a daily ration equivalent to the intake of control animals (DP). The latter group was included as a control for the hyperphagia which follows such a period of food restriction. No differences were found in birth weight or carcass composition however, male DA offspring weaned onto a high-fat diet were significantly overweight by 60 days of age ($p < .05$). No group differences were found in hepatic lipogenic enzyme activity nor were any differences detected in P-450 levels, core temperature, nor IBAT weight following 24 hour cold exposure.

In conclusion, increased body weight in rats deprived during early gestation does not appear to be due to changes in the synthesis or storage of lipids, nor in energy expenditure as measured by locomotor activity, core temperature, IBAT weight, and P-450 levels. Supported by NIMH MH09169, HD18378 and the Developmental Psychobiology Research Group.

23.2 AMINO ACIDS IN BRAIN REGIONS OF UNDERNOURISHED RATS. M.J. Druse-Manteuffel and W. E. Rathbun*. Department of Biochemistry and Biophysics, Loyola University Stritch School of Medicine, Maywood, Illinois 60153.

Sprague Dawley rat mothers were fed either a protein-calorie deficient (30% reduction) or control diet from the 5th to the 21st postnatal day. The concentrations of aspartate, glutamate, γ-aminobutyric acid (GABA), glycine, glutamine, serine and taurine were determined in the cortex, cerebellum, corpus striatum, hippocampus, hypothalamus, brain stem and midbrain of 17- and 35-day-old undernourished and control offspring. Amino acids were derivatized with o-pthaldialdehyde, and then separated and quantitated using reverse phase HPLC coupled with fluorometric detection.

At 17 days of age, taurine was the amino acid with the highest concentration, while at 35 days glutamate had the highest concentration. This change was due to the fact that the levels of taurine decreased significantly in all brain regions between 17 and 35 days, while those of glutamate remained high or increased somewhat in all brain regions except the hypothalamus and brain stem.

In comparison to control rats, the concentrations of glutamate and aspartate were significantly lower (decreased 16 to 34%) in the cerebellum, brain stem, cortex and midbrain of 17-day-old undernourished rats. Aspartate was also significantly decreased in the corpus striatum and hypothalamus in 17 day offspring. However, normal levels of aspartate and glutamate were found in all brain regions of 35-day-old undernourished rats. In contrast to the transient changes in aspartate and glutamate, the concentration of taurine was increased in the hypothalamus (31%) and hippocampus (12 to 33%) at both 17 and 35 days of age. Taurine was also increased in the midbrain (17%) of 17-day-old undernourished rats. Other transient abnormalities in the regional levels of amino acids were found in the undernourished offspring.

The results of these experiments suggest that undernutrition during lactation causes delayed CNS development which is manifested in altered concentrations of the neurotransmitters aspartate, glutamate and taurine.

This research was supported by a grant from the Potts Fund.

23.3 MAINTENANCE OF LONG TERM POTENTIATION OF THE EPSP IN THE DENTATE GYRUS OF PROTEIN MALNOURISHED RATS. K. Austin * and P.J. Morgane (SPON:O.Resnick). Worcester Foundation for Expt. Biol., Shrewsbury, MA 01545.

To determine the effects of protein malnutrition on brain development and function, we are studying hippocampal long-term potentiation (LTP) in the offspring of protein restricted dams. Field potentials evoked by stimulation of the perforant path were studied in the dentate gyrus of anesthetized adult rats. These animals were born to dams fed either a 6% or 25% casein diet initiated 5 weeks prior to mating. The prenatally malnourished group (designated 6/25) consisted of pups born to malnourished dams that were cross-fostered at birth to normal (25% casein diet) lactating dams and maintained on 25% casein after weaning. The chronically malnourished group (designated 6/6) were derived from malnourished dams and maintained on a 6% casein diet after weaning. Control animals were derived from dams fed the 25% casein diet and maintained on this diet after weaning. Dams subjected to the 6% casein diet yielded pups with significantly lower brain ($p < .05$) and body weights ($p < .001$) than the controls (Resnick et al., Neurosci. Biobehav. Rev., 6:55-75, 1982). After obtaining baseline field potentials, a brief burst of pulses was administered once every 5 seconds for 20 seconds (5 bursts total). Test pulses were administered periodically for 4 hours after conditioning to track the maintenance of the established potentiation. Following this paradigm, the control group showed potentiation of the EPSP slope of 39%. Potentiation was maintained through the 4 hours after conditioning. In contrast, both experimental groups lost the EPSP potentiation they had initially gained. Prenatally protein malnourished rats (6/25) had EPSP slopes that potentiated 22% but returned to baseline after 3 hours. The chronically malnourished animals (6/6) potentiated the EPSP by 9% which returned to baseline after 2 hours. These results suggest that a purely prenatal dietary protein restriction has an effect on synaptic plasticity in otherwise normally reared offspring when tested in adulthood. This prenatal influence when combined with chronic postnatal malnutrition leads to a further deficit in establishing and maintaining LTP. This data supports our previous findings showing that chronically malnourished (6/6) animals potentiate the EPSP significantly less than controls when conditioning stimulation was delivered during the still, alert state of waking. The ability to modify synaptic activity for the long-term is a prerequisite for neuronal information storage and retrieval. Although the behavioral and functional consequences of a deficit in developing and maintaining LTP are unknown, it can be speculated that some memory processes are affected which may be associated with long-term learning deficits (Supported by NIH Grant HD-06364).

23.4 BEHAVIORAL EFFECTS OF SEVERE AND MODERATE EARLY MALNUTRITION. C. Wolf*, C. R. Almli, S. Finger, S. Ryan*, and P. J. Morgane. Dept. Psychol., Washington Univ., St. Louis, MO 63130 and Worcester Found. Exper. Biol., Shrewsbury, MA 01545.

Two recent studies on radial arm maze performance in previously undernourished rats have presented contradictory results. Jorden et al. (Dev. Psychobiol., 1981) reported that early undernourished rat offspring (50% food restriction to the dam during pregnancy and lactation) performed poorly relative to well-fed rats, whereas, Hall (Dev. Psychobiol., 1983) found no group differences in a study involving offspring of rats fed low protein diets (8% casein) during pregnancy and lactation. For this reason, radial arm maze performance was reexamined in the present study, but under 2 undernutrition conditions and in conjunction with other behavioral measures.

Dams were prenatally and postnatally undernourished (6 or 8% casein diets) or well-fed (25% casein). All female offspring received 25% protein diets after day 21, and approximately 100 days later were tested in an open field and in an 8-arm radial maze. The 6 and 8% rats weighed less than the 25% rats at testing, but did not differ from each other.

Although the 6% rats seemed hyperactive, the groups only showed a trend toward differences in activity and rearing up in the open field. Inspection and further analysis of the data showed that the failure to achieve statistical significance was due to one deviant (hypoactive) 6% rat. In the radial arm maze, the 6% rats again appeared to be hyperactive and ANOVAs revealed significant group x test day interactions. The undernourished rats (6% and 8%) made more entry errors as well as correct entries than the 25% group during the first 10 days of testing. After this, the undernourished group scores more closely approximated those of the well-fed rats. The scores of the 6% rats deviated more than those of the 8% rats on these measures.

These results show that rats subjected to severe, early undernutrition (6% casein) display greater performance deficits than those experiencing milder undernutrition (8% casein). Further, the data suggest that severe, early nutritional deficiencies may result in hyperactivity and an inability to inhibit responding. The radial arm maze and open field performance profiles of the 6% rats may be comparable to descriptions of hyperactive children. Further experiments are underway to evaluate the possible relationship between early nutritional deficiencies and hyperactivity. (Supported by BRSG-7054 & HD-06364 Grants).

23.5 DIFFERENCES IN PASSIVE AVOIDANCE BEHAVIOR DUE TO MILD PERINATAL ZINC DEFICIENCY AND/OR UNDERNUTRITION. E.S. Halas, T.P. Tinius* and B.E. Beckwith. USDA, ARS, Grand Forks Human Nutrition Research Center and University of North Dakota, Department of Psychology, Grand Forks, ND 58202.

Hesse, Hesse & Catalanotto (1979) attempted to determine if young adult rats, who were chronically zinc deficient, behaved like hippocampal lesioned rats in a passive avoidance paradigm. The Hesse et al. (1979) results showed that chronic zinc deficient rats (ZD) had slower entry times (latency) than undernourished (PF) rats and concluded that the abnormal behaviors associated with zinc deficiency are opposite from those observed in hippocampal lesioned animals. The present experiment tested the hypothesis that adult male rats who were zinc deprived or undernourished during gestation and lactation would have slower test latencies in a passive avoidance paradigm than animals fed a normal diet (AL). Thirty-nine male Long Evans rats were used for this study. The test apparatus was a passive avoidance chamber. Beginning on the day of conception, one group of dams was fed ad libitum a mildly zinc deficient (ZD) diet (10.00 µg Zn/g) and maintained on the diet until their pups were weaned. Since zinc deficiency causes anorexia, a second group of dams, pair-fed (PF), was fed the same quantity of the diet as consumed by their ZD mates. A third group of dams was fed the diet ad libitum (AL). After weaning at 23 days of age, all litters were fed Purina Chow ad libitum. On the first day of training, each animal was placed in the dark chamber for 2 min. This was immediately followed by a single trial in which the animal was placed on the runway facing away from the door. The door was opened immediately and the animal was allowed to enter the dark chamber. Ten sec later the animal was removed and placed in its home cage. On the second day of training, all animals received 3 more trials to enter the dark chamber, with a inter-trial interval of 2 min. On the third trial, each animal received a 2 sec unavoidable foot-shock (0.5 mA supplied by a shock scrambler) through the grid floor immediately after entering the chamber with all four feet. The animal was removed from the chamber 10 sec after the completion of the shock and placed in its home cage. Test trials for each animal were conducted at 24, 48, 72, and 96 hr intervals after the learning trial. The present study found that only the AL rats showed a decrease in test latency ($p < .05$) over a 4 day period and illustrates why it is necessary to use both the PF and AL groups when studying zinc deficiency. The ZD rats had faster latencies ($p < .05$) than the PF rats only on day 3 and both the PF (246 sec) and ZD (209 sec) rats had longer latencies ($p < .05$) than the AL (163 sec) rats on days 2 to 4. The PF group is not an adequate substitute for the AL group.

23.6 DEVELOPMENTAL MALNUTRITION IMPAIRS REVERSAL LEARNING OF A SUCCESSIVE CONDITIONAL DISCRIMINATION. C.R. Goodlett and M.L. Valentino. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

An increasing number of studies indicate that the hippocampal formation may be vulnurable to permanent structural and physiological alterations following maternal dietary protein restriction. Behaviorally, we have observed that chronically malnourished rats exhibit perseverative deficits on delayed spatial alternation learning, but are not impaired in simple spatial location learning in the Morris maze. To further characterize the behavioral effects of developmental malnutrition on learning tasks thought to involve hippocampal processing, we examined the acquisition and reversal of a successive conditional discrimination.

Virgin female Sprague-Dawley rats were provided either a 6%, 8% or 25% casein diet for five weeks prior to mating. The dams were maintained on their respective diets throughout gestation and lactation, and at weaning all pups were given the 25% casein diet. At 4 months of age, female rats from each maternal dietary treatment were tested on the successive conditional maze discrimination. The maze contained a start box, four discrimination units (each having two alleys) and a goal box. Over a three week period all rats were adapted to a water deprivation schedule and trained to traverse the maze. For the successive conditional discrimination training, all rats were given 4 training trials per day, encountering four choices on each trial. During training, the correct alley (allowing passage through the unit) was contingent on the illumination of the unit.Thus, when both alleys were illuminated the right alley was the correct choice; when neither alley was illuminated the left alley was correct. The order of the correct choices across units within each trial and across trials within each unit was randomized each day. Choices at each unit were recorded and retracing of units was prevented. All rats were given 17 days of acquisition training followed by 12 days of training on the reversal problem.

All three groups acquired the original successive conditional discrimination, and no statistically significant effects of dietary history were seen for errors during acquisition. However, on the reversal problem, the rats with a history of malnutrition committed significantly more errors than controls ($p<.001$ for both 6% and 8% groups). The rats from the 6% group also committed more errors than those of the 8% group ($p<.05$). Continuing studies are examining the relative importance of gestational versus lactational protein restriction in producing the learning deficits in mature rats. (Research supported by NIH grant HD 06364).

23.7 ALTERED BEHAVIORAL RESPONSE TO KINDLING FOLLOWING PRENATAL PROTEIN MALNUTRITION. R. J. Austin-La France,* J. D. Bronzino, E. Muik,* J. Senaldi,* P. J. Morgane (SPON:D. Jones).Trinity College Hartford, Ct. 06106 and The Worcester Foundation For Experimental Biology, Shrewsbury, Ma. 01545.

Previous studies have indicated that animals subjected to various forms of malnutrition are more susceptible to seizures than animals reared on normal diets (Taber et al., Experientia, 36: 69-70, 1982). The present studies were designed to evaluate the impact of a specific form of malnutrition - prenatal protein malnutrition - on the electrophysiological and behavioral correlates of the kindling process. In order to evaluate these effects, rats born to dams maintained on either a 25% or 6% casein diet were bilaterally implanted in homologous regions of hippocampal field CA1 and in the frontal cortex with chronic electrodes at 30 days of age. Kindling was induced by daily electrical stimulation of the CA1 field of the hippocampus. We found that animals raised on the 6% diet had a significantly lower ($p < 0.01$) mean threshold intensity to afterdischarge (AD) and a significantly longer ($p < 0.01$) mean AD duration compared to the 25% diet group. The spread of AD activity to the frontal cortex was markedly enhanced in the 6% diet group, appearing on day 1 of stimulation as opposed to an average of day 15 in the 25% diet group. The behavioral manifestations of the kindling process were also considerably different in the 6% group. While the 25% diet group progressed through four behavioral stages as described by Araki et al., (Jap. J. Pharmacol., 33: 57-64, 1983), 6% diet animals rarely followed this normal progression. For example, they seldom showed rearing as a stage 2 behavior and instead would progress from stage 1-type behaviors to a behavior characterized by freezing with rhythmic waves of myotonic contractions moving from neck to tail. Finally, all of the 25% diet animals reached the convulsive stage after an average of 22 daily stimulations while 80% of the animals in the 6% group failed to reach this stage after 40 stimulations. These findings suggest that prenatal protein malnutrition may retard or alter the development and functional maturation of neuronal mechanisms involved in local excitability, generalized spread and the behavioral correlates of epileptogenic activity within the limbic system.(Supported by NIH Grant HD 06364).

23.8 AUTORADIOGRAPHIC CHANGES IN DOPAMINE AND MET-ENKEPHALIN RECEPTOR BINDING IN RATS PRENATALLY EXPOSED TO ETHANOL. D.E. Hand and S.F. Hoff, Dept. of Pharmacology, University of Health Sciences/ The Chicago Medical School, North Chicago, IL 60064.

Cognitive and behavioral deficits found in animals exposed to alcohol in utero may result from underlying aberrations in the ontogeny of central neurotransmitter systems. We examined the distribution of dopamine and enkephalin receptor binding sites using in vitro autoradiography to localize and quantitate [^{3}H]-spiroperidol and [^{3}H]-Met-enkephalin binding in the CNS of 15 day old rats.

Pregnant rats were fed a liquid diet (BioServ) containing 35% ethanol derived calories and pairfed controls received the caloric equivalent in liquid diet without alcohol. Alcohol exposure was terminated on the day of birth as the litters were culled to eight pups and cross-fostered to mothers that consumed normal rat chow diets throughout pregnancy. On day 15, animals were sacrificed by decapitation, and the brains were quickly removed and frozen in isopentane at -25°C. Serial sections six microns in thickness were collected in the coronal plane, mounted onto slides, and incubated in buffers containing radioligands for total and nonspecific binding analysis. The sections were rapidly dried and apposed to Ultrofilm alongside brain paste standards for varying lengths of time. The film was developed and analyzed densitometrically for changes in binding between the two treatment groups.

Decreased dopamine binding in ethanol vs. pairfed animals occured in the frontal cortex, olfactory tubercle, nucleus accumbens septi, and caudate-putamen, while and increase in [^{3}H]-spiroperidol binding was observed in the olfactory bulb. Decreased [^{3}H]-Met-enkephalin binding in ethanol animals was observed in regions of the cerebral cortex, hippocampal formation, and thalamic nuclei while an increase in binding was observed in the caudate-putamen. Many of these regions receive dopaminergic innervation from the mesolimbic, mesocortical, and nigrostriatal systems. Alterations in these systems have been correlated with disorders of behavior and movement and may underly similar neurologic deficits associated with fetal alcohol exposure. (Supported by NIAAA AA06156.)

23.9 A BIOCHEMICAL EVALUATION OF BRAIN DEVELOPMENT IN OFFSPRING OF RATS FED WITH ETHANOL DURING GESTATION. F. E. Lancaster, J. -R. Yu* and L. L. Hsu. Dept. of Biology, Texas Woman's Univ. Houston, TX, and Dept. of Psychiatry and Behav. Sci., UTMB, Galveston, TX 77550.

Our previous work has shown that postnatal exposure to ethanol through lactation altered the specific activities of ^{3}H-spiperone (SPD) binding, glutamic acid decarboxylase (GAD) and choline acetyltranferase in the female rat brain striatum at 30 days old. We have further examined the possible effects of gestational exposure to ethanol on the neurochemistry of the developing brain of the offspring. Timed pregnant Long-Evans rats were received on day 4 of gestation, and housed separately in a temperature controlled room with a light, dark cycle of 12 hours. On days 4-19 of gestation, one group of dams (ET) had ad libitum access to a liquid diet containing 30% of calories as ethanol. A second group of dams (PF) had ad libitum access to control liquid diet on day 4 of gestation. Beginning on day 5 of gestation and through day 19 of gestation, the PF group received control liquid diet in amounts equal to the average consumption of the ET animals on the previous day. A third group (CT) had ad libitum access to control diet on days 4-19 of gestation. Following day 19 of gestation, all dams received ad libitum access to laboratory chow and water. On day 1 (day 0 = day of birth) litters were culled to 8 pups (4 males and 4 females) and toe clipped for identification. On days 14 and 28, pups (n = 15 litters per dietary group) were sacrificed by decapi-tation and brains were rapidly removed. Striata were dissected immediately from the brains over ice, frozen on dry ice and stored at -60 ^{o}C until used. Striatal tissues were homogenized in 5 vol. of K-phosphate buffer, pH 7.2, and aliquots were used for GAD and AChE assays. The remaining portions were used to repare the plasma membranes (Pm) for ^{3}H-SPD binding and adenylate cyclase (AC) assays. Results indicated that at 14 days old, the specific AC activity in the striatum was significantly increased in the ET group compared to the PF or CT group (20% and 130% respectively, $p < .005$), and the specific GAD activity was moderately but not significantly increased in the ET group compared to either the PF (29%) or CT (7%) group. At 28 days old, the striatal AC activity was slightly but not significantly decreased in the ET group compared to the PF group, and the GAD activity was not altered in the ET group compared to either PF or CT group. Moreover, no changes were observed in the striatal ^{3}H-SPD binding or AChE activities in either age group after the gestational ethanol exposure. Whether the increase of AC activity also exists in other brain regions after gestational ethanol exposure remains to determined.

23.10 A DOSE-RESPONSE STUDY OF THE EFFECTS OF ETHANOL ON CORPUS CALLOSUM DEVELOPMENT IN BALB/c AND C57BL/6 MICE. S.B. Cassells*[1], P. Wainwright[2] and K. Blom*[1]. [1]Dept. of Psychology, and [2]Dept. of Health Studies, Univ. of Waterloo, Waterloo, Ont. Canada N2L 3G1

The intent of this study was to further explore the interaction between the effects of heredity and ethanol on brain development in mice. Animals of the BALB/c inbred strain are prone to defective growth of the corpus callosum (CC) where this forebrain commissural tract is either absent at midline or greatly reduced in size (Wahlsten, D. Brain Res., 68: 1-18, 1974). Previous work has shown that ethanol affects the growth of the CC in BALB/c but not in C57BL/6 mice (Wainwright, P. and Gagnon, M. Exp. Neurol. 88: 84-94, 1985). The present experimental design was that of a dose-response study in each of the two strains, with food intake adjusted to control for strain differences in alcohol preference. Animals in all groups were fed 0.6 Kcal/g/day of a Sustacal-based liquid diet, with the ethanol content being 0, 15, 17.5 and 25% of the total calories. Maltose-dextrin was substituted isocalorically for ethanol so that all groups received 25% of their calories from non-nutritive sources. Preliminary work had indicated that BALB/c animals would not produce litters at an ethanol dosage level of 25% and therefore this group was not included in the study. Fetal development was assessed on day 18 of gestation. The dependent variables included the cross-sectional area in a midsagittal section of both the CC and anterior commissure (CA), as well as fetal brain and body weight. In addition, measures were taken of maternal blood alcohol concentrations. The results indicated an effect of ethanol on body and brain growth, with the effect on brain weight being independent of that on body weight. C57's had heavier bodies and brains than the BALB's and there was evidence of a strain by ethanol interaction on body weight, with the C57's showing a larger reduction in body weight at the higher doses. Preliminary analyses of the data indicated an effect on the growth of the CC, independent of an effect on brain weight, only in the BALB's. In contrast, there did not appear to be such an effect on the CA in either strain. Maternal blood alcohol concentrations reflected the ethanol content of the diet and there were no significant strain differences at any dose. These results suggest that hereditary factors may be an important consideration when predicting the effects of ethanol on specific aspects of fetal brain growth.

This research was supported in part by NSERC grant #A7617 to P. Wainwright.

23.11 MICROENCEPHALY INDUCED DURING THIRD TRIMESTER EQUIVALENT IS DEPENDENT ON ALCOHOL EXPOSURE PATTERN. D.R. Pierce and J.R. West. Dept. of Anatomy, Univ. of Iowa, College of Medicine, Iowa City, IA 52242.

Using a rat model system to study fetal alcohol effects (FAE) during a period of rapid brain development equivalent to the human third trimester requires exposing rats to alcohol postnatally. An artificial rearing procedure was implemented in which chronic gastric cannulas were surgically implanted in rat pups on postnatal day 4 (West, Hamre, and Pierce, Alcohol, 1:213, 1984). Pups were fed a milk formula in twelve 20 minute fractions daily.

Three groups of 7 pups each were analyzed on postnatal day 10. The groups were gastrostomized controls (G/C) fed the control formula, gastrostomized alcohol group with a uniform alcohol exposure (G/UAE) of 2.5% EtOH added to the diet for each feeding, and a gastrostomized alcohol group with a condensed alcohol exposure (G/CAE) of 5.0% EtOH added to the diet each day for 6 feedings (12 hours) followed by 6 feedings of alcohol-free diet. Both alcohol groups received an identical dose of 6.57 g/kg for each 24 hour period. Blood alcohol concentrations (BACs) taken on day 6 revealed BACs of 55.2 ± 9.9 mg/dl for the G/UAE group. BACs peaked at 268.7 ± 12.1 mg/dl in the G/CAE animals and dropped to 11.0 ± 7.8 mg/dl by the end of the alcohol free period.

There were no significant differences at day 10 in body, liver, or adrenal weights between any of the groups. However, significant microencephaly ($p<0.05$) was observed in the G/CAE animals. Brain weight and the brain weight/body weight ratio were reduced in the G/CAE group by 8.3% and 13.6%, respectively, compared to the G/C group. The G/C and G/UAE groups were not statistically different for these measurements.

Microencephaly was induced in the G/CAE animals using the same daily alcohol dose as the G/UAE animals by varying the alcohol exposure pattern. The different alcohol exposure patterns resulted in markedly different BACs. These data indicate that the blood alcohol concentration is more important than the dose for inducing microencephaly during the third trimester equivalent in the rat. This study was supported by NIAAA grant AA05523 to J.R.W.

23.12 **NICOTINE ADMINISTRATION DURING PREGNANCY AND ITS EFFECT ON STRIATAL DEVELOPMENT.** **L.C. Murrin, J.R. Ferrer* and W. Zeng* Dept. of Pharmacology, Univ. Nebraska Med. Ctr., Omaha, NE 68105**

Studies indicate a strong relationship between exposure to nicotine *in utero* via maternal smoking and increased incidence of CNS developmental problems, particularly learning and behavioral disorders such as minimal brain dysfunction (MBD). Other studies suggest an involvement of the nigro-striatal dopaminergic pathway in MBD and nicotine has been shown to affect dopaminergic neuronal activity in adults and neonates. The objectives of this study were to develop a reliable means of delivering nicotine to female rats during pregnancy and to study the effects of prenatal nicotine exposure on striatal receptors postnatally. Initial studies administered nicotine in drinking water, a procedure reported successful in the literature. Female rats displayed an apparent aversion to nicotine in drinking water. At 0.02% nicotine, which delivered approx. 2 mg/kg-day (eqivalent to a human smoking 1-2 packs of cigarettes/day), there was short term weight loss and a long term 50% decrease in water consumption. At higher doses water and food consumption were depressed further. At 0.4% nicotine water consumption was not sufficient for survival. Adding sucrose or adjusting pH to 7 did not improve water consumption. Because of the limitations on a dose response curve and the probability that water intake was probably insufficient for normal fetal development, we administered nicotine via Alza osmotic mini-pumps implanted on day 3 of pregnancy. With this method nicotine up to 4.5 mg/kg-day did not produce any significant effect on weight gain, water or food consumption in dams beyond those ascribable to surgery. Plasma nicotine and cotinine levels (J. Chronic Dis. 36:439, 1983) correlated directly (r^2=0.998) with dose delivered. Nicotine treatment of dams up to 4.5 mg/kg-day did not affect litter size, pup birth weight or weight gain for two weeks postnatally. Pups were cross-fostered at birth.

Striatal dopamine D2, cholinergic muscarinic and opiate mu receptors were examined at 14 days of age using membrane binding techniques and ^{3}H-spiperone (0.5nM:SP), ^{3}H-N-methyl-scopolamine (1.5nM:NMS) and ^{3}H-diprenorphine (1nM:DPN) as ligands, respectively.

Ligand	Control (vehicle)	Low nicotine (1.5mg/kg-day)	High nicotine (4.5mg/kg-day)
^{3}H-SP	18.2 ± 1.3	30.7 ± 2.4a	17.1 ± 2.1b
^{3}H-NMS	575.0 ± 56.0	741.0 ± 53.0	401.0 ± 33.0a,b
^{3}H-DPN	71.6 ± 13.8	97.8 ± 10.1	43.2 ± 4.6b

Data are specific fmol/mg protein ± SEM, n = 8-14.
a - $p < .05$, significantly different from control, Peritz' F test.
b - $p < .05$, significantly different from low dose, Peritz' F test.

It appears that prenatal exposure to nicotine alters normal striatal development, as seen by receptor binding at 14 days of age, and receptors are affected differentially. **Supported by the State of Nebraska Department of Health (#85-44).**

23.13 DOCOSAHEXAENOIC ACID DEPLETION IN RHESUS MONKEYS: PERSISTENT EFFECT ON RECOVERY TIME OF THE ELECTRORETINOGRAM. M. Neuringer*, W.E. Connor*, and S.L. Luck* (SPON: D. Rhodes). Oregon Health Sciences University, Portland 97201, and Oregon Regional Primate Research Center, Beaverton 97006.

Neural and photoreceptor outer segment membranes are unique in their very high content of docosahexaenoic acid (22:6ω3), a fatty acid of the ω3 series. 22:6ω3 must be obtained directly from the diet or by biosynthesis from other dietary ω3 fatty acids, primarily linolenic acid (18:3ω3).

We are examining the effects of dietary deprivation of ω3 fatty acids in rhesus monkeys during prenatal and postnatal development. Adult females were fed a semipurified diet containing very low levels of ω3 fatty acids (≤0.3% of total fatty acids) and their infants received a similar diet from birth. A control group of mothers and infants received semipurified diets providing ample linolenic acid (8% of total fatty acids).

At birth, levels of 22:6ω3 in phosphatidyl ethanolamine and phosphatidyl serine were reduced by 50% in the retina and by 75% in the cerebral cortex of deficient animals, relative to control values. Postnally, 22:6ω3 levels in control tissues doubled, while those in deficient tissues failed to increase. At two years, 22:6ω3 was reduced by 80-85% in the phosphatidyl ethanolamine of both retina and cerebral cortex of deficient animals. 22:6ω3 was almost entirely replaced by 22:5ω6, an ω6 fatty acid.

Electroretinograms were recorded at 7, 14, and 21 months of age. Following a saturating flash, the recovery of the dark-adapted ERG was significantly delayed in deficient animals. The time required for recovery to half maximal amplitude was increased by 80% and time for complete recovery by 70%.

The reversibility of these biochemical and ERG abnormalities was examined in four deficient monkeys, two at ten months and two at two years of age, after their diets were supplemented with high levels of 22:6ω3 and 20:5ω3. Biopsies of frontal cortex were obtained during the deficient state and at 8-12 week intervals after supplementation. Levels of 22:6ω3 in cortical phospholipids increased rapidly and achieved control levels within 12 weeks. Thus, even after the period of rapid brain growth, the fatty acid composition of neural tissues can be altered by changes in the diet. The reversibility of retinal 22:6ω3 depletion will be confirmed after functional tests are completed. ERG recordings, repeated at 12 and 24 weeks of supplementation, showed no improvement in recovery time. Delayed recovery of the ERG therefore appears to be a persistent effect ω3 fatty acid deficiency.

Supported by NIH grants AM-29930 and RR-00163.

23.14 DEPRESSED GLUCOSE METABOLISM BY CORTICAL BRAIN SLICES FROM BRINDLED MICE (Mo^{br}). J.E.Goldman and C.Peterson, (SPON: W.T.Norton), Department of Pathology (Neuropathology), Albert Einstein College of Medicine, Bronx, N.Y. 10461.

The brindled mouse (Mo^{br}) is an X-linked murine mutant with a defect in copper transport. Previous studies demonstrate neuronal degeneration in the cerebral cortex that is characterized by swollen dendrites, enlarged mitochondria and cytoskeletal abnormalities (Acta Neuropathol. 45:17 (1978)). Since copper deficiency may interfere with carbohydrate metabolism, glucose oxidation and its incorporation into the acid insoluble precipitate were examined in vitro with normal and brindled mice. Brain slices (0.3 x 0.3 mm) were prepared from the forebrains of 15 day old brindled mice and normal male littermates. The slices were incubated for 1 hr at 37°C in bicarbonate buffer with high potassium (31 mM) that contained 5 mM- [U-^{14}C] glucose. The incubation was terminated by acidification. Glucose incorporation into $^{14}CO_2$ and the acid insoluble precipitate were determined by liquid scintillation. Each condition was examined in triplicate and protein was assayed in the acid insoluble precipitate.

	Normal	Brindled
$^{14}CO_2$	19.36±0.64	4.49±0.14*
acid-insoluble	2.48±0.15	0.74±0.08*
number of mice	(6)	(6)

Values are nmol/mg protein per hr.
*Denotes difference ($P<0.05$)

Thus, deficits in glucose metabolism due to copper deficiency may contribute to neuronal degeneration. Supported in part by grant AG05386.

23.15 VULNERABILITY AND RECOVERY FROM TRAUMA DURING FAST BRAIN GROWTH. E. Murowchick, E. Moore* and J. Diaz. Dept. of Psych., Univ. of Washington, Seattle, WA 98195.

The procedure of rearing rat pups away from their mothers using a chronic intragastric cannula and a replacement formula has been found to result in 7-10% whole brain weight deficits compared to mother reared siblings, despite comparable whole body weights. This procedure is typically applied during the rat's brain growth spurt (BGS). Dobbing and Sands (1971) have hypothesized that a period of accelerated growth may also be a period of heightened vulnerability to insults. The purpose of this experiment is twofold: 1) to determine whether the insult of artificial rearing will affect brain growth differentially at different phases of the BGS and 2) to determine the efficiency of short term recovery from these insults depending on the phase of the BGS in which the trauma and subsequent recovery phase occurs.

Four day old Long-Evans rats were randomly assigned to either the gastrotomy reared (AR) or mother reared (NR) condition. Those animals assigned to the AR condition were then assigned to one of the three BGS phases (early-days 4 to 8, peak-days 8 to 12, late-days 12 to 16). Within each phase, each animal was assigned either to a recovery group (with an 8 day recovery period) or a non-recovery period. On the first day of the assigned phase, each AR animal was lightly anesthetized and implanted with an intragastric cannula. At the end of the four days of artificial rearing the animals were either sacrificed immediately (no recovery) or returned to a lactating dam and sacrificed 8 days later. NR siblings of the AR animals were sacrificed as age matched controls. At sacrifice, each animal's brain and visceral organs were removed and weighed.

Preliminary analysis of the data suggest that the magnitude of the effect of artificial rearing varies depending on when, during the BGS, the insult is sustained.

24.1 ARM MOVEMENT CONTROL STRATEGIES: HAND TRAJECTORY VS. JOINT PLANNING. T. Kaminski*.& A.M. Gentile. Teachers College, Columbia University, New York, NY 10027.

Two control strategies could underlie rapid pointing movements: (1) planning hand trajectory or (2) planning joint movement parameters. If a strategy based on hand trajectory planning is used, then certain hand movement parameters should remain constant regardless of whether a single or multijoint movement is required. If a joint planning strategy is used, then certain joint movement parameters should remain constant.

Velocity profiles of the hand, shoulder and elbow were analyzed for 8 subjects who performed rapid pointing movements to a variety of target locations. A two degree of freedom manipulandum permitted shoulder and elbow motion in the horizontal plane. Joint displacements were equivalent during both single and multijoint movements. Single joint movements required either elbow or shoulder movement to three different target locations.

Velocity profiles of the hand differed during single and multijoint movements. The hand always had a higher peak velocity, shorter rise time and movement time during single joint movements, given the same required magnitude of displacement. The only consistency observed in the profile across conditions was its shape: smooth and bell-shaped. In contrast, the velocity profiles of the shoulder remained the same during both single and multijoint movements, while that of the elbow joint changed.

The results do not support a strategy based on hand trajectory planning because neither hand path nor velocity profile were the same for single and multijoint movements. At best, the consistent shape of the profile indicates a strategy that economizes effort by minimizing jerk of the hand. The consistency of the shoulder velocity profile indicates that arm movements can be planned in terms of joint parameters. Maintaining the same shoulder parameters for a variety of movements provides a stable base upon which additional components can be placed.

24.2 CHARACTERISTICS OF VELOCITY PROFILES OF HUMAN ARM MOVEMENTS AND SPEECH. D.J. Ostry*, J.D. Cooke and S.H. Brown. McGill University, Montreal, Quebec and University of Western Ontario, London, Ontario.

In recent years there has been interest in the idea that the geometric form of the velocity profile of voluntary movements is invariant under transformations of movement amplitude and rate. We have explored this problem by examining cyclical and discrete elbow and tongue movements. The form of the velocity profile of movements can be described by $V_{max}/A = c/T$, where V_{max} is the maximum velocity, A is amplitude, T is duration and c is a parameter that is characteristic of the shape of the velocity profile.

We examined both cyclical and discrete movements because the form of their velocity profiles has been shown to differ even if the movements are similar in duration and amplitude. For example, if movements are made so as to minimize jerk, c is equal to 1.56 for cyclical movements (Nelson, 1983) and 1.88 for discrete movements (Hogan, 1984).

For limb movements, our findings to date indicate that the numerical value of the velocity profile parameter ranges from 1.5 to 1.6 for cyclical movements. This holds for both flexion and extension movements of different amplitudes and durations. These estimates are consistent with predicted values for cyclical movements. In contrast, estimates of the velocity profile parameter for discrete movements vary systematically with movement duration, ranging from about 2.4 for short duration movements to approximately 1.8 for long duration movements. This suggests that in discrete arm movements velocity profiles do not form a single family of geometrically equivalent curves.

Values for the velocity profile parameter in speech movements are similar to those observed for elbow flexion and extension. Parameter estimates are higher for discrete than for cyclical movements and as in limb movements, parameter estimates for discrete movements vary systematically with movement duration.

The assumption of equivalence of the geometric form of velocity profiles thus appears reasonable in the case of repetitive or cyclical movements but appears untenable in the case of discrete movements. The findings point to an underlying similarity in the control of speech and limb movements.

24.3 TRAJECTORY COMPENSATIONS IN PRACTICED MOVEMENTS. W.G. Darling and J.D. Cooke. Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

In recent studies we have shown that although movement variability decreases during practice variability in the EMGs of movement related muscles may increase. Increased EMG variability was associated with increases in movement speed. Since the EMG reflects the neural activity controlling the muscle this suggests that fast movements are made with variable neural commands to agonist and antagonist muscles. Movement trajectory (velocity versus position during movement) could be maintained relatively constant under these conditions if, for example, variations in the first agonist burst were compensated by appropriate variations in the antagonist burst. This could be viewed as a form of trajectory compensation in which departures from a learned trajectory due to EMG variations are corrected to return the limb to the intended trajectory.

The interrelationships between movement trajectories and EMGs of movement-related muscles were studied in 20 normal human subjects performing 10^o and 30^o amplitude elbow flexion and extension movements in a visual step tracking task. Subjects were instructed to make accurate movements and to attempt to increase movement speed during practice while maintaining accuracy. Arm position and velocity were recorded along with surface EMGs from the biceps and triceps (lateral head) muscles. Data were sampled on-line at 500 Hz.

Averaged data from practiced movements provided an indication of the intended trajectory of the learned movements. The trajectories of individual movements deviated from the intended trajectory due to variations in the first agonist burst of EMG activity. These deviations could be compensated and the limb returned toward the intended trajectory by appropriate modifications in the timing and/or amplitude of the antagonist burst. The data indicates an ongoing control of the precise movement trajectory even in movements about a single joint. Compensatory modifications for errors in the initial trajectory are achieved through the antagonist burst and may occur through peripheral feedback influences, segmental mechanisms or through efference copy of the burst of neural activity initiating agonist contraction.

24.4 CHANGES IN AGONIST AND ANTAGONIST EMG PATTERNS AS A FUNCTION OF DISTANCE, TARGET SIZE AND VELOCITY. D.M. Corcos, G.L. Gottlieb, G.C. Agarwal and R.D. Penn. Departments of Neurosurgery and Physiology, Rush Medical College, Chicago, Illinois 60612

This study investigated the EMG pattern associated with accurate, rapid elbow flexion and extension movements. Six individuals made movements over 18, 36 and 72 degrees to targets 3, 6, 9 and 12 degrees wide. They also made 72 degree movements to a 24 degree target.

Movement time increased as a function of increasing target distance and decreasing target size. The time to peak velocity occurred later with respect to increasing distance and earlier with respect to increasing target size.

Even though different strategies affect the agonist EMG, duration and area increased as: 1) distance moved increased: 2) target size increased. Both these factors are explained by the relationship between agonist EMG and velocity which increases as distance and target size increase. This relationship can be described by the equations:

$IAEMG = -27.0 + 1.65\ A + 3.7\ W\ R^2 = .93,\ F(2,9) = 61.2\ p < .05$

$IAEMG = -26.1 + .42\ V\ r^2 = .95,\ F(1,10) = 172.6\ p < .05$

where IAEMG is the integrated agonist EMG corresponding to the movement as determined from the onset of the EMG until the velocity of the movement falls below 5% of peak velocity, A=movement amplitude, W=target width and V=peak velocity of the movement.

The antagonist EMG duration and area under the EMG envelope do not appear to follow any clear scaling properties similar to those of the agonist EMG.

With reference to the onset of the agonist, the longer the distance moved, the later the antagonist was activated. When distance is held constant, higher movement velocities were associated with earlier antagonist activation.

The agonist was often activated before observable movement onset and, as such, can not be reflexively initiated. However, in some subjects another burst of antagonist activity occurred later which may be compatible with reflexively initiated EMG.

Early antagonist activation suggests that its function is not only to halt the movement but also to increase the impedance of the joint and thus stabilize it during and after movement. As a consequence, the EMG signal can only be understood in combination with information about the load, the direction of movement, a subject's specific strategy and the forces involved.

(Supported by NIH Grant NS - 15630 and AM - 33189)

24.5 HUMAN TRACKING PERFORMANCE: PARALLEL SPECIFICATION OF AMPLITUDE AND DIRECTION. M. Favilla*, W. Hening, & C. Ghez. Center for Neurobiology & Behavior, Columbia Univ., NYS Psychiatric Inst., New York, NY 10032.

This study examines whether the amplitude and direction of targeted motor responses are specified by serial or by parallel processes. We have used a paradigm which allows us to independently control the processes responsible for trajectory specification and those responsible for response initiation (Soc. Neurosci. Abstr., 10:801, 1984). Four human subjects were trained to initiate isometric force impulses (elbow flexion and extension) in synchrony with the last of a series of predictable tones; after reliable performance was achieved, subjects were instructed to also match both the amplitude and direction of their force impulse to those of a visual target. The interval between target presentation and the response-synchronizing tone was randomly varied from 0 to 500 ms to control stimulus-response (SR) interval; targets were unpredictable in direction and amplitude (three force amplitudes in both flexion and extension).

At short SR intervals, before the target could have an effect, subjects produced "default" responses whose amplitudes were clustered around the average force required, but which were of random direction (50% directional errors). An influence of the preceding target on response amplitude was first detectable at SR intervals of about 150 ms. Specification was complete at about 350 ms when response amplitudes correctly matched the targets. Directional specification occurred more abruptly, starting later (at SR intervals of about 200 ms) and finishing sooner, so that no directional errors were present after 250 ms. Thus, at SR intervals greater than 150 ms, the amplitudes of responses in the wrong direction correctly reflected the target force (correlations of the absolute values of peak force to the target force gradually increased to values between 0.6 to 0.9). In no session did directional specification precede amplitude specification.

Contrary to previous suggestions that response features must be specified sequentially, we conclude that subjects can utilize parallel processes to specify the amplitude and direction of motor responses. Specification of either response feature can begin without complete specification of the other.

24.6 EFFECTS OF INITIAL POSTURE ON POSTURAL ADJUSTMENTS DURING RAPID AND SLOW VOLUNTARY ARM MOVEMENTS. W.A. Lee and S.H. Tang*. Northwestern University and Rehabilitation Institute of Chicago, Chicago, IL 60611.

The speed of disturbances to balance has been shown to influence EMG patterns of postural adjustments (PAs) in standing humans (Diener, Exp. Br. Res.,52:423, 1983; Horak, Neurol., Neurosurg. & Psychiat.,47:1020, 1984). For slow as compared with rapid voluntary arm movements, variability in the timing of PAs increases almost 10-fold (Lee, W. Neuros Abs:54.6, 1983). Some variability in postural EMG onsets for slow movements could reflect bias from initial posture accompanying sway. For rapid arm movements, initial posture might influence PAs less but still account for some variability reported in the order of postural and task muscle onsets (e.g., Belenkii, Biophys., 12:135, 1967; Lee, W., Jnl Mot Behav 12:185, 1980).

This study examined interactive effects of initial posture and arm velocity on EMG and mechanical correlates of PAs associated with voluntary arm flexions. Nine adult male subjects performed 120 bilateral arm flexions to 90 degree while standing. Twenty movements were performed at two speeds (as fast as possible; 2 sec duration) from three initial postures (neutral, leaning slightly forward or backward). EMG activity (anterior deltoid: AD; hamstring: HM; medial gastrocnemius: GS) and body motion (ankle and arm angles, hip and trunk sagittal displacements) were measured. EMG signals were normalized to maximal isometric contractions. The sagittal projection of the center of mass (CM) was estimated computationally.

HM and GS onsets were significantly delayed (post-arm movement) for slow as compared with rapid movements, which is consistent with previous studies. For rapid flexions, HM and AD onset latencies did not differ significantly and were followed by GS. Initial posture significantly influenced HM and GS latencies only for slow, not rapid flexions: earlier onsets occured with forward-leaning postures, as predicted by a peripheral bias model. Initial posture influenced EMG amplitudes for both slow and rapid arm movements (higher amplitudes for more forward postures). Results on mechanical correlates of PAs during rapid flexions showed that: (1) changes in ankle, hip and trunk typically lagged initiation of arm movement; (2) CM moved forward during arm flexion and was not fully compensated for by posterior trunk and hip movements; and (3) hip and trunk but not CM displacements were constant over the range of postures studied. These data imply that PAs were not modified to minimize changes in the location of the CM during arm movement.

24.7 TRANSITION FROM 'SLOW' TO 'FAST' MOVEMENTS: SUPERPOSITION OF MOTOR PROGRAMS. J.D. Cooke and S.H. Brown (SPON: J.D. Brown). Dept. of Physiology, Univ. of Western Ontario, London, Canada.

The division of movements into two functional types, fast and slow, has often been made on the basis of their patterns of muscle activation. Fast movements are initiated by a phasic burst of activity in the agonist muscle which may be followed by a burst in the antagonist and a second agonist burst. This is the triphasic pattern which is seen in movements of a wide range of speed and amplitude. In contrast, slow movements are made without phasic muscle activation, the tonic EMG levels in one or both muscles being changed. Tonic EMG levels in the opposing muscle groups have also been shown to determine the end-position of movement. The present study addressed the transition from slow to fast movements. The specific question asked was whether, as movement speed is increased, the phasic EMG activity characteristic of fast movements is simply superimposed on the tonic EMG activity characteristic of slow movements.

Experiments were performed on normal human subjects making flexion-extension movements about the elbow. The subjects moved a manipulandum arm which was pivoted at one end and which could be rotated horizontally about the pivot. Subjects tracked a target which moved at constant velocity between two positions. The target was presented as an audio signal whose pitch varied with the target position. Handle position (taken from a precision potentiometer) was also used to modulate the target tone. Thus the subject was to reproduce the target tone by moving the manipulandum. Ramp movements of different durations and amplitudes were studied. Handle position and velocity were recorded as were surface EMGs from the biceps muscle and the lateral head of the triceps.

The slower movements studied were produced without phasic EMG activity. Tonic agonist activity gradually increased throughout the movement to its final value when the movement end position was attained. As movement speed increased, the final tonic EMG level was reached progressively earlier in the movement. At the limit of these 'slow' movements, the tonic EMG changed in a step-like manner. With further increases in movement speed phasic EMG activity appeared. Movements were initiated with a brief phasic burst which was superimposed on the step-like tonic activity. The initial phasic burst increased in amplitude with further speed increases, remaining superimposed on the tonic activity.

The data indicate that the transition from 'slow' to 'fast' movements is accomplished by the superposition of phasic muscle activation on the tonic activation and that movements of different speeds form part of a continuum.

24.8 SIMULATED BALLISTIC MOVEMENTS. M.M. Wierzbicka*, A.W. Wiegner, B.T. Shahani. Clinical Neurophysiology Lab., Mass. General Hospital, Boston, MA 02114.

Fast goal-directed voluntary movements are known to be associated with three distinct bursts of EMG activity in antagonistic muscles. The role of each burst (AG1, ANT, AG2) in controlling limb motion is not fully understood. Overall limb response is a complex function of the entire sequence of bursts recorded during experimental trials. In voluntary movements it is impossible to control bursts individually to determine the contribution of each burst to the overall motion.

The objective of the present study was to use simulation techniques to investigate relationships between activation patterns of antagonistic muscles acting at elbow and kinematic responses of the forearm. Two methods have been used. First, a computer-simulated mathematical model of antagonistic muscles was developed to calculate movement trajectories (position, velocity) for a given sequence of input torques. Secondly, in an experimental approach, agonist and antagonist muscles of normal subjects were stimulated with surface electrodes at their motor points and resulting trajectories were recorded. Both methods were shown to reproduce very closely the results of voluntary movement experiments in man.

A parametric study was performed for different amplitudes, durations, and relative timings of the input signals. Our results show that distance of fast movements is primarily controlled by the agonist muscle while time to reach peak displacement is a function of antagonist muscle activity. To move to a target in a minimum time, decelerative torque has to be of the same magnitude or larger than accelerative torque. Minimum movement time is independent of the distance traveled but depends on the duration of the torque pulses. The role of the antagonist in controlling the motion is not only to decelerate the arm, as has been suggested previously, but also to minimize time of the movement. Imbalance of accelerative and decelerative forces (including passive restoring forces), which tends to move the arm away from the target position, is corrected instantaneously by the third burst.

It can be concluded that the nervous system has a certain flexibility in choosing patterns of muscle activation to produce fast movements of similar distance, velocity and accuracy. The present techniques, in which any of the signals in the triphasic pattern can be independently changed, offer a convenient way to study the control of limb motion.

23.9 MUSCLE RESPONSES TO STOPPING LIMB MOVEMENTS OF RHESUS MONKEYS
V. A. Jennings* (SPON: I. Tasaki).
Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205.

Deviations from an intended movement trajectory evoke changes in muscle activity that reflect an error between the actual and intended displacement. This error signal was studied by stopping wrist movements in three operantly conditioned monkeys. A visual tracking paradigm was used in which monkeys, with their hand secured to a handle, performed wrist flexion-extension movements between two hold zones of 1.5° separated by 15° of wrist arc. These two zones ("start" and "target") were shifted together over a 15° range so that constant amplitude movements were made in up to five different angular regions. During randomly chosen trials, movements were stopped for 200 ms by a servo-controlled torque motor. In one task (A), stops always occurred at the same angular position (the "stop position"). Thus, shifts of the start and target zones relative to this position altered the distance between the stop position and the target zone (the "remaining distance"). In a second task (B), the remaining distance was kept constant (at 12°) by shifting the stop position along with the start and target zones. Two effects of stop were examined: (1) the change in muscle (EMG) activity in comparison to unstopped movements and (2) a sustained build-up of torque applied by the monkey against the handle. These stop effects were analyzed in relation to the magnitude of the remaining distance (task A) and the stop position (task B).

Stops caused increases in agonist EMG activity at a latency of 15 ms to 45 ms. In task A, both the magnitude of the EMG stop response and the magnitude of the sustained torque build-up were proportional to the magnitude of the remaining distance. The EMG stop response increased by about 7%/deg (in comparison to the maximum response) as the remaining distance increased from 1.5° to 13.5°. The torque build-up increased by approximately 0.05 Nm/deg. At the maximum remaining distance tested (13.5°), the magnitude of the EMG stop response was similar to the magnitude of the pre-movement burst of EMG activity. In task B, the magnitude of the EMG stop response increased by approximately 3%/deg as the stop position was shifted towards joint angles at which the muscle was shorter. In contrast, the sustained torque build-up was independent of the stop position.

These results show that the magnitude of the agonist EMG response and associated build-up of torque during the stop of an active limb movement depend critically on the distance between where the stop occurred and the intended terminal position. This suggests that the torque during such an interruption is regulated via a mechanism that adjusts the EMG response according to the muscle length at the time of stop so that the torque build-up depends primarily on the angular distance remaining to be moved.

23.10 KINEMATICS OF CONSTRAINED MOVEMENTS.
T.E. Milner* and M.M. Ijaz*. (SPON: W.A. Richards). Dept. of Psychol. and Dept. of Mech. Eng., Massachusetts Institute of Technology, Cambridge, MA 02139.

Recently, Flash and Hogan (J. Neurosci., in press) have shown that the kinematics of horizontal point-to-point arm movements are very similar to those obtained by minimizing the third derivative of motion (jerk). We have examined the ability of jerk-minimization to predict hand trajectories in two tasks with kinematic constraints. Motion of the hand, forearm and upper arm were studied using a Selspot-based tracking system (TRACK: MIT Biomech. Lab.).

In the first task, subjects were required to toss a tennis ball (using an underhand motion) to targets placed on the floor. The hand followed an arc restricted primarily to the saggital plane. All subjects began the swing from a point behind them and released the ball as the hand was moving upward in front of them. The height at which the ball was released appeared to be independent of target distance. As target distance increased, the swing became longer and higher peak tangential velocities were achieved. The ball was always released near the point of peak tangential velocity. The release angle corresponded closely to the angle that minimized the kinetic energy of the ball needed to reach the target. The trajectory obtained by minimizing jerk and applying endpoint and interior point constraints fit the observed hand paths well.

The second task involved horizontal positioning movements of 20 cm in which a 3/8" peg was placed in target holes 7/16, 11/16, 1 or 2 inches in diameter. Subjects were instructed to move as quickly as possible. As the accuracy requirement became more stringent, peak velocity along the principal movement direction (X) decreased and movements became increasingly asymmetric (deceleration longer than acceleration). Movements made to smaller holes appeared to consist of several segments, as judged from inflections in the X-velocity profiles. Sometimes these inflections were correlated with abrupt changes of the hand path in the frontal plane, although deviations from a straight-line path to the hole were generally less than 1 cm. The wrist was relatively rigid in the saggital plane, but often rotated about its vertical axis. Peak velocity was reduced when the amplitude of movements to the smallest target hole were halved. However, the basic asymmetry of the movements was preserved. In particular, the ratio of peak velocity to average velocity did not change. Furthermore, the characteristic asymmetry of these movements was not replicated when subjects were asked to voluntarily slow the movements to the largest hole. We conclude that a constraint on the endpoint accuracy of a movement is dealt with by adopting a control strategy that generates a characteristic movement asymmetry, critically dependent on the severity of the constraint. A model that incorporates a penalty function related to positional error has been proposed to explain this asymmetry. (Supported by the AHFMR).

23.11 THE REGULATION OF MULTI-JOINT ARM POSTURE.
F.A. Mussa-Ivaldi*, N. Hogan* and E. Bizzi. Whitaker College, MIT, Cambridge, MA 02139.

The purpose of these experiments was to investigate the way in which the CNS regulates the postural response of the hand to external perturbations by tuning the elastic properties of arm muscles.

Recent investigations of multi-joint arm posture have revealed that hand posture is completely described by an ellipse which expresses the directional properties of hand stiffness (Mussa-Ivaldi et al., 1984). This stiffness ellipse is characterized by three parameters: size (area), orientation (direction of maximum stiffness) and shape (ratio of maximum and minimum axes).

In the present study we applied perturbations to the hand aimed at changing parameters of the ellipses. To this end, we asked our subjects to generate a voluntary imbalance in muscle activity or to adapt to external perturbations with simple and constant directional properties. Subjects were asked to maintain hand posture in the horizontal plane while holding the handle of a two-joint manipulandum. The stiffness was measured by applying small servo-controlled displacements to the hand along several directions. Three different tasks were considered at each work-space location: (1) Voluntary Co-contraction. While maintaining hand posture (the hand under a visual target), the subject was asked to co-contract selectively the muscles acting about one joint (either the shoulder or the elbow). To facilitate this task, EMG recorded by surface electrodes from the biceps and the pectoralis were simultaneously presented to the subjects. (2) Constant Bias Force. The subject was asked to maintain steady posture while a constant load (6-8 N) was applied to the hand. (3) Oscillating Bias. The subject was asked to maintain posture against a load characterized by constant direction and by a sinusoidally varying amplitude (0.5 Hz and 3 Hz).

Our results indicated that a significant (> 100%) increase of stiffness size occurs during co-contraction and constant and oscillating forces when compared with normal posture. In contrast, only minor changes in shape and orientation were detected. However, the changes in shape and orientation resulted in a predominant increase of the stiffness along the direction of the disturbing force, a trend that was more evident with the oscillatory bias. The increase in stiffness size suggests that the CNS has only a limited control over the other stiffness parameters and that the preferred strategy in face of external perturbation is a synergistic activation of arm muscles which preserves the pattern of shape and the orientation of the postural fields in the work space. This pattern, which consists in the polar orientation of the stiffness ellipses with respect to the shoulder (Flash and Mussa-Ivaldi, 1984) may play an important role in simplifying the control of posture and movement when the tasks are specified in terms of hand-related variables.

23.12 MISREACHING FOLLOWING DAMAGE TO POSTERIOR PARIETAL CORTEX.
Deborah Claman and Thomas Zeffiro.Neurology Service, Massachusetts General Hospital, Boston MA 02114 and Dept. Psychology, M.I.T., Cambridge MA 02139.

Deficits in visually guided reaching have been described following damage to the posterior parietal cortex. The specific nature of the misreaching errors, including their spatial distribution has not been well described in the human literature. We have investigated the changes in reaching accuracy by measuring constant and variable error in control subjects and in patients with focal cortical damage under varying conditions of visual guidance.

Fifteen patients with unilateral damage to the posterior parietal cortex and eighteen control subjects performed a step tracking task on a digitizing tablet. In a condition without visual feedback, subjects sat in the dark and moved a stylus to targets that were only illuminated until the subject commenced movement. In a condition that permitted visual feedback, the targets remained illuminated throughout the entire trial. Each subject performed a total of 576 movements in each condition, alternating hands every 48 trials.

The magnitude and direction of the reaching errors were determined for each hand and each spatial hemifield separately. We define the constant error as a vector originating at each target position and terminating at the final hand position and the variable error as the standard deviation of these vectors. Since error direction is heavily dependent on movement direction, the error vectors were rotated by the direction of movement and thereby transferred into a reference frame where errors are represented normal and perpendicular to the direction of movement.

Patients with unilateral posterior parietal lobe lesions show two significant differences from the controls in the condition without visual feedback: 1) An increase in variable error, most pronounced in the hand contralateral to the lesion. 2) An exaggeration of the normal directional bias for reaching to the right of target locations with the left hand and to the left of target locations with the right hand. There was no effect on constant or variable error for either controls or patients when the movements were analyzed by spatial hemifield. With visual feedback, the errors were greatly reduced for both populations.

The finding that the misreaching deficit is most severe with the contralateral limb is consistent with results seen following similar lesions in subhuman primates. Damage to the posterior parietal cortex interferes with the execution of goal directed arm movements and results in final position errors.

24.13 THE EFFECTS OF PRACTICE WITH INERTIAL LOADS UPON PREVIOUSLY-LEARNED BALLISTIC MOVEMENT PATTERNS. M.W. Cornwall* and G. Kamen (SPON:K.Klueber). Motor Control Laboratory, Indiana University, Bloomington, IN 47405.

The purpose of this study was to assess the effect of inertial loading on changes in EMG patterns following a previously-learned ballistic movement. Thirty-two subjects between the ages of 18 and 35 were randomly assigned to one of two practice conditions. Each subject performed a series of horizontal elbow flexion movements with the right arm over a 5 day period. The movement was a 100 degree arc and subjects were asked to move as rapidly as possible and stop within a 5 degree target. Subjects in the unloaded group (U) initially practiced the movement without additional weight on the limb. The loaded group (L) practiced with an inertial load of 4 times the moment of inertia of their forearm and hand. Following 4 days of practice (40 trials per day) in their respective conditions, subjects performed 40 trials on each of 2 days in the opposite condition. At the conclusion of this practice period, 40 trials were again performed under the original load condition. Surface EMG was recorded from the biceps and triceps brachii muscles using Ag-AgCl bipolar electrodes. The EMG signal was amplified and sampled at a frequency of 2 kHz. The kinematic, amplitude and frequency properties of the displacement and EMG signals were analyzed for any transfer of learning from one condition to the other. For subjects who initially practiced in condition U, the number of zero crossings (NZC) increased after practice with a load. Movement time showed a 13 msec improvement, but was not statistically significant. An increase in the NZC of the antagonist muscle as well as a delay in reaching its peak activity was also seen. Little or no change was noted in the kinematic variables of those subjects who first practiced with the load. A significant decrease in the number of turning points (NTP) of the agonist EMG was seen, however. It appears that practicing under different loads can alter the surface EMG characteristics of both agonists and antagonists with little or no change in movement time or other kinematic parameters.

24.14 INTER-LIMB RESPONSES TO MUSCLE-TENDON VIBRATION IN HUMANS. D.A. Al-Senawi and J.D. Cooke. Dept. of Physiology, Univ. of Western Ontario, London, Ontario, Canada N6A 5C1.

Mechanical vibration of muscle tendon affects the sense of position, probably through activation of spindle afferents. It has also been shown that tendon vibration during movement affects the end position reached; vibration of the lengthening muscle results in an undershoot of the movement. Previously, we have shown that normal humans tend to closely match movements performed by the two arms. In the present study we report disruption of this matching by unilateral vibration during performance of simultaneous, bilateral arm movements.

During experiments subjects held handles on the end of two manipulanda, which were pivoted on the other ends and could be rotated horizontally. Subjects performed alternate flexion/extension movements about the elbow with visual guidance. After a period of practice, the subjects were able to make symmetrical movements of matched amplitudes without visual guidance. Mechanical vibration (120 Hz) of the biceps or triceps tendon of one arm was applied during arm movement. In some experiments subjects held one arm stationary while moving the other and vibration was applied continuously (15 sec) to the stationary arm.

During simultaneous, bilateral arm movements, vibration of the tendon of the lengthening muscle of one arm produced an overshoot of the intended movement of the contralateral arm. This effect was seen whether the lengthening muscle vibrated was the biceps or the triceps. When the subject was asked to hold one arm stationary and make alternate flexion/extension movements with the other, vibration of the tendon of the stretched muscle on the stationary arm produced an overshoot of the movements of the contralateral arm. This overshoot occurred in flexions when the contralateral triceps was vibrated and in extensions when the contralateral biceps was vibrated.

The data show that vibration of one arm affects movements being made at the same time with the other arm. The changes in movements of the non-vibrated arm are opposite to those which occur in the vibrated arm. The data suggest a reciprocally organized linkage between the limbs which can be activated by proprioceptive inputs during movement.

24.15 ROLE OF THE UPPER MOTOR NEURON IN INCREASING THE EFFECTS OF MUSCLE WEAKNESS ON POSTURAL CONTROL L.D. Lehmkuhl, B.L. Bowser,* M.R. Dimitrijevic, M. Gregoric* and I.S. Solis*. Dept. Clin. Neurophysiology, The Institute for Rehabilitation & Research and Dept. Rehabil., Baylor Coll. Med., Houston, TX 77030.

We hypothesize that deficiencies in postural control of lower extremity muscles in patients with muscular weaknesses due to progressive neuromuscular diseases such as Duchenne muscular dystrophy and spinal muscular atrophy are due not only to the biomechanical consequence of weak muscles but also to the neurophysiological consequence of the sensorimotor reaction to such weaknesses. We propose that the neurocontrol response to muscle weakness paradoxically interferes with the utilization of relatively strong muscle groups. In order to test this hypothesis, we studied volitional efforts to lean forward and backward in five neurologically healthy adult subjects. Position of the subject was indicated by the displacement of the center of body mass as recorded on a force platform, together with electromyographic recording of motor unit activity from quadriceps, hamstrings, tibial anterior and triceps surae muscles of both legs. As expected, leaning forward from a neutral standing position induced a characteristic activation of triceps surae, hamstrings and paraspinal muscles near the peak of forward excursion, and leaning backward activated the tibialis anterior, quadriceps and abdominal muscles.

The deep branch of the peroneal nerve or tibial nerve was injected with a 2% solution of Xylocaine to block conduction, thereby causing complete motor paralysis and loss of sensation. The deficits were temporary and were followed by slow recovery of motor and sensory functions. During this procedure we noticed that, regardless of the degree of motor deficit, the subject was "locked" into the neutral position while attempting to lean in a direction requiring use of the affected muscle. We interpreted this to mean that the central neurocontrol of the sequential activation of leg and trunk muscle groups was blocked due to a lack of information from muscle groups which are essential to the movement (ankle flexor or extensor). We shall compare the features of temporary weakness and altered sensory function induced by peripheral nerve block with the characteristic features of neurocontrol in patients with muscle weakness, and discuss our hypothesis in light of these findings.

24.16 NEURONAL ACTIVITY IN MONKEY POSTARCUATE PREMOTOR CORTEX BEFORE VISUALLY-CUED ARM MOVEMENTS. M. Godschalk[x] and R.N. Lemon[x]. Dept. of Anatomy, Erasmus University Rotterdam, P.O. Box 1738, 3000 DR Rotterdam, The Netherlands. (SPON: European Neuroscience Association).

Macaque postarcuate premotor area neurones receive information from cortical and subcortical areas and project somatotopically into the precentral motor cortex (Godschalk, M., Lemon, R.N., Kuypers, H.G.J.M., & Ronday, H.K., Exp. Brain Res. 56: 410-424, 1984). Some premotor neurones modulate their firing frequency in relation to motor tasks which require visual information. We previously reported the behaviour of premotor neurones during execution of a detour reaching task in which the movement phase was separated in time from the phase in which the monkey received a visual cue for the movement required to retrieve a food reward (Godschalk, M., Lemon, R.N., Nijs, H.G.T., & Kuypers, H.G.J.M., Exp. Brain Res. 44: 113-116, 1981). A large proportion of task-related neurones (75%) were modulated during this 'visual' phase, in which no task-related movements were made. This modulation was associated with changes in the position of the food reward, which served as the visual cue.

In the present experiments, carried out in monkeys prepared for chronic recording under barbiturate anaesthesia, several variations of the task were used in order to test whether the 'visual'-related neuronal modulation could be involved in preparation of the upcoming movement. This modulation is unlikely to be related to any eye or arm movements occurring during the visual phase or to environmental illumination. Neither can it be related to the presence of the visual cue in a particular part of the visual field, since the pattern of neuronal modulation was similar when a cue with a fixed position was used. This modulation was, however, contingent upon the occurrence of food retrieval during the subsequent 'movement phase', since it was abolished or diminished during presentation of a 'food-reward' which the monkey did not retrieve.

For several neurones, modulation pattern during the visual phase depended on whether the food reward was to be retrieved with a gross hand movement or with fractionated finger movements.

It is likely, therefore, that neurones in the postarcuate premotor cortex are involved in preparation of arm movements with the help of visual cues.

24.17 MECHANISMS CONTRIBUTING TO ACCURACY IN AIMED FORCE IMPULSES: RISE TIME REGULATION AND CORRECTIVE ADJUSTMENTS. J. Gordon* & C. Ghez. Dept. Mov't. Sci. Teachers Coll. & Center for Neurobiology & Behavior, Columbia Univ., NYS Psych. Inst., New York, NY 10032.

When human subjects produce rapid isometric force impulses of different amplitudes, peak force is proportional to the peaks of the first and second time derivatives, while force rise time is largely independent of peak force. The trajectory must be substantially pre-programmed because early features of the trajectory are highly predictive of the final force achieved; rise time invariance allows for proportional control of response amplitude. We now examine: 1) whether the apparent regulation of force rise time promotes accuracy or merely reflects constraints related to short rise times; 2) whether the trajectory of these brief force impulses also reflects ongoing error correction. Six human subjects were trained to produce isometric elbow flexion pulses and to match their peak force to visual targets of random amplitudes. Subjects were to refrain from amending their responses once initiated; reaction time was left unconstrained. They were given two alternative instruction sets: 1) Fast, i.e. produce the briefest possible force rise time; 2) Accurate, i.e. be as accurate as possible, and select the optimal force rise time.

Accurate responses showed less variable error than fast responses; average absolute errors and overall scaling to different targets were similar in the two conditions. Rise time increased (mean was 80ms in fast, 100ms in accurate). In fast responses, 5 of 6 subjects showed a small but statistically significant dependence of peak force on force rise time. In accurate responses, this dependence disappeared. All responses were produced with sequential agonist and antagonist bursts. While the strong relation of agonist EMG to force was similar in both conditions, the antagonist burst was markedly reduced and occurred later in the accurate condition.

We used multiple regression analysis to determine whether the peak force and its rise time incorporated corrections for initial trajectory errors (i.e. errors in peak d^2F/dt^2). All subjects showed compensatory adjustments (e.g. initial positive errors in d^2F/dt^2 were compensated by shortening the rise time thus reducing peak force eventually achieved).Corrections were implemented by modulation of both the antagonist and the latter half of the agonist burst. The degree of compensation varied among subjects (15-76% of the peak force variance unexplained by the peak d^2F/dt^2); in some subjects accurate performance was achieved by improved scaling of initial trajectory parameters (i.e. improved programming), in others by enhanced error correction. These results indicate that 1) regulation of rise time is greatest when subjects seek to maximize accuracy; 2) error corrections, presumably utilizing internal feedback, can be implemented shortly after response initiation.

24.18 SENSE OF EFFORT IN DEAFFERENTED HUMANS. J. N. Sanes. Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205.

The sense of muscular effort is thought to be mediated by internal recognition of central nervous system signals generating muscular activity. A potential implication of central effort sense is that maintenance of muscular steady states, requiring continuous or periodic evaluation, can be achieved simply by monitoring output from motor brain areas. Nevertheless patients with pathological loss of large-fiber sensory afferents have considerable difficulty in setting the muscular activity necessary to sustain constant postures or to perform accurate movements. These results suggest anew that proprioceptive afferent inputs are integral for effort sense.

Six patients with large-fiber sensory neuropathy were examined. These patients had no position or vibration sense or deep tendon jerks, and had severe impairment of cutaneous sense. Muscular strength was normal or near normal. Effort sense was evaluated with three methods all using the wrist joint. First patients were required to position the wrist at 0^o while torques were changed every 4-6 s to 1 of 6 pre-determined levels (0-0.8 Nm). In the second task patients were pushed against a stop by one of the torques (45^o extension)and were required to move to 0^o. For both tasks the patients had to compare torque on the current trial with torque on the previous trial. In the third task, a reference torque (0.16-0.8 Nm opposing flexion) was applied continuously to the left hand (reference) while a load applied to the right hand (matching) varied (0.08 Nm steps). A tracking procedure based on the Method of Limits was used in which patients noted the hand with the greater torque. Ascending and descending thresholds were obtained for 5-10 reversals of torque.

Deafferented patients were impaired in their ability to detect changes in torque in all tasks. For the unimanual tasks errors when torques actually changed ranged in the posture task from 13%-71% (normals-12%) and in the movement task from 25%-55% (normals-12%). When no torque change occurred the patients incorrectly responded that torque had changed more so than normals--posture task, 32%-70% (normals-13%); movement task 34%-73% (normals-33%). Both patients and normals made most of their errors when shifts in torque were smaller than 0.5 Nm, though patients made more of these errors. For the bimanual task, the ascending and descending thresholds of patients deviated from unity (i.e. perceived equality between matching and reference torques).

These results suggest that proprioceptive information is important in perception of muscular effort. It was noted, however, that the deafferented patients successfully recognized large changes in torque. It is concluded that static or active muscular sense relies extensively on proprioceptive afferent information, though for relatively high levels of torque shifts a central sense of effort, or corollary discharge, prevails.

24.19 CHARACTERISTICS OF MUSCLE ACTIVITY PATTERNS DURING CYCLING UNDER VARIOUS SPEED AND LOAD CONDITIONS. J.A. Johnson* and A.E. Patla (SPON: R. Beauchamp). Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

EMG signals were recorded from seven lower limb muscles during cycling under two conditions: 1 kp load at constant speeds of 30, 50, 70, 90 and 110 rpm (N = 5), and 70 rpm speed with constant loads of 1, 2.5 and 4 kp (N = 4). Sixteen seconds of processed EMG and pedal position signals for each trial were ensemble averaged.

Average EMG for each muscle was normalized to its average value during the 70 rpm, 1 kp trial. EMG gain increase with increased load was greatest for rectus femoris (RF), vastus lateralis (VL) and biceps femoris (BF), while the increase in tibialis anterior (TA), medial gastroc nemius (MG) and gluteus maximus (GM) were lowest in all cases. Increase for the soleus (SO) though lower than RF and BF, was more variable. There was more inter-subject variability with increased speed; the greatest increases were seen in GM for 3 subjects, MG and SO for one subject each. Gain increases at a power output of 110 W (110 rpm, 1 kp) were greater than increases at 175 W (70 rpm, 2.5 kp). This may reflect both greater accelerations and decelerations of the limbs during high speed cycling, and reduced need for muscles to stabilize joints when resistance is higher.

The phasic component of the EMG patterns were analysed using the Karhunen-Loeve expansion. This analysis gives common features among muscle patterns, while residual error (unaccounted variance) when a few features are selected to approximate the muscle pattern, gives some insights into how the patterns are modulated. Across condition analyses for each muscle revealed some common features; this suggests that EMG patterns for different conditions do not have to be generated independently. GM showed the highest residual error in both the speed and load condition. The GM pattern during a cycle changed from a series of poorly defined peaks at 30 rpm, 1 kp to distinct peaks at higher speeds and loads. The proximal muscles (RF,BF,VL) showed more complex changes (higher residual error) in phasic activity than distal muscles (MG,SO,TA) when the speed was increased. This greater modulation of the proximal muscle activity patterns across speeds is similar to the results obtained during walking at different speeds. These results are discussed in terms of possible control strategies adopted by the nervous system during cycling.

24.20 MODULATION OF THE RESPONSE TO PERTURBATION DURING CYCLING. A.E. Patla and M. Belanger, Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

The response of the ipsilateral limb to perturbation (20 ms train, 10 - 1ms pulses, 4 x 5 threshold) applied to the foot at four phases during bicycling were analysed. Tibialis anterior (TA), soleus (SO), medial gastrocnemius (MG), vastus lateralis (VL), biceps femoris (BF), and rectus femoris (RF) were monitored. The subjects (N = 6) wore no toe clips. The difference in the area under the curve (calculated over 100ms starting at 20ms after stimulus) between a perturbed and a normal cycle gave the magnitude and the sign of the response. Subtraction of averaged (5 trials) EMG patterns of perturbed from the normal cycle provided the reflex response from which the latencies were determined.

When the stimulus was applied to the limb in the top pedal position, flexor response was observed in the ankle joint (TA-82ms) while an extensor response was seen at the knee (VL-128ms,RF-118ms) and hip (BF-112ms) joint. This enhanced extensor response resulted in a shorter cycle duration ($p<.06$). In the pedal position at 90 deg. going down, the stimulus elicited a flexor response in the ankle joint (TA-57ms), and enhanced BF(114ms) and RF(121ms) response. This could be interpreted as a flexor response at the knee and hip joint or as a stabilizing response at the two joints. No significant changes in the cycle duration were observed. Similar responses were observed in the pedal position at 90 deg. going up (TA-56ms,SO-111ms,RF-111ms,BF-78ms), the only difference being the facilitation of SO. When the stimulus was applied to the limb in the bottom pedal position, a flexor response was observed in the ankle joint (TA-59ms), while an extensor response was observed in the knee and the hip joint (VL-123ms,RF-117ms,BF-138ms). No significant changes in the cycle duration were seen.

Unlike responses to perturbation during walking, these responses show a relatively simpler organization. This could be due to the fact that there is no need to actively control postural stability during stationary cycling. One major difference was the uncoupling of the MG response from the SO.

Supported by a grant from NSERC (#A0070).

24.21 BEHAVIORAL CONTEXT ALTERS TRIGEMINAL SENSORIMOTOR FUNCTION. K.C. Berridge* and J.C. Fentress. Dept. Psychology, Dalhousie University, Halifax, Nova Scotia B3H 4J1, Canada.

Simple actions (e.g., rhythmic tongue protrusions, forelimb facial strokes, and forelimb flails) are emitted by rats both during taste-elicited ingestion/aversion and during postprandial grooming. This study combined peripheral trigeminal deafferentation with a detailed analysis of action form to examine the use of cutaneous reafference from the face in the production of these actions.

Male Sprague-Dawley rats were anesthetized and implanted with chronic oral cannulae, to allow the infusion of taste solutions (sucrose, HCL, or quinine). Responses to taste solutions were videotaped and subsequently scored in slow motion by an observer who keyed the class, amplitude, and laterality of each action into a computer. Spontaneously occurring grooming was similarly videotaped and scored. Rats were then subjected either to hemilateral (n=6) or bilateral (n=11) trigeminal deafferentation or to a control procedure (n=4). Deafferentation (peripheral transection of the lingual, inferior alveolar, and auriculotemporal nerves of the mandibular branch, and of the anterior superior alveolar and infraorbital nerves of the maxillary branch) eliminates pain and somatosensation from the face and mouth while sparing gustation and trigeminal motor function. After deafferentation, the ingestive/aversive and grooming actions of the rats were again videotaped and scored.

Changes in action form after deafferentation were found to be context dependent: deformations characterized rhythmic tongue protrusions when they occurred in ingestive but not in grooming contexts. The opposite was true for alterations in forelimb actions: the amplitude distribution of facial forelimb strokes was distorted during postprandial grooming but not during aversive face washing. Similarly, forelimb flails intruded and disrupted postprandial grooming but not aversive face washing. Further, postprandial grooming as a whole was found to comprise distinct sequentially-defined phases. Actions occurring in one highly stereotyped sequence phase were protected from deafferentation effects, although the same actions occurring outside of this phase were not. These results suggest that behavioral context (motivational state and sequence phase) can shift the integration of sensory guided and endogenous mechanisms that pattern simple actions.

24.22 PROGRAMMING OF SERIAL MULTIARTICULATE MOVEMENTS: DATA FROM SPEECH MOVEMENT SEQUENCES. Vincent L. Gracco & James H. Abbs. Speech Motor Control Labs. Waisman Center, University of Wisconsin, Madison, WI 53705-2280.

Numerous investigations have focused on the sensorimotor control of single unidirectional movements. The control of sequential movements has not been addressed to the same degree, although serial movements characterize many purposive motor behaviors. It is not known, for example, whether the control parameters for an entire movement sequence are specified in advance, or whether each movement element is specified individually. In the present study we investigated this issue by examining the sensorimotor control of sequential multiarticulate speech movements.

Subjects produced the word 'sapapple' which requires two successive lip and jaw opening/closing movements separated by the vowel 'a'. Movements of the upper lip, lower lip and jaw were transduced and EMG was recorded from multiple lip muscles and one jaw closing muscle. Unanticipated perturbations (40 gms; 15 ms rise time) were applied to the lower lip prior to EMG onset associated with the first 'p' in 'sapapple', under two conditions. In the load-sustained condition, loads remained on for the duration of the movement sequence. In the load-terminated condition, the load was removed prior to the onset of EMG activity for the second 'p' movement. EMG magnitude, timing and movement changes were analyzed for the control and the two load conditions.

For the load-sustained condition, statistically significant EMG and movement increases were observed. For the load-terminated condition, EMG activity associated with the second lip closing was found to approximate the control (no load) condition. Close inspection of the EMG and kinematic adjustments revealed that the magnitude of the adjustments systematically varied with load-offset timing. For the load-off condition it was also observed that the EMG onset for the second 'p' (relative to the first EMG onset) was significantly delayed.

Overall, the results of the present study augment those previously reported for single multiarticulate speech movements (Gracco & Abbs, J. Neurophysiol., 1985). It appears that speech movement sequences may be composed of strings of single movements, each parameterized individually prior to movement execution. Such sensorimotor updating suggests a continuous sampling of the peripheral conditions and eliminates the need for separate representations of both simple and compound actions. (Supported by NIH; NS-20668, NS-13274, and HD-03352).

24.23 SENSORIMOTOR CONTRIBUTIONS TO ORAL-LARYNGEAL COORDINATION FOR SPEECH. Susan Shaiman*, James H. Abbs, & Vincent L. Gracco, (SPON: F. Graham). Speech Motor Control Labs., Waisman Center, University of Wisconsin, Madison WI 53705-2280

Previously we demonstrated that oral movement coordination for speech (Abbs & Gracco, J. Neurophys. 1984) depends in part upon nonautogenic sensorimotor actions (i.e., lower lip perturbations yield corrections in upper lip movements). Perhaps the most studied pattern of speech motor coordination is between oral and vocal fold movements. The timing between movements in these remote muscle groups is critical to generate linguistically significant acoustic distinctions between different consonants (e.g., "p" vs. "b", "k" vs. "g"). For example, when the lips close for a "p" (as in "apa"), the vocal folds are abducted actively and their vibration is terminated, giving the "p" its distinct voiceless character and contrasting it to the voiced "b". The tolerance for timing errors between oral and laryngeal movements for these consonants is very narrow, clearly not exceeding +/- 15 msec. Predictably, individuals with nervous system impairment (e.g., with lesions of premotor cortex and Broca's area, cerebellar patients) manifest problems in oral-laryngeal coordination for these consonant contrasts.

In this context, the purpose of the present study was to determine if ascending afferent signals from lip movements for these consonants might be utilized to control the critical timing of parallel vocal fold movements. On 13% of the trials, unanticipated lower lip perturbations were introduced prior to and during the lip closing for the first "p" in the word "sapapple", using a dc brushless torque motor. Five subjects, naive as to the experimental purposes and motor control research, were studied. As reported previously, these lip perturbations yield a finite increase in the duration of the compensatory lip closing movement, essentially delaying the time of lip closure for "p". As hypothesized, in response to the lip perturbations, the timing of vocal fold movements, transduced with an impedance technique, was adjusted correspondingly. That is, with perturbation-induced delays in lip closure, there were: (1) increased durations of vocal fold vibration for first "a" in "sapapple", i.e., delayed abduction, (2) reduced durations of the nonvibrating (abduction) interval associated with the "p" voiceless segment, and (3) reduced durations of the combined vibratory ("a") plus voiceless segment ("p") interval.

These data suggest that the critical timing between oral and vocal fold movements is not wholly pre-specified, but rather adjusted on-line, via nonautogenic sensorimotor processes, in accord with movement variations. Such sensorimotor linkages are significant particularly inasmuch as the lips and larynx are innervated by different cranial nerves and are quite independent mechanically. (Supported by NIH; NS-13274 & HD-03352).

24.24 TASK-DEPENDENT SENSORIMOTOR ACTIONS ARE INHERENT IN SPEECH MOTOR PROGRAMS. James H. Abbs, Susan Shaiman*, Vincent L. Gracco, & Kelly J. Cole. Speech Motor Control Labs. Waisman Center, University of Wisconsin, Madison WI 53706-2280

Recent studies indicate that certain sensorimotor actions are gated dynamically with variations in actual or perceived postural support, subject intentions, or task-inherent mechanical coupling. These data support the supposition that neural networks underlying a given class of voluntary motor acts are configured and reconfigured, flexibly, by subtle changes in intended goals (cf. Abbs et al., J. Motor Behav.,1985). Based on the need to perform strings of similiar, but subtly different motor acts such as are involved in grooming, food gathering, sign language, speech, tool making/using, etc.,such neural variations are of considerable interest. Most previous studies addressing this issue have, by necessity, involved variations in voluntary motor behaviors that were not inherent in the organism's repertoire.

The present experiments were aimed at exploring such task-dependent sensorimotor variations in the motor control of speech. The value of examining speech is that this motor behavior is learned naturally and of considerable ecological significance. The paradigm involved perturbations of the lower lip during different speech sounds that required subtle, but linguistically-significant contrasts in lower and upper lip movements. It thus was possible to manipulate the intended motor goals in a natural manner,i.e., reading of different syllables.

One speech contrast studied was the generation of two vowels ("ah and "oo") which vary in their lip positions for generation of appropriate acoustic patterns; i.e., for "ah", labial positioning is of minimal significance while for "oo" the lip positions are critical for its normal generation. When the lower lip was perturbed for these two vowels, distinct differences were seen in the sensorimotor compensations; Viz., minimal or no compensations were observed to perturbations introduced during "ah", while consistent responses were observed to loads introduced during "oo". In a second speech motor contrast, lower lip loads were applied during "p" which requires movements of both the upper and lower lips and during "f" which only requires movement of the lower lip. Predictably, while there were upper lip (and lower lip) responses to lower lip loads during "p", there were no discernible upper lip movement responses to loads introduced during "f".

These data suggest that one element of motor programs for voluntary acts is the prescription of those sensorimotor pathways to be enabled and those to be inactive, based upon subtle, task-dependent features. As such these and like data appear to render moot the classical debates regarding afferent-independent, motor "preprogramming". (Supported by NIH; NS-13274 and HD-03352).

25.1 PATHWAYS MEDIATING HORIZONTAL OPTOKINETIC NYSTAGMUS IN THE RAT: NUCLEUS OF THE OPTIC TRACT PROJECTIONS TO THE NUCLEUS RETICULARIS TEGMENTI PONTIS AND PRAEPOSITUS HYPOGLOSSI. B.G. Korp*, R.H.I. Blanks and Y. Torigoe* (SPON: S.E. Fraser) Depts. of Anatomy and Surgery, Coll. of Med., Univ. of Calif. Irvine, Irvine, CA 92717.

Electrolytic lesions of the n. reticularis tegmenti pontis (NRTP) in rat abolish the slow and fast components of horizontal optokinetic nystagmus. However, it is not certain whether it is the neurons of the NRTP and/or currently unknown fiber bundles which pass through the NRTP that mediate visual information from the n. of the optic tract (NOT) to the praepositus hypoglossi (ph) and vestibular nuclei. In order to examine the connections between the NOT, NRTP and ph, injections of tritiated leucine were placed into the NOT (4 rats) or NRTP (8 rats) and the tissue processed autoradiographically. The topography and projections of these nuclei were examined using the retrograde horseradish peroxidase (HRP) technique.

Autoradiographic injections into the NOT identify a strong projection to the medial parts of the rostral two-thirds of the NRTP and a smaller projection to the ph. Both are entirely ipsilateral. The fibers destined for the ph travel with the NOT-NRTP-bundle, pass through the NRTP and are distributed to the rostral one-half of the ph with the strongest labelling being in the supragenual part. Injections into the NRTP in the region of the NOT-NRTP terminal fields, demonstrate an ipsilateral bundle of axons which descend in a paramedian position to terminate similarly within the supragenual part of the praepositus nucleus. Retrograde studies in which HRP was injected into the ph or NRTP confirm these pathways and further show that the NOT projections to the NRTP and ph arise largely from the superficial portions of the NOT.

Both the direct NOT-ph and indirect NOT-NRTP-ph connections provide the anatomical basis for visual-vestibular interaction within the vestibular nuclei given the abundance of reciprocal connections between the ph and vestibular nuclei. However, the relative importance of the two pathways is currently unknown given that the earlier electrolytic lesion studies destroyed the neurons of the NRTP and the fibers en passage of the NOT-ph pathway. (Supported by grants EY03018 and EY000160 to RHIB. YT is a recipient of NASA Research Associate Award #MAGW-70.)

25.2 FURTHER EVIDENCE FOR OPTOKINETIC VELOCITY STORAGE IN DIRECT AND INDIRECT VISUOMOTOR PATHWAYS. S.Lafortune*, D.J.Ireland* and R.M.Jell. Depts. of Physiology and Otolaryngology, University of Manitoba, Winnipeg, Canada.

The dependence of human optokinetic afternystagmus (OKAN) velocity storage and optokinetic nystagmus (OKN) characteristics on optokinetic stimulus velocity and exposure time was investigated using the two component double exponential model for human OKAN decay: A exp(-Bt) + C exp(-Dt), where coefficients A and B define the fast component of OKAN decay and coefficients C and D define the slow component (Jell,R.M., Ireland,D.J., Proden,O., Soc Neurosci Abstr 9:866,1983). Optokinetic drum velocities were varied from 10 deg/sec to 70 deg/sec at a constant exposure time of 60 seconds. Optokinetic exposure times were varied from 5 seconds to 60 seconds at a constant drum velocity of 40 deg/sec, that which produces maximal OKAN as measured by cumulative eye displacement. Coefficients A and C of the OKAN decay were found to be velocity dependent and exhibited velocity saturation characteristics above 40 deg/sec. OKN and OKAN cumulative eye displacements demonstrated a velocity sensitivity such that two distinct levels of response were apparent: a low level response at drum velocities in the pursuit range (10,20,30 deg/sec) and a high level response in the non-pursuit range (40,60,70 deg/sec). These results provide further support for our postulate that the fast and slow components of OKAN represent direct (pursuit) and indirect (non-pursuit) visuomotor pathways respectively. Both the fast component time constant (1/B) and the slow component time constant (1/D) appeared to be independent of both velocity and exposure time, while coefficient C of the slow component of OKAN was clearly shown to be dependent upon stimulus exposure time. There was some indication of direction sensitivity in the latter response. Results are compatible with the concept of two velocity storage integrators involved in OKAN, which may be direction sensitive: one responsible for the short time constant decay (mediated by direct pathways) and the other for the long time constant decay (mediated by indirect pathways).

25.3 THE EFFECTS OF STIMULUS DURATION ON OPTOKINETIC AFTERNYSTAGMUS AND SECONDARY OPTOKINETIC AFTERNYSTAGMUS IN RABBITS. B. J. Winterson. University of New England College of Osteopathic Medicine, Biddeford, ME 04005.

The rabbit, subjected to moderately high velocity (5°-30°/sec) continuous optokinetic stimulation, shows a slow rise in the velocity of the slow phase of optokinetic nystagmus (OKN) during stimulation. When the stimulation is removed, the nystagmus continues, showing a slow fall in the velocity of the slow phase of OKN until the nystagmus disappears. This is called optokinetic afternystagmus (OKAN). These phenomena suggest neural circuitry which functions as a leaky storage mechanism for slow phase eye velocity.

In order to further explore the properties of the rabbit's eye velocity storage mechanisms, Dutch belted rabbits were exposed to continuous optokinetic stimulation for various durations: 20 sec, 1, 3, 10, 30, and 90 min. The optokinetic drum was 29.5 cm in diameter, subtended 45° superior and inferior to the horizontal plane passing through the interocular axis. The drum was lined with a black and white checkerboard pattern whose elements subtended 1.4°. Drum velocity during stimulation was 26°/sec. Stimulation was monocular for the left eye and always in the nasal direction. Eye movements of the left eye were recorded with the search coil technique.

OKAN observed after 20 sec, 1 min, and 3 min stimulation was not markedly different than that observed in prior studies. However, after 10 min and 30 min stimulation there was an increase in the duration of optokinetic afternystagmus and the appearance of secondary OKAN in which the slow phase was in the opposite direction. Once secondary OKAN appeared during an experimental session, which were typically about 4 hours long, it did not disappear from the responses of subsequent testing. This implies that the storage mechanism responsible for secondary OKAN is more sluggish than for OKAN.

After 90 min of stimulation, some animals showed a further increase in the duration of OKAN but still showed secondary afternystagmus. Other animals showed a substantial increase in OKAN duration (17 - 20 min) which was then followed by no secondary OKAN.

Continuous optokinetic stimulation is clearly artificial, but such continuous unidirectional visual input could occur if neuronal cell losses caused the vestibulo-ocular reflex (VOR) to become imbalanced. The changes observed in OKAN suggest that restoring the balance of the VOR with visual input can begin at one and one half hours in the rabbit.

25.4 EFFECTS OF SPATIAL FREQUENCY ON OPTOKINETIC NYSTAGMUS AND AFTERNYSTAGMUS IN THE CAT. W. B. Thoreson* and J. H. Anderson. (Spon: R. Purple) Depts. of Otolaryngol. and Physiol., Univ. of Minn., Minneapolis, MN 55455.

Changing the pattern of an optokinetic stimulus will influence the response of the neural elements which generate optokinetic nystagmus (OKN) and the optokinetic after-nystagmus (OKAN). To examine this quantitatively we measured the OKN and the OKAN due to various visual patterns rotated horizontally around restrained, alert cats. The stimulus patterns used were black and white vertical bars with spatial frequencies of 0.07, 0.18, and 0.64 c/deg; a two-dimensionally varying pattern of irregular black blots; and a number of "offset" patterns created by shifting the bars of the 0.18 c/deg vertical bar pattern one-half cycle in parts of the visual field. The stimulus velocity ranged from 10 to 80 deg/sec. Both monocular and binocular stimulation were used. The results show that the gain of the slow phase eye velocity (SPV) during OKN is greater for a vertical bar pattern with a spatial frequency of 0.18 c/deg than when the spatial frequency is higher or lower. Also, two-dimensionally varying patterns produce a greater gain than one-dimensional patterns. The SPV during the OKAN was fitted by the function $A(1-e^{-t/\tau}\sin(\omega t+\alpha)/\sin\alpha)+B$, describing a bounded, underdamped, second-order system, where B is the eye velocity at time zero, the onset of OKAN, and A+B is the final velocity. The variability of the time course of the OKAN seems to be strongly correlated with the amplitude of the OKAN (A) and not with the type of pattern; when A is greater than 17 to 20 deg/sec, the mean of tau is 10.3 (±4.0) sec; the mean of omega is 0.05 (±0.001) rad/sec; and the mean of alpha is -0.41 (±0.084) rad. The variability of the parameters during nasotemporal monocular stimulation is similar to that during binocular stimulation, when the gains are comparable. These and results from others suggest that visual cortical mechanism affect the dynamics of the OKAN only indirectly by influencing the gain during OKN.

(Supported by NINCDS grants P50-NS12125 and RO1-NS16567.)

25.5 VERTICAL COMPONENT OF QUICK PHASES DURING OPTOKINETIC AND VESTIBULAR NYSTAGMUS. M. LeTaillanter* and J. H. Anderson. Depts. of Otolaryngol. and Physiol., Univ. of Minn., Mpls, MN 55455.

The asymmetry of the vertical component of slow phase eye movements during vestibular and optokinetic stimulation has been described. It has been shown that the upward slow phase attains higher velocities than downward slow phases during rotation in the dark and during optokinetic after-nystagmus (OKAN). It is also known that there is some coupling of slow phase eye movements to the generation of the quick phases (QP). The present experiments were aimed at quantitating the parameters of the vertical component of QP and to correlate the QP profile with that of burst neurons recorded in the midbrain.

The magnetic search coil was used to record the vertical and horizontal components of eye movements in 8 cats. They were positioned on their sides and either rotated in darkness or viewed the inside of a drum which rotated around them. After 45 to 60 seconds of optokinetic stimulation, the light was turned off and the after-nystagmus recorded. 7,000 quick phases were identified and the amplitude vs. duration (A-D) and maximum eye velocity vs. amplitude (E-A) were plotted. 3,800 quick phases were averaged over one-half degree increments in amplitude, giving an average profile for the QP of different amplitudes and under different stimulus conditions. During optokinetic nystagmus (OKN), the slope of the regression line for A-D shows considerable variability. The slopes for each cat for QP up ranged from 14 to 70; for QP down, the slopes ranged from 14 to 171. For down QP, the mean of the slopes for A-D was 67 deg/sec and was significantly higher than the mean of the slopes during OKAN, which was 32 deg/sec. The linear regression of E-A is not different for OKN compared to OKAN. These results indicate that the profile and time course of the down QP during OKN is different than that during OKAN. During vestibular stimulation in the dark, the down QP had a significantly steeper A-D curve than the up QP.

The differences in the vertical component's A-D during OKAN in the dark may be due to oblique eye movements with a large horizontal component. If this were also the case for vestibular nystagmus in the dark, then there would be a preferred direction for the oblique movements in order to account for the up-down asymmetry.

(Supported by NINCDS grants P50-NS12125 and R01-NS16567.)

25.6 **Visual and Oculomotor Response Properties of Single Units in the Pretectum of the Behaving Rhesus Macaque.**

M. J. Mustari, A. F. Fuchs, and J. Wallman. Reg. Primate Res. Ctr., Univ. of Washington, Seattle, WA 98195; City Univ. of N.Y., New York, NY 10031

The pretectum of lower mammals has been shown to play a role in visually elicited eye movements. In order to assess whether the primate pretectum also plays a role in eye movement generation we recorded the activity of one-hundred units histologically verified to be within the borders of the pretectum in four rhesus monkeys. The monkeys were trained to make eye movements in response to a target moving either against a dark or a textured visual background. While the monkeys fixated a stationary target spot, the visual sensitivity of units was tested with both flashing and moving full field or small stimuli.

Based on their discharge during smooth pursuit and/or their response to visual stimulation, the units were divided into three main types. 1) VISUAL-ONLY units (21 %) responded to either flashed full field background stimulation and/or to moving visual stimuli during fixation. 2) EYE-MOVEMENT-ONLY units (51%) discharged during smooth pursuit tracking but not during saccades. These units showed no evidence for any visual sensitivity when tested with either flashed or moving stimuli. In a few eye movement units (N=8) we tested the effect of extinguishing the target briefly (400 msec) during smooth pursuit (during which time the monkey continued tracking) and found that the unit response continued throughout the period when the target was off. 3) EYE-MOVEMENT-AND-VISUAL units (28%) showed both a visual response and an eye movement related discharge. Many of these units demonstrated a response to smooth pursuit of a target as well as a response to full field background movement during fixation. The eye movement and visual direction selectivities of these units could be either the same or opposite. The majority (79%) of pretectal units encountered in our study had discharges that were modulated during smooth pursuit of a small target spot against a dark background over the full range of velocities tested (6.3-63 deg/sec).

Our results demonstrate that the primate pretectum has units that discharge in relation to smooth pursuit eye movements. Therefore, in addition to its possible role in vision and control of the pupillary light relex, at least parts of the primate pretectum appear to be involved in eye movements.

25.7 RASHBASS REVISITED: ACTIVE AND PASSIVE RESPONSES TO STEP-RAMP TARGET MOTION. H.J. Wyatt and J. Pola, Institute for Vision Research, SUNY State College of Optometry, NY, NY 10010.

In the classic Rashbass experiment (1961), subjects tracked a target that made a step in one direction followed by an opposite ramp. The initial response was often a smooth eye movement away from target position but in the direction of target velocity; the stimulus for such a response must presumably be target velocity.

Based on work with periodic open-loop stimuli, we suggested earlier that the component of smooth pursuit that is specifically a response to target velocity might sometimes be largely non-attentional, resembling passive optokinesis. If this also held for step-ramp closed-loop targets, it would imply that the initial response might similarly be largely non-attentional.

We have tested the roles of attention and velocity-sensitivity in pursuit by asking subjects to view step-ramp motion of small targets and extended targets (with vertical flanking stripes). Subjects remained passive or actively tracked the target. Step size was 2 deg; ramp velocity was 4 or 8 deg/sec.

We found that:

(1) A substantial passive response occurred; it had the same latency as the active response and, for some subjects, a comparable velocity. (This was especially true for the extended target and the lower stimulus velocity.) This argues for a significant role for a non-attentional velocity mechanism.

(2) The earliest response was often a small, brief, smooth eye movement in the step direction. This appears to arise from a movement-sensitive mechanism responding to the brief stimulus generated by the step.

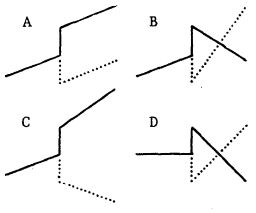
(3) Velocity overshoots (eye velocity > target velocity) were common in the active responses; these sometimes occurred while the eye was leading the target. This does not fit with the view that such overshoots are based entirely on target position error.

(4) Extensive oscillations (~3 Hz) often occurred during active pursuit of the 8 deg/sec extended target.

Findings (3) and (4) seem to depend on a high-gain velocity mechanism with a gain modulated by attention and augmented by the stripes. We have modeled our results with considerable success using a simple model of the pursuit system which has a short dead-time, and position- and velocity-sensitivity. The model also predicts values for pursuit of open-loop sinusoidal target motion that are in reasonable agreement with experiment.

25.8 HUMAN SMOOTH PURSUIT: THE RESPONSE TO CONFLICTING VELOCITY AND POSITION STIMULI J.R. Carl and R.S. Gellman, Laboratory of Sensorimotor Research, National Eye Inst., NIH, Bethesda, MD 20205

In a companion presentation we note that the response to a ramp differs from that to a ramp accompanied by an oppositely directed step, again raising the question of the role of position errors in smooth pursuit. We evaluated the pre-saccadic pursuit in response to tracked targets that stepped onward or backward and either continued at the same velocity (A) or changed velocity so that the retinal slip was towards the fovea (B). The search coil was used to record the responses of 7 subjects. They tracked a $1/10^{o}$ spot of light moving at either 5 or $10^{o}/s$ before one of 12 or more stimulus conditions was presented in pseudo-random order.



For steps up to 4^{o}, with no change in velocity (A), all subjects responded with a latency of 100 ms and an acceleration in the direction of the step that lasted about 40 ms and then tapered off. There was a pronounced asymmetry with a greater acceleration to backward steps (dotted line in A) than to onward steps ($35^{o}/s^{2}$ vs $8^{o}/s^{2}$). This asymmetry occurred for horizontal and vertical stimuli, but not when the steps were combined with retinal slip away from the fovea (C).

When a step was combined with an oppositely directed velocity stimulus so that the retinal slip was towards the fovea (B), the initial 40 ms of response was identical to that for a step alone (A). The initial acceleration was always in the direction of the step and only after 60 ms did the acceleration reverse to the direction of the target velocity. The amplitude of the initial acceleration in the direction of the step was as asymmetric as when a step alone was used.

If the subjects were not tracking but viewed a fixation spot before a step-ramp (D), they responded with a much smaller initial acceleration, but still in the direction of the step, and with the same latency. Comparison of this response with an open-loop version of (D) showed at 200 ms an identical deceleration of the eye to match the original target velocity, suggesting that the system was responding to an internal representation of the target motion ("prediction" or "feed forward").

In summary, (i) the latency of the response to position errors is 100 ms, the same as to velocity errors, (ii) the acceleration to position errors is dependent on the direction of the step relative to the tracking, (iii) when position and velocity errors are in opposite directions, the response to position predominates for the first 60 ms, (iv) predictive mechanisms become apparent at about 200 ms.

25.9 HUMAN SMOOTH PURSUIT: EARLY RESPONSES TO SUDDEN CHANGES IN TARGET VELOCITY. R.S. Gellman and J.R. Carl, Laboratory of Sensorimotor Research, National Eye Inst., NIH, Bethesda, MD 20205.

Studies of the initiation of pursuit have generally used a target which steps away from the fixation point, then ramps back. This delays the pursuit response and eliminates early saccades, but raises a question: Is the response merely delayed pursuit or does it reflect a different mechanism? We have used ramps and evaluated only the pre-saccadic elements of the response. In particular, we have addressed three issues: (i) Are the dynamics of pursuit initiation determined by target velocity? (ii) What is the influence of retinal target position? and (iii) Is the response different when the subject is already tracking? The responses to steps alone and to retinal slip towards the fovea are examined in a companion presentation.

We used the search coil method to record the eye movements of 7 normal adults. The target, a $1/10^{o}$, bright spot, underwent velocity changes in one of three ways: (i) it moved away (ramp); (ii) it stepped to an eccentric retinal location (up to 20^{o}) and moved away at a constant velocity (step-ramp); (iii) it changed velocity while the subject was tracking it (ramp-ramp). The timing and the sequence of the different stimuli were varied pseudo-randomly to minimize anticipatory and predictive responses.

The objectively determined latency of the pursuit movement in the ramp condition varied little from the mean of 100 ms ±4 (SD) over the stimulus velocity range $10\text{-}40^{o}/s$, but was about 7 ms longer at $5^{o}/s$. In the step-ramp condition the latency increased slightly as the eccentricity increased. The latency in the ramp-ramp condition was indistinguishable from that in the ramp condition, regardless of the direction and magnitude of the final velocity, including the case where the final velocity was $0^{o}/s$.

The acceleration for the first 40 ms of the response, which was invariably pre-saccadic, was low, fairly constant, and weakly dependent on target velocity. Over an 8-fold change in target velocity ($5\text{-}40^{o}/s$) the acceleration varied only between $42^{o}/s^{2}$ and $53^{o}/s^{2}$ (±13). In the step-ramp experiments the acceleration declined rapidly for steps $>2^{o}$, plateauing at $14^{o}/s^{2}$ by 10^{o}. As with the latency, the accelerations in the ramp-ramp condition were the same as those in the ramp condition, regardless of the initial and final velocities of the target.

In summary, we note that: (i) The latency, 100 ms, is about 30 ms shorter than that commonly reported; (ii) The initial acceleration shows little sensitivity to the magnitude of the velocity, but is determined almost entirely by the direction of the stimulus. This contrasts with the strong dependence on velocity found in studies using a "Rashbass" step-ramp; (iii) The initial acceleration is strongly dependent on the eccentricity of the target.

25.10 A COMPUTER MODEL THAT PREDICTS MONKEY SMOOTH PURSUIT EYE MOVEMENTS ON A MILLISECOND TIMESCALE. E. J. Morris* and S. G. Lisberger (SPON: M. Merzenich). Dept. Physiol., Div. Neurobiol., UCSF, San Francisco, CA 94143.

The aim of our study was to predict the time course of monkey smooth pursuit (SP) eye movements in single behavioral trials. Our model was based on data showing that SP eye velocity is sustained in the absence of visual error signals and that three error signals are commands for eye acceleration: retinal position error (RPE = target position - eye position), retinal velocity error (RVE = target velocity - eye velocity), and retinal acceleration error (RAE = target acceleration - eye acceleration).

We determined the functions relating eye acceleration to each error signal in two ways: i) Presentation of "open-loop" retinal errors, where we prevented the monkey from correcting an error by driving target motion with a signal composed of the output from the eye position monitor plus the desired error. We measured average eye acceleration in response to imposed RPEs, RVEs, and RAEs of various amplitudes. ii) Cross-correlation of transient retinal errors with eye acceleration during normal "closed-loop" pursuit. The two methods gave very similar results. Acceleration increased approximately linearly as a function of RPE, RVE, or RAE amplitude and acceleration commands due to the three different error signals added approximately linearly with one another. The response latency to these visual inputs was 90 msec.

We then constructed a computer model for each monkey in which eye velocity at each msec was computed as eye velocity at the previous msec plus the integrated eye accelerations due to RPE, RVE, and RAE 90 msec earlier. The model accurately predicted each monkey's SP eye movements in single behavioral trials for at least 500 msec and often more than 1000 msec. But the relative sensitivity to RPE, RVE, or RAE varied greatly from monkey to monkey, so that the optimum acceleration functions for any one monkey predicted his own SP much better than they predicted SP of other monkeys.

All of our monkeys exhibited spontaneous oscillations of the eye about the target during SP of constant-velocity targets. The period of oscillations was fairly constant for each monkey but varied from 180 to 390 msec among monkeys. Both the presence of oscillations and the different periods for different monkeys are predicted by the feedback and time-delay properties of our model. If a monkey's SP system is insensitive to RPE and RAE, our model predicts that the period of oscillation must satisfy the equation: cos(2 x pi x latency/period) = 0, implying period = 360 msec. This agrees with our experimental finding that a monkey insensitive to RPE and RAE had SP oscillations with a period of 390 msec. Our model also predicts that sensitivity to RAE will decrease the period, and we found that the monkeys with faster oscillations did have greater sensitivity to RAE. (Supported by NIH Grant EY03878.)

25.11 MONKEY SMOOTH PURSUIT EYE MOVEMENTS TO SINE-WAVE AND SQUARE-WAVE TARGET MOTION UNDER OPEN-LOOP CONDITIONS. C. Neary*, J. Pola and H.J. Wyatt. (SPON: V. Sutija). Institute for Vision Research, SUNY College of Optometry, New York, N.Y. 10010

We have studied monkey smooth pursuit eye movements to sine-wave and square-wave target motion under open-loop conditions (target motion stabilized on retina). The purpose was (a) to determine the relationship between open-loop and closed-loop responses during steady state pursuit, and (b) to examine the role of target position (offset from the fovea) in the control of smooth pursuit eye movements. Monkeys were trained to look at and track a small target light (detection of a brief dimming of the light was rewarded). The monkey's task during all experimental trials was to track the horizontal motion of the target. Open-loop trials began with closed-loop target motion (target motion fixed in space); after a number of cycles, the target motion was stabilized at the monkey's fovea and tracking continued for 20-40 secs. Eye position was monitored by the search-coil technique.

Relationship between open- and closed-loop: Monkeys tracked sinusoidal target motion (3 deg peak-to-peak) in the open-loop condition (sine-wave motion stabilized at the fovea) over a range of frequencies (0.75-3.0 Hz). The same stimuli were also used in the closed-loop condition. Gain and phase lag of the smooth eye movement response were determined as a function of frequency for both the open- and closed-loop conditions. The open-loop sine-wave stimulus produced a vigorous pursuit response, i.e. a high open-loop gain. As frequency increased, gain decreased and phase lag increased. Using simple linear assumptions, the open-loop data were found to accurately predict the closed-loop data.

Sensitivity to target position: Monkeys tracked square-wave target motion in the open-loop condition (square-wave motion stabilized at the fovea). As target velocity on the retina is zero, except for the brief jump, this open-loop square-wave was considered to be a pure position stimulus. Over a range of frequencies (0.5-1.5 Hz) the square-wave stimuli produced slow sinusoid-like eye movements interspersed with saccades. Smooth response velocity increased with target offset from the fovea up to 2 deg; the response fell off for larger offsets. These results demonstrate that target position can be a stimulus for the monkey smooth pursuit system and that it is most potent for targets close to the fovea. Furthermore, the response magnitude appeared to be related to the monkey's level of attention, suggesting that the pursuit response is not purely stimulus-bound.

25.12 CHANGES IN EYE VELOCITY DURING SMOOTH PURSUIT TRACKING INDUCED BY MICROSTIMULATION IN THE DORSOLATERAL PONTINE NUCLEUS OF THE MACAQUE. J.G. May, E.L. Keller and W.F. Crandall*. Smith-Kettlewell Inst. of Vis. Sci., San Francisco, CA 94115 and Dept. Elect. Eng., University of California, Berkeley, CA 94720.

The dorsolateral pontine nucleus (DLPN) has been implicated in the control of smooth pursuit eye movements by virtue of its anatomic connections, the electrophysiological response properties of DLPN units and by the effects of chemical lesions in this area on smooth pursuit tracking. In this study we report that microstimulation within the DLPN produces short-latency alterations in slow eye velocity, but only when the stimulus train is delivered during the initiation or steady state maintenance of smooth pursuit eye movement. While electrical stimulation is known to produce saccadic eye movements from a variety of different brain structures, there have been few reports of stimulation induced smooth eye movements.

Animals were trained to fixate and track a visual target which appeared briefly at primary position and then ramped away at a constant velocity. The DLPN was located by monitoring neural activity during pursuit tracking through 0.5-0.8 mohm microelectrodes. Electrical stimuli (pulse train width - 40-200 msec, 0.5 msec cathodal pulses, frequency -300 Hz) were delivered through the same recording electrode during 1) fixation, 2) the initial eye acceleration phase of pursuit, or 3) the following phase of steady-state pursuit tracking. Current levels were restricted to below 80 μ amps. Thresholds for smooth changes in eye velocity during pursuit ranged from 25-70 μ amps. Current levels above 70 μ amps usually elicited rapid saccadic type eye movements.

Eye velocity was augmented when the stimulation occurred during the initial phase of pursuit such that eye velocity often exceeded target velocity. This was followed in most cases by a smooth deceleration at the end of stimulation to a level either matching or somewhat below that of target velocity. Stimulation during the initial fixation period failed to elicit smooth eye movements. Latencies for these effects on eye velocity were as short as 18 msec. These stimulation effects were directional in that stimulation induced velocity perturbations were only seen during pursuit tracking in specific directions. We feel that current spread was reasonably small since stimulations on penetrations only 250 microns apart often elicited effects for different directions.

These results provide additional evidence that the DLPN forms part of a pathway involved in the control of smooth pursuit tracking in the macaque.

25.13 EYE-POSITION NEURONS IN THE PARAMEDIAN PONTINE RETICULAR FORMATION (PPRF) OF ALERT CATS. R.S. Remmel and R.D. Skinner. Biomedical Engineering Dept., Boston Univ., Boston, MA 02215 and Anatomy Dept. Univ. of Ark. for Medical Sciences, Little Rock, Ark. 72205.

A central oculomotor problem is understanding the behavior of brainstem neurons in relation to those of motorneurons. We thus recorded from abducens motorneurons and from 25 PPRF eye-position neurons (located immediately rostral to the abducens nucleus and lateral to burst neurons).

Cats were prepared surgically through the implantation of a head mount and recording chamber. A 6th-nerve stimulating electrode was used to antidromically identify motorneurons. Eye movements were recorded with a scleral coil (Remmel, IEEE Trans. Biomed. Eng., BME-31 (1984) 388). A turntable produced vestibular stimulation and moving stripes produced optokinetic stimulation. Units were recorded extracellularly with micropipettes. Spike trains and eye and turntable positions were recorded on magnetic tape. A PDP11/23 computer performed pattern recognition on spikes (Remmel, EEG Clin. Neurophysiol. 56 (1983) 528).

For modeling we started with Robinson's model of the plant (J. Physiol. 174 (1964) 245), which includes 2 viscoelastic elements for the passive orbital tissues. We assumed that the force $f_0(t)$ of the contractile elements is proportional to the ensemble average of the motorneuronal firing rates. The model was solved numerically. For motorneurons it well predicts firing rates.

The prediction for PPRF eye-position neurons was never adequate. The model has therefore been extended as follows.

$$F_0(s) = [a + b/(1 + \tau s)] X(s). \qquad (1)$$

Here $F_0(s)$ is the Laplace transform of the contractile force $f_0(t)$ from Robinson's model; the plant dynamics are thus accounted for. $X(s)$ is the Laplace transform of the firing rate $x(t)$ of a PPRF eye-position neuron. The "a" is the proportional term, i.e., the neuron carries an eye-position signal. The b-term describes a leaky integrator with time constant τ. We calculated $x(t)$ from $f_0(t)$ numerically, with the parameters, a, b, τ and the threshold of firing varied for best fit. (Eq. 1 is not a transfer function.)

The fits to PPRF eye-position neurons were well described by eq. 1 with τ of the order of 0.5 sec. In general the "a" term was somewhat larger than the "b" term. Eq. 1 applied during saccadic, vestibulo-ocular and optokinetic movements. The $b/(1+\tau s)$ leaky-integrator term is suggestive that PPRF eye-position neurons may be involved in the oculomotor integrator.

25.14 PATTERNS OF EYE AND HEAD MOVEMENTS PRODUCED BY MICROSTIMULATION OF THE MIDBRAIN RETICULAR FORMATION (MRF). M. Gerez and D. Sparks. University of Alabama at Birmingham, Birmingham, AL 35294

The purpose of the present series of experiments was to compare, in head-free and head-fixed conditions, eye and head movements produced by stimulation of the midbrain reticular formation (MRF).

Search coils attached to the eye and to the head were used to obtain measurements of gaze, eye and head position. With the head free, the eye coil provides a direct measure of gaze; records of eye position were obtained by subtracting head position from gaze position. The most commonly used stimulation parameters were: train duration - 200 msec; pulse duration - 0.2 msec; pulse frequency - 500 Hz; and current - 30 μA.

Different patterns of eye and head movements were obtained depending on the site and depth of stimulation. The contribution of head or eye movements to the total gaze shift varied from pure eye movements to predominantly head movements. Stimulation at some sites produced constant trajectory eye movements regardless of the initial eye position, in both, head-fixed and head-free conditions. In the head-free condition, the gaze shift was the same as the eye movement shift since no head movement occurred.

Stimulation at other sites produced "goal-directed" eye movements in the head-fixed condition. With the head free, stimulation at some of these sites produced changes in gaze that were clearly goal-directed. In this condition, the eye and head moved in the same direction until the goal region was obtained. Continued movement of the head was compensated for by the VOR. Stimulation at other sites produced large changes in gaze, and "goal-areas", if present, were difficult to detect. For these large gaze shifts, the head and eye moved in the same direction and the VOR was not active.

The MRF appears to be involved in the generation of both eye and head movements. Very little is known about the signals carried by neurons in this region. Is information about changes in gaze encoded spatially or by discharge frequencies proportional to gaze error? How are head and eye motor error signals extracted from signals of gaze motor error and proportionally channeled to the appropriate subsystem?

(Supported by NIH grants EY01189, EY05486 and EY02293.)

25.15 INTERACTIONS BETWEEN VESTIBULAR NYSTAGMUS AND EYE MOVEMENTS EVOKED BY ELECTRICAL STIMULATION OF THE SUPERIOR COLLICULUS OF THE CAT. Robert M. Douglas, Aerospace Medical Research Unit, Dept. of Physiology, McGill University, Montreal, Quebec, Canada.

Stimulation of the caudal superior colliculus (SC) in cat evokes saccadic eye movements that take the eye to a constant orbital position (Guitton et al, Exp Brain Res 39:1980). Besides these "goal-directed" saccades, head movements are also evoked (Roucoux et al, Exp Brain Res 39: 1980), and thus it is of some interest to see how the evoked eye movements interact with the vestibular signals produced by head motion. In the present study this was done in a controlled manner by keeping the head fixed and passively moving the whole animal while occasionally stimulating the SC with 333 Hz trains lasting from 300 to 5000 ms. The interactions observed were very similar to those we have seen during voluntary eye-head movements (Guitton et al, J Neurophysiol 52: 1984).

Slow phases. When the head was stationary and the SC stimulated, the eyes did not hold a constant gaze direction after the evoked saccade. Rather they continued to move outwards with a velocity which gradually declined from about 20 deg/s. Both horizontal and vertical drifts were observed at different SC stimulation sites, with the direction being similar to that of the preceding saccade. When the animal was rotated while stimulating, the drift added to the slow phase velocity, either increasing or decreasing the net ocular gain. While the summation was almost linear for low head velocities, there was a suggestion of relatively more suppression with velocities above 40 deg/s. The feline SC thus may use pursuit eye movements as well as saccades and head movement to correct errors in gaze.

Quick Phases. Long stimulation trains did not block any ongoing vestibular nystagmus. However when the evoked saccade was in the same direction as the quick phases, the amplitude of the quick phases was reduced and the rate increased. When the evoked saccade was in the opposite direction to the quick phases, the subsequent slow phase took the eyes to a more eccentric position near the limits of the oculomotor range where the eyes then rapidly oscillated until the stimulation was turned off.

The direction of vestibular nystagmus had only a slight effect on the "goal" position of electrically-evoked saccades. Moreover both the collicular saccades and vestibular quick phases typically took the eyes to a position about 10-12 deg from center. They thus may share a common saturation element.

25.16 THE SYNAPTOLOGY OF LARGE EFFERENT NEURONS IN THE CAT SUPERIOR COLLICULUS. M. Behan, P.P. Appell*, M.J. Graper* and C.R. Norris*. School of Veterinary Medicine and Neurosciences Training Program, University of Wisconsin, Madison, Wis. 53706.

Multimodal cells have been identified in the intermediate and deep layers of the cat superior colliculus which respond to visual, auditory and somatosensory stimuli. These cells in turn, relay integrated multisensory information in descending efferent projections, to areas which control movements of the eyes, head and pinnae (Merideth & Stein, Sci., 227:657, '85). These multimodal cells are included in the population of large efferent neurons (>30 μm diameter) located beneath the stratum opticum. We have examined the distribution of large neurons in the superior colliculus, and can demonstrate consistent variations rostrocaudally, mediolaterally and dorsoventrally.

Many of these large neurons can be retrogradely labeled from either the crossed medial efferent (predorsal) bundle or the uncrossed lateral efferent bundle. We have examined at the light and electron microscopic level those neurons whose axons project in the predorsal bundle, by retrogradely labeling them with HRP. Eight cells from three animals were examined in detail. Their location, size, and dendritic arborization pattern was measured. In addition, we used the classification system of Norita (J.C.N., 190:29, '80) to identify synaptic terminals contacting cell bodies, proximal and distal dendrites, and the axon hillock region. The data are based on analysis of single sections and serial reconstruction of selected regions of these cells.

The cells are located for the most part in the stratum griseum intermediale, in the lateral half of the colliculus. Soma diameters range from 35 to 60 μm. The mean dendritic field diameter is 1.3 mm, and dendrites of some cells extend into the lower part of the stratum opticum. Cells are multipolar, with from 5-10 primary dendrites extending to at least eighth, and in some cases twelfth order dendrites. Over 80% of the surface of somata and dendrites are contacted by synaptic terminals, while the axon hillock region has fewer synaptic contacts. Very few spines are present on the somata and dendrites of these cells. Significant differences are apparent between the distribution of specific terminal types on different regions of the cells: for example, between the soma and axon hillock region, between proximal and distal dendrites, and between apical and basal dendrites.

It is hoped that such detailed study of the synaptology of these large multimodal efferent cells in the superior colliculus may yield information as to how they integrate convergent sensory information.

Supported by NIH grant EY04478.

25.17 EYE-POSITION-RELATED UNITS IN THE SUPERIOR COLLICULUS OF THE CAT. C. K. Peck, School of Optometry, University of Missouri-St. Louis, MO 63121

Many recent observations of oculomotor function appear to require a neural signal of the position of the eye in orbit. Current models of the saccadic oculomotor system assume that neural signals representing eye position are added to retinal error signals in order to produce an internal representation of target position in space. In cat, the visual responses of some neurons in the superior colliculus (SC) are contingent on direction of gaze, and saccadic eye movements produced by electrical stimulation in the same region are also dependent on the position of the eye in the orbit. Moreover, in monkey, the discharge patterns of both auditory and saccade-related SC neurons shift with changes in eye position, suggesting that SC is organized in motor ccordinates. An unresolved issue is whether sensory signals are translated into motor commands within the SC.

Single unit activity was recorded in the SC of two alert cats using standard recording procedures. The cats were trained on fixation and saccade tasks, eye position was monitored with the scleral search coil technique, and the head was fixed.

Of 67 units which were isolated from the intermediate-deep layers and studied extensively in the absence of visual input, 6 discharged regularly during periods of steady eye position, and their rate of discharge increased with eye position in one direction. Discharge rates were nearly identical in light and during fixation of visual targets. For most units, a linear regression line provided a roughly satisfactory fit to the rate-position plots. Units varied in preferred direction (contralateral, up, or down, direction being dependent on location within the collicular "map" of motor error), in slope (from about 2 spikes/sec./deg. to about 11 spikes/sec./deg.), and in the threshold for steady discharge (usually near primary position).

Another group of units showed tonic activation (N=14) or suppression (N=5) during fixation of small (1^0) spots of light but not during periods of steady gaze in the absence of visual stimuli.

These findings suggest: 1. that an internal representation of either eye position (which was monitored) or head position (which may be closely correlated with eye position) is available within the SC even in total darkness, and 2. that only a fraction of SC neurons which discharge tonically during fixation of a visual target are also active during steady gaze in the absence of visual stimuli. The eye (or head) position signal may arise from proprioception or from corollary discharge. Experiments are currently being conducted in cats free to move their heads in order to determine if this signal is better related to eye position or to head position.

25.18 **SHORT TERM SACCADIC ADAPTATION DOES NOT AFFECT THE SACCADES EVOKED BY ELECTRICAL STIMULATION OF THE MONKEY SUPERIOR COLLICULUS** **Edmond J. FitzGibbon*, Michael E. Goldberg, and Mark A. Segraves Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, Maryland 20205.**

Man and monkey can adapt the gain of the saccadic system when extraocular muscle activity is inappropriate for moving the eye accurately to a visual target. This inaccurate muscle activity can be mimicked by requiring a subject to make a saccade to a target that moves consistently during the saccade. This target movement is inapparent to the subject. After the saccade it is clear that the eye undershot when the target moved in the same direction of the the saccade (lengthening paradigm) or overshot when the target moved back towards the original fixation point (shortening paradigm). To acquire the target the subject must make a saccade either greater or smaller than that dictated by the target's original position.

Two rhesus monkeys were trained to make saccades between two spots of light. The saccade target was moved consistently during the eye movement so that at the end of the saccade the monkey had over- or undershot the target by 25% to 50%. Within 400-800 trials the monkeys had learned to adjust the gain of their saccade so that they now made a longer or shorter saccade in response to the original target. When the target first began to move during the saccade, the monkey would make a saccade to the first target and then a corrective. In the lengthening paradigm the latency and amplitude of the corrective saccade progressively decreased over multiple trials until no corrective was necessary. The velocity profile of the now larger saccade revealed a biphasic waveform, suggesting the rapid initiation of two succcessive saccades. In the shortening paradigm, 50-200 trials were required to achieve adaptation and no such biphasic velocity waveform was apparent.

In two awake behaving monkeys prepared for chronic neurophysiological recording we electrically stimulated the superior colliculus to evoke saccades. The amplitude and direction of these saccades were consistent with neuronal activity recorded at the stimulation site. The monkeys' saccadic gain was then altered along the vector of the stimulated eye movement using either lengthening or shortening paradigms. The superior colliculus was again stimulated and we noted no change in the amplitude of the electrically evoked saccade after adaptation. Alternating electrical stimulation trials and visually guided trials resulted in adapted saccades to visual stimuli and unadapted saccades to electrical stimuli. These results imply either that the superior colliculus plays no role in the generation of adapted saccades or that the adaptation occurs before the superior colliculus is activated.

25.19 THE MORPHOLOGY AND CONNECTIONS OF PREDORSAL BUNDLE CELLS IN THE RAT'S SUPERIOR COLLICULUS. M. E. Bickford,* P. D. Levine,* C.-S. Lin, C. Owen,* and W. C. Hall, Dept. of Anatomy, Duke Univ., Durham, N.C. 27710

Determining the afferent connections of predorsal bundle cells is of importance for understanding the mechanisms of sensorimotor interactions in the superior colliculus. As a step toward determining the afferent connections of the rat's predorsal bundle cells, retrograde transport and intracellular injections of HRP were used to study their morphology and distribution. HRP was injected into the decussation of the predorsal bundle to retrogradely fill the cells. For the intracellular injections, stimulating electrodes were placed in the decussation and predorsal bundle cells were identified by their antidromic responses.

The majority of the predorsal bundle cell somas are located either within the deep part of or just beneath stratum griseum intermediale (SGI). They are most common in the lateral parts of SGI. Their dendrites branch radially in the intermediate grey layer and also often extend superficially into stratum opticum and ventrally into stratum profundum. In the lateral parts of the SGI, dendrites may extend to the pial surface, but in this area there is no stratum griseum superficiale (SGS) overlying the stratum opticum (SO).

In one set of experiments, the nigrotectal tract was anterogradely labelled with WGA - HRP to compare the distribution of its terminations with the location of the predorsal bundle cells. The nigrotectal terminals form a band within the intermediate and deep layers which corresponds closely to the distribution of the predorsal bundle cells. In particular, the band is widest and densest in the lateral portions of SGI, where predorsal bundle cells are most common.

In other experiments, following intraocular injections of HRP, the retinal terminals in the superior colliculus were anterogradely labeled. Retinal fibers terminate in the SGS and the upper SO. Overlap of these terminal distributions with the dendrites of predorsal bundle cells was found only at the lateral edge of the superior colliculus. This is the area in which no SGS overlies the SO. The zone of SGI that lies beneath this lateral edge receives heavy projections from both the substantia nigra and the trigeminal nucleus (Huerta et al., J. Comp. Neurol. '83).(SupportedbyNIH#EY04060, #EY05490 and NSF #BNS 8109794).

25.20 EFFECTS OF LESIONS OF THE SUPERIOR COLLICULUS, STRIATE CORTEX AND ANTEROMEDIAL CORTEX ON INSTRUMENTAL HEAD MOVEMENTS IN THE RAT. E. Garcia*, C. Charman*, J. Sotsky*, H.M. Sinnamon (Spon: D.B. Adams). Neuropsych. Laboratory, Wesleyan Univ., Middletown, CT 06457

To study the neural systems that control head position, we made brain lesions in water-deprived rats that were highly trained to make various head movements. The test apparatus presented a 3X3 array of holes each of which contained a water-baited dipper. A subject were required to approach the array, orient its head, sample each dipper once and withdraw to a waiting chamber so that the dippers could be baited again. The insertion of the snout in the hole was detected by infrared sensors and a computer recorded for each dipper the order in which it was sampled when baited (preference), the number of times it was not sampled (neglect), and the number of times it was sampled when dry (perseveration). After proficiency was achieved (approximately 20 sessions), radio-frequency lesions were made and following 2-3 days recovery, testing resummed for five sessions.

Unilateral lesions of the superior colliculus produced a severe neglect of dippers contralateral to the lesion and an increase in perseverative errors to the dippers ipsilateral to the lesion. In the most severe cases, the center dippers were also neglected. The neglect showed a pronounced recovery in subsequent sessions but contralateral dippers continued to show a decreased preference in the sampling sequence. Bilateral lesions of the superior colliculus produced a bilateral neglect that was less severe than would be expected from the addition of two unilateral neglects.

Unilateral lesions of the anteromedial cortex which damaged the medial precentral region, the anterior cinglulate and prelimbic cortex did not produce a neglect and only slight effects on the preference of sampling of the dippers. However, these lesions markedly increased the number of perseverative errors. Bilateral lesions produced more errors. The perseverative errors were not lateralized and showed significant recovery.

Unilateral or bilateral lesions of the striate cortex produced no apparent effects on performance.

25.21 ELECTROPHYSIOLOGY OF THE TECTOFACIAL PATHWAY. P.-P. Vidal*, P.J. May and R. Baker. Dept. Physiol. & Biophysics, New York Univ. Med. Ctr., New York, NY 10016.

In addition to a role in the control of eye and head movements, the superior colliculus also coordinates the activity of numerous facial muscles to orient the whiskers and pinna. In fact, the facial nucleus offers a unique site for studying the manner in which the spatially organized tectum plays on motoneurons to initiate orienting movements. Consequently, we studied the physiologic attributes of the tectofacial pathway in the acute cat by electrically stimulating the superior colliculus and recording intracellularly from facial motoneurons identified antidromically following stimulation of dissected facial nerve branches. In contrast to the situation in extraocular and neck motoneurons, small (<1mV), graded, monosynaptic EPSPs with latencies ranging from 0.7-1.1 msec were produced in nearly all facial motoneurons by supramaximal stimulation of the contralateral superior colliculus. This potential was followed by either a larger (<4mV) disynaptic EPSP with a latency of 1.2-1.8 msec or a (<7mV) disynaptic IPSP with a latency of 1.5-1.9 msec in motoneurons of the temporal, auriculoposterior and ventral divisions of the facial nucleus. Furthermore, tectal inputs were not limited to motoneurons involved in orienting the ears and whiskers, for those neurons supplying the platysma and orbicularis oculi muscles displayed tectally elicited monosynaptic potentials despite the fact they move the skin and eyelid. Thus all the facial muscles may be influenced directly by the tectum. Surprisingly, stimulation of the ipsilateral superior colliculus produced essentially the same spectrum of synaptic potentials and latencies in facial motoneurons. The monosynaptic EPSP elicited from the contralateral superior colliculus was eliminated by cutting the predorsal bundle at the level of the rostral pons, but the disynaptic potentials were not affected. In another series of experiments the effect of collicular topography on the synaptic potentials elicited in pinna motoneurons was tested by placing an array of 3-6 stimulating electrodes 2mm deep in the superior colliculus. Each motoneuron exhibited topographic differences in the presence and amplitude of the mono- and disynaptic EPSPs and disynaptic IPSPs elicited from points in either superior colliculus. As predicted from the spatial map in the tectum, rostral sites produced EPSPs in the temporozygomatic division while caudal ones produced EPSPs in the auriculoposterior division. Larger IPSPs were generally elicited by stimulation of the caudal tectum. We conclude, that these topographic differences provide a structural substrate for the spatiotemporal transformation by which the superior colliculus initiates and sustains orienting movements of the pinna and whiskers.

25.22 ELECTROPHYSIOLOGY OF THE PARALEMNISCAL-FACIAL PATHWAY. P.J. May, P.-P Vidal* and R. Baker. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

The previous abstract reported the presence of disynaptic inhibitory and excitatory potentials in facial motoneurons following electrical stimulation of the contralateral superior colliculus. Henkel and Edwards (1978) suggested that the paralemniscal nucleus in the midbrain provides the relay for a disynaptic tectofacial pathway controlling pinna movements. Therefore, we studied the electrophysiological attributes of the paralemniscal-facial projection in the acute cat by stimulating the contralateral paralemniscal nucleus with concentric bipolar electrodes and recording in antidromically identified facial motoneurons. Within the auriculoposterior and temporal divisions of the facial nucleus, which supply the pinna muscles, motoneurons displayed monosynaptic EPSPs (<3mV) with latencies ranging from 0.6-0.9 msec. Other motoneurons exhibited monosynaptic IPSPs (<3mV) with latencies of 0.8-1.2 msec or, more frequently, combinations of EPSP and IPSP. These monosynaptic potentials were often followed by longer latency synaptic potentials. In contrast, monosynaptic potentials were not seen in motoneurons supplying either the inferior buccal nerve or platysma muscle, although longer latency synaptic potentials (>1.2 msec) were sometimes present. While these results support the contention that the paralemniscal nucleus subserves pinna movements, further examination showed that those motoneurons in the zygomatic division that supply the whiskers also exhibit mono- and disynaptic potentials following stimulation of the paralemniscal nucleus. Sagittal cuts extending the length of the fourth ventricle floor did not alter the potentials evoked in facial motoneurons following either tectal or paralemniscal stimulation, demonstrating that the pathways from these structures cross in the midbrain. Indeed, following HRP injections in the facial nucleus, axons from retrogradely labelled cells in the contralateral paralemniscal nucleus, pass ventral to the brachium conjunctivum, cross the midline just posterior to the trochlear nucleus, and then turn to run caudally in the central tegmentum. When this pathway was cut in the pons, electrical stimulation of the contralateral superior colliculus only elicited monosynaptic EPSPs in facial motoneurons. We conclude that the paralemniscal nucleus is a critical part of the system by which the superior colliculus controls the orientation of both pinna and whiskers. Furthermore, we suggest that both the size and topographically determined differences in amplitude of the disynaptic tectofacial potentials mediated by the paralemniscal nucleus indicate its importance for altering motoneuron activity. Thus, the paralemniscal nucleus may be a critical site in which to investigate spatiotemporal transformation.

25.23 EYE FIXATION UNITS IN THE SUPPLEMENTARY EYE FIELD OF MONKEY. J. Schlag and M. Schlag-Rey. Dept. of Anatomy and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Single-unit recordings were made at the dorsomedial edge of the frontal lobe in 4 trained monkeys (Macaca nemestrina). Just rostral to the classical supplementary motor area and about 10 mm medial to the frontal eye field a small region has been previously described which contains neurons active with eye movements and yields contraversive saccades upon low-threshold (e.g. less than 20 μA) microstimulation.

The 2 most frequent firing patterns observed in this region are: 1) gradual and long (e.g. 400 msec) build-ups of activity preceding saccades, and 2) changes in discharge frequency accompanying fixation of a visual stimulus. We studied 85 neurons showing this fixation pattern in order to clarify its significance. Besides the usual mode of presenting stimuli by turning them on and leaving them to be observed for several sec (paradigm #1), we let them appear progressively from subthreshold to suprathreshold brightness until they were discovered by the animal (paradigm #2), and we also used 50 msec flashes (paradigm #3). In all cases including paradigm #3 reinforcement was made contingent on fixation of the target for 1-4 sec.

Two-thirds of the units were tonically activated during fixation, one-third was silenced. In either case, the latency of the fixation pattern in paradigm #1 and #3 was usually longer than the delay for targeting. The pattern persisted for the whole fixation time and beyond stimulus offset, but it was interrupted before and during eventual glances away. The frequency of firing changed slightly after small corrective saccades. The fixation pattern was not due: 1) to photic stimulation because it was present for several sec after flashes when fixation was maintained (paradigm #3), 2) to eye position because it never appeared at any position in absence of a target, or 3) to eye immobility because it was evoked as readily by slowly moving stimuli as by stationary ones. Three types of unit behavior were seen with periodically moving stimuli: 1) constant fixation pattern any time during pursuit in 80% of the cases, 2) gradual acceleration as stimulus-and-eye position became more eccentric in a preferred direction, and deceleration in the off-direction, 3) gradual acceleration in a preferred direction of movement and silence in the opposite direction. Most position-dependent or movement-dependent fixation units also had the property of discharging before saccades in the same preferred direction. Microstimulation at these sites evoked saccades in this direction. The results indicate that fixation units of the supplementary eye field must be involved in the maintenance or signalling of active fixation.

(Supported by USPHS Grant EY05879)

25.24 PRESACCADIC UNITS IN THE SUPPLEMENTARY EYE FIELD OF MONKEY, HEAD FIXED AND FREE. M. Schlag-Rey and J. Schlag. Dept. of Anatomy and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Single units discharging before spontaneous saccades were recorded in the supplementary eye field (dorso-medial edge of the frontal cortex) of 4 monkeys (Macaca nemestrina) trained to acquire and fixate visual targets with head fixed or entirely free. Eye and head positions were recorded by search coils attached to one eye and to the head. All facial movements were continuously observed through an infra-red video-monitor.

1. In the head fixed condition, 61 units were found increasing their firing rate before spontaneous saccades in a preferred direction. To determine how presaccadic preludes were related to saccade parameters, quantitative analyses were made on units at which site microstimulation induced saccades with minimum currents (6μA-30μA, 10-40 pulses, 0.2ms duration, 250 Hz). None of these units appeared to encode saccade direction only, i.e. they discharged most vigorously when saccades in a preferred direction had a preferred amplitude. For the majority of units, presaccadic preludes also depended on initial or end position in orbit. For instance, among units prefering rightward vectors, some discharged more if the saccades terminated at eccentric right positions; others discharged more if the saccades originated at eccentric left positions. These observations applied to units having different amplitudes of preferred saccade vector (15-30°).
2. Experiments with head free (19 units) showed that most presaccadic activities were related to eye, possibly to gaze, but not to head movement because (a) all units active before saccades, with head fixed, also discharged before saccades in absence of voluntary head movement; (b) microstimulation with head free induced eye saccades only. At more caudal recording sites, simultaneous head and eye saccades were obtained with low thresholds (e.g. 12μA) but head movement was never induced alone.
3. Fast (e.g. 200°/s) and repeated 50-60° horizontal head movements within ± 30° from center were induced by requiring the monkey to get the reward (following a successfull visual fixation) at one of two spouts, 25° left and right. Gaze strategies varied depending on whether voluntary head movements were made to get the reward or to look at the target. Up to now, units studied during comparable head rotations were seen to fire with eye saccades or quick phases but not compensatory movements in their preferred direction; their discharges were also affected by vertical eye components in gaze shifts involving pure horizontal head rotation. These results suggest that presaccadic units in the supplementary eye field participate in the initiation of voluntary saccades.

25.25 ELECTROMYOGRAPHIC ACTIVITY IN NECK MUSCLES DURING HEAD MOVEMENT IN THE ALERT, UNRESTRAINED CAT. F.J.R. Richmond, G.E. Loeb and D. Reesor*. Department of Physiology, Queen's University, Kingston, Canada K7L 3N6 and Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205

The cat neck contains more than twenty muscles that can participate in head movement, but the varying internal architectures and fiber-type compositions of these muscles suggest that they may play specialized roles. Theoretical models have been developed recently to predict the contributions of neck muscles to head position on the basis of their anatomically defined actions. However, missing from the experimental literature is a systematic description of neck muscle activity during normal head movements in the alert, freely moving cat. In the present work, chronic electromyographic (EMG) recordings were made simultaneously from up to 16 neck muscles or muscle compartments in each of three untrained cats. Cats were allowed to move their heads freely as they executed routine eating, grooming, orienting and locomotor behaviors. Head movements were videotaped from two directions. Changes in vertical head position were additionally monitored using a length transducer implanted between the skull and the axis. Patterns of EMG activity were analyzed both while the cat held its head stationary in different positions and as it moved the head in different directions and at different speeds.

In most stationary postures, moderate EMG activity was recorded in only a few muscles (eg., biventer cervicis, occipitoscapularis, semispinalis cervicis). Activity levels in these muscles were modulated in relation to head position, but were reduced to near zero levels in only a few, extreme postures. In contrast, other neck muscles (eg., splenius, complexus, clavotrapezius, obliquus capitis caudalis) showed little or no EMG activity when the head was held stationary in most positions. During active head movements, each neck muscle showed a characteristic pattern of EMG activity that was consistent with its anatomy and fast:slow fiber ratio. Again, most normal movements of the head were associated with moderate levels of EMG activity in only a few muscles. Vigorous EMG activity was observed in these same muscles during fast, forceful movements, such as head shakes. Patterns of recruitment in most muscles were influenced greatly by the initial posture of the head and neck and the specific intervertebral joints around which the movement appeared to be made. In particular, some vertical movements appeared to depend on the action not only of neck muscles acting on the head, but also of shoulder muscles inserting onto cervical and thoracic vertebrae. These observations emphasize the complex nature of movements and muscle behavior in a multiarticular system like the neck. Supported by the MRC of Canada.

25.26 Gaze shift related neck muscle activity in trained cats. A. Roucoux, M. Crommelinck*, M.F. Decostre*, J. Crémieux* and A. Al-Ansari*. Lab. of Neurophysiology, Univ. of Louvain, Fac. of Med., B-1200 Brussels, Belgium.

We have shown (Roucoux et al, 1983, Abstracts, Society for Neuroscience, Vol. 9, Part. 2, p. 865) that, in the head fixed alert cat, various neck muscles discharge in relation with eye position. Horizontal as well as vertical eye position influence each neck muscle in variable proportion. These patterns of activity roughly fit the discharge seen when the head actually moves. In order to quantify the activity of neck muscles in a visual orientation behavior, we trained two cats to fixate small spots of light presented at various positions in the visual field. This training procedure yielded a strong and constant arousal level of the animal. The integrated EMG activity was measured in six pairs of muscles in two conditions : head fixed and head free. Eye and head movements were recorded by the coil technique.

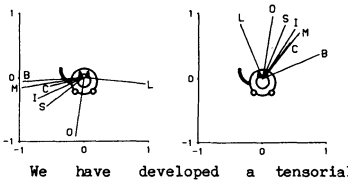
With head fixed, we found that the activity of each muscle is proportional to horizontal and vertical eye deviation. This confirms the previous findings. The discharge of the muscles shows no relation with eye velocity (no phasic bursts during the saccade), but only the eye position. In general, the discharge intensity is very often higher than with the head free to move). This high level of activity is attained after a rather long latency, variable from one muscle to the other. Biventer cervicis is mainly related to upward eye deviations and slightly to lateral deviations. Splenius is sensitive to downward eye movements, very slightly to upward extreme deviations but mostly to lateral eye movements. Longissimus is strongly related to downward and lateral eye deviations. Rectus capitis is related very strongly with upward eye positions and moderately with the horizontal component. Complexus is equally sensitive to upward and horizontal eye position. Finally the obliquus capitis cranialis is clearly related to downward deviations of the eye and very strongly to horizontal eye position. These relations have been obtained with a bipolar recording of a rather restricted volume of the muscle and do not represent the behavior of the whole muscle.

With head free, phasic discharges related to head displacements are predominant. These discharges reveal "pulling directions" that are in good accordance with patterns of activity observed with head fixed. In some muscles no tonic activity related to head position appears (for example the splenius of the longissimus). Other muscles, especially related to upward head movements like the biventer and rectus capitis show both phasic and tonic activity. This is probably related to their role in posture as well as in orientation of the head. "Phasic" muscles would be primarily involved in orientation and very little in posture.

25.27 RELATION BETWEEN PULLING DIRECTIONS OF NECK MUSCLES AND THEIR ACTIVATION BY THE VESTIBULOCOLLIC REFLEX: TESTS OF A TENSORIAL MODEL. B. Peterson, J. Baker, C. Wickland, A. Pellionisz, Northwestern Univ. Med. School, New York Univ. Med. School.

The vestibulocollic reflex (VCR) transforms a head rotation stimulus $\bar{S}$ into a pattern of neck muscle activity $\bar{N}$ that generates a head movement $\bar{H}$ directed opposite to $\bar{S}$. The sensory input responsible for generating $\bar{N}$ is activation of the 6 semicircular canals ($\bar{C}$). The sensorimotor transformation between $\bar{C}$ and $\bar{N}$ depends upon the geometry of the canals and muscles. To complement existing knowledge of the former, we measured stereotaxically the origins and insertions of 15 neck muscles in cats whose positions were adjusted so that a line from the center of the lambdoidal ridge to the T1 articular process was at a 73 deg angle with the stereotaxic horizontal plane. Pulling directions of 15 muscles/side were determined by calculating the cross products of vectors extending from the insertion towards the origin and towards the neck rotation point thus defining a 3D dimensional motor space.

When viewed as a 6-to-3D dimensional transformation, the VCR is overcomplete in that many $\bar{N}$ could generate a given $\bar{H}$. To determine the relation of $\bar{N}$ to $\bar{H}$, we measured electromyographic activity of 7 neck muscles during whole body rotations in many planes in 6 decerebrate cats. Muscle activation varied sinusoidally with the direction of rotation $\bar{S}$ and was maximal for rotation about a single best external space axis $\bar{V}xyz$. A muscle's $\bar{V}^i$ was consistent over time and across animals but typically did not align with the muscle's pulling direction (see figure). The question then is what criterion does the CNS use in selecting the $\bar{V}^i$s?



Frontal views of cat showing pulling vectors (left diagram) and activation vectors ($\bar{V}^i$s, right diagram) of 7 neck muscles. Note especially large misalignment of longus capitis (L) and rectus major (M) vectors.

We have developed a tensorial model of the VCR which incorporates 2 simple matrix transformations between $\bar{C}$ and $\bar{N}$ and minimizes the sum of squares of $\bar{N}$ for generating each $\bar{H}$. As described in an accompanying abstract, the model is based on the canal and neck geometry and generates predicted maximal activation axes $\bar{M}xyz$ for each muscle, which can be compared with the measured $\bar{V}^i$s. This comparison reveals an encouraging agreement at this stage of the project. Work is continuing to measure additional $\bar{V}^i$ for comparison with the 15 $\bar{M}^i$ and to refine the neck muscle geometry on which the model is based by recording muscle activity accompanying voluntary head movements in trained cats.

25.28 TENSOR MODELS OF PRIMARY SENSORIMOTOR SYSTEMS, SUCH AS THE VESTIBULO - COLLIC REFLEX (VCR), AND OF THE METAORGANIZATION OF HIERARCHICALLY CONNECTED NETWORKS. A. Pellionisz and B. Peterson, Dept. Physiol. & Biophys., NYU Med. Ctr., New York, NY 10016 and Dept. Physiol., Northwestern Univ. Med. School, Chicago IL 60611.

The accompanying abstract (Peterson et al. 1985) shows why and how a tensorial VCR model is built from experimental data and how it is experimentally tested. Here we open a broader perspective; ask how primary sensorimotor networks (eg. VCR) may emerge in the CNS and how their hierarchy may develop into connected networks.

The VCR is a closed-loop primary sensorimotor system since it both generates and measures the same physical invariant: Head movement is generated by a contravariant vector of neck muscle effectors and directly measured by a covariant vector of vestibular sensors. When both frames of reference are available in a quantitative manner (Blanks et al 1972, Baker et al 1985) general sensorimotor tensor models can interpret such transformations of one vectorial expression in one frame into a different version in another frame (Pellionisz 1984). The transfer, accomplished in the VCR by neuronal networks, can be expressed by a vestibular tensor and a neck motor tensor. First, the head-movement sensory reception vector is converted into a covariant motor intention vector by the contracted tensors of the contravariant vestibular metric and a sensorimotor operator that projects the sensory axes onto the motor axes. Second, motor intention is transformed into execution by a covariant-contravariant operation by the least squares formula of Moore-Penrose inverse of the motor metric.

Tensor theory of the Metaorganization of CNS networks, which implement functional geometrical counterparts of the physical geometry of a sensorimotor apparatus, offers an explanation of how such closed-loop networks as the VCR may emerge (Pellionisz & Llinas 1985). In particular, the Moore-Penrose generalized inverse may be constructed by the CNS from the eigenvectors and eigenvalues, found by reverberative oscillations of the motor action - sensory proprioception. In gaze control, however, there are other systems beyond the VCR; some are primary while others are not. Another primary system that may emerge by Metaorganization is the retino-ocular reflex (ROR), which generates an eye movement in the motor frame of extraocular muscles, and also measures it in coordinates, intrinsic to the retina. As a result of a separate Metaorganization of each primary system, both a fast but grossly over-complete and high-inertia VCR and a slow but pseudo-complete and low-inertia ROR may emerge. The VCR and ROR can then be linked by a further network to form the secondary (hierarchical) VOR, which is not a primary system (it is governed by the VCR and ROR), but it combines their advantages; it is a pseudo-complete and low-inertia, fast and precise gaze system.

26.1 TWO POPULATIONS OF ASTROCYTES IN THE GOLDFISH CENTRAL NERVOUS SYSTEM. R.L. Levine*, A. Tsang*, and C. Verdone-Smith* (SPON: E. Cooper). Dept. of Biology, McGill U., Québec, Canada H3A 1B1

We have been examining the glial cell population in the goldfish central nervous system (especially the visual system). Our evidence indicates that there are at least two forms of astrocytes in these animals, one in the optic nerve and the other in the rest of the brain.

In the optic nerve, EM reveals that typical astrocytes form sheaths around fascicles of optic axons. These cells are characterized by bundles of filaments in an electron-lucent cytoplasm which contains masses of glycogen. There is an astrocytic glia limitans at the periphery of the nerve and the astrocytes are held together everywhere by well developed desmosomes. In contrast, in the brain, all astrocytes appear to be radial glia, with cell bodies in the periventricular grey layers and expanded end feet, which form a glia limitans on the pial surface of the brain.

Immunocytochemical studies have further underscored the differences between optic nerve and brain astrocytes. We used commercially available anti-GFAP as primary antibody (Ab) and both fluorescent and HRP secondary markers to visualize its distribution. In our hands, anti-GFAP stains radial glia in the brain but stains optic nerve glia poorly, if at all. On the other hand, we have raised polyclonal Ab's to optic nerve antigens (48 Kd and 58 Kd) and find that while these stain a lattice-work in the optic nerve they do not stain cells in the brain. EM examination of immunochemically stained tissue confirms that anti-GFAP stains radial glia but we have been unable, at this point, to determine what cell types the anti-48 Kd and 58 Kd Ab's are staining. Finally, we have stained immunoblots of nerve and brain homogenates with anti-GFAP and we find that the two extracts show different staining patterns. In addition, anti-48 Kd and anti-58 Kd Ab's stain nerve blots very effectively but stain brain blots very weakly, if at all.

In summary, our data indicate that in the goldfish, optic nerve and brain astrocytes differ morphologically and biochemically.

26.2 DISTRIBUTION OF BIOGENIC AMINES IN THE FROG CNS: EFFECTS OF 5,6DHT. T. Ritchie, G. Karp*, and B. Haber. Mental Health-Mental Retardation Program, UCLA, Los Angeles, CA 90024 and Marine Biomedical Inst., Depts. of HBC&G and Neurology, University of Texas Medical Branch, Galveston, TX 77550.

The terminale portion of the frog spinal cord, the filum terminale, contains a large number of astrocyte like glia, and a neuropile with a dense network of 5HT immunoreactive fibers. The most caudal part of the FT contains significant quantities of GABA, acetylcholine and 5HT suggesting a possible glial storage mechanism for some neurotransmitters. We, therefore, have analyzed the entire frog central nervous system following pretreatment with the MAO inhibitor Pargylline and the intraventricular injection of the neurotoxin 5,6 dihydroxytryptamine (5,6DHT). Animals were sacrificed 5 or 14 days after the injection of 5,6DHT or saline in the controls. Tissues were frozen on dry ice, stored at -70° C and homogenized in 0.2M PCA for HPLC analysis with electrochemical (Coulochem, ESA) detection. The FT contains 84.8 ng/mg Prot. of 5HT, with somewhat higher levels seen in the conus medullaris and lumbar enlargement. The highest 5HT levels are seen in the brainstem (178 ng/mg Prot.) and lowest in the cerebellum and olfactory bulbs (17.7 ng/mg Prot.). Five days after the intraventricular injection of 5,6DHT, the 5HT levels in the caudal FT are reduced to 30% of control values, whereas depletions of 90% or greater are seen in the conus medullaris, the entire spinal cord and the Telencephalon. Parallel changes are seen in the distribution of 5HIAA after 5,6DHT. In contrast, only a 50% drop is seen in the diencephalon. Norepinephrine is present in the FT, though only at 10% of the 5HT values, and the greatest amount is seen in the brainstem (15 ng/mg Prot.). DA is present throughout the frog nervous system at concentrations similar to those of 5HT. It is interesting to note that the epinephrine (E) distribution does not parallel that of NE and DA, and E levels are double that of NE and DA (FT 19.2, CM 22.3). 5,6DHT results in small and inconsistent decrements in NE, DA and E levels, suggesting that 5,6DHT has neurotoxic effects on catecholamine terminals. We chose not to use 5,7DHT due to its greater toxicity in the frog. In all instances, analysis of the treated tissues reveals an HPLC peak that is identical to 5,6DHT. The observations suggest that 5,6DHT effectively destroys serotonergic terminals throughout the frog nervous system and that the large amounts of serotonin remaining in the caudal FT represents glial storage of that amine.

26.3 DIFFERENT PROTEIN INCORPORATION PATTERNS FOR ^{3}H-LEUCINE AND ^{3}H-PROLINE IN ADULT CAT DORSAL COLUMN NUCLEI. N.Contos, J.Elam and K.J.Berkley. Dept. of Psychology (NC,KJB) and Dept. of Biology (JE), Florida St. Univ., Tallahassee, FL 32306.

Previous studies have shown that injection of ^{3}H-proline or ^{3}H-leucine into the cat dorsal column nuclei (DCN) results in a differential cellular incorporation pattern as assessed by EM autoradiography at 24h post injection. ^{3}H-proline produced heavy labeling of macroglia but negligible labeling of DCN neurons. ^{3}H-leucine, in contrast, was extensively incorporated into both neurons and glia (Molinari and Berkley, 1981).

We now report preliminary assessment of differences in the protein labeling patterns produced by the two amino acid precursors. Equal amounts of ^{3}H-proline or ^{3}H-leucine of the same specific radioactivity were injected into the DCN of different cats. Twenty four hours after injection, a 10-30 mg sample of the injected DCN tissue was excised and immediately frozen. Upon thawing, tissue samples were subjected to homogenization in distilled H_2O followed by separation into acid soluble and acid insoluble fractions by adjustment to 5% with respect to cold trichloroacetic acid (TCA). The acid insoluble fractions were further extracted with a mixture of ether and ethanol to remove lipids. A separate sample of homogenate was adjusted to 1% in SDS and subjected to PAGE on a 10 to 16% gradient gel.

Results indicated that proline, despite its lack of incorporation into neurons, labels total DCN tissue to a significantly higher extent than leucine (an average of 32.3dpm/μg protein/μCi for proline vs. 10.9dpm/μg protein/μCi for leucine). Of total radioactivity remaining at 24h past injection for either isotope, greater than 90% was recovered in protein. For proline, the average distribution of radioactivity was 96.5% in protein, 2% in TCA soluble and 1.5% in lipid soluble fraction, while for leucine, it was 92.5% in protein, 3.5% in TCA soluble and 4% in lipid soluble fraction.

Fluorographic analysis of acrylamide gels showed labeling of a wide variety of individual proteins with either amino acid. However, several differences were consistently seen in the specific radioactivity distribution patterns, presumably reflecting differences in the cellular origins of the radioactive proteins. Overall, the results indicate that the striking differences in cellular distribution of incorporated proline and leucine as observed by EM autoradiography are accompanied by differences in the extent of labeling and specific labeling pattern of proteins isolated from the tissue.

26.4 IMMUNOCYTOCHEMICAL LOCALIZATION OF GD3 GANGLIOSIDE TO ASTROCYTES IN MURINE CEREBELLAR MUTANTS. S.M.LeVine*, T.N.Seyfried, R.K.Yu and J.E.Goldman. Dept. Pathology (Neuropathology), Albert Einstein Coll. Med., Bronx, NY 10461; Dept. Neurology, Yale Univ. School of Med., New Haven, CT 06510

GD3 ganglioside, a major species of the immature CNS, is a minor species of the mature CNS. Substantially elevated levels of GD3 are found, however, in several murine mutants, staggerer (sg), lurcher (Lc), and Purkinje cell degeneration (pcd), characterized by neuronal degeneration in the cerebellar cortex (J. Neurochem. 38:551, 1982) and in gliotic human CNS. Astrocytes in sg and pcd cerebella elaborate sheet-like cytoplasmic extensions which wrap around neuronal processes (Neurology 18:1093, 1968; J. Neurosci. Res. 6:789, 1981). Seyfried et al. (J. Neurochem. 38:551, 1982) hypothesized that elevated GD3 in gliosis is due to its expression by astrocytes.

Using a monoclonal antibody to GD3 ganglioside (J. Exp. Med. 155:1133, 1982) and a polyclonal antibody to glial fibrillary acidic protein (GFAP) (J. Neurochem. 42:166, 1984) we explored GD3 localization in cerebella of mutants. Using 10 um-thick frozen sections of adult mutant and littermate control cerebella with an immunofluorescence method, positive GD3 staining was observed in sg, pcd, and Lc mice, but not controls or in weaver (wv) cerebella, a mutant in which GD3 levels are not elevated (J. Neurochem. 41:491, 1983). Sg, pcd, and Lc are also characterized by profound Purkinje cell loss, while wv is not. The localization of reaction in Lc and pcd was confined to the granule cell layer, usually the outer half, with no reaction in Bergmann glia of the molecular layer or astrocytes of white matter. In sg, in which cortical distortion was pronounced and no clear molecular layer was seen, GD3 reaction was present through the entire cortex. GD3 reaction appeared as many punctate or fine linear profiles, consistent with binding to thin cytoplasmic processes. Because of the staining pattern it was difficult to associate the profiles with specific cells, however. The large majority of GD3+ profiles were not also GFAP+. Therefore, ultrastructural localization was performed using pre-embedding immunocytochemistry in sg mice, with a PAP technique. The cytoplasmic processes of astrocytes were labeled, as well as astrocyte cell bodies. Thin processes did not contain intermediate filaments. Neuronal processes appeared unstained. Thus, GD3 is expressed by astrocytes in these pathological states. Expression of GD3 is localized to a specific astrocyte population(s) within the mutant cerebella, however. Our observations suggest that important changes in astrocyte membrane composition occur in pathological conditions. Neuronal degeneration, especially that of Purkinje cells, may induce changes in astrocyte membranes, changes that persist after neuronal loss has occurred. Supported by USPHS grants NS17125, NS00524, NS17704, and NS11853.

26.5 **LOCALIZATION OF PHOSPHORYLATION SITES WITHIN VIMENTIN AND GLIAL FIBRILLARY ACIDIC PROTEIN (GFA) OF CULTURED ASTROCYTES.** Edward T. Browning. Dept. of Pharmacology, Rutgers Medical School, Piscataway, New Jersey 08854.

Past studies identified two cytoskeletal intermediate filament proteins of astrocytes as phosphoproteins whose phosphorylation is stimulated by elevation of intracellular cyclic AMP (cAMP) (J. Cell Biol., 90, 803, 1981; J. Neurochem., 42, 718, 1984). The purpose of the present experiments was to localize the phosphorylation sites within the primary structure of the two polypeptides. First, the ^{32}P-labeled vimentin and GFA from intact, forskolin treated rat astrocytes were selectively cleaved with BNPS-skatole at the single tryptophan residue present in each of the molecules. For vimentin, 84% of the ^{32}P-labeling was associated with the 37K N-terminal fragment, the remainder was associated with the 20K C-terminal fragment. For GFA, all recovered ^{32}P-labeling was localized in the 30K N-terminal fragment. As the amino acid composition of the C-terminal peptides of the two proteins are highly conserved and that of the N-terminal peptides are much less conserved, most of the phosphorylation was associated with the less conserved portions of the polypeptides. Next, the two ^{32}P-labeled filament proteins were cleaved to limit peptides with trypsin and the peptides were resolved by HPLC. ^{32}P-labeled peptides were hydrolyzed with 6N HCl and the amino acid composition of each was determined by HPLC of orthophthaldehyde derivatives using a reverse phase system. From the amino acid composition of the peptides and a knowledge of the amino acid sequence of each polypeptide it was possible to localize the phosphorylation sites of each polypeptide. The procedure yielded a small labeled peptide for each filament protein. For vimentin the labeled peptide corresponded to a 16 or 18 amino acid peptide at or near the N-terminus of the molecule and localized the possible phosphorylation sites to serine residues at positions 9, 12 and/or 18. Independent experimentation had identified serine as the phosphorylated amino acid of vimentin. For GFA, the labeled peptide corresponded to a 16 amino acid peptide containing a single serine residue at position 52. The amino acid sequence in the region of both phosphorylation sites differs from that known to be recognized by the cAMP dependent protein kinase. These results suggest that one or more protein kinase other than cAMP dependent protein kinase is responsible for the direct phosphorylation of vimentin and GFA. The data further suggest the presence of a cascade mechanism in the cAMP stimulated phosphorylation of these sites in vimentin and GFA. (Supported by NSF Grant BNS84-06889)

26.6 Phospholipase C Stimulates Diacylglyercol Production In C6 Rat Glioma Cells. Joseph Bressler*(spon P. Kornblith Surgical Neurology Branch, NIH, Bethesda, MD. 20205

We have previously suggested an important role for diacylglycerols in glial cell differentiation (J. Neurochem. in press) by demonstrating that phorbol esters, which bind to the natural diacylglycerol receptor (protein kinase C), inhibits the glucocorticoid-mediated induction of glycerol phosphate dehydrogenase (GPDH) in C6 rat glioma cells. In order to further elucidate this mechanism, we have used a system whereby these cells can be artificially stimulated to produce diacylglycerols. A choline dependent phospholipase C (PLC, from C. perfringens), stimulates a 2.5 fold increase in diacylglycerols wtih an ED 50 of 0.01 unit. This enzyme was also able to induce the cells to release choline into the media. The number of phorbol ester binding sites on the glioma cells was reduced by approximately 50%, but the affinity of the ligand for the receptor was not significantly altered. GPDH induction was inhibited at an ED 50 of 0.03 units and the beta-adrenergic mediated increase in cAMP was also inhibited at an ED 50 of 0.02 units. The advantage of this enzyme over the use of synthetic diacylglycerols is its stability. For example, 1-oleoyl-2-acetyl-glycerol at 250 uM given to C6 cells every 12 hours gives a similar amount of inhibition that 0.1 unit gives after only one treatment. Therefore, this enzyme can help us learn more about the role of diacylglycerols in glial function.

26.7 CULTURED ASTROGLIAL CELLS RELEASE FOUR DISTINCT AGENTS ADDRESSING NEURONS. J.S. Rudge,* M. Manthorpe and S. Varon. Dept. of Biology, Sch. of Med., Univ. Calif. San Diego, La Jolla, CA 92093.

A protocol is described by which thousands of replicate microcultures of rat brain astroglial cells can be set up and maintained within a chemically defined medium and on a defined substratum. Neonatal cerebra are dissociated and the cells grown for 10 days on culture plastic in a fetal calf serum-supplemented Eagle's Basal Medium as described (J. Neurocytol. 8: 605-621, 1979). The cells in these primary cultures are harvested and reseeded on a poly-ornithine-fibronectin substratum in microtiter plate wells and cultured in Eagle's Basal Medium without serum. These secondary confluent microcultures contain nearly exclusively GFAP-positive cells which can be maintained at the initially attached cell number (75% of seed) for 7 days without refeeding or for weeks with medium changes every 3 days.

Conditioned media were collected for these secondary cultures at various times and tested for their content of neuronotrophic and neurite promoting activities. The test neurons used to quantitate activities were from (i) chick E8 (embryonic day 8) dorsal root ganglia for the measurement of Nerve Growth Factor; (ii) chick E8 ciliary ganglia for Ciliary Neuronotrophic Factor; (iii) chick E8 telencephalon for trophic activity addressing CNS neurons and (iv) E8 chick ciliary ganglia again for determination of Polyornithine-binding Neurite Promoting Factor. All four activities are present in the conditioned medium and can be physically separated from one another. The activities accumulate and/or decline in the astroglial cell conditioned medium with reproducible and distinct temporal patterns, suggesting the independent regulation of production, release and/or stability of the corresponding molecules. This astroglial microculture method will be used in future studies to identify and investigate specific substances which may regulate astroglial cell content/release of these neuroactive agents. Supported by NSF grant BNS 82-18366 and NINCDS grant NS 16349.

26.8 **SEROTONIN STIMULATES TAURINE RELEASE FROM GLIAL CELLS IN CULTURE.** D. L. Martin, J. E. Abunaw* V. Madelian and W. Shain. Wadsworth Center for Laboratories and Research, New York State Health. Dept., Albany, NY 12201.

Glial cells are known to have receptors for a variety of neurotransmitters, but their functional significance is unclear. Previous studies from this laboratory have established that activation of beta-adrenergic or kappa-opiate receptors stimulates release of the neuroactive amino acid taurine from glial cells in culture. We now report that taurine is also released upon stimulation by serotonin. To study release LRM55 glial cells were preloaded with ^{3}H-taurine and then superfused with Hepes-buffered Hank's medium without or with drugs. Radioactivity appearing in the superfusate was measured. Taurine release was strongly stimulated by low doses of serotonin (EC_{50} = 0.4 μM), and this effect was inhibited by the serotonin receptor blockers methysergide and mianserine (IC_{50} = 0.04 nM and 5 nM when tested against 1 μM serotonin). Tryptamine was a much less potent agonist (EC_{50} 300 μM). Release stimulated by serotonin and beta-adrenergic agonists were mediated by different receptors, as the beta-adrenergic antagonist propranolol did not inhibit stimulation of release by serotonin and methysergide did not inhibit stimulation of release by the beta-agonist isoproterenol (IPR). The temporal pattern of release in response to prolonged stimulation by serotonin was similar to that observed with IPR. There was a rapid rise in release that reached a maximum after 5 min. Release then declined to a new steady-state level that continued until drug application ceased. IPR and serotonin were synergistic when initially applied together. However this synergism was lost if either agent was applied for 15 min before the other. Unlike IPR, serotonin did not stimulate cyclic-AMP synthesis and there was no synergistic increase in cyclic-AMP if both were applied together, indicating that serotonin acts via a different second messenger than beta-adrenergic agonists.

26.9 DESENSITIZATION OF BETA-ADRENERGIC RECEPTOR STIMULATED TAURINE RELEASE FROM GLIAL CELLS. W. Shain, V. Madelian, D.L. Martin, and L. Memmo*. Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, NY 12201.

Stimulation of beta-adrenergic receptors on LRM55 glial cells and primary cultures of astrocytes results in cyclic AMP (cAMP) mediated release of the inhibitory amino acid taurine. When cells were continuously exposed to beta-agonists for 30 min, three phases of release were observed: activation, inactivation, and elevated steady state. We have previously demonstrated that activation of release is mediated by cAMP The experiments described here were designed to elucidate the regulatory processes mediating inactivation and elevated steady-state. Several observations indicated that inactivation was not dependent on the intracellular concentration or changes in adenylate cyclase activity. (i) Inactivation of release occurred more rapidly than attenuation of intracellular cAMP levels during continuous application of agonist. (ii) When activation was studied by pretreating cells with 10 nM isoproterenol (IPR) for various lengths of time and then challenging them with 100 nM IPR the magnitude of the challenge response declined rapidly with a $t_{1/2}$ = approx. 2.5 min. This was more rapid than the $t_{1/2}$ for the observed decrease in intracellular cAMP. (iii) Continuous treatment of cells with dibutyryl cAMP and forskolin results in release profiles similar to that observed with beta-agonists, even though high levels of intracellular cAMP are sustained during both treatments. These results suggested that regulation occurred at a site distal to adenylate cyclase along the intracellular cAMP-protein kinase pathway. Regulation of the phosphorylated substrate(s) by protein kinase and phosphoprotein phosphatase is one possible site of control. Protein phosphorylation was studied by incubating cells with ^{32}P for 5 hrs to permit intracellular ATP pools to come to steady-state with ^{32}P. Cells were then stimulated with IPR and prepared for polyacrylamide gel electrophoresis at 0, 5, and 30 min after agonist application. Analysis of the phosphorylated proteins showed that several labelled bands had little or no ^{32}P incorporation at 0 min, maximal incorporation a 5 min, and low levels of incorporation at 30 min. Since the elevated steady-state was maintained as long as agonists were applied, these last observations suggested that inactivation may occur via rapid dephosphorylation and that the elevated steady-state represents the steady-state condition between protein phosphorylation and dephosphorylation.

26.10 DESENSITIZATION OF cAMP PRODUCTION IN LRM55 GLIAL CELLS BY THE BETA-ADRENERGIC AGONIST ISOPROTERENOL. V. Madelian, D.L. Martin, and W. Shain. Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, NY 12201.

Beta-adrenergic stimulation of LRM55 glial cells produces cyclic AMP (cAMP) mediated release of taurine. Prolonged exposure to agonists resulted in attenuation, i.e. desensitization, of both intracellular cAMP accumulation and taurine release. The regulation of cAMP during desensitization was studied by describing the kinetics of attenuation, determining changes in response to receptor stimulation during attenuation, and pharmacologically manipulating cells to separate cAMP degradation from receptor-stimulated changes in cAMP synthesis. The kinetics of attenuation were described by exposing cells continuously to various concentrations of isoproterenol (IPR) and by pretreating cells for various periods of time and then challenging them for one min with IPR. During a 30 min continuous exposure intracellular cAMP levels increased rapidly to dose-dependent maxima then declined steadily to values about 80% lower than the peak values. Attenuation of the response, determined as a function of time of pretreatment, was observed by one min and had a $t_{1/2}$ of approx. 5 min. Receptor stimulation during attenuation was studied by pretreating cells with various concentrations of IPR and then generating dose-response curves for intracellular cAMP levels to determine if pretreatment resulted in changes of either the apparent affinity, i.e. ED_{50}, or the apparent V_{max}, i.e. maximal stimulation, of the response. There was no significant change in the EC_{50} values (60 nM) but there was a 70% decrease in maximal stimulation. Pharmacological manipulation of receptor-stimulated cAMP response was achieved by first producing a maximal response with IPR and then either inhibiting phosphodiesterase with RO20-1724 (RO20) in the continued presence of agonist or inhibiting receptor activation by removal of IPR or addition of propranolol, a beta-antagonist. When RO20 was added in the presence of agonist, cAMP continued to rise for another 15 min at which time the cAMP level in cells in the presence of agonist alone had dropped to 10% of peak values. When receptor activation was inhibited, there was a very rapid decrease in cAMP levels. However, when cells were changed to media containing RO20 alone this drop was prevented. These data demonstrate that attenuation of intracellular cAMP accumulation in LRM55 glial cells may be principally a result of cAMP hydrolysis and not to a reduced rate of synthesis.

26.11 (^{3}H)-NITRENDIPINE BINDING IN NON-NEURONAL CELLS FROM MOUSE SPINAL CORD CULTURES. M.J. Litzinger and D.E. Brenneman, Lab. of Dev. Neurobiology, NICHD, NIH, Bethesda, Maryland 20205

(^{3}H)-Nitrendipine (NTP) is believed to bind to the voltage-sensitive calcium channel (VSCC). Recently, electrophysiological evidence has indicated that VSCC is present in primary glial cultures grown in 10% fetal calf serum (MacVicar, Science 226: 1345, 1984). The purpose of the present study was to determine if non-neuronal cells exhibit specific NTP binding sites which would correlate with the physiological evidence of the VSCC.

Previous studies of (^{3}H)-NTP binding in dissociated spinal cord cultures from the fetal mouse demonstrated two NTP binding sites throughout development (Litzinger and Brenneman, BBRC 127: 112, 1985). The culture preparation utilized for these studies consisted of both neuronal and non-neuronal cells. These mixed cultures were maintained in Eagle's minimal essential medium (MEM) with 5% horse serum supplemented with defined medium components. In the present study, spinal cord cultures were grown in MEM with 10% fetal calf serum. With these conditions, spinal cord neuron growth was not supported, although a small number of dorsal root ganglion cells did survive this treatment. The plating density for the background cultures was 2.5 x 10^5 cells per 16 mm diameter well. After 3-4 weeks, the cultures were comprised of glial cells and fibroblasts.

(^{3}H)-NTP binding was conducted on living cells at 37° C. Unlabeled NTP (50 µM) was used to determine specific binding. NTP was dissolved in ethanol. Vehicle controls indicated no significant effect on (^{3}H)-NTP binding. Specific binding was found to range between 48% and 62% of the total binding. Curve fitting analysis (the Bright program) indicated that the best estimate of the Scatchard plot was linear. The apparent Kd was 25 nM and the B_{max} was 293 fmoles per well or 13.0 fmoles per µg protein. These values are similar to those reported for the low affinity component of NTP binding in cultures which contained both neurons and background cells. Our data suggest the existence of a single, low affinity class of binding sites in background cells. These studies are consistent with the conclusion that VSCC is present on non-neuronal cells derived from spinal cord cultures.

26.12 Pharmacology and Ionic Mechanism of the (-)NE Induced Depolarization of Astrocytes in Primary Culture. Charles L. Bowman* and Harold K. Kimelberg. Division of Neurosurgery, Albany Medical College, Albany, New York 12208.

Astrocytes, derived from an enzymatic dissociation of cerebral hemispheres of neonatal rats (Frangakis and Kimelberg Neurochem Res 9:1689 1984), were grown in primary cell culture. It is well established that the membrane potential of astrocytes is depolarized by (-)NE. The NE induced depolarization is mediated by an α- rather then a β-adrenergic receptor (Hosli et.al. Neurosci 7:2867 1982; Hirata et.al. Brain Res 270:358 1983). We are investigating the pharmacological characteristics and ionic mechanisms underlying the NE induced depolarization of astrocytes in primary cell culture.

It appears that an α_1-rather then an α_2-adrenergic receptor may be involved because prazosin (an α_1-adrenergic receptor antagonist) was a more effective inhibitor of the NE induced depolarization then either yohimbine or idazoxane (RX 781094) (both α_2-adrenergic receptor antagonists). These results are in general agreement with the hypothesis that α_1-adrenergic receptors are postsynatic.

It is well established that astrocytes in primary culture have a high affinity Na^+dependent uptake mechanism for catecholamines. This uptake mechanism is blocked by the tricyclic antidepressents (amitriptyline (AMT); desipramine (DMI)) and by dopamine (Kimelberg and Pelton J. Neurochem 40:1265 1983). Perfusion of DMI, AMT or dopamine (10^{-6}M) only partially (approx 30%) inhibited the NE (10^{-5}M) induced depolarization. We conclude from these results that the NE response is not due to the high affinity catecholamine uptake system alone.

Using a double impalement current clamp technique, we have measured the current-voltage characteristics of the astrocytes. In the absence of agonist, the IV curve was linear. Perfusion of NE (10^{-5}M) resulted in some degree of nonlinearity in the presence of agonist. Washout of NE caused an irreversible increase in the input resistence so that subsequent perfusion and washout of NE was without effect on the input resistence. These results suggest that NE either closed K^+ channels in the plasmalemma or closed junctional channels between cells, and suggest the presence of multiple ionic conductance changes or the presence of chemically gated - voltage dependent channels.

We have studied the effect of varying the chloride equilibrium potential on the NE response. In the presence of high $[K^+]_o$ (130 mM) and low $[Na^+]_o$(5 mM), varying $[Cl^-]_o$ results in either a depolarization (5 mM $[Cl^-]_o$) or hyperpolarization (122 mM $[Cl^-]_o$). These results suggest that NE opens a chloride channel in the plasmalemma. Supported by NINCDS grant NS19492, and by NSF grant BNS 8213873.

26.13 BARIUM INDUCED RHYTHMIC DEPOLARIZATION OF GLIAL CELLS IN BRAIN SLICES. W. Walz[1] and B.A. MacVicar[2], [1]Dept. of Physiology, University of Saskatchewan, Saskatoon, S7N OWO and [2]Dept. of Medical Physiology, University of Calgary, Calgary, Alberta T2N 4N1, Canada.

Voltage-dependent calcium channels have been observed in glial cells in primary cell culture (MacVicar, 1984, Science 226:1345). However we wished to confirm that glial cells in in situ preparations such as brain slices also have the same properties. We used intracellular recordings from presumed glial cells in the CA1 layer of the rat hippocampal slice to examine this question. Glial cells were identified by the following criteria: 1. high resting potential (>-70 mV in 5 mMK^+); 2. low input resistance (<2 MΩ as compared to neuronal input resistance of >15 MΩ); 3. current injection did not evoke any spikes; 4. repetitive synaptic stimulation did not lead to post-synaptic potentials but to a slow depolarization (∿20 mV) which was followed by a slow hyperpolarization (2-4 mV) lasting for about 5 min. These properties have all been previously described as characteristics of glial cells. In these experiments low calcium (0.1-0.2 mM) solutions were perfused to block transmitter-mediated synaptic transmission and ensure that the glial response was endogenous. After synaptic responses were blocked barium (10-25 mM) solutions were perfused and in some experiments tetraethylammonium (10 mM) was included. We observed the following phenomena during stable long-term recordings from 12 cells: 1. all cells depolarized by 20-30 mV in barium; 2. rhythmical oscillations of the membrane potential were observed in 35% of the cells. The frequency was approximately 1Hz and the amplitude 10 to 20 mV. The depolarization phase of the oscillation was associated with a decreased input resistance; 3. an after-depolarization followed depolarizing current pulses (100 msec duration) in 25% of cells. The amplitude of the after-depolarization was increased when the cell was hyperpolarized and the after-depolarization was correlated with a decrease in input resistance.

Therefore the membrane properties of glial cells in brain slices are altered by barium. The depolarization observed in all cells may indicate that resting K^+ permeability of glial cells is decreased by barium. The rhythmic and evoked depolarizations may result from barium entry through voltage dependent calcium channels.

26.14 A POTASSIUM DEPOLARIZATION OF THE OLIGODENDROCYTE PARANODAL REGION IN RAT OPTIC NERVE. V. Lev-Ram* (SPON: Z. Wollberg). Department of Cell Biology, The Weizmann Institute of Science, Rehovot 76100, Israel

The present study describes the use of fluorescence voltage-sensitive probes and an optical recording technique for investigating the physiological relationship between axons and oligodendrocytes in myelinated nerves. This optical technique allows direct recording from structures that cannot be penetrated by electrodes. Rat optic nerves were stained in vitro and action potentials were stimulated and recorded with suction electrodes. Simultaneously, electrical activity in axonal membrane and potential changes in the glial cells were recorded optically. Two types of optical signals were detected: a fast signal (3-5 msec) that could account for the sum of intracellular action potentials of a population of axons, and a slow signal (latency to peak 40-90 msec, decay time 700-1300 msec) (Fig. A). We concluded that the slow signal originated from the oligodendrocyte myelin sheath, because it could be elicited neither in nonmyelinated optic nerves of newborn rats (Fig. B) nor when myelinated nerves were stained with axon-specific dyes that did not bind to glial membranes. Furthermore, the slow signal recorded from myelinated nerves disappeared after demyelination was produced by repetitive osmotic shocks. This glial signal showed the following characteristics: varied with extracellular K^+ in a glial depolarization manner (1.2-11.2 mM); increased by 4-AP (5 mM); was absent in Cs^+-loaded nerves; decreased upon temperature elevation; and was abolished by TTX (except for near the stimulating electrode where passive spread could evoke the glial signal). The glial signal was found to be Ca^{2+}-dependent, as it could not be detected in the absence of Ca^{2+} or when Ca^{2+} was replaced by its antagonists. It appears that the slow signal represents glial membrane depolarization caused by Ca^{2+}-dependent K^+ accumulation which results from axonal activity. The function of this glial response in the physiology of myelinated nerves remains to be ascertained.

COEXISTENCE OF TRANSMITTERS

27.1 DISSOCIATED RAT SYMPATHETIC NEURONS IN MICROCULTURE: NON-ADRENERGIC EXCITATION OF CARDIAC MYOCYTES AND THE VARIETY OF MULTIPLE-TRANSMITTER STATES. S.G. Matsumoto*, D.W.Y. Sah, S.C. Landis, D.D. Potter and E.J. Furshpan. Dept. of Neurobiol. Harvard Med. Sch., Boston, MA. 02115.

Neurons dissociated from the superior cervical ganglion (SCG) of both neonate and adult rats have been shown to release norepinephrine, acetylcholine and adenosine (or a related purine) in various combinations when co-cultured with cardiac myocytes (Furshpan et. al. J. Neurosci. in press). We have now observed the release of at least 2 additional substances that produce slow depolarizations in the cardiac myocytes. These responses are insensitive to adrenergic, cholinergic and purinergic antagonists.

The non-adrenergic excitatory (NAE) effects on the cardiac myocytes were small (1-5 mV) and usually detected only after any other transmitter effects were blocked. One of the agents responsible for NAE has been tentatively identified as serotonin (5-HT) (see also Sah and Matsumoto Neurosci. Abs., 1985). This type of effect is blocked reversibly by methysergide and/or gramine and irreversibly by reserpine. Ultrastructural experiments are in progress to determine the 5-HT storage compartment. A second NAE effect had a longer duration than the putative 5-HT responses and was not affected by 5-HT antagonists or reserpine. Long trains of neuronal impulses (20s) at high frequency (20 Hz) were required to evoke this response, which then persisted for several minutes. Long inter-stimulus intervals were usually required to evoke these responses reproducibly. The mediator(s) of this second NAE effect has not been identified. Attempts to mimic the effects of this agent(s) with peptides whose immunoreactivities have been reported in adult sympathetic neurons in vivo have thus far been unsuccessful.

The transmitter repertoire of microcultured SCG neurons is extremely diverse. Two types of diversity are observed; first in the combination of transmitters released and second, in the relative strengths of their effects on the cardiac myocytes. A summary of the different combinations of co-released transmitters reveals a broad spectrum of multi-functional states. A majority of the possible combinations of 5 distinct transmitter actions have been observed. The variability in the relative strengths of the transmitter effects appear to be due to their graded expression within the individual neurons.

(supported by NIH and NSF)

27.2 DISSOCIATED CELL CULTURES OF RAT SUPERIOR CERVICAL GANGLION NEURONS: SEROTONIN UPTAKE AND RELEASE. D. W. Y. Sah and S. G. Matsumoto*. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Cultures of dissociated sympathetic principal neurons from newborn and adult rat superior cervical ganglia have been shown to release norepinephrine, acetylcholine and a purine (probably adenosine). In some microcultures of single sympathetic neurons and cardiac myocytes, a non-adrenergic excitatory (NAE) interaction, sensitive to serotonin (5-HT) antagonists, has been observed (see Matsumoto et al, Neurosci. Abs. 1985). To examine further the possibility that 5-HT is a neurotransmitter in these neurons, we used HPLC and electrochemical detection to study its uptake, presence and release, and immunocytochemistry to study its distribution. Electrophysiological recording was used to further study uptake.

Mass cultures of approximately 1000 neurons were used for biochemical and immunocytochemical experiments. Culture homogenates contained a substance that co-migrated with authentic 5-HT. As a further test of the identity of the extract peak, a voltammogram was obtained and compared with that of authentic 5-HT. The profile for putative 5-HT from the culture homogenates superimposed upon that of authentic 5-HT in the presence or absence of an ion-pair. When the cultures were examined with immunocytochemical staining using the peroxidase-antiperoxidase technique, many neuronal processes, as well as 2-48% of the somata contained 5-HT-like immunoreactive material.

Serotonin was present in the rat serum added to the growth medium; the concentration of 5-HT in the medium was 0.25-0.50 μM. The serum was probably at least a major source of the 5-HT present in the neurons, since levels of 5-HT in the cultures were highest just after replacing the culture medium with fresh medium, and declined to very low levels over the next 4 days.

The 5-HT in the cultures was released in a Ca^{2+}-dependent manner by high K^+ or veratridine, consistent with a neurotransmitter role. In electrophysiological experiments on microcultures, a non-adrenergic excitatory interaction, sensitive to 5-HT antagonists, could sometimes be obtained after exposing the neurons to 5-hydroxytryptophan. In our observations so far, neurons with adrenergic function could take up 5-hydroxytryptophan and release 5-HT, but neurons with cholinergic function and no adrenergic function could not.

There are several reports that autonomic nerve terminals can take up exogenous 5-HT, e.g. in the vas deferens and blood vessels. In vivo, the terminals of SCG neurons are not normally exposed to serum, but are exposed to mast cells in the target tissues, a major source of 5-HT. Perhaps the 5-HT uptake that occurs in cultured sympathetic neurons also occurs in vivo under certain conditions.

(Supported by NIH and NSF).

27.3 COEXISTENCE OF ENKEPHALIN AND DYNORPHIN IMMUNOREACTIVITIES IN NEURONS IN THE DORSAL GRAY COMMISSURE OF THE LUMBOSACRAL SPINAL CORD IN RAT. Cathrine A. Sasek and Robert Elde. Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

In a recent report (Neurosci. 12:855) we described the distribution of several peptides in the dorsal gray commissure (DGC) of the sixth lumbar (L) and first sacral (S1) spinal cord segments in the rat and hypothesized that two or more peptides might coexist in neurons in the DGC. This hypothesis was supported by the abundance and wide variety of peptides found in the DGC. Of the peptides present in the DGC the opioids enkephalin (ENK) and dynorphin (DYN) are especially interesting in that they appear to be present in a greater number of neuronal perikarya than most other peptides. Additionally, opiates have been shown to be important in the regulation micturition. Thus, the present study was undertaken to determine if DYN and ENK coexist in neurons in the DGC in L6 and S1 of rat spinal cord.

Frozen (5um) sections of L6 and S1 from colchicine treated rats were processed for immunofluorescence using anti-DYN as the 1 antiserum. After photographing the sections the DYN antiserum was eluted with acid potassium permanganate. The sections were then rinsed, incubated in fluorescein labeled secondary antiserum as a control, and if no staining was seen, incubated with anti-ENK and FITC labeled 2 antibody. Sections were rephotographed and the negatives were used to compare the number and location of DYN immunoreactive cells to that of ENK immunoreactive cells in each section. A chi square test for independence was used to determine if there was a significant difference between L6 and S1 in the proportion of cells with only ENK to those with ENK and DYN coexistence. Both ENK and DYN antisera were tested extensively for cross reactivity and were found to be specific.

It was found that of 67 ENK containing cells counted in 20 sections through L6, 54 also contained DYN immunoreactivity and that of 100 ENK containing cells in counted 47 sections through S1, 95 also contained DYN immunoreactivity. No cells containing only DYN immunoreactivity were seen. A statistically significant difference ($p<0.004$) was seen between L6 and S1 in the ratio of the number of cells containing both ENK and DYN immunoreactivity to those containing only ENK immunoreactivity.

The results of the present studies indicate that ENK and DYN immunoreactivities coexist in most, but not all neurons in the DGC of L6 and S1 and that a significant difference exists between L6 and S1 in the extent of coexistence of these peptides. The functional significance of the expression of two opioids by a single neuron is unknown, but it can be speculated that the role of opioids in neurons in the DGC must be important, as so much of the neurons biosynthetic machinery is dedicated to the synthesis of opioids. Supported by DA 02148.

27.4 SUBSTANCE P AND SEROTONIN COEXIST IN NERVE FIBERS APPOSED TO IDENTIFIED SYMPATHOADRENAL PREGANGLIONIC NEURONS IN RAT INTERMEDIOLATERAL CELL COLUMN. N.M. Appel, M.W. Wessendorf and R. Elde. Dept. of Anatomy, U. Minnesota, Minneapolis MN 55455.

Physiological evidence has accumulated implicating serotonin (5-HT) and substance P (SP) in the regulation of sympathetic nervous system activity. In addition, anatomical studies have demonstrated the existence of SP and 5-HT-immunostained neuronal processes in close proximity to identified sympathoadrenal preganglionic (SAP) neurons in the intermediolateral cell column (IML) of spinal cord. In the present study we examined the possibility that these putative neurotransmitters were localized within the same neuronal processes.

Adult male Sprague-Dawley rats were anesthesized and Fast Blue (5µl, 1% w/v in water) was pressure injected via a glass micropipette into the left adrenal medulla. Five days later they were deeply anesthesized and perfusion-fixed with buffered 4% paraformaldehyde. Spinal cords were collected, sectioned on a cryostat (10µ) and processed for simultaneous demonstration of 5-HT and SP immunoreactivities. This protocol resulted in 5-HT- and SP-immunostained material fluorescing red and green, respectively.

With appropriate ultraviolet illumination, Fast Blue-labeled SAP neurons appeared as "ice-blue" colored cells in IML. When illumination was adjusted to visualize rhodamine- (5-HT) or fluorescein-labeled (SP) structures, nerve terminals and fibers immunostained for 5-HT or SP were observed in the vicinity of Fast Blue-labeled cell bodies in IML. Furthermore, some, but not all of these structures fluoresced using both rhodamine and fluorescein excitation filters. This was not due to "bleed-through" of weak red fluorescence since a 560nm short-pass filter did not affect their appearance. In addition to being in proximity to SAP neurons, dual-labeled structures were also apparent in regions where SAP neurons were not observed.

We conclude from these studies that nerve terminals and fibers in which 5-HT and SP immunoreactivities coexist occur in close proximity to SAP neurons. While the presence of these immunostained fibers and terminals in the vicinity of labeled SAP neurons suggest their interaction with these cells, synaptic contact must be established with ultrastructural studies. In view of contradictory reports regarding the effects of 5-HT on IML, our data suggest that consideration of an interaction between 5-HT and SP in this setting may be necessary.

27.5 CATECHOLAMINE, SEROTONIN, AND SUBSTANCE P-LIKE PEPTIDE CONTAINING INTERNEURONS IN A PARASYMPATHETIC GANGLION. D.S. Neel* and R.L. Parsons (SPON: G. Webb). Dept. of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

There are two neuron types in the mudpuppy cardiac ganglion; large parasympathetic ganglion cells and small catecholamine containing interneurons (SIF cells) (1). The function of these interneurons is not known and direct application of catecholamines to the parasympathetic ganglion cells produce no electrophysiological effect (2). It is now well known that many different classes of neurons can synthesize and use more than one transmitter type, therefore experiments were done to test whether putative transmitter substances other than catecholamines are also present within these interneurons.

Whole mount septal preparations were dissected from Necturus maculosus, pinned onto Sylgard coated petri dishes and processed for indirect immunocytochemistry. Two protocols were used: a) to examine for neuropeptides or other putative transmitters, the preparations were incubated in cold Zamboni's fixative for eighteen hours prior to application of primary antisera (3); b) to determine coexistance of catecholamine and other transmitter substances, the preparations were fixed for approximately 30 min. in buffered 4% paraformaldehyde and 0.25% glutaraldehyde solution (4). Primary antisera included: Substance P 1:200 (Sera Labs) and serotonin (5-HT) 1:200 (Immunonuclear Corp.). Absorption controls for the specificity of the immunoreactivity were produced by incubating purified peptide or 5HT-congugate complex with its respective antisera for 24 hours before incubating whole mounts in the antisera.

From these studies, it was concluded that several combinations of the substances examined can occur in the interneurons. Some interneurons and their processes contain a substance P-like peptide and 5-HT. Other interneurons were reactive for only one substance. Many interneurons exhibited immunoreactivity for either substance P or 5-HT and also were positive with aqueous-aldehyde-induced fluorescence which indicated the presence of a catecholamine. Finally, observations were made that showed certain interneurons contain all three, a catecholamine, 5-HT and substance P-like peptide.

27.6 SEROTONIN AND SUBSTANCE P COEXIST IN AXON TERMINALS OF THE HYPERINNERVATED INFERIOR OLIVE AFTER INTRAVENTRICULAR 5,6-DIHYDROXYTRYPTAMINE. M. Paré* and L. Descarries (SPON: A. Ferron). Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal, Qué., Canada H3C 3J7.

In order to investigate the possible coexistence of serotonin (5-HT) and substance P (SP) in axon terminals of the inferior olive (IO) of adult rats (Hökfelt, T. et al., *Neuroscience, 3:* 517, 1978), paired histological sections taken at regular intervals across the lower half of medulla oblongata were processed for PAP-immunohistochemistry using anti-5-HT and -SP antibodies. Observations were made in rats subjected to cerebro-ventricular injection of 5,6-dihydroxytryptamine (5,6-DHT, 75 µg f.b. in 20 µl of saline) 1-2 weeks or 6-21 months earlier, as well as in saline-injected controls of the same age. In the short term experiments, the effects of the neurotoxin on 5-HT neurons were manifested by the presence of enlarged, tortuous and/or bulbous "dystrophic" immunostained axonal profiles in all regions of the IO and neighboring tissue normally innervated by 5-HT fibers, and a reduced number of axonal varicosities especially in the dorsal accessory olive (DAO). Some 5-HT-immunopositive nerve cell bodies were still visible in the adjacent nuclei raphe pallidus and obscurus. Immunoreactivity to SP appeared to be unchanged in certain portions of the IO (dorsal cap of Kooy, dorsal ramus of principal olive (PO) and patches in DAO) but, in other areas (area b of caudal MAO and lateral DAO), dystrophic immunostained fibers were visible. At the prolonged time intervals after 5,6-DHT, the expected 5-HT hyperinnervation in IO (Wiklund, L. and Björklund, A., *Brain Res. 191:* 129, 1980) was evidenced by marked increase in the number of immunostained axons and varicosities, not only in the DAO, where the 5-HT innervation normally predominates, but also in the MAO where it is weak in the controls. Concomitant changes in the distribution of SP immunoreactivity were seen in the very same regions, including the rostral MAO where SP terminals appear exceedingly scarce in the controls. These results strongly suggest the coexistence of 5-HT and SP within certain axon terminals of adult rat IO in addition to categories of IO fibers containing 5-HT and SP independently. The presence of SP-immunoreactivity in IO 5-HT axons regrown and hyperdeveloped after 5,6-DHT-lesioning is consistent with earlier hypotheses that the production of the peptide and that of the biogenic amine are interregulated at the level of the cell bodies and/or controlled by a signal(s) issued from the terminals. Such an experimental model might be of use in discriminating between these alternatives. (Supported by grant MT-3544 from the MRC of Canada).

27.7 CO-LOCALIZATION OF GABA- AND TYROSINE HYDROXYLASE-LIKE IMMUNOREACTIVITIES IN NEURONS OF THE RAT OLFACTORY BULB. C.M. Gall, S.H.C. Hendry, K.B. Seroogy, and E.G. Jones. Department of Anatomy, University of California, Irvine, CA 92717.

Tyrosine hydroxylase (TH), the biosynthetic enzyme for dopamine, and glutamic acid decarboxylase (GAD), the biosynthetic enzyme for gamma aminobutyric acid (GABA), have both been localized within periglomerular neurons in the rat main olfactory bulb. The present study was conducted to determine whether the two "classical" transmitter substances, dopamine and GABA, are co-localized within individual neurons in this brain region.

Sprague Dawley rats were perfused with either 4% paraformaldehyde or 2% paraformaldehyde and 0.1% glutaraldehyde. Using indirect immunofluorescence, we processed sections through the olfactory bulb for the simultaneous detection of TH (sheep antiserum supplied by J. Haycock, Rockefeller Univ.) and GABA (rabbit antiserum, Immunonuclear Corp.). In agreement with previous reports we found TH immunoreactivity (TH-I) localized primarily within numerous small (5-7um) periglomerular cells and within somewhat larger neurons (major diam. 10-15um) in the glomerular and external plexiform layers. The larger neurons presumably include external and middle tufted cells as well as some short-axon cells. GABA immunoreactivity (GABA-I) was also localized within the small periglomerular cells and larger (major diam. 10-12.5um) neurons in the glomerular and external plexiform layers as well as within large numbers of internal granule cells. The vast majority of the TH-I neurons in both the glomerular and external plexiform layers also contained GABA-I. However, in each field some neurons were immunoreactive only for TH and a larger number were immunoreactive only for GABA. The larger, presumably middle tufted, TH-I neurons in the EPL generally did not contain GABA. These data demonstrate that the majority of the dopamine containing periglomerular cells, which others have suggested to comprise 20% of the total periglomerular cell population, contain GABA. The co-localization of TH and GABA in larger neurons within the periglomerular and external plexiform layers indicates that dopamine and GABA coexist within a number of external tufted and short-axon cells as well.

27.8 **MOST GABA-ERGIC NEURONS IN THE RAT CEREBRAL CORTEX CONTAIN THE CALCIUM-BINDING PROTEIN PARVALBUMIN.** L. Schärer*, M.R. Celio (SPON: H.P. Lipp) Anatomisches Institut der Universität Zürich, CH-8057 Zürich (Switzerland).

Gamma-amino-butyric-acid (GABA) is recognized as one of the major inhibitory neurotransmitters in the central nervous system. In the cerebral cortex, a subpopulation of interneurons is GABA-ergic. Parvalbumin (PV) was also shown to be a marker for a subpopulation of cortical neurons (Celio and Heizmann, Nature 293,300-302,1981). In this study we sought to determine whether the two substances, GABA and PV, coexist in the same cortical neurons.

Rats were perfused transcardially with fixative and pieces of the somatosensory cortex were frozen in liquid nitrogen after imbibition with sucrose. Consecutive semi-thin cryo-sections (0.5-1 um) were cut with a Reichert Ultra-cryo-microtome and mounted on glass slides. The sections were alternatively incubated with the PV- or the GABA-antiserum, and further processed by the peroxydase-anti-peroxydase method. GABA-ergic and parvalbuminic neurons were scattered in the somatosensory cortex in a similar manner. A closer scrutiny revealed two different populations of interneurons: the major (approx. 70%) were both GABA- and PV-immunoreactive, whereas a minor (approx. 30%) had only GABA-immunoreactivity. PV distributed itself only in GABA-ergic neurons.

What could be the role of PV in GABA-ergic neurons of the neocortex? If it can be assumed that parvalbumin in the brain binds Ca^{++} in exchange of Mg^{++}, as in skeletal muscles, then PV could modulate the excitability and the activity of GABA-ergic neurons. In fact, by binding Ca^{++} after its entry in the cytoplasm, PV would prevent the activation of the Ca^{++} activated K^{+} current, thus reducing the after-hyperpolarization of the neuron. The shortening of the refractory period might enable a higher firing rate of the neuron. By discharging Mg^{++} in the cytoplasm, PV may trigger the multitude of Mg^{++} dependent enzymes, thus linking cell activity and cell metabolism. Abnormalities of parvalbumin in the GABA-ergic cells of the neocortex could lead to ineffective inhibition, and serve as a causative factor in the development of epileptiform discharges.

27.9 TYROSINE HYDROXYLASE AND NEUROPEPTIDE Y-LIKE IMMUNOREACTIVITY IN RABBIT MEDULLA OBLONGATA. W.W. BLESSING, T.H. JOH, J.R. OLIVER* AND J.O. WILLOUGHBY. Centre for Neuroscience and Department of Medicine, Flinders University of South Australia, Bedford Park, South Australia, 5042.

The distribution and co-localization of tyrosine hydroxylase (TH) and neuropeptide Y (NPY)-like immunoreactivity in the rabbit medulla were studied, with special reference to the possible presence of these substances in vagal preganglionic neurons.

Rabbits were perfused with a solution of formaldehyde and picric acid and the brain was post-fixed for 24 hours. Additional rabbits received unilateral intramedullary injections of colchicine (1-2 ug) 36 hours before perfusion. In some rabbits, vagal preganglionic neurons were identified by Fast Blue, retrogradely transported from the cervical vagus nerve. Vibratome sections (50 um) were washed in 50% ethanol, rinsed in TRIS buffer and blocked with 20% normal horse serum. Sections were processed either by the avidin-biotin-peroxidase method with rabbit anti-TH antiserum and sheep anti-NPY antiserum used separately, each diluted 1/5000, or by fluorescence procedures with combined antisera, each diluted 1/500. By using combined rhodamine labelled anti-rabbit IgG and FITC-labelled anti-sheep IgG and appropriate filters it was possible to study, simultaneously, co-localization of TH, NPY and Fast Blue.

TH-positive cells were distributed within the ventrolateral region (A1-C1) of the entire medulla and in the nucleus tractus solitarius - dorsal motor nucleus of the vagus (nTS-dmnX) (A2-C2). No cells were seen within the medial longitudinal fasciculus (C3). No TH-positive vagal preganglionic neurons were demonstrated, either in the dmnX or within and around the nucleus ambiguus. NPY-positive cells were observed in the A1 and C1 areas except at the most caudal and most rostral (A5) levels. TH and NPY were co-localized in the A1-C1 cells but some TH neurons were negative for NPY at every rostrocaudal level, especially in the more caudal regions. Rostral to the obex, many NPY cells were found within the dmnX itself. These neurons were TH-negative. A substantial proportion contained Fast Blue and and were therefore vagal preganglionic neurons. At this rostrocaudal level other NPY cells, scattered around the TS and medial to the dmnX, were TH-positive. Others, in the dorsal portion of the nTS, were TH-negative. Few NPY-positive neurons were observed in the nTS-dmnX caudal to the obex. Other NPY-positive, TH-negative cells were found in the caudal spinal trigeminal nucleus, in the ventral portion of the rostral medullary raphe nucleus and in the medial reticular formation, dorsal to the rostral portion of the inferior olive.

27.10 DIFFERENTIAL PROJECTIONS OF NEUROPEPTIDE Y CONTAINING NEURONS IN THE LOCUS CERULEUS OF THE RAT. E.L. Gustafson and R.Y. Moore. Departments of Psychology, Neurology and Neurobiology & Behavior, SUNY @ Stony Brook, Stony Brook, New York, 11794.

The locus ceruleus (LC) is a dense concentration of noradrenergic neurons in the brainstem that has extensive projections to many areas of the central nervous system (CNS). Recent studies have demonstrated that a subpopulation of these neurons also contain neuropeptide Y (Everitt et al., '84). In addition, some areas of the CNS contain NPY-immunoreactive axonal plexuses which are similar to the noradrenergic innervation arising from the LC, while other areas which receive a noradrenergic projection from the LC are lacking in NPY-immunoreactive axons. The observations raise the possibility that the co-localization of NPY with noradrenaline in a subpopulation of LC neurons may provide a mechanism for functionally discrete projections from this nucleus. We have addressed this question by combining immunohistochemical analysis of NPY in the LC with retrograde transport of the dye fast blue from the cerebral cortex and cerebellum of the adult rat. Both of these areas receive a noradrenergic innervation from the LC and also contain NPY-immunoreactive axons which are similar to the noradrenergic innervation in both morphology and distribution.

Bilateral injections of fast blue into the cerebral cortex result in numerous retrogradely labeled perikarya in the LC. The majority of these cells are concentrated in the dorsal two-thirds of the LC, but scattered cells are also present in the ventral aspect of the nucleus. There is also a differential distribution of labeled cells through the rostrocaudal axis of the LC with the greatest concentration of neurons occurring in the posterior portion of the nucleus. After processing the same sections for immunohistochemical localization of NPY, many but not all, of the cells which were retrogradely labeled with fast blue also exhibit NPY-like immunoreactivity, particularly in the posterior and dorsal aspect of the LC. In contrast, following bilateral dye injections of the cerebellar cortex, retrogradely labeled neurons were present primarily in the ventral aspect of the LC with only scattered labeled cells in the dorsal LC. However, there does not appear to be any rostrocaudal gradient in their distribution. Processing of this tissue for immunohistochemistry demonstrated that only a small percentage of these neurons contain NPY-like immunoreactivity.

These data demonstrate that the extensive efferent projections of the LC are divided into discrete subfields through the co-localization of NPY with only a subpopulation of the noradrenergic neurons in this nucleus. This raises the possibility of differential functional output of the LC which is specified by the presence or absence of NPY in noradrenergic afferents. Supported by NIH grant N5-16304.

27.11 AMPHETAMINE-INDUCED CHANGES IN IMMUNOREACTIVE NEUROPEPTIDE Y IN BRAIN, PINEAL GLAND AND PLASMA. R.E. Tessel*, D.A. DiMaggio* and T.L. O'Donohue (SPON: C. Rutledge). Experimental Therapeutics Branch, Neuroendocrinology Unit, NINCDS, NIH, Bethesda, MD 20205.

Acute injection of d-amphetamine sulfate to rats (10 mg/kg) 60 min prior to sacrifice doubled neuropeptide Y-like immunoreactivity (NPY-LI) in the pineal gland but had no effect on gross or micro-dissected brain-regional or plasma NPY-LI concentrations. However, when amphetamine was injected twice daily for six days and once more 60 min prior to sacrifice, several additional changes were found. NPY-LI was decreased in micro-dissected regions of the caudate-putamen, and the paraventricular and dorsomedial nuclei of the hypothalamus, and increased in medial preoptic hypothalamic nucleus and in plasma; NPY-LI in other hypothalamic nuclei was unchanged. Pineal NPY-LI was also elevated. The data indicate that NPY-LI concentrations are susceptible to manipulation by amphetamine but that the extent and direction of change (increase or decrease) depends on the frequency of drug administration and the tissue being sampled. Based on the effects of amphetamine on central and peripheral norepinephrine and epinephrine disposition observed in other studies, the data also suggest that NPY-LI and catecholamine dispositions are not directly correlated and may be inversely related in some tissues.

27.12 COEXISTENCE OF HIGH-AFFINITY UPTAKE MECHANISMS FOR PUTATIVE NEUROTRANSMITTER MOLECULES IN CHICK EMBRYO RETINAL NEURONS IN PURIFIED CULTURE. M. Pessin* and R. Adler, (SPON: P. Hoffman). Wynn Center, Wilmer Institute, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Autoradiographic detection of neuronal labelling with radioactive neurotransmitter molecules is frequently used as a criterion for the identification of different neuronal subpopulations in vitro. The usefulness of this parameter would be somewhat limited, however, if a same neuron could take up more than one putative neurotransmitter via high-affinity mechanisms. To investigate this question, purified neuronal cultures from chick embryo retina were incubated with radioactive GABA, aspartate (ASP) or taurine (TAU) either individually or in binary or tertiary combinations. Measurements of the cells radioactive content showed lack of inhibition when the cultures were exposed to combinations of these radioactive amino acids. The percentage of labelled cells in autoradiograms of cultures exposed simultaneously to two or more radioactive amino acids was substantially lower than the number that would be expected from the values observed in cultures labelled with each amino acid individually. The only possible interpretation for these observations is that there is coexistence of high-affinity uptake mechanisms for GABA, TAU and ASP in cultured retinal neurons. Numerical analysis of the autoradiographic data showed that approximately 20% of the neurons have only the high-affinity uptake mechanism for TAU whereas very few if any neurons have high-affinity uptake mechanisms for GABA alone or ASP alone. Our experiments have also identified populations of cells which take up GABA and TAU (but not ASP) or ASP and TAU (but not GABA). Interestingly, we have not seen any neurons which can take up ASP and GABA and can not take up TAU, whereas as many as 50% of the neurons can take up ASP, GABA and TAU simultaneously.

By showing concomitant uptake of different putative neurotransmitters within individual neurons, then, our results emphasize the limitations of transmitter uptake autoradiography as a criterion for neuronal identification in vitro.

Supported by USPHS Grant EY04859 and Medical Scientist Training Grant 5T32GM07309-10.

27.13 CEREBRAL CORTICAL NEURONS OF DEVELOPING AND ADULT RATS CONTAIN THE TACHYKININS, SUBSTANCE P AND SUBSTANCE K. J.R. Loesche, J.F. McGinty and J.-S. Hong (SPON: M.E. McNeill). Dept. of Anatomy, East Carolina Univ. Sch. Med., Greenville, NC 27834 and Lab Behav. Neurol. Toxicol. NIEHS/NIH Research Triangle Park, NC 27709.

Tachykinin peptides contain a common C-terminal amino acid sequence PHE^{8}-X-GLY-LEU-MET^{11}-NH_2. Recently, Nawa, et al., (Nature 306:32, 1983) have reported that alternative mRNA splicing generates two different preprotachykinin mRNAs in bovine striatum. Alpha preprotachykinin (PPT) contains a single Substance P (SP) sequence whereas beta-PPT contains one SP and one Substance K (SK) sequence. In the course of comparing regional CNS differences in SP and SK distributions, we discovered a wide-spread population of cortical neurons which contained SP and SK immunoreactivity (IR). SP and SK were coupled to thyroglobulin and injected into rabbits. The antigenic determinants of the resulting SP antiserum (SP1) appeared by radioimmunoassay to be between LYS^{3}-PHE^{7} with minimal cross-reactivity with other tachykinins. The SK antiserum (SK3) has less than 1% cross-reactivity with SP. Rats ranging from 2 days postnatal to young adults (150-200 g) were perfused with a 1% saturated picric acid/4% paraformaldehyde solution and brain tissue was prepared for immunocytochemistry as described (McGinty, et al., J. Neuroscience 4:1117, 1984). Adult rats were pretreated with 100-150 µg colchicine in 10-15 µl of saline intraventricularly. The distribution of both peptides was similar if not identical in subcortical and cortical neurons. In the cerebral cortex, SP-IR and SK-IR were barely detectable in neuronal cell bodies by postnatal day 2. The intensity of SP/SK-IR and number of cortical neurons stained increased until the fourth postnatal week when it became necessary to administer colchicine in order to visualize cortical neurons. In an attempt to enhance the intensity of SP immunostaining in cortical neurons of adult rats, a number of free-floating sections were incubated with affinity purified electric eel acetylcholinesterase (80 U/ml phosphate buffer) for 4 hrs prior to incubation with the primary antiserum (Millar and Chubb, Neuroscience 12:441, 1984). In medial frontal and perirhinal cortex, small polymorphic neuronal cell bodies containing SP/SK-IR were surrounded by a dense band of fibers in layers V-VI. A less densely packed band of fibers and fewer immunoreactive cell bodies were present in layers II-III of medial frontal cortex. In the remainder of the neocortex, cell bodies containing SP/SK-IR were present in layers II-III and V-VI. Within the hippocampal formation, SP/SK-IR cell bodies were present in the subiculum and throughout the CA fields and dentate gyrus, scattered in all layers with particular prominence in stratum oriens. AchE incubations markedly enhanced the SP-IR in cortical and hippocampal neurons allowing extensive visualization of neuronal processes and morphology. Radioimmunoassays of SP-IR and SK-IR are underway to determine the SP:SK ratios in discrete cortical regions.

27.14 ACETYLCHOLINE AND PEPTIDE SCP(b) WHICH CO-OCCUR IN AN IDENTIFIED BUCCAL NEURON B11 OF TRITONIA, HAVE OPPOSITE EFFECTS UPON THE FEEDING MOTOR PROGRAM. A.O.Dennis Willows. Friday Harbor Laboratories, Univ. of Washington, Friday Harbor, WA 98250.

In prior experiments, we showed that a large re-identifiable pair of buccal ganglion neurons (B11) in the marine nudibranch mollusc Tritonia diomedia contain the neuroactive peptide SCP(b) and also the classical neurotransmitter acetylcholine (ACh) (P.E. Lloyd, B. Masinovsky, R.E. McCaman, and A.O.D. Willows. Soc. Neurosci. Abstract 209.6, 1981). Additionally, we have shown that intracellular electrical stimulation of B11 modulates the output of the motor program generator (MPG) for swallowing (Willows, A.O.D. and P.E. Lloyd. Soc. Neurosci. Abst. 115.11, 1983). In this work I report that the complex modulation of the MPG elicited by stimulation of B11 has two components. One (initiation of MPG bursting in previously inactive preparations and increased spiking rate during bursts) is mimiced by superfusion of the ganglia with SCP(b) and the other (increased interburst intervals), is mimiced by superfusion with acetylcholine.

In these experiments, B11 was stimulated and recorded in isolated buccal ganglia preparations continuously superfused with sea water to which test serially diluted solutions of SCP(b), and ACh could be added. Additionally, motor neurons B5 were recorded to monitor the output of the MPG. The characteristic background activity of the MPG in the unstimulated preparation was cyclic volleys of subthreshold psp's or bursts. Intracellular stimulation of B11's (5-7 Hz for 30 s) elicited three prominent changes in the output of the MPG all of which outlasted the period of stimulation by as much a 3 min.: (i) enhanced likelyhood of B5 firing in bursts, in preparations that were inactive, (ii) increased spike rate in the bursts, and (iii) decreased burst rate. In summary, B11 stimulation turns on the MPG, and both intensifies the bursts and reduces their frequency.

As reported earlier, exposure to SCP(b) alone in the perfusion solution enhances the bursting likelyhood, increases the spike rate within bursts, and increases the bursting rate.

In the present experiments I report that exposure to ACh causes the rate of bursting to be reduced in a dose dependent manner, and blocks it completely at about 5X10-3M. However, ACh does not markedly alter the firing rate during each burst. Furthermore, during ACh exposure the membrane of B5 is prominently depolarized, and the input resistance of the cell is reduced, indicating a membrane conductance increase.

These results are consistent with the suggestions that SCP(b) and ACh are released from B11 and that they may produce the combined enhancement and inhibition of the MPG respectively, as seen when B11 is electrically stimulated.

27.15 **EFFECTS OF THE PENTAPEPTIDE, PROCTOLIN, ON RAT SPINAL MOTONEURON EXCITABILITY.** S.R. White (SPON: F.White). Dept. of VCAPP, Col. of Vet. Med., Washington State Univ., Pullman, WA 99164.

Proctolin, originally identified in proctodeal nerves of the cockroach, enhances contractions of a variety of arthropod neuromuscular preparations and modulates excitability of certain insect central nervous system neurons. Recently, proctolin-like immunoreactivity has been identified in cell bodies in the caudal medulla oblongata of rats and in terminal plexuses near cell bodies and dendrites of large motoneurons in rat spinal cord ventral horn. Much of the proctolin-like immunoreactivity appeared to be co-localized in somata and terminals with serotonin-like immunoreactivity. Serotonin is known to enhance spinal motor neuron excitabilitiy in rats, but nothing is known about the effects of proctolin on mammalian neuronal activity. The present study compared the effects of iontophoretically applied serotonin and proctolin on lumbar motoneuron excitability in urethane-anesthetized rats.

Seven barrel microdot glass micropipettes contained NaCl, 4.0 M, pH 7, for recording extracellular action potentials, for automatic current balance and for control current ejection; glutamate, 0.2 M, pH 7, for activating the silent motoneurons; 5-hydroxytryptamine bimaleate (5HT, serotonin), 0.16 M, pH 4; and proctolin, 0.002 M, pH 6, in 0.9% NaCl. Motoneurons were identified electrophysiologically and were driven at low stable firing rats by automatically cycled ejections of glutamate. 5HT, applied with low ejection currents (15-20 nA, 60 sec) consistently facilitated glutamate evoked motoneuron excitability without directly firing the motoneurons in the absence of glutamate. Proctolin (10-40 nA, 30-120 sec) had less consistent effects on motoneuron excitability than did 5HT. Although proctolin facilitated glutamate evoked excitation of 14/20 motoneurons tested, the facilitation was delayed as much as 90 sec after current offset in some cells and was not consistently repeatable within the same cell. Electrode barrels containing proctolin tended to block after several current applications which may account for the lack of repeatability of proctolin effects in some cells. Application of proctolin by micropressure may produce more consistent facilitation of motoneuron excitability than was found in the present study using microintophoretic application. However, the majority of cells in the present study responded to proctolin and serotonin application in a qualitatively similar manner. Both substances produced a delayed, long lasting facilitation of motoneuron excitability which was sometimes preceded by a brief period of inhibition during current application.

27.16 INTERACTION OF CHOLECYSTOKININ AND DOPAMINE IN THE NUCLEUS ACCUMBENS AND IN THE DORSAL HIPPOCAMPUS: MICROIONTOPHORETIC STUDIES IN THE RAT. G. de Bonnel* and C. de Montigny. Centre de recherche en sciences neurologiques and Institut Philippe Pinel, Université de Montréal, Montréal, Canada.

Cholecystokinin (CCK) and dopamine (DA) coexist in a subpopulation of neurons of the ventral tegmental areas (VTA) projecting to the nucleus accumbens and other limbic areas. DA neurons of the VTA projecting to the dorsal hippocampus do not contain CCK. The present experiments were carried out to study the interaction of CCK and DA in these two regions in naive rats and in rats in which DA neurons of the VTA had been destroyed.

Male Sprague-Dawley rats (200-400 g) were injected unilaterally in the VTA with 12 µg of 6-hydroxydopamine (6-OHDA) under chloral hydrate anesthesia (400 mg/kg, i.p.), one hour after a pretreatment with desipramine (25 mg/kg, i.p.) to protect the noradrenergic system. One to three weeks later, five-barrelled micropipettes were used for extracellular recordings of dorsal hippocampus pyramidal neurons and of neurons in the dorsomedial part of the nucleus accumbens, under urethane anesthesia (1.25 g/kg, i.p.). The following solutions were used for microiontophoresis: sulphated octopeptide CCK (1 µM or 10 µM in 200 mM NaCl; pH: 5), DA (100 mM; pH: 4), kainate (KA) 1 mM in 400 mM NaCl; pH: 8), glutamate.HCl (GLU) (20 mM in 20 mM NaCl; pH: 8). DA was assayed with HPLC from punches of the dorsomedial region of the nucleus accumbens.

The 6-OHDA injection produced an 80% decrease of DA content in the ipsilateral nucleus accumbens. In the latter nucleus, the excitatory effect of CCK was markedly increased. The inhibitory effect of DA on KA- and GLU-induced activations was also increased. Strikingly, however, when the neurons were activated with CCK, DA applications resulted in the same degree of inhibition in naive and 6-OHDA rats.

In the dorsal hippocampus ipsilateral to the 6-OHDA injection, the effect of CCK was unchanged in both the CA_1 and CA_3 regions. The effect of DA was markedly enhanced in the CA_1 region, whether the neurons were activated with CCK or KA. However, the effect of DA was not modified in the CA_3 region by the 6-OHDA injection.

The present finding of a supersensitivity to CCK in the nucleus accumbens but not in the hippocampus following a VTA lesion is consistent with the coexistence of CCK and DA in the projection to former but not to the latter. The fact that, in the accumbens, a supersensitivity to DA was present when the neurons were activated with GLU or KA but could not be detected when they were activated with CCK might be an indication of a postsynaptic interaction between the cotransmitters CCK and DA. The absence of supersensitivity to DA in CA_3 suggests that this hippocampal region does not receive a DA input from the VTA.

CHARACTERIZATION OF CHOLINERGIC RECEPTORS I

28.1 METHYLLYCACONITINE, A NATURALLY OCCURRING INSECTICIDE WITH A HIGH AFFINITY FOR THE INSECT CHOLINERGIC RECEPTOR. K. R. Jennings, D. G. Brown* and D. P. Wright, Jr.*, Agricultural Center, American Cyanamid Co., P. O. Box 400, Princeton, NJ 08540.

The seeds of Delphinium (Ranunculaceae) have long been know to possess insecticide properties. The earliest recorded reference to the use of the plant as an insecticide is given in the Naturalis Historia by Pliny, where it is described as a treatment for headlice control.

An experiment was conducted to evaluate the insecticidal properties of chloroform extracts of seeds from the Delphinium hybrid cv. "Pacific Giant", King Arthur. An oil prepared from these seeds was demonstrated to have insecticidal and/or antifeeding properties against a series of insects and mites including: Spodoptera eridania (Cramer), Empoasca abrupta Delong and Tetranychus urticae Koch.

Preparative TLC of the alkaloidal component gave six fractions. Fraction 3 was observed to be a very potent inhibitor of ^{3}H-propionyl-α-bungarotoxin binding to the nicotinic cholinergic receptor in a Musca domestica head homogenate preparation. This alkaloid was shown by mass spectrometry, ^{13}C and proton NMR spectroscopy to be methyllycaconitine (MLA). A pure sample of MLA.citrate was obtained from Dr. Benn of the University of Calgary. This material displayed insecticidal activity similar to that observed for the original seed extract.

In addition, the Kinh values obtained for the pure MLA.citrate were identical to those observed for the Delphinium oil TLC fraction 3: Kinh=0.25 ± 0.05 nM. This very potent inhibitor of the insect receptor may prove to be a useful neurobiological tool for studies of the comparative pharmacology of cholinergic receptors.

28.2 STRUCTURAL AND PHARMACOLOGICAL STUDIES ON THE CHOLINERGIC RECEPTOR FROM MANDUCA SEXTA. D.J. Prescott* and M.L. Perez* (SPON. E. Yadin). Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

The brain (protocerebrum, subaesophageal ganglion, optic and antennal lobes) of the hawk moth, Manduca sexta is a rich source of acetylcholine receptor. The AchR is an integral membrane protein, since disruption of the membrane is required for maximal extraction. High concentrations of salt are also necessary for maximal extraction. Even in the presence of 1% Triton X 100 large aggregates of the receptor are detected in sucrose density gradients. The approximate sedimentation value of 9S for the toxin-receptor complex may represent the monomeric structure with larger aggregates forming during storage or conditions of low ionic strength and dilute detergent. Pharmacological studies have revealed that AchR exhibits largely nicotinic character. The following drugs were shown to inhibit formation of the radioiodinated alpha-bungarotoxin-receptor complex starting with the most effective: nicotine, gallamine, curare, atropine, carbachol, and decamethonium, while hexamethonium and muscarine had little effect at 10^{-3}M. The I_{50} values for these drugs fall in the range of 10^{-5}M to 10^{-3}M which indicates that this receptor has similar sensitivity to these agents compared to that of the Drosophila receptor except for nicotine. The Manduca receptor appears to be less sensitive to this agent by about one order of magnitude than that of Drosophila. This may represent a functional adaptation of the receptor since high concentrations of nicotine are present in hemolymph of the larval stages when the organism is consuming a diet of tobacco leaves. Since the antennal lobes of Manduca exhibit sexual dimorphism [Matsumoto, S.G. and J.G. Hildebrand Proc. R. Soc. Lond., B213, 249 (1981)], with the male lobe exhibiting an additional large macroglomerular area, we are quantitating the amount of receptor present in male vs. female lobes.

28.3 KAPPA-BUNGAROTOXIN: BINDING OF A NEURONAL NICOTINIC RECEPTOR PROBE TO CHICK OPTIC LOBE AND SKELETAL MUSCLE. V.A. Chiappinelli, K. Wolf* and A. Ciarleglio*. Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

Kappa-Bungarotoxin (KBgT) is a snake venom neurotoxin isolated from the venom of Bungarus multicinctus (Chiappinelli, Brain Res. 277:9, 1983) that blocks nicotinic transmission in a variety of autonomic ganglia (Chiappinelli and Dryer, Neurosci. Letts. 50: 239, 1984). This property distinguishes the toxin from alpha-bungarotoxin (ABgT), which is ineffective in blocking transmission in avian and murine autonomic ganglia.

The complete amino acid sequence of KBgT has recently been obtained (Grant and Chiappinelli, Biochemistry 24:1532, 1985). While the toxin demonstrates considerable homology (47%) with the long postsynaptic neurotoxins (a family of polypeptides to which ABgT also belongs), several structural features of the toxin are unique. Of particular interest is the shortened COOH-terminal tail, which KBgT shares with only one other postsynaptic toxin, namely L.s. III. In addition, KBgT is the only postsynaptic neurotoxin which exists entirely in dimeric form in physiological buffers (Chiappinelli and Lee, J. Biol. Chem. 1985, in press).

To examine which of the structural features of KBgT most likely account for its unusual physiological effects, a series of binding experiments was carried out in skeletal muscle and optic lobe homogenates from chick embryos.

Skeletal muscle nicotinic sites. A single nicotinic site was detected in skeletal muscle by all three neurotoxins tested. The IC_{50} values for inhibition of ^{125}I-ABgT binding were as follows: ABgT=0.56 nM; L.s. III=20.3 nM; KBgT=127 nM. Hill plots of the competition data yielded slopes approximating unity for all three toxins.

Optic lobe nicotinic sites. Both ABgT and L.s. III bound with similar affinity (Kd=1.8 nM) to a high concentration (14.4 fm/mg tissue) of nicotinic sites in optic lobe. In contrast, KBgT bound to only a portion of these sites with high affinity (3.36 fm/mg tissue; Kd=1.3 nM). At higher doses, KBgT bound to the remaining sites detected by the other two neurotoxins. The Hill plot of the KBgT data revealed a slope of 0.51, indicating the presence of either negative cooperativity or multiple sites with differing affinities. Evidence obtained thus far favors the hypothesis that KBgT distinguishes two different classes of neuronal nicotinic sites. It remains to be shown which of these neuronal nicotinic sites is involved in nicotinic transmission in the optic lobe.

28.4 LOCATION OF A POLYPEPTIDE SEQUENCE WITHIN THE α-SUBUNIT OF THE ACETYLCHOLINE RECEPTOR CONTAINING THE CHOLINERGIC BINDING SITE. N.D. Boyd,* B. Oblas,* and R.H. Singer* (SPON: J. Walsh) Dept. of Physiol., Univ. Mass. Med. Sch., Worcester, MA 01605

The identification of the location of the acetycholine (AcCh) binding site on the primary sequence of the α-subunit of the nicotinic AcCh receptor is important information for understanding the molecular basis of AcCh receptor activation. We have previously addressed this question by identifying through the use of a nitrocellulose protein transfer binding assay, various proteolytic fragments of the α-subunit of the AcChR from Torpedo electric organ that contain the α-bungarotoxin (α-BgTx) binding site. Here we report further studies in which a toxin binding fragment of the α-subunit (M_r=17K), was obtained by V_8 protease digestion, isolated by preparative SDS-PAGE and chemically characterized. The amino acid sequence at the amino-terminus of this 17K polypeptide fragment is Val-Asn-Gln-Ile-Val-Glu which is identical to a unique sequence on the α-subunit beginning at Val_{46}. The 17K polypeptide fragment was shown to contain carbohydrate and thus Asn_{141}, the only site of N-glycosylation on the α-subunit. The 17K polypeptide fragment was not labelled by 4-(N-maleimido) benzyl-tri[^{3}H]methylammonium iodide and thus does not contain $Cys_{191}$the site of attachment of this cholinergic affinity ligand. Based on considerations of the apparent molecular weight of the fragment, the enzyme specificity of V_8 protease, computer analysis of the partial amino acid composition of the 17K polypeptide fragment, together with the above identifying landmarks, the most likely locations of the carboxy-terminus are Glu_{161}, Glu_{172} or Glu_{175}. Although the carboxy-terminus is thus 15-30 amino acids residues distant on the primary sequence of the α-subunit from Cys_{191} which has been proposed to be part of a reducible disulphide bond that is within 1nm of the AcCh binding site, both non-radiolabelled αBgTx and d-tubocurarine were able to displace ^{125}I-αBgTx binding to the 17K polypeptide fragment with potencies of IC_{50}=100nM and 600μM respectively. These values are not significantly different from those obtained in similar experiments using the intact α-subunit indicating that the 17K polypeptide sequence contains all the essential structural elements present in the undigested α-subunit that are necessary for the binding of both cholinergic ligands.

The 17K polypeptide sequence is located in the middle of a large extracellular hydrophilic domain of the α-subunit and is predicted to have a highly ordered structure which may account in part for the existence within the cholinergic binding region of sufficient secondary and tertiary structure to bind α-BgTx and d-tubocurarine despite prior exposure to high concentrations of the denaturing detergent SDS.

28.5 AMINO ACID SEQUENCE OF A NEUROTOXIN THAT BLOCKS NEURONAL NICOTINIC RECEPTORS AND THE LOCALIZATION OF ITS BINDING SITES IN CHICK CILIARY GANGLION. R.H. Loring and R.E. Zigmond. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

The amino acid sequence has been determined for toxin F, a postsynaptically acting neurotoxin purified from the venom of Bungarus multicinctus (Loring et al., Neuroscience 11:989, 1984). Toxin F blocks nicotinic transmission in the chick ciliary ganglion and in the rat superior cervical ganglion (Loring et al., Neurosci. Abst. 9:1143, 1983). α-Bungarotoxin, a toxin derived from the same snake venom and well known for its ability to block nicotinic transmission at the neuromuscular junction, has no effect on transmission in these ganglia. When compared to previously sequenced snake toxins, toxin F has greatest sequence homology with the "long" postsynaptic neurotoxins although it has a number of unusual features. For example, it contains the following unusual sequence starting at position 22:

F L K A Q C D K F C S I R G P V I E Q G.

In other postsynaptic neurotoxins, positions 22-41 are considered to contain most of the functional residues involved in binding to the receptor. The six underlined residues are unusual substitutions including a Phe/Tyr substitution at position 22 and a Gln/Trp substitution at position 26. Tyr-22 and Trp-26 are usually invariant in postsynaptic neurotoxins.

To determine the localization of toxin F binding in the chick ciliary ganglion, ganglia were incubated at 37°C in 10 nM ^{125}I-toxin F for 45 min. Previous work in our laboratory has demonstrated that toxin F binds to two sites in this ganglion, one to which α-bungarotoxin also binds and an additional site unique to toxin F. Therefore, 1 μM α-bungarotoxin was present to prevent ^{125}I-toxin F binding to the α-bungarotoxin site. Control ganglia were incubated in ^{125}I-toxin F in the presence of 1 μM unlabeled toxin F or 100 μM dihydro-β-erythroidine (DHBE), a nicotinic antagonist. The ganglia were fixed in aldehydes, counted in a gamma counter, and then sectioned for electron microscopic autoradiography. Of 307 autoradiographic grains observed within 0.25 μm of neuronal plasma membranes, 117 (38%) were within 0.25 μm of synaptic profiles. In the presence of unlabeled toxin F or DHBE, few grains were observed near plasma membranes of ciliary neurons. A previous study in our laboratory demonstrated that less than 3% of the autoradiographic grains observed from the localization of ^{125}I-α-bungarotoxin binding to ciliary neurons were found within 0.25 μm of synaptic profiles (Neuroscience 14:645, 1985). Together, these results demonstrate that the α-bungarotoxin binding site and the unique toxin F binding site are distributed differently over the surface of ciliary neurons and suggest that toxin F is a useful probe for localizing neuronal nicotinic receptors. Supported by USPHS grants NS12651 and MH00162.

28.6 MONOCLONAL ANTIBODIES THAT DISTINGUISH BETWEEN THE TWO α-BUNGAROTOXIN-BINDING SITES OF TORPEDO-ACETYLCHOLINE RECEPTOR. A.J.Dowding* and Z.W.Hall. Dept. Physiol., Univ. Calif., San Francisco, CA 94143.

Antigenic differences between the two cholinergic ligand-binding sites of acetylcholine receptor (AChR) from Torpedo marmorata have been demonstrated using Mabs (e.g. Watters,D.and Maelicke,A.,Biochem.22:1811-1819, 1983). However, the molecular causes for these antigenic differences remain to be elucidated. The most likely reasons for these differences are either that the posttranslational modifications are not identical for the two α-subunits or that their antigenicities may be modulated by their neighboring δ- and β- or β- and γ-subunits. The positions of the ligand-binding sites within AChR dimers may also influence their antigenicities.

In order to obtain probes with which to investigate these possibilities we have generated a library of hybridomas that secrete Mabs against detergent solubilized Torpedo-AChR, which compete with α-bungarotoxin (α-BTX). Female C57 Bl mice were immunized with α-BTX-AChR complex and then treated with cycloposphamide with the intention of suppressing the immune response against various regions of AChR other than the masked toxin-binding site. Three weeks later, the mice were immunized with AChR alone and finally they were boosted with AChR in saline on three consecutive days prior to fusion with SP2/0 myeloma cells.This method was based on that of W.D. Matthews and P.H. Patterson (Cold Spring Harb. Symp. Quant. Biol. 48, 625-631). In the best two fusions using this protocol, about 20-25% of the hybridomas against AChR secreted Mabs which were found to be blocked by α-BTX and which also inhibited α-BTX-binding to AChR.

When tested against detergent solubilized AChR, two of the Mabs blocked 100% of toxin-binding, five caused 50% inhibition and four caused about 20% inhibition. The Mabs which cause partial inhibition of α-BTX-binding fall into two mutually exclusive classes as shown both by competition between Mabs in direct binding experiments and by assays to detect additive or nonadditive inhibition of α-BTX-binding by various pairs of Mabs. Because both classes of Mab bind to the same AChR molecules, our results suggest that each class of Mab is specific for one of the two toxin-binding sites in the AChR pentamer. With the exception of one Mab (which blocks 50% of α-BTX-binding to solubilized AChR) all of these Mabs bind to Torpedo-AChR in membranes. All of the Mabs which react with membrane-bound AChR, are partially or fully inhibited from binding to detergent solubilized AChR by various cholinergic agonists or antagonists. Further characterization of these and other toxin-blocking Mabs is in progress.

28.7 IDENTIFICATION OF THE Mr-43,000 N_3ATP-BINDING PROTEIN IN TORPEDO POST-SYNAPTIC MEMBRANES. K. Miles, S. Froehner, and R. Huganir. Lab. Mol. & Cell. Neurosci., The Rockefeller Univ., N.Y., N.Y. 10021. Dept. Biochem., Dartmouth Med. School, Hanover, N.H. 03755

We recently demonstrated the existence of an endogenous tyrosine-specific protein kinase in postsynaptic membranes enriched in the nicotinic acetylcholine receptor (AcChR) isolated from the electric organ of Torpedo californica. The tyrosine-specific protein kinase phosphorylated the β, Y, and δ subunits of the Torpedo AcChR. In an effort to identify this protein kinase, postsynaptic membrane fractions enriched in AcChR were incubated with [Y-^{32}P] 8-azido ATP (N_3ATP) under optimal conditions for tyrosine protein kinase activity. N_3ATP, when photo-activated by UV light, binds covalently to ATP-binding sites. In agreement with previous reports by Gordon et.al. (PNAS 79:3666,1982), a Mr-43,000 protein was specifically labeled in UV irradiated samples. However, it is well established that there are at least three proteins migrating in Mr-43,000 in Torpedo membrane fractions. These are ν_1 (the 43K protein associated with the AcChR and located on the cytoplasmic surface of the postsynaptic membrane), ν_2 (creatine kinase) and ν_3 (actin). We have determined that N_3ATP does not covalently label the 43K (ν_1) protein but appears to react with a protein with the characteristics of creatine kinase (ν_2). By using monoclonal antibodies against the 43K protein and rabbit antisera against creatine kinase to detect these two proteins on immunoblots, an inverse distribution of 43K and creatine kinase could be seen between cytoplasmic and AcChR-enriched membrane fractions. While creatine kinase was enriched in the cytoplasmic fraction, the 43K protein was found in highest concentrations in the membrane fractions. The distribution of the N_3ATP binding protein corresponded with that of creatine kinase and not the 43K protein. In addition, the Mr-43,000 proteins of Torpedo postsynaptic membranes may be resolved by 2-D electrophoresis. Following N_3ATP labeling and 2-D electrophoresis, only one protein in the Mr-43,000 range was found to be labeled with N_3ATP. Immunoblot experiments using anti 43K monoclonal antibodies or antisera against creatine kinase established that the N_3ATP binding protein migrated with an isoelectric point similar to that reported for the BB isozyme of creatine kinase. Finally, purified commercially available rabbit BB and MM forms of creatine kinase were labeled with N_3ATP and electrophoresed in parallel with N_3ATP labeled proteins in Torpedo AcChR-enriched membranes. The N_3ATP labeled protein in AcChR-enriched membranes migrated with isoelectric point and Mr similar to that of the N_3ATP labelled BB form of rabbit creatine kinase. Taken together, these findings suggest that N_3ATP-binding activity in the Mr-43,000 range of Torpedo membrane fractions may be attributed to creatine kinase and not to the 43K protein.

28.8 CHARACTERIZATION OF THE TYROSINE-SPECIFIC PROTEIN KINASE WHICH PHOSPHORYLATES THE NICOTINIC ACETYLCHOLINE RECEPTOR R. L. Huganir, A. Hirano and K. Miles. Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

We have recently reported the presence of a tyrosine-specific protein kinase activity in postsynaptic membranes enriched in the nicotinic acetylcholine receptor isolated from the electric organs of Torpedo californica (Huganir et al., PNAS 81:6968-6972, 1984). This tyrosine kinase(s) phosphorylated the nicotinic acetylcholine receptor on tyrosine on the β, Y and δ subunits. The tyrosine kinase(s) also phosphorylates tyrosine on exogenous substrates such as the tyrosine containing synthetic peptides [Val^5]-angiotensin II and poly (Glu^{80}, Tyr^{20}). Using these synthetic peptides as substrates we have started to characterize the acetylcholine receptor tyrosine-specific protein kinase(s). The tyrosine kinase(s) is a membrane associated enzyme which has the characteristics of an integral membrane protein. Alkaline treatment of the postsynaptic membrane which removes peripheral membrane proteins such as the 43K protein does not extract the tyrosine-specific protein kinase activity. The tyrosine kinase activity however is easily extracted from the membrane by nonionic detergents such as NP-40 and Triton X-100. The nicotinic acetylcholine receptor is not itself the tyrosine kinase since the tyrosine-specific protein kinase activity is separated from the receptor after affinity chromatography of detergent extracts of the postsynaptic membrane on an acetylcholine affinity column. The tyrosine-specific protein kinase(s) has a relatively high Km for ATP of ~ 50 μm and has a Km of ~1.0 mM for [Val^5]-angiotensin and a Km of ~ 150 μgm/ml for poly (Glu^{80}, Tyr^{20}). The V_{max} of the tyrosine-specific protein kinase is approximately 50-100 pmoles/min/mg using [Val^5] angiotensin II or poly (Glu^{80}, Tyr^{20}) as substrates. We are currently attempting to purify the tyrosine-specific protein kinase(s) to determine if the kinase is a unique type of tyrosine kinase which is specific for the nicotinic acetylcholine receptor. The possible role of tyrosine phosphorylation in the regulation of the function of the nicotinic acetylcholine receptor will be discussed.

28.9 SPECIFIC ANTIBODIES TO THE cAMP-DEPENDENT PHOSPHORYLATION SITES IN THE ACETYLCHOLINE RECEPTOR. S. Fuchs, M.C. Souroujon*, D. Neumann* and S. Pizzighella*. Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot 76100, Israel.

Phosphorylation of the acetylcholine receptor (AChR) was suggested to be involved in the stabilization of the receptor in the neuromuscular junction. Based on substrate requirements, the putative phosphorylation sites for a cAMP-dependent protein kinase, a tyrosine specific kinase and a calcium phospholipid dependent kinase have been proposed (Huganir et al., PNAS, 81:6968, 1984). We have synthesized a tridecapeptide corresponding to residues 354-366 in the δ subunit of Torpedo AChR and containing the sequence Arg-Arg-Ser-Ser. This sequence has been proposed as the substrate for phosphorylation by an endogenous cAMP-dependent kinase. We have shown that the synthetic peptide is phosphorylated by the catalytic subunit of bovine heart cAMP-dependent kinase, whereas other serine or threonine-containing peptides are not phosphorylated under the same conditions.

Antibodies elicited against peptide 354-366 were shown to cross react with native AChR and to bind specifically to the γ and δ subunits in immunoblotting experiments. This indicates that the phosphorylation sites in the γ and δ subunits are highly cross reactive, and is in agreement with the demonstration that an endogenous cAMP-dependent kinase phosphorylates these two subunits, probably on homologous sequences. Tryptic digestion of the δ subunit isolated from phosphorylated AChR yields a single 25 Kd phosphorylated fragment. Immunoblotting experiments demonstrate that the antibodies against peptide 354-366 bind to this same phosphorylated fragment. Preliminary experiments suggest that the anti-peptide antibodies interfere specifically with the cAMP-dependent phosphorylation of the γ and δ subunits of AChR. Such antibodies are being employed in order to assess the role of AChR phosphorylation in synaptogenesis.

28.10 [^{3}H]ACETYLCHOLINE AND [^{3}H](-)NICOTINE LABEL THE SAME NICOTINIC CHOLINERGIC BINDING SITE IN BRAIN. A.M. Martino*, V. Hamui* and K.J. Kellar (SPON: F.G. Standaert) Department of Pharmacology, Georgetown University School of Medicine, Washington, D.C. 20007.

[^{3}H]Acetylcholine ([^{3}H]ACh) and [^{3}H]nicotine ([^{3}H]N) bind to sites in brain that have characteristics of nicotinic cholinergic receptors. These sites appear to be different from the sites in brain to which alpha-bungarotoxin binds. Autoradiographic analyses indicate that the distributions of [^{3}H]ACh and [^{3}H]N binding sites in brain are virtually identical (Clarke et al., J. Neurosci, 1985). Nevertheless, certain differences between the binding of [^{3}H]ACh and [^{3}H]N to homogenate preparations have raised questions of whether these two ligands bind to the same site. For example, the K_d of [^{3}H]ACh is approximately 10 nM, but the IC_{50} value of acetylcholine in competing for [^{3}H]N binding sites was found to be greater than 200 nM in some studies. Similarly, the K_i of carbachol for [^{3}H]ACh binding sites is approximately 13 nM, but its apparent affinity for [^{3}H]N binding sites was found to be 500-2000 nM. In addition, the reported distribution of the [^{3}H]N binding sites in homogenates appears to be different from that of [^{3}H]ACh binding sites.

These apparent differences between [^{3}H]ACh and [^{3}H]N binding characteristics could be due to differences in incubation conditions, such as temperature and duration of incubation, as well as to the use of racemic [^{3}H]N, which binds to two sites in brain. We have compared the binding of [^{3}H]ACh and [^{3}H](-)nicotine ([^{3}H](-)N) in rat brain homogenates incubated in parallel under the same conditions: 2°C, 45 min, presence of 100 uM DFP to inhibit cholinesterases and 1.5 uM atropine to occupy muscarinic receptors. Nonspecific binding was defined in the presence of 100 uM carbachol. In cerebral cortex under these conditions, both [^{3}H](-)N and [^{3}H]ACh bind to a single class of sites (n_H = 1) with a density (B_{max}) of 3-4 fmol/mg tissue. The K_d of [^{3}H](-)N is 4 nM and that of [^{3}H]ACh is 10 nM. In competition experiments, the K_i of acetylcholine for the [^{3}H](-)N binding site is 12 nM, and the n_H = 1, while the K_i of (-)nicotine for the [^{3}H]ACh binding site is 6 nM and the n_H = 1. The K_i of cytisin, a nicotinic agonist, is approximately 1 nM in competition against either [^{3}H](-)N or [^{3}H]ACh. Regional distribution studies of [^{3}H](-)N and [^{3}H]ACh binding sites indicate that the density of sites for both ligands is high in the thalamus, cerebral cortex and striatum and low in the hippocampus. Taken together, these data strongly suggest that [^{3}H](-)N and [^{3}H]ACh label the same nicotinic cholinergic site under these conditions. Furthermore, in rats treated with nicotine (1 mg/kg twice daily for 10 days), both [^{3}H](-)N binding sites and [^{3}H]ACh binding sites are increased by approximately 30%.

28.11 PYRIDOSTIGMINE AFFECTS THE RECEPTORS ON GUINEA PIG ILEUM MUSCLES IN A COMPLEX MANNER. P.L. Donaldson, B. O'Neill*, M.E. Wettig*, and K.J. Gall*. Neurotoxicology Branch, US Army Med Rsch Inst of Cml Def, Aberdeen Proving Ground, MD 21010-5425.

Pyridostigmine (PYR), a reversible inhibitor of acetylcholinesterase (AChE), has been shown to be an agonist to nicotinic cholinergic receptors in skeletal muscle, but PYR's effects on muscarinic acetylcholine receptors (mAChR) are not well known. To examine these effects, PYR was assayed on the isolated guinea pig ileum. One inch pieces of ileum were placed in tissue baths containing warm (34-37°C) Tyrodes solution with Hexamethonium Bromide 0.1 mM and Diphenhydramine 1 uM (pH=7.6). Dose-response curves were obtained for acetylcholine (ACh) and carbachol (CARB). ACh (1-5 nM) initiated a small contraction and a peak response at 0.5-1 uM. Concentrations of ACh greater than 1 uM caused a gradual decline in the contractile amplitude. In contrast, CARB initiated contractions at 5-10 nM, a peak contraction at 1-10 uM, and a decline in contractile amplitude at concentrations above that. Muscles exposed to pyridostigmine without any previous exposure to an agonist or antagonist did not respond until the concentration was >= 1 mM. At 1-5 mM, pyridostigmine elicited a very dramatic relaxation in the muscle tone that persisted for the duration of the exposure. At these doses, the carbamate also abolished all spontaneous contractions in the muscle. When the muscle was washed with normal Tyrodes, the muscle tone recovered rapidly, while the spontaneous contractions returned at a much slower rate. When the muscle was first exposed to an agonist, used as a "primer," the responses were much more variable. After CARB, the muscle usually reacted much as it did to pyridostigmine without a primer. Its tone relaxed and the spontaneous contractions were always abolished at high concentrations of pyridostigmine. Occasionally, there was a slight increase in tone exhibited at concentrations of 1-2 uM. In contrast, after ACh, pyridostigmine exhibited a biphasic response; at concentrations of 1-100 uM the muscle contracted, while at the usual high concentrations (1-5 mM) the muscle relaxed. Pyridostigmine after DFP, an essentially irreversible inhibitor of AChE, did not have a much greater response, suggesting that the effects it had on the muscarinic receptor were independent of its affinity for AChE. These data suggest that pyridostigmine may have some direct effects on the muscarinic ACh receptor of smooth muscle, but just how it is affecting the muscle to cause both contractions and a decrease in muscle tone at different concentrations is unresolved.

28.12 CHARACTERISTICS OF ACETYLYCHOLINE RECEPTOR-IONIC CHANNELS (ACHR) ACTIVATED BY THE SECONDARY AMINE (+) ANATOXIN. K.L. Swanson[1], C.N. Allen[1], R.S. Aronstam[2], and E.X. Albuquerque[1]. [1]Dept. Pharmacol. & Exper. Therap., Univ. Maryland Sch. Med., Baltimore, MD 21201, [2]Dept. Pharmacol & Toxicol. Med Col. Georgia, Augusta GA 30912.

(±)-Anatoxin-a (AnTX) is a semi-rigid nicotinic agonist which is more potent than acetylcholine (ACh) in inducing contractures of frog rectus abdominus muscle. Further, (+)-AnTX is a more potent agonist than ACh or its enantiomer (-)-AnTX. However, the decay of end-plate currents were the same for carbamylcholine and (±)-AnTX and the ionic channel conductance measured by fluctuation analysis was less for (±)-AnTX than carbamylcholine (Spivak et al., Mol Pharmacol 18: 384, 1980). We therefore used receptor binding and patch clamp techniques to investigate the mechanisms mediating the potency of (+)- and (-)-AnTX.

The AChR of frog interosseal muscles was studied using cell-attached patch clamp techniques. The ionic channels were activated at 20 and 200 nM (+)-AnTX and occurred in bursts of openings. Very high concentrations of (-)-AnTX were required to activated channels. The conductances of channels activated by ACh (27 pS) and (+)-AnTX (28 pS) were similar. The mean duration of individual openings was shorter with (+)-AnTX than with ACh. Short closures, which interrupted the bursts, failed to demonstrate the kinetics common to most ionic channel blockers: 1) the duration of short closures (τ = 0.3-0.5 msec) and the number of openings per burst were voltage independent and 2) the frequency of closures was concentration independent (20-200 nM). The toxin-bound receptor entered a closed channel conformation from which reactivation was voltage independent. Hypotheses describing the possible significance of the short closures will be discussed. Because the unique kinetics may be related to the binding of a secondary amine (pK_a = 9.36) to the receptor, the characteristics of channels activated by other secondary and tertiary amine agonists including arecoline, arecolone and nicotine have also been explored.

The AChR from Torpedo californica had higher affinity for (+)-AnTX (K_d = 80 nM) than (-)-AnTX (K_d = 4000 nM) and (+)-AnTX also had higher affinity than ACh (K_d = 300 nM). The rate of desensitization was slower with AnTX (50% maximal effect at 3 min) than with ACh (50% maximal effect at 1.2 min). These binding data suggest that (+)-AnTX is a more potent agonist than ACh due to its greater affinity for the receptor and its lower rate of desensitization. (Supported by U.S. Army Med. Res. & Devel. Command Contract DAMD 17-84-C-4219.)

28.13 EFFECTS OF SUBSTANCE P ON CARBAMYLCHOLINE-INDUCED DESENSITIZATION OF NICOTINIC ACETYLCHOLINE RECEPTORS IN THE NEURONAL CELL LINE PC12. G. A. Weiland and S. M. Simasko. Department of Pharmacology, NYSCVM, Cornell University, Ithaca, NY 14853.

Substance P (SP) has been shown in a number of systems to modulate nicotinic acetylcholine receptor function by noncompetitive inhibition of receptor activation. In the neuronal cell line PC12 this appears to reflect an enhancement of desensitization. To further investigate this mechanism we examined the effect of SP on desensitization in PC12 cells. Exposure of the cells to carbamylcholine (CARB) caused a decrease in the subsequent CARB-induced rate of $^{22}Na^+$ flux. The rate of onset of CARB-induced desensitization appeared to be increased by SP. However, SP by itself also appeared to induce desensitization. The steady state level of desensitization induced by CARB was concentration dependent (EC50 = 32 μM) and at maximum steady state desensitization 15% of the control flux rate remained. SP increased the apparent potency of CARB; 1 μM SP decreased the steady state EC50 16 μM. However the peptide had no effect on the maximum level of desensitization. Examination of the time course of recovery following 15 min exposure to CARB revealed two components of desensitization. The rate of the first component of recovery (k = 0.5/min) was independent of the inducing concentration of CARB and was not affected by the presence of SP during desensitization. This recovery from CARB-induced desensitization was slower than recovery from desensitization induced by SP alone (k = 0.8/min) or by the less potent analog 7-11SP (k = 1.2/min). For concentrations of CARB greater than 0.1 mM, recovery was not complete and flux rates plateaued below control values. We have termed this nonrecoverable component inactivation. The extent of inactivation was dependent on the concentration of CARB (20% at 0.1 mM, 40% at 1 mM). This inactivation appeared to be mediated specifically by the nicotinic receptor since it was blocked by d-tubocurarine, could not be produced by depolarization of the cells with high K^+, and was not accompanied by increased LDH in the medium. SP alone did not appear to induce an inactivation as seen with CARB, but the peptide did increase the amount of inactivation produced by CARB (from 20% with 0.1 mM CARB alone to 40% with 0.1 mM CARB plus 1 μM SP). It thus appears that there are two components to desensitization in PC12 cells. SP can modulate nicotinic receptor function by affecting both processes, adjusting receptor responsiveness in the minute time range by increasing the rate of desensitization and adjusting receptor responsiveness over longer periods by increasing the extent of inactivation. (Supported by NSF BNS 82-15572)

28.14 ACETYLCHOLINE RECEPTOR SYNTHESIS IN RETINA & TRANSPORT TO OPTIC TECTUM IN GOLDFISH. J. Henley*, J. Lindstrom and R.E. Oswald. Department of Pharmacology, N.Y.S. College of Veterinary Medicine, Cornell University, Ithaca, NY 14853, USA, and The Salk Institute for Biological Studies, San Diego, CA 92138 USA.

Previous studies have suggested that the retinotectal system of the goldfish contains a nicotinic acetylcholine receptor which is sensitive to α-bungarotoxin (Oswald & Freeman, Neurosci., 6 (1981) 1-14). Extracellularly recorded field potentials elicited in response to visual stimulation can be blocked by α-bungarotoxin, and α-bungarotoxin can interfere with the maintenance of retinotectal synaptic connections. The question remains as to whether the transmission between the retinal ganglion cells and the tectal cells is mediated by acetylcholine and whether acetylcholine receptors exist on the dendrites of tectal cells. These experiments were designed to determine the site of synthesis of the acetylcholine receptors associated with the goldfish retinotectal projection. We have found that a subset of monoclonal antibodies raised against Electrophorus electricus and Torpedo california electroplaque acetylcholine receptor are capable of interacting with α-bungarotoxin binding protein in goldfish retina and tectum. Immunohistochemistry with a fluorescent second antibody demonstrated that the antibody binding colocalizes with α-bungarotoxin binding in the goldfish optic tectum. To determine the site of synthesis of these receptors, [^{35}S]methionine was injected into one eye, and the incorporation of radioactivity into acetylcholine receptors was measured by immunoprecipitation using a monoclonal antibody. Immunoprecipitation could be inhibited by preincubation of detergent solubilized retinal or tectal membranes with Sepharose 4B coupled to α-bungarotoxin or by inclusion of affinity chromatography-purified acetylcholine receptor from Torpedo nobiliana electroplaque in the immunoprecipitation cocktail. Radioactivity was found to be incorporated into the acetylcholine receptor in the contralateral optic tectum 6 hours after injection into the eye, and the radioactivity incorporated peaked at 12 hours after injection. Furthermore, the incorporation of radioactivity into the acetylcholine receptor in the contralateral tectum could be totally blocked by crushing the optic nerve immediately before the injection. These results suggest that the nicotinic acetylcholine receptor associated with the goldfish retinotectal projection is synthesized in the retina and transported to the optic tectum.

29.1 FUNCTIONAL AND PHYSICAL STUDIES OF GUANINE NUCLEOTIDE REGULATORY PROTEINS IN MUSCARINIC RECEPTOR MEDIATED PHYSIOLOGICAL RESPONSES IN THE EMBRYONIC CHICK HEART. J.M. Martin*, E.M. Subers*, S.W. Halvorsen*, and N.M. Nathanson. Dept. of Pharmacology, Univ. of Washington, Seattle, WA 98195.

Activation of muscarinic receptors (mAChRs) by agonists in chick atria but not ventricles causes an increase in K^+ permeability. Because of suggestions that this may be due to differences in the guanine nucleotide regulatory protein associated with the receptor, we compared the properties of these proteins in atria and ventricles from 8-day chick embryos. The affinity of agonists for mAChRs in either the absence or presence of guanine nucleotides was the same in membranes from atria and ventricles; similar concentrations of Gpp(NH)p were required to regulate agonist binding in both tissues. Forskolin-stimulated adenylate cyclase activity in atria and ventricles was equally sensitive to inhibition by Gpp(NH)p. Inhibition of basal adenylate cyclase activity by the muscarinic agonist carbachol was similar in atria and ventricles. After covalent modification by Islet Activating Protein (IAP), two labelled polypeptides were detected with molecular weights of 39 KD and 42 KD, corresponding to N_o and N_i, respectively. Identical amounts of both proteins were found in atrial and ventricular membranes. Isoelectric points of atrial and ventricular forms of the IAP labelled substrates were identical. Peptide mapping demonstrated that while the 39 KD and 42 KD proteins had non-identical peptide maps, atrial and ventricular peptide maps were identical. Thus, the regulation of K^+ permeability by mAChRs in atria but not ventricles does not appear to be due to a qualitative or quantitative alteration in N_i or N_o, since these two proteins appear to be functionally and physically identical in atria and ventricles.

To investigate if N_o/N_i are involved in mAChR-mediated increases in K^+ permeability, the effect of IAP treatment on mAChR stimulation of $^{86}Rb^+$ efflux from cultured cardiac cells was determined. Treatment of cultures overnight with 5 ng/ml IAP caused complete covalent modification of N_o and N_i and blocked the stimulation of $^{86}Rb^+$ efflux evoked by mAChR agonists. Because previous work has demonstrated that changes in cAMP levels do not mediate mAChR regulation of K^+ permeability, these results suggest that N_o and/or N_i may directly couple the mAChR to the K^+ channel.

29.2 *GUANINE NUCLEOTIDE MODULATION OF MUSCARINIC RECEPTOR BINDING IN PC12 CELLS: EFFECTS OF NERVE GROWTH FACTOR AND ORGANOPHOSPHATES.* *L.H. Davis* and F.C. Kauffman. Dept. Pharmacology & Exp. Therap., University of Maryland School of Medicine, Baltimore, MD 21201.*

Nerve growth factor (NGF)-enhancement of muscarinic receptor binding by rat pheochromocytoma cells (PC12) is inhibited if the cells are exposed to an organophosphate within 30 min of adding NGF. Soman, pinacolyl methylphosphonofluoridate, was approximately 10-fold more potent than DFP in inhibiting this response. Binding of [^{3}H]N-methylscopolamine ([^{3}H]NMS) decreased with passage of cells and varied between different subcultures of PC12 cells. Thus, experiments were performed with early passages of a subculture which contained about 12,000 [^{3}H]NMS binding sites/cell in the absence of NGF and approximately 20,000 binding sites/cell when maintained 2 days in the presence of 100 μg 7S NGF. Half-inhibition of NGF-stimulated binding to whole cell preparations occurred with 70 μM soman. Isolated crude membrane fractions from PC12 cells demonstrated multiple binding sites for [^{3}H]NMS as revealed by Scatchard analyses and competitive binding of the agonist, carbamylcholine. The response to the guanine nucleotide analog, guanylimidodiphosphate (Gpp(NH)p) was also stimulated by NGF as shown below. Pretreatment of PC12 cells with the organophosphate, soman, enhanced the sensitivity to guanine nucleotide regulation in native but not in NGF-treated cells.

Carbamylcholine Inhibition of [^{3}H]-NMS Binding by Membrane Fractions Isolated from Native and NGF-Treated Cells

	Native Cells	*NGF-treated Cells*
	IC_{50}, μM	
Control		
-Gpp(NH)p	*31.6*	*47.3*
+Gpp(NH)p 100 μM	*39.8*	*177.2*
Soman, 50 μM		
-Gpp(NH)p	*70.8*	*30.9*
+Gpp(NH)p 100 μM	*281.8*	*141.2*

The data suggest that NGF treatment increased the sensitivity of muscarinic receptor binding sites in PC12 cells to regulation by guanine nucleotides. Although soman inhibited the elevation of [^{3}H]NMS binding sites produced by NGF-treatment, the organophosphate did not inhibit the reduction in muscarinic receptor affinity for carbamylcholine produced by Gpp(NH)p. (Supported, in part, by US Army Contract DAMD-17-85-C-5091 and NIH grant HD1-6596.)

29.3 INFLUENCE OF HALOTHANE ON MUSCARINIC ACETYLCHOLINE RECEPTOR BINDING AND INTERACTIONS WITH GTP-DEPENDENT REGULATORY PROTEINS. R.L. Dennison, Jr.*[1], B.L. Anthony*[2], G.O. Carrier[2] and R.S. Aronstam[2]. (SPON: B.B. Gallagher). Depts. of [1]Anesthesiol. and [2]Pharmacol. & Toxicol., Med. Coll. of Georgia, Augusta, GA 30912 and [1]Anesthesia Service, Vet. Adm. Med. Ctr., Augusta, GA 30910.

The influence of halothane on muscarinic receptor binding was examined in membranes isolated from rat cerebral cortex and brainstem using [^{3}H]methylscopolamine ([^{3}H]MS) as a probe. Halothane (0.5-10%) enhanced [^{3}H]MS binding in both cortex and brainstem membranes. Halothane (2%) did not affect the number of muscarinic binding sites. [^{3}H]MS binding affinity, however, was increased in the presence of halothane (K_D, air = 0.41 nM; K_D, 2% halothane = 0.26 nM). This increase reflected a 50% decrease in the the dissociation rate constant rather than a change in the bimolecular rate constant of association (Table 1).

Table 1.

	Binding Constants		
Halothane	K_D, nM	k_1, $x10^{-7}M^{-1}min^{-1}$	k_{-1}, $x10^{-3}min^{-1}$
0	0.41±0.03	1.8±0.2	13.0±1.1
2%	0.26±0.04	1.9±0.2	6.5±0.3

Carbamylcholine affinity for brainstem and cortex muscarinic receptors was not affected by halothane. The ability of 5'-guanylylimidodiphosphate (Gpp(NH)p; a stable GTP analogue) to lower carbamylcholine affinity for brainstem receptors, however, was eliminated after equilibration with 2% halothane (Table 2).

Table 2.

		Binding Constants		
Halothane	Gpp(NH)p	B_H	K_H	K_L
0	0	.57±.05	.05±.02	12±4
	10 uM	.40±.03	.13±.04	40±6
2%	0	.54±.04	.06±.03	15±3
	10 uM	.51±.03	.05±.02	18±5

(B_H = fraction of receptors displaying high affinity binding.)

The selective enhancement of muscarinic antagonist binding may reflect the relatively greater importance of hydrophobic interactions in the binding of cholinergic antagonists compared to agonists. Halothane may interact with lipophilic binding domains, thereby stabilizing hydrophobic interactions. The elimination of the guanine nucleotide effect by halothane may reflect a stabilization of the receptor-G protein complex due to either a direct action on the G protein or to an alteration of the physical state of the membrane. Alternately, the ability of G protein to bind guanine nucleotides may have been eliminated by halothane.

Supported by NIH grants HL-31518 and NS-17429.

29.4 **ONTOGENY OF MUSCARINIC RECEPTOR BINDING SITES AND MUSCARINIC RECEPTOR-MEDIATED STIMULATION OF PHOSPHOINOSITIDE BREAKDOWN AND INHIBITION OF CYCLIC AMP ACCUMULATION IN RAT FOREBRAIN.** W. Lee*, K.J. Nicklaus*, D.R. Manning* and B.B. Wolfe. Dept. of Pharmacology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104

The existence of subtypes of muscarinic cholinergic receptors has been proposed based on evidence from studies of function and binding of radioligands. Pirenzepine (PZ) is a muscarinic antagonist that appears to distinguish the subtypes of muscarinic receptor assessed by radioligand binding and some functional assays. The receptor with high affinity for pirenzepine has been termed M_1 and the receptor with low affinity has been termed M_2. Thus, the quantity of binding sites labelled by (^{3}H)-PZ is used as an estimate of the number of M_1 sites, and the binding sites labelled by (^{3}H)-quinuclidinylbenzilate (^{3}H-QNB, a nonselective muscarinic antagonist) represent the sum of M_1 and M_2 sites. Additionally, it has been suggested that M_1 receptors mediate the breakdown of phosphatidylinositol (PI), while M_2 receptors mediate the inhibition of adenylate cyclase activity.

We have examined the developmental time courses of M_1 and M_2 binding sites as well as muscarinic receptor-mediated stimulation of PI breakdown and inhibition of cyclic AMP accumulation, in order to determine if these parameters develop at different times. Both types of muscarinic receptor binding sites develop at the same time: binding site densities were 30% of adult levels at 1 week, 70% at 2 weeks, 90% at 3 weeks and equal to adult levels at 4 weeks postpartum. Acetylcholine (ACh)-stimulated PI breakdown was detected at all ages tested (1,2,3,4 and 6 weeks); the greatest amounts of (^{3}H)-inositol 1-P (^{3}H-Ins 1-P) accumulation were found at the earliest ages (1 and 2 weeks). There were, however, much higher levels of (^{3}H)-PI (i.e., precursor) in tissues from younger animals, and when the data were expressed as a percent of the (^{3}H)-PI converted to (^{3}H)-Ins 1-P, tissues from young (1 and 2 weeks) rats were less responsive than tissues from more mature (4 and 6 weeks) rats, with tissues from 3-week-old rats being intermediate. ACh inhibition of (^{3}H)-cyclic AMP accumulation, on the other hand, was undetectable in tissues from 1- and 2-week-old rats, while in tissues from 3-, 4- and 6-week-old rats, the responses were at adult levels. (^{3}H)-ATP levels and forskolin-stimulated cyclic AMP accumulation were the same at all ages. Thus, especially for ACh inhibition of cyclic AMP accumulation, a time in development existed (2 weeks) at which receptors were present but response to receptor stimulation was absent. The potential involvement of guanine nucleotide-binding regulatory proteins is currently under investigation. (Supported by GM 31155 and the AHA.)

29.5 REGULATION OF MUSCARINIC AND ADRENERGIC RECEPTORS COUPLED TO PHOSPHOINOSITOL METABOLISM IN THE RAT BRAIN. R.H. Lenox, D.D. Hendley and J. Ellis. Neurosci. Res. Unit, Dept. of Psychiatry, Univ. of Vermont, Burlington, VT 05405.

Among the various neurotransmitters thought to mediate the hydrolysis of phosphoinositides upon activation of their respective receptors, acetylcholine and norepinephrine have both been shown to elicit such a response in hippocampal slices from rat brain. Ongoing studies in our laboratory have focussed upon subtypes of muscarinic receptors in the central nervous system (Ellis and Lenox, BBRC, 126 (3), 1985) and the coupling of monoamine receptors to second messenger systems in intact cell preparations (Lenox et al., Mol. Pharm. 27(1), 1985). In a series of recent studies we have been examining the characteristics of cholinergic receptor vs adrenergic receptor mediation of phosphoinositol turnover in brain slices from the rat.

Hippocampal slices (350 x 350 um) were washed in Krebs-Ringer bicarbonate buffer at 37°C for 30 minutes under O_2/CO_2 (95:5). The slices were then preincubated for 1 hr under O_2/CO_2 with 0.3uM [^{3}H]-myo-inositol. The slices were then washed at 20°C and incubated with various concentrations of receptor agonists. The hydrolysis of the phosphoinositides was measured by the accumulation of [^{3}H]-myo-inositol-1-phosphate (M-1-P) in the presence of LiCl (10mM) (Berridge et al., Biochem. J. 206, 1982). The reaction was stopped by the addition of chloroform:methanol (1:2 v/v). The aqueous phase was loaded onto a Dowex-1 column and the accumulated [^{3}H]-M-1-P was determined as the radioactivity retained by the resin and eluted by 0.1M formic acid in 0.4M ammonium formate. Values were expressed as the ratio of the amount of label in the [^{3}H]-M-1-P to the total label incorporated into M-1-P and lipid fractions.

A concentration dependent increase in the M-1-P fraction was demonstrated for both carbachol and epinephrine with EC_{50} values of approximately 10uM and 1uM respectively. Competition by antagonists was consistent with the activity of muscarinic and alpha$_1$ adrenergic receptor populations. The maximal increase of the percent of the label in the M-1-P fraction in the presence of either carbachol (1mM) or epinephrine (30uM) was approximately 3-4 fold over a 40-60 minute period. Concurrent addition of both carbachol and epinephrine resulted in an increase of 5-6 fold. In the absence of agonist little change was observed over time. Exposure of hippocampal slices to carbachol during the preincubation period significantly reduced the [^{3}H]-M-1-P response to the subsequent addition of the agonist and LiCl during the incubation period. Similar exposure to epinephrine did not result in any reduction of [^{3}H]-M-1-P response to epinephrine during the incubation period. These data suggest that cholinergic and adrenergic receptors in the hippocampus regulate separate pools of phosphoinositides, possibly located on separate cells and that the two classes of receptors may be regulated differently. (Supported by grant RO1-05214 NIA.)

29.6 NEUROTRANSMITTER RECEPTOR-STIMULATED Ca^{2+} MOBILIZATION AND INOSITOL PHOSPHOLIPID METABOLISM IN NEUROBLASTOMA CELLS. R. M. Snider and B. W. Agranoff. Neuroscience Lab, University of Michigan, Ann Arbor, MI 48109

Murine neuroblastoma (clone N1E-115) cells, known to have muscarinic, histamine H_1, bradykinin and neurotensin receptors which are coupled to a Ca^{2+}-dependent cyclic GMP response, are shown to also participate in stimulated inositol phospholipid turnover in the presence of these agonists. Inositol phospholipid metabolism was studied in this preparation by measuring agonist-induced stimulation of $^{32}P_i$ incorporation into PI and PA over a 30 min period. Carbachol stimulates a 2 to 4-fold increase in PI and a 2-fold increase in PA, which is blocked by atropine. Similar results on phospholipid labeling were produced by histamine, bradykinin and neurotensin. There is little agonist-induced effect on PIP_2 or PIP labeling under any of these conditions. With carbachol, the EC_{50} was 40-100 μM while K_i values for atropine and pirenzepine were 0.2 and 3 nM, respectively. Carbachol, acetylcholine, muscarine and methacholine were found to be full agonists; arecholine, bethanechol, pilocarpine and oxotremorine, partial agonists; and McN-A-343 was without effect. These results are in close agreement with those found for muscarinic receptor-stimulated phospholipid labeling in nerve endings (Fisher et al., J. Biol. Chem. 258:7358, 1983) and for cyclic GMP formation in neuroblastoma cells (McKinney et al., Mol. Pharmacol. 27:233, 1985). In additional studies, cells were loaded with the Ca^{2+}-binding probe quin2, the fluorescence of which reflects $[Ca^{2+}]_i$ (intracellular calcium concentration) within physiological ranges. Resting $[Ca^{2+}]_i$ of neuroblastoma cells was determined to be 80-100 nM. Receptor stimulation by maximally effective concentrations of agonists increased the $[Ca^{2+}]_i$ by 20-150 nM within 5-10 sec of addition in the following rank order of efficacy: neurotensin > bradykinin > histamine > carbachol. There was a return to baseline within 1-2 min except for carbachol, in which instance $[Ca^{2+}]_i$ remained elevated, but decreased rapidly upon addition of atropine. The present studies thus confirm in neuroblastoma cells a number of findings seen in nerve endings derived from brain, and extends these observations to the level of Ca^{2+} mobilization. (Supported by NIH Grants NS 20920 and NS 15413.)

29.7 RECEPTOR OCCUPANCY AND INHIBITION OF STIMULATED PI TURNOVER BY SELECTIVE MUSCARINIC ANTAGONISTS. F.J. Monsma, Jr.* and W. Hoss. Ctr. for Brain Res., Univ. of Roch. Sch. of Med. & Dent., Rochester, NY 14642

The non-classical muscarinic antagonists, pirenzepine (PZ) and gallamine (GAL), have been reported to distinguish subtypes of the muscarinic acetylcholine receptor in brain and peripheral tissues. This selectivity has been assessed for the most part through radioligand binding studies and, in the case of PZ, by its ability to block the turnover of inositol phospholipids stimulated by muscarinic cholinergic agonists. Recently, another muscarinic antagonist, trihexyphenidyl (THP), has been proposed as a selective antagonist, distinguishing between peripheral and CNS muscarinic receptors with a selectivity similar to PZ (Tien & Wallace, Biochem. Pharmacol. 34:588, 1985). We report here on the abilities of these three compounds to inhibit specifically the carbachol-stimulated accumulation of labeled inositol phosphates in slices of rat corpus striatum, as well as the affinities of these compounds for the muscarinic receptor as assessed by competition with ^{3}H-QNB in the striatal slice preparation.

Radioligand binding studies with ^{3}H-QNB in striatal slices reveal a single class of saturable, high affinity QNB binding sites exhibiting a K_d for QNB of 0.79 nM, and a B_{max} of 0.22 pmole/mg tissue (wet wt.). The antagonists examined were able to inhibit the binding of ^{3}H-QNB with the following rank order of potency: THP (K_i=47.1 nM)>PZ (K_i=1900 nM)>>GAL (K_i=109,000 nM).

The ability of these antagonists to inhibit the carbachol-stimulated turnover of inositol phospholipids in the corpus striatum slice preparation was assessed by analyzing the accumulation of ^{3}H-inositol phosphates in the presence of LiCl (Berridge et al., Biochem. J. 206:487, 1982). In the presence of 0.1 mM carbachol (CCh), the accumulation of labled inositol phosphates was increased 2-3 fold above control (basal) levels (ED_{50}=2.17 μM). Inclusion of antagonists in the assay resulted in a dose-dependent inhibition of the CCh-stimulated inositol phosphate accumulation. Pirenzepine and THP were equally potent, exhibiting an IC_{50} value of 0.2 M. Gallamine was a poor inhibitor of the CCh-stimulated PI turnover, having an IC_{50} of 1.6 mM.

Based on the comparison between receptor occupancy and inhibition of PI turnover, these results support the hypothesis that PZ is a selective antagonist for the muscarinic receptor subtype coupled to PI turnover (M1), whereas GAL shows a selectivity towards a different subtype, probably the M2. However, the antagonist THP, which apparently distinguishes peripheral and central muscarinic receptors, may not discriminate subtypes in the CNS.

29.8 SOLUBILISED CARDIAC MUSCARINIC RECEPTORS. P. Horodeckyj* and J.W. Wells. Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada M5S 1A1.

(-)-N-[^{3}H]Methylscopolamine (NMS) has been used to study muscarinic receptors in a solubilised preparation from the left ventricle and interventricular septum of Syrian golden hamsters. Binding was measured at equilibrium and 30° in 0.8% digitonin, 50 mM HEPES and 1 mM Mg^{2+} at pH 7.45. Bound radioligand was separated by chromatography on Sephadex G-50. Non-specific binding of [^{3}H]NMS, taken as total binding measured in the presence of 1 mM unlabelled NMS, increases linearly with the concentration of free radioligand. Binding inhibitable by cold NMS, or specific binding, is well described in terms of a single and uniform population of sites. The apparent dissociation constant of [^{3}H]NMS (K_D = 534 ± 47 pM) compares favourably with that found in a particulate preparation from the same tissue (K_D = 385 ± 2 pM). Four muscarinic agonists (carbachol, arecoline, bethanechol, methacholine) inhibit the specific binding of 3 nM [^{3}H]NMS with Hill coefficients markedly less than one; in each case, maximal inhibition is the same as that achieved by unlabelled NMS. In all experiments, total binding in the absence of agonist represented less than 5% of the total radioligand added. The inhibitory behaviour is well described by the expression $Y = F_1K_1/(K_1 + [A]) + F_2K_2/(K_2 + [A])$, in which $K_1 = K_H(1 + [[^3H]NMS]/K_D)$, $K_2 = K_L(1 + [[^3H]NMS]/K_D)$, and F_1 and F_2 sum to one (Eq. 1). Receptors in solution thus appear heterogeneous with respect to the binding of agonists, in common with those in suspension. Among the four agonists studied, the higher affinity (K_H) is the same in both preparations; in contrast, the lower affinity found in solution (K_L) is 32- to 60-fold weaker than the lower (K_M) of the two affinities (K_H, K_M) found in suspension. GMP-PNP at 0.1 mM is without effect on the specific binding of [^{3}H]NMS to the solubilised preparation: the data are well described assuming a single class of sites, and the affinity is unchanged from that measured in the absence of the nucleotide. With carbachol, however, GMP-PNP increases the Hill coefficient for inhibition of [^{3}H]NMS from 0.35 to 0.48. Analysis in terms of Eq. 1 reveals that the nucleotide is without effect upon the apparent dissociation constant at the sites of lower affinity (K_L), but causes a 25-fold increase in that at the sites of higher affinity; there is essentially no change in the value of F_2. This contrasts with the effect in suspension, where the nucleotide is observed to increase F_2 with little or no change in K_H or K_M. Interestingly, the higher affinity found with GMP-PNP in the solubilised preparation agrees well with the lower affinity (K_M) found with or without GMP-PNP in suspension. The data suggest that K_H and K_M reflect receptors in two different states of association with the G/F-protein, with the nucleotide favouring the appearance of K_M. The sites of lowest affinity (K_L) observed only in solution may reflect receptors no longer able to interact with a G/F-protein, a situation that may not exist to any appreciable extent in the membrane. (Supported by the Medical Research Council of Canada and by the Heart and Stroke Foundation of Ontario.)

29.9 GALLAMINE'S INTERACTIONS WITH CNS MUSCARINIC RECEPTORS: ALLOSTERISM AND SUBPOPULATION-SPECIFICITY ARE SEPARATE PHENOMENA. J. Ellis and R.H. Lenox. Neurosci. Res. Unit, Dept. of Psychiatry, Univ. of Vermont, Burlington, VT 05405.

There is agreement among several laboratories that gallamine inhibits the binding of tritiated ligands to muscarinic receptors from both heart and brain. However, the mechanism by which gallamine achieves the inhibition of binding remains somewhat controversial. On the basis of studies of the binding of [^{3}H]-quinuclidinyl-benzilate (QNB) to brain membranes, Ellis and Hoss (Biochem. Pharmacol. 31, 1982) concluded that gallamine interacts competitively with distinct subpopulations of muscarinic receptors. Dunlop and Brown (Mol. Pharmacol. 24, 1983) have reported that gallamine inhibits the binding of [^{3}H]QNB to heart membranes in a competitive manner, but that it induces, rather than detects receptor heterogeneity. On the other hand, Stockton et al. (Mol. Pharmacol. 23, 1983) concluded that gallamine inhibits the binding of [^{3}H]N-methylscopolamine (NMS) in brain and heart by an allosteric mechanism. We have recently reported that in brain membranes gallamine appears to allosterically regulate the binding of [^{3}H]NMS by slowing both on- and off-rates, but that the on- and off-rates of [^{3}H]QNB are not affected by gallamine (Ellis and Lenox, Biochem. Pharmacol., in press, 1985). In the same system, quaternary antagonists other than gallamine (including NMS and N-methylatropine) have been shown to distinguish between the subpopulations of [^{3}H]QNB binding sites that are defined according to affinity for gallamine (Ellis and Lenox, BBRC, 126, 1985). These findings led us to suggest that the subpopulation-specificity of gallamine and the effect of gallamine on the kinetics of the binding of [^{3}H]NMS may be mediated by separate mechanisms (ibid).

Recently, Waelbroeck et al. (BBRC, 121, 1984) found that verapamil affects the kinetics of binding of [^{3}H]NMS to heart membranes in the same way that gallamine does. Since verapamil is not a quaternary ligand, we expected that it would not possess the subpopulation specificity of gallamine. Therefore, to test our suggestion of separate mechanisms, we have assessed the abilities of verapamil and N-methylatropine to (1) recognize the subpopulations defined by gallamine and (2) regulate the off-rate of [^{3}H]NMS in rat brain membranes. We have found that verapamil is as potent as gallamine in slowing the off-rate of [^{3}H]NMS but that it does not discriminate between the subpopulations. Conversely, N-methylatropine is not effective at slowing the off-rate of [^{3}H]NMS but exhibits approximately 1000-fold difference in affinity between the subpopulations defined by gallamine. Thus, it appears that the two effects exhibited by gallamine are mediated by separate mechanisms, with different pharmacological characteristics.

29.10 THIORIDAZINE DOES NOT ACT AS AN ANTICHOLINERGIC AGENT AT ACH RELEASE MODULATING RECEPTORS IN THE RABBIT STRIATUM. D.M. Niedzwiecki, R.B. Mailman and L.X. Cubeddu. Depts. of Pharmacology and Psychiatry and Biological Sciences Research Center, Univ. of North Carolina School of Medicine, Chapel Hill, NC 27514.

In order to determine their relative potency at muscarinic receptors within the CNS, we measured the effects of THD and two of its pharmacologically active metabolites, mesoridazine and sulforidazine, on the electrically evoked release of (3H)ACh from rabbit striatal slices. Unlike anticholinergic agents such as quinuclidinyl benzilate (QNB), neither THD nor its two metabolites significantly antagonized the inhibition of evoked ACh overflow from the striatal slices produced by either of the muscarinic cholinergic agonists, carbachol or oxotremorine. Carbachol (10μM) inhibited the release of ACh evoked by stimulation at 0.3 Hz., 39 pulses by 55.6+/-3%. QNB, at a concentration of 30nM antagonized this inhibition by 37.2% (20.6% inhibition compared to controls), and completely antagonized the carbachol effect at 300nM. In contrast, neither THD nor its metabolites, even at concentrations as high as 30μM, had any effect on the inhibition of evoked ACh overflow produced by 10μM carbachol. In a similar manner, perfusion of striatal slices with oxotremorine (1000nM) resulted in 37.1+/-5% inhibition of electrically stimulated ACh release compared to controls. Again, this inhibition was significantly antagonized by QNB (1μM) but not by THD (1μM).

Concentrations of THD and its metabolites above 1μM significantly elevated the spontaneous or basal overflow of radiolabelled DA from these same slices. This granular effect has been demonstrated for most DA receptor antagonists. Neither QNB, THD, nor the two metabolites tested, had any effect on the spontaneous release of ACh. Additionally, none of the drugs when perfused through the slices in the absence of a cholinergic agonist, significantly enhanced ACh release evoked under these stimulation conditions.

In summary, THD did not appear to antagonize the inhibitory effect of two different muscarinic agonists at the muscarinic receptors which modulate ACh release from striatal slices. This result was unexpected because THD had some potency in competing for (3H)QNB binding sites in homogenates of rabbit striata. In preliminary experiments, the K_I for THD in competing for (3H)QNB binding sites in rabbit striatal membranes was 37.23 nM, compared to 1.21 nM for the classic anticholinergic agent, atropine. These data suggest either that the muscarinic receptors which modulate ACh release and those that bind QNB are different or that the population of striatal muscarinic receptors which modulate ACh release make up too small a proportion to be seen with the conventional (3H)QNB binding techniques.

29.11 FEATURES OF LIGAND BINDING IN HOMOGENATE AND SECTION PREPARATIONS. G. Dohanich, S. Halpain, L. Lambdin* and B.S. McEwen. Rockefeller University, New York, New York, 10021.

With in vitro autoradiographic techniques used to study neurotransmitter binding, radiolabeled ligands are incubated with tissue sections mounted on microscope slides. Following incubation, the unbound ligand is washed from the sections and the slides are placed in contact with tritium-sensitive film in order to generate an autoradiographic image. A typical procedure used to validate the binding of radiolabeled ligands to sections consists of incubting the sections with the ligand and, subsequently, wiping or scraping the washed sections from the slide into scintillation vials to determine the amount of radioactivity bound by standard scintillation counting. In a series of experiments, we compared the binding of [^{3}H]N-methylscopolamine (NMS) to muscarinic receptors in homogenates and slide-mounted sections from rat brain.

In homogenate assays, rat forebrain tissue was incubated for 60 min. at 23°C in 1 ml volumes of phosphate buffer containing [^{3}H]NMS. Free ligand was separated from bound ligand by rapid filtration through glass fiber filters. For binding to sections, frozen mash from rat forebrain was cut on a cryostat and thaw-mounted on microscope slides. Sections of varying thickness were incubated for 60 min. at 23° in 8-12 ml volumes of phosphate buffer containing [^{3}H]NMS. Free ligand was separated from bound ligand by a 10 min. wash in cold buffer. Sections were then wiped from the slide with glass fiber filters and counted with standard liquid scintillation procedures. For both homogenates and sections, nonspecific binding was determined in the presence of 5 uM atropine sulfate.

A comparison of binding parameters indicated that the apparent K_d for [^{3}H]NMS binding was at least one order of magnitude lower for homogenates (K_d=0.15 nM) than for 30u-thick sections (K_d = 1.25 nM). B_{max} values were equivalent for the two preparations. Furthermore, inhibition constants were also lower for carbachol inhibition of [^{3}H]NMS binding in homogenates (K_i=5 uM) than sections (K_i=100 uM). The larger K_d observed in sections was dependent upon section thickness since a reduction in K_d was evident as section thickness decreased (30u, K_d=1.20 nM; 20u, K_d= 0.86 nM; 10u, K_d=0.55 nM). A slower observed equilibration rate (K_{obs}) appears to account, at least in part, for the higher apparent K_d seen in thicker sections (30u, K_{obs}=0.02 min^{-1}; 10u, K_{obs}= 0.04 min^{-1} at 0.2 nM [^{3}H]NMS).

The results support previous evidence (Gilbert et al, Br. J. Pharm. 65:451; Nonaka and Moroji, Brain Res. 296:295) that certain ligands exhibit different binding profiles in homogenate and section preparations. These differences are probably related to the ability of the ligand to access available binding sites in the preparation.

29.12 DEMONSTRATION AND CHARACTERIZATION OF [^{3}H](-)QUINUCLIDINYL BENZILATE ([^{3}H](-)QNB) BINDING TO HUMAN NEUROBLASTOMA CELL LINE (SH-SY5Y). M. Serra*, K. Gulya* and H.I.Yamamura., Department of Pharmacology, University of Arizona, Tucson, AZ. 85724.

To demonstrate for the presence of muscarinic cholinergic receptors in clonal cell lines, we have begun to characterize for the presence of muscarinic receptors using the classical antagonist, [^{3}H](-)QNB. Our initial studies indicate that muscarinic receptors are present in the human neuroblastoma cell line, SH-SY5Y. Specific QNB binding showed tissue linearity up to 4 x 10^6 cells/assay. Kinetic experiments were performed to determine the association and dissociation rate constants. Using 200pM of [^{3}H](-)QNB, steady state levels of binding were reached after 60 minutes of incubation at 37°C. Dissociation of specifically bound [^{3}H](-)QNB from the receptor yielded a t 1/2 value of 110 minutes. Saturation studies were performed and gave a dissociation constant of 20pM and a maximal density of receptors of 230 fmoles/mg protein. The Kd value obtained from the saturation studies were in good agreement with the kinetic value. Pharmacological specificity was determined using atropine and pirenzepine. The classical antagonist atropine inhibited [^{3}H](-)QNB binding with a steep Hill slope and a Ki value of 0.4nM while the nonclassical antagonist pirenzepine inhibited the binding with a shallow Hill slope and a IC50 value of 400nM. The latter results with pirenzepine were analyzed using a 2-site computer model. This model gave a best fit of the data of K_H=5nM and K_L=180nM with the high affinity site being about 48%. To determine whether pirenzepine was binding to the QNB binding site, saturation studies using [^{3}H](-)QNB were performed in the absence and presence of varying concentrations of pirenzepine. A Schild plot showed that pirenzepine appeared to be a competitive antagonist of [^{3}H](-)QNB binding in these membranes.

Because pirenzepine showed muscarinic receptor heterogeneity on [^{3}H](-)QNB binding, direct studies with [^{3}H]pirenzepine were carried out to demonstrate for the presence of M_1 receptors. In membrane preparations, saturation studies resulted in a Kd value of 5nM and a Bmax value of 130 fmoles/mg protein thus indicating that [^{3}H]pirenzepine labels about 50% of the QNB binding sites.

In summary, the human neuroblastoma cell line, SH-SY5Y appears to have muscarinic cholinergic receptors and a portion of these muscarinic receptors show high affinity [^{3}H]pirenzepine binding. Further studies are being done in intact cells to correlate the radioligand binding data with biochemical responses.

29.13 IN VIVO TURNOVER OF MUSCARINIC RECEPTORS AS ASSESSED BY RECOVERY FROM RECEPTOR ALKYLATION. J. Waite and D.J. Jenden. Pharmacology Dept. and Brain Research Inst., UCLA School of Med., Los Angeles, CA 90024.

A clear understanding of homeostatic receptor regulation in vivo may provide insights into mechanisms of drug tolerance or supersensitivity and perhaps suggest ways of manipulating receptor numbers for therapeutic benefit. The time course of receptor recovery from irreversible blockade must ultimately depend on these basic parameters of receptor regulation.

N-[4-(2-chloroethylmethylamino)-2-butynyl]-2-pyrrolidone (BM123), a potent and specific alkylator of muscarinic receptors (Ehlert et al., Life Sciences 34:985, 1984), was injected into rat tail veins in a dose schedule which blocked more than 90% of cortical and striatal muscarinic receptors (8, 20, and 50 μmoles/kg at 1-hr intervals). Animals were decapitated at later time points and densities of unalkylated receptors present were determined by specific (10^{-6} M atropine displaceable) binding of 0.4 nM ^{3}H-l-quinuclidinyl benzilate (QNB) to well-washed membrane fragments from homogenates of cerebral cortex, striatum, and longitudinal muscle of the ileum. The binding incubation was conducted in 50 mM Na/K PO_4, pH 7.4, for 1 hr at 37°C. Rapid filtration through GF/B filters and 3 washes with cold saline terminated the assay. Receptor densities were quantified in terms of fmoles/mg protein.

The recovery time course in each tissue was found to approximate a single exponential curve described by this model:

$$R_t = R_{ss} - R_a e^{-kt}$$

R_t is free receptor density at time, t(hrs), as measured by ^{3}H-QNB binding. R_{ss} is steady state receptor density which was found to be the same before (control tissue) and after alkylation. R_a is the alkylated receptor density, extrapolated to t=0, and k is the degradation rate constant (hr^{-1}). This model assumes 1) a constant rate of receptor synthesis; 2) first order rate of receptor degradation; 3) the R_{ss} after recovery is the same as R_{ss} before alkylation.

The model was fitted to recovery curves by least squares non-linear regression yielding a best fit rate constant, k, of 0.021 ± .001 hr^{-1} (half-time 33 hrs) in all 3 tissues. Since the degradation rate constant was found by ANOVA to be identical in all 3 tissues, the different steady state densities in these tissues are likely due to different, tissue-dependent, rates of receptor synthesis.

29.14 CHOLINERGIC SENSITIVITY OF CA1 PYRAMIDAL CELLS IN MOUSE HIPPOCAMPAL SLICES. R. K. Freund, S. L. Herzberger*, and J. M. Wehner*. Institute for Behavioral Genetics and School of Pharmacy, Univ. of Colorado, Boulder, CO 80309.

We examined the cholinergic pharmacology of the CA1 region in transverse hippocampal slices from 55-65 day old DBA/2Ibg female mice. Cholinergic agents were bath-applied to submerged hippocampal slices, and the effects of these drugs on the stimulus-evoked synaptic field potentials (recorded in Schaffer collateral-CA1 synaptic fields) and on the population spike amplitudes (PSAs; recorded in CA1 pyramidal cell layer) were monitored with an extracellular recording electrode. The effect of nicotine (Nic), oxotremorine (Oxo), mecamylamine (Mec), and atropine (Atr) on PSAs were compared by examining the drug-induced shift of the input-output curve (stimulus intensity vs. PSAs) at test concentrations of 80 and 800 uM. The sensitivity of synaptic field potentials toward acetylcholine (ACh), Nic, Oxo, Mec, Atr, and pirenzepine (Pir) was examined by comparing concentrations required for inhibition of the response amplitude. At both 80 and 800 uM Atr enhanced the PSA, shifting the input-output curve to the left, whereas the muscarinic agonist Oxo inhibited the initial population spike. Both Atr (800 uM) and Oxo (80 and 800 uM) induced the development of multiple spikes. Results for the nicotinic agents were less pronounced; Nic slightly enhanced the population spikes and induced multiple spikes at 800 uM, while the nicotinic antagonist Mec had a small depressant effect on the PSA. For inhibition of synaptic field potentials, Oxo was the most potent drug tested, but the inhibition pattern was complex. The data are consistent with a model describing an Oxo-sensitive component to the Schaffer collateral synaptic response, comprising 50% of the response and with an IC_{50} = 2-6 uM, and a less sensitive component comprising the remainder of the response. The other cholinergic drugs were much less potent; ACh, Mec, Pir, and Atr monotonically inhibited synaptic field potentials with IC_{50} values in the 1-5 mM range (potency rank order: Atr > Mec > Pir > ACh), while Nic had no inhibitory effect at concentrations up to 6.4 mM. Synaptic population spikes were observed as responses to Oxo (> 40 uM), Nic (> 1 mM), ACh (6.4 mM), and Atr (> 400 uM), but not to Pir or Mec. These results indicate that while CA1 pyramidal cells are sensitive to both muscarinic and nicotinic agents, the muscarinic sensitivity predominates. The data also suggest that activation of nicotinic cholinergic receptors, as well as blockade of muscarinic receptors, results in an increase in the number of discharging CA1 pyramidal cells. The classical muscarinic agonist Oxo may interact with both classes of cholinergic receptors. (Supported by NIDA grants DA 07043 and DA 03194.)

SYNAPTOGENESIS AND SYNAPSE ELIMINATION I

30.1 INTERACTIONS BETWEEN SYMPATHETIC PREGANGLIONIC NEURONS AND SYMPATHETIC GANGLION NEURONS IN VITRO. M. G. Honig and R. I. Hume. Div. of Biol. Sci., Univ. of Michigan, Ann Arbor, MI 48109.

The complex dendritic geometries of neurons raise important questions regarding how presynaptic terminals are apportioned over the surfaces of target neurons. We have chosen to approach this issue using a cell culture system, because it allows us to have access to both pre- and postsynaptic neurons. We are studying the interaction between sympathetic preganglionic neurons and lumbosacral sympathetic ganglion neurons dissected from chick embryos and placed in dissociated cell cultures.

These experiments require that we be able to identify each class of neuron. We have done this by using fluorescent carbocyanine dyes, which other researchers have shown are incorporated into the lipid portion of the plasma membrane. We label preganglionic neurons by retrograde transport following injection into the sympathetic chain of diI-C_{18}-(3), a dye which fluoresces orange-red. Sympathetic neurons are labeled by dissociation in the presence of a second dye, diO-C_{18}-(3), which fluoresces green. These dyes have several advantages over other markers that have been used previously to identify cells in culture. For the first day or two in culture, cells are labelled in their entirety, which allows us to follow process outgrowth. In older cultures, label is retained in small granules, and does not appear to spread to other neurons. Under our current culture conditions, many viable preganglionic neurons and ganglion neurons can be observed after two weeks in culture. The dyes have no discernable effect on the physiological properties of neurons. Ganglion cells are depolarized by acetylcholine, preganglionic neurons are capable of evoked transmitter release and both types of cells fire action potentials.

To study synaptogenesis in this system, we have begun by examining the morphology of preganglionic neurons using intracellular injections of Lucifer yellow. At 4-7 days in culture, preganglionic neurons are multipolar. They have 3-8 primary processes which are similar to dendrites in vivo in that they have many branches and sometimes short spines, but also have occasional varicosities. In addition, these neurons generally have one process which appears to be axonal in that it is much longer than the other processes and usually extends for several hundred micrometers before branching. At least some "axons" then break up into multiple collaterals which can branch extensively and show varicosities. These arborizations are sometimes, but not always, found in the vicinity of sympathetic neurons. This morphology is strikingly similar to the morphology of some presynaptic axons in autonomic ganglia in vivo. Our next step will be to test whether dissociated preganglionic neurons make functional synapses onto sympathetic neurons in vitro.

30.2 CHANGES IN SYNAPTIC STRUCTURE AND DENSITY; A DEVELOPMENTAL LIFE-SPAN APPROACH. E.J. Markus, T.L. Petit and J.C. LeBoutillier*. Department of Life Sciences, University of Toronto, Scarborough, Ontario M1C 1A4.

Studies showing changes in synaptic structure and/or density in relation to age, have usually focused on a narrow age span and few synaptic properties.

In this study, the molecular layer of the sensori-motor cortex of Wistar rats aged 1 to 90 days and aged rats (28 months) were used.

Staining half the tissue with osmium and the remainder with EPTA, the following structural characteristics were studied:

Presynaptic element length, area, maximum height and number of vesicles; and the postsynaptic length, area and average height. In addition synaptic cleft width and overall synaptic density were analyzed.

Results to date indicate:

- A rise in synaptic density with development particularly between P10 and P15, with no apparent synaptic loss with aging.
- The presynaptic membrane appears to lengthen with age, while both pre and post synaptic membrane areas increase with age.
- Presynaptic maximal height also increases with age.

Research supported by a grant from Natural Sciences and Research Council to T.L.P.

30.3 PATTERN OF DENDRITIC DEVELOPMENT IN THE RAT NEOCORTEX. J.C. LeBoutillier*, T.L. Petit, H. Libstug* and A. Gregario*. (SPON: J. Gurd). Dept. of Life Sciences, University of Toronto, Scarborough, Ontario M1C 1A4.

The dendritic development of layer V pyramidal cells in the sensorimotor neocortex of the rat was studied in Golgi preparations. Animals were sacrificed on postnatal days (P) 1, 3, 5, 7, 10, 20, 25, 30, and 60, their brains processed, and cells from the sensorimotor cortex examined for maximal apical and basilar dendritic field, number of dendritic branches at 20 µm intervals from the cell body, number of apical and basilar branches (branching order), the length of each dendritic branch, and dendritic spine density on apical, basilar, and terminal dendrites. On P3, cells have an apical and a few oblique and basilar dendrites, most of which are restricted to primary and secondary branches ending within 60 µm of the cell body. The number of primary dendrites leaving the cell body increases until reaching a plateau around P7-10. However, the maximal dendritic field and measures of dendritic branching indicate increased differentiation until approximately P20. After this time, a plateau is observed in measures of branching order and the number of dendritic branches within 140 µm of the cell; however, there is a continued increase in the maximal dendritic field, the number of branches at the most distal portions of the dendritic field, average branch length and total dendritic length into adulthood. Protospines were evident at P3, but decreased in frequency over time, while mature spines appeared between P7 and P10 and increased dramatically until approximately P20-25. While a plateau or decline in spine density was seen on proximal dendrites, spine density did not decline on terminal branches into adulthood.

This research was supported by a grant from the Natural Sciences and Engineering Council of Canada to T.L.P.

30.4 **PLASTICITY OF HIPPOCAMPAL CIRCUITRY IN ALZHEIMER'S DISEASE.** J.W. Geddes, D.T. Monaghan, I.T. Lott*, H.C. Chui*, R.C. Kim* and C.W. Cotman. Department of Psychobiology, University of California, Irvine, CA 92717.

The severe cell loss in the entorhinal cortex of Alzheimer's patients has recently been suggested to destroy the perforant path input to the hippocampus and may underly the memory deficit in this disease. Extensive studies in rodents have shown that entorhinal lesions result in the compensatory growth of adjacent afferents and the replacement of lost synapses. At present, it is uncertain if the human CNS is capable of a plastic response to neuronal loss induced by aging, injury, or disease. In this study we investigated the plasticity of kainic acid receptors in the rodent brain after entorhinal lesions and compared this response to that in postmortem tissues obtained from Alzheimer's patients. Our results suggest that in both rodents and man, kainic acid receptor distribution parallels afferent fiber expansion in the dentate gyrus molecular layer following entorhinal cell loss.

Glutamate, or a related excitatory amino acid, is thought to be the transmitter of the perforant path and the commissural/associational (C/A) system, which terminate on granule cell dendrites in the dentate gyrus molecular layer. Glutamate receptor subtypes are laminated in this region, with kainic acid (KA) receptors having a high density in the C/A system terminal zone (the inner 1/3 of the dentate molecular layer) and a much lower density in the perforant path terminal zone (the outer 2/3 of the dentate molecular layer). We used ^{3}H-KA autoradiography to determine if the KA binding site distribution parallels the expansion of C/A system afferents following an entorhinal cortex lesion and to see if such an expansion occurs in Alzheimer's disease. In male Sprague-Dawley rats which had received entorhinal cortex lesions, the region of high density KA binding sites in the dentate molecular layer expanded 50% into the deafferented hippocampus. This parallels the sprouting response of the C/A afferent fibers. The KA binding pattern observed in hippocampal sections of human brain samples obtained postmortem from non-demented patients was very similar to that identified in normal rodent brain, with a high density of KA binding sites occupying the inner 1/3 of the molecular layer. In brains obtained from Alzheimer's patients, the KA receptor field had expanded 60% so that it occupied over 1/2 of the molecular layer. The additional KA receptors may compensate for input loss and may increase vulnerability to excitoxic activity.

These results illustrate a striking similarity of the CNS response to entorhinal cell loss in Alzheimer's disease with lesion-induced denervation in the rodent. The parallel expansion of C/A afferents and KA binding sites in rodents and the similar increase in KA receptors in Alzheimer's disease suggests that new functional connections are formed. This is the first evidence that the human CNS is capable of plasticity in response to a pathologically-induced denervation. The Alzheimer's brain is therefore capable of at least limited compensatory growth in the wake of a severe degenerative disorder. (Supported by NIA grant AG00538).

30.5 NUMERICAL DENSITY OF BOUTONS AND ITS RELATIONSHIP TO NEURONAL, AXONAL AND DENDRITIC DENSITY IN THE OCCIPITAL CORTEX OF RATS REARED IN COMPLEX, SOCIAL AND ISOLATED ENVIRONMENTS. Anita M. Sirevaag and William T. Greenough. Depts. Psychol. & Anat. Sci. and Neur. & Behav. Biol. Prog., Univ. Illinos, Urbana-Champaign, IL 61820.

Electron microscopic studies of the occipital cortex have shown that rats reared in complex environments (EC) have a greater number of synaptic contacts per neuron than socially (SC) or individually caged animals (IC) (Brain Res. 1985, 329, 1985). The present study confirms these estimates, using numerical density of boutons (vesicle-containing processes), a parameter with different stereological shape assumptions, to estimate synapses.

Members of 11 littermate triplet sets of male Long Evans Hooded rats were reared in EC, a group of rats in a large toy filled cage with daily exposure to a playbox; SC, pairs in a cage; or IC, individual cages, for 30 days postweaning. Micrographs representing 236 µm^2 at a final magnification of 41,786X were randomly taken from cortical layers I, II-III, and IV of area 17 excluding somata and blood vessels. Neuronal densities were estimated from 0.5 µm toluidine blue light microscopic sections. Bouton measurements were calculated from digitized tracings of the minimum area occupied by vesicles. Numerical density of boutons was almost twice that of synapses. Paralleling the synapse per neuron estimates, EC rats had 13% more boutons per neuron in the upper cortical layers than IC's with SC values intermediate. In layer IV EC's had vesicle aggregates that were 25% larger than IC's. Aggregate size did not differ in layers I and II-III; this is also in agreement with differences in synaptic size. The number of boutons per cubic µm of myelinated axonal or dendritic material did not differ among the groups but the volume of myelinated axon and dendrite per neuron was significantly greater in EC's than IC's. This suggests that the addition of more myelinated axons per neuron is associated with an increase in synaptic or bouton number per neuron. The stability of dendritic material per bouton similarly suggests a minimum required intersynaptic distance.

	EC	SC	IC	EC vs. IC
Nv boutons/µm^3	1.25±.10	1.23±.13	1.27±.14	NS
boutons/neuron	17030±1329	15100±1549	14783±1725	p<.05

30.6 BLOOD VESSEL VOLUME FRACTION IN OCCIPITAL CORTEX OF RATS REARED IN COMPLEX OR ISOLATED ENVIRONMENTS. J. E. Black, A. M. Sirevaag, C. Gorman* and W. T. Greenough. College of Medicine and Neural & Behavioral Biology Program and Departments of Psychology and Anatomical Sciences, Univ. Illinois, Urbana-Champaign, IL 61820.

Rats reared in complex environments (EC) have more synaptic contacts per neuron in occipital cortex than individually caged animals (IC), and their neurons are farther apart (Brain Research, 1985, 329, 195). The additional synapses may impose a heavier metabolic load, as might any greater synaptic activity. The added volume in cortical layers may further alter the capability of local vasculature to support neural function. This study examines vasculature in occipital cortex of rats reared in EC and IC environments.

Eleven littermate pairs of male Long Evans hooded rats were randomly assigned to EC or IC rearing conditions. EC rats were raised for 30 days postweaning in a large cage toy-filled cage with daily opportunities to explore a playpen with additional toys. IC rats were raised individually in standard laboratory cages for 30 days postweaning. Micrographs from 0.5 µm toluidine blue stained sections of cortical area 17 were assembled into montages which included Layers I, II-III and IV. The volume fraction of vasculature, excluding pial vessels, was calculated from point counts of a double latticed grid placed over the montage. Neuronal densities across all upper cortical layers were similarly estimated for the same tissue, and synapse densities were estimated from EM micrographs of adjacent sections at 41,786X. The volume fraction of vasculature was 35% greater in EC's than in IC's across all upper cortical layers. There was a corresponding reduction in the number of neurons served per unit vascular volume. The synapse per unit vascular volume comparison failed to reach statistical significance. The difference in vascular volume fraction was greatest in layer I. Intersubject variability was high, indicating that a larger tissue area must be sampled to provide accurate percentage estimates. The large difference in the vascular volume fraction suggests greatly increased metabolic demand in the occipital cortex of rats reared in more stimulating environments.

30.7 CHANGES IN POLYRIBOSOMES AND CISTERNAL STRUCTURES DURING SPINE FORMATION AND SYNAPTOGENESIS IN RAT VISUAL CORTEX. H.-M. Hwang and W. T. Greenough Neural & Behavioral Biology Program, and Departments of Psychology & Anatomical Sci., University of Illinois, Champaign, IL 61820

Polyribosomal aggregates (PRAs) are associated with synaptic formation in developing rat visual cortex (Hwang & Greenough, Neurosci. Abst. 10, 1984) and hippocampal dentate gyrus (Steward & Falk, J. Neurosci. Res. 13, 1985). In developing dendrites, they were found to be intimately associated with cisternal structures and usually located near the membrane, especially near or inside spines. PRAs are found in the spine proper during development, and cisternal structures, including tubules and sacs, appear to accumulate in and near spines. To elucidate possible contributions of PRAs and cisternae to synaptogenesis and spine formation, dendritic spines, including PRAs and cisternae, on apical dendrites in layer IV of developing rat visual cortex were reconstructed through serial thin sections. Preliminary data showed that PRAs appear to become located near cisternal structures in the spine base at about the time that identifiable synapses have formed on the spine. Synapses were located in various positions on spines: They appear to migrate toward the tip of spines with maturation, although there is a large age difference in innervation on spines of apical dendrites, such that new synapses could confound this measure. Whether cisternae process locally synthesized protein is not certain. No rough endoplasmic reticulum is apparent. However, the appearance of coated vesicles pinching off cisternae suggests that cisternal structures may play a role in membrane expansion and recycling. PRAs in the spine proper are sometimes associated with cisternal structures in innervated spines. The PRA in the spine become less frequent as the synapse matures, while cisternally-associated PRAs in the spine base remain frequent. There is a shift in the distribution of PRA size (number of ribosomes) toward smaller numbers from day 20 to 25. Non-cisternally-associated PRAs are often seen in the spine proper prior to the appearance of an evident synaptic specialization. Non-innervated spines (no evident membrane specialization) were often surrounded by several boutons, one of them typically contacting the membrane at the junction of the spine and dendrite. Some non-innervated spines, filled with abundant cisternae, had no PRAs in the spine and no boutons touching any part of the spine. The association of PRA with cisternae may be induced by the presence of presynaptic boutons which appear to first contact the spine at its junction with the dendrite in most cases. Supported by NIMH 35321.

30.8 PROTEIN PRODUCTION IN THE NEUROPIL OF THE DENTATE GYRUS DURING DEVELOPMENTAL SYNAPTOGENESIS. L. Phillips, A. Pollack*, and O. Steward. Dept. of Neurosurgery, Univ. of Va. Sch. of Med., Charlottesville, VA 22908.

The neuropil of the post-natal dentate gyrus shows a dramatic accumulation of polyribosomes under dendritic spines which spans the period of developmental synaptogenesis (Steward, O. & Falk, P., J. Neurosc. Res. 13:75-88, 1985). The density of polyribosome-containing spines rises to a peak at 7 days of age, and then declines between 8 and 20 days, while synapse density continues to increase at a relatively constant rate. Because protein production might mark the different phases of developmental synaptogenesis, we were interested in determining protein synthetic activity during the periods of polyribosome accumulation under dendritic spines.

Fifteen to 20 living hippocampal slices were prepared from albino rat pups sacrificed at 4, 7, 10, 12, 14 and 21 days after birth. Slices were equilibrated for 1-2 hours in a modified Eagle's medium, and then incubated in medium supplemented with 3H-leucine (54 Ci/mmol;0.3 mCi/ml) for 30 mins. After a brief rinse with cold medium, the dentate molecular layer, enriched in developing dendrites, was dissected free from the remainder of the hippocampus. Protein within each region was acid precipitated, radioactivity determined through liquid scintillation spectroscopy and protein content assayed by the Bradford method. Incorporation of 3H-leucine into acid precipitable protein was expressed as counts/min/ug protein (cpms/ug) for each post-natal time period. These data were compared to previously obtained values for adult tissue.

The amount of 3H-amino acid incorporated into protein was higher than that of the adult (583 cpms/ug) for all post-natal time periods. This was true for both dissected regions, with the largest range of increase (8-33 fold) in the dentate molecular layer: from 4,416 cpms/ug at 7 days to 19,385 cpms/ug at 12 days and 4,315 cpms/ug at 21 days post-natal. Maximal protein synthetic activity during developmental synaptogensis did not directly coincide with the peak in polyribosome accumulation under dendritic spines. Sites of synapse formation might be marked by aggregations of polyribosomes prior to the protein synthetic burst associated with the elaboration of the mature contact. The specific polypeptide products of these post-synaptic polyribosomes and their regulation must still be determined. Supported by NIH grant NS12333 to O.S.

SYNAPSE ELIMINATION AND COMPETITION

31.1 SYNAPSE ELIMINATION IS DELAYED IN THE ANDROGEN-SENSITIVE LEVATOR ANI MUSCLE OF THE RAT. C.L. Jordan, M.S. Letinsky, and A.P. Arnold. Laboratory of Neuroendocrinology, Ahmanson Laboratory, Jerry Lewis Neuromuscular Research Center, and Department of Psychology, University of California, Los Angeles, CA 90024.

Although mammalian muscle fibers are multiply innervated at birth, adult muscle fibers are typically innervated by only one axon. The loss of polyneuronal innveration generally is complete by the end of the second week after birth. In the present study, we compared this process of synapse elimination in two fast-twitch, glycolytic muscles, the levator ani (LA) and the extensor digitorum longus (EDL) in the rat. These two muscles differ in the androgen sensitivity of their development, since survival of the LA requires androgens, whereas this is not true for the EDL. We find that in the adult, 10-15% of LA muscle fibers are innervated by more than one axon, but that all EDL muscle fibers are singly innervated. Although both muscles experience a developmental elimination of multiple inputs, the process of synapse elimination is substantially delayed in the LA compared with the EDL, and is not complete in the LA by the fourth postnatal week.

Male rats ranging in age from 14-28 days postnatal and also 90 days of age were overdosed with sodium pentobarbital and the LA and EDL muscles were removed, prepared as whole mounts, and stained with a modified tetranitroblue tetrazolium stain. The number of preterminal axons/junctional site was counted for surface muscle fibers, and was restricted to those sites which were fully visible. No fewer than 35 junctional sites/muscle/animal contributed to the estimates with 4-6 animals/time point. At postnatal day 14, when two thirds of EDL muscle fibers are singly innervated, LA muscle fibers are virtually all polyneuronally innervated, with more than 50% having three or more inputs. The adult pattern of single innervation is established in the EDL muscle by postnatal day 21. At this time, however, about half of LA muscle fibers are multiply innervated, although three or more inputs are relatively rare. By postnatal day 28, the innervation pattern for the LA is not fully adult, since a third of LA muscle fibers are still multiply innervated.

The time course of synapse elimination for the LA and EDL differs by almost two weeks. We do not currently understand the basis of this difference, but work is underway to determine whether the LA muscle is like the lumbrical muscle in that it is increasing in muscle fiber number while undergoing a protracted time course of elimination. On the other hand, the androgen sensitivity of LA development suggests the intriguing possibility that androgens might regulate synapse elimination in this muscle.

31.2 SYNAPSE ELIMINATION BY FIBER TYPE IN NEO-NATAL RABBIT SOLEUS. J. M. Soha*, C. Yo* and D. C. Van Essen. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

We have compared the time course of the elimination of polyneuronal innervation from histochemically identified fast and slow fibers in a mixed muscle, the neo-natal rabbit soleus. Individual muscle fibers whose state of innervation was determined electrophysiologically were labeled intracellularly in a partially curarized in vitro preparation by pressure injection of the fluorescent dye Lucifer Yellow. In one series of muscles, only singly innervated fibers were labeled; multiply innervated fibers were labeled exclusively in a second set of muscles. Sections were stained for alkali stable ATPase activity, and the histochemical type of each labeled fiber determined as Type I (slow) or Type II (fast).

Two age groups were studied, at early and late stages of the appearance of singly innervated fibers. In the first group (7-8 days postnatal), singly innervated fibers constituted about 25% of the total. At this earlier age, we saw no significant difference by fiber type in the level of polyneuronal innervation. Of 22 singly innervated fibers, 13 were of the slow type, while 14 of 26 multiply innervated fibers were slow. In the second group (10-11 days), less than 20% of the fibers examined remained multiply innervated. Interestingly, at this later age, the clear preponderance (16 of 17) of multiply innervated fibers is of the slow histochemical type. Of 18 singly innervated fibers, 12 were of the slow type, indicating a moderate sampling bias for this type, probably owing to their larger size. These results contrast with the suggestion of Riley (Exp. Neurol. 56: 400, 1977), based on indirect evidence from neo-natal rat soleus, that synapse elimination proceeds somewhat more rapidly for Type I (histochemically slow) fibers.

We have also examined the innervation state at 18-22 days of age using the cut muscle technique to increase epp size. About 8% of the fibers examined were multiply innervated. As seen by Taxt et al. (Acta Physiol. Scand. 117: 557, 1983), these fibers consistently exhibit one very small epp component along with one much larger. We are now using the Lucifer Yellow labeling technique to determine if this residual polyinnervation reflects a hypothesized secondary synaptic reorganization in which slow motor units expand in size at the expense of fast motor units. Supported by NSF grant BNS 8408213.

31.3 FIBER TYPE COMPOSITION OF SINGLE MOTOR UNITS IN NEONATALLY REINNERVATED RAT SOLEUS MUSCLE. Carmen Soileau and Wesley J. Thompson, Dept. of Zoology, University of Texas, Austin, TX 78712.

Single motor units in the neonatal rat soleus muscle are composed of muscle fibers which are predominantly of one or the other of the two ATPase fiber types present in the muscle, despite the fact that all of the muscle fibers are polyneuronally innervated and the motor units are several times their adult size (Nature 309: 709; Gordon, thesis, Cal. Tech.). In hope of gaining some indication of whether this innervation pattern might represent a selective innervation of the different types of muscle fibers by the motor neurons, we have examined the selectivity with which single motor neurons reinnervate the different fiber types early in postnatal life. Rat soleus muscles were denervated by crushing the soleus nerve at its entry into the muscle at postnatal day 2. At day 14-18, the fibers contained in a single motor unit were marked in each of several muscles using the technique of glycogen depletion. The fiber types of the marked fibers were then determined by staining an adjacent muscle section for myofibrillar ATPase following alkaline preincubation at pH 10.4.

As reported previously (Neurosci. Abs. 10: 641), these neonatal muscles contained a reduced number of muscle fibers following reinnervation (about 55% of the number present in normal muscles). Nonetheless, the proportion of the fiber types was roughly normal: on average 52% of the fibers were type I and 48% were type II. The total number of motor units following reinnervation ranged between 19 and 25 (as compared with the normal 20-26), indicating that the majority of the motor axons had regenerated but that they now innervated a smaller number of muscle fibers.

Following glycogen depletion, units were found to contain 49-76 depleted fibers (avg. = 67). These fibers were distributed differently from those in normal muscles: the fibers were often confined to one area of the muscle (rather than being dispersed throughout the muscle as in normal animals) and in several cases the reinnervated fibers occurred in discrete clusters or groups.

While all depleted units were found to contain some mixture of the two fiber types, the mixtures have been, for 4 of the 6 units examined to date, far from random. For example, the most impressive deviations from randomness were in one unit which contained 99% type II fibers and in a second unit which contained 83% type I fibers. These results indicate an order to the innervation of the fiber types in the muscle at ca. 2 weeks following denervation, suggesting that there may be some selectivity to the reinnervation of the fiber types. At the moment however, we can not exclude the possibility that the reinnervation is initially random and that, within these 2 weeks, the fibers are converted to match their innervating motor neuron.

31.4 THE COMPARTMENTAL ORGANIZATION OF THE RAT EXTENSOR DIGITORUM LONGUS DURING POSTNATAL DEVELOPMENT. Rita J. Balice-Gordon and Wesley J. Thompson, Dept. of Zoology, University of Texas, Austin, TX 78712.

The nerve to the EDL divides into two branches prior to entering the muscle. We have investigated the distribution of the fibers innervated by each branch in young adult and newborn animals. In the adult muscle, the twitch and tetanic tensions elicited from each branch summate, indicating that each innervates a separate, non-overlapping population of muscle fibers. Using glycogen depletion to mark fibers innervated by each branch, we find that each innervates a contiguous subvolume or "compartment" containing roughly half of the muscle fibers. A sharp boundary exists between the two compartments which is rarely violated.

To investigate whether synapse elimination plays any role in setting up this compartmentalized innervation, we have determined the innervation pattern of each branch in newborn muscles. Even though each muscle fiber is polyneuronally innervated, and motor unit size measurements show that each motor unit is 2-3 times its adult size, each branch appears to polyinnervate fibers only within its own compartment. Tension measurements indicate that the innervation territory of each branch is discrete; moreover, glycogen depletion shows that the compartment boundary is as sharp at 1 day as in the adult. Therefore, it appears that the compartments are set up prenatally: alpha motor neurons are segregated into at least two nerve branches which subsequently confine their innervation to distinct muscle territories. One possible cause for this segregation would be some kind of physical barrier to axons crossing between the muscle regions; in the light microscope we see no obvious barrier. At this time, we have no clear explanation for how the innervation becomes segregated in this manner.

Several levels of compartmentalization exist in young adult as well as newborn EDL muscles. While EDL has one tendon of origin, it has four tendons which insert on the four digits of the foot. The proximal nerve branch innervates fibers which insert on digits 3, 4, or 5 whereas the distal branch innervates fibers which insert on digits 2 or 3. Silver stains reveal several intramuscular branches which may further compartmentalize the muscle into more than two innervation territories. Furthermore, the distribution of fiber types is non-homogeneous: a region of the muscle, containing the fibers that insert on the largest digit, 2, is devoid of type I or slow fibers. This distribution may be indicative of an additional level of compartmentalization: segregation of motor unit types. Although the functional significance of this regionalization is still unclear, the compartmental organization of EDL might allow the different regions of the muscle, each inserting onto separate digits, to function independently during locomotion.

31.5 NEONATAL SYNAPSE ELIMINATION IN THE RAT SUBMANDIBULAR GANGLION: EFFECTS OF TARGET ATROPHY. M.D. Womble*, K. Vanderslice*, and S. Roper. (SPON: M. McPheeters) Dept. of Anatomy, Univ. Colo. Med. Sch. Denver, CO 80262.

The elimination of excess synapses during development is a general phenomenon seen in many regions of the vertebrate nervous system, such as at neuromuscular junctions, several areas of the central nervous system, and peripheral autonomic ganglia. We have studied synapse elimination in the submandibular ganglion of neonatal rats, to determine the effects of target tissue atrophy on synaptic development. This ganglion provides parasympathetic innervation to the submandibular and sublingual salivary glands. Atrophy of the developing salivary glands was produced by ligating the main salivary ducts 2-4 days after birth at a point where postganglionic nerve fibers were not damaged. Ductal ligations produced marked salivary gland atrophy, reducing gland weight to approximately 40% of contralateral control wet weight at 9-12 days after birth. Intracellular recordings from postganglionic neurons which innervated these atrophied glands were conducted to determine the number of presynaptic inputs to these ganglion cells. In control unoperated animals, the average number of preganglionic inputs per cell normally declined from 2.13 0.77 (S.D.) (n=47) during the 3rd week after birth to 1.73 0.81 (n=45) during the 5th week after birth. This latter value was not different from that in ganglia from control adult rat (1.59 0.67; n=68). Ganglionic neurons projecting to atrophied salivary glands in newborn rats showed an acceleration in the process of input elimination. The average input number during the 3rd week was reduced to 1.65 0.70; (n=40), significantly lower than the above value for the 3rd week after birth, and not different from data taken from control ganglia either during the 5th week after birth or in adult animals. These changes are confined solely to the ganglion which innervates the atrophied gland, and thus are not due to bilateral or systemic changes governing synaptic development. The loss of preganglionic inputs was not further enhanced by prolonged target atrophy at later stages of development: the number of inputs/neuron was 1.64 0.75 (n=61) by the 5th week and 1.42 0.61 (n=19) in adult animals, neither of which were different from age-matched, unoperated controls. No differences were seen in average resting potentials or input resistances between neurons from experimental or control animals. Thus, target atrophy in the salivary glands leads to an acceleration in the process of normal synaptic elimination. This effect may be mediated by changes in the level of activity or alterations in trophic factors emanating from the target.

31.6 ACTIVITY SHARPENS THE REGENERATED RETINOTECTAL PROJECTION: SENSITIVE PERIOD FOR STROBE AND TTX. L.E. Eisele* and J.T. Schmidt. Dept. Biol. Sci., SUNY Albany, Albany, NY 12222.

The regenerating optic nerve of goldfish initially forms a crude retinotopic map on the tectum, then sharpens it over several weeks, as determined with HRP staining of optic arbors (Schmidt et al., NS Abstr., 1984). Before 35 days postcrush, electrophysiological recordings from the tectum fatigue rapidly and are difficult to map. After 35 days normally organized maps with multiunit receptive fields (MURF's) of normal size, (approximately 11°) are obtained. Manipulations of visual activity (e.g. intraocular tetrodotoxin (TTX) to block spike activity or strobe illumination to synchronize activity) allow a correctly oriented map to form but the MURF's average 25° to 40° (Schmidt and Edwards, Brain Res., 1983; Schmidt and Eisele, Neurosci., 1985). Single unit receptive fields remain small (11°) in both experiments. Since these recordings are from presynaptic arbors of the ganglion cells, the enlarged MURF's are thought to reflect errors in targeting of the regenerating arbors. Our hypothesis is that appropriate synapses are stabilized based on correlated activity of neighboring ganglion cells that could lead to summation of their postsynaptic potentials and strengthen synapses in appropriate areas. The studies described here extend these findings by defining more precisely the period of sensitivity to TTX and strobe in two ways: 1) using a constant two week period begun at different times postcrush, and 2) looking for maximal effects with long strobe exposures.

In parallel TTX and strobe experiments, fish were recorded after their respective two week intervals. The least sharpened maps (MURF's averaged 29°) came from fish treated from 20 to 35 days. At 35 days the map is already sharp, but two weeks of strobe or TTX unsharpen it. After 50 days the regenerating projection becomes progressively less sensitive to both TTX and strobe. After 130 days, the projections are virtually unaffected, as are mature projections. The periods of sensitivity to TTX block and to strobe are very similar and correspond roughly to the time course of synaptogenesis (Murray and Edwards, JCN, 1982).

Fish reared under strobe conditions from 20 to 80 days have MURF's no larger than 20-35 day fish. Therefore there is no accumulative effect. Fish strobed from 14 days postcrush onwards had larger MURF's (36°) than those strobed from 20 days onward (24°). This indicates the importance of activity cues between 14 and 21 days, when the fibers first invade the tectum. (Supported by NIH grant EY 03736).

31.7 IMBALANCE IN SPONTANEOUS ELECTRICAL ACTIVITY CAUSES OCULAR DOMINANCE SHIFT IN KITTEN VISUAL CORTEX. B. Chapman*, M.D. Jacobson, H.O. Reiter and M.P. Stryker. Dept. of Physiology, School of Medicine, UCSF, San Francisco, CA 94143.

Classical studies in which monocular deprivation produced ocular dominance shifts in the visual cortex have involved rearing conditions in which at least one eye experienced patterned vision. More recently a similar shift in ocular dominance toward the less impaired eye has been produced in the absence of patterned vision (Jacobson, Reiter, Chapman and Stryker, this meeting). We hoped to determine whether a change in ocular dominance could be produced by an imbalance in spontaneous activity alone, or whether some vision, even if only the diffuse temporally modulated light seen through a fused eyelid, is necessary.

Five kittens, 28-33 days old, received intravitreal injections of tetrodotoxin (TTX) in one eye to block ganglion cell activity in that eye. All visual input from the other eye was eliminated by suturing the eyelid and keeping the kittens in continuous darkness. Action potential blockade was maintained for one week. The kittens then remained in the dark to prevent vision during recovery of retinal activity.

Single units were recorded in the lateral geniculate nucleus (LGN) and in area 17. In the LGN no difference in responsiveness was detected between cells driven by the two eyes, indicating that the retinal blockade was no longer in effect. In area 17, however, there was a significant ocular dominance shift favoring the eye that had been spontaneously active throughout the experiment.

Our results indicate that vision is not necessary to produce an ocular dominance shift in the kitten visual cortex. An imbalance in spontaneous activity alone can shift ocular dominance toward the more active eye. There was no statistical difference between the shift produced by our condition of spontaneous activity in one eye versus no impulse activity in the other eye, and the shift produced by vision through a sutured eyelid versus no activity (Jacobson, et al.). This supports the hypothesis that changes in the amount of retinal illumination alone have no effect on ocular dominance in the cortex.

Supported by fellowships from the NSF and grants from the March of Dimes Birth Defects Foundation and the National Eye Institute.

31.8 OCULAR DOMINANCE SHIFT IN KITTEN AREA 17 IN THE ABSENCE OF PATTERNED VISUAL EXPERIENCE. M.D. Jacobson, H.O. Reiter, B. Chapman* and M.P. Stryker. Dept. of Physiology, School of Medicine, UCSF, San Francisco, CA 94143.

Earlier work on various forms of monocular deprivation has revealed ocular dominance shifts in the visual cortex only when at least one eye had received patterned visual experience. The present results demonstrate that patterned vision is not necessary; rather an imbalance of electrical activities from the two eyes is sufficient to cause changes in the ocular dominance of neurons in area 17.

We sutured one eyelid of six 28-34 day old kittens and blocked all impulse activity from the other eye by intravitreal injection of tetrodotoxin (TTX). We maintained this imbalance--both eyes deprived of patterned vision but one of spontaneous activity as well--for one week, and then sutured the blocked eye's lid just before the TTX blockade wore off. We finally recorded the activity of single units in the lateral geniculate nucleus (LGN) and visual cortex area 17.

LGN cells responded as vigorously to the formerly TTX-blocked eye as they did to the other eye, demonstrating that the TTX blockade had completely subsided. In area 17, however, neurons were driven less strongly by the formerly blocked eye, resulting in an ocular dominance shift towards the previously lid-sutured eye. This shift was significant in all six experimental animals compared with untreated normal kittens recorded at the same age. In addition, neuronal cell bodies in geniculate laminae innervated by the blocked eye were smaller than those in laminae innervated by the sutured eye. Similar changes in geniculate cell sizes have been observed in older kittens treated in the same way as in our experiment (Kuppermann & Kasamatsu, Nature. 306: 465-468. 1983).

Our results demonstrate that vision is not an absolute requirement for causing ocular dominance shifts in the cat's visual cortex. Imbalances in the activities of the two eyes can shift eye preference towards the less-impaired eye even without patterned visual experience.

31.9 TRANSPLANTATION OF GRANULOPRIVAL CEREBELLAR CULTURES WITH OPTIC NERVE CAUSES REDUCTION IN THE NUMBER OF SYNAPSES. C.K. Meshul and F.J. Seil, Neurology Research, VA Med. Ctr., and Dept. of Neurology, Oregon Health Sciences University, Portland, OR 97201.

Exposure of neonatal mouse cerebellar explants to cytosine arabinoside (Ara C) (5 ug/ml) for the first 5 days in vitro (DIV) destroyed granule cells and arrested those surviving glia in an early stage of maturation. Purkinje cells lacked an astroglial ensheathment and underwent marked sprouting of recurrent axon collaterals. Recurrent axon collateral terminals synapsed not only with somata of other Purkinje cells, but also with dendritic spines, sites normally occupied by terminals from granule cell axons (parallel fibers)(Blank et al., Neurosci., 7:1509, 1982). Transplantation of such granuloprival cultures with granule cells and mature glia resulted in Purkinje cell ensheathment by astroglia, and a marked reduction in the number of recurrent axon collaterals and of recurrent collateral terminals synapsing on Purkinje cell somata and dendritic spines. Synapses were formed between parallel fibers and Purkinje cell dendritic spines (Blank and Seil, J. Comp. Neurol., 214:267, 1983).

It was of interest to determine the role of glial cells alone in inducing changes toward normal organization in the transplanted granuloprival cultures. Neonatal mouse cerebellar explants, exposed to Ara C for 5 days, were transplanted with 7 day old mouse optic nerve at 13 DIV and maintained in normal nutrient medium until 22 DIV. They were then fixed and processed for light and electron microscopy. At the light microscopic level, it was observed that transplantation caused no significant reduction in the number of Purkinje cell axon collaterals. It was seen ultrastructurally that not only were Purkinje cells almost completely ensheathed by astroglia, but there was a significant reduction in the number of Purkinje cell somatic and dendritic synapses compared to the granuloprival cultures. The transplanted cultures also contained many more dendritic spines that were not making synaptic contact with presynaptic terminals. At the time period studied, there was no indication of glial fingers separating the pre- and postsynaptic elements. There was also no widespread degeneration of presynaptic terminals. The ensheathment of Purkinje cells by astroglia could be the physical element provoking the reduction in the number of Purkinje cell somatic synapses. Since a significant reduction in the number of recurrent axon collaterals was not observed, a detailed time course study of events leading to the reduction in the number of dendritic synapses will be needed.

Supported by the Veterans Administration.

31.10 WHY ARE TRANSIENT CEREBROCEREBELLAR PROJECTIONS TRANSIENT? D.L. Tolbert* (SPON: P.A. Young), Francis and Doris Murphy Neuroanatomy Res. Lab., Depts. of Anatomy and Surgery (Neurosurgery), St. Louis Univ. Sch. of Med., St. Louis, MO 63104

Two non-mutually exclusive mechanisms may direct the elimination of transient projections during normal development of brain pathways. One mechanism involving competition between overlapping afferents in the target for a limited amount of trophic substance or synaptic space may result in unsuccessful axons being eliminated. Alternatively, the elimination of some collateral pathways may be intrinsically directed; reflecting a mechanism whereby collaterals, in excess of the number that the neuron can support through maturation, are selectively pruned. If pruning occurs, one might expect that eliminating the collaterals that normally persist will result in the persistence of the transient collaterals. This theory was tested on transient cerebrocerebellar projections in neonatal cats. In the second postnatal week, pyramidal tract axons branch and project to both the cerebellum and to the brainstem or spinal cord. Later all cerebrocerebellar collaterals are selectively eliminated, while the collateral projections in the pyramidal tract persist. In this study, the collaterals in the pyramidal tract were cut prior to the elimination of the cerebellar collaterals. Later orthograde labeling techniques were used to test for the persistence of cerebrocerebellar projections. In some animals, labeled pyramidal tract axons either ended abruptly at the lesion site or coursed around the lesion and continued through the brainstem and into the spinal cord. There were labeled projections to brainstem nuclei, both rostral and caudal to the level of the pyramidotomy, but none were ever observed projecting into the cerebellum. Injections of Fast Blue were made into the spinal cord to determine if the pyramidotomy caused the death of the axotomized cortical neurons. Fast Blue labeled cells were not present in the cerebral cortex ipsilateral to the pyramidotomy when the lesions were made in neonates, although in older animals (> 33 PND) retrogradely labeled cortical neurons remained after pyramidotomy. These findings suggest that the transience of cerebrocerebellar projections is not due to the inability of cortical neurons to sustain both cerebellar and brainstem/spinal collaterals but rather their transience is determined by axon-axon or axon-target interactions in the cerebellum. Furthermore, cortical projections to the cerebellar nuclei will persist if the nuclei are partially deafferented prior to the elimination of the cerebrocerebellar pathway (Anat. Rec., 211:146A, 1985). Ongoing experiments will determine whether cerebrocerebellar projections persist after combined pyramidotomy and partial deafferentation of the cerebellum.

32.1 GLUTAMATE-ACTIVATED ION CHANNELS IN CULTURED HIPPOCAMPAL NEURONES. R.B. Clark*, M. O'Beirne* and B.A. MacVicar, Dept. Medical Physiology, University of Calgary, Calgary, Alberta, T2N 4N1, Canada. (Spon: S. Roth).

L-Glutamate is a putative excitatory neurotransmitter in the hippocampus, but little is known concerning the properties of the elementary events underlying the membrane response to glutamate and its analogues.

We have measured single ion channel currents, induced by glutamate, in neurones cultured from embryonic rat hippocampus, using the patch clamp technique of Hamill et al. (Pfugers Arch., 391, 85). "Cell-attached" patch recordings were made from neurones after 1-2 weeks in culture. Both cell bathing saline and patch pipette solution were nominally Mg^{2+}-free, but contained 1 mM Ca^{2+}. L-Glutamate (50-250 μm) was added to the patch pipette solution. Temperature was about 20^{0} C.

With glutamate in the pipette, inward current steps of ~2 pA amplitude were recorded at the resting potential of the neurones. Resting potential, measured with conventional (40-60 MΩ) intracellular microelectrodes, averaged -62 mV (± 7, n=5). Single channel current increased approximately linearly with membrane hyperpolarization up to 100 mV from rest (ie. Vm ~ -160 mV), and decreased with depolarizations of 20-30 mV. The slope conductance of the channel over this potential range was 49-55 pS. The apparent reversal potential of the single channel current, obtained by extrapolation, was 50-55 mV positive to cell resting potential, ie. near 0 mV.

Hyperpolarization appeared to reduce the fraction of time that the channel was open (P_o). For example, in one patch (50 μm Glutamate), P_o was 0.19 at the resting potential and decreased to 0.15 with 50 mV hyperpolarization and 0.08 with 100 mV hyperpolarization.

Channel currents occassionally exhibited transitions to 70% of the mean current level, suggesting the existence of subconductance states.

Supported by MRC of Canada and AHFMR.

32.2 A COMPARISON OF THE EFFECTS OF NMDA AND KAINATE ON CA1 PYRAMIDAL NEURONS IN VITRO. C. Rovira*, M. Gho*, Y. Ben-Ari and E. Chérubini. LPN1, CNRS, 91190 Gif-sur-Yvette, France.

The excitatory amino acids N-methyl-aspartic acid (NMDA) and kainic acid (KA) produce a long lasting increase of the excitability of hippocampal neurons. The aim of the present study was to compare their actions on CA1 pyramidal cells recorded intracellularly from the slice preparation.

When CA1 pyramidal cells are excited by a long intracellular depolarizing pulse the increase in the firing rate is not maintained (accommodation) perhaps as a result of the activation of K^+ channels (notably $gKCa^{2+}$ and the M-current, e.g. Madison and Nicoll, 1984). Application of kainate (50-200 nM) produces a small depolarization ($<$10 mV) and an increase in the firing rate. At the resting membrane potential, the accommodation and the after-hyperpolarization (AHP) which followed the depolarizing pulse were reduced. NMDA (AHP) induced a small depolarization ($<$5 mV), bursts of spikes but, in contrast to kainate, a clear cut enhancement in the amplitude and duration of the AHP.

In the presence of TEA (5-10 mM) and TTX (1 μM), the depolarizing pulse produced Ca^{2+} spikes (blocked by Co^{2+}). NMDA augmented and kainate reduced the number of these spikes. When an AHP was still present (lower doses of TEA), it was increased in amplitude and duration by NMDA and decreased or abolished by KA. Barium spikes (produced in 0 Ca^{2+}, TTX (1 μM) and Ba^{2+} : 2 mM) were completely blocked by kainate but not by NMDA. Finally, in Mg^{2+} free medium, the effects of NMDA were completely abolished.

In summary, NMDA and KA induce epileptiform activity but have opposite effects on Ca^{2+} spikes and AHP mediated events. The enhancement by NMDA of Ca^{2+} spikes and AHP and its blockade in the absence of Mg^{2+} is in keeping with the suggested Mg^{2+} associated region of negative slope conductance (Nowak et al., 1984). The mechanisms of action of kainate are still unclear ; our results however suggest that the blockade by kainate of the accommodation and AHP may play a more direct role in the epileptogenic properties of this compound.

32.3 MICROMOLAR AND NANOMOLAR CONCENTRATIONS OF D-2-AMINO-5-PHOSPHONOVALERATE HAVE OPPOSITE EFFECTS ON EPILEPTIFORM BURST-FIRING IN THE RAT HIPPOCAMPAL SLICE. G.L. King and R. Dingledine. Dept. of Pharmacology, Univ. North Carolina, Chapel Hill, NC 27514.

2-Amino-5-phosphonovalerate (APV) is thought to be a selective antagonist for N-methyl-D-aspartate (NMDA) receptors, which when activated by N-methyl-aspartate turn on a voltage- and calcium-dependent cation conductance in hippocampal pyramidal cells. We have previously reported (Hynes & Dingledine, 1984, Neurosci. Abstr. 10: 229) that 10-100 μM DL-APV reduces the duration of epileptiform bursting induced in the CA1 region by bicuculline. This action appears specific as micromolar concentrations of DL-APV do not affect: 1) excitatory synaptic transmission, 2) spike-frequency adaptation, 3) voltage-dependent calcium spikes or 4) cell membrane potential and input resistance. We have further characterized the action of the more potent D isomer of APV on epileptiform burst-firing induced in the CA1 region by 100 μM picrotoxin. These studies were performed in both an interface and submersion chamber and compounds were applied either in the superfusate or by pressure ejection.

In extracellular recordings of population spike bursts evoked by stratum radiatum stimulation, 1-100 μM concentrations of D-APV, like DL-APV, selectively reduced burst duration without affecting the amplitude of the first population spike; the latter was reduced by 1000 μM concentrations. Half-maximal inhibition of bursting occurred at 1-10 μM APV. Intracellular recordings showed that, in a fashion also similar to DL-APV, 10-100 μM concentrations of DAPV reduced the number of population spikes in an evoked burst and decreased the duration of the depolarizing wave underlying the burst, with no effect on either input-resistance or membrane potential. Furthermore, at current intensities below threshold for evoking an action potential in disinhibited slices, D-APV reduced the amplitude of the excitatory postsynaptic potential (EPSP) in a weakly voltage-dependent manner. These results are consistent with D-APV blocking a synaptically-activated NMDA receptor, and also suggest that the postsynaptic receptor responsible for the epileptiform burst is distinct from that which mediates the conventional EPSP.

In contrast, and quite unexpectedly, nanomolar concentrations (10-100) of D-APV prolonged the extracellularly recorded epileptiform burst. Such burst prolongation was also seen under low-magnesium conditions. These results raise the possibility that D-APV, like nicotine action on ACh receptors, may activate and then block NMDA receptors. We are presently investigating whether this effect of D-APV at lower concentrations is mediated by the NMDA receptor. Supported by NS-06953, NS17771 and DA-12360.

32.4 EXCITATORY ACTIONS OF L-PROLINE IN THE RAT HIPPOCAMPAL FORMATION: PHARMACOLOGY, EXCITOTOXICITY AND SODIUM-DEPENDENT UPTAKE. J. Victor Nadler, Brian Ault, Abraham Hakim* and Debra Pistorino*. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

L-Proline blocks the response of hippocampal pyramidal cells to orthodromic and antidromic stimulation, as judged by recording of field potentials in the rat hippocampal slice (Ault and Nadler, Soc. Neurosci. Abstr., 10, 229 (1984)). The block appears attributable mainly to excessive postsynaptic depolarization, because (1) enhancement of cell firing preceded the block, (2) acidic amino acid excitants produced the same effects and (3) the effects of L-proline on antidromically-evoked firing were only partially reduced by superfusion with Ca^{2+}-free medium. Because few neutral amino acids appear to possess neuroexcitatory activity, we studied the pharmacology, excitotoxicity and sodium-dependent uptake of L-proline for comparison with the well-characterized acidic amino acid excitants.

The pharmacology of excitatory responses to L-proline was tested on the antidromic population spike in area CA1 of the rat hippocampal slice. Antidromically-evoked pyramidal cell firing was completely blocked by 8 mM bath-applied L-proline, but was unaffected by D-proline. The suppressive effect of L-proline was reversibly abolished by 500 μM γ-D-glutamylglycine or kynurenate. 25 μM 2-amino-5-phosphonovalerate (2-APV, AP5), which totally prevented any response to N-methyl-D-aspartate, did not alter responses to L-proline. Removing Mg^{2+} from the superfusion medium increased the potency of L-proline about 4-fold. These results suggest that L-proline acts at some type of excitatory amino acid receptor, although its pharmacology does not appear to coincide with that of any excitatory amino acid receptor yet described. Interestingly, all treatments that affected the action of L-proline similarly affected transmission at Schaffer collateral-commissural synapses.

L-Proline produced axon-sparing lesions of the hippocampus upon focal injection into that region. These lesions closely resembled those produced by equal doses of L-aspartate.

Crude synaptosomal fractions of hippocampal formation took up L-[^{3}H]proline in a sodium-dependent manner. Among hippocampal regions, regio superior exhibited the greatest uptake and fascia dentata the least. Preliminary lesion studies indicate an association of proline uptake with projections of CA3 pyramidal cells.

These results provide further evidence for an excitatory action of L-proline and suggest that this amino acid may play a role in the neuroexcitation produced by projections of CA3 pyramidal cells. (Supported by NIH grant NS 16064.)

32.5 **DICARBOXYLIC AMINO ACIDS BLOCK EPILEPTIFORM ACTIVITY IN RAT HIPPOCAMPAL SLICE.** J. ffrench-Mullen* & R.S. Fisher. Neurology, Johns Hopkins Hospital, Baltimore, Md. 21205.

A recent study (Bernstein & Fisher, 1985) has shown that L-GLUT perfusion over hippocampal slices produces blockade of excitatory transmission, relatively preserving function of parallel inhibitory pathways. Utilizing field and intracellular recordings in the in vitro rat hippocampal slice we show that exposure to dicarboxylic amino acids can block epileptiform activity. Penicillin (PEN),1.7-3.4 mM, was used to produce epileptiform potentials. Subsequent perfusion with 1-2 mM L- and D-GLUT, and L-ASP, blunted epileptiform activity. N-methyl-aspartate (NMA) at 5-15 micromolar enhanced epileptiform field activity produced by PEN, but depressed it at higher doses.

Intracellular recordings were obtained from 16 CA1 pyramidal cells. A transient depolarization averaging 4.0±0.9 mV occurred with 2 mM GLUT. Steady-state RMP at 5 minutes after start of perfusion was 57±1.6 mV in control versus 57±1.9 mV in PEN + L-GLUT (n=10, N.S.). Over-depolarization of the post-synaptic neuron did not appear to be a major factor in the decline of penicillin-induced epileptiform activity. Changes in input resistance were also of small magnitude (megohms): 36.0±3.3 in control vs. 37.6±3.7.

The major action of 2 mM L-GLUT perfusion (in the presence of PEN) was blockade of evoked EPSPs and depolarization shifts. On the average, s. radiatum test shocks produced depolarizations of 9.5±1.4 mV in control perfusate, 14.6±1.4 mV in penicillin and 1.9±0.8 mV in 2 mM L-GLUT (n=8, p<.01 CONTROL vs PEN+GLUT and PEN vs PEN+GLUT, paired t-tests). Changes reversed with wash to control perfusate. The decrease with 1 mM L-GLUT was less severe, but still statistically significant. Intracellular effects of D-GLUT and L-ASP paralleled those reported above.

This blockade of synaptic transmission and epileptiform activity by exposure to dicarboxylic amino acids suggests a mechanism for physiological "down-regulation" of neurotransmission during periods of excessive excitation.

32.6 INHIBITION OF HIPPOCAMPAL EXCITATORY TRANSMISSION AND DISPLACEMENT OF DL-[^{3}H]-2-AMINO-4-PHOSPHONOBUTANOIC ACID (DL-APB) BINDING BY CYCLIC ANALOGUES OF APB AND GLUTAMATE. M.B Robinson, S.L. Crooks*, R.K. Freund, J.F. Koerner and R.L. Johnson*. Depts. of Biochemistry and Medicinal Chemistry, Univ. of Minnesota, Minneapolis, MN 55455.

L-APB selectively inhibits excitatory lateral entorhinal inputs to hippocampal granule cells [Koerner & Cotman, Brain Res., 216 (1981),192]. A class of [^{3}H]-glutamate binding sites distinguished by Ca^{++}/Cl^- dependence [Fagg et al., J. Neurosci., 2 (1982) 958] is displaced by L-APB in the same concentration range (1-10 µM) as that observed for inhibition of synaptic transmission. A DL-[^{3}H]-APB binding site shows similar ligand specificity and ion dependence [Monaghan et al., Brain Res., 278 (1983) 137; Robinson et al., Biochemistry, 24 (1985) in press].

We have synthesized the following cyclic analogues of glutamate and APB to identify structural properties necessary for inhibition of the perforant path and to compare these properties to those for displacement of APB binding: (±)-trans-1-amino-1,3-dicarboxycyclopentane (trans-ADCP), (±)-parf-1-amino-3-phosphonocyclohexanecarboxylic acid (trans-cyclohexyl APB), (±)-pref-1-amino-3-phosphonocyclohexanecarboxylic acid (cis-cyclohexyl APB), and one of the racemic diastereoisomers of 1-amino-3-phosphonocyclopentanecarboxylic acid (cyclopentyl APB). These compounds were bath-applied to the submerged rat hippocampal slice. Evoked synaptic field potentials were recorded with an extracellular electrode placed in the terminal field of lateral or medial entorhinal projections to dentate granule cells. They were also tested for displacement of DL-[^{3}H]-APB binding from synaptic plasma membranes prepared from rat forebrain. Except for trans-ADCP, they all required concentrations greater than 1 mM to inhibit synaptic responses by 50%, and they did not induce population spiking (indicative of postsynaptic depolarization). Trans-ADCP inhibited lateral perforant path responses with an IC_{50} = 400 µM. The inhibition curve for medial perforant path responses spanned a wide range of concentrations suggesting heterogeneity in the response with IC_{50}'s in the range of 30 µM to 1.5 mM. Population spiking occurred at the higher concentrations. Trans- and cis-cyclohexyl APB inhibited 50% of the DL-[^{3}H]-APB binding at 1 mM while cyclopentyl APB and trans-ADCP inhibited 50% of this binding at 3-6 µM.

To summarize, trans- and cis-cyclohexyl APB showed weak potency in both assay systems. Cyclopentyl APB was also a weak inhibitor of lateral perforant path responses, but in contrast to the cyclohexyl derivatives of APB, was 200-fold more potent as a displacer of DL-[^{3}H]-APB binding than as an inhibitor of synaptic responses. These data support our previous suggestion that this binding site is a different or altered receptor from that identified by electrophysiology. [Supported by NIH NS17944].

32.7 KAINIC ACID-EVOKED SEIZURES AND BINDING SITES IN EPILEPTIC AND NON-EPILEPTIC FOWL. D.D. Johnson, J. Tuchek*, R. Wilcox* and R.D. Crawford*. Depts. of Pharmacology and Animal and Poultry Science, Univ. of Saskatchewan, Saskatoon, Canada S7N 0W0.

Epileptic fowl have a high seizure susceptibility as the result of an autosomal recessive mutation. Homozygotes (epileptics) seize spontaneously and in response to photic stimulation or hyperthermia. The heterozygote hatchmates (carriers) do not respond to photic stimulation. In order to begin to test the hypothesis that the high seizure susceptibility may be due to abnormalities in the function of excitatory amino acids we have compared kainic acid (KA) binding parameters and the dose-response relationships for kainic acid-evoked seizures in epileptic and carrier fowl. Binding studies were performed using [^{3}H]-kainic acid and a synaptosomal membrane preparation from adult chickens in a filtration assay system. As in rodents, saturable high affinity binding of [^{3}H]-kainic acid at two sites could be demonstrated in adult chicken brain. Specific binding was always greater than 70% of total binding. In both carriers and epileptics two binding sites for KA were detected. The K_D values (mean ±S.D.) were 2.49±0.96 nM and 66.5±7.8 nM for epileptics; 5.69± 0.64 nM and 67.9±7.5 nM for carriers. The K_D of the high affinity site in epileptics was significantly lower than that in carriers (2.49 vs 5.69, n=6). No differences were detected in B_{max} values (21.3±11.4 and 405.6 fmols/mg protein in epileptics; 42.1±9 and 429.3 fmoles/mg (40 nM) protein for carriers). In displacement studies of bound KA, IC_{50} values were 81.7 nM for kainic acid, 3.5 µM for glutamate and 1.1 µM for quisqualate. No differences between carriers and epileptics was detected. GABA, flurazepam, glycine, metrazol and phenobarbital in the concentration range 10^{-3}-10^{-5}M had no effect on KA binding.

In order to determine dose-response relationships for the induction of seizures by KA, groups of ten one-day-old epileptic or carrier chicks were given i.p. injections. KA evoked ataxia, and repeated clonic seizures. Epileptic chicks were more sensitive to the convulsant effects of KA than their heterozygote hatchmates. The percentage incidence of seizures was 70, 70, and 90 in epileptics and 10, 50, 50 in carriers for doses of 4, 6 and 8 mg/kg respectively. In addition the mean time to onset of the first seizure was significantly less in epileptic than in carrier chicks. These data suggest that the high seizure susceptibility of epileptic chickens may be associated with abnormalities in the function of excitatory amino acids or their receptors.

32.8 A PUTATIVE G_1 EXCITATORY AMINO ACID RECEPTOR MEDIATES VESTIBULAR AFFERENT TRANSMISSION IN RATS. M. R. Lewis*, J. P. Gallagher and P. Shinnick-Gallagher. Dept. of Pharmacology and Toxicology, Univ. Tex. Medical Branch, Galveston TX 77550.

The neurotransmitter and receptor mediating afferent transmission in the medial vestibular nucleus (MVN) was studied using intracellular recording in an in vitro rat brain slice preparation. The preparation consists of a transverse slice of the rostral medulla, containing the major portions of the MVN and entering tracts of the VIIIth nerve. Excitatory postsynaptic potentials (EPSPs) in second-order neurons with latencies of 1mSec were evoked by focal stimulation of VIIIth nerve tracts within the slice. Drugs were applied by drop or superfusion.

EPSPs in second-order neurons were not affected by the cholinergic antagonists hexamethonium or atropine, the H_1-antagonist diphenhydramine or the P_1-antagonist caffeine. However, the excitatory amino acid antagonists kynurenic acid, DL-α-aminoadipate and DL-aminophosphonobutyrate (APB) reduced the EPSPs while D-aminophosphonovalerate and γ-D-glutamylglycine had no effect. These reductions in EPSP size occurred in the absence of nonspecific membrane effects. However, the D- and L- forms of α-aminoadipate separately caused depolarizing or hyperpolarizing effects. APB was the most potent antagonist of the EPSP.

Additionally, the second-order neurons demonstrated non-desensitizing depolarization to DL-homocysteate, and desensitizing depolarization to other agonists such as quisqualate and N-methyl-D-aspartate (NMDA). During desensitization to quisqualate, the EPSP was not reduced.

EPSPs and depolarizations induced by DL-homocysteate and L-aspartate consistently involved increases in conductance while responses to quisqualate, NMDA, and kainate were associated with decreases in conductance. Conductance changes associated with glutamate were highly variable.

These results support our hypothesis that the EPSPs recorded from rat MVN are mediated by an excitatory amino acid (possibly aspartate). The receptor appears to be of the classification "G_1" as defined by Fagni, Baudry and Lynch (J. Neurosci., 3:1538, 1983). We are currently investigating the ionic mechanism of the synaptic response. (Supported by NASA NAG 2-260)

32.9 DIFFERENTIATION BETWEEN GLUTAMATE RECEPTORS BASED ON DESENSITIZATION C.F. Zorumski, G.D. Fischbach Depts. of Psychiatry and Anatomy and Neurobiology, Washington U. Med. School, St. Louis, MO 63110

Glutamate produces excitation by activating two conductances. One, G_1, exhibits a non-linear current-voltage relation with decreasing inward current at hyperpolarized membrane potentials, is activated by N-methyl-D-aspartate and is blocked by 2-amino-5-phosphonovalerate (APV). The other conductance, G_2, exhibits a linear current-voltage relation, is activated by kainate or quisqualate and is insensitive to APV (Mayer & Westbrook, 1984). By voltage-clamping chick spinal cord neurons, we have obtained evidence that these conductances can also be distinguished on the basis of desensitization.

Spinal cord neurons were dissociated from six-day chick embryos and studied between 3 to 10 days after plating with gigaseal whole-cell recording techniques. For recording, growth media was replaced with a solution containing 140 mM NaCl, 5 mM KCl, 0.8 mM $MgCl_2$, 10 mM glucose, 12.5 mM HEPES, pH=7.2. Patch pipettes contained 140 mM KCl, 2 mM $MgCl_2$, 10 mM HEPES, 11 mM EGTA·KOH, 1 mM $CaCl_2$, pH=7.2. Glutamate was applied by pressure ejection from pipettes positioned 10-50μ from the cell body.

Prolonged (10 second) glutamate applications led to a 27% decline in the glutamate current (N=16). Repeated, 500 msec glutamate applications, at 30 second to 1 minute intervals, also led to a decline in the peak inward current. The desensitization was completely reversible in five minutes. The effect was glutamate concentration dependent, being most reliably produced by concentrations above 100 μM and was critically dependent on extracellular calcium. At an external calcium of 10 mM, the glutamate current showed a 41% decline on repeated administration (N=35).

Two lines of evidence indicate that this desensitization involves the G_1 conductance. First, in the presence of saturating concentrations of APV (1 mM), no rundown of the glutamate current was seen. Furthermore, $CoCl_2$ (1 mM), which also blocked G_1 responses, eliminated the desensitization. Second, very little desensitization was observed when the membrane was clamped to -85 mV, a potential at which the G_1 conductance is markedly decreased. The decrease in G_1 current at hyperpolarized potentials is due to a voltage dependent channel block by Mg^{++} (Nowak et al, 1984). In the absence of Mg^{++}, the voltage dependence of glutamate desensitization was eliminated.

In summary, cultured chick spinal neurons exhibit desensitization to prolonged or repeated glutamate applications. This desensitization is calcium dependent and primarily involves the G_1 conductance.

32.10 KYNURENIC ACID DISTINGUISHES BETWEEN QUISQUALATE AND KAINIC ACID RECEPTORS IN THE MUDPUPPY RETINA. R.F. Miller and P.A. Coleman*. Department of Ophthalmology, Washington University School of Medicine, St. Louis, MO 63110.

We have discovered that kynurenic acid (KynA) distinguishes kainic acid (KA) and quisqualate (QQ) responses among third order neurons of the mudpuppy retina. This raises the possibility that different receptors mediate KA and QQ actions.

We used bath application of all agents in a perfused retina-eyecup preparation. Kynurenate was applied in concentrations of 2.5 to 10 mM and KA and QQ were used at 10 to 100 μM.

In the outer retina KynA has an antagonist action similar to that of cis, 2,3 piperadine dicarboxylic acid (PDA)[1]. Horizontal cell and off-bipolar light responses are blocked by KynA, while on-bipolars are comparatively unaffected.

Among second order neurons QQ appears to be a somewhat weaker agonist when compared to KA: The action of KA is entirely blocked by continuous 5 mM KynA, but an attenuated effect of QQ (100 μM) persists.

Among third order neurons (amacrine and ganglion cells) QQ is generally a more effective agonist compared to KA and evokes strong excitation at 10 μM levels. At a concentration of 5 mM, KynA significantly reduces light-evoked responses and entirely blocks the depolarization of exogenously applied KA (100 μM); at this concentration of KynA, QQ still produced significant depolarizations. Strong QQ and KA effects are seen after synaptic transmission is blocked with Co^{++} suggesting that receptors for these agonists are intrinsic to third order cells.

These findings raise the possibility that QQ receptors may be distinct from KA receptors. However, a single receptor type with differential affinity for QQ and KA cannot be eliminated.

Further evidence in support of separate QQ and KA receptors has come from some selective ganglion cell recordings. Most recordings show QQ and KA cause a depolarization. In a small percentage of ganglion cell recordings KA depolarizes, whereas QQ hyperpolarizes. At higher concentrations both KA and QQ inhibit. This inhibitory effect is converted to excitation by blocking inhibition with a picrotoxin/strychnine cocktail (10 μM each). Thus the QQ inhibition appears to be mediated by inhibitory amacrine cells in these special cases. This observation raises the possibility that inhibitory amacrine cells may contain receptors which are comparatively more QQ sensitive than those of ganglion cells.

KynA is also an effective NMDA antagonist and is, therefore, a broad spectrum antagonist. As far as we know this is the first report of a separate KA vs. QQ antagonism for kynurenate.

32.11 THE APPEARANCE OF CHEMOSENSITIVITY TO EXCITATORY AMINO ACIDS IN CULTURES OF MOUSE SPINAL CORD NEURONS. C.L. Mitchell and G.L. Westbrook. Lab. of Developmental Neurobiology, NICHD, IRP, NIH, Bethesda, Md. 20205

L-glutamate (GLU) and L-aspartate (ASP) are neurotransmitter candidates at primary afferent and intraspinal synapses in the mammalian spinal cord. Several receptor types exist for the excitatory amino acids based on selective activation by kainate (KA), quisqualate (QA) and N-methyl-D-aspartate (NMDA), whereas GLU can activate both NMDA and non-NMDA (i.e. either QA or KA) receptors. Recent evidence in culture suggests that a non-NMDA receptor mediates monosynaptic EPSPs formed between dorsal root ganglion and dorsal horn neurons (Jahr & Jessell, J.Neurosci., In press), as well as between spinal cord neurons (Nelson, Pun & Westbrook, submitted). To study the development of these receptors and their relationship to synaptic activity, we have used whole-cell patch recording to test the chemosensitivity of spinal cord neurons during the first week in culture.

Neurons were dissociated from 13 day embryonic mice and plated on collagen-coated 35 mm dishes at 6 X 10^5 cells per plate. Growth medium contained 5 % horse serum and a nutrient supplement. Whole-cell patch recordings were made in physiological saline containing 2 mM Ca^{2+} and 1 mM Mg^{2+}. Agonists were dissolved in recording solution and pressure ejected from pipettes near the soma. Under these culture conditions, neurite outgrowth begins within 24 hours and Na^+-dependent action potentials can be evoked with intracellular stimulation. However no detectable spontaneous EPSPs or IPSPs (> 200 μV) are present for the first 2-3 days, then spontaneous synaptic activity develops rapidly between days 4 and 7 (Westbrook, et al., Soc. Neurosci Abs. 9, 505, 1983).

At day 2-3, most spinal cord neurons were sensitive to QA (10 μM) and GLU (100 μM) as well as γ-aminobutyric acid (GABA, 100 μM). Responses to KA (10 μM) were small or absent. QA and GABA responses were associated with conductance increases while GLU responses resulted in little or no apparent conductance change. Under voltage clamp GLU-activated currents had a region of zero or negative slope conductance consistent with a mixed agonist action on both NMDA and non-NMDA receptors. Both QA and GLU-activated currents had reversals potentials near 0 mV. GABA responses reversed at -50 mV with $KMeSO_4$ and at 0 mV with CsCl solutions in the patch electrode, consistent with a chloride conductance. By day 7, spinal cord neurons were highly sensitive to all agonists tested.

These results suggest that both NMDA and non-NMDA receptors are present before detectable synaptic activity, but that sensitivity increases during a period of rapid synapse formation.

32.12 CONTINUOUSLY INFUSED 2-AMINO-7-PHOSPHONOHEPTANOIC ACID ANTAGONIZES N-METHYL-D-ASPARTATE MEDIATED INCREASES OF CYCLIC GMP IN SEVERAL BRAIN REGIONS. P.P. McCaslin* and W.W. Morgan. Dept. Cellular and Structural Biology, Univ. Texas Hlth. Sci. Ctr. at San Antonio, TX 78284.

2-amino-7-phosphonoheptanoic acid (APH) has been shown to be a comparatively selective antagonist of N-methyl-d-aspartate (NMDA)-mediated excitation as well as a potent anticonvulsant in some species. The effects of the continuous intracerebroventricular (icv) administration of this compound were examined as a prelude to the use of APH in investigations of the role of central excitatory dicarboxylic acidic amino acid neurotransmitter pathways in the development of barbiturate dependence. A 0.023 inch internal diameter polyethylene cannula was stereotaxically implanted into the lateral cerebroventricle of ovariectomized Sprague-Dawley rats and connected to a subcutaneously implanted Alzet minipump. The minipump delivered saline or 54, 27, 2.7 or 0.27 microgram (μg) of APH icv/day for 48 hours before further experimentation. The 27 μg/day dosage was the highest which by itself did not produce behavioral depression. The continuous icv administration of APH produced a dose-related suppression of cyclic guanosine monophosphate (cGMP) levels in the cerebellum but not the cerebral cortex, thalamus or hippocampus. The acute icv injection of 1000 nanograms (ng) of NMDA produced a marked elevation of cGMP in all the above brain regions and induced overt wild running behavior. Pretreatment by the continuous icv infusion of 27 μg of APH for 48 hours completely suppressed the effects of NMDA on cGMP and on behavior. However, this same treatment with APH was totally ineffective in suppressing convulsions induced by acute subcutaneously administered pentylenetetrazol (PTZ, 30 mg/kg). These results suggest that NMDA receptor-related pathways may play a tonic role in the regulation of cerebellar cGMP levels and that there is an NMDA receptor mechanism with input to similar cGMP-related pathways in other brain regions. On the other hand, this mechanism in these other brain regions does not appear to be tonically active. In the rat, APH does not appear to be effective against PTZ-induced convulsions. These data call into question whether an antagonism of NMDA receptors is responsible for the anticonvulsant effects of this drug observed in other species. Supported by NIDA grants DA00755 and DA00083 and by USAF Contract F33615-83-C-0624.

32.13 MODELS OF N-METHYL-D-ASPARTATE ANTAGONISM: A COMPARISON OF 2-AMINO-7-PHOSPHONOHEPTANOIC ACID WITH MUSCLE RELAXANT DRUGS. P.S. Bernard,* G. Pastor* and J.M. Liebman. Neuroscience Research, Pharmaceuticals Division, CIBA-GEIGY Corp., Summit NJ 07901

It has been proposed that antagonists of N-methyl-D-aspartate-type excitatory amino acid receptors may have various useful therapeutic properties (Meldrum, Clinical Science 68:113, 1985). The reliable in vivo detection of novel NMDA antagonists therefore constitutes an important research problem. These substances have been shown to antagonize audiogenic seizures in DBA/2 mice (Meldrum, Epilepsia 25:Suppl. 2, S140, 1984) but since a wide variety of other substances are also effective, this test procedure lacks selectivity. The present experiments have characterized two effects of systemically administered NMDA (hindlimb scratching and seizures) in mice and their relative responsiveness to a putative NMDA-type receptor antagonist, 2-amino-7-phosphonoheptanoic acid (AP-7). Because the muscle relaxant propeties of AP-7 pose potential difficulties of interpretation, other muscle relaxants, including baclofen and diazepam, have also been assessed for comparison.

Male CF-1 mice were treated with 54 mg/kg i.p. to induce hindlimb scratching behavior, and with 154 mg/kg to induce seizures. Audiogenic seizures were assessed in DBA/2 mice, a seizure-prone strain following exposure to a 110 db bell. Animals received all drugs intraperitoneally 45 min prior to treatment. AP-7 reduced both NMDA-induced hindlimb scratching (ED_{50} = 48 mg/kg) and NMDA-induced clonic seizures (ED_{50} = 36 mg/kg). These ED_{50} values were only slightly higher than that for AP-7 to inhibit audiogenic seizures (ED_{50} = 22 mg/kg) and were considerably lower than that for blockade of the traction reflex (ED_{50} = 110 mg/kg), an indication of neuromuscular impairment. All three models, therefore, appeared to reflect the pharmacological action of AP-7. Baclofen antagonized both NMDA-induced scratching (ED_{50} = 0.7 mg/kg) and audiogenic seizures (ED_{50} = 4 mg/kg) at doses lower than those blocking the traction reflex (ED_{50} = 10 mg/kg). However, baclofen did not block NMDA-induced seizures. Diazepam also blocked audiogenic seizures and NMDA-induced scratching but not NMDA-induced seizures.

In conclusion, the NMDA seizure model discriminates between AP-7 and at least two other muscle relaxants to a greater extent than does the audiogenic seizure model or the NMDA hindlimb scratching model. The in vivo detection and characterization of NMDA-like receptor antagonists should be facilitated by the use of this simple rodent model.

32.14 THE EXCITATORY AMINO ACID RECEPTOR ANTAGONIST, 2-AMINO-7-PHOSPHONOHEPTANOIC ACID (AP7), PRODUCES ANTICONFLICT ACTIVITY, D.A. Bennett, C.L. Corradi and J. Lehmann. Neuroscience Res., Pharm. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

2-Amino-7-phosphonoheptanoic acid (AP7) has been identified as an antagonist of the cortical excitatory amino acid receptor sensitive to N-methyl-D-aspartate (NMDA) (Perkins et al., Neurosci. Lett., 23:333,1981). As the excitatory amino acid system functions in opposition to the inhibitory amino acid system, it is not unrealistic to propose that an excitatory amino acid receptor antagonist would produce effects comparable to an inhibitory amino acid agonist (i.e. GABA). AP7 has been reported effective in antagonizing seizure behavior (Czuczwar et al., Eur. J. Pharmacol., 83:335, 1982; Croucher et al., Science, 216:899,1982) and effective as a muscle relaxant in genetically spastic rats (Turski et al., Neurosci. Lett., 37:75,1983). These effects are produced after either i.c.v. or i.p. administration. HPLC analysis of mouse brain indicates that AP7 crosses the blood brain barrier with a peak concentration at 30 min (Chapman et al., Neurosci. Lett., 37:75,1983).

We now report that AP7 produced a significant anticonflict effect in rats. At doses of 10 and 30 mg/kg i.p., increases in punished responding (FR-10) of 191 and 130% were seen as compared with baseline controls. No significant decrease in non-punished (VI-30 sec) responding was noted, although at 30 mg/kg i.p. this response was reduced by 11%. At 3 mg/kg i.p. AP7 produced an insignificant increase (34%) in punished responding, whereas 100 mg/kg i.p. produced severe response suppression. In rats trained to discriminate diazepam (10 mg/kg p.o.) from vehicle, AP7 produced dose-dependent (ED_{50} approx. 54 mg/kg i.p.) generalization. This finding might be construed as further evidence of anxiolytic activity. An alternative explanation is that the diazepam cue may be based partly upon muscle relaxant activity. This latter interpretation is consistent with rotorod deficit (60-70%) seen in rats after doses of 100 and 173 mg/kg i.p. of AP7. When the benzodiazepine antagonist, CGS 8216, was given in combination with a dose of AP7 (173 mg/kg i.p.) that induced 90% rotorod deficit in mice, no antagonism was seen. This is in contrast to the complete antagonism of the diazepam-induced rotorod deficit seen in mice following CGS 8216 (ED_{50} = 3.9 mg/kg p.o.), and suggests that the muscle relaxant effect of AP7 is not mediated through benzodiazepine mechanisms.

In summary, like diazepam, AP7 produced anticonflict activity, generalized to diazepam stimuli and produced rotorod deficit. These effects are thought to be directly or indirectly mediated through the excitatory amino acid system without involving the benzodiazepine receptor. The behavioral profile of AP7 reflects activity comparable to what would usually be found with inhibitory amino acid system agonists.

32.15 SYSTEMIC INJECTION OF N-METHYL-ASPARTIC ACID INCREASES ESTROUS CYCLE LENGTH IN FEMALE C57BL/6J MICE. S.G. Kohama,* P.C. May and C.E. Finch. Andrus Gerontology Ctr., USC , Los Angeles, CA 90089.

Mature mice treated as neonates with monosodium glutamate exhibit a variety of neuroendocrine impairments consonant with an excitotoxic lesion of the arcuate nucleus. However, neuroendocrine functions of mice treated as adults with systemic administration of excitotoxins has not been examined. N-Methyl-D,L-aspartic acid (NMA), a neuronal excitotoxin, was administered by s.c. injection (0, 100 or 200 mg NMA/kg body weight; n=13/group) to 8 mo old female C57BL/6J mice and their estrous cycles monitored by analysis of vaginal cytology. Estrous cycle length increased in NMA treated mice compared to their pre-treatment cycle length ($p<0.05$) while vehicle injection had no significant effect on cycle length. The average cycle length one month following treatment was greater in the 200 mg/kg NMA treated mice than controls (6.6 $\pm$ .4 days vs. 5.4 $\pm$ .4 days, $p<.05$). By two months after injection, there were no differences between the groups, in part due to a gradual increase in cycle length of controls and a partial recovery in NMA treated mice. In addition to affecting estrous cycle length, NMA treatment also produced a significant weight gain by one month following injection, but again, a partial recovery of NMA treated mice occurred in the second month. We are continuing to monitor the estrous cycles of these mice to determine if NMA treatment affects the age-related onset of acyclicity. Preliminary results from a separate study indicate that a similar NMA treatment regimen resulted in detectable cell loss within the arcuate nucleus. This presumptive cell loss in the arcuate is consistent with NMA induced alterations in estrous cycle and body weight.

32.16 MODIFICATION OF DOSE RELATED RESPONSES TO L-GLUTAMATE MICROINJECTED INTO THE NUCLEUS TRACTUS SOLITARIUS OF RATS AFTER DEGENERATION OF VAGAL AFFERENT NERVES. W.T. Talman. Lab. of Neurobiol. Univ. of Iowa & Vets. Admin. Med Center, Iowa City, IA 52242.

Biochemical, pharmacological, physiological, and receptor binding data support a role for L-glutamate (L-glu) in the mediation of the baroreceptor reflex in the nucleus tractus solitarius (NTS). If L-glu were the neurotransmitter of primary baroreceptor afferents, denervation supersensitivity might be expected to occur with degeneration of the afferent fibers. Thus, we sought to determine whether the dose related changes in arterial pressure (AP) elicited by the microinjection of L-glu into the NTS were significantly altered after removal of the nodose ganglion, the site of cell bodies of baroreceptor and other visceral afferent fibers. Ten adult male Sprague-Dawley rats were used in these experiments. Five were unoperated controls and five were studied 10 days after the removal of the left nodose ganglion. Each rat was anesthetized (halothane 1.5-2%), cannulated for recording AP via the femoral artery, and mounted in a stereotaxic frame. After exposure of the brain stem, microinjections (50 nl) of saline vehicle or increasing doses of L-glu (3 to 1500 pmoles) were made alternately into the right and left dorsomedial NTS. Each dose was usually injected twice on each side. The last injection on each side contained a 2% concentration of pontamine blue in saline for histologic confirmation of injection sites. In control rats the lowest dose of L-glu that elicited a significant fall of AP was 30 pmoles, while the threshold dose in the left NTS of ganglionectomized rats was 3 pmoles. In lesioned, but not in control, rats all doses of L-glu elicited greater responses from the left NTS than from the right NTS. Left NTS dose responses in lesioned rats were also consistently greater than those from the left NTS of control rats. In control rats there was no significant difference between the dose response elicited from the right and left NTS. In lesioned rats the maximal response from the left NTS was 41 $\pm$ 5.4 mmHg fall of AP vs. 34.2 $\pm$ 6.6 mmHg ($p<0.05$) from the right in lesioned rats and 30 $\pm$ 4.3 mmHg ($p<0.05$) from the left in control rats. All injections were confirmed to be symmetrically placed in the right and left NTS for each animal. These data provide evidence suggesting that denervation supersensitivity develops for L-glu after nodose ganglionectomy. If supported by other criteria of denervation supersensitivity and by similar observations after more selective degeneration of baroreceptor afferents, the data would support the hypothesis that L-glu is a neurotransmitter of baroreceptor afferents.

32.17 SPIDER VENOMS BLOCK SYNAPTIC TRANSMISSION MEDIATED BY NON-N-METHYL-D-ASPARTATE RECEPTORS IN THE AVIAN COCHLEAR NUCLEUS. H. Jackson, M. Urnes*, W.R. Gray*, and T.N. Parks. Depts. of Anatomy and Biology, Univ. of Utah, Salt Lake City, UT 84132.

The study of excitatory amino acid transmission in the CNS would be facilitated by the availability of more specific, potent, and slowly-reversible ligands that act on receptor complexes. We have examined the ability of milked venoms from seven American spider genera (of five families) to suppress synaptic transmission (mediated by receptors of the non-N-methyl-D-aspartate class) between the avian cochlear nerve and cochlear nucleus (nuc. magnocellularis, NM). The ability of bath-applied whole venom, or venom fractions purified by gel filtration and reverse phase HPLC, to depress synaptically evoked responses was assessed by recording field potentials from NM following electrical stimulation of the cochlear nerve in in vitro preparations of the brain stem of hatchling chickens 1-10 days old. In the initial screening experiments, when whole venom was applied at 0.33% (v/v), venoms from Neoscona arabesca and Plectreurys tristes were without effect, while venom from Araneus gemma caused a partial and fully reversible depression of transmission. Whole venom from Argiope aurantia and Peucetia viridens produced potent but fully reversible suppression; the active component of the Argiope venom is positively charged and has a molecular weight of 659 daltons. Venom from the wolf spider (family Lycosidae) produced a rapid and reversible suppression both of postsynaptic currents in NM and the afferent volley, suggesting that this venom contains at least one component that acts presynaptically. In contrast, venom from Hololena curta produced complete but apparently irreversible suppression of transmission without affecting the afferent volley; in repeated experiments, the postsynaptic field potential failed to recover, even after more than 3 hr of washing in venom-free avian Tyrode solution. The active component(s) of this venom resides in a fraction of about 10,000 daltons and appears capable of acting at even lower concentrations than the Argiope venom. The effect of Hololena venom on the survival of cultured chick ciliary ganglion cells and their ability to extend neurites was also assessed. At a concentration that completely suppresses synaptic transmission in NM, the venom did not produce increased mortality of the cultured cells or interfere with the extension of neurites. Further, action potentials could still be evoked from NM neurons by direct electrical stimulation after several hours of transmission blockade. These results indicate that Hololena venom is not generally neurotoxic at the concentrations tested and that the apparent irreversibility of transmission blockade does not result from NM neurons being rendered electrically inexcitable.

32.18 CORTICAL CHOLINERGIC MARKERS FAIL TO RECOVER FOLLOWING INJECTION OF QUINOLINIC ACID (QUIN) OR IBOTENIC ACID (IBO) INTO THE RAT NUCLEUS BASALIS MAGNOCELLULARIS (nbM). K. Jhamandas*, S. El-Defrawy*, R.J. Boegman, L. Shipton*, and R.J. Beninger. Departments of Pharmacology and Toxicology, and Psychology, Queen's University, Kingston, Ontario, K7L 3N6.

Injections of axon-sparing excitotoxins into the nbM of the rat produce a marked decrease in the neocortical cholinergic markers, choline acetyltransferase (CAT), high affinity choline uptake (HACU) and acetylcholinesterase (AChE). Recently, it was reported that full recovery of CAT occurs 3 months after injection of IBO into the nbM (Wenk and Olton, Br. Res. 293: 184, 1984). In the present study we examined neocortical CAT, HACU, AChE and ^{3}H-acetylcholine release over a 3 month period following a single injection of either QUIN (an endogenous neurotoxin) or IBO into the nbM.

Stereotaxic injections of QUIN (120 nmol) or IBO (25 nmol) in saline were administered as 1 µl infusions into the nbM of halothane-anesthetized rats. The cortical cholinergic markers (CAT, HACU, AChE), as well as spontaneous and potassium evoked (35 mM) ^{3}H-acetylcholine release, were measured 1, 3, 6 and 12 weeks post-injection. Within 1 week, all markers showed a decrease of 40-50% (QUIN) or 35-45% (IBO). No recovery of these markers were observed at 3, 6 and 12 weeks post-injection.

In support of our neurochemical data, light microscopy of cresyl violet stained brain sections 3 months after lesioning showed extensive gliosis at the site of toxin application.

Wenk and Olton (1984) reported significant recovery in cortical CAT activity 3 weeks after an IBO lesion and complete recovery by 12 weeks. In our experiments, we obtained the same maximal degree of cholinergic deficit in the cortex as that reported by Wenk and Olton; however, our results with QUIN or IBO show that cholinergic markers remain depleted following excitotoxin lesions of the nbM.

32.19 SEPARATE ENZYMATIC ASSAYS FOR CYTOSOLIC AND MITOCHONDRIAL ASPARTATE AMINOTRANSFERASE ACTIVITIES. J.A. Parli*, D.A. Godfrey and C.D. Ross, Dept. Physiol., Oral Roberts Univ., Tulsa, OK 74171

The enzyme aspartate aminotransferase (AAT), which catalyzes the interconversion of glutamate and oxaloacetate with aspartate and α-ketoglutarate, consists of two isoenzymes, cytosolic AAT (cAAT) and mitochondrial AAT (mAAT). Although immunohistochemical procedures have been developed for the determination of both isoenzymes, and most staining results are for the cytosolic isoenzyme, there have not been enzymatic assays which distinguish between their activities. Toward this end, fluorometric assay procedures have been developed for the separate determination of cAAT and mAAT activities. In the cAAT assay, samples are preheated to 70 ^{0} C for 15 minutes, to destroy the mitochondrial isoenzyme. In the mAAT assay, the pH of the incubation medium is 5.0 instead of the usual 7.4, and the aspartate concentration 2mM instead of 40 mM. These parameters were determined from experiments using a commercially prepared cytosolic AAT (cyt. AAT) from pig heart, a mitochondrial preparation produced from mouse liver homogenate (mit. prep.), and whole rat brain homogenate (RBH), which contains both isoenzymes. The apparent K_m values for aspartate and α-ketoglutarate were determined:

	RBH	Heated RBH	Cyt. AAT	Mit. Prep.
K_m Asp (m M)	0.8	2.5	3.3	0.2
K_m αKG (m M)	0.19	0.03	0.05	0.34

The heated RBH and cyt. AAT values are similar, with RBH falling between cyt. AAT and mit. prep. values. When enzyme activity was examined vs. pH, it was found that as pH decreased, both heated RBH and cyt. AAT activity decreased greatly, whereas reduction of the mit. prep. activity was much less. These experiments document that the heated RBH has characteristics similar to those of the cyt.AAT. When the three assay procedures, for total AAT (tAAT), cAAT and mAAT were done for the cyt. AAT, mit. prep., and RBH, the following results were obtained:

	tAAT	cAAT	mAAT	corr mAAT
cyt. AAT (mol/g/hr)	28.5	29.2	0.5	
mit. prep. (mol/kg/hr)	14.5	0.4	6.4	
RBH (mol/kg/hr)	14.7	6.4	3.9	8.8

Since the mit. prep. had virtually no cAAT activity, a correction factor for the mAAT assay was determined by dividing the mit. prep. activity in the tAAT assay by that in the mAAT assay. Evidence that this correction factor is appropriate for rat brain is provided by the finding that using the thereby corrected mAAT activity of RBH, summed with its cAAT activity, gives a value very close to the tAAT activity. The availability of these separate quantitative assays for the AAT isoenzymes, capable of measuring their activities in microgram amounts of tissue, permits more specific comparisons of quantitative with stain histochemical results. (Supported by NIH Grants NS17176 and EY03838)

33.1 FIRST IMMUNOHISTOCHEMICAL DEMONSTRATION OF N-ACETYL-ASPARTYL-GLUTAMATE IN SPECIFIC NEURONS. C.B.Cangro*, D.E.Garrison*, P.A.Luongo*, M.E.Truckenmiller, M.A.A.Namboodiri* and J.H.Neale, Department of Biology, Georgetown University, Washington D.C. 20057

N-Acetyl-aspartyl-glutamate (NAAG) is a nervous system specific dipeptide which is found in millimolar concentrations in certain regions of the central nervous system including the spinal cord. NAAG is reported to displace glutamate binding to the quisqualate subclass of glutamate receptors (Koller and Coyle, Eur. J. Pharm. 98:193, 1984). In order to better understand the role of NAAG in nervous system function, we have developed antisera which recognize NAAG in tissue sections and have applied these immunological reagents initially to study the distribution of the immunoreactivity (IR) of NAAG in spinal sensory neurons.

NAAG was synthesized by the acetylation of aspartylglutamate with acetic anhydride, purified by reverse phase HPLC, characterized by mass spectroscopy and coupled to thyroglobulin using carbodiimide. Rabbit antisera, produced by immunization with this hapten-carrier conjugate, were applied to cryostat sections of dorsal root ganglia which had been fixed by perfusion with carbodiimide and post fixed with paraformaldehyde. The diluted antisera, when used in conjunction with fluoresceinated secondary antiserum, demonstrated a subpopulation of neuronal cell bodies within the spinal ganglia which exhibited immunoreactivity well above other neurons in the ganglia. This differential NAAG-IR was not observed when tissues were fixed with paraformaldehyde alone, suggesting that the IR was due to a small diffusable molecule which was covalently coupled to cellular proteins by carbodiimide mediated peptide bond formation. When antisera were preincubated with 5mM N-acetyl-aspartate, N-acetyl-glutamate, aspartylglutamate, aspartate or glutamate, the immunoreactivity was not affected, whereas it was eliminated by treatment of the antisera with 0.2mM NAAG. Antisera generated against N-acetyl-aspartate (NAA) by a similar procedure failed to demonstrate any differential immunoreactivity within spinal sensory ganglia. Consistent with this observation of NAAG-IR within spinal sensory neuronal cell bodies is our finding that an extract of fresh rat spinal ganglia (H_2O:methanol, 1:9) contains a major absorbance peak which co-migrates with synthetic NAAG during anion exchange HPLC. These data suggest that NAAG is differentially distributed within spinal sensory neurons and that its cellular distribution in other areas of the nervous system can be identified using these antisera.

33.2 DISTRIBUTION OF [^{3}H]N-ACETYL-ASPARTYL-GLUTAMATE BINDING SITES IN RAT BRAIN: A QUANTITATIVE IN VITRO AUTORADIOGRAPHIC STUDY. M.E. Abreu*, R.D. Blakely* and J.T. Coyle. Nova Pharmaceutical Corp., Balto. MD 21224 and Dept. of Neuroscience, Johns Hopkins Univ. School of Medicine, Balto., MD 21205. (SPON: W.J. Kinnier)

N-Acetyl-aspartyl-glutamate (NAAG) is an endogenous dipeptide that binds to a subpopulation of glutamate receptors in a chloride dependent and calcium enhanced manner. Electrophysiologic studies in pyriform cortex indicate that the potent neuroexcitatory action of NAAG mimics the response of the endogenous transmitter of the lateral olfactory tract. Both responses are selectively blocked by D,L-2-aminophosphonobutyric acid (AP4) suggesting that NAAG interacts specifically with an AP4 sensitive receptor and may serve as a neurotransmitter in this pathway.

A modification of the method described by Greenamyre et al. (J. Neurosci. 4:2133, 1984) was utilized in the current studies. Briefly, slide-mounted rat brain tissue sections (10 micron) were preincubated at 4°C for 1 hr in 50 mM Tris Cl (pH 7.4) containing 2.5 mM $CaCl_2$ followed by a 45 min incubation at 4°C with 200 nM [^{3}H]-NAAG (44.1 Ci/mmol) or 200 nM [^{3}H]L-glutamate (45.9 Ci/mmol). At the end of the incubation, tissue sections were rapidly rinsed in cold buffer, followed by a rinse with 2.5% glutaraldehyde in acetone and immediately dried on a slide warmer (40°C). L-glutamate (10^{-3}M) was used to determine non-specific binding.

Scatchard analysis indicated that [^{3}H]-NAAG binds to a single site with an apparent K_D of approximately 300 nM. The binding of [^{3}H]-NAAG was heterogeneously distributed in a pattern similar to that of [^{3}H]-glutamate binding; and, in addition, the density of NAAG sites represents a substantial fraction of glutamate sites ranging from 50-75%. For both ligands, the highest density of binding was found in the hippocampus in which a distinct laminar pattern was apparent with the greatest binding observed in the stratum moleculare of the dentate gyrus and in the CA_1 region of the stratum radiatum while lower levels of binding were measured in stratum oriens, the granule cell layer of the dentate gyrus and the subiculum. Most regions of the cerebral cortex were heavily labeled, exhibiting a dense band of binding in the external cortical layers. Other forebrain structures including the caudate-putamen, accumbens, anterior olfactory nuclei and olfactory tubercle demonstrated moderate to high levels of binding. An intermediate level of binding was observed in the thalamus and superior colliculus while lower levels were apparent in the cerebellum, substantia nigra and substantia gelatinosa of the spinal cord. Very little specific binding was observed in the mesencephalic and pontine tegmentum. These initial studies demonstrate that [^{3}H]-NAAG binding exhibits a marked regional variation that is co-extensive with sites labelled by [^{3}H]-glutamate.

33.3 A HIGH-AFFINITY SYNAPTOSOMAL UPTAKE SYSTEM INVOLVING N-ACETYL-ASPARTYL-GLUTAMATE. R. Blakely*, L. Ory-Lavollee*, R. Thompson* and J.T. Coyle. Dept. of Neuroscience. Johns Hopkins Univ. School of Medicine, Balto., MD 21205 (SPON: D. Braitman).

N-Acetyl-aspartyl-glutamate (NAAG), an endogenous brain peptide which acts as a competitive inhibitor at a subpopulation of Cl-dependent, Ca^{2+} stimulated [^{3}H]-glutamate ([^{3}H]-Glu) binding sites may be involved in neurotransmission at some synapses generally considered to use glutamate and/or aspartate as transmitters. In the present study, we examined the possibility that NAAG might be inactivated by a high-affinity synaptosomal transport system. Crude rat brain synaptosomes, prepared by differential centrifugation, were washed twice with 0.32M sucrose and resuspended in 50mM Tris Cl buffer (pH 7.4) containing 120mM NaCl, 10mM dextrose, 4.7mM KCl, 4.9mM $MgSO_4$, and 2.5 mM $CaCl_2$. Choline chloride was substituted for NaCl to assess Na^+ dependency. Following a 5 min preincubation at 37°C, aliquots containing ~300ug of synaptosomal protein were transferred to tubes containing uptake buffer, N-acetyl-aspartyl-[^{3}H]-glutamate(46.6Ci/mmol, 4nM), or [C14]-acetyl-aspartyl-glutamate(55uCi/mmol, 10uM) or [^{3}H]-Glu(50 Ci/mmol, 4nM) with or without potential inhibitors. Assays were performed at 37°C in a shaking water bath and terminated by filtration with a modified Brandel Cell-Harvester. Uptake of label from [^{3}H]-NAAG (Km=5uM) was saturable, occurred in an osmotically sensitive compartment, was temperature- and Na^+-dependent and linear with time up to 10 min. Subsequent studies were thus conducted with 5 min incubations. The initial rate of transport of label varied across CNS regions from 1.5 (cerebellum) to 9.5 (hippocampus) pmol/mg/hr while the ratio of uptake of label from [^{3}H]-NAAG to [^{3}H]-Glu varied from 4% (cerebellum) to 10.5% (septum/hypothal). Transport of both compounds was sensitive to ouabain and veratrine treatment. All inhibitors of [^{3}H]-Glu uptake also inhibited transport of [^{3}H]-NAAG label. HPLC analysis of radioactivity transported by synaptosomes from [^{3}H]-NAAG revealed no [^{3}H]-NAAG but rather an increase with time in material which co-eluted with [^{3}H]-Glu. One mechanism which could account for these findings is the action of a peptidase cleaving labeled Glu from NAAG, which is then subject to a high-affinity uptake system. In support of this hypothesis, we found that transport was not detected when [^{14}C]-NAAG, labeled at the N-terminal acetate, was the substrate. Structural specificity of such a protease is suggested by the ability of N-acetyl-glutamyl-glutamate (NAGG)(IC50=8uM) but not N-acetyl-glutamyl-aspartate (IC50>100uM) to compete with this transport process. The unacetylated dipeptides, AG and GG, were potent inhibitors of this process (IC50=10uM). Observation that NAAG, NAGG, AG, GG and quisqualate (IC50=2uM) fail to interfere with [^{3}H]-Glu transport argues that these agents exert inhibition not at the level of the carrier but target another recognition site, possibly a protease.

33.4 EFFECTS OF GLUTAMATE CONTAINING DIPEPTIDES ON THE BINDING OF [3H]-L-GLUTAMATE TO RAT BRAIN MEMBRANES. R. Zaczek*, S. Arlis*, A. Markl*, T. Murphy* and J.T. Coyle. Dept. of Neuroscience. Johns Hopkins Univ. School of Medicine, Balto., MD 21205.

Phenylalanyl-glutamate (Phe-Glu) and other dipeptides containing glutamate at the carboxy terminus have been shown to increase the binding of [3H]-2-amino-7-phosphonoheptanoic acid while inhibiting the binding of [3H]-kainic acid. We have extended the study of these compounds to their effects on the binding of [3H]-L-glutamate to rat brain membranes. Phe-Glu increases glutamate binding in a dose dependent (EC50=50uM) and reversible manner. This effect is robust with the binding increasing 20-fold in the presence of 100 uM Phe-Glu. Saturation isotherms of glutamate binding in the presence and absence of Phe-Glu indicate that the increase in binding is due to an increase in the Bmax of glutamate binding. This increase in binding is temperature dependent displaying a Gaussian temperature curve with an optimal temperature of approximately 37°C. Phe-Glu dependent [3H]-L-glutamate binding has both chloride dependent and independent components. Rate experiments have shown that glutamate binding to Phe-Glu dependent sites is an ordered process, Phe-Glu having to be present at the binding complex before [3H]-L-glutamate is able to bind. Several dipeptides related to Phe-Glu can also increase glutamate binding (Arg-Glu > Phe-Glu > Tyr-Glu > Tryp-Glu). Preincubation experiments suggest that an endogenous functional analogue of Phe-Glu may exist in brain.

The increase in binding with Phe-Glu represents the appearance of novel sites rather than an increase in the number of existing ones since Phe-Glu dependent and independent glutamate binding display several differences. There is a 3-fold difference in the affinity of glutamate for the two sites (Kd=700nM independent; Kd=2.0uM dependent). The pharmacology of the two sites also differs. N-acetyl-aspartyl-glutamate, a potent inhibitor of Phe-Glu independent binding (Ki=300nM), is ineffective at inhibiting the binding of glutamate to the Phe-Glu dependent site (Ki>100uM). While quisqualic acid displays a biphasic displacement of glutamate binding to the Phe-Glu independent site and is more potent than ibotenic acid, it shows monophasic displacement of equal potency to ibotenic acid at the Phe-Glu dependent site. Finally, the ontogenetic profiles of the two sites differ. While postnatal levels of Phe-Glu independent binding increase only 2-fold in forebrain, there is a several-fold increase in Phe-Glu dependent glutamate binding from postnatal day 7 to adult. These results suggest that certain excitatory amino acid processes may be modulated by small peptides containing glutamate.

33.5 GLUTAMATE CONTAINING DIPEPTIDES ENHANCE THE NEUROTOXIC ACTIONS OF KAINIC ACID IN VIVO. J.Ferkany and L. O'Brien* Nova Pharmaceutical Corp., Div. Mol. Pharmacology, Baltimore, MD 21224.

Carboxyterminal L-glutamate (GLU) containing dipeptides (leucyl-GLU; LG: methionyl-GLU; MG) enhance the specific binding of [3H]GLU and [3H]2-amino-7-phosphono heptanoic acid and inhibit the specific binding of [3H]kainic acid (KA) to brain membranes in vitro (Ferkany et al., Neurosci. Letts. 44:281, 1984; Zaczek et al. Tr. Am. Soc. Neurochem. 16:303, 1985). We now report that intra-striatal coinjections of LG or MG with KA but not ibotenate (IBO) enhance the toxic actions of KA on striatal interneurons.

Male Sprague Dawley rats (200-250 g) were anesthetized with Chloropent@ and positioned in a stereotaxic apparatus. Drugs dissolved in saline and titrated to a neutral pH were injected into the striatum over a period of 60 sec in a final volume of 1 ul. Animals allowed to recover for 3 days were sacrificed by decapitation, the striata dissected and assayed for choline acetyltransferase (CAT) and glutamic acid decarboxylase (GAD) activity. Striata contralateral to the injection site served as controls.

Injection of KA (7.5 nmole; nm) resulted in a 30±4 and 45±5 (N=8) percent decline in CAT and GAD activities, respectively. Although injections of 300 nm LG or MG alone had no effect on the activity of either enzyme, coinjection of LG or MG (300 nm) with KA (7.5 nm) induced a further 15-20 percent decline in GAD and CAT activities when compared to striata of animals injected with KA alone ($p<0.05$). Like the dipeptides, injections of GLU (1000 nm) or D-GLU (500 nm) had no effect on the activities of striatal GAD or CAT. However, coinjection of GLU (500 nm) but not D-GLU (500 nm) with KA (7.5 nm) produced a decline in the activities of both enzymes comparable to that observed following coninjections of LG or MG with KA. Thus, the possibility exists that the interaction of LG and MG with KA results from the metabolism of these compounds to GLU. Coinjection of the aromatic dipeptide, phenylalanyl-GLU (PG) (300 nm) with KA also caused an additional decline in enzymes activities; however, this effect was not significant ($p = 0.08$). None of the compounds tested increased the toxic actions of IBO (100 nm) on striatal enzyme activities when coinjected with the latter neurotoxin.

LG, MG and PG allosterically modulate the binding of excitatory amino acids (EAA) in vitro; they do not block the uptake of EAAs in vitro. Preliminary investigations indicate that PG is not metabolized by brain slices, homogenates or synaptosomes. Injection of large amounts of these compounds into the hippocampus fail to produce behavioral or EEG-detectable effects suggesting the compounds are not neuroexcitatory (Zaczek, personal comm.). The current results suggest that substances other than EAAs may influence the neurotoxic actions of KA in vivo. Supported in part by NINCDS grant 1 R43 NS21400-01.

33.6 [3H]AMPA BINDS TO TWO SITES IN RAT CRUDE SYNAPTIC MEMBRANES: PHARMACOLOGICAL CHARACTERIZATION. Deborah E. Murphy, Elaine W. Snowhill* and Michael Williams. Neuroscience/Cardiovascular Research, Pharmaceuticals Division, CIBA-GEIGY Corp.,Summit,NJ 07901

The binding of [3H]AMPA (amino-3-hydroxy-5-methylisoxazole-4-propionic acid,α-[5-methyl-^{3}H]) an agonist for the putative quisqualate-type excitatory amino acid receptor (Krosgaard-Larsen et al., Nature,284: 66,1980) was examined in rat brain membranes. Filtration and centrifugation procedures were examined; the latter greatly increased specific binding and was used routinely. Tissues were incubated with [^{3}H]AMPA (27.5 Ci/mmol, NEN, Boston) in 50 mM Tris-HCl, pH 7.4 (4°C). Specific binding observed with freshly prepared crude synaptic membranes (CSMs; 34%) increased two-fold when the tissue was pre-treated with detergent (0.04% Triton-X 100) or when the tissue was frozen and thawed three times. Association studies indicated that binding reached equilibrium within 20 min and remained stable for nearly 2 hr: binding was reversed by the addition of 1mM l-glutamate. Scatchard analysis on the frozen/thawed CSMs indicated the presence of two distinct binding sites: one with high affinity (Kd= 17±6 nM) and one with low affinity (Kd=3.8±0.4 µM). Apparent Bmax values were 0.2±0.3 and 22.9±0.6 pmol/mg protein respectively. The biphasic inhibition curves seen with quisqualate and unlabeled AMPA further supported the presence of two separate binding components. The inhibition of [^{3}H]AMPA binding was consistent with the labeling of a quisqualate-type receptor being stereoselective for the isomers of glutamate. The order of potency of various amino acids studied was: quisqualate>AMPA>l-glutamate>kainate, l-glutamic acid diethylester> d-glutamate. N-methyl-D-aspartate, d&l-aspartate and d&l-amino adipate were inactive at 100 uM. These data show considerable agreement with those reported previously (Honoré et al., J. Neurochem. 38:187, 1982). However, in contrast, the use in the present study of higher specific radioactivity AMPA showed clear evidence for two binding sites in tissue that had been frozen and thawed three times. Binding was also weakly sensitive to kainate in contrast to the lack of effect of this amino acid in mouse brain membranes at pH 5.5 (Tsai and Lehmann, this volume).

33.7 QUISQUALATE-TYPE RECEPTOR SITES LABELED BY [^{3}H]AMPA - LACK OF INTERACTION WITH KAINATE. C. Tsai* and J. Lehmann (SPON: D.L. Cheney). Neurosci. Res., Pharm. Div., CIBA-GEIGY Corp., Summit, NJ 07901.

The previous description of conditions for the specific binding of [^{3}H]α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) showed that the profile of [^{3}H]AMPA binding was largely in agreement with the labeling of a quisqualate-type receptor (Honore et al., J. Neurochem. 38:173, 1982). However, under these conditions, kainate also inhibited binding of [^{3}H]AMPA. We report here the development of conditions for [^{3}H]AMPA binding which do not show this interaction with kainate, and hence provide a more specific assay for quisqualate-type receptor binding sites. While the present conditions yield a pharmacological profile which is more in agreement with the labeling of a quisqualate-type receptor, they also yield a very unusual pH maximum (5.5). The results shown below (performed at 24°C in mouse whole brain minus cerebellum and brain stem) support the hypothesis that [^{3}H]AMPA labels a quisqualate-type receptor.

Test Compound	IC_{50} values (uM)		
	centrifugation	filtration	Honore et al.
AMPA	12	38	0.3
Bromowillardiine	14	25	-
L-GLU	43	55	1.3
Quis	52	55	0.3
IBO	500	400	>100
L-Asp	700	320	>100
D-Asp	1000	>1000	>100
D-GLU	>1000	875	100
Kainate	5000	>12500	6
NMDA	>1000	>1000	-
Muscimol	>1000	>1000	-
GABA	>1000	>1000	>100
GDEE	76% ↑ @1000	78% ↑ @1000	>100

All of the following compounds showed no inhibition when tested at 1 mM in the centrifugation assay: AP3, AP4, D-AP5, L-AP5, AP7, γ-D-GLU-GLY, kynurenic acid, L-cysteic acid, streptomycin, NAAG, (+/-)cis-2,3-piperidine dicarboxylic acid, N-α-aspartic acid-L-glutamate, DL-2-amino-6-hexanoic acid, and γ-D-glutamylaminomethyl-phosphonic acid.

33.8 N-METHYL-D-ASPARTATE (NMDA) RECEPTORS: PHARMACOLOGICAL AND BIOCHEMICAL CHARACTERIZATION. G.E. Fagg and J. Baud. Friedrich Miescher Institute, P.O. Box 2543, Basel, Switzerland.

The A1 (NMDA-preferring) sub-type of acidic amino acid receptor is being implicated increasingly in a wide range of brain mechanisms, including excitatory synaptic transmission, long-term potentiation, seizure activity and neurodegeneration. Recently, we demonstrated that this receptor may be labeled in vitro using L-^{3}H-glutamate (Glu) and that it is enriched in postsynaptic densities (PSDs) isolated from the rat brain (Fagg & Matus, Proc. Nat. Acad. Sci.USA, 81, 6876-6880; 1984). Here we describe the general ligand selectivity and basic biochemical properties of this receptor.

L-^{3}H-Glu bound reversibly to PSD fractions with Kd 0.3 µM. Specific binding at 50 nM ^{3}H-Glu (non-specific determined using 0.5 mM L-Glu) represented 87% of total binding, of which 80% was sensitive to inhibition by A1 receptor ligands such as NMDA (Ki 6.3 µM) and 2-amino-5-phosphonopentanoate (Ki 1.0 µM). This site could also be labeled with ^{3}H-NMDA, but the percentage specific binding (29%) was less favourable for routine analyses. Structure-activity studies showed that L-Glu was the most potent inhibitor of NMDA-sensitive L-^{3}H-Glu binding examined (Ki 0.2 µM), while the higher and lower homologues (L-α-aminoadipate, L-asp) were weaker. Replacement of the ω-carboxyl group of Glu with other acidic groups decreased inhibitory potency in the order carboxyl > sulphonic > phosphonous >> phosphonic, while replacement of the α-carboxyl function with phosphonous or phosphonic moieties abolished activity. In the case of D-asp, inhibitory potency declined as N-substituents increased in size (methyl > ethyl > propyl), while lack of an amino group (succinate, glutarate) destroyed activity. A number of peptides were moderately effective inhibitors of ^{3}H-Glu binding (e.g., Phe-Glu, Ki 7 µM), while substances such as phencyclidine and Mg^{2+} were without effect.

Receptor binding activity was retained after freezing or lyophilizing PSD fractions, but was abolished by heating at 60°C for 15 min. Treatment of PSDs with trypsin or chymotrypsin (1% of PSD protein) markedly decreased L-^{3}H-Glu binding, while the Ca^{2+}-activated proteases calpain I and II had little effect. The thiol reagent p-hydroxymercuribenzoate (0.1 mM) similarly did not modify binding to a marked extent.

These data indicate that the A1 receptor is a proteinaceous component of the postjunctional membrane. The receptor recognition site exhibits a high degree of ligand selectivity and is distinct from those sites regulated by Mg^{2+} and the 'sigma opiates'.

We thank Drs. J. Dingwall, L. Maier and P. Diel for gifts of compounds, and Dr. T. Murachi for samples of calpain I and II.

33.9 **EXCITATORY AMINO ACID BINDING SITES: CORRESPONDENCE BETWEEN AUTORADIOGRAPHIC AND MEMBRANE FRACTION PREPARATIONS.** D.T. Monaghan, D. Yao*, L. Nguyen* and C.W. Cotman. Dept. of Psychobiology, Univ. Cal., Irvine, CA 92717.

The excitatory amino acids, especially L-glutamate, are thought to exert their neurotransmitter action through the activation of at least four receptor classes. Previously, we have used quantitative autoradiographic techniques to describe four pharmacologically distinct L-[^{3}H]-glutamate binding sites, three of which appeared to correspond to physiologically defined excitatory amino acid receptors. There are few studies of these particular L-[^{3}H]-glutamate binding sites in membrane preparations. Consequently, the following experiments were performed to determine the correspondence of the autoradiographically determined binding sites to those observed in membrane preparations.

1)N-Methyl-D-aspartate (NMDA) receptors appear to be labelled by L-[^{3}H]-glutamate in autoradiographic preparations. To assess the similarity of NMDA-sensitive L-[^{3}H]-glutamate binding sites in membrane fragments to those we have described in autoradiography we have determined their pharmacological profile in rat brain synaptic plasma membranes (SPMs) (J. Neurosci. 1 (1981) 620-625). Following the incubation of SPMs with 10 nM L-[^{3}H]-glutamate (44-50 Ci/mmol, ICN or NEN), 50 mM Tris-acetate, pH 7.0, for 2.5 minutes at 0-4°C, 80% of the specific binding is displaced by NMDA with a Ki value of 4 ± 1μM. The pharmacological profile of these sites correspond to both the NMDA receptor and to the autoradiographically determined binding site For example, the NMDA antagonists D-α-aminoadipate and D-2-amino-5-phosphonopentanoate exhibited Ki values of 10.1 ± 0.6 and 2.3 ± 0.4μM. Furthermore, binding to both autoradiographic and membrane fraction NMDA sites was inhibited by 100μM GTP. Nucleotide inhibition exhibited the same specificity as that found for other GTP-sensitive receptors.

2)Kainate (KA) receptors labelled in autoradiography by L-[^{3}H]-glutamate are readily displaced by Ca^{++} ions, but [^{3}H]KA sites show partial displacement. We have used EGTA (5mM) washed SPMs to assess the effect of Ca^{++} upon the affinity and Bmax of [^{3}H]KA binding sites. [^{3}H]KA (60 Ci/mmol, NEN, 0°C, 30 min., in 50 mM Tris acetate, pH 7.0) exhibited two affinities, 6.6 ± 0.8 nM and 25.6 ± 4.9 nM. However, in the presence of 5mM Ca^{++} only a 23.1 ± 1.9 nM site was detected. Thus, the previously described L-[^{3}H]-glutamate binding site which was both KA and Ca^{++}- sensitive may represent high affinity KA binding sites. (Ca^{++}-sensitive [^{3}H]KA binding sites were not equivalent to slow-dissociating sites.)

3)We previously reported that the Cl^-/Ca^{++}-enhanced binding sites observed in autoradiography were distinct from those determined in membrane preparations. Using previously described methods (Nature 306 (1983) 176-179) we find that the autoradiographically observed sites are potently inhibited by 4-acetamido-4'-isothiocyano-2,2'-disulfonic acid stilbene (SITS, Ki value 10 ± 3μM), moderately by 100μM L-aspartate, and insignificantly by 5mM Na^+ or 100 μM D-aspartate. Consequently, these sites may represent binding at Cl^--dependent L-[^{3}H]-glutamate uptake carrier sites in astrocytes. (Supported by DAAG 29-82-K-0194)

33.10 IMMUNOCHEMICAL CHARACTERIZATION AND IMMUNOHISTOCHEMISTRY OF THE GLUTAMATE BINDING PROTEIN IN RAT BRAIN, S. Roy, T. Stormann*, L. Vacca, M. Cunningham*, and E. Michaelis. Depts. of Biochemistry, Anatomy, and Human Development, U. of Kansas, Lawrence, KS 66045.

A glutamate-binding protein [GBP] has been purified from rat and bovine brain synaptic membranes. Based on the selectivity of the GBP binding sites for L-glutamate analogs and its lack of glutamate metabolizing enzymatic activity, it was proposed that the GBP is the recognition macromolecule of an L-glutamate receptor complex [Michaelis et al., J. Neurochem. 42, 397, 1984]. The GBP has been reconstituted in liposomes where it functioned both as a glutamate-recognition and ion channel-forming protein [Stormann et al., Neurosci. Abstr. 10, 958, 1984]. Antibodies (Ab's) against the bovine brain GBP raised in rabbits show very high immunological selectivity for this protein. They also inhibit the binding activity of GBP from either bovine or rat brain and block the activation of ion channels by glutamate in rat brain synaptic membranes [Roy and Michaelis, J. Neurochem. 42, 838, 1984; Roy et al., ibid., 44, in press]. These Ab's bound to denatured bovine and rat GBP that had been subjected to SDS-electrophoresis and blotted onto nitrocellulose paper. The Ab's that were raised in rabbits were also used to map the glutamate binding protein distribution in brain sections. The distribution of GBP antigenic sites in neurons was examined by the peroxidase-anti-peroxidase (PAP) immunohistochemical procedure in vibratome sections from the hippocampus and cerebellum. The highest immunoreactivity was localized in the dentate gyrus, hilar regions, and the CA_3 region of the hippocampus. The distribution was frequently seen as doublets or singlets on the dentrites of the pyramidal and granule cells in this region. The protein A-gold particle staining procedure was used to examine the distribution of antigenic sites at the electron microscopic level. Gold particle clustering in synaptosomal preparations was associated with membrane sites, particularly sites on dendritic fragments. The synaptic localization of this protein in intact brain tissue at the electron microscopic level is currently being explored by the immunogold and PAP staining procedures. (Supported by grants KS-84-G-21 from AHA, AA04732 from NIAAA, and DAAG-29-83-0065 from ARO.)

33.11 **STEREOSPECIFIC BINDING OF L-GLUTAMATE TO ASTROCYTE MEMBRANES** R.J. Bridges*, M. Nieto-Sampedro, and C.W. Cotman. (SPON: R. Vicedomini, Univ. of Kentucky) Department of Psychobiology, University of California, Irvine, CA 92717.

Glutamate appears to be a major excitatory transmitter in the mammalian central nervous system. Multiple types of glutamate binding sites have been identified. These binding sites may represent any number of functions (e.g., transmitter receptor, modulatory sites, transport systems) and may be present on either neurons or their associated glia.

Recently we have identified an L-glutamate binding site on membranes prepared from cultures of primary astrocytes. The binding of glutamate was determined using ^{3}H-L-glutamate and separating bound ligand, from that in solution, by rapid centrifugation. Assays were performed in 50 mM Tris-acetate, pH 6.9, for 60 minutes at 30° C. Non-specific binding was corrected for by subtracting the amount of ^{3}H-L-glutamate bound in the presence of 500μM L-glutamate. Sodium was omitted from the assay buffers to prevent binding to the Na^+-dependent transport site. Under these conditions the specific binding of glutamate was difficult to discern from non-specific binding. However, when Cl^- (Tris-Cl^-) was included in the buffer, specific binding increased 10-fold. This Cl^--enhanced L-glutamate binding is stereoselective and has a relatively high affinity (K_D~ 0.5μM). The specificity of the binding was examined by determining the extent to which ^{3}H-L-glutamate (100 nM) is displaced by various analogues (100 μM). Little or no inhibition is observed with kainic acid, N-methyl-D-aspartate, or α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA). A small amount of inhibition (25% or less) is seen with D-aspartate or L-2-amino-4-phosphonobutyric acid. Substantial inhibition is observed with quisqualic acid (50%) and L-aspartic acid (95%).

The pharmacological properties of the astrocyte binding site are different from the Cl^- dependent glutamate binding site observed in synaptic membrane preparations (SPMs) (Fagg, G.E., Mena, E.E., and Cotman, C.W.(1983) Adv. in Biochem. Psychopharm. 37,199). Importantly, the binding site on the astrocyte membranes is insensitive to freezing, unlike the site in SPMs. The specificity is, however, quite similar to that of a Cl^- dependent glutamate transport system recently described in glioma cells (Waniewski, R.A. and Martin, D.L. (1984) J. Neuro. 4, 2237). The pharmacological profile of the site also suggests that it may be present in brain slice autoradiographs of ^{3}H-glutamate binding when Cl^- is included in the binding medium.This presence of a class of glutamate binding sites on astrocytes demonstrates the difficulty in assigning a transmitter receptor function to a binding site in a heterogenous preparation, such as a brain homogenates or a brain slice. A detailed characterization of the binding site specificity and ionic requirement should allow this astrocytic site to be studied independently from the other glutamate binding sites and provide insight into its physiological role. (Supported by DAAG 29-82-K-0194)

33.12 AUTORADIOGRAPHIC LOCALIZATION OF CEREBELLAR GLUTAMATE RECEPTOR SUBTYPES. J.M.M. Olson*, J.T. Greenamyre, J.B. Penney and A.B. Young. Neuroscience Lab. Bldg., 1103 E. Huron, University of Michigan, Ann Arbor, MI 48104.

Glutamate is believed to be an excitatory neurotransmitter of the central nervous system and it has been implicated in the pathogenesis of several neurodegenerative diseases including Huntington's disease and olivopontocerebellar atrophy. Its actions are mediated by 3 distinct receptors named for the specific agonists N-methyl-D-aspartate (NMDA), kainate (KA) and quisqualate (QA). Certain glutamate analogues which interact with these receptors produce excitotoxic lesions resembling those seen in human disease.

In order to determine the synaptic location of these receptors, [^{3}H]glutamate and [^{3}H]kainate were used to label receptors autoradiographically in cerebella of control mice, mice lacking presynaptic glutamatergic granule cells due to treatment with the cytotoxic agent methylazoxymethanol acetate, and nervous mutant mice which lack the postsynaptic Purkinje cells. In control mice, [^{3}H]glutamate binding was found throughout cerebellar cortex. The majority of the molecular layer glutamate binding sites had a high affnity for QA, whereas most of the granule cell layer sites were sensitive to NMDA. This indicates that QA and NMDA receptors are located predominantly in the molecular and granule cell layer, respectively. In addition, [^{3}H]kainate binding sites are more abundant in the granule cell layer than in the molecular layer in control mice.

There was minimal [^{3}H]glutamate binding in the granule cell layer of granuloprival mice but the adjacent molecular layer showed "hot spots" of increased QA-sensitive binding, suggesting up-regulation of QA receptors in this layer. In these mice, NMDA-sensitive binding and [^{3}H]kainate binding were decreased in the granule cell layer but were normal in the molecular layer. In Purkinje cell-deficient mice, QA-sensitive sites were almost entirely absent from the molecular layer but NMDA-sensitive binding was normal.

This study indicates that QA sites are postsynaptic to granule cells and are located on dendrites of Purkinje cells. These sites can apparently up-regulate in response to denervation. NMDA sites are associated with granule cell perikarya but not with Purkinje cell dendrites. Finally, KA sites are associated with both granule cell perikarya and non-granule cell elements in the molecular layer.

33.13 L-GLUTAMATE BINDING SITES IN RAT SPINAL CORD MEMBRANES: EVIDENCE FOR TWO CHLORIDE ION DEPENDENT SITES. E. Edward Mena, Central Research Division, Pfizer Inc., Groton, CT 06340.

Membrane preparations from cortex and cerebelum are routinely employed in L-Glu binding studies. However, in vitro preparations of spinal cord frequently have been used to characterize the electrophysiological responses elicited by L-Glu. Thus, the inability to equate the binding sites of L-Glu with spinal cord receptors may be due, in part, to differences in L-Glu binding sites in cortex and spinal cord.

The effects of various ions on the major classes of ionically regulated L-Glu binding sites (Na^+-dependent, Cl^--dependent and Cl^--independent) (Mena et al., Brain Research, 243, 378, 1982) in synaptic plasma membranes (SPM) from rat spinal cord and forebrain were examined. Chloride ion dependent binding sites were nearly 1.7-fold higher in spinal cord SPM (Bmax values of 108 + 18 pMol/mg protein) as compared to forebrain SPM (Bmax values of 62 + 12 pMol/mg protein). Sodium ion dependent binding, on the other hand, was nearly 6-fold less in spinal cord (Bmax = 74 + 10 pMol/mg protein) compared to forebrain SPM (408 + 26 pMol/mg protein). Uptake of L-Glu (Na^+-dependent) was also 8-fold less in the P2 fraction from spinal cord relative to forebrain (Vmax of 2.89 and 22.3 pMol/mg protein/min, respectively). The regulation of L-Glu binding sites by Na^+, K^+, $NH4^+$ and Ca^{++} was similar in both regions of the central nervous system. In addition, in spinal cord membranes, Br^-, I^-, NO_3^- were equivalent to Cl^- in their ability to stimulate L-Glu binding. The effect of each of these ions was increased in the presence of Ca^{++}. F^- and CO_3^{--} did not significantly enhance binding in the absence of Ca^{++}. However, in the presence of Ca^{++} (0.5 mM) these ions were capable of increasing L-Glu binding over the levels in acetate buffer alone. Phosphate and sulfate were ineffective in the presence or absence of Ca^{++}.

2-Amino-4-phosphonobutyric acid (AP4) (100 uM) was able to inhibit only 80% of the total Cl^- ion dependent L-Glu binding in spinal cord SPM. However, the remaining Cl^- ion dependent binding could be blocked by quisqualic acid (QUIS) (100 uM). More detailed analysis showed that the predominant Cl^- ion dependent site had characteristics similar to the Cl^--dependent binding site in forebrain membranes (i.e. IC_{50} values of 5.7 + 1.4 uM and 119 + 24 nM for AP4 and QUIS, respectively). The other Cl^- ion dependent site was unaffected by 100 uM AP4 but was blocked by QUIS (IC_{50} = 6.7 + 1.4 uM). The results show that, in spinal cord membranes, Cl ion stimulation of L-Glu binding consists of two components, only one of which can be equated with the AP4-sensitive L-Glu binding site.

33.14 AUTORADIOGRAPHIC LOCALIZATION OF AMINO ACID RECEPTORS IN RAT AND HUMAN SPINAL CORD. J.T. Greenamyre, R. Albin*, J.B. Penney and A.B. Young. Neuroscience Lab. Bldg., 1103 E. Huron, Univ. of Michigan, Ann Arbor, MI 48104.

The inhibitory amino acids, glycine and GABA, and the excitatory amino acids, glutamate and aspartate, have all been proposed as major neurotransmitters in the mammalian spinal cord. Each of these amino acid transmitters acts through specific receptor mechanisms to produce its physiologic response(s). Furthermore, it has been shown that GABA, glutamate and aspartate each act at multiple receptor subtypes. Using quantitative receptor autoradiography, we have mapped the anatomical location of the various receptors with which these amino acids interact in rat and human spinal cord.

Glycine receptors were labelled with [^{3}H]strychnine as described previously (Penney et al., Eur.J.Pharmacol. 72:421, 1981). Glycine receptors were found in all laminae of the rat spinal cord and at all levels. The receptors were rather uniformly distributed throughout the laminae with a slightly higher density in substantia gelatinosa. A similar distribution was found in human thoracic spinal cord sections.

$GABA_A$ receptors were labelled with [^{3}H]GABA in Tris-citrate buffer and $GABA_B$ receptors were labelled with [^{3}H]GABA in Tris-HCl buffer with 2.5 mM $CaCl_2$ in the presence of 40 µM isoguvacine. $GABA_A$ receptors were found in both dorsal and ventral horns of rat spinal cord with the highest levels being in the substantia gelatinosa. In contrast, $GABA_B$ receptors were found almost exclusively in substantia gelatinosa. Similar patterns of $GABA_A$ and $GABA_B$ binding were seen in human spinal cord.

Excitatory amino acid receptors were labelled with [^{3}H]glutamate and subtypes of receptors distinguished pharmacologically as described previously (Greenamyre et al., J. Pharmacol. Exp. Ther. 233:1, 1985). Glutamate binding was highest in substantia gelatinosa in both rat and human spinal cords and was otherwise uniformly distributed in the dorsal and ventral horns. Most of the sites in substantia gelatinosa were of the high affinity quisqualate type; about 50% of the sites in the ventral horn were sensitive to N-methyl-D-aspartate.

The distribution and pharmacology of the receptors labelled autoradiographically corresponds well with the receptors described in electrophysiological studies.

33.15 CHANGES IN AMINO ACID LEVELS IN THE SPINAL GRAY MATTER AFTER AXOTOMY OF PRIMARY SENSORY AND DESCENDING FIBERS. S.J. Potashner and L. Dymczyk*. Dept. of Anatomy, University of Connecticut Health Center, Farmington, CT, 06032.

L-glutamate and/or L-aspartate (L-GLU/L-ASP) are proposed as putative transmitters of dorsal sensory neurons and of one or more of the pathways descending from the brain to the spinal cord, because axotomy of primary sensory and descending tracts depressed the high affinity uptake and the release of D-ASP in the guinea pig spinal cord (Potashner and Tran, J.Neurochem. 42: 1135 1984); J.Neurochem. in press (1985)). D-ASP is a nonmetabolizable marker taken up and released by glutamatergic and/or aspartatergic neurons. In this study, we determined if these lesions altered the stores of endogenous GLU, ASP, and other amino acids in the guinea pig spinal gray matter.

Bilateral dorsal rhizotomy (DR; roots C5-T1) and hemicordotomy (HC; at segment C5) were used in separate studies to interrupt primary sensory and descending tracts. The resulting preterminal degeneration of fibers in the spinal cord was visualized with the Nauta-Rasmussen silver stain in light microscopic preparations. In biochemical studies, performed 2 days after surgery, spinal segments C5-C8 were rapidly excised from anesthetized animals, quick-frozen, cut in a cryostat into transverse sections (40um), and lyophilized at -40°C. Using typical silver-stained sections as guides, areas of the spinal gray that receive heavy projections from the primary sensory and the descending tracts were microdissected from the lyophilized sections and weighed on a quartz fiber microbalance. The levels of amino acids in acid extracts of the microdissected pieces were determined using an HPLC amino acid analyzer.

After DR, the heaviest preterminal degeneration in the spinal gray appeared in laminae III-IV and medially in laminae IV-VI. DR reduced the levels of GLU, ASP, and GABA by 21, 34, and 26% in laminae III-IV and by 33, 28, and 23% in the medial parts of laminae IV-VI. The levels of other amino acids were increased. After HC, the heaviest preterminal degeneration in the spinal gray appeared in the lateral parts of laminae IV-VI and the dorsolateral part of lamina VII. HC reduced the levels of GLU and ASP by 28 and 22% in the lateral parts of laminae IV-VI and by 28 and 26% in dorsolateral lamina VII. Levels of other amino acids were unchanged or raised. These findings suggest that the axonal endings of the primary sensory and of one or more of the descending tracts contain stores of L-GLU and L-ASP. Together with previous findings, these results are consistent with a transmitter role for L-GLU/L-ASP in primary sensory and in one or more descending pathways. Possible reasons for the reductions in GABA levels are under investigation. (Supported by NS17219 from NINCDS)

33.16 PHARMACOLOGICAL STUDIES OF EXCITATORY AMINO ACID RECEPTORS USING A NEW TECHNIQUE OF GLUTAMATE INDUCED TRANSMITTER RELEASE FROM CULTURED NEURONS. J. Drejer*[1], T. Honoré*[1] and A. Schousboe*[2]. Ferrosan Res. Div., Soeborg, DK-2860 (1) and Panum Institute, Dept. Biochem. A, Copenhagen, DK-2200 (2), Denmark. (SPON: ENA)

Using a simple and sensitive method for the study of transmitter release from cultured neurons stimulated with excitatory amino acids, different receptor populations for excitatory amino acids were found in two different primary neuronal cultures. Neuronal cultures prepared from 7-day-old mouse cerebella have been shown to be an almost pure culture of glutamatergic granule cells. Cultured cerebral cortex neurons obtained from 16-day-embryo mice contain mainly GABA-ergic interneurons. For release studies cerebellar granule cells were preloaded with ^{3}H-D-aspartate as a tracer for the proposed transmitter L-glutamate and cerebral cortex neurons were preloaded with ^{3}H-GABA. The release of radioactivity from the cultures was studied in a continuous superfusion system and neurons were intermittently stimulated by the addition of excitatory amino acid agonists to the superfusion medium in the presence or absence of antagonists.

L-glu, L-asp, NMDA, quisqualate, kainate and AMPA were found to induce ^{3}H-GABA release from cerebral cortex neurons. The stimulated release was shown to be calcium-dependent and all stimulations by agonists could be blocked by one or more of the antagonists D-APV, D-APH, GDEE, D-α-AA and γ-DGG according to their known pharmacological selectivities. In granule cells only L-glu and L- and D-asp induced ^{3}H-D-asp release from the neurons. From the relative potencies of antagonists on L-glu induced ^{3}H-D-asp release from granule cells it is suggested that a unique population of excitatory amino acid receptors are present on granule cells and that such receptors might mediate the stimulation of granule cells in vivo via mossy fiber terminals. Binding experiments supported the existence of different types of receptors for excitatory amino acids on the two neuronal cultures; thus quisqualate was found to be a potent displacer of ^{3}H-L-glu binding to cultured cortex neurons whereas in granule cells only L-glu and L- and D-asp were potent displacers of ^{3}H-L-glu binding. The results are summarized in table I.

Table I.

	Displacement of ^{3}H-L-glu binding. IC_{50} (µM)		Induced transmitter-release. EC_{50} (µM)	
	cortex neurons	granule cells	cort. neuron (^{3}H-GABA)	granule cells (^{3}H-D-asp)
L-glutamate	0.05	0.41	6	30
L-aspartate	0.26	0.65	16	33
D-aspartate	-	21	-	140
quisqualate	0.50	36	0.06	>1000
kainate	>10	>60	30	>1000
NMDA	>70	>70	4	>1000

33.17 STIMULATION OF $^{22}Na+$ EFFLUX FROM RAT FOREBRAIN MEMBRANES BY GLUTAMIC ACID AND KAINIC ACID. John C. Matthews* (SPON: W. Marvin Davis). Dept. of Pharmacol., Univ. of Miss., Sch. of Pharm., University, MS 38677.

Glutamic acid, kainic acid and quisqualic acid stimulate $^{22}Na+$ efflux from membranes prepared from rat forebrain in a glass-fiber filter assay. Glutamic acid showed the greatest efficacy with an ED_{50} of ∿ 3μM. Kainic acid produced ∿ 28% of the maximal efflux seen with glutamic acid with an ED_{50} of ∿ 1μM. Quisqualic acid never showed statistically significant increases in $^{22}Na+$ efflux over control experiments. However, values with quisqualic acid were consistently lower than control at concentrations above 0.5 μM reaching ∿ 12% of the maximal efflux seen with glutamic acid. N-methyl-D-aspartic acid showed no detectable efflux activity in this preparation. 2-Amino-phosphonobutyric acid (APB) blocked glutamate or kainate stimulated efflux with IC_{50} values of ∿ 0.1 μM. Calcium was required for the inhibitory action of APB, but not for the stimulatory actions of glutamic or kainic acids. Glutamic and kainic acids at concentrations above 100 μM were found to inhibit rather than stimulate $^{22}Na+$ efflux. Veratridine and tetrodotoxin had no influence on efflux stimulated by glutamic or kainic acids.

33.18 **A COMPARISON OF POTASSIUM RELEASE EVOKED BY STIMULATING AFFERENT FIBERS OF DIFFERENT DIAMETER AND BY APPLICATION OF PUTATIVE NEUROTRANSMITTERS.** **R.A.Davidoff, J.C.Hackman, and C.J. Wohlberg. Neurophysiology Laboratory, VA Medical Center, and Departments of Neurology and Pharmacology, University of Miami School of Medicine, Miami, Fl. 33101.**

The excitatory amino acid, glutamate, has been proposed as the neurotransmitter released by large diameter afferent fibers and the peptide, substance P, has been postulated to be one of the transmitters released by unmyelinated afferents. In addition, several other putative peptide transmitters have been identified in dorsal root ganglion cells. The present experiments investigated the amount of K^+ released by afferent fibers of different diameter and by the application of possible primary afferent transmitters.

Frogs (Rana pipiens) were decapitated, the spinal cord removed, hemisected and placed in a sucrose gap recording chamber. The cords were superfused with HCO_3^--Ringer's solution bubbled with 95%:5% O_2:CO_2 and maintained at 15°C. DC membrane potentials were recorded from the ninth dorsal and ventral root. K^+-sensitive microelectrodes were used to measure changes in extracellular potassium concentrations in the dorsal horn and intermediate gray matter, produced by tetani (5Hz,10sec) applied to the sciatic nerve with various voltages.

The stimulus voltages required to elicit Aα,Aγ and C fiber compound action potentials were recorded in the dorsal root in response to sciatic nerve stimulation. The largest diameter afferents (Aα, 0.43V+/-0.09,n=3) were responsible for 73.9%+/-6.5% (n=5) of the amount of potassium released by supramaximal stimulation of the sciatic nerve. Aγ fibers (1.03V+/-0.09,n=3) were responsible for an additional increment in the amount of potassium released to 84.0%+/-5.4% (n=5). Maximal release was produced by C-fiber stimulation (100%,11.7V+/-1.7,n=3).

The superfusion of L-glutamate and L-aspartate (1mM, 30sec) resulted in the release of potassium in the dorsal horn. The change of potassium activity above baseline levels was 1.3+/-0.4mM for L-glutamate and 1.1+/-0.2mM for L-aspartate (n=4). Application of N-methyl-DL-aspartate (100uM,30sec), kainate (20uM,30sec), and quisqualate (10uM, 30sec) also evoked the release of potassium; the increase was 1.3+/-0.2, 1.5+/-0.2, and 1.2+/-0.3 mM, respectively. In contrast, the application of several putative peptide neurotransmitters (substance P, cholecystokinin, vasoactive intestinal peptide, somatostatin, neuromedin K, bombesin, substance K, and physalaemin; 1uM,60sec) produced slow depolarizations of the ventral root and an increase in spontaneous activity but did not cause any change in K^+ activity. The only peptide tested which released small amounts of K^+ was eledoisin.

In summary, it appears that the largest diameter afferent fibers are responsible for the majority of the K^+ released as a result of sensory stimulation. **(Supported by VAMC MRIS #1769 and 3369 and USPHS #NS17577 and #HL07188).**

PSYCHOTHERAPEUTIC DRUGS: NEUROLEPTICS

34.1 POSSIBLE ANTI-DYSKINETIC EFFECTS OF CANNABIDIOL L. H. Conti*, L. Stein*, M. Cogen*, P. Consroe* and R.E. Musty (SPON.D. Lorenz, Department of Psychology, University of Vermont, Burlington, VT 05405 and Department of Pharmacology, College of Pharmacy, University of Arizona, Tucson, AZ 85712

Cannabidiol (CBD) is a natural cannabinoid which does not produce a psychological high, but has recently been shown to have anti-epileptic properties in animals and man (Cunha, et al., Pharmacol., (1980),21,175) anti-anxiety properties in animals (Musty, The Cannabinoids, Academic, (1984), 795). In addition, data in humans suggest that CBD suppresses dyskinesia (Snider, S.R. and Consroe, P. Neurology, (1984), 34, 147). The present experiments were designed to test this possibility, using drug induced circling behavior in rats with unlilateral lesions of the substantia nigra produced by injection of 6-hydroxydopamine.

Rats were prepared with unilateral substantia nigra (SN) lesions by injection of 8 ug of 6-OHDA (in 2% ascorbic acid + saline) in 4 ul via cannula at Pellegrino coordinates: 3 mm posterior to and 2 mm lateral from bregma and 8.5 mm ventral from dura.

Six to 8 days after surgery, rats were injected with 5mg/kg meth-amphetamine (MEA), i.p., or 5 mg/kg MEA plus 10 mg/kg CBD. Turning behavior was assessed in a stainless steel bowl 32.5 cm in diameter in a sound attenuated chamber for 15 min. CBD blocked the MEA induced contralateral turning behavior which was observed in the MEA group alone.

In a second experiment, SN lesions were produced, as before. A 35 day period was allowed to elapse in order to test for denervation supersensitivity following apomorphine challenge. On the 35th day, 0.5-1.0 mg/kg of apomorphine hydrochloride (APO) i.p., was administered to each rat. Ipsilateral turning behavior was induced. At two day intervals, the following sequence of drug tests were conducted: APO (as before) + 10 mg/kg CBD, i.v.; APO alone; APO + 40 mg/kg CBD, i.v.; APO alone; APO + 20 mg/kg CBD,i.v.; and APO alone. At 10 mg/kg, CBD produced slight reductions in ipsilateral turning; at 20 mg/kg, CBD produced moderate reductions; and at 40 mg/kg, CBD completely blocked turning.

These results suggest that CBD may block both contralateral turning induced by MEA and ipsilateral turning produced by APO. It may be that CBD blocks changes in turning behavior regardless of its source, i.e., presynaptic or postsynaptic. In addition, the SN lesion technique may serve as a model for testing anti-dyskinetic drugs. Given these conclusions it seems reasonable to propose that CBD has anti-dyskinetic effects.

34.2 SULPIRIDE: EFFECTS ON APOMORPHINE- AND AMPHETAMINE-INDUCED BEHAVIORS SUGGEST A PREFERENTIAL ACTION ON PRESYNAPTIC DOPAMINE RECEPTORS. A. Robertson, J. Rudski*, and C. MacDonald*. Dept. of Psychology, McGill Univ., Montreal, Quebec, Canada H3A 1B1.

We recently reported that the atypical neuroleptic sulpiride enhanced amphetamine-induced stereotypy (Robertson & MacDonald, Eu. J. Pharm., 1985, 109, 81). This might be explained by its greater affinity for presynaptic vs. postsynaptic dopamine receptors (Jenner & Marsden, Acta Psych. Scand., 1984, Suppl. 211, 109). The present experiments examined this possibility in two ways. In the first experiment, the effects of sulpiride (5 & 20 mg/kg SC) on behaviors induced by apomorphine were tested. A low dose of apomorphine (0.1 mg/kg SC) produced hypomotility, an effect believed to represent a presynaptic action (DiChiara et al. Nature, 1976, 264, 564). Amongst a number of atypical and typical neuroleptics tested, only sulpiride antagonized this hypomotility. Apomorphine in higher doses (0.2-1.0 mg/kg, SC) produced stereotypy (sniffing down and licking or gnawing), which has generally been attributed to its postsynaptic activity (Ernst, Psychopharmacol., 1967, 10, 316). Sulpiride did antagonize stereotypy, although its effects were weaker than those of other neuroleptics tested. In the lower dose, sulpiride acted primarily to antagonize stereotyped sniffing down whereas in the higher dose, it blocked stereotyped sniffing down and licking or gnawing. The effects of sulpiride on apomorphine-induced hypomotility and stereotypy are consistent with the notion that this drug has strong presynaptic and weak postsynaptic blocking abilities.

In the second experiment, the effects of sulpiride on amphetamine-induced turning behavior in rats with small electrolytic lesions of the nigrostriatal dopamine bundle were examined. Sulpiride was ineffective in blocking turning; in fact, it had a tendency to enhance the number of turns produced by amphetamine. This effect cannot be accounted for by general increases in motoric behavior as sulpiride itself does not change locomotion nor does it interact with amphetamine-induced locomotion (Robertson & MacDonald, op. cit.). Thus sulpiride has similar enhancing effects on both amphetamine-induced turning and amphetamine-induced stereotypy. The data further suggest that the locus of action of this neuroleptic might be on the nigrostriatal dopamine system.

34.3 **DIFFERENT PROFILES FOR CLOZAPINE, CHLORPROMAZINE, AND PIMOZIDE ON THREE ACTIVITY MEASURES DURING CHRONIC DOSING IN RATS.** H.B. Freese*, J.H. Porter, C.A. Bjornsen*, & G.L. Kaempf* (SPON: M.J. Kallman). Psychology Dept., VA Commonwealth Univ., Richmond, VA 23284.

The classic antipsychotic drugs are effective in the clinical treatment of schizophrenia; however, these "typical" neuroleptics produce extrapyramidal motor side effects. Other "atypical" neuroleptics also have been shown to have antipsychotic activity, but have a much smaller liability for producing motor side effects. To date, there are no preclinical screening procedures which both identify drugs as potential antipsychotic agents and which separate typical from atypical neuroleptics. The present study examined the typical neuroleptics, chlorpromazine (CPZ) and pimozide (PMZ), and the atypical neuroleptic, clozapine (CLOZ), on three different activity measures with chronic dosing regimens.

In Exp., 1 the effects of CPZ (4mg/kg,IP) and CLOZ (10mg/kg,IP) on photocell activity and wheel running in adult male rats were assessed over a 22 day chronic dosing regimen. As shown in the table below, different profiles were evident for CPZ and CLOZ on photocell activity. Over the first 10 days, photocell activity declined for CPZ; whereas, CLOZ produced an initial suppression of photocell activity which diminished over the next 10 days and remained fairly constant until the end of the 22 days. Wheel running was suppressed equally by both drugs over the 22 days.

In Exp. 2, PMZ (1mg/kg,IP) and CLOZ (10mg/kg,IP) were administered to adult male rats for a total of 38 days and spontaneous motor activity (Automec Activity Monitors) was measured on days 1, 8, and 38. Over the first 8 days, the profile for CLOZ was very similar to that for photocell activity. PMZ also suppressed activity, but no recovery was evident over the first 8 days. By day 38, however, activity for CLOZ and PMZ recovered to Vehicle levels.

These preliminary findings suggest that photocell and spontaneous motor activity measures yeild different profiles for typical and atypical antipsychotic drugs during chronic dosing regimens and may be useful for screening potential antipsychotic agents.

PHOTOCELL ACTIVITY

DRUG	DAY 1	DAY 10	DAY 22
VEH(N=6)	157.8	165.6	149.2
CLOZ(N=7)	36.3[a]	75.8[a]	71.5[a]
CPZ(N=6)	62.1[a]	9.8[a,b]	25.5[a]

WHEEL RUNNING

DRUG	DAY 1	DAY 10	DAY 22
VEH(N=6)	86.1	77.3	78.5
CLOZ(N=7)	35.3[a]	22.2[a]	14.9[a]
CPZ(N=7)	36.6[a]	20.1[a]	23.5[a]

SPONTANEOUS MOTOR ACTIVITY

DRUG	DAY 1	DAY 8	Day 38
VEH(N=12)	314.2	296.0	254.8
CLOZ(N=6)	28.2[a]	120.2[a]	209.3
PMZ(N=6)	205.0[a,b]	175.0[a]	262.3

a = sign. diff. from VEH (p<.05) b = sign. diff. from CLOZ(p<.05)

34.4 **THE EFFECTS OF PIMOZIDE AND EXTINCTION ON OPERANT BEHAVIOR AND WHEEL RUNNING ACTIVITY IN RATS.** J. M. Willis* & J. H. Porter. Psychology Dept., Va. Commonwealth Univ., Richmond, VA 23284.

The suppression of operant responding by antipsychotic drugs in rats and other laboratory animals has often been attributed to the motor side effects of these drugs; however, Wise (The Behavioral and Brain Sciences,5:39,1982) has proposed that neuroleptic drugs interfere with operant behavior by decreasing the hedonic value of rewards (i.e.,anhedonia) before producing any significant impairment of performance capability. The fact that neuroleptic drugs produce an extinction-like pattern of response cessation has been offered as support for this theory. However, these studies primarily have used only continuous reinforcement schedules and have not obtained any independent measure of motor activity during the operant test sessions.

In the present study, six adult male rats maintained at 80% body weight were tested on a fixed-interval (FI) 1-min food reinforcement schedule and given simultaneous access to a running wheel attached to the operant chamber. After stable FI responding and wheel running were obtained, the rats were tested for four days under extinction (EXT). This was followed by four days on the FI schedule, and then four days of testing with pimozide (PMZ) while the FI schedule was still in effect. Three rats were tested with .5 mg/kg PMZ and three rats with 1.0 mg/kg PMZ.

A typical extinction curve was evident for barpressing during the four day test periods for EXT and for both doses of PMZ. As shown in the table below, both EXT and PMZ produced a significant suppresion of barpressing (responses/min) and the number of food pellets earned (no pellets were actually delivered during EXT); however, the rats continued to earn most of their pellets during PMZ testing in spite of the reduced rate of barpressing. Examination of the pattern of responding revealed that EXT disrupted the FI scallop, but that PMZ did not. Wheel running (revolutions/min) increased significantly during EXT testing, but PMZ produced no significant change in the rate of running.

These data demonstrate that while both EXT and PMZ produced a similar pattern of response cessation over the four day test periods, their effects on the pattern of responding, number of pellets earned, and wheel running differed. Also, the lack of suppression of wheel running by PMZ argues against a motor impairment interpretation of PMZ's suppression of operant behavior.

MEANS FOR THE LAST DAY OF EACH TEST CONDITION

	FI	EXT	FI	.5 mg/kg PMZ	1.0 mg/kg PMZ
BARPRESSING	16.7	0.4	17.3	3.3	2.2
NO. OF PELLETS	58.4	8.3	58.6	53.3	50.0
WHEEL RUNNING	4.6	8.0	2.8	1.6	2.1

34.5 THE EFFECT OF ATYPICAL NEUROLEPTICS ON HORMONE SECRETION IN THE RAT. H.Y. Meltzer, M. Simonovic, T. Koyama, G.A. Gudelsky, and J.I. Koenig, Dept. of Psychiatry, University of Chicago, Chicago, IL. 60637

It has recently been shown that neuroleptics can elevate plasma levels of beta-endorphin (END) as well as PRL in the rat (Endocrinology, 110:657). The current studies were designed to compare the effects of the atypical neuroleptics, clozapine (CL) and fluperlapine (FL), with those of the typical neuroleptics haloperidol (HA), and spiroperidol (SP) on PRL, END and corticosterone (B) secretion in the rat. All drugs and their respective vehicles were injected i.p. The adult male Sprague-Dawley rats were sacrificed by decapitation and trunk bloods were collected into chilled plastic tubes containing EDTA. Concentrations of PRL, B and END in plasma were determined by RIA. The rate of dopamine (DA) synthesis in tuberoinfundibular neurons was determined by measuring the accumulation of DOPA in the median eminence following treatment with NSD 1015 (100 mg/kg). DOPA levels were determined by HPLC with electrochemical detection. As previously reported, the administration of CL, FL, HA and SP elevated plasma levels of PRL. However, the time course of this effect differed: CL (20 mg/kg) and FL (20 mg/kg) elevated PRL levels for 2 hrs, while the PRL levels after HA (1 mg/kg) were elevated for more than 4 hrs. In contrast to PRL, HA and SP did not stimulate the secretion of either B or END, whereas CL and FL both elevated the plasma concentrations of B and END in a dose-related manner. FL was more potent than CL in stimulating PRL secretion while the reverse was true for B and END. The shortened stimulatory effect of CL and FL on PRL secretion prompted us to study the effect of these agents on the activity of the tuberoinfundibular DA neurons. Both CL and FL increased the accumulation of DOPA in the rat median eminence; HA was without effect. Therefore, these atypical neuroleptic agents not only block DA receptors but also stimulate the synthesis and release of DA from the median eminence while typical neuroleptics are devoid of the latter effect. These actions could account for the abbreviated PRL response and the elevation of both serum B and END levels.

Supported, in part, by USPHS MH 30938.

34.6 EFFECTS OF A POTENTIAL ANTIPSYCHOTIC COMPOUND, BMY14802, ON SINGLE-UNIT ACTIVITY OF DOPAMINE NEURONS OF THE RAT SUBSTANTIA NIGRA ZONA COMPACTA. R.T. Matthews, D. Blair*, and R. Sallis*, Dept. of Anatomy, Texas A&M Univ. Sch. of Med., College Station, TX 77843.

BMY14802 [α-(4-fluorophenyl) - (5-fluoro-2-pyrimidinyl)-1-pipirazine butanol] has several behavioral and biochemical effects in rats suggesting it may influence dopaminergic (DA) neurotransmission in the CNS. Thus BMY14802 inhibits conditioned avoidance responding, reverses apomorphine (APO)-induced stereotyped behaviors and increases striatal and frontal cortex levels of the DA metabolite, DOPAC. However, BMY14802 has little affinity for ^{3}H-spiperone binding sites (IC_{50} >10^{-6} M) and reverses haloperidol-induced catalepsy. The present experiments were designed to measure the effects of BMY14802 on the activity of DA neurons in vivo using electrophysiological techniques in chloral hydrate anesthetized rats. Extracellular single-unit activities of DA neurons in the substantia nigra zona compacta (SNC) were recorded with tungsten electrodes (Bunney et al., J.P.E.T., 185:560, 1973; McMillen et al., J. Neurosci., 3:733, 1983). BMY14802 increased the firing rates of DA neurons (effective dose range 0.5-12.5 mg/kg, i.v., n=7). BMY14802 at similar doses also (1) reversed APO-induced inhibition of firing rate (10 µg/kg, i.v., n=8), (2) blocked the inhibitory effect of a second 10 µg/kg of APO on these same neurons (n=4), (3) reversed D-amphetamine-induced inhibition of firing rate (1.0-3.0 mg/kg, i.v., n=5), and (4) attenuated the effect of a second dose of d-amphetamine. From these data, the effect of BMY14802 alone or after DA agonists resembles the effect of neuroleptics such as haloperidol on the firing rate of SNC DA neurons. Further experiments were designed to test whether the effects of BMY14802 may be mediated by blockade of DA receptors. BMY14802 at 10 mg/kg, i.v. increased DA neuronal impulse flow after blockade of most or all DA receptors by haloperidol (0.5 mg/kg, i.v.). This suggests a non-DA receptor mechanism of action of BMY14802 on SNC DA neuronal impulse flow which may account for the reversal of haloperidol-induced catalepsy by this compound. Preliminary microiontophoretic experiments showed that neither systemic (10 mg/kg, i.v.) nor locally applied BMY14802 (50 mM, co-microiontophoresed) blocked the inhibitory effect of microiontophoresed DA on SNC DA neuronal firing rates. This suggests that BMY14802 does not block DA autoreceptors in the SNC.

In summary, BMY14802 appears to increase SNC DA neuronal impulse flow and reverse the impulse flow depressant effects of DA agonists through a non-DA receptor mechanism. (Supported by Bristol-Myers Co., Evansville, Indiana)

34.7 COMPARATIVE EFFECTS OF BMY 14802, A POTENTIAL ANTIPSYCHOTIC DRUG, AND HALOPERIDOL ON RAT BRAIN DOPAMINERGIC TRANSMISSION. Brian A. McMillen and Helen L. Williams*, Dept. of Pharmacology, School of Medicine, East Carolina Univ., Greenville, NC 27834.

The potential antipsychotic drug, BMY 14802 [α-(4-fluorophenyl)-5-fluoro-2-pyrimidinyl)-1-piperazinebutanol], is a moderately potent inhibitor of conditioned avoidance responding and apomorphine stereotyped behavior. This drug does not cause catalepsy and has no affinity for D2 receptors. At 3.0 mg/kg s.c., BMY reduced haloperidol (HALO) catalepsy. BMY exhibited an IC50 > 10^{-5}M against striatal membrane binding of 0.1 nM 3H-spiperone. From 1.0-30 mg/kg, BMY exhibited a flat dose-response effect on striatal and frontal cortical (FCTx) dopamine (DA) metabolism (DOPAC concentrations). After 10 or 30 mg/kg BMY, striatal DOPAC levels increased 55% or 109% compared to a 283% increase after 0.3 mg/kg HALO. When this dose of HALO was combined with 2.5 mg/kg amfonelic acid (AFA), AFA-induced behavioral stimulation was blocked and DOPAC concentrations increased 8 fold. When AFA was combined with BMY, DOPAC concentrations were less than after BMY alone including doses that blocked AFA-stimulated behavior. This result indicated that the inhibition of stimulated behavior was not due to a strong blockade of postsynatpic D2 receptors. Data from FCTx were qualitatively similar. To test whether BMY altered in vivo DA synthesis, BMY was injected 30 min before 100 mg/kg NSD-1015 and L-DOPA allowed to accumulate for 30 min. Doses of BMY that did not alter striatal DOPAC levels markedly increased L-DOPA accumulation. This effect was not due to inhibition of DA autoreceptors because BMY failed to block apomorphine's inhibition of GBL-activated tyrosine hydroxylation.

The subchronic effects of BMY on the ability of DA metabolism to respond to HALO challenge and on striatal D2 receptor Bmax and K_D were used to assess risk of extrapyramidal dysfunction. Two week osmotic minipumps were used for administration of BMY at either 3 or 15 mg/kg/day s.c. The larger dose of BMY significantly reduced FCTx DOPAC levels and reduced the response of striatal DOPAC levels to acute challenge by HALO. Despite the reduced response to HALO, D2 receptor sensitivity was unchanged when determined by 3H-spiperone binding 4 days after stopping the 15 mg/kg/day infusion. The lack of altered postsynaptic DA receptor sensitivity by BMY suggests this drug may have fewer extrapyramidal side-effects than classical antipsychotic drugs. The data indicate that the pharmacological effects of BMY to inhibit stimulated behavior and conditioned avoidance responding may have a nondopaminergic mechanism. Should clinical trials of BMY demonstrate antipsychotic efficacy, then this drug would truly be an atypical drug since it has no affinity for DA receptors.

(Supported by Bristol-Myers Co., Evansville, IN).

34.8 IN VITRO AUTORADIOGRAPHY OF ^{3}H-BUSPIRONE AND ^{3}H-2-DEOXYGLUCOSE AFTER BUSPIRONE ADMINISTRATION. S.L. Moon [1,2] and Duncan P. Taylor[1]. [1]Pharmaceutical Research and Development Division, Bristol-Myers Company, Evansville, IN 47721 and [2]Indiana University School of Medicine, Evansville, IN 47732.

Buspirone (BuSpar®) is a new, effective, anxiolytic drug. Structurally distinct from the benzodiazepines widely prescribed to treat anxiety, buspirone lacks the untoward side effects associated with benzodiazepine use. While the benzodiazepines bind with high affinity to gamma-aminobutyrate sites in brain, buspirone interacts with serotonin (5-HT) and dopamine sites. Previously, we demonstrated ^{3}H-buspirone in the rat is nonuniformly distributed in brain after an anxiolytically-relevant dose of 10 mg/kg (Soc. Neurosci. Abstr. 10:17, 1984). Many of the regions preferentially labeled in vivo were limbic-related structures and regions rich in 5-HT receptors or dopamine. To evaluate further the sites that interact with buspirone, we have used in vitro autoradiography to visualize the distribution of: (1) ^{3}H-buspirone and receptors for (2) dopamine and (3) 5-HT on alternate sections of rat and human brain. Moreover, we have analyzed the effect of buspirone administration on glucose uptake in rat through the use of ^{3}H-2-deoxyglucose autoradiography.

Our in vitro autoradiography in the rat shows that ^{3}H-buspirone densely labels medial frontal and entorhinal cortices, lateral septum, and the dentate gyrus. Moderate to high amounts of ^{3}H-buspirone are found in all fields of the hippocampus, the interpeduncular, dorsal raphe, facial, trigeminal, and oculomotor nuclei. The striatum shows a gradient of label with moderately high levels rostrally and laterally, but diminishing in the medial and caudal portions. A sparse distribution of ^{3}H-buspirone in the thalamus contrasts with heavier labeling of the hypothalamus. The labeling in substantia nigra is slightly enhanced. There is a strong resemblance in the pattern of ^{3}H-buspirone and ^{3}H-5-HT labeling; however, both ligands concentrate in regions where the other does not. For example, in rat and human, ^{3}H-5-HT not ^{3}H-buspirone, binds to the globus pallidus and substantia nigra, pars reticulata. This suggests that buspirone has a greater preference for 5-HT 1A rather than 1B receptors and is consistent with binding data from homogenates (Riblet et al., Psychopathol. 17: Suppl. 3, 69, 1984). However, that buspirone labels the facial and trigeminal nuclei may reflect an interaction with another 5-HT receptor as well.

Buspirone (15-40 mg/kg, p.o. or i.p.) increased glucose uptake in the medial portion of nucleus accumbens and substantia nigra, pars compacta. Decreased metabolism occurred in the lateral habenula, hippocampus, interpeduncular nucleus, and layers IV-V of cortex. Higher doses may alter metabolism in other brain regions. Thus, the metabolic pattern also suggests a strong interaction for buspirone with the limbic system.

34.9 BMY 14802: A POTENTIAL ANTIPSYCHOTIC AGENT THAT DOES NOT BIND TO D-2 DOPAMINE SITES. Duncan P. Taylor, Michael S. Eison, W. G. Lobeck, Jr.*, L. A. Riblet, D. L. Temple, Jr. and J. P. Yevich, CNS Research, Pharmaceutical Research and Development Division, Bristol-Myers Company, Evansville, IN 47721.

The potential antipsychotic agent BMY 14802, known chemically as α-(4-fluorophenyl)-4-(5-fluoro-2-pyrimidinyl)-1-piperazinebutanol, was first identified by its ability to block the conditioned avoidance response in rats with potency comparable to clozapine (ED_{50} values of 26.4 and 24.0 mg/kg, p.o., respectively). BMY 14802 also inhibits apomorphine-induced stereotypy (ED_{50}=33.0 mg/kg, p.o.) and has a clozapine-like profile in the Sidman avoidance test. Unlike currently-marketed antipsychotics, BMY 14802 does not produce catalepsy; indeed, BMY 14802 can reverse a previously-established trifluoperazine-induced catalepsy (ED_{50}= 16.9 mg/kg, p.o.). Chronic administration of 15 or 30 mg/kg, p.o., for 29 days had no effect on the maximal number of [^{3}H]-spiperone binding sites in rat striata. On the other hand, the antipsychotic haloperidol (3 mg/kg, p.o.), whose long-term clinical use is associated with the occurrence of tardive dyskinesia, produced a significant increase in the number of binding sites. These findings suggest that the clinical use of BMY 14802 would not be associated with extrapyramidal side effects. In contrast to clozapine, BMY 14802 does not interact with muscarinic cholinergic receptor binding sites in vitro and does not protect against the lethal effects of physostigmine in rodents. This suggests that cholinergic mechanisms are not directly involved in BMY 14802's ability to reverse neuroleptic-induced catalepsy. In further contrast to clozapine, BMY 14802 has minimal interaction with α_1-adrenergic or H_1-histaminergic binding sites in vitro. It is likely that this may account for the absence of α_1-adrenergic blockade in vivo and sedation as measured by reduction in spontaneous motor activity, production of incoordination on the rotarod and potentiation of ethanol in the production of hypnosis. In vitro receptor binding studies have not provided insight into the mechanism of action of BMY 14802 as it does not block any sites at concentrations less than 500 nM (among them α_2-adrenergic, β-adrenergic, type 1 and 2 serotonergic, benzodiazepine, opiate, glycine, glutamate, imipramine, or nitrendipine). Significantly, BMY 14802 does not block [^{3}H]spiperone binding to rat striatal sites in vitro (IC_{50}>1000 nM). Furthermore, metabolites which might interact with dopamine binding sites are not formed in vivo as no such activity is present in serum or directly in the striatum using ex vivo techniques. Thus, BMY 14802 appears to be a potential antipsychotic drug which lacks the side effect potential of conventional agents (movement disorders) or atypical agents (sedation, cardiotoxicity). (Further data on BMY 14802 will be presented by McMillen and Williams, this meeting).

34.10 ANTAGONISM OF AMPHETAMINE-INDUCED BEHAVIORAL CHANGES BY BMY13859-1 IN A PRIMATE MODEL OF PSYCHOSIS. R.F. Schlemmer, Jr. & J.M. Davis. Ill. St. Psychiat. Inst., Chicago, IL 60612

BMY13859-1,8-(4-(4-(1,2-benzisothiazol-3-YL)-piperazinyl)butyl)-8-azaspiro(4.5)decane-7,9-dione HCl, is a compound which demonstrates an antipsychotic profile in rodent screening models for these agents. The present study was designed to determine the effect of BMY13859-1 on the amphetamine (Amphet) model of psychosis in a primate social colony. This model is of particular relevance because Amphet induces several behavioral changes in this paradigm which resemble characteristics of amphetamine psychosis and schizophrenia. Also, these changes can be antagonized by known antipsychotic agents. The subjects for the study were members of a stable social colony of 5 adult Stumptail macaques (Macaca arctoides), 1 male and 4 females. The expt was designed as a cross-over study where 2 females received drug treatment at one time followed by similar treatment of the other 2 females. The male remained untreated throughout the study. The expt began with observation of undrugged behavior (Base-1) followed by administration of d-amphet, 1.6 mg (base)/kg in time-release form, n.g. every 12 hr for 12 consecutive days. Five months later after Base-2 observation, the monkeys received BMY13859-1, 5 mg (salt)/kg, n.g. every 12 hr for 7 days, then BMY13859-1 + Amphet, as before, for the next 12 days. During the expt, "blind", experienced primate observers conducted two 60-min observation sessions daily where the behavior of each animal in the colony was recorded on a computer according to a 40 item checklist using the focal-sampling technique. Chronic Amphet treatment induced several behavioral changes of particular interest for the study of psychosis including: 1) intense scratching (which has been associated with tactile hallucinations in humans), 2) increased submissive gestures 3) increased checking (visual scanning), 4) the induction of stereotypies, and 5) social withdrawal characterized by increased distancing from other colony members and decreased social grooming. BMY13859-1 significantly antagonized the amphet-induced intense scratching and increase in submissive gestures to Base-1 & Base-2 levels in those monkeys who developed these responses when treated with Amphet alone. Amphet-induced increase in checking & stereotyped behavior was prevented by BMY13859-1 in all monkeys throughout treatment. Increased distancing scores induced by Amphet were significantly antagonized & returned to Base-1 & Base-2 levels in 2 monkeys during the later stages of Amphet treatment. At the same time, severely reduced social grooming scores in Amphet-treated monkeys were significantly increased by concomitant treatment with BMY13859-1 in 2 monkeys. It is unlikely that the antagonistic effects of BMY13859-1 can be attributed to sedation since resting scores for BMY13859-1 alone or concomitantly with Amphet did not exceed Base-2 levels for any monkey. The results of this study demonstrate that BMY13859-1 is a good antagonist of Amphet-induced behavior in primates. Importantly, the activity of BMY13859-1 in this model is consistent with known antipsychotic drugs. (Supported through a grant from Bristol-Myers).

34.11 THE NOVEL ANTIPSYCHOTIC BW 234U ANTAGONIZES ENVIRONMENTALLY INDUCED ELEVATION OF DOPAMINE METABOLISM IN PREFRONTAL CORTEX. D.M. Vaughn, K. Viik and B.R. Cooper. Dept. of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

BW 234U, a new drug with antipsychotic effects in open clinical trials, represents a potentially new generation of novel non-neuroleptic antipsychotic agents. Prior work in animals has shown that BW 234U blocks apomorphine-induced aggression but does not block apomorphine-induced or amphetamine-induced stereotyped behaviors, and high doses do not cause catalepsy. BW 234U does not block dopamine receptors nor elevate dopamine metabolism in whole brain over a behaviorally relevant dose range (Vaughn et al., Neurosci. Abstr. 77.16, 1984; Ferris et al., Neurosci. Abstr. 77.13, 1984). Since BW 234U does not interact directly with dopamine neurons in a manner similar to neuroleptic antipsychotic drugs, the present experiments were conducted to explore the possibility that BW 234U might affect "psychological" activation of dopaminergic neurons. Male Long Evans rats (Blue Spruce Farms, Altamont, NY) were injected with 12.5 mg/kg i.p. and 25 mg/kg i.p. BW 234U and compared with two control groups, a pH adjusted (pH = 4) saline injected, handled group brought into the lab environment and treated in every way similar to the BW 234U injected animals, and a group of rats sacrificed at the same time of day (10:00-11:00 a.m. EST) immediately upon removal from the animal quarters. Dopamine, DOPAC, HVA, 5HT, 5HIAA and NE were measured in slices of prefrontal cortex or striatum cut approximately 2 mm thick, using a brain mold (Wheeler, S.C. and R.H. Roth, Naunyn-Schmiedeberg's Arch. Pharmacol., 312:151-159, 1980). Relative to the uninjected controls, the saline injected group had a 27% increase in DOPAC and 50% increase in HVA in prefrontal cortex but not striatum, and the elevation of dopamine metabolism was significantly reduced by prior treatment with BW 234U. 5HIAA levels were also elevated by saline injection, but BW 234U did not reduce this environmentally induced change in serotonin metabolism. Norepinephrine levels were not significantly altered by any treatments in these tissues. Results show that the novel antipsychotic BW 234U can reduce the activation of dopamine neurons in prefrontal cortex produced by an environmental change. The mechanism of this effect at the cellular level is not known.

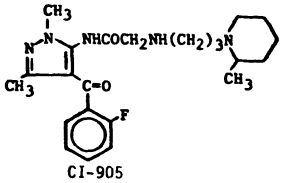
34.12 NEUROCHEMICAL PROPERTIES OF CI-905 AND CI-913, AGENTS WHICH EXHIBIT ANTIPSYCHOTIC-LIKE EFFECTS IN ANIMALS. T. A. Pugsley*, Y. H. Shih*, S. F. Stewart*, L. L. Coughenour*, (SPON: B. P. Poschel). Warner-Lambert/Parke-Davis Pharm. Res., Ann Arbor, MI 48105.

CI-905 (N-[4-(2-fluorobenzoyl)-1,3-dimethyl-1H-pyrazol-5-yl]-2-[[3-(2-methyl-1-piperidinyl)propyl]amino]acetamide (Z)-2-butandioate (1:2)) and CI-913 (2-(diethylamino)-N-[4-(2-fluorobenzoyl)-1,3-dimethyl-1H-pyrazol-5-yl]acetamide monohydrochloride) are novel agents which have been shown to have an antipsychotic-like profile in animal tests and to exhibit no propensity to cause extrapyramidal side effects (EPS). The present study examined the in vitro and in vivo biochemical properties of behaviorally active doses of CI-905 and CI-913.

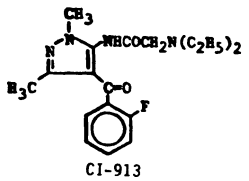
CI-905 and CI-913 did not cause any significant changes in rat striatal dopamine (DA) or homovanillic acid levels, did not effect the α-methyl-p-tyrosine-induced disappearance of DA in rat brain and did not alter the γ-butyrolactone-induced increase in rat striatal DA indicating no effect on DA turnover. In addition neither agent affected brain norepinephrine turnover. Both agents elevated rat brain 5-hydroxyindoleacetic acid levels without altering serotonin (5-HT) levels suggesting that CI-905 and CI-913 increased brain 5-HT turnover. Unlike known antipsychotics which elevate rat serum prolactin levels, CI-905 and CI-913 caused a decrease in prolactin. CI-905 and CI-913 did not exhibit any significant in vitro affinity for DA, muscarinic, adrenergic, serotonergic, adenosine A_1, benzodiazepine, GABA or slow-calcium channel receptors. Nor did CI-905 and CI-913 affect rat striatal DA-stimulated adenylate cyclase activity. The lack of affect of CI-905 and CI-913 on rat brain Da turnover indicates that these agents would have little or no propensity to cause EPS and is in agreement with behavioral studies in monkeys. Although studies with these agents have been terminated because of animal toxicity, these findings demonstrate together with the behavioral results, that it is possible at the preclinical level to discover non-dopaminergic antipsychotic-like candidates.

34.13 ANTIPSYCHOTIC-LIKE EFFECTS OF CI-905 & CI-913 IN PRECLINICAL TESTS. T.G. Heffner, D.A. Downs, H.A. DeWald*, S.E. Harrigan*, K.L. Sledge*, J.N. Wiley*, and L.D. Wise*. Departments of Pharmacology and Chemistry, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

The preclinical and clincial efficacy of available antipsychotic (AP) drugs is commonly attributed to their blockade of brain dopamine (DA) receptors. However, available AP drugs have incomplete efficacy in man and produce neurological side effects. In an attempt to discover AP drugs with improved efficacy and lesser propensity for extrapyramidal dysfunction (EPS) and tardive dyskinesia, we have sought to identify agents which display the behavioral profile of AP drugs in preclinical tests but which do not interact with brain DA receptors.



CI-905



CI-913

CI-905 and CI-913 are novel fluorobenzoylaminopyrazoles which are not brain DA receptor antagonists; they lack affinity for brain DA receptors in vitro and do not elevate serum prolactin in rats in vivo. Like known AP drugs, CI-905 and CI-913 reduce spontaneous locomotion in mice at doses that do not produce ataxia. Neither agent reduces cage climbing in mice induced by the DA agonist apomorphine. CI-905 and CI-913 display AP-like selective inhibition of one-way conditioned avoidance behavior in rats; each attenuates shelf-jump avoidance at doses that do not impair escape responding. Each agent also inhibits continuous (Sidman) avoidance responding in rats and squirrel monkeys at doses that do not impair shock termination responding. Both CI-905 and CI-913 attenuate rewarding intracranial self-stimulation in rats. Unlike known AP drugs, neither CI-905 nor CI-913 elicits dystonic movements in Cebus monkeys sensitized to haloperidol, a primate model of EPS. The preclinical profiles of CI-905 and CI-913 would predict efficacy in the treatment of schizophrenia without liability for EPS. Although adverse toxicological findings in animals precludes clinical evaluation of these agents, the present results indicate that many of the behavioral effects of AP drugs in animals do not require blockade of brain DA receptors.

34.14 D1 AND D2 DOPAMINE RECEPTOR ANTAGONIST CHARACTER OF SELECTED NEUROLEPTICS. B. K. Koe, R. Sarges* and W. M. Welch*. Pfizer Central Research, Groton, CT 06340.

Recently, in a study of the pyrroloisoquinoline neuroleptic, Ro 22-1319, a selective D2 DA receptor antagonist, interactions of neuroleptics at this receptor are envisioned to involve "pi" interactions with the two aryl rings of tricyclics, diphenylpiperidines and dexclamol/butaclamol, or aryl ring plus adjacent C=O of haloperidol, sulpiride, molindone and Ro 22-1319, as well as ionic interactions with the basic nitrogen. An "auxiliary binding site" was also proposed, interaction with which confers D1 antagonist characteristics (Olson *et al.*, in Dopamine Receptors, ACS Symposium Series, 1983, p. 251). Thus, sulpiride, molindone and Ro 22-1319, predominantly D2 antagonists, lack a lipophilic group at the basic N for binding at this auxiliary site. We describe below the relative D1 and D2 characteristics of several new neuroleptics based on inhibition of [3H]spiperone binding and DA stimulated adenylate cyclase activity of rat striatal preparations. The potent activity of these DA antagonists is shown by the low doses for half-maximal increase in striatal dopa accumulation. Flutroline, a potent 5-aryltetrahydro-γ-carboline neuroleptic (Koe *et al., The Pharmacologist* 21:180, 1979; Harbert *et al., Mol. Pharmacol.* 17:381, 1980), exhibits less D1 character than its hexahydro-γ-carboline analog, CP-52,215 (Sarges *et al., J. Med. Chem.*, in press), even though they contain the same lipophilic group on basic N. The corresponding 5-arylhexahydro-γ-carbolines with only H (CP-52,344) or Me (CP-47,276) on basic N potently inhibit both DA stimulated adenylate cyclase and [3H]spiperone binding. Two 2-aminomethyl-8-chloro-3,4-dihydro-5-methoxynaphthalene neuroleptics, CP-34,771 and CP-35,988 (Welch *et al., J. Med. Chem.* 21:257, 1978), with lipophilic 4-hydroxy-4-phenylpiperidinomethyl residues that could extend into the auxiliary binding site, are virtually inactive on D1 adenylate cyclase. These findings suggest that the auxiliary binding site proposed by Olson *et al.* (1983) may not be a major determinant of D1 or D2 receptor antagonist character.

34.15 ELECTROPHYSIOLOGICAL EFFECTS OF REPEATED ADMINISTRATION OF APOMORPHINE, EMD 23 448 AND (+)3-PPP ON A9 DOPAMINE AUTORECEPTORS. Jeffrey M. Goldstein, Linda C. Litwin* and Jeffrey B. Malick. Biomedical Research Department, Stuart Pharmaceuticals, Division of ICI Americas Inc., Wilmington, Delaware 19897.

Recent data suggest that dopamine (DA) neurons possess autoreceptors which inhibit neuron function. Administration of low doses of the DA agonist apomorphine inhibits the activity of DA neurons through selective activation of DA autoreceptors. This effect mimics the functional blockade of DA neurons obtained after neuroleptic administration and may explain the clinical efficacy of low dose apomorphine in schizophrenia. However, there have been several reports that have demonstrated subsensitivity of DA autoreceptors after repeated stimulation by DA agonists (e.g., apomorphine, bromocriptine). These findings may compromise the DA autoreceptor-stimulation strategy in the treatment of schizophrenia. In the present studies, we have addressed the issue of DA autoreceptor subsensitivity by determining the effects of repeated administration of apomorphine, EMD 23 448 (3-(4-(4-phenyl-1,2,3,6-tetrahydropyridyl-(1))-butyl)-indole, hydrochloride), and (+)3-PPP ((+)-3-(3-hydroxyphenyl)-N-n-propylpiperidine) on A9 DA cell firing using conventional extracellular recording techniques.

Repeated administration of apomorphine (3x daily for 9 days), at a dose selective for the autoreceptor (0.05 mg/kg, sc; Rebec and Lee, Brain Res 250, 188, 1982) caused a 51-fold shift in the median effective dose (MED50) of apomorphine required to suppress A9 DA cell firing (0.0032 mg/kg, iv in vehicle group compared to 0.16 mg/kg, iv in subacute apomorphine group). Similarly, EMD 23 448 (3x daily for 9 days), at a dose selective for the autoreceptor (2 mg/kg, ip; determined behaviorally) caused a 5.8-fold shift in the EMD 23 448 MED50 for suppression of cell firing (0.06 mg/kg, iv in vehicle group compared to 0.36 mg/kg, iv in subacute EMD group). In contrast to these findings, (+)3-PPP (3x daily for 9 days), also at a selective dose for the DA autoreceptor (10 mg/kg, ip; determined behaviorally) did not cause a significant change in the (+)3-PPP MED50 for suppression of cell firing. In fact, there was a slight increase in the sensitivity of the autoreceptor following repeated administration of (+)3-PPP (MED50 = 1.42 mg/kg, iv in vehicle group compared to 0.35 mg/kg, iv in subacute (+)3-PPP group).

The results with apomorphine and EMD 23 448 clearly indicate that there is DA autoreceptor subsensitivity after repeated administration. Although the results with (+)3-PPP suggest that DA autoreceptor subsensitivity does not occur following subacute treatment, further studies should be performed before definitive conclusions can be drawn.

34.16 PHARMACOKINETICS OF REDUCED HALOPERIDOL IN RODENTS AND NONHUMAN PRIMATES. J.L. Browning†, C.A. Harrington†† and C.M. Davis*††. Tex. Res. Inst. of Mental Sci., Houston, TX 77030†† and Baylor College of Medicine, Dept. of Neurosurgery, Houston, TX 77030†.

Reduced haloperidol, a major metabolite of haloperidol may have effect on the therapeutic efficacy of haloperidol (Ereshefsky et al J. Clin Psychopharm 4:138). We have investigated some of the pharmacokinetics of haloperidol and reduced haloperidol in several species using a radioimmunoassay developed in our lab (Browning et al J. Immunoassay 6:45). In rodents and non-human primates, reduced haloperidol had a longer half-life than haloperidol in plasma and red blood cells. In rats and non-human primates, no detectable levels of haloperidol or reduced haloperidol were found twenty-four hours after the last dose of acute or chronic dosage given orally or by injection. However, the rabbit exhibited significant quantities of reduced haloperidol twenty-four hours after a single injection (2 mg/kg IM).

Additionally in all species tested, levels of haloperidol and reduced haloperidol had a greater half-life in red blood cells as compared to plasma. After ten days of 4 mg/kg haloperidol IM once per day, the brain levels of haloperidol and reduced haloperidol were almost ten fold the plasma levels in rabbits.

These results indicate that reduced haloperidol may accumulate in brain tissues and that plasma levels may be insufficient as an indicator of brain cells.

34.17 REDUCED HALOPERIDOL AND HALOPERIDOL IN RED BLOOD CELLS AND PLASMA OF PSYCHIATRIC PATIENTS. C.A. Harrington and C.M. Davis*. Tex. Res. Inst. of Mental Sci., Houston, TX 77030.

We have developed a means of measuring the concentration of both reduced haloperidol (RH) and haloperidol (H) in plasma and tissue that utilizes chemical derivatization, liquid chromatography, and radioimmunoassay (J. Immunoassay 6:45). Quantification of H and RH in the plasma of psychiatric patients has demonstrated that high doses of H can result in an increased plasma concentration of RH in excess of the plasma H concentration. In addition Ereshefsky, et al (J. Clin. Psychopharm. 4(3):138) has observed in schizophrenic patients that high plasma concentrations of RH (RH/H>1) are correlated with poor treatment outcome, although in subsequent treatment with Prolixin patients showed demonstrable improvement. Due to these observations we have begun to study the pharmacokinetic of H and RH in animals (Browning, et al, Neurosci. Abstr.) and begun to refine the relationship between plasma and red blood cell drug concentrations and therapeutic effect in patients receiving H.

Plasma levels of H and RH were quantified in a group of over 100 patients. Levels of H exhibited a seeming linear relationship with dose, however, RH levels accumulated in a non-linear fashion at doses exceeding ~30 mg/day. Analysis, in another group of patients, of plasma and whole blood levels of both H and RH allowed the red blood cell level of both compounds to be determined. H exhibited a linear relationship between plasma and red blood cell levels with a ratio of RH-RBC/H-Plasma = .9. RH also exhibited a linear relationship between plasma and red blood cell levels, however, RH-RBC/RH-Plasma = 2.7. RH was sequested approximately 3 fold more effectively in RBC than H when compared to plasma. This relationship was seen at all dosages. If RH does correlate with negative therapeutic outcome, then its measurement seems called for in clinical assessment of patients treated with H. In addition RBC levels, if they simulate CNS levels of drugs more accurately, may be a better index of the relationship between therapeutic effects of neuroleptics and blood levels. Finally, assessment of the pool size in pharmacokinetic analysis of H and RH may have to address the issue of RH's greater affinity for RBC's as well as other cellular stores.

34.18 BEHAVIORAL EFFECTS OF INTRACEREBRAL CALCIUM CHANNEL INHIBITORS (CCI). R. de Beaurepaire, W.J. Freed and J.A. Grebb. (SPON: J.R. Stevens). Preclinical Neurosciences Section, Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

CCIs have recently been tested in the treatment of mania and depression. Signs of these diseases include abnormal locomotor activity and abnormal feeding behavior. We have therefore tested the effects of two CCI's (verapamil and diltiazem) on locomotor activity and feeding behavior after intracerebral injection.

Methods: Male Sprague-Dawley rats weighing 300 to 400 g were bilaterally implanted with 24 gauge cannulae placed above the lateral ventricles, striatum and paraventricular nucleus of the hypothalamus (PVN). One week after recovery animals were infused with vehicle or CCI: 0.5 mg in 5 µl for intraventricular (I CV) injections, 0.5 mg in 2 µl for striatal injection and 0.15 mg in 0.6 µl for PVN injection. Three behavioral tests were conducted: 1) feeding behavior during satiation (amount of wet mash eaten in one hour), 2) amounts of food eaten by 23-hour deprived rats habituated to eat mash one hour per day, 3) locomotor activity measured in an open field during one hour following injection.

Results: There was no change in feeding behavior after ICV or PVH injection of CCI. Feeding behavior after intrastriatal injection has not been tested. Results for locomotion are shown below.

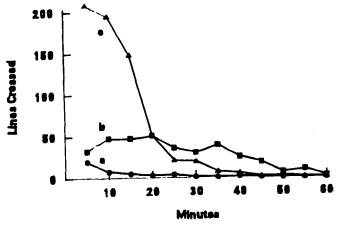

Figure 1: Locomotor activity (mean number of lines crossed during 1 hr) for animals receiving vehicle (n=20; circles), CCI in the ventricle (n=10; squares), or CCI in the PVH (n=10; triangles). Data for verapamil and diltiazem are combined.

Intrastriatal infusion (not represented), produced a decrease in locomotor activity but requires further investigation due to the low baseline activity levels. Verapamil and diltiazem (data are combined in the graph) both produced a similar stimulation of locomotor activity.

Discussion: Thus CCI do not influence feeding behavior even when injected in the PVH, which is known to be involved in the regulation of feeding. Nonetheless, CCI are very active in stimulating locomotor activity, particularly when injected into the PVH. This further supports a role of the hypothalamus and particularly the PVH in the regulation of locomotor activity and contrasts with the inhibition of locomotor activity produced by injections of calcitonin in the PVH (submitted). These results may be relevant to possible clinical applications of CCI's in the treatment of neuropsychiatric disorders.

35.1 ELECTRICAL THRESHOLD STABILITY OF PRIMARY AFFERENT NEURONS IN DOG TOOTH PULP. R. C. Kramis*, A. C. Kloka*, A. C. Brown, W. J. Beeler*, and R. W. Fields*. (SPON: L. Gronke). Dept. Physiol. & Biophysics SD, Oregon Health Sci. U., Portland, OR 97201.

The object of these experiments was to investigate adaptation and/or sensitization of primary afferent fibers in dog incisor and canine teeth upon repeated electrical stimulation. In anesthetized dogs, the superior alveolar nerve was surgically exposed, desheathed, and dissected into small branches. Individual branches were placed upon small hook electrodes for recording unit responses from the test teeth. Electrical stimuli were applied to the teeth at two sites: coronal and apical. Coronal stimuli were delivered through the intact enamel, using a monopolar paste electrode incorporated into a custom-molded acrylic cap to obviate possible inflammation-induced nociceptive ending sensitivity changes, a possible consequence of hard tissue removal. In addition, apical stimulation was delivered using bipolar amalgam electrodes placed in cavities prepared in the hard tissue near the site of nerve exit from the tooth, in order to enable measurement of conduction velocity in the nerve axon outside the tooth. Eighty-one units were tested in six dogs. Conduction velocities determined from apical stimulation ranged from 0.5 to 42 meters/sec. Coronal stimulation resulted in lower mean conduction velocities, presumably due to slower conduction within the tooth pulp. Refractory period averaged about 2 msec when stimulus intensity was just threshold, and decreased to about 1 msec when intensity was raised to twice threshold. The more rapidly conducting fibers showed stable thresholds (±10%) even after 20 minutes of 1 per second repeated stimulation. However, all units with conduction velocities in the C-fiber range required progressively greater stimulus intensity to reach threshold, and some adapted so rapidly that it was impossible to determine the threshold value. It was concluded that myelinated fibers in the A-beta and A-delta conduction velocity range do not adapt upon repeated 1 hz electrical stimulation, but that C-fibers adapt rapidly. Supported by NIDR grant DE-05895.

35.2 MESENCEPHALIC TRIGEMINAL SENSORY AXONS IN CATS FORM UNENCAPSULATED RUFFINI-LIKE MECHANORECEPTORS IN PERIODONTAL LIGAMENT BUT NOT TOOTH PULP. M.R.Byers, R.F.Martin*, T.A.O'Connor*, and W.K.Dong. Depts. of Anesthesiology and Biological Structure. Univ. of Washington, Seattle, WA, 98195.

Mesencephalic trigeminal sensory neurons are involved in dental proprioception as well as reflex sensitivity of masticatory muscles. The location of mesencephalic (mes V) receptors in dental tissue has not been determined previously. Functional studies have suggested that periodontal ligament is the main site of innervation (Jerge, J.Neurophys 26:379, 1963) but tooth pulp has also been suggested. We have injected ^{3}H-proline into the mes V nucleus in order to map the location of mes V receptors in cat dental tissue using autoradiography and to analyse their fine structure using EM-autoradiography. The entire right mes V nucleus was injected stereotaxically in two adult cats with 3 ul of ^{3}H-L-proline (25uCi/ul) divided among 3 sites along the rostral-caudal extent of the nucleus. The ipsilateral trigeminal main sensory and motor nuclei were not labeled. Heavily labeled axons were followed in semi-serial light microscopic autoradiograms from the mes V tract, out the ipsilateral root, past the trigeminal ganglion and along trigeminal dental nerves to endings in apical periodontal ligament of all ipsilateral maxillary and mandibular teeth in both cats. No labeled axons or endings were found in any tooth pulps, or in bundles of axons entering the tooth roots. Instead, labeled endings were confined to a narrow ring in the periodontal ligament around the root apex. Their distribution was much less extensive than for mechanoreceptors originating in the trigeminal ganglion (Byers, J.Comp.Neurol. 231:500, 1985). EM-autoradiography showed that labeled mes V endings are unencapsulated Ruffini-like mechanoreceptors; nearby bundles of unmyelinated axons or rare corpuscular receptors were not labeled.

Our results show that dental proprioceptive information carried by sensory neurons of the mes V nucleus originates in unencapsulated Ruffini-like mechanoreceptors in periodontal ligament. Moreover, those receptors are much less numerous than similar mechanoreceptors in periodontal ligament originating in trigeminal ganglion. Finally, the location of mes V receptors just outside the tooth root apex makes them suitable for monitoring the confinement of neuroanatomical tracers such as HRP to tooth pulp; if mes V neurons label after such injections, then the tracer must have leaked out of the tooth.

35.3 MORPHOLOGY AND SYNAPTIC CONNECTIONS OF SMALL MYELINATED PRIMARY TRIGEMINAL AXONS ARBORIZING AMONG THE NEURONS IN THE BORDER ZONE OF RAT TRIGEMINAL NUCLEUS ORALIS. W. M. Falls and M. M. Alban*. Department of Anatomy, Michigan State University, East Lansing, MI 48824-1316.

The narrow, 100 to 200 μm wide, border zone (BZ) of rat trigeminal nucleus oralis lies immediately adjacent to the entire dorso-ventral extent of the spinal V tract (SVT). Preliminary Golgi and retrograde horseradish peroxidase (HRP) transport studies indicate that the dendritic arbors of the majority of BZ neurons are oriented in the rostrocaudal axis and are confined, for the most part, to this zone. Some BZ cells project to the cerebellum while others send descending intratrigeminal projections to the medullary dorsal horn. This study examines the morphology and synaptic connections of a population of small diameter primary trigeminal axons which generate bouton bearing terminal strands throughout BZ. These strands parallel and closely approximate the dendrites of BZ neurons and are in a position to provide input directly to these cells. Primary axons were brought into view by injecting 0.05 to 1.0 μl of 30% of HRP in 2% DMSO into the sensory root of the trigeminal nerve and allowing two days for the anterograde transport of the HRP-DMSO into the terminal axonal strands. Portions of these axons were also visualized in Golgi preparations. Thinly myelinated parent branches (0.5-1.5 μm in diameter) descending in SVT leave the tract by making a sharp medial bend and enter BZ directly. Within BZ many of these branches terminate by giving rise to a sparsely branched, long (up to 500 μm), rostrocaudally oriented, unmyelinated terminal strand characterized by several relatively widely spaced axonal endings. Based on the size and morphology of the parent branches in SVT these endings are considered to be from small Aσ primary trigeminal axons. The dome-shaped endings of the primary axons measure 1.0 to 2.0 μm in diameter and contain numerous agranular, spherical synaptic vesicles (40-60 nm) evenly dispersed throughout the terminals. In the BZ neuropil the endings lie in simple triadic arrangements where each forms a single asymmetrical axodendritic synapse on a dendritic shaft. It is at these synapses that this population of primary axons is thought to transfer its input directly to BZ neurons. A small (0.5-1.5 μm) axonal ending filled with flattened synaptic vesicles (29 x 60 nm) forms a symmetrical axoaxonic synapse on the primary ending as well as an axodendritic synapse on the same dendritic shaft receiving the primary input. In view of their symmetrical synaptic contacts terminals containing flattened synaptic vesicles are thought to belong to axons derived from at least one source which can inhibit or diminish the firing of BZ neurons. This would be accomplished either postsynaptically through the axodendritic synapses on the dendritic shafts or presynaptically through the axoaxonic synapses on the primary endings. Supported by N.I.H. Grant DE06725.

35.4 SIZE AND DISTRIBUTION OF IDENTIFIED CAT DORSAL ROOT GANGLION (DRG) NEURONS, R.D. Rose, M.J. Sedivec & L.M. Mendell Dept. Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.

Adult cat spinal ganglion (DRG) somata (in L6-S2) were identified by (i) orthograde labeling with wheat germ agglutinin or horseradish peroxidase, or (ii) a combination of intracellular recording/labeling and physiological characterization techniques (electrodes filled with Lucifer Yellow, LYCh, in 1-2 M LiCl; 8-35 Mohm). Cats were anesthetized deeply throughout surgery and other experimental procedures. Transport experiments labeled sural or triceps surae afferent pools bilaterally. Typically, orthogradely labeled primary afferent pools spanned one or more ganglia. The distributions suggest that afferent pools are unimodally distributed rostro-caudally, bilaterally symmetrical, and variable between animals. Adjacent labeled neurons were frequently observed. LYCh labeled somata were limited to units with fast peripheral fiber conduction velocities (PCV, 77 m/s±4 SE, range 31-113). These units were large (2836 um^2 ±253, cross section through nucleus, range 801-6743). LYCh labeled somata (n=30) included neurons with peripheral fibers supplying muscle spindles, tendon organs, hair follicles, mechanoreceptors, etc. There was no significant difference in size (radius, area, volume) of these LYCh labeled muscle and cutaneous afferents (t-test, $p>0.1$). Size of our LYCh labeled somata did not correlate with PCV (but see Lee et al., Soc. Neurosci. Abstr. 9:257) nor rheobase (Rh, 4nA±0.8 range 1-7) of the soma using simple linear and non-linear regression techniques over the range of PCV and Rh examined. The finding that there is no simple relationship between rheobase and somal size among DRG neurons suggests that differences in membrane properties (active or passive) or the site of spike initiation during intrasomal activation contribute to differences in rheobase. In motoneurons the range in size is not sufficient to account for observed range in Rh and differences in specific membrane resistance for the different motoneuron types have been implicated (Gustafsson and Pinter, J. Physiol. 357:453-83). Although size and PCV are not correlated in our data, combining our data with that from rat (Harper & Lawson, J. Physiol. 359:31-46) and mouse (Yoshida & Matsuda, J. Neurophysiol. 42:1134-45) reveals a good relationship across species as PCV range is extended to smaller values. Thus analysis of means shows: radius = 7.8 $PCV^{0.28}$ ($r=.95$, $p<0.01$); and PCV is linearly related to somal volume ($r=.86$, $p<0.05$). The strength of this correlation derives primarily from the differences between the groups; within each group correlations are much weaker. Supported by NIMH MH08323 (RDR), NS14899 & NS16996 (LMM).

35.5 RHEOBASE OF PHYSIOLOGICALLY IDENTIFIED DORSAL ROOT GANGLION NEURONS. M.J. Sedivec, R.D. Rose, H.R. Koerber & L.M. Mendell, Dept. Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.

In anesthetized cats, we have characterized properties of intracellularly recorded dorsal root ganglion (DRG) cells with peripheral fibers in sural and triceps sural nerves. The major aims of these studies are (i) to examine correlations between properties of cell bodies and peripheral fiber conduction velocity (PCV), and (ii) to compare these findings with those from similar studies in α-motoneurons (MN). The present studies are limited almost exclusively to units with peripheral A fibers. Recordings were made with 4% Lucifer Yellow in LiCl (1-2 M) filled electrodes (8-35 Mohm). Reconstructions of labeled fibers and somata confirmed the correlation of spike shape and recording site (Ito, Japan J. Physiol. 186:189-212, Sato & Austin, J. Neurophysiol. 24:569-82). We recorded from 107 somata (>60 mV action potential amplitude with resting membrane potential = 61mV±1 SE). These units were characterized electrophysiologically according to PCV and rheobase (Rh); the latter was examined in view of its diagnostic value in categorizing MNs supplying different motor unit types (Fleshman et al., J. Neurophysiol. 46:1326-38). Rh of DRG somata ranged from < 1 to 15 nA with most (78%) under 5 nA. This overlaps the lower end of the MN Rh spectrum (1-40 nA). Cells with high values of PCV uniformly have small values of Rh. As PCV decreases, somata with higher values of Rh are observed: thus, over the range of PCV from 40-125 m/s, there is a small (r= -0.3) but highly significant negative correlation between PCV and Rh ($p<0.01$). For cells with PCV in the Aδ range (n=14) this relationship is reversed ($r=+0.7, p<0.01$). Two cells activated by high threshold mechanical stimulation and with PCV in C fiber range had Rhs of 1 and 6 nA. The lowest mean value of Rh was observed for cells innervating muscle spindles (2.4±0.4nA; n=12) and the highest mean value was noted for cells innervating G2 hairs (5.3±1.4nA; n=11).The finding that Rh increases as PCV decreases from 125-40 m/s is unexpected considering the opposite relationship over this same range for MNs. The relationship for MNs is in the expected direction: cells with fast PCVs have large soma-dendritic surface areas (Burke et al., JCN:17-28), and the highest Rhs (i.e., they require more current to reach threshold). DRG soma size remains roughly constant in the Aβ range of PCV (Rose et al., Soc. Neurosci. Abstr. 11) and rheobase did not correlate with input resistance in DRG somata. Therefore, we suggest that other factors, e.g. differences in somal membrane properties (active and/or passive) or location of spike initiation site, may be responsible for these findings in DRG cells. Supported by NIMH MH08323 (RDR), NS14899 & NS16996 (LMM).

35.6 CENTRAL TERMINAL DISTRIBUTION OF UNMYELINATED AFFERENT FIBERS. Y. Sugiura*, E. Schrank* and E. Perl. Dept. of Physiology, University of North Carolina, Chapel Hill, NC 27514.

In anesthetized guinea pigs, pipette microelectrodes were used to record electrical signs of activity intracellularly from single dorsal root ganglion neurons. After characterization of their responses to dorsal root volleys and to peripheral tissue stimulation, the neurons were stained intracellularly by iontophoresis of horseradish peroxidase (HRP) from the recording electrode. Second cervical ganglion cells with C fibers (ca. 0.5 m/sec conduction velocity) and with nociceptive characteristics, i.e., excited by noxious pinch and either intensive heating or cooling of the ear, were marked with HRP. After histological and histochemical treatment the dorsal root fiber was successfully traced into the spinal cord. The distribution pattern of the central fiber was studied at the light level. Reasonably extensive staining of terminal regions for two nociceptive units was found. These fibers bifurcated within the dorsal rootlet. Upon entering the spinal cord, one branch projected rostrally, and the other caudal-medially. The rostral branch entered into Lissauer's tract, and after several hundred microns left it to pass into the deeper layers. Terminal and en passant enlargements were found in lamina I and in the dorsal part of lamina III. The en passant enlargements were 1 μM in diameter. The end terminals were smaller, about 0.3 μM in diameter. The caudal-medial directed branch passed along with myelinated fibers in the dorsal columns or Lissauer's tract and then passed into the gray matter. In the most completely stained example, the caudal-medial branch took a U-turn laterally and terminated in lamina I.

Supported by a grant NS10321 from the NINCDS of the NIH.

35.7 SUBSTANCE P SUPRESSES THE RESPONSE TO BRADYKININ AND TO HEAT OF NON-MYELINATED FIBERS IN EXPERIMENTAL NEUROMA OF THE CAT'S SURAL NERVE

G.M. Koschorke, R.D. Helme*(*) and M. Zimmermann
(SPON: European Neuroscience Association)
II. Pysiologisches Institut der Universität Heidelberg, FRG
(*) Monash University Melbourne, Australia

Substance P (SP) released from the peripheral nerve endings of the somatosensory nerve fibers is vasoactive, it mediates antidromic vasodilatation and neurogenic inflammation. We have studied whether SP is also neuroactive, by testing its effects onto the regenerating nerve sprouts in a neuroma. In addition, we have investigated the release of SP from neuroma sprouts.
In 9 cats, experimental neuroma were produced by transecting and ligating the sural nerve under pentobarbital sodium (40mg/kg) anesthesia. After 2-3 weeks, the animals were again anesthetized and the sural nerve was exposed for electrical stimulation and single fiber recording. The desheathed neuroma was put in a perspex chamber for perfusion with Ringer's solution with or without SP, bradykinin (BK), or Ringer's solution heated to 50°C. Of 81 identified C-fibers, 23 responded to BK (10μg/ml - 100μg/ml). In contrast, no fibers were excited by SP (10pg/ml-100μg/ml). However, when SP was given before BK we observed supression of the BK response to 34% of control with SP (1μg/ml) and to less than 5% of control with SP (10μg/ml). The responses to 50°C heat were completely supressed by SP (1μg/ml).
In 3 experiments we collected the perfusate and measured the SP concentration by radioimmunoassay. We found a significant SP release with BK (100μg/ml) which was 2 - 7 times higher (up to 610pg/5min) than the control Ringer's solution.
From these findings we conclude that SP released from nerve sprouts in a neuroma may decrease chemical excitability of the sprouts.

35.8 POTASSIUM CHANNEL-BLOCKING AGENTS AFFECT SPONTANEOUS DISCHARGES FROM NEUROMAS IN RATS. L. C. Russell* and K. J. Burchiel* (SPON: John Bonica). Neurosurgery Research, Veterans Administration Medical Center (151), 1660 S. Columbian Way, Seattle, WA 98108.

Spontaneous impulse generation originating in the end-bulb neuroma is frequently observed in experimental models of chronic deafferentation. Acute microfilament recordings were performed in the proximal nerve of 35 Sprague-Dawley rats with saphenous neuromas. The effect on observed spontaneous activity in A-fibers terminating in the neuroma of the potassium channel-blocking agents tetraethylammonium bromide (TEA) and 4-aminopyridine (4-AP), as well as the effects of gallamine were tested. TEA reliably increased spontaneous firing in active fibers and initiated spontaneous activity in some fibers with no spontaneous baseline discharge. 4-AP had no effect on baseline activity of either spontaneously-active or quiescent fibers. However, 4-AP inhibited spontaneous activity induced by prior TEA treatment. Gallamine application produced effects similar to TEA in that spontaneous activity was dramatically increased. These results imply that a tonic potassium conductance is present in regenerating fibers in the neuroma and that this conductance moderates the tendency toward hyperexcitability and spontaneous firing. Spontaneous activity in nociceptive afferents may represent the mechanism of chronic pain and paresthesias which often accompany peripheral nerve injury. These results would suggest that agents which either increase potassium conductance or selectively inhibit the sodium current in regenerating axons might be effective in the treatment of these chronic pain syndromes.

36.1 RELATIONS BETWEEN STIMULUS FORCE, SKIN DISPLACEMENT, AND DISCHARGE CHARACTERISTICS OF SLOWLY ADAPTING TYPE I CUTANEOUS MECHANORECEPTORS IN GLABROUS SKIN OF SQUIRREL MONKEY HAND. Benjamin H. Pubols Jr. and Melissa E. Benkich*. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209

The viscoelastic properties of the glabrous skin of the squirrel monkey hand are similar in many ways to those of the raccoon forepaw (B. H. Pubols, 1982). A major difference, however, is that squirrel monkey skin is more compliant, in that a given force applied to either a digital or a palmar skin pad produces a greater displacement in squirrel monkey than in raccoon skin.

The purpose of the present study was to examine the contribution of viscoelastic properties of squirrel monkey glabrous skin to slowly adapting Type I (SAI) mechanoreceptive afferent fiber discharge. Individual fibers of the median and ulnar nerves were isolated by microdissection in six monkeys anesthetized with pentobarbital sodium. Both threshold and suprathreshold responses to punctate mechanical stimuli controlled with respect to either force or displacement were studied.

The median absolute force threshold (N = 21) was 80 mg (range = 48-340 mg), and the median absolute displacement threshold was 17.5 μm (range = 5-30 μm). Both of these sets of values are lower than corresponding absolute thresholds for SAI mechanoreceptors of the raccoon forepaw. Squirrel monkey absolute force and displacement thresholds were significantly positively correlated ($P < .001$).

Application of suprathreshold forces (range = 1-8 gm) and displacements (range = 500-1000 μm) revealed greater interunit variability in response to maintained stimulation than previously found in the raccoon. In 11 out of 14 cases, the rate of adaptation was significantly less during constant force than during constant displacement stimulation. In the most extreme example, a 1 gm stimulus force applied to the distal pad of one of the digits produced a negligible decline in discharge rate over a 10 sec period, while a constant 500 μm displacement resulted in a decline in discharge rate to approximately 1/3 the initial value. In two examples, it was found that adaptation was faster to constant displacement than to constant force stimuli only when relatively high amplitude stimuli were employed.

Because the distribution and morphological features of the SAI mechanoreceptor, the Merkel cell-neurite complex, are similar in glabrous skin of raccoon forepaw and monkey hand (Munger, Pubols, and Pubols, 1971; Halata, 1975; Munger, unpublished observations), we propose that differences in their functional characteristics may be attributable to differences in properties of surrounding tissues, rather than in properties of the receptor organs themselves. (Supported in part by research grant NS-19487, USPHS.)

36.2 PERIPHERAL NEURAL REPRESENTATION OF THE SHAPE OF A STEP STROKED ACROSS THE MONKEY'S FINGERPAD. R.H. LaMotte and M.A. Srinivasan*. Dept. of Anesthesiology, Yale Univ. Sch. Med., New Haven, CT 06510

In the present study, we investigated the peripheral neural representation of small shapes stroked across the finger. Each shape was a step change in height of a plate. The cross-sectional shape of the step from low to high approximated that of a half-cycle of a sinusoid. Step height was maintained at 0.5mm, while the half-cycle wavelength was varied from 0.45mm (steep) to 3.1mm (gradual). A servocontrolled mechanical stimulator stroked the step back and forth over the glabrous skin of the fingertip while maintaining contact force at 20g wt. Stroke distance along the mediolateral axis was 18mm and stroke velocity varied from 1 to 40mm/s. Each step was stroked first from the high to the low side of the step, i.e. step-stroking off the skin (SS-off) and then back again from low to high (step stroking onto the skin, SS-on).

Evoked action potentials in single primary mechanoreceptive afferent fibers innervating the fingerpad of the anesthetized monkey (M. fascicularis) were recorded by the methods of fiber dissection and single unit recording. Ten rapidly adapting fibers (RA) (Meissner type) and eight slowly adapting fibers (SA) (type I) were studied. Each fiber's responses to a step stroked in one direction provided a spatial response profile in which the occurrence of each action potential corresponded to a position of the step on the skin. The SAs, but not RAs, exhibited a base discharge that was interrupted by a sequence of "pause-burst-pause" for SS-on and "burst-pause" for SS-off. RAs exhibited a single burst to a step moved in either direction. Both SAs and RAs had a greater burst frequency for the SS-on than SS-off.

The spatial response profile of SAs and RAs were also altered by changes in step-shape and stroke velocity. For both SAs and RAs, discharge rate during the burst increased with increases in stroke velocity and with steepness of the step. The only response feature that remained more or less invariant over a range of stroke velocities was the spatial width of the burst in SAs which, for SS-on, decreased as step shape became steeper.

These results were interpreted as showing a close relationship between the spatial response profile and the profile of skin deformation expected to occur when a step was stroked across the skin. The base discharge of SAs and their greater sensitivity to changes in skin curvature distinguished the response profiles of SAs from those of RAs.

36.3 ARE MERKEL CELLS THE MECHANOSENSORY TRANSDUCERS IN RAT TOUCH DOMES AND XENOPUS TOUCH SPOTS? L. Mills*, K. Mearow, B. Visheau and J. Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

Since their discovery over a century ago only one function has been firmly established for the Merkel cells of skin, namely to act as targets for growing mechanosensory nerves (Diamond (1982); Curr. Topics in Dvptl. Biol. 17:147). However in the EM synapses are observed between neurites and Merkel cells (reciprocal synapses in salamander and Xenopus), supporting the common assumption that these specialized epidermal cells are mechanosensory transducers. We have now attempted to destroy the Merkel cells in situ by utilizing their ability selectively among epidermal cells to take up and store quinacrine (Nurse et al. (1983); Cell and Tissue Research 228:511-524). In anaesthetised rats pre-injected with the fluorescent dye (10-15 mg/kg) the skin was depilated, and identified touch domes irradiated (330-500 nm) for 2 or more min totally to bleach their population of ca. 90 quinacrine fluorescent Merkel cells (dome cells were unable to be quinacrine labelled for at least the next 8 d). After 1-5 d recordings were made from the cutaneous nerves, and the mechanosensitivity across single domes was mapped with a 16 μm prodder tip, responsive and unresponsive regions being resolved to within about 50 μm (cf. Diamond et al. (1984) Soc. for Neurosci. Abs. Vol.10 #307.15). While some irradiated domes showed a regional (occasionally total) loss of responsiveness, others behaved apparently normally, or with moderately increased thresholds. However, examination in the EM revealed that many of these domes were dramatically affected. In these, the very few Merkel cells that could be identified had no, or very few, of the characteristic cytoplasmic dense-cored granules, and sometimes these were "empty". These presumed Merkel cells were almost all "sick" by EM criteria (although neighbouring basal cells were normal) and none had identifiable neuritic contacts. In these domes the relatively infrequent recognisable nerve endings (with their underlying Schwann cells) occupied their usual position just above the basal lamina, but most of them abutted spaces containing pockets of granular material, presumably glycogen.

Preliminary findings from similar experiments on Xenopus skin resemble those in the rat. Thus both the slowly adapting Merkel cell - neurite complexes of the touch dome, and the rapidly adapting ones of Xenopus (Mearow & Diamond (1983) Soc. for Neurosci. Abs. Vol.9 #228.12) can function when their Merkel cells are absent or grossly abnormal, and these cells seem unlikely therefore to be actively involved in the initiation of the mechanosensory responses. While e.g. receptor adaptation and fatigueability have yet to be quantified, we believe our findings raise the question - could the synapses between Merkel cells and their nerves relate to trophic, rather than to physiological, nerve-target interactions? (Supported by MRC Canada, and PHS Grant NS. 15592.)

36.4 EFFECTS OF SYNTHETIC CAPSAICIN ON THE INNERVATION OF THE SKIN. K. Chung, R.J. Schwen*, D.D. Anderson* and R.E. Coggeshall. (SPON: H.J. Nauta). Marine Biomedical Institute and Departments of Anatomy and Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550; and The Procter and Gamble Company, Cincinnatio, OH 45247.

We have reported (Neuro. Lett., 53: 221, 1985) that subcutaneous injection of synthetic capsaicin (N-vanillylnonanamide) caused loss of unmyelinated ureteral axons even though axons in the dorsal roots seemed to be undamaged. Thus, we suggested that these unmyelinated axons are damaged peripherally but spared more proximally. If these findings are generalizable, we would predict loss of somatic unmyelinated axons near their termination but no such loss in the nerves conveying these axons. To test this, we developed a fine structural assay for the axons in the skin of the posterior leg of the rat. This assay depends on the observation that bundles of 1-8 unmyelinated axons are found with regularity near the basal lamina that underlies the epidermis. We counted these axons in a 1 mm length of subepidermal tissue of the posterior leg as well as in the sural nerve in 4 animals that received 50 mg/kg of N-vanillylnonanamide 24 hours prior to sacrifice and in 4 control animals that received only the vehicle for N-vanillylnonanamide. Routine electron microscopic fixation and embedding procedures were used. The data show that the number of axons in N-vanillylnonanamide-treated animals was only 22% of the number of axons in control animals, which is a significant difference ($p<.01$), whereas there is no significant difference in sural nerve axon numbers. We thus propose that capsaicin injections cause destruction of unmyelinated axons near their site of peripheral termination but these same axons are spared where they are gathered in nervs. Further experiments to extend these observations, to determine the types of axons that are damaged and to see if there is regeneration of these axons over time, are underway.

Supported by the Procter and Gamble Company, Cincinnati, Ohio.

36.5 THE ACTION OF CAPSAICIN ON CORNEAL FREE NERVE ENDINGS. R.W. Beuerman, M. Vigo*, B. Dupuy*, and C.E. Crosson*. LSU Eye Center, New Orleans, LA 70112.

Despite a large number of studies examining several aspects of capsaicin's action on the peripheral nervous system, it is unclear how it affects the excitation of free nerve endings. In the cornea, the free nerve endings lie within 50 microns of the surface of the epithelium. Only the barrier function of the epithelium separates the nerve endings and the extracellular environment from the tear layer. In this system, the physiology of the corneal epithelium and of the free nerve endings can be compared in their response to capsaicin.

Albino rabbits (1.5 - 2 kg) were anesthetized with urethane (1.5 g/kg) and tracheotomized. The long ciliary nerve was isolated in the orbit and prepared for action potential recording by conventional techniques. Care was taken not to damage the epithelial surface. Integrated (1.5 sec t.c.) multi-unit records were used to determine the relative effectiveness of the stimuli. Stimuli consisted of sodium chloride in a concentration series which covered the range of osmotic pressures from 20 mOsm to 1800 mOsm. In other experiments, rabbit corneas were isolated and mounted in a Lucite chamber and the epithelial cells impaled with microelectrodes to determine epithelial barrier function prior to and following the addition of capsaicin.

Preparation responsiveness was initially tested to the sodium chloride series (31°C) as well as to cold (20°, 10°C) and warm saline (40°C). Response profiles of sensory afferents to a concentration series of capsaicin (0.01% to 1%) were similar in amplitude. Therefore, in succeeding experiments a .1% capsaicin solution was used. This was subjectively equivalent to a moderately hot sensation when placed on the tongue. The vehicle was not stimulatory and did not affect the responses to sodium chloride or thermal stimuli. However, capsaicin did decrease the response amplitudes to the sodium chloride series. The results indicated that the response inhibition required several minutes to develop but was long lasting. Forty minutes of continuous washing with isotonic saline failed to restore the responsiveness to sodium chloride. In other studies, the corneal innervation was visualized by light microscopy and using the gold chloride stain following topical application of 0.1% capsaicin solution. The free nerve endings within the epithelium appeared normal. An analysis of corneal epithelial component resistances in response to the acute addition of 0.1% capsaicin indicated that it did not alter the apical, basal, or shunt resistances of the epithelium. In summary, it is suggested that capsaicin has a selective action on neural membranes and may be useful in studying transduction processes.

36.6 CHANGES IN CONFORMATION OF EPIDERMAL-DERMAL BORDER REGIONS OF GLABROUS SKIN WITH DIGITAL DEFORMATION. C.J. Vierck, Jr., R.H. Cohen and D.C. Yeomans*. Dept. of Neuroscience, Univ. of Fla. Col. of Med., Gainesville, FL 32610.

Cutaneous deformations of the glabrous skin of deeply anesthetized Macaque monkeys were viewed through a dissecting microscope fitted with a video camera for taping and subsequent analysis of changes in conformation at the surface and in depth. The tip of a digit was amputated, and the proximal end was viewed through a glass plate, producing clear images of the epidermal-dermal border. Vertical and tangential deformations of the skin with probes positioned near the cut end produced consistent patterns of change in conformation of the secondary dermal papillae (containing quickly adapting receptors) and at the tips of intermediate ridges (containing slowly adapting receptors). With vertical deformations, the epidermal ridges shifted as integral units, in contrast to the pattern expected of a corrugated membrane. As a consequence, the tips of intermediate ridges (rete pegs) maintained constant, mediolateral spacings, rather than fanning out. Most of the vertical shifting occurred at the limiting ridges and the superficial portions of the intermediate ridges, producing consistent patterns of change in conformation of the secondary papillary ridges. For example, the far dermal papilla of a pair bordering a limiting ridge was distorted more than the near papilla of that pair. Distortions of the dermal papillae could be discerned at a distance from the indenting probe, but measurable changes in conformation of the intermediate ridges were more confined to the ridge(s) compressed directly by the probe. These patterns of mechanical deformation are consistent with the relatively lower thresholds and larger receptive fields of quickly adapting receptors. (Supported by NS 07261).

36.7 DOES THE EXTERNAL CUNEATE NUCLEUS PROJECT TO NEURONS IN UPPER CERVICAL DORSAL ROOT GANGLIA IN THE CAT? M.T. Stechison* and J.A. Saint-Cyr. Playfair Neuroscience Unit, and Department of Surgery, Division of Neurosurgery, and Department of Anatomy, University of Toronto, Toronto, Canada M5T 2S8.

In a series of 7 cases of cervical dorsal root ganglion injections of WGA-HRP, retrograde labelling of cells in the ipsilateral external cuneate nucleus (ECN) was noted in addition to the expected anterograde labelling of terminals. Labelled cells were clearly noted to be distinct from anterograde labelling making silhouetting of the cells in labelled terminations an unlikely explanation for the phenomenon. In order to distinguish between true retrograde labelling of these cells, and transsynaptic transport of WGA-HRP, injections of a mixture of tritiated leucine, lysine, and proline were placed in the ECN region of the dorsal medulla in three cats. Injection sites were large encompassing the ECN as well as the adjacent reticular formation, main cuneate nucleus and the medial and descending vestibular nuclei. Following 24 hour survival times, transcardial perfusion with 10% formalin was carried out. In one case all 16 cervical dorsal root ganglia were removed, mechanically pulverized, and placed in tissue solubilizer followed by counting fluid. Liquid scintillation counts were obtained, and activity levels in the ipsilateral C1 - 3 dorsal root ganglia (DRG) were 2.7 - 6.6 times those recorded from the contralateral DRG. The two remaining cases were histologically processed for standard autoradiography. Examination of 7um sections in both bright and dark-field illumination revealed clusters of silver grains in association with some cells in the ipsilateral upper cervical DRG. The greatest amount of labelling was present in C2 and 3, followed by C1. Labelling appeared clearly extracellular in location. Approximately 1 in 10 cells on the strongest labelled sections appeared to be associated with a terminal field. This finding suggests that first order cervical afferents are in receipt of input from ECN neurons. Such centrifugal projections to first order neurons have been described in other sensory systems in mammals, but have not previously been reported in the somatosensory system. Previous investigators (Kayahara et al., Brain Res. 216: 277-290, 1981) have detected the presence of chemical type synapses in C5 to C8 DRG in E.M. sections, but the source of these was not identified. The present findings indicate that ECN may be a source of projections to more rostral cervical DRG. Such a connection could function in the modulation of upper cervical afferent inputs to spinal and supraspinal centres.

Supported by MRC grant MT-7209 awarded to J.S.C.

36.8 DIFFERENTIAL PATTERNS OF LABELING IN THE RAT DORSAL HORN AND DORSAL COLUMN NUCLEI WITH TRANSGANGLIONIC TRANSPORT OF WGA-HRP AND HRP. J.E. Swett Dept. of Anatomy, Coll. of Med., Univ. of Calif., Irvine, CA 92717

It is widely assumed that the wheat germ conjugate of horseradish peroxidase (WGA-HRP) is a sensitive substitute for free HRP as a neuroanatomical tracer substance. This may be valid for retrograde labeling of motoneurons from cut nerves but not for transganglionic labeling from cutaneous afferents. In 35 experiments 5-10% WGA-HRP (Sigma) was applied for 4 hours to the cut end of the saphenous (or sural) nerve in one leg while 40% free HRP (Sigma VI or Boehringer Grad I) was applied to the homologous nerve in the opposite leg. After survival periods of 24-108 hours, frozen serial sections (40 um) were obtained through appropriate dorsal root ganglia (DRG) in the longitudinal plane and N. gracilis (DCN) and spinal segments L2-L6 in the coronal plane. Tissues were reacted with TMB as the chromogen. No differences were found in comparing numbers, sizes or densities of labeled DRG cells on either side, but the patterns of distribution of label differed in the dorsal horn and DCN. On the WGA-HRP side a dense band of label was found in lamina II (Swett & Woolf, JCN 231:66, 1985) for all survival times. Label was sparse or absent elsewhere in the dorsal horn and DCN. Lissauer's tract was well labeled while axons in the dorsal columns were not. On the HRP side the band of label seen on the WGA-HRP side was present in 24 hr and absent after 48 hr. Laminae I, III and IV contained the bulk of the reaction product. Massive labeling appeared in afferent terminals in DCN as well as axons in the dorsal columns. Lissauer's tract was weakly labeled. A marked decrease in the amount of reaction product in axons proximal to the DRG's on the WGA-HRP side, but not on the HRP side, suggests that the conjugate is poorly transported centrally from large DRG cells. When a cocktail of 5% WGA-HRP and 30% free HRP was applied to cutaneous nerves in control experiments, the individual labeling characteristics of the two tracers were superimposed. WGA-HRP was preferentially, but not exclusively, transported by small diameter primary afferent fibers, presumably mostly by C fibers rich in FRAP. Conversely, HRP appeared to be transported in both large and small diameter fibers with reaction products in the latter being relatively labile. Thus, neither tracer substance is alone capable of revealing the complete distribution of afferent terminations in the CNS. (Supported by NIH, NINCDS Grant NS-17630).

37.1 PHYSIOLOGY AND PHARMACOLOGY OF THE RELEASE OF SUBSTANCE P FROM SPINAL PRIMARY AFFERENTS. T.L. Yaksh* and V.L.W. Go* (SPON: J.P. Whisnant). Laboratories of Neurosurgical Research and Gastroenterology, Mayo Clinic, Rochester, MN 55905.

In spinal cord, substance P (sP) is found in intrinsic neurons, terminals of descending pathways and primary afferents. Superfusion of the spinal cord in halothane (0.8%) anesthetized cats, artificially ventilated under Pavulon with artificial cerebrospinal fluid (CSF) containing albumin (120 µg/ml) and bacitracin (30 µg/ml) reveals the presence of sP-like immunoreactivity (sP-LI) appearing at the rate of 26±3.9 fmol/30 min. (antisera: R4892; assay sensitivity 3 fmol/tube) which co-chromatographs with sP 1-11, (HPLC: C-18 column with acetonitrile 10-60% gradient in 0.1 M acetate at 1 ml/min). The following properties of the release were noted: 1) Electrical stimulation of the sciatic nerves at intensities which evoke an Aß-Aδ-C fiber compound action potential results in a 2.6±0.4-fold increase in sP-LI. 2) The release is frequency dependent over the range of 10 to 100 Hz with frequencies of 100 Hz showing a reduction in the amount of sP released. 3) Double pulse experiments carried out at 20 Hz, reveals that the apparent refractory period(s) of the afferent fibers from which the sP is released are 10 msec $< x <$ 50 msec, suggesting a small axon population. 4) Reversible cold block of the cervical cord did not abolish the release, excluding a contribution from bulbospinal sP pathways. 5) Treatment with intrathecal capsaicin ($5x10^{-4}$) resulted in a 3.4±0.5-fold increase in sP-LI secretion. This treatment blocked the ability of subsequent electrical stimulation to evoke further sP release. 6) The addition of morphine (µ: 10^{-4}M), D-Ala^2-D-Leu^5-enkephalin (δ: 10^{-5}M), but not U50488H (κ: 10^{-3}M) diminished the stimulation evoked release of sP to less than 50% as compared to pretreatment control. 6) ST-91 (α_2-agonist: 10^{-4}M) but not serotonin (10^{-4}M) depressed the stimulation evoked sP-release. 7) GABA (10^{-3}M) had no effect on sP release. 8) Electrical stimulation of the dorsal lateral quadrant at the cervical level did not alter the levels of sP-LI in the spinal superfusate, but the effects of sciatic nerve stimulation on sP release were greatly diminished. Yohimbine ($5x10^{-5}$M), but not naloxone (10^{-4}M) produced a significant reduction in this suppressent effect of dorsolateral funiculus stimulation of evoked sP-LI release. These observations support the concept that sP-LI is released from small primary somatic afferents and its release is under the influence of spinal µ, δ and α_2 receptor systems known to be present in primary afferent terminals. Spinal pathways traveling in the DLF appear to alter spinal terminal activity in part by an α_2, but not opioid receptor. (Funds from NS-16541.)

37.2 HYPERALGESIA TO HEAT IN HUMAN SUBJECTS AND SENSITIZATION OF C-NOCICEPTORS IN MONKEYS DO NOT OCCUR ADJACENT TO A MECHANICAL INJURY OF THE HAIRY SKIN. J.N. Campbell[1], R.A. Meyer[1,2], A.A. Khan*[1], and S.N. Raja[1]. School of Medicine[1] and Applied Physics Lab[2], The Johns Hopkins University, Baltimore, MD 21205.

Secondary hyperalgesia refers to the alteration in pain sensitivity that occurs outside the site of an injury. Sensitization of nociceptors has been shown to account for the primary hyperalgesia at the site of injury. It has been proposed that sensitization also spreads to adjacent uninjured skin to account for secondary hyperalgesia. Fitzgerald (J. Physiol. 297:207, 1979) reported that a cut in the skin adjacent to the receptive field of C-fiber nociceptors in rabbit resulted in a lower heat threshold relative to that of the control population (i.e., spreading sensitization). We were unable to confirm this finding in monkey. Also, we failed to demonstrate hyperalgesia to heat adjacent to a mechanical injury in human subjects.

The mechanical injury consisted of a 1 mm deep scalpel cut. In the psychophysical experiments, two parallel cuts were made in the volar forearm, 1.5 cm apart and 8 mm long. Heat testing was performed in the uninjured area between the cuts. In the neurophysiological experiments, the cut was 1-4 mm from the edge of the receptive field (RF), and was 5-8 mm long on the distal side of the RF (n=5) or was U-shaped (n=4) so as to surround all but the proximal side of the RF. Heat stimuli were 1s in duration, ranged from 39° to 49°C, and were delivered at 30s intervals. The sequence of heat stimuli were repeated with 10 minute inter-run intervals. The injury was delivered between two of the runs once a stable response to heat was established.

Standard teased-fiber techniques were used to record from single C-nociceptors that innervated the hairy skin of the forearm and hand in pentobarbital anesthetized monkeys. A magnitude estimation technique was used by the human subjects to rate the painfulness of the heat stimuli. The total response to the test heat sequence was used as a measure of the responsiveness of the nociceptors (sum of action potentials) and of the human subjects (sum of ratings). For the nine C-nociceptors, the response after the mechanical injury was 101 ± 6% (mean ± S.E.M) of the response immediately before the injury and, therefore, spreading sensitization did not occur. For the six human subjects, the response after the mechanical injury was 80 ± 12% of the response before injury and, therefore, hyperalgesia to heat did not occur. These results for adjacent mechanical injury are similar to those reported for adjacent heat injury where neither spreading sensitization of C-nociceptors nor hyperalgesia to heat of human subjects was observed.

37.3 ANTIDROMIC NERVE STIMULATION IN MONKEY DOES NOT SENSITIZE C-FIBER NOCICEPTORS TO HEAT. R.A. Meyer, J.N. Campbell and S.N. Raja, School of Medicine and Applied Physics Lab, Johns Hopkins Univ., Baltimore, MD 21205.

Spreading sensitization of nociceptors has been proposed as the mechanism for the secondary hyperalgesia that surrounds an injury. Activation of part of the nociceptive receptor by an injury stimulus could lead to antidromically propagated action potentials to the other part of the receptor resulting in the release of sensitizing substances. A similar axon reflex mechanism is thought to account for the flare that surrounds an injury. Fitzgerald (J. Physiol. 297: 207-216, 1979) reported that antidromic electrical stimulation of the peripheral nerve in rabbit resulted in a lower heat threshold (and therefore sensitization) of C-fiber nociceptors relative to that of the control population. We attempted, without success, to confirm this finding in monkey.

Standard teased fiber techniques were used to record from single C-fiber nociceptors in monkey under pentobarbital anesthesia. A stimulating electrode was placed on the parent nerve proximal (PSE) or distal (DSE) to the recording electrode. A laser thermal stimulator provided constant temperature stimuli to the receptive field. Before and after electrical nerve stimulation, the C-fiber nociceptors were stimulated with test heat stimuli of 1s duration ranging from 39° to 49°C. These heat stimuli do not cause sensitization and have proven useful in monitoring receptor sensitivity (Campbell and Meyer, J. Neurophys., 49: 98-110, 1983). Various electrical stimulation parameters were used over the ranges of 50-100 volts, 0.1 ms, 1-50 Hz, for duration of 1-6 mins. Evidence for effective C-fiber stimulation included pilomotor response, goose flesh, decreased skin temperature, and sweating in the distribution of the nerve.

Following PSE stimulation, the heat threshold for 10 C-fiber nociceptors did not change significantly ($\Delta T = -0.3 \pm 0.2$°C, mean ± SEM), the total response to the test heat stimuli did not change (97 ± 5% of control), and spontaneous activity did not develop. Thus no signs of sensitization were observed. Following DSE stimulation, the responses of 6 C-fiber nociceptors were blocked completely for 4.3 ± 0.8 min. Twenty minutes after electrical stimulation, the response was 88 ± 8% of control. Ten similar experiments in halothane anesthetized monkeys also failed to demonstrate sensitization to heat of C-fiber nociceptors following proximal or distal nerve stimulation.

We conclude that antidromic stimulation of C-fiber nociceptors in the monkey does not result in sensitization of their response to heat. Except for differences in species and in general anesthetics used, we cannot account for the differing results reported by Fitzgerald in rabbit.

37.4 NARCOTICS DO NOT ALTER THE RESPONSE OF C-FIBER NOCICEPTIVE AFFERENTS IN MONKEYS, S.N. Raja[1], R.A. Meyer[1,2], J.N. Campbell[1], A.A. Khan*[1], School of Medicine[1] and Applied Physics Lab[2], Johns Hopkins University, Baltimore, Maryland 21205.

We previously reported that the general anesthetic, halothane, sensitizes nociceptors in a reversible, dose-dependent manner. To determine if narcotics alter the response of primary afferents, we studied the effects of fentanyl on the responses of single C-fiber nociceptive afferents to heat stimuli delivered to their cutaneous receptive field. Standard teased-fiber techniques were used to record from 10 C-nociceptors sensitive to mechanical and heat stimuli (CMHs), in pentobarbital anesthetized (4-6 mg/kg/hr), mechanically ventilated monkeys. Blood pressure, heart-rate, end-tidal CO_2 and core temperature were monitored. Three additional CMHs were studied in brain-dead, unanesthetized monkeys. To determine the effects of the narcotic fentanyl, we recorded responses to repeated suprathreshold heat stimuli (46-48°C) before, during and after the administration of incremental i.v. doses (5-30 ug/kg) of fentanyl. Step increases in skin temperature for specified periods were produced by a laser thermal stimulator under radiometer feedback control. Naloxone (0.8 mg i.v.) was given 5 min after the highest dose of fentanyl. Stimuli were of 1 or 3 sec duration and were repeated at 30 or 60 sec intervals. After a stable baseline response was observed, incremental doses of fentanyl were administered at 5 min intervals. For each of the 10 CMHs, the mean response of 5-10 trials before the administration of fentanyl was compared to the mean response of 5-10 trials after fentanyl administration. The responses of the CMHs at the 5,10,20 and 30 ug/kg doses of fentanyl were 93 ± 3%, 96 ± 2%, 99 ± 4% and 102 ± 6% (Mean ± S.E.M.) of control respectively. The mean response after the administration of naloxone (0.8 mg) was 101 ± 5% of control. In 6 of the 13 CMHS we later studied the change in response to heat stimuli after the administration of halothane (2% inspired concentration for 10 min). The response was significantly increased (146 ± 12% of control, $P<0.02$). Fentanyl (up to 30 ug/kg) also did not affect the responses of 3 CMHs recorded in the brain-dead, unanesthetized monkeys, thus excluding a confounding interactive effect of pentobarbital and fentanyl. In conclusion, fentanyl has no significant effect on the response to heat of C-nociceptive afferents. Thus, the effects of spinally or systemically administered opiates are unlikely due to an alteration of nociceptor function.

37.5 SINE WAVE ANALYSIS OF "COLD" THERMORECEPTOR SENSIVITITY. R.D. Wurster, F.K. Pierau* and C.J. Robinson. Rehabilitation R&D Ctr., VA Med. Ctr., Hines, IL 60141; Kerckhoff Inst., Max Planck Gesellschaft, 6350 Bad Nauheim, F.R.G.: and Dept. Physiol., Loyola Univ. Med. Ctr., Maywood, IL 60153.

"Cold"-sensitive thermoreceptors exhibit peak static mean firing rates at a temperature (Tmax) in the 25 to 30 C temperature range. Dynamic sensitivity has been previously assessed using rapid step-like or ramp temperature changes. However, because of the variations of sensitivity at different static temperatures, analysis of dynamic sensitivity is difficult. In the present study, sine wave analysis of thermal sensitivity was utilized. Lingual nerve thermoreceptor units were recorded from cats anesthetized with alpha chloralose. The dorsal surface of the tongue was placed upon a water-perfused thermode which was capable of producing sine wave temperature changes, as well as maintaining various static temperatures. The lingual nerve was isolated, desheathed and then recorded using bipolar electrodes and an AC amplifier. The nerve was subdivided until a single, cold thermosensitive unit, not sensitive to mechanical stimulation, was recorded. Adaptation temperature was changed in steps (3 to 5 C) from 38 to 18 C. Following adaptation for about 5 min at each step, the temperature was modulated by a 0.5C sine wave oscillation at 0.01, 0.05, 0.1 and 0.3 Hz.

The changes in response from static firing rates depended on whether the temperature was rising or falling. During temperature decreases, the maximum change in firing rate above the static rate was nearly linearly related to the sine wave frequency from 0.05 to 0.3 Hz. During temperature increases, the depression of firing rates below static levels was quite sensitive to temperature shifts, in that the activity decreased to minimal levels (>2 IPS) with any 0.5 degree increase regardless of the modulation frequency. The maximum changes in firing rates were much greater to increasing than decreasing temperatures at all frequencies and static temperatures tested; in other words, the rate of change in firing of cold thermoreceptors was much more pronounced during temperature increases than decreases.

At the slowest frequency (0.01 Hz), the response of the cold units all approached that which would be expected from their static sensitivity curves. At temperatures > Tmax, very slow incremental temperature increases resulted in decreases in firing rate; while at temperatures < Tmax, such increases increased the rate. As the frequency of temperature modulation was increased, the phase shift of the response decreased above Tmax while increasing below Tmax.

From these response characteristics, a model can be constructed of cold nociceptor dynamic sensitivity. Supported by the Max Planck Gesellschaft and the Veterans Administration.

37.6 BLOOD PRESSURE EFFECTS PRODUCED BY VENTRAL ROOT AFFERENT FIBERS. H.K. Shin*, J. Kim* and J.M. Chung. (SPON: D.J. McAdoo). Marine Biomedical Institute, Department of Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Although a large number of afferent fibers are found in the mammalian ventral root their functional role is not clear. To reveal the potential physiological role of ventral root afferent fibers in cardiovascular function, changes in arterial blood pressure evoked by ventral root stimulation were observed in anesthetized cats.

Eighteen adult cats were anesthetized with α-chloralose (70 mg/kg) and systemic arterial blood pressure was monitored through a cannula inserted into the carotid artery. To reduce baroreceptor-mediated reflex compensation of blood pressure, animals were vagotomized and the carotid sinuses denervated bilaterally. The lumbosacral spinal cord was exposed by a laminectomy, and a heated mineral oil pool was formed over the exposed spinal cord. Ventral roots of the 7th lumbar and 1st sacral spinal segments were cut near the spinal cord. The peripheral stump of the cut ventral root was placed on a tripolar stimulating electrode; the most distal lead was grounded to prevent current spread to nearby neural structures.

Low intensity electrical stimulation (< 20T; less than 20 times the threshold for motor fiber activation) of the distal stump of the cut ventral root caused a rise in blood pressure. This elevation was abolished by paralyzing the muscles with gallamine. High intensity electrical stimulation (500T) of the distal stump of the cut ventral root caused a second and marked pressor response. This was not affected by muscular paralysis or cutting the sciatic nerve, but it was abolished by cutting the dorsal root. It was found that the threshold intensity for the second component of the pressor response was within the same range as the intensity needed for activation of C fibers in the ventral root, ranging between 200T and 300T. This response was graded with increasing stimulus intensity, and it showed both spatial and temporal summation. No changes in blood pressure have been observed when the proximal stump of the cut ventral root was stimulated, regardless of intensity.

From the above results, we conclude that unmyelinated fibers in feline spinal ventral root course distally to the dorsal root ganglion and then enter the spinal cord via the dorsal root. Activation of these fibers results in a marked elevation of the systemic arterial blood pressure as in other somato-sympathetic reflexes induced by peripheral C fiber activation.

Supported by NIH grants NS21266, NS18830 and NS11255.

37.7 ARRANGEMENT OF VENTRAL ROOT AFFERENT FIBERS IN THE CAT. J. Kim*, H. K. Shin* and J.M. Chung. (SPON: J.E. Blankenship). Marine Biomedical Institute and Department of Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Although the existence of a large number of afferent fibers in the mammalian ventral root has been demonstrated, their peripheral arrangement is not clear. The present study is to investigate the peripheral course of these fibers electrophysiologically using the collision method.

Fifteen cats were anesthetized with α-chloralose (70 mg/kg). After a tracheotomy, the animal was ventilated with a respirator and paralyzed with gallamine. The lumbosacral spinal cord was exposed by a laminectomy and the spinal roots of the S1 segment were cut near the spinal cord. The spinal nerve of the same segment was exposed in the hindlimb and cut where it joins the sciatic nerve. Single fiber recordings were made from dorsal root filaments while the peripheral stump of the cut ventral root was being stimulated. If a single fiber was activated by ventral root stimulation, a peripheral spinal nerve was also stimulated to see if the same unit could be activated. Attempts were made to collide the unit activity that was elicited by stimulation of the ventral root with that of the peripheral nerve and vice versa. Then the conduction velocity was calculated from the latency and the conduction distance and also from results of collision data.

Among a total of 33 dorsal root units that were activated by stimulation of the ventral root, the activity of 17 units was collided with peripherally elicited activity. These results suggest that these primary afferent neurons have 3 processes; one in the dorsal root, one in the ventral root and one in the periphery. For another 11 units, we were unable to verify any collision. In the remaining 5 units, peripheral nerve stimulation did not elicit any electrical activity recordable in the dorsal root. The results of collision data indicated the conduction velocity of the process along the length of the ventral root changed so that it seemed to get slower as it approached the spinal cord.

From the above results, we conclude that many of the ventral root unmyelinated afferent fibers in the feline S1 spinal segment have processes both in the dorsal root and in the periphery. The size of each process may be different.

Supported by NIH grants NS21266, NS18830 and NS11255.

38.1 THE PHYSIOLOGICAL BASIS FOR SYMPATHETICALLY MAINTAINED PAINS. W. J. Roberts and M. E. Foglesong*. Neurological Sciences Inst., Good Samaritan Hospital & Medical Center, Portland, OR 97209.

In some chronic pain syndromes such as causalgia and sympathetic reflex dystrophy, the continuous pain is most effectively treated by sympathetic block, yet the physiological basis for these disorders is not clearly understood. A review of the clinical findings associated with the family of sensory disorders which can be collectively labeled "sympathetically maintained pains" (SMP) reveals certain features which are common to all. These are: 1) continuous burning pain subsequent to trauma; 2) allodynia (touch-evoked pain); 3) relief from pain when the relevant nerve or sympathetic trunk is blocked or quanethidine is infused (this depletes norepinephrine peripherally). The clinical findings suggest that sympathetic excitation of afferents contributes to these pains and that an abnormal sensitivity of spinal nociceptive neurons is also involved.

It is proposed that these pains are initiated by trauma-induced nociceptor activity which causes prolonged sensitization of spinal wide-dynamic range (WDR) or multireceptive neurons. After sensitization these WDR neurons respond vigorously to activity in low-threshold mechanoreceptors (e.g. slowly-adapting type I's) which can be induced either by gentle mechanical stimulation (allodynia) or by sympathetic efferent activity (leading to SMP).

Slowly-adapting type I afferents are likely to contribute to SMP because they can be activated by sympathetic stimulation in cats (Roberts and Elardo, Somatosens. Res., in press), because they have been shown to have excitatory actions on WDR neurons (Tapper, et al., 1985), and because they respond vigorously to gentle mechanical stimulation. Other classes of afferents may also contribute to the allodynia in these syndromes, but none appear to respond appropriately to sympathetic stimulation.

Testing of this proposed mechanism is presently being done in anesthetized cats. Single unit recordings from functionally identified spinal sensory neurons are used to test responses to both cutaneous and sympathetic stimulation. Preliminary results to date have shown that some WDR neurons give a sustained response to maintained, low-frequency (5 Hz) stimulation of the sympathetic trunk. Nociceptor specific spinal neurons tested under the same conditions are not activated by sympathetic stimulation. The results to date are consistent with the physiological mechanism for SMP described above.

38.2 DEPRESSED SEROTONIN AND DOPAMINE METABOLITES IN CSF OF PAIN PATIENTS. R. Weiner, G. Karp*, and B. Haber. Division of Neurosurgery, Dept. of Surgery, Marine Biomedical Institute, Depts. of Human Biol. Chem. and Genetics, and Neurology, Univ. of Texas Med. Branch, Galveston, TX 77550.

It is widely believed that serotonin (5HT is released as an inhibitory neurotransmitter from descending axons that modulates the processing of afferent noceceptive information. Thus, chronic pain may in part be due to a defficiency of central inhibitory 5HT mechanisms, and such a defficiency may in turn be reflected in the levels of either 5HT or its metabolite, 5HIAA, in the cerebrospinal fluid. We have analyzed a substantial number of cerebrospinal fluid samples obtained by lumbar puncture. The patients in the general pain category had neck pain, head and neck pain, pain in the lumbar or cervical areas, spinal stenosis and cancer pain. The non-pain group included hydrocephalus, aneurysms, spinal cord atrophy, closed head injury and cervical spondylosis. CSF samples in 0.2M perchloric acid were analyzed by high pressure liquid chromatography with electrochemical detection. The mobile phase was 0.2mM SOS (1-octanesulfonate, sodium) in 7.5% Acetonitrile, pH 2.5, containing 0.05mM EDTA, at a flow rate of 1.5ml/minute, using a 3 micron ODS short column. 5HT was not detected under these or other chromatographic conditions, and therefore, CSF needs to be concentrated at least ten fold to permit 5HT detection. In contrast, the 5HT metabolite, 5HIAA was present in all CSF samples, at concentrations ranging from 9-441 ng/ml. The mean value for 5HIAA in eighteen pain patients was 30.8 ± 3.1 ng/ml, and 110.4 ±19.3 ng/ml in 35 non-pain patients. An unidentified compound that chromatographs with Dopamine under these conditions was present at 357 ± 64 ng/ml in the pain group, and at 177 ± 50 ng/ml in the non-pain group. Homovanilic acid (HVA), the dopamine metabolite was consistently higher in the non-pain group (144.3 ± 2.68 ng/ml), than in the pain patients (55.5 ± 7 ng/ml). Comparison of pain patients with lesions vs. those with chronic pain showed the same pattern, with very little scatter in the values, as opposed to the large scatter in both selected (hydrocephalus) and random control CSF. The significance of the pain related depression of HVA is at present unclear, whereas the consistent depression of 5HIAA levels supports the notion of a decreased activity in descending serotonergic pathways in chronic pain.

38.3 NEUROGENIC SPREAD OF HYPERALGESIA AFTER INTRACUTANEOUS INJECTION OF CAPSAICIN IN HUMANS. D.A. Simone*, J.Y.F. Ngeow* and R.H. LaMotte (SPON: J.G. Collins). Dept. of Anesthesiology, Yale Univ. Sch. of Med., New Haven, CT 06510

Injury to the skin often results in an increased sensitivity to pain within the injured area, i.e. primary hyperalgesia ($1^{o}H$), and in the surrounding skin, i.e. secondary hyperalgesia ($2^{o}H$). Although nociceptors can be sensitized by chemical substances within an injury, there is controversy as to whether $2^{o}H$ results from the diffusion of the sensitizing chemical from injured to non-injured skin or by a neurogenic mechanism (e.g. chain of axon reflexes in periphery). In the present study, an intracutaneous injection of capsaicin produced $1^{o}H$ to heat and both $1^{o}H$ and $2^{o}H$ to mechanical stimuli. A neurogenic basis for the $2^{o}H$ is suggested.

Human subjects gave informed consent to a University-approved protocol. Each subject received a superficial injection of 10ul of capsaicin (1%) into the volar forearm. Capsaicin produced a flare surrounding the injection site and spontaneous burning pain. Within a few minutes there was pain to gentle rubbing with a cotton swab and decreased heat pain threshold (from 41.6 to 32.8°C) within a 1cm area centered over the injection site (area of $1^{o}H$). All subjects experienced pain or tenderness to gentle rubbing in a larger area ($2^{o}H$) surrounding the $1^{o}H$ area within which heat pain sensitivity was usually normal. The mean area of $2^{o}H$ was 37 ± 13 cm^2 (S.D.) and extended beyond the flare area which averaged 17 ± 9 cm^2.

Cooling the injection site to 1-2°C (1 cm^2 thermode) eliminated within 1-5 min the background burning pain and greatly reduced or eliminated the area of $2^{o}H$. The $2^{o}H$ returned to its original or slightly larger area upon rewarming the injection site. This sequence could be repeated several times.

In separate experiments, both $1^{o}H$ and $2^{o}H$ were abolished following an injection of 20-50ul of 0.5% xylocaine into the capsaicin injection site. Similarly, a narrow strip of xylocaine injected 1cm proximal to the capsaicin injection site did not alter $1^{o}H$ but blocked the spread of $2^{o}H$ proximally.

Finally, a pressure block of conduction in A fibers did not alter the development of $2^{o}H$, wherein light rubbing evoked pain but not tactile sensations.

Intracutaneous injection of capsaicin produced $1^{o}H$ to heat and $1^{o}H$ and $2^{o}H$ to mechanical stimulation. The $2^{o}H$ spread by a neurogenic mechanism and involved nociceptors with C fibers. It is possible that capsaicin-induced hyperalgesia may be a useful model for the study of clinical cutaneous hyperalgesia. (Supported by NIH Grant NS 14624)

38.4 REGIONAL SPECIFICITY OF VAGINAL STIMULATION SITES PRODUCING ANALGESIA IN WOMEN. Beverly Whipple* and Barry R. Komisaruk, Institute of Animal Behavior, Rutgers Univ., Newark, NJ 07102.

The present findings confirm and extend our earlier report that vaginal stimulation (VS) differentially elevates pain thresholds but not tactile thresholds in humans. In this study we compared the effects of pressure or pleasurable self-stimulation applied to the anterior (ant) or posterior (post) vaginal wall and clitoris in counterbalanced sequence. Pain thresholds were determined by applying a gradually increasing force to each finger using a Ugo Basile Analgesia Meter. The subject reported when finger pain was perceived (threshold for detection: (Td)) and when finger pain became too uncomfortable to continue (threshold for tolerance: (Tt)). Tactile thresholds were determined on the dorsal surface of the hand using force-calibrated von Frey fibers. VS was self-applied using a specially designed force-calibrated plastic cylinder. The 10 subjects, not previously known to the experimenters, were paid volunteers who received medical and psychological screening prior to participation. The study received prior approval by the University IRB. All values are reported as group mean % increase over the non-stimulation reference threshold obtained at the end of each subject's testing session. The increase in Tt during VS pressure (ant) (26.8%) was significantly greater than that of the no-VS control (1.6%) (Duncan test $p < .05$), but the effects of VS (post) (20.8%) or clitoral pressure (12.2%) were not significant. During self-stimulation applied so that it was experienced as pleasurable rather than just pressure, each showed a significant and greater increase over the control condition (VS ant: 36.6%, VS post: 32.7%, and clitoral: 27.5%; Duncan each $p < .05$). As pleasurable stimulation continued to a maximum of 5 minutes, the Tt increased further (55.7%, 43.5%, and 47.3%, Duncan each $p < .05$), respectively. A distraction (reading) control did not elevate the Tt. Td during VS ant pressure (35.7%) was significantly greater than control (5.7%), while those during VS post pressure (28.4%) or clitoral pressure (19.1%) were not (ANOVA t-tests $p < .05$). The highest Td's were reached after 5 minutes of pleasurable stimulation (VS ant: 67.4%, post: 62.8%, or clitoral: 62.5%; each significantly greater than control; Duncan $p < .05$). The distraction (reading) condition (24.9%) did not significantly increase Td. In contrast to the elevations in Tt and Td, tactile thresholds were not significantly affected by any VS or clitoral stimulation condition (range 4.9% to -34.1%), while there was a significant (78.6%) increase in the reading control condition. It is noteworthy that a) the analgesia-producing self-stimulation was reported by the subjects as neither painful nor stressful, and b) the stimulation self-reported as pleasurable produced greater elevations in Td and Tt than did self-applied pressure. Supported by the Research Council, Rutgers-The State University.

38.5 VAGINAL STIMULATION-PRODUCED ANALGESIA IS PROLONGED BY LEUPEPTIN, A PROTEASE INHIBITOR. S.B. Heller, A.R. Gintzler, A. Stracher* and B.R. Komisaruk. Inst. Animal Behavior, Rutgers Univ., Newark, N.J. 07102 and Dept. Biochemistry, Downstate Medical Center, SUNY, Brooklyn, N.Y. 11203

Vagino-cervical mechanical stimulation (VS) in rats reduces behavioral responsivity to a variety of noxious stimuli, including tail-flick in response to noxious heat. VS is more effective in reducing responsivity to noxious stimuli than a standard dose of morphine sulfate (2mg/kg). Recent evidence implicates intra-spinal mechanisms in behavioral withdrawal responses to noxious stimulation. In spinal rats, VS blocks leg flexion in response to foot pinch. Intrathecally administered protease inhibitors potentiate endogenously released or exogenously administered opioids to increase analgesia.

The present study was designed to determine whether intrathecal administration of Leupeptin (L), a naturally occurring, calcium activated, serine protease inhibitor, would prolong the analgesia resulting from VS in the tail-flick test. Following ovariectomy and implantation of an intrathecal catheter into the lumbo-sacral region, animals were placed into one of four groups (N=10 per group); (1) L+VS, (2) saline (S)+VS (S+VS), (3) L+no VS or (4) S+no VS. Following pre-injection baseline (B) testing, Groups L+VS and S+VS were injected and given B, VS and post-VS (PVS) trials 3, 5, 10, 20, 40 and 60 mins. post-injection. Groups L+no VS and S+no VS were given three series of B trials at each of the corresponding time periods.

Results demonstrate that pre-injection tail-flick latencies (TFL's) did not differ among the four groups. Following injection, TFL's of Groups L+no VS and S+no VS did not change significantly over the entire test period; thus, Leupeptin itself did not produce analgesia. During VS trials, TFL's were equivalent for Groups L+VS and S+VS, but were significantly greater than those of Groups L+no VS and S+no VS in the corresponding test period (Duncan Test, $p < .05$). During PVS trials 5, 10 and 20 mins. following injection, Group S+VS TFL's were significantly greater (Duncan Test, $p < .05$) than those of Group S+no VS at the corresponding test period, confirming that analgesia can persist for minutes following termination of VS. Furthermore, during PVS trials 3, 5 and 40 mins. post-injection, Group L+VS TFL's were significantly greater (Duncan Test, $p < .05$) than those of Group S+VS. Thus, L potentiated vaginal stimulation-produced analgesia after cessation of VS.

Our results show that Leupeptin prolongs analgesia resulting from VS. This may be due to Leupeptin inhibiting the enzymatic breakdown of (a) neuropeptide(s) released in the spinal cord by VS.

38.6 THE EFFECT OF HELIUM-NEON LASER ON LATENCY OF SENSORY NERVE, Snyder-Mackler L*, Bork C*, Fernandez J*, (SPON: J. McElligott) Department of Physical Therapy, Temple University College of Allied Health Professions, 3307 North Broad St., Philadelphia, PA 19140.

Helium-Neon (He-Ne) laser has been reported to have pain relieving effects in humans. One possible mechanism of pain control was investigated in this double blind study. The effect of Cold Laser Therapy (CLT) on the distal latency of peripheral nerve in man was studied.

Twenty normal subjects were randomly assigned to one of two groups: placebo (8) and treatment (12). Antidromic distal latencies of the right superficial radial nerve were recorded prior to the laser or placebo (mock laser) treatment. Six, one square cm areas of skin overlying the superficial radial nerve were irradiated with continuous He-Ne (or mock) laser held .5mm from the skin surface. A second latency reading was recorded immediately after the treatment. Both the subjects and the experimenters were prevented from knowing whether the laser or placebo was used by an opaque shield which covered the fiberoptic tip.

A t-test was employed to analyze the data. The treatment group displayed a statistically significant increase (for $p<.05$) in the distal latency of the superficial radial nerve when compared with the placebo group.

An increase in distal latency corresponds to a decrease in nerve conduction velocity. This decrease in nerve conduction velocity could begin to provide an explanation for the pain relieving effect of He-Ne laser.

PAIN MODULATION: PEPTIDES, MONOAMINES

39.1 INTRASPINAL PEPTIDERGIC REARRANGEMENT FOLLOWING SECTION OF RAT SCIATIC NERVE. A.M.Di Giulio, F.Borella*, P.Mantegazza*, M.Parenti, A.Groppetti,* R.Zanoni*† and A.Gorio*†. Dept. of Pharmacol. Univ. of Milano, Milano and † Fidia Res.Labs., Abano Terme, PD, Italy.

Substance P (SP) is considered to be a putative transmitter in the central terminals of primary sensory neurons in the dorsal horn of the spinal cord. Section of the peripheral processes of these neurons produces a dramatic depletion of SP in the lumbar spinal cord. We have measured the levels of SP, met-enkephalin (ME), dynorphin (DY) and serotonin (5-HT) in the rat lumbar cord following sciatic nerve section. Rat sciatic nerve was cut mono or bilaterally a few millimiters distally to the point where L4 and L5 form the sciatic nerve, then the proximal stump was either ligated or sutured intraperitoneally. The former way caused the formation of a small neuroma which conversely is very large in the latter case. The results obtained can be summarized as follows: 1) the emilateral section of sciatic nerve causes a dramatic depletion of both SP and ME in the lumbar cord starting at day 10 and persisting at day 30 postoperatively. These changes are not magnificated nor anticipated by the bilateral lesion. 2) The different extent of neurite outgrowth, does not affect differently SP and ME decline. 3) 5-HT turnover rate increases rapidly after the lesion and is back to control values 10 days later. 4) immunocytochemistry shows that there is a decrease in both SP and ME in the dorsal horn ipsilaterally to the lesion. The extent of the damage and the time-course are similar if the lesions are performed bilaterally. On the other hand, the anatomical loss of both peptides is bilateral but less remarkable than in the case of monolateral lesion, as if the peptide decrease was intraspinally regulated. The loss of FRAP staining from the dorsal horn is, however, bilateral and quantitatively similar to that observed after monolateral lesions. This result would suggest that FRAP staining faithfully reflects nerve lesions, while peptidergic losses may be regulated by more sophisticated intraspinal mechanism. These data suggest that following peripheral nerve lesion the depletion of SP in the dorsal horn of the spinal cord is associated with a dramatic loss of opioid peptides, which is independent on the extent of aberrant neurite outgrowth and could be regulated intraspinally. 5-HT might represent one of the intraspinal mechanisms related to the peptide loss. Preliminary results indicate that dynorphin may not be greatly altered in this experimental paradigm.

39.2 THE NUCLEUS RAPHE MAGNUS; THE RELATIONSHIP BETWEEN THE PEPTIDERGIC AND SEROTONERGIC NEURONS. R.M. Bowker and L.C. Abbott.* Dept. of VCAPP, Washington State University, Pullman, WA 99164

The nucleus raphe magnus and adjacent portions of the medial reticular formation are known to have important roles in several regulatory functions, including nociceptive and cardiovascular inputs to the spinal cord. Several different putative neurotransmitters are believed to be involved in these functions, including the enkephalins (M-ENK), serotonin (5HT) and substance P (SP), as well as several others. We examined several different putative neurotransmitters in the rostral medullary raphe nuclei for their localizations, distributions, microcircuitry, and potential for interactions with other brainstem neurons. Caudal brainstem tissues were obtained from guinea pigs (Cavia porcellus) perfused with 3.5-4% paraformaldehyde in phosphate buffer followed by sectioning (22-28 μm) and incubation of the sections for 24-36 hours in antiserum raised to M-ENK, 5HT, SP and somatostatin (SOMA) (INC) at dilutions ranging from 1:10,000 to 1:15,000. The sections were then processed for routine immunocytochemistry. Control experiments were also performed.

In these portions of the medullary raphe nuclei anterior to the inferior olivary nucleus (rostral parts of the nucleus raphe pallidus and the nucleus raphe magnus) numerous perikarya were found to contain positive immunoreactivity. These immunoreactive neurons appeared to have several different sizes depending upon their locations in the nucleus. Neurons stained for M-ENK, SP and 5HT were not distributed homogeneously throughout these nuclei, but were concentrated caudally in the nucleus raphe magnus. At the level of the trapezoid body, smaller clusters of stained neurons were present. The SOMA immunoreactive cells appeared to extend more laterally in the adjacent parts of the reticular formation. Morphometric analyses indicate differences between the immunoreactive neurons stained for the various antisera. Quantitative studies are currently being performed.

These results indicate the nucleus raphe magnus and the adjacent parts of the medullary brainstem contain several different putative neurotransmitters. These different chemical agents within the rostral medullary nuclei are potentially capable of modulating many of the physiological effects seen in the spinal cord, either directly by their descending projections to the spinal cord, or indirectly via their interactions in the brainstem and/or spinal cord. While the microcircuitry of these four putative neurotransmitters and their pathways remains to be examined, their interrelationship will be critical for understanding the functions of these midline cell groups.
(Supported by NS22321 and RR05465)

39.3 **CONFORMATIONAL STATES OF 5-HT_1 RECEPTORS MODULATING SPINAL PAIN TRANSMISSION: DIVALENT CATIONS.** J. Hirschowitz*, F.P. Zemlan, R.M. Murphy* and M.M. Behbehani (SPON: D.L. Garver). Laboratory of Psychobiology, Univ. of Cincinnati College of Medicine, Cincinnati, Ohio 45267-0559.

Several lines of evidence indicate that the descending bulbospinal serotonin (5-HT) system suppresses incoming noxious input to the spinal cord and mediates narcotic analgesia. The present paper reports our initial studies characterizing multiple spinal cord ^{3}H-5-HT binding sites which is a prelude to the identification of spinal cord 5-HT_1 receptor subtype specific agonists and antagonists. These 5-HT_1 selective compounds will then be tested in our ongoing microiontophoretic recording studies of spinal cord dorsal horn nociceptive neurons. Incubation of dorsal horn membranes with ^{3}H-5-HT concentrations ranging from 0.10 to 50 nM in the absence of divalent cations revealed a complex ligand-receptor interactions. Computer analysis revealed that a two component model identified a higher affinity binding site with an apparent K_D of 0.034 ± 0.023 nM and a B_{max} estimated to be 36.1 ± 7.6 fmoles/mg and a lower affinity binding site with an apparent K_D of 12.1 ± 2.1 nM and a B_{max} of 295 ± 11 fmoles/mg.

As many ligand-receptor interactions are dependent on divalent cation concentration, the effect of divalent cations (1 mM Ca++, 5mM Mg++) on ^{3}H-5-HT binding in spinal cord was examined. Computer analysis revealed that a two component model identified a higher affinity binding site with an apparent K_D of 0.046 ± 0.024 nM and a B_{max} of 124.8 ± 21.2 fmoles/mg protein, and a lower affinity binding site with a K_D of 12.1 ± 2.4 nM and a B_{max} of 137.6 ± 12.5 fmoles/mg. The present study suggests that two forms of spinal cord 5-HT_1 receptors exist. Further, about 75% of the high affinity receptors appear to undergo a conformational change dependent on divalent cations. This conformational change decreases the receptors K_D from about 40 pM to about 12 nM in the absence of cations.

39.4 **SUBSTANCE P/5-HT COEXISTENCE AND PAIN: SUBSTANCE P EFFECT ON SPINAL CORD 5-HT_1 RECEPTORS.** Robert J. Hitzemann, F.P. Zemlan, R.M. Murphy*and M.M. Behbehani (SPON: T. Mandybur). Laboratory of Psychobiology, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267-0559.

Substance P (SP) and serotonin (5-HT) have been shown to coexist in the same bulbospinal neurons and are colocalized in the same dense core synaptic vesicles in spinal cord. In a separate presentation at this meeting, we report that SP antagonists block the inhibitory effect of stimulation of ventral medullary 5-HT/SP fibers on spinal cord neurons responsive to noxious stimulation. These data suggest that 5-HT and SP are coreleased and that the functional effect of SP corelease is to amplify the effect of 5-HT on spinal cord nociceptive neurons. The data presented below suggests that this amplification is mediated by the ability of SP to increase the number (B_{max}) of 10-15 nM ^{3}H-5-HT binding sites.

Increasing doses of SP [10 nM to 10 uM] produced a dose-response related increase in specific high affinity ^{3}H-5-HT binding [2 nM] to spinal cord membranes. Maximal ^{3}H-5-HT binding was observed at about 1 to 10 uM SP where binding increased about 30% ($p<0.001$). The specificity of this SP increase in ^{3}H-5-HT binding was assessed by determination of the effect of other peptides on ^{3}H-5-HT binding:

Peptide	Number of Amino Acids	Specific ^{3}H-5-HT Binding (fmoles/mg)
Buffer	--	85.4 ±3.1
Substance P	11	98.3 ±3.6***
Leu-Enkephalin	5	80.6 ±5.2
Met-Enkephalin	5	81.7 ±4.6
LH-RH	10	80.3 ±4.9
Neurotensin	13	89.2 ±7.1
Somatostatin	14	88.3 ±3.9
Bombesin	14	79.5 ±6.1

Preliminary saturation experiments ([^{3}H-5-HT] = 0.1 to 50 nM) conducted in the presence or absence of 1 um SP indicated that SP increases the B_{max} of the 10-15 nM ^{3}H-5-HT binding sites from 169 fmoles/mg protein to 240 fmoles/mg protein.

39.5 **CONFORMATIONAL STATES OF 5-HT_1 RECEPTORS MODULATING SPINAL CORD PAIN TRANSMISSION: GTP SENSITIVITY.** F.P. Zemlan, R.M. Murphy* and M.M. Behbehani, Laboratory of Psychobiology, Univ. of Cincinnati College of Medicine, Cincinnati, Ohio 45267-0559.

It has been clearly established that spinal cord 5-HT_1 receptors mediate the 5-HT induced inhibition of dorsal horn neurons to noxious stimulation. Several studies suggest that cortical 5-HT_1 receptors are coupled to a C subunit (adenylate cyclase) which catalyzes the formation of cyclic AMP from ATP. The coupling of 5-HT_1 receptors to the C subunit appears mediated by a G subunit which binds GTP and Mg++. The purpose of the present study was to explore the relationship between GTP and 5-HT_1 receptors in spinal cord. Such studies are preliminary to an investigaton of a possible cyclic AMP mediated 5-HT induced inhibition of the response of dorsal horn units to noxious stimulation. The present study investigated the ability of GTP to alter the conformational state (K_D) of dorsal horn 5-HT_1 receptors. By determining the percent of 5-HT receptors demonstrating GTP dependent binding; the percent of dorsal horn 5-HT_1 receptors coupled to adenylate cyclase may be estimated by inference. Incubation of dorsal horn membranes in the presence of divalent cations (5 mM Mg++, 1 mM Ca++) with ^{3}H-5-HT concentrations ranging from 0.10 to 50 nM revealed a complex ligand-receptor interaction. Computer analysis revealed that a two component model identified a higher affinity binding site with an apparent K_D of approximately 0.046 nM and a B_{max} of approximately 125 fmoles/mg protein; and a lower affinity binding site with a K_D of approximately 12.1 nM and a B_{max} of approximately 138 fmoles/mg protein. In the presence of 1 mM GTP, fixed affinity computer modeling indicated that the B_{max} of the higher affinity binding site was decreased to approximately 20.4 fmoles/mg protein while the B_{max} of the lower affinity site increased to 261 fmoles/mg. These data indicate that GTP induced a conformational change in about 44% of the 5-HT_1 receptors suggesting that as many as 44% of dorsal horn 5-HT_1 receptors may be coupled to adenylate cyclase. This study suggests the feasibility of examining whether the inhibition of dorsal horn responsiveness to noxious stimulation observed after iontophoretic 5-HT application can be mimiced by iontophoretic application of db cyclic AMP.

39.6 IMMUNOREACTIVE SEROTONERGIC AXONS IN THE DORSOLATERAL FUNICULUS (DLF) OF THE CAT AND RAT. K. Zahs*, S. Lakos* and A.I. Basbaum. (SPON: A. Enjalbert). Dept. of Anatomy, University of California San Francisco, CA 94143

Although there is considerable evidence for a contribution of raphe-spinal (DLF) serotonergic pathways to opiate and stimulation-produced analgesia, there is some question as to the physiological properties of these axons. Furthermore, a recent study in the rat suggested that there are, in fact, few, if any, descending 5HT axons in the DLF. To address this question, we have examined the DLF in the cat and rat for the presence and fiber caliber of immunoreactive 5HT axons.

The PAP technique was used to localize 5HT-labelled DLF axons. Although these could often be seen in the cat without pharmacological or surgical intervention, this was not so in the rat. Thus, rats underwent a lesion of the cervical DLF two days prior to perfusion with a mixed aldehyde fixative. This resulted in damming of 5HT-immunoreactive axons rostral to the lesion. To characterize the distribution and size of the 5HT axons, EM montages of transverse sections of the DLF were constructed.

Consistent with the fluorescent histochemical studies of Dahlstrom and Fuxe ('65), we found considerable labelling of 5HT axons in the DLF of both the cat and the rat. These undoubtedly are the source of most of the dorsal horn 5HT terminals. EM analysis revealed that almost all of the labelled axons in the DLF of the cat are unmyelinated. Unmyelinated 5HT-immunoreactive axons also predominate in the rat, however, patchy immunoreactive material was present in small caliber myelinated fibers as well.

These data confirm earlier studies suggesting that bulbospinal 5HT axons are predominantly unmyelinated and indicate that the previous recordings of raphe-spinal axons and/or raphe neurons with conduction velocities that ranged from 10 to 50m/s probably originated from nonserotonergic cells in the nucleus raphe magnus. The physiology of 5HT-containing cells of the nucleus raphe magnus thus remains to be determined.

Supported by NS 14627 and NS 16033.

39.7 THE ULTRASTRUCTURAL LOCALIZATION OF POLYCLONAL GABA AND MONOCLONAL GLUTAMATE IMMUNOREACTIVITY IN THE RAT MIDBRAIN PERIAQUEDUCTAL GRAY. J.R. Clements, A.J. Beitz, A.A. Larson and J.E. Madl*. Dept. of Veterinary Biology, Univ. of Minnesota, St. Paul, MN 55108.

Injection of glutamate into the PAG has been reported to induce a rage reaction in animals and has also been shown to activate components of the descending intrinsic analgesic system. Injection of the gamma-aminobutyric acid (GABA) agonist, muscimol, into the PAG causes ipsiversive rotation. Since both GABA and glutamate appear to play a significant role in the PAG, we chose to examine the distribution and ultrastructural characteristics of GABA and glutamate-immunoreactive processes in the midbrain periaqueductal gray of the rat. Four adult, male Sprague-Dawley rats were perfused with 4% paraformaldehyde and 0.3 - 0.5% glutaraldehyde and used for examination of GABA-immunoreactivity. An additional five rats were perfused with 5% carbodiimide and 0.5% glutaraldehyde, postfixed with 5% glutaraldehyde and utilized for analysis of glutamate immunoreactivity. Midbrain sections from these 9 rats were cut on a vibratome, stained immunohistochemically for either GABA (with rabbit anti-GABA antisera) or glutamate (with a recently developed monoclonal antibody against carbodiimide-fixed glutamate) using the peroxidase-anti-peroxidase and indirect peroxidase procedures, respectively.

Light microscopic examination of PAG sections showed GABAergic cells concentrated dorsally and dorsolaterally, while immunoreactive fibers were dispersed throughout all regions of the PAG at all rostrocaudal levels. Glutamate-immunoreactive cells were identified in all PAG subdivisions, but were concentrated in the ventrolateral and dorsolateral subdivisions.

Electron microscopic analysis showed that GABA-like immunoreactivity was present in myelinated axons, dendrites, unmyelinated axons, axon terminals containing synaptic vesicles and cell bodies. In the tissue analyzed, the majority of reactive profiles in the ventral PAG were myelinated axons, while the majority of profiles in the dorsal PAG were dendrites. Occasional contacts between immunoreactive axons and both immunoreactive and non-immunoreactive dendrites were seen.

Glutamate-like immunoreactivity was also observed in dendrites, myelinated axons, unmyelinated axons and cell bodies. In samples examined, dendrites comprised the majority of immunoreactive profiles. Immunoreactive axon terminals containing synaptic vesicles were also observed in close apposition to non-immunoreactive processes. Our results suggest that both GABAergic and glutamatergic cells and processes are present in the PAG and are consistent with the proposal that these putative transmitters are important in PAG function.

We thank Dr. Bruce Maley for the GABA-antiserum. Supported by NSF grant #BNS83-11214 and NIH grants DE06682 and NS17407.

39.8 PHENCYCLIDINE SELECTIVELY BLOCKS A SPINAL ACTION OF GLUTAMATE ANALOGS. L. M. Aanonsen*and G. L. Wilcox. Dept. of Pharmacology, Univ. of Minnesota, Minneapolis, MN 55455

Several laboratories are investigating the effects of phencyclidine (PCP) and other sigma receptor agonists on responses of the mammalian CNS to glutamate receptor agonists. PCP seems to antagonize many of the actions of glutamate. We have found that l-glutamate (G) and a potent glutamate analog, L-2-amino-4-(5-tetrazoly)butanoic acid (gamma-glutamyl tetrazole, GG) when injected i.t. in mice elicits biting and scratching. This behavior was similar to but more intense than that elicited by i.t. administration of substance P (SP). We have found a conc/response relationship for G (ED50=12.3mM [9.1-16.8]) and GG (ED50=0.54mM [0.49-0.61]). In order to determine if there was a synergistic action of glutamate with SP an ineffective conc of SP (65nM) was co-administered with effective concs of GG. The results did not indicate a significant shift in the conc/response curves of GG + vehicle (ED50=0.54mM [0.49-0.61]) compared with GG + SP (ED50=0.52mM [0.47-0.58]).

PCP has been shown to have antinociceptive properties and to block glutamate responses in the spinal cord and in the striatum. PCP (1mM, i.t.) alone had no effect while PCP administered with GG significantly shifted the GG conc/response curve to the right. PCP, at similar concs had no effect on SP behavior.

By contrast, studies have indicated that [D-Ala-D-Leu] enkephalin (DADL), a potent opioid agonist (delta>mu) and NE (alpha-2) inhibit behaviors elicited by SP. Since the behaviors evoked by glutamate are similar to SP, the effects of DADL and NE were examined with glutamate. The conc of NE required to inhibit GG was 125x higher than that needed to inhibit SP behavior. Inhibition by DADL of GG-induced behaviors required concs 5000x higher than that necessary to block SP, and motor toxicity was observed at these concs.

The studies presented suggest that the action of intrathecal glutamate may be independent of or indirectly related to the action of SP in the spinal cord. DADL inhibits biting and scratching induced by glutamate only at very high concs and NE inhibits at concs 125x higher than those necessary to inhibit SP behavior. PCP appears to have selective inhibitory action on glutamate-induced behavior. The fact that intrathecal glutamate elicits a much more intense behavioral response than SP and that it is pharmacologically different from SP suggests that glutamate may represent a neurotransmitter involved in a unique, spinally-mediated nociceptive pathway. (supported by NIDA grant #1933 and by a grant from Procter and Gamble Co.)

39.9 **NOREPINEPHRINE INHIBITS FIELD STIMULATION-EVOKED RELEASE OF SUBSTANCE P FROM CHICK DORSAL ROOT GANGLION CELLS IN CULTURE.** G.G. Holz, R.M. Kream and K. Dunlap. Depts. Physiology and Anesthesia Research, Tufts Univ. Schl. Med., Boston, MA 02111.

Recordings from the cell bodies of embryonic chick dorsal root ganglion cells in culture have demonstrated a direct inhibitory action of norepinephrine (NEpi) on voltage-dependent calcium currents. This response results in a decrease in action potential duration which is thought to reflect a decrease in depolarization-induced calcium influx. In a previous study of these cells, Fischbach et al. (Adv. Biochem. Psychopharm. vol. 28, pp. 175-188, 1981) reported that NEpi reduced calcium-dependent substance P release triggered by high K^+ depolarization. Our interest is to determine, through pharmacological criteria, whether NEpi is acting through identical amine receptors to inhibit calcium influx and substance P release. We report here a newly developed in vitro system in which transmitter effects on substance P release may be examined using a more physiological form of depolarization: field stimulation.

Embryonic chick dorsal root ganglion cells were dissociated and grown in the absence of non-neuronal cells on 60 mm collagen-coated tissue culture plates. After 2-3 weeks in culture, each dish contained 4,076 + 265 pg (mean + S.E.M., n=19) of substance P-like immunoreactivity (SPLI). SPLI, as determined by RIA, was authenticated by demonstration of co-elution with synthetic substance P by reverse phase HPLC. SPLI release was triggered by field stimulation under sterile conditions using bipolar platinum stimulating electrodes (square wave DC pulses, 110 V, 1 Hz, 3.0 msec for 10 min). In HEPES-buffered saline containing 2.0 mM Ca^{++}, field stimulation increased SPLI by 3.3 + 0.3 fold over baseline to give 95 + 5 pg SPLI per dish, equivalent to 2.3 + 0.1% of the mean total cellular content (n=23). SPLI release was calcium-dependent in that it was completely blocked by solutions containing 0.1 mM Ca^{++} and 5.0 mM Co^{++} (n=6). In contrast, in solutions containing 2.0 mM Ca^{++} and 1.0 mM Ba^{++}, field stimulation increased SPLI by 7.3 + 1.2 fold over baseline to give 356 + 20 pg SPLI per dish equivalent to 8.7 + 0.5% of the mean total cellular content (n=12). The amount of SPLI released in the Ca^{++}/Ba^{++} solution was significantly reduced to 59 + 4% of control by 50 uM NEpi (n=6, $p < 0.001$, 2 tailed Students t-test). Baseline values of SPLI were unaffected. Tests for release of SPLI were repeated at 5 hour intervals with the plates returned to the incubator in between each period of stimulation. This allowed a test for release before, during and after exposure to NEpi. The mean values of SPLI release before and after treatment with NEpi were compared with the value obtained in the presence of NEpi. Intracellular recordings from the same dishes demonstrated a 36 + 12% decrease in spike duration in response to 50 uM NEpi (n=10) when tested in the Ca^{++}/Ba^{++} solution.

Studies are presently underway to characterize the pharmacological properties of this NEpi receptor, as well as to examine the effects of 5-HT, GABA, baclofen and morphine on substance P release. Supported by a grant to K. Dunlap from the Klingenstein foundation, and R. Kream from New Eng. Med. Ctr.

39.10 DISSOCIATION BY DIAZEPAM OF THE ANALGESIC AND AVERSIVE EFFECTS OF PERIAQUEDUCTAL GRAY STIMULATION IN THE RAT. M.M. Morgan*, A. Depaulis, and J.C. Liebeskind. Department of Psychology, UCLA, Los Angeles, CA 90024.

Both analgesia and escape behavior can be induced by electrical stimulation of the periaqueductal gray (PAG) in the rat. In a previous study it was shown that pentobarbital anesthesia, by suppressing behavioral reactions, allows for stimulation-produced analgesia (SPA) to be measured in 95% of the PAG stimulation sites in the rat. This suggests that the behavioral effects induced by PAG stimulation prevents the measurement of the underlying analgesia. The aim of the present study was to determine, at sites supporting aversion, whether SPA can be obtained following administration of diazepam which has been shown to suppress the aversive component of PAG stimulation in the rat.

Male Sprague-Dawley rats were chronically implanted with a bipolar electrode directed at the PAG. Stimulation consisted of 50 Hz monophasic pulses of 0.4 msec duration at intensities ranging from 0.01 to 1.0 mA. Each rat was injected with 4 doses of diazepam (0, 1.0, 2.0, 4.0 mg/kg, i.p.) administered in a counterbalanced order with a minimum of 5 days between tests. Baseline pain sensitivity (tail-flick test), SPA threshold if present, and threshold for the first behavioral response (i.e. escape, rotation) were measured before and 10 min after drug injection. Histology was performed to verify electrode placement.

Treatment with diazepam did not alter baseline tail-flick latencies regardless of dose. Similarly, at sites supporting analgesia prior to drug treatment, SPA threshold was not altered by diazepam. Threshold for aversive reactions (e.g. running, jumping) was increased by diazepam and it was thus possible to measure SPA at an intensity previously inducing aversion. These results support the hypothesis that aversive reactions interfere with the measurement of SPA. It is further suggested that concomittant with aversive reactions produced by PAG stimulation, pain inhibitory mechanisms are activated. (Supported by NIH grant NS-07628, Fondation Fyssen, and a gift from the Brotman Foundation).

39.11 REDUCTION OF THE INHIBITORY ACTION OF NUCLEUS RAPHE MAGNUS STIMULATION ON DORSAL HORN NEURONS BY SUBSTANCE P ANTAGONIST. T.A. Vaughn*, M.M. Behbehani, and F.P. Zemlan. Department of Physiology and Biophysics and Department of Psychiatry. University of Cincinnati College of Medicine, Cincinnati, Ohio 45267-0576 (sponsored by G. Khodadad).

There is considerable evidence that stimulation of the nucleus raphe magnus (NRM) inhibits the response of dorsal horn neurons to noxious stimulation. Immunohistochemical methods have shown that many terminals of NRM neurons in the dorsal horn contain both serotonin (5-HT) and substance P (SP). The current study was undertaken to determine the effect of SP and its antagonist (D-Pro^{2}, D-Trp ^{7,9})-SP on the response of nociceptive dorsal horn cells to NRM stimulation.

Rats weighing 250-300 grams were used. Each animal was anesthetized with choral hydrate (400 mg/Kg), placed in a spinal stereotaxic unit and the spinal cord between L1 to L4 was exposed. A tungsten stimulating electrode was placed in the NRM and this region was stimulated with constant current of 10 to 100 μA with duration of 400 μ seconds at a rate between 10 to 300 Hz. A five barrel electrode consisting of a recording electrode and drug electrodes filled with 200 mM glutamic acid (GLU), 3 mm SP in 20 mm sodium acetate and 3 mm substance P antagonist (SPA) in 20 mm sodium acetate. One barrel was filled with 3 M NaCl and was used as a balance electrode. Once a cell was isolated, its response to noxious stimulation was tested. Since the majority of nociceptive neurons in the dorsal horn are silent, continuous application of glutamic acid was used to cause spontaneous firing of these neurons. For each cell (n = 40) the effect of NRM stimulation at 10, 100, and 200 Hz for 100 msec repeated every second in the presence and absence of substance P antagonist was tested.

NRM stimulatron at 10 Hz produced a very slight inhibition of glutamate induced firing rate. In contrast, stimulation at 100 and 200 Hz caused a significant decrease in the glutamate induced firing rate. In presence of SPA, the inhibitory effect of NRM stimulation was reduced in a dose-related manner and in some neuron application of SPA totally blocked the inhibitory effect of NRM stimulation. In several cells the effect of 5-HT antagonist, methysergide was also examined. In these cells, methysergide totally abolished the effect of NRM stimulation.

The results of these experiments are consistent with a hypothesis that SP plays a role in the inhibitory effect of NRM stimulation on dorsal horn nociceptive neurons which may be related to corelease of SP and 5-HT from terminals of NRM neurons at the dorsal horn. The mechanism by which SP amplifies the inhibitory effect of 5-HT, as we report elsewhere at this meeting, may be related to a SP induced increase in the number of 5-HT receptors; as SP increased the number of ^{3}H-5-HT binding sites in spinal cord. Supported by grant NS 18326.

PAIN MODULATION: STRESS ANALGESIA

40.1 CONDITIONED STRESS-INDUCED ANALGESIA (CSIA) IN RATS: OPIATE AND NONOPIATE MECHANISMS. H. S. Hagen* and K. F. Green. Psychology Dept., Cal. State Univ., Long Beach, CA 90840.

CSIA produced by pairing the compound CS of handling, lab room and apparatus cues with footshock has been reported to be naloxone-sensitive by some (e.g., Watkins et al., Brain Res., 1982, 243, 119-132) and to be naloxone-insensitive by others (e.g., Chance & Rosecrans, Pharmacol., Biochem. & Behav., 1979, 11, 643-646). The present experiments used hybridized procedures and delineated conditions for producing opiate and nonopiate varieties of CSIA. In both experiments the compound CS was 1) gloved handling followed by 2) placement in smooth white tubes for restraint during 8 tail flick trials (1/min) and 3) placement in a shock chamber. The UCS of 0.0, 2.5 or 5.0 mA of shock was delivered to separate groups of rats for 15 sec. After shock the rats were placed in rough black tubes (lined with hardware cloth) and given 8 tail flick trials.

In Experiment 1 four days of training with shock were given as described. On Day 5 naloxone (10 mg/kg, ip) was injected into half the rats in each shock condition (volume equivalent of saline into the other half). Shock was omitted on Day 5 for evaluation of conditioning to shock apparatus cues. Preshock tail flick latencies showed that CSIA began on Day 2 and grew through Day 4. The latencies of rats in the 2.5 and 5.0 mA groups were equally elevated over those of the 0.0 mA group. On Day 5 naloxone attenuated the "preshock" latencies of the 2.5 mA group but did not affect the other groups. On Day 5 naloxone did not affect the "postshock" latencies of any group, although the "postshock" latencies were lower than the "preshock" latencies in the shocked groups.

In order to examine the development of opiate CSIA, rats in Experiment 2 were injected on alternate days (counterbalanced order) with naloxone (10 mg/kg, ip) and saline, and trained for three pairs of days. Preshock latencies increased steadily over pairs of days, and again the shocked groups were equally elevated over the nonshocked group. Naloxone attenuated latencies in the 2.5 mA group on the second pair of days and in the 5.0 mA group on the third pair of days.

The two experiments indicate an interaction between shock level and amount of training. After minimal training of only one day, CSIA was present in both shocked groups. Nonopiate CSIA was strongest in the 5.0 mA group after moderate training and in the 2.5 mA group after more training. The opiate component was strongest in the 2.5 mA group after moderate training and in the 5.0 mA group after more training.

Thus, the overall level of CSIA increased with number of CS-UCS pairings. The contributions of the opiate and nonopiate components appeared to complement each other, with the exact proportion depending upon the level of shock and the amount of training.

40.2 AN ENDOGENOUS ANXIOGENIC SUBSTANCE IS INVOLVED IN NON-OPIATE STRESS INDUCED ANALGESIA. A.E.Panerai, P.Sacerdote*, and P.Mantegazza. Dept.Pharmacology, Chemotherapy and Medical Toxicology, School of Medicine, Univ. of Milano, Milano, Italy.

Inescapable, but not escapable foot shock can induce either a naloxone reversible or a naloxone non reversible analgesia, according to the modalities of application of the shock. We also showed that at least one kind of naloxone non reversible shock induced analgesia can be reversed by antagonists of the K opiate receptor.

There is evidence, however, that more than one naloxone non reversible stress induced analgesia exist. It is possible that while naloxone reversible analgesia is sustained by beta-endorphin, and the naloxone non reversible by dynorphine, anxiety itself, might play an important role in the development of stress induced analgesia, possibly through the activation of an endogenous factor. In order to evaluate this possibility, we administered to rats benzodiazepines or different substances to be pure benzodiazepine antagonists or inverse antagonists.

Of these substances only benzodiazepines show a slight analgesic effect when administered alone, while the antagonists seem to be devoid of any significant effect.

Benzodiazepines, administered before the administration of inescapable foot shock, yielding a naloxone reversible analgesia, blunted the analgesic response and this no more reversible by naloxone.

When the antagonist drugs were administered before the administration of shock, analgesia was increased and prolonged when compared to diluent treated rats by the pure, but not the inverse antagonist. Again, despite the characteristics of the shock administered, the analgesia obtained was not reversible by naloxone. These observations suggest the presence of an endogenous anxiogenic substance, that might unveil a naloxone non reversible analgesia.

40.3 FACILITATED TAIL-FLICK PERFORMANCE FOLLOWING STRESSFUL FOOTSHOCK. G.D. Coover, C.E. Lints, and W.E. Briner. Dept. of Psychology, Northern Illinois University, DeKalb, IL 60115.

A stress-induced analgesia paradigm (e.g. Exp.5, Maier, Davies, Grau, Jackson, Morrison, Moye, Madden IV, & Barchas. JCPP. 94:1172, 1980) was designed to minimize 4 potential sources of response bias. Footshocks were delivered to male hooded rats in a small chamber (rather than tail shocks in the same restraint tube used for tail-flick testing) to reduce associative effects such as learned helplessness. The pretreatment shocks (2.4 ma no-load intensity; BRS-Foringer SGS-003 shocker scramblers; about 1 ma on most shockers) averaged 2-sec duration since longer ones may facilitate learned immobility. Since motor debilitation produced poor avoidance behavior 30 min after intense footshock (Sutton, Coover, & Lints. Physiol. Psychol. 9:127, 1981), the rats were tested for debilitation 5-10 min after pretreatment using the absence of a forepaw placing response and 10-25 min after using rearing during a 3-min exposure to a 1 m^2 open field. Tail-flick latencies were measured on rats gently restrained in a towel since this procedure produces shorter latencies than restraint in a tube. In general, the rats were assessed on Days 1, 2, & 3 for baseline activity in the open field and tail-flick latencies (IITC tail-flick apparatus, model 33). On Day 4 all rats were tested for motor debilitation and then tail-flick latencies (median of 3 trials presented at 2-3 min intervals) in the 35 min following a 45-min pretreatment session of 90 footshocks or placement in a chamber without shock (Control).

In Exp.1 three groups were pretreated. The escape group (ES) could terminate shock by pressing a lever inserted 1 sec after shock onset (or lever retraction and shock termination were at 4 sec if no response was made). Duration of shock for the inescapable group (IS) was determined by yoked ES rats. Yoked controls received no shock. Debilitation was determined as above. Tail-flick latencies differed, $F(4,60)=13.8$, $p < .001$, with the shocked rats showing longer latencies if they were debilitated. Debilitated IS (DIS) rats showed longer latencies than DES and Controls. Most importantly, the nondebilitated (ES and IS) groups had shorter latencies than the Controls (Means = 2.59, 2.82, and 3.50, respectively).

In Exp.2 no ES condition was used, tail-flick testing was with a more intense light beam, and following testing in gentle restraint the rats were given 3 more trials restrained in Plexiglas tubes. The IS rats had a mean latency of 2.46 $\pm$ .11 ($\pm$SE) sec in gentle restraint compared to 2.90 $\pm$ .15 for the Controls, $t(44)=2.41$, $p < .025$. In the tubes the latencies for the IS and Control groups were 10.2 $\pm$ 1.0 and 9.8 $\pm$ 1.0 sec, respectively.

Under the conditions of these experiments, shock pretreatment only produced longer latencies when the rats were debilitated. Thus response bias may contribute to findings of stress-induced analgesia.

40.4 STRESS-INDUCED ANALGESIA VARIES AS A FUNCTION OF ESTROUS CYCLE AND SEX STEROID REPLACEMENT THERAPY. S. Ryan, H. Goodale*, D. Weiss* and S. Maier. Department of Psychology, University of Colorado, Boulder, CO 80309.

The following studies find significant variation in stress-induced analgesia (SIA) in female rats as a function of stage of the estrous cycle, and implicate estradiol as an important determinant of SIA.

Experiment I examined SIA in four groups of rats; each group was tested in one of the four stages of the estrous cycle. Pain sensitivity was assessed by rear paw lick latency on the hotplate. Baseline latencies did not differ between groups. Subjects were restrained in Plexiglas tubes where ten 1-mA tailshocks (5 sec each) were delivered on a one-minute variable time schedule. Post-shock latencies indicated that all groups were analgesic to some extent. Estrus subjects were most analgesic, metestrus subjects were least analgesic, and these two groups differed significantly ($p < .01$).

Both estradiol and progesterone levels vary regularly over the estrous cycle. Experiment II assessed the effects of these steroid hormones on SIA. Three to four weeks following bilateral ovariectomy, rats were either treated with 5 µg estradiol benzoate (EB) or equivolume oil vehicle (V) administered subcutaneously (sc) for two consecutive days. Forty-eight hours later, rats were administered sc either 5 mg progesterone (P) or equivolume V. Six hours later, subjects were tested before and after 10 tailshocks as in Experiment I. Again, baseline latencies did not differ. Following shock, groups receiving V only or V + P were the least analgesic and the group receiving EB + V was the most analgesic. The EB + V group differed from the V group ($p < .05$), suggesting that estradiol is an important determinant of brief-shock stress-induced analgesia. The EB + P group did not differ from the V or the EB + V groups, suggesting that progesterone may play some role in prevention or suppression of this analgesia.

These experiments suggest that estradiol contributes to the variable expression of SIA over the estrous cycle.

40.5 EFFECTS OF ADRENERGIC AND SENSORY NEURON BLOCKADE ON HYPERALGESIA PRODUCED BY HEAT INJURY. T.J. Coderre and R. Melzack*. Dept. of Psychology, McGill Univ., Montreal, P.Q., Canada H3A 1B1.

Sensory neuron blockade produced by capsaicin reduces the inflammatory responses to cutaneous injury. Adrenergic neuron blockade produced by guanethidine reduces pain and hyperalgesia following nerve injury. This study reports on the effects of these two treatments on the increase in pain sensitivity which typically follows a heat injury. Rats were given a s.c. injection of 0.05 ml of 1.5% capsaicin or vehicle (10% tween, 10% ethanol in normal saline) into the plantar surface of one hindpaw, and 4 once-daily injections of guanethidine (30 mg/kg s.c.) or saline. Capsaicin was administered 24 h before injury by immersion of the treated hindpaw into 55°C water for 15 s. The last guanethidine injection was given 4 h prior to the injury. Foot-withdrawal latencies of the injured paw from 47°C water were recorded in the 30 min before and after the injury. Latencies of the paw contralateral to the injury were recorded 24 h after the injury.

The results indicate that the injury produces a reduction in the latencies in both the injured paw and the paw contralateral to the injury indicating the presence of hyperalgesia. Capsaicin produced a significant elevation in the pre- and post-injury latencies of the injured paw. In contrast, guanethidine produced a significant elevation in the latencies of the contralateral paw. Since capsaicin reduced the hyperalgesia in the injured region it is suggested that it is acting on a local neurogenic mechanism. However, the fact the guanethidine reduces hyperalgesia in the paw contralateral to the injury suggests that the spreading of hyperalgesia is mediated by a mechanism which involves abnormal activity in sympathetic fibers.

40.6 AN OPIOID-TRYPTAMINERGIC MECHANISM OF HYPOALGESIA PRODUCED BY MILD STRESS. K.B.J. Franklin, F.V. Abbott and B.J. Connell .Dept. of Psychology and School of Nursing, McGill University,Montreal, Quebec, CANADA.

The relationship between endogenous opioids and basal pain sensitivity is unclear. In animal and human studies opioid antagonists are reported to produce hyperalgesia, no effects and even hypoalgesia. It has recently been shown that the hypoalgesia induced by stress can be prevented by naltrexone or by treatments that reduce brain 5-HT activity. Since common laboratory handling procedures are stressful, it is possible that the inconsistancies result from varying degrees of environmental stress in different laboratories. To test this hypothesis we examined effects of testing in a novel environment on basal pain sensitivity using the formalin test which assesses an animals response to minor tissue injury. As predicted, rats that were exposed to the stress of a novel environment showed less pain than rats that had been prehabituated to the environment.

The role of opioids was tested by administering naloxone 82.0 mg/kg) 5 min before a 15 min test period (30-45 min after formalin). Nalaxone had no significant effect on pain in habituated or nonhabituated rats.

Some forms of stress analgesia can be blocked by treating rats with l-valine which prevents the stress-induced rise in brain tryptophan and 5-HT activity. Valine (200 mg/kg), given prior to formalin, also had no signigicant effect on pain sensitivity, although the habituated rats given valine had somewhat lower pain scores ($.05<p<.1$). The combination of naloxone and valine reversed the hypoalgesia ($p<.01$) in rats exposed to a novel environment but had no significant effect on habituated rats. These results suggest that mild stress can activate an opioid-tryptaminergic system through which stress reduces pain sensitivity.

40.7 **TRYPTOPHAN UPTAKE, OPIOIDS, AND SYMPATHETIC ACTIVITY IN ANALGESIA INDUCED BY STRESS OR BY AN INTERACTION OF STRESS AND MORPHINE.** S. J. Kelly and K. B. J. Franklin. Dept. of Psychology, McGill University, Montréal, P.Q., Canada, H3A 1B1.

We have recently shown that an increase in brain tryptophan uptake is critical to analgesia induced by prolonged restraint and to analgesia induced by an interaction of stress and morphine (Kelly & Franklin, Neuropharmacol., 1985). The studies presented here further examine the biochemical aspects of these two forms of analgesia in rats.

Three hours of restraint in wire mesh restrainers induced an increase that lasted for 10 min in the latency of tail withdrawal from 55°C water. We found that this analgesia was unaffected by naltrexone methobromide (10 mg/kg) given before the restraint, indicating that peripheral opioid receptors were not involved in the analgesia. Naltrexone hydrochloride (1 mg/kg) did not reverse the analgesia when given 15 min before the end of the restraint period but did prevent the analgesia when given before the restraint ($p<.005$). Naltrexone hydrochloride might have prevented the analgesia induced by prolonged restraint by preventing the restraint-induced increase in brain tryptophan uptake which is critical to this form of analgesia. To examine this hypothesis, HPLC with fluorescence detection was used to assay tryptophan levels in the brainstem of rats subjected to restraint. Three hours of restraint were found to increase brain tryptophan levels ($p<.001$). Naltrexone hydrochloride (1 mg/kg) given before the restraint did not affect tryptophan levels. Therefore, the prevention of analgesia induced by prolonged restraint by naltrexone hydrochloride was not due to an effect on brain tryptophan uptake.

In order to explore how restraint increases brain tryptophan uptake, we examined the effect of a chemical sympathectomy induced by guanethidine sulphate (30 mg/kg every day for five days) on analgesia and brain tryptophan. Instead of using analgesia induced by 3 hours of restraint, the potentiation of analgesia in the tail withdrawal test which results from an interaction of a short period of restraint and morphine was used. This effect has also been shown to be dependent upon an increase in brain tryptophan uptake and appears to be a more robust, pharmacologically-induced form of the analgesia produced by prolonged restraint. Guanethidine treatment prevented the analgesia induced by an interaction of restraint and morphine sulphate (5 mg/kg) but had no effect on analgesia induced by morphine sulphate (5 mg/kg) in unrestrained rats. Furthermore, guanethidine treatment prevented the increase in brain tryptophan uptake elicited by restraint.

These studies further delineate the physiological systems that can cause analgesia in response to restraint stress. An opioid mechanism critical to the analgesia is in the central nervous system but does not need to be active at the time of the analgesia. The increase in brain tryptophan uptake that is also critical to the analgesia is dependent upon sympathetic activity and not upon the opioid mechanism.

40.8 Inhibition of Acoustic Startle in the Rat by a Noxious Prestimulus: Effects of Morphine and Naloxone. D. S. Leitner and D. D. Kelly. New York State Psychiatric Inst. and Dept. of Psychiatry, Columbia University, New York, NY 10032.

The startle response is elicited by intense stimulation with an abrupt onset. Its amplitude can be reduced if the startle-eliciting stimulus is preceded by a mild stimulus which does not elicit startle (a prestimulus); the prestimulus must lead the startle stimulus by 50 to 500 msec. Startle inhibition is dependent only upon the characteristics of the prestimulus, not those of the startle stimulus.

In the present experiment, a noxious prestimulus was used to inhibit startle and the effects of morphine and naloxone upon this were investigated. Nine rats were assessed for footshock sensitivity with a flinch-jump test. Based upon the mean thresholds obtained from this procedure, intensities of .1, .2, .4, and .8 mA were selected for use in the startle inhibition procedure. Subjects were presented with 50 startle-eliciting bursts of white noise. On 40 of these trials, the startle stimulus was preceded at 400 msec by a 300 msec footshock, the intensity of which varied among the above values. The 5 types of trials (4 on which the startle stimulus was preceded by a footshock and 1 on which it was presented alone) were presented 10 times each in a block-randomized sequence. The intertrial interval was 20 sec.

All subjects were exposed to each of 4 conditions: An injection of morphine sulfate (5 mg/kg, i. p.) followed after 20 min by an injection of naloxone hydrochloride (2 mg/kg, i. p.); morphine followed by a saline injection; a saline injection only; or a naloxone injection only. The sequence in which each subject was exposed to the conditions was determined by a Latin squares matrix. In a given condition, ten min after the last injection subjects were given a brief tail-flick test to assess nociception, and were then tested in the startle inhibition procedure.

Tail-flick latency was reliably increased, and startle amplitude on control trials was reliably decreased, in the morphine/saline condition; the other 3 conditions were not reliably different from each other. Footshock reliably reduced startle amplitude. This effect was maximum at .2 mA; higher intensities did not produce reliably more inhibition. Finally, at each intensity the percent amplitude reduction was reliably attenuated in the morphine/saline condition; no other comparisons were reliably different.

These data demonstrate that mild footshock reliably inhibits startle, that morphine administration interferes with this effect, and that the interference was reversed by naloxone. This supports previous work which has shown that stimuli on the threshold of perception can inhibit startle, and suggests that this procedure may be useful as an analgesimetric test.

PAIN MODULATION: CENTRAL PATHWAY MECHANISMS

41.1 MIDBRAIN SUPPRESSION OF A NOCICEPTIVE WITHDRAWAL REFLEX IN THE RAT. I. G. Campbell* & E. Carstens (SPON: M. McNamee). Dept. Animal Physiology, Univ. Calif., Davis, CA 95616.

Midbrain periaqueductal gray (PAG) and more lateral reticular formation (LRF) stimulation produces analgesia and inhibits spinal neurons. PAG stimulation reduced the slope of spinal neuronal stimulus-response functions for graded noxious hindfoot heating, while LRF stimulation shifted the functions in a parallel manner to the right. We have investigated whether these midbrain areas also differentially modulate the force of flexion withdrawals to graded noxious heating of hindfoot skin. Hindpaws of lightly anesthetized rats were attached to a transducer to measure force of hindlimb withdrawal elicited by noxious heat stimuli (42-52°C; 10 s) under isometric conditions; this and direct and integrated EMG activity via 0.1 mm teflon-coated steel wires in the biceps femoris were recorded on a penwriter. The upper 3 rows in Fig. 1A show that withdrawal force (upper trace) and integrated (middle) and direct (lower) EMG activity increased with graded increases in temperature (below each column). During 100 uA stimulation (100 msec trains at 100 Hz, 3/s) in PAG, force and EMG at each temperature were reduced (middle 3 rows) such that slopes of curves relating integrated force (B) or EMG (C) to temperature were reduced, whereas 35 uA LRF stimulation shifted the curves in a parallel manner toward the right. Note rebounds in EMG after termination of midbrain stimulation (brackets). These findings suggest that this spinal nociceptive withdrawal reflex is under the same descending controls that modulate dorsal horn neurons.

Supported by NIH grants NS 20037 and NS 19330.

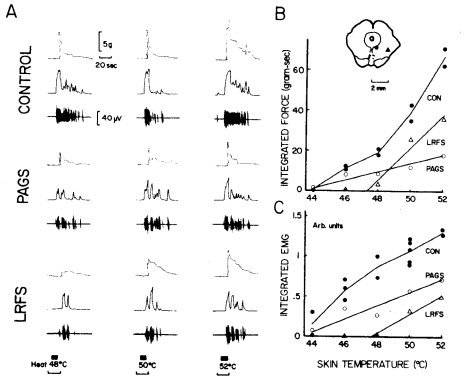

Fig. 1

41.2 CENTRIFUGAL MODULATION OF THE TAIL FLICK REFLEX EVOKED BY GRADED NOXIOUS HEATING OF THE TAIL. T.J. Ness* and G.F. Gebhart (SPON: G.R. Dutton). Dept. Pharmacology, University of Iowa, Iowa City, IA. 52242.

The stimulus-response function (SRF) of spinal dorsal horn neurons to peripherally applied noxious radiant heat has been shown in electrophysiologic studies to be attenuated by supraspinal electrical stimulation in two qualitatively different ways: a reduction in the gain of the SRF, or an increase in response threshold. The purpose of this study was to determine in a simpler, more physiologic preparation whether a SRF characterizing the nociceptive tail-flick (TF) reflex in the rat was similarly modified by stimulation in the brainstem.

Rats were initially deeply anesthetized with pentobarbital (45 mg/kg) for craniotomy and cannulation of the femoral vein and artery. Noxious radiant heat from a projector lamp was focused upon a 1.5 x 11 mm area of the ventral surface of the tail. Heat intensity was varied using a rheostat and five different rates of heat transfer (RHT) were employed to evoke the TF reflex in rats maintained in a lightly anesthetized state by an iv infusion of pentobarbital (3-6 mg/kg/hr). Inhibition of the TF reflex was produced by stimulation in the brainstem (continuous 100 Hz monopolar constant current cathodal pulses of 100 μsec duration) started 10 sec prior to the application of heat to the tail. The inhibitory threshold was defined as the minimum stimulating current which increased the TF latency ≥ 3 times baseline; an intensity, 50% or 80% of this inhibitory threshold, was used subsequently.

The TF latency was established to be linearly related to the RHT. However, the temperature of the tail at which the TF occurred was found to be independent of the RHT. Focal electrical stimulation produced two qualitatively different modifications of the SRFs depending upon the site of and intensity of focal electrical stimulation in the brainstem: Type I, an increase in the thermal threshold of the TF reflex at low RHT's, was produced by stimulation in the rostral medial medulla (n.raphe magnus and n. r. gigantocellularis) and in the lateral midbrain periaqueductal gray (PAG); and Type II, an accelerating increase in the thermal threshold of the TF reflex as a function of the RHT, was produced by stimulation in the medial PAG and the dorsolateral pons. These results are analogous to the centrifugal modulation of spinal dorsal horn SRFs to graded heating of the skin produced by focal electrical stimulation in the brainstem, further establishing the utility of the lightly anesthetized rat preparation for studies on nociception/antinociception.

41.3 CHARACTERIZATION OF INHIBITION OF THE TAIL FLICK REFLEX FROM THE LATERAL HYPOTHALAMUS. L.M. Dilts and G.F. Gebhart. Dept. of Pharmacology, Univ. of Iowa, Iowa City, IA. 52242.

Stimulation produced antinociception (SPA) can be evoked from a wide variety of sites in the brain, including the diencephalon. The most frequently examined diencephalic site has been the rostral extension of the periventricular gray matter, but SPA can be produced from other sites, including the lateral hypothalmus (LH). The objective of this study was to characterize the descending inhibition of the nociceptive tail-flick (TF) reflex produced by focal electrical stimulation in the LH, including the neurotransmitter(s) mediating the inhibition at the level of the lumbar spinal cord.

Rats were initially deeply anesthetized with pentobarbital (45 mg/kg) for craniotomy and cannulation of the femoral vein and artery. The rats were subsequently maintained in a lightly-anesthetized state (corneal and flexion reflexes present) with an iv infusion of pentobarbital (3-6 mg/kg/hr). Constant current stimulation (100 Hz, 100 µsec, 20-200 µA) with monopolar, cathodal 0.15 mm dia. electrodes was begun 10 sec prior to the application of heat to the tail.

Stimulation in the diencephalon (e.g. VPL) outside of the hypothalmus did not affect the TF reflex. Inhibition of the TF reflex was produced, however, throughout the hypothalamus at intensities of stimulation typically between 75-150 µA. These intensities are considerably greater than required for TF inhibition at sites of stimulation in the brainstem. The area requiring the lowest intensity of stimulation (50-75 µA) to inhibit the TF reflex was a diffuse region of the LH, inferior to the zona incerta and internal capsule, medial to the supraoptic decussation and including the median forebrain bundle. Microinjection of monosodium l-glutamate (100 mM, 0.5 µl) in the LH failed to inhibit the TF reflex, indicating that the descending inhibition was produced by activation of fibers of passage rather than cell bodies.

To further characterize the inhibition from the LH, intrathecal injections of pharmacological antagonists were made at the level of the lumbar enlargement. The stimulation threshold in the LH for inhibition of the TF reflex was determined, after which the effects of methysergide (15 + 30 µg), naloxone (15 + 30 µg) or phentolamine (15 + 30 µg) on the inhibitory stimulation threshold were examined. To date, only phentolamine reliably increased the intensity of stimulation required for inhibition of TF reflex, indicating that spinal adrenoceptors mediate the inhibitory effects of stimulation in the LH.

Supported by DA02879 and NS19912.

41.4 COERULEOSPINAL INHIBITION OF HEAT-EVOKED SPINAL DORSAL HORN NOCICEPTORS IN THE RAT. S.L. Jones and G.F. Gebhart. Dept. of Pharmacology, University of Iowa, Iowa City, Iowa 52242.

The involvement of spinopetal efferents from the pontine nucleus locus coeruleus/subcoeruleus (LC/SC) in the centrifugal modulation of spinal nociceptive transmission has been demonstrated functionally in the rat using the nociceptive tail-flick model and electrophysiologically in the cat. However, anatomical differences exist between these species with regard to the organization of the noradrenergic pontine nuclei. The purpose of this study was to characterize, in the rat, the responses of spinal dorsal horn neurons to controlled noxious heating of the footpad in the presence and absence of electrical stimulation of the dorsolateral pons (DLP), in particular the LC/SC. Rats were deeply anesthetized with pentobarbital (45mg/kg) for cannulation of the femoral artery and vein and tracheotomy. They were paralyzed with pancuronium bromide (0.4mg/kg, iv) and ventilated with a gaseous mixture of N_2O:O_2 (2:1) and maintained deeply anesthetized with hourly iv infusions of pentobarbital throughout the duration of the experiment (12-14h). A craniotomy was done to allow for focal electrical stimulation in the LC (monopolar, cathodal constant current stimulation; 100Hz, 100 µs). The spinal cord between segments T12-L1 was exposed by laminectomy. The left hindpaw was fixed in paraffin wax and placed pad upward in a holder; the left tibial nerve was isolated and placed across a pair of stimulating electrodes. All neurons studied to date were driven by stimulation of the nerve at intensities supramaximal for activation of Aα,δ- and C-fibers and also responded to mechanical stimuli and to noxious radiant heating (50°C) of the skin of the foot- or toepads. The heat-evoked responses of all neurons were attenuated by LC stimulation. The mean threshold intensity of stimulation for inhibition of the units examined to date was 26.87 ± 4.73 µA and the mean intensity of LC stimulation attenuating the heat-evoked response at 50°C to 50% of control was 63.31 ± 11.41 µA. Monosodium l-glutamate (100 mM, 0.5 µl) microinjected into the DLP at the same site as electrical stimulation attenuated the neuronal heat-evoked responses (n=7 to date) and decreased blood pressure a mean 20mmHg immediately following the microinjection. Responses of spinal dorsal horn neurons to graded noxious heating of the skin (42-52°C) was a linear monotonic function. Stimulation in the LC/SC resulted in a mean 60.19% decrease in slope of the stimulus-response function without altering the threshold of the response (n=8 to date). Supported by DA02879 and NS19912.

41.5 EFFECT OF DEPLETION OF SPINAL NOREPINEPHRINE (NE) ON DESCENDING INHIBITION FROM THE LATERAL RETICULAR NUCLEUS (LRN). A.J. Janss and G.F. Gebhart. Dept. of Pharmacology, University of Iowa, Iowa City, IA. 52242.

Intrathecal (i.t.) injection of yohimbine or phentolamine significantly increases the threshold of focal electrical stimulation in the LRN (LRNS) required to inhibit the tail flick (TF) reflex, suggesting that LRNS produces an antinociception by releasing NE in the spinal cord (Gebhart and Ossipov, Neurosci. Abs. 10: 98). The effect of depletion of spinal NE on LRNS was evaluated in this study. Intrathecal catheters extending to the lumbar enlargement were surgically implanted in male Sprague-Dawley rats and three days later 20 µg of 6-hydroxydopamine (6OHDA) or vehicle (.1% ascorbate) in 5 µl was administered i.t. Nine days after treatment animals were lightly anesthetized and the threshold of constant current cathodal electrical stimulation (100 Hz, 100 µs) in the LRN for inhibition of the TF reflex was established. 30 µg of yohimbine was injected i.t. and its effects on LRNS and TF latency were determined. The spinal cords of the rats were removed and monoamine content and α_2-adrenoceptor binding estimated:

Pre-Drug	Vehicle-Treated	6OHDA-Treated
TF latency (sec)	2.41 ± .16	2.47 ± .36
LRNS threshold (µA)	19.37 ± 3.20	17.08 ± 7.11
30µg Yohimbine		
TF latency (sec)	1.59 ± .30	1.64 ± .24
% change LRNS	88.12 ± 28.17	165.00 ± 71.42*
Lumbar Monoamines		
NE (µg/g tissue)	.363 ± .042	.040 ± .033*
5-HT (µg/g tissue)	.456 ± .167	.456 ± .137

* Significantly different from vehicle-treated group.

Despite an 89% depletion of spinal NE, there was no change in the threshold of LRNS in the 6OHDA-treated group. Yohimbine produced a significantly greater increase in the LRNS threshold in the 6OHDA- than in the vehicle-treated group. These data suggest the possibility that receptors mediating LRNS-produced antinociception upregulate in NE-depleted animals. Binding studies with [^{3}H]Rauwolscine revealed an increase in α_2-adrenoceptors in lumbar spinal cord depleted of NE. Dose response studies of clonidine-produced inhibition of the TF reflex in lightly anesthetized rats also suggest development of adrenergic supersensitivity following NE depletion; the dose-response curves were shifted leftward 3,7,10 and 14 days following i.t. 6OHDA treatment. Supported by DA02879, NS19912 and T32 GM07337.

41.6 POTENTIATION OF THE ANTINOCICEPTIVE EFFECT OF NOREPINEPHRINE BY THE ADENOSINE ANALOG, 5'-N-ETHYLCARBOXAMIDE ADENOSINE. S. Aran*, N.M. Porter and H.K. Proudfit (SPON: M. Radulovacki). Dept. of Pharmacology, Univ. of Illinois at Chicago, Chicago, Il 60612

Intrathecal administration of norepinephrine (NE) into the lumbar subarachnoid space of the spinal cord produces a dose-dependent analgesia in the rat. Recently, adenosine and adenosine analogs have been shown to modulate the effects of noradrenergic neurons in the CNS. The present studies were undertaken to determine whether there is an interaction between NE and adenosine in the regulation of pain transmission in the spinal cord.

In the first study, the effects of an adenosine agonist, 5'-N-ethylcarboxamide adenosine (NECA), were assessed on a dose of NE that produced submaximal analgesia. Male Sprague-Dawley rats (400-500 gm) were implanted with intrathecal catheters projecting to the subarachnoid space of the lumbar spinal cord. One week after surgery, animals were tested using the tail flick (TF) and hot plate (HP) tests, divided into three groups and then given the following intrathecal injections 20 minutes apart: NE (3ug) + saline, NE + NECA (1ug) or saline + NECA. Following each drug administration, nociceptive thresholds were determined at fixed intervals for 60-90 minutes. Saline + NECA produced no change in TF latencies. In contrast, the group that received NE + saline showed a significant increase in TF latencies. An even greater increase in TF latencies was observed in animals that received NE + NECA.

In the second study, the capacity of theophylline, an adenosine antagonist, to block the NE + NECA induced antinociception was examined. Rats were pretreated with an intrathecal injection of theophylline (100ug) and then NE + NECA were co-administered. The antinociceptive effect of NE + NECA was attenuated in rats pretreated with theophylline. No changes in HP latencies were observed with any drug treatment in either study.

These data suggest that there is an interaction between the adrenergic and purinergic systems in the spinal cord and provide further support for the involvement of adenosine in the regulation of pain transmission.

41.7 ANTINOCICEPTION PRODUCED BY MORPHINE INJECTION INTO THE NUCLEUS RETICULARIS PARAGIGANTOCELLULARIS BUT NOT BY INJECTION ONTO SPINAL CORD INVOLVES NOREPINEPHRINE. I.H. Pang and M.R. Vasko. VA Med.Ctr., Univ. Texas Hlth. Sci. Ctr., Dallas, TX 75216

The purpose of this study is to determine if norepinephrine (NE) containing neurons that descend into the spinal cord are important in antinociception produced by morphine (M) microinjected into the nucleus reticularis paragigantocellularis (NRPG) or by intrathecal (i.t.) injection of M onto the spinal cord.

Male Sprague-Dawley rats (250-350g) were anesthetized and implanted with bilateral metal guide cannulae directed at the NRPG and with a polyethylene cannula (PE 10) inserted into the spinal cord subarachoid space with the tip positioned between T10 and L2. After recovery from surgery, spinal cord NE concentrations were depleted by i.t. injection of 200µg of 6-hydroxydopamine HBR (6-OHDA) after pretreatment with trazadone HCl (50mg/kg i.p.). All drug concentrations were calculated as base content. Control rats received trazadone and i.t. injection of vehicle. After 3-5 days, awake, unrestrained rats were administered M sulfate into NRPG (2.5µg/0.2 µl/side) or onto spinal cord (2 or 10 µg/10 µl). Antinociception was determined using the paw-pressure technique. Two hours after M injection, rats were decapitated, the spinal cords removed and homogenized in 0.1N perchloric acid and NE and 5-hydroxytryptamine(5HT) concentrations determined by HPLC with electrochemical detection.

When microinjected into NRPG, M produced profound antinociception (paw-pressure threshold (PPT) before M: 88 ± 4 mmHg; 30min after M: 224 ± 6 mmHg, n=5) which lasted for 120 min. Pretreatment with 6-OHDA significantly attenuated the antinociceptive effects of M (PPT before M: 84 ± 5 mmHg; 30 min after M: 96 ± 9 mmHg, n=5). The neurotoxin decreased the NE concentrations in the spinal cord to less than 15% of control (control: 296.5 ± 32.5 ng/g wet weight tissue; 6-OHDA treated: 30.0 ± 11.8 ng/g; n=5) without affecting the concentrations of 5-HT (control 649.1 ± 48.7 ng/g; 6-OHDA treated: 588.4 ± 82.1 ng/g). Intrathecal injection of 2 or 10 µg of M also produced significant antinociception (2µg PPT before M: 86 ± 2 mmHg; 30 min after M: 145 ± 10 mmHg, n=4; 10µg PPT before M: 86 ± 4 mmHg; 30 min after M: 205 ± 13 mmHg, n=4). Unlike NRPG injections, however, pretreatment with 6-OHDA did not affect the antinociception produced by i.t. injection of either 2 or 10µg of M even though the concentrations of NE in spinal cord were diminished to less than 15% of controls (controls: 264.2 ± 26.1 and 383.4 ± 48.2ng/g; 6-OHDA treated: 39.5 ± 16.3 and 7.1 ± 3.3 ng/g for 2 and 10µg experiments, respectively).

Thus, although antinociception produced by morphine microinjected in NRPG appears to involve NE-containing neurons in the spinal cord antinociception produced by i.t. morphine appears to be independent of NE-containing neurons. (Supported by the Veterans Administration)

41.8 STIMULATION OF THE DORSAL COLUMN NUCLEI (DCN) BY CHRONICALLY PLACED ELECTRODES IN AWAKE RATS INHIBIT THE TAIL FLICK THROUGH SUPRASPINAL MECHANISMS. S.J. Jabbur, N.E. Saadé*§ and S.F. Atweh. Fac. of Med Amer. Univ. of Beirut, Beirut and §Fac. of Sci., Lebanese Univ., Hadath-Beirut, Lebanon.

Dorsal column stimulation (DCst) in humans has been used for the treatment of intractable pain. In order to study the rostral effects of this stimulation in awake rats, we developed an experimental model with chronic stimulating electrodes on DCN.

Fourteen male Sprague-Dawley rats (150-200 g) were anesthetized with chlorpromazine and ketamine and operated under sterile conditions. The interparietal, occipital and atlas bones were exposed and the posterior arch of the atlas was removed; the occipital membrane and the dura were incised to expose the DCN and the rostral part of the cervical spinal cord. Both dorsal columns (DC) were lesioned at the C_1-C_2 level. Two small holes were drilled in the occipital bone on each side. Two insulated copper wires (0.17mm) were introduced through the holes, threaded between the bone and the dura and pulled out through the caudal margin of the occipital bone. The wires were fixed by multiple knots on the inner and outer aspects of the occipital bone and the central ends were bared and placed 0.5 mm apart on either side of the midline on the surface of the two DCN. The peripheral ends of the wires were further fixed to the skull by knotting them through holes in the upper part of the occipital and interparietal bone leaving the distal ends of the wires exposed. The latter were shortened to 1cm and their insulation removed for later connection to the output of a stimulator. The muscles and skin were sutured and the rats were allowed to recover for a period of one week. Five rats underwent a sham operation with no DC cuts or electrode placement.

Baseline tail flick latencies (TFL) were obtained and averaged on all rats prior and after surgery in three (30 min) testing sessions. Conditioning stimulation was then delivered to the DCN while testing the TFL for a period of 10 min at the start of each session in 7 rats. Compared to sham operated rats, DC lesion produced a small but significant increase in TFL. Conditioning stimulation produced a marked increase (more than 100% of control) in TFL. The place of the stimulating electrodes and the extent of the DC lesions were verified at the end of the experiments.

The results are in accordance with our previous electrophysiological demonstration that DC stimulation can modulate pain related activities in the spinal cord through a supraspinal (brainstem) loop (Saadé et al., Brain Res., 310:180, 1984; 335:306, 1985; and in Press, 1985).

Supported by two grants from the Lebanese National Research Council.

41.9 EFFECT OF MORPHINE ON THE RELEASE OF ENDOGENOUS MONOAMINES INTO SPINAL CORD SUPERFUSATES. H.K. Proudfit, A. Arai,* and M. Monsen.* Dept. of Pharmacology, Univ. of Illinois at Chicago, Chicago, IL 60680.

There is evidence which indicates that opiates induce antinociception by activating raphe-spinal serotonergic neurons located in the nucleus raphe magnus, a midline nucleus located in the rostral medulla oblongata. There is additional evidence to suggest that bulbospinal noradrenergic neurons may also be involved in mediating the antinociceptive actions of opiates. The following experiment was designed to directly test whether these monoamines are involved mediating the actions of opiates by measuring the release of endogenous serotonin (5-HT) and norepinephrine (NE) into spinal cord superfusates before and after the systemic injection of morphine.

Male rats (400-500 g) were anesthetized with urethane (1200 mg/kg) and fitted with inflow and outlfow tubes for spinal cord superfusion. Two control samples, three ml each per 30 min period, were collected and then morphine sulfate (5 mg/kg) was injected subcutaneously. Three 30 min samples were collected following the injection. The amount of norepinephrine and serotonin released into the superfusates was determined by isolating the amines on columns containing Bio-Rex 70 exchange resin, lyophilizing the eluate, and quantitating the amount in each sample using HPLC and electrochemical detection.

An additional experiment was done in which animals were superfused and injected with parachloroamphetamine (PCA, 7.5 mg/kg, sc) to induce the release of monoamines in the spinal cord. The purpose of this experiment was to verify that the experimental methods were capable of detecting increases in amine release into the spinal cord superfusates.

The average basal release of NE and 5-HT before the injection of morphine was 0.41 +/- 0.06 and 0.42 +/- 0.06 ng/ml per 30 min, respectively. Following the injection of morphine there were no statistically significant changes in either NE or 5-HT release into the superfusates. However, the injection of PCA induced a significant release of both NE and 5-HT. Thus, the basal release of NE and 5-HT was 0.37 +/- 0.07 and 0.35 +/- 0.06 ng/ml per 30 min, respectively. The efflux of NE in the first three 30 min samples following the injection of PCA was 0.59 +/- 0.09, 0.65 +/- 0.09, and 0.78 +/- 0.14 ng/ml. The 5-HT efflux in these samples was 0.65 +/- 0.09, 0.83 +/- 0.11, and 0.96 +/- 0.17 ng/ml.

These data do not support the proposal that the antinociception induced by systemic administration of opiates is mediated by the activation of bulbospinal monoaminergic neurons. (This work was supported by USPHS Grant NS 18636).

41.10 THE EFFECT OF ETHANOL CONSUMPTION ON THE FORMALIN TEST. D. S. Kirtland*, K. R. Gogas, C. A. Barba*, A. A. Ratzin* and J. T. Cannon. Dept. of Psychology, University of Scranton, Scranton, PA 18510.

In contrast to measures of acute pain, behavior on the formalin test has been found to possess some intriguing properties (e.g., Dubuisson & Dennis, 1977). In part, these differences have led to the suggestion that the formalin test may prove to be a valuable model of some human chronic pain states. A modification of the ethanol training procedure designed by Steward and Grupp (1983) was used. Thirty-nine male Sprague-Dawley rats (300-350 g) were food deprived and maintained at 85% of their free feeding weights. Subjects were divided randomly into three groups (n=13): Group 1 received only water throughout the training period; Group 2 was trained to drink ethanol and then deprived of it three days prior to formalin testing; Group 3 was trained to drink and was maintained on ethanol throughout the study. Subjects were housed individually with water freely available in home cages. One hr per day, 6 days per week, the animals were moved to training cages which contained a fluid source (see below) and their daily portion of food. At first, only water was available during the training sessions. Each animal in the two ethanol groups was subsequently offered increasing concentrations of ethanol (2,4 and 8%) using a 3 day stabilization period as the prerequisite for increasing the ethanol strength. The day after 8% ethanol stabilization, a preference test was run over three days for animals in all three groups. The animals in Group 1 (water) were matched to the ethanol groups based on body weight and were preference tested in a yoked fashion. Subjects in Groups 1 and 3 were formalin tested immediately following preference testing while subjects in Group 2 were offered only water for an additional 3 days before formalin was administered. Formalin testing was done using a modification of Dubuisson & Dennis's (1977) methods. All animals were given a .05 ml injection of formalin (2.5%) into the dorsal surface of the left hind paw. Subjects were then placed in clear Plexiglas tubes. Flinches of the injected paw were recorded during alternate 5 min intervals over a 1 hr period.

A repeated measures ANOVA demonstrated that during preference testing, the ethanol-trained groups consumed a significantly greater percentage of ethanol than did untrained animals ($p<.05$). Data from the two control conditions (Groups 1 and 2) were combined for data analysis. A repeated measures analysis of variance showed a significant main effect for group and time ($p<.05$), with the ethanol group exhibiting fewer flinches than the controls. These results suggest that ethanol consumption can attenuate pain reactivity in the formalin test.

41.11 VARIATIONS IN SACCHARIN INTAKE ARE RELATED TO FORMALIN PAIN REACTIVITY AND THE ANALGESIC EFFECTS OF MORPHINE. K. R. Gogas, D. S. Kirtland* and J. T. Cannon. Dept. of Psychology, University of Scranton, Scranton, PA 18510.

Recent evidence suggests that the intake of a sweet solution may trigger the release of endogenous opioids and that chronic intake may result in tolerance to opioid-mediated phenomena. Lieblich et al. (1983) found that selectively bred rats given chronic access to a 3 mM saccharin solution show tolerance to the analgesic effects of morphine and an opioid form of stress analgesia. Two experiments are presented here which examined the influences of saccharin intake on morphine analgesia and formalin pain reactivity in a common laboratory strain of rats. Forty male Sprague-Dawley rats (300-350 g) were housed individually with food and liquid freely available. All testing was performed during the dark phase of a 12 hr light/dark cycle. In each study, 20 rats were assigned randomly to receive 3 mM solutions of either Na saccharin or NaCl as their only fluid source. Behavioral testing began 7 days after introduction of the preceding solutions. In Experiment 1, all animals were given s.c. injections of morphine sulfate (2.5 mg/kg/ml). Prior to morphine injection, 5 tail-flick trials were conducted at 1 min intervals. Forty min after injection, 5 tail-flick latencies were determined again at 1 min intervals. A repeated measures ANOVA revealed no significant effects for solution, time or solution x time ($p > .05$). However, there was a significant correlation ($r = -.77$, $p < .05$) between total solution intake and post-morphine tail-flick latencies for animals drinking saccharin but not NaCl. In Experiment 2, formalin testing was done using a modification of the Duboisson & Dennis (1977) method. All animals were injected with .05 ml formalin (2.5%) into the dorsal surface of the left hind paw. Subjects were then put into Plexiglas tubes and the number of times that the injected paw flinched was recorded during alternate 5 min intervals over a 1 hr period. A repeated measures ANOVA showed no significant effects for solution or solution x time ($p > .05$). There was a significant main effect for time ($p < .05$). A significant correlation ($r = .88$, $p < .05$) was found between the amount of formalin flinches and total solution intake in saccharin but not NaCl animals.

These results demonstrate that high levels of saccharin intake are associated with decreases in the analgesic effectiveness of morphine and with greater pain reactivity on the formalin test. The lack of significant differences between saccharine and NaCl groups suggests that the preceding correlations may not be due to a causal influence of saccharin, but rather to a third variable that contributes to variations in both saccharin intake and performance on these two pain-related measures.

41.12 MORPHINE ATTENUATION OF CONDITIONED AUTOANALGESIA: IMPLICATIONS FOR ENVIRONMENT-SPECIFIC MORPHINE ANALGESIC TOLERANCE. J. Rochford* and J. Stewart, Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Quebec, Canada H3G 1M8.

It is known that exposure to cues predictive of noxious stimulation produces analgesia by activating endogenous pain suppression mechanisms, so-called conditioned autoanalgesia (CA). In the present study the effect of morphine administration on the development of CA was examined. We predicted that, by reducing the intensity of noxious stimulation through its analgesic action, morphine would attenuate the development of CA.

Autoanalgesia was induced in rats by administering 1 mA shock for 45 sec for 7 days in a distinctive room. Group RM-M/HC-S received 5 mg/kg morphine in the distinctive room 0.5 hr before shock administration and saline in the home cage; group RM-S/HC-M received the reverse drug treatment while group RM-S/HC-S received saline in both environments. To test for CA all animals were injected with saline (following the first, fourth and seventh shock administration days) or with 5 mg/kg morphine (following the last saline test day) in the distinctive room and then given 50°C hot plate tests at 30, 45 and 60 min post-injection. No shock was administered on the test days. It was found that group RM-M/HC-S displayed shorter response latencies on the hot plate than either of the other two groups on the saline test days. Moreover, the analgesic effectiveness of morphine was reduced in group RM-M/HC-S.

Two further studies investigated whether attenuation of CA would occur with different shock parameters, either 2.5 mA for 180 sec or 1 mA for 15 sec. No significant differences in response latencies on the hot plate were found between groups RM-M/HC-S and RM-S/HC-M at the higher shock intensity. The analgesic potency of morphine was significantly reduced in group RM-M/HC-S at the 1 mA for 15 sec shock intensity, although no significant differences from group RM-S/HC-M were obtained when tests for CA were conducted under saline.

These results provide some support for the possibility that environment-specific morphine analgesic tolerance is attributable, at least in part, to morphine attenuation of CA. That is, the degree of tolerance to morphine may be overestimated when animals are tested in an environment in which they have previously been given noxious stimulation under morphine, provided that the intensity of noxious stimulation is not excessively severe. Furthermore animals exposed to noxious stimulation under morphine will appear hyperalgesic when subsequently given nociceptive tests under saline.

NEUROTRANSMITTERS AND RECEPTORS IN HUMAN DISEASE

42.1 MECHANISMS OF CO_2-INDUCED ANXIETY. S.W.Woods*, D.S.Charney*, G.R.Heninger, W.K.Goodman*, J.Loke*, D.E.Redmond, Jr. (SPON: E. Nestler). Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT., 06508.

Breathing air supplemented with CO_2 stimulates anxiety in humans. In order to elucidate the mechanism of the anxiogenic effect of CO_2, experiments were conducted in 5 chair-adapted male rhesus monkeys, 23 healthy human subjects, and 14 medication-free patients with agoraphobia and panic attacks. METHOD: Five days/week for 6 weeks, the monkeys were chaired and breathed air vented through a transparent hood at 25 l/min for 3.5 hrs. Four test days were scheduled in random order during weeks 3-6 when air, 5%, 7.5%, or 10% CO_2 were given for 3 hrs. after a 30 min. air baseline. All gas mixtures contained 21% O_2. Plasma was obtained for determination of the norepinephrine (NE) metabolite 3-methoxy-4-hydroxyphenylethyleneglycol (MHPG) 30 and 5 minutes before and 30, 60, 90, 120, and 180 minutes after substitution of test gas mixture. After pulmonary function testing, human subjects underwent testing of ventilatory response to CO_2 as a reflection of central medullary chemoreceptor sensitivity through a hyperoxic hypercapnic rebreathing technique (Read, D.J.C., Aust.Ann.Med., 16:20,1967). Inspired CO_2 concentration rose from 5% to 7-10%, depending on rebreathing duration. A psychiatrist rated all subjects on 31 anxiety symptoms of the Clinician-Rated Anxiety Scale 30 minutes before and immediately after rebreathing. In 8 patients, the rebreathing test was repeated 3 months later following successful treatment with alprazolam in daily dose of 3.1±0.6 mg. (Mean±SEM). RESULTS: In the monkeys on 7.5% and 10% but not on 5% CO_2 days, plasma free MHPG increases over baseline were significant ($p<.05$) at 60, 90, 120, and 180 minutes. Ventilatory response to CO_2 was similar in patients and controls (1.58±0.16 vs. 1.58±0.14 l/min/mmHg, N.S.). Anxiety ratings increased markedly during rebreathing both in patients and controls; anxiety increases were significantly greater in patients ($p<.01$) in comparison to healthy subjects matched for age, sex, and rebreathing duration. Alprazolam treatment robustly attenuated anxiety increases during rebreathing ($p=.0001$). COMMENT: The increases in plasma MHPG in monkeys are consistent with prior preclinical studies which suggest that CO_2 stimulates NE turnover. Differences in anxiogenic sensitivity to CO_2 between patients and controls cannot be explained by variability in chemoreceptor sensitivity but may be due to differences in the regulation of NE or other neuronal systems. Since alprazolam blocks both naturally occurring and CO_2 induced anxiety, CO_2 exposure may provide a useful model to study the pathophysiology of anxiety disorders. Supported by MH25642, MH30924, and MH38007.

42.2 SYNERGISTIC EFFECTS OF ALPHA-2 ADRENERGIC AND OPIATE RECEPTOR BLOCKADE ON ANXIETY AND SEXUAL FUNCTION IN HEALTHY SUBJECTS D.S.Charney*, G.R.Heninger, Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT., 06508. (SPON: E.Giller).

Preclinical and clinical studies indicate that brain noradrenergic and opiate neuronal systems have important effects on the regulation of anxiety and sexual function. In addition, there is substantial evidence from neuroanatomical, neurophysiological, biochemical, and behavioral investigations indicating that there are functional interactions between these two neuronal systems. In the present investigation the functional interaction between opiate and noradrenergic neurons was evaluated by determination of the effects of yohimbine and naloxone, alone and in combination, in healthy human subjects. METHODS: The subjects were five males (38±13 years) and four females (37±6 years). They participated in four separate test days: placebo; yohimbine 20 mg p.o.; naloxone 1 mg/kg I.V.; yohimbine and naloxone 15 minutes later. Blood was sampled for plasma cortisol and MHPG and behavioral ratings (visual analogue mood scales, somatic symptom scales) and vital signs were obtained at baseline and at intervals thereafter. Changes in sexual function was assessed by questions from research nurses. RESULTS: Yohimbine and naloxone significantly increased plasma MHPG and cortisol, respectively. These drugs, when given alone, had modest effects on behavior, sexual function, somatic symptoms, and blood pressure, in comparison to placebo. In contrast, the yohimbine-naloxone combination produced large increases in cortisol and patient rated anxiety, nervousness, nausea, palpitations, tremors, and hot and cold flashes, which were significantly greater than the sum of effects produced by the drugs when given separately. All 5 of the male subjects reported full penile erections shortly following the yohimbine-naloxone administration which lasted 60 minutes. There was no associated increase in libido. IMPLICATIONS: The robust synergism of the yohimbine-naloxone combination in producing anxiety, demonstrates an interaction between these two systems, that has important clinical implications for the understanding and treatment of human stress reactions and anxiety disorders. During stressful or anxiety-provoking situations endogenous opioids are released which could have modulatory or inhibitory actions on the increased noradrenergic activity associated with anxiety. New treatments for stress and anxiety disorders could be developed by improving opiate modulation of noradrenergic systems. The ability of the yohimbine-naloxone combination to produce penile erections suggests that a new treatment for impotence could be developed if the negative side effects of the combination can be reduced. Supported by MH36229, MH25642, MH30924 and MH38007.

42.3 PLATELET MONOAMINE OXIDASE ACTIVITY IN DEPRESSION AND ANXIETY. A. Khan, E. Lee, T. Hyde, S. Dager, D. Avery, D. Dunner, Dept. of Psychiatry, Harborview Medical Ctr., University of Washington, Seattle, WA.

Platelet monoamine oxidase (MAO) activity has been reported to be abnormal in patients with major depression and anxiety disorders. It has been suspected that MAO activity may be related to level of anxiety. We report that MAO activity in a large group of patients (n=197) and explore the relationship between MAO activity and degree of anxiety as well as effect of benzodiazepine treatment.

MAO activity was measured in psychotropic free, medically stable adults. The assay was based on benzylamine substrate and has excellent reliability. 56 subjects (48% Fem.) had major depression, 25 (32% Fem.) had generalized anxiety disorder, 53 (66% Fem.) had panic disorder, 29 (65% Fem.) had agoraphobia, and 34 (47% Fem.) had no psychiatric illness. MAO activity was not related to the age of patients. There was no difference with regard to mean MAO activity for the 3 groups of anxious patients. 2-way ANOVA showed that sex (P 0.0001) and diagnosis (P 0.02) contributed to the distribution of MAO activity. In females mean MAO activity was as follows: major depression (10.99) anxiety disorders (12.97) controls (13.41). In males, mean MAO activity was as follows: anxiety disorder (8.68) major depression (10.11) controls (11.85).

In a subset of 40 anxious patients no correlation was found between MAO activity and Hamilton Anxiety Scale ratings prior to treatment. Furthermore, MAO activity was not altered during 2 weeks of treatment with placebo or benodiazepines.

The implications of these findings are discussed.

42.4 PLASMA GAMMA-AMINOBUTYRIC ACID IN PSYCHIATRIC ILLNESS. F. Petty. Psychiatry Service, V.A. Medical Center and University of Texas, Dallas, TX

Abnormalaties in Gamma-aminobutyric Acid (GABA) metabolism have been implicated in several neurological and psychiatric illnesses. Also, psychotropic agents useful in treating psychiatric conditions such as anxiety and depression are thought to exert at least some of their action through GABA mechanisms. Although most GABA is found in CNS, small amounts exist in the periphery and GABA levels can be accurately measured in blood plasma. We have obtained plasma GABA levels in over 300 patients with psychiatric illness and in normal controls. Plasma GABA levels in patients with unipolar depression are significantly lower than control values (35 ± 12 vs. 58 ± 12 ng/ml), this lowering of plasma GABA probably reflects the familial (and therefore genetic) nature of this type of depression. By comparison, patients with secondary depression and with bipolar depression have plasma levels of GABA that are in the control range, although their symptoms in cross-section resemble those of unipolar depressives. Patients with bipolar affective disorder who had recovered had elevated levels of GABA as did bipolar patients in the manic phase of their illness, suggesting that elevated GABA levels may represent a trait marker for bipolar affective disorder. Schizophrenics demonstrated a very large scatter in their GABA levels, perhaps reflecting the heterogenous nature of this disease. Finally, patients with alcoholism had GABA levels that were even lower than those of unipolar depressives, corroborating the well established clinical relation between these syndromes. Effects of diet, activity, and menstrual cycle on plasma GABA will be presented. Plasma GABA may develop into a useful clinical and research tool for further studies on biological mechanisms in affective disorder.

42.5 FURTHER STUDIES OF CORTICOTROPIN-RELEASING FACTOR-LIKE IMMUNOREACTIVITY (CRF-LI) IN CSF OF PATIENTS WITH AFFECTIVE DISORDERS. G.Bissette, F.Spielman, M.Stanley, C.Banki*, M.Fink*, B.Stanley*, L.Traskman-Bendoz*, R.N.Golden*, M.Arato*, and C.B.Nemeroff. Laboratory of Psychoneuroendocrinology, Duke Univ. Med. Center, Durham, N.C. 27710

We have previously reported increased concentrations of CRF-LI in the CSF of patients with diagnoses of major depression (Science, 226:1342-1344, 1984). Here we report CSF concentrations of CRF-LI in several groups of patients with affective disorders from five different institutions. Moreover, patients with other psychiatric diagnoses and controls receiving diagnostic lumbar puncture for neurologic or urologic examination were studied. The radioimmunoassay for CRF-LI uses an antiserum directed toward the 33-41 amino acid region of CRF and iodinated Tyr-CRF as the radioactive trace. Maximum sensitivity is 0.625 pg/tube and the IC_{50} is 30 pg. Duplicate 400 µl aliquots of unextracted CSF samples were lyophilized and equal artificial CSF aliquots were included in the standard curve tubes. Two groups of younger (21-34 yrs., n=21) and older (54-86 yrs., n=12) controls from N. C. Memorial Hospital, Chapel Hill, N. C., had CRF-LI concentrations of 53.0 ± 2.6 pg/ml and 41.3 ± 2.9 pg/ml, respectively. A group of patients (from S.U.N.Y.-Stonybrook) with an RDC diagnosis of primary major depression (n=13, 28-72 yrs.), were also studied as well as two schizophrenic and one bipolar depressed patient before and after ECT. The patients with major depression had CRF-LI concentration of 80.0 ± 6.6 pg/ml before and 61.9 ± 2.4 pg/ml after ECT. The schizophrenic patients had pre- and post-ECT concentrations of CRF-LI that were 55.6 ± 6.8 and 50.7 ± 0.6 pg/ml, respectively. There was no correlation between post-dexamethasone plasma cortisol levels and CRF-LI either before or after ECT for any group. A group of Hungarian psychiatric patients with DSM-III diagnosis of major depression (n=14, 25-69 yrs.) were also studied. Their mean concentration of CRF-LI was 101.0 ± 15.9, and again, no correlation was seen between CRF-LI and post-DST cortisol concentrations. Another group of patients from the Lafayette Clinic, Detroit, Michigan with DSM-III diagnoses of unipolar depression (n=13), bipolar depression (n=19), personality disorder (n=22) or schizophrenia (n=20) were also included. Their mean concentrations of CRF-LI were 47.6 ± 3.7, 55.0 ± 5.1, 51.2 ± 2.9 and 52.0 ± 3.6, respectively. Finally, a group of patients from the NIMH (n=14) with DSM-III diagnoses of major depression were found to have CRF-LI concentrations of 44.7 ± 1.7 pg/ml. These data reveal that certain groups of depressed patients exhibit elevated CSF concentrations of CRF-LI. (Sponsored by NIMH MH-39415)

42.6 BIOGENIC AMINE METABOLITES IN CSF OF SCHIZOPHRENICS BEFORE AND AFTER TREATMENT WITH HALOPERIDOL. C.L. Bowden, K.I. McIntyre*, and M.A. Javors*. Departments of Psychiatry and Pharmacology, The University of Texas Health Science Center, San Antonio, Texas 78284.

Our purpose was to study the effect of the neuroleptic drug haloperidol on the concentrations of 3-methoxy-4-hydroxyphenylethyleneglycol (MHPG), 5-hydroxyindoleacetic acid (5HIAA), and homovanillic acid (HVA) in cerebrospinal fluid (CSF) of schizophrenic subjects. Thirteen patients were diagnosed with the SADS-RDC criteria for schizophrenic disorder and, in addition, met criteria indicative of greater chronicity of illness and poor response to prior neuroleptic treatment. Once diagnosed, the patients were hospitalized and underwent a drug washout period of at least seven days. At the end of the washout period (day zero), the subjects began a flexible dosage regimen with 20 mg haloperidol per day. During the next 14 days, the dosage was adjusted as clinically indicated, then the dosage was maintained during the next and last 14 days of treatment. Blood and mixed CSF samples were drawn at day zero prior to haloperidol and after 28 days of haloperidol. Mean (± SD) CSF concentrations of MHPG, 5HIAA, and HVA for 13 subjects prior to haloperidol were 7.8 (1.3), 13.1 (4.0), and 27.0 (10.0) ng/ml; after 28 days of haloperidol, they were 6.0 (1.2), 13.5 (4.1), and 34.2 (11.6) ng/ml. The mean MHPG concentration in CSF decreased significantly during treatment ($p < .01$) and mean HVA increased significantly ($p < .001$). The CSF concentration of 5HIAA in these subjects did not change with haloperidol treatment. The increase in HVA concentration from day zero to day 28 correlated significantly with increased age of the subjects ($p < .001$). Furthermore, higher HVA concentrations in CSF at day zero correlated with greater severity of illness by two measures, the Global Assessment Scale ($p < .01$) and the SADS-psychoticism scale ($p < .01$). Lithium was taken concurrently with haloperidol treatment by six subjects. However, there were no differences in the significant relationships mentioned above between the lithium and non-lithium groups. These results indicate that the concentration of HVA in CSF is an index for severity of psychotic illness, and that change in HVA concentration in CSF may be an important indicator of dopaminergic responsiveness. (Supported by a grant from the Kleberg Foundation, San Antonio, Texas).

42.7 REDUCTIONS IN NICOTINIC CHOLINERGIC RECEPTORS MEASURED USING [^{3}H] ACETYLCHOLINE IN ALZHEIMER'S DISEASE. P. J. Whitehouse, A. M. Martino*†, P. G. Antuono*, J. T. Coyle, D. L. Price, and K. J. Kellar†. The Johns Hopkins University School of Medicine, Baltimore, MD 21205; †Georgetown University School of Medicine and Dentistry, Washington, DC 20007

In Alzheimer's disease (AD), presynaptic cholinergic markers, such as choline acetyltransferase (ChAT) activity, are consistently reduced due to dysfunction and death of neurons in the basal forebrain cholinergic system. However, the nature of alterations in cholinergic receptors in this disease is, at present, unclear. Evidence has been presented for increases, decreases, and no changes in receptor densities. In the present investigation, we used [^{3}H] acetylcholine (ACh) to measure both muscarinic cholinergic receptors and nicotinic receptors in left and right frontal, temporal, and occipital cortices from 13 patients with AD (average age 75 years) and 11 intellectually intact matched controls (average age 62 years). Nicotinic receptors were measured using 6 nM [^{3}H] ACh in the presence of 1.5 μM atropine to displace [^{3}H] ACh from the muscarinic cholinergic receptor. Muscarinic cholinergic receptors were assessed by two approaches: incubation with 15 nM [^{3}H] ACh in the presence of 1.5 μM cytisin to displace [^{3}H] ACh from nicotinic receptors and incubation with [^{3}H] quinuclidinyl benzilate (QNB). Nonspecific binding was measured in the presence of 100 μm carbachol. Statistically significant differences in muscarinic cholinergic receptors were not detected as measured by either [^{3}H] ACh or [^{3}H] QNB, although a trend towards increased concentration of muscarinic cholinergic receptors was noted. In AD, a statistically significant (50%) reduction of nicotinic receptors occurred primarily in the left hemisphere which paralleled reductions of ChAT activity in magnitude and distribution. This study demonstrates relationships between changes in neurons of the basal forebrain cholinergic system and alterations in nicotinic cholinergic receptors in forebrain targets.

42.8 AUTORADIOGRAPHIC LOCALIZATION OF MUSCARINIC CHOLINERGIC AND BETA ADRENERGIC RECEPTORS IN HUMAN SKIN. H.I.Ryer[1]*, B.Nock[2], M.Serby[1]*, S.Katz[3]* and B.S.McEwen[2]. (1)Dept. of Psychiatry, V.A. Medical Center, New York, N.Y. 10010 (2)The Rockefeller University, New York, N.Y. 10021 (3)Dept. of Dermatology, Albert Einstein College of Med., Bronx, N.Y. 10466.

Central cholinergic and adrenergic mechanisms are thought to be involved in a number of neuropsychiatric disorders, e.g. Alzheimer's disease and depression. Peripheral markers for CNS deficits would be of use in diagnosing these disorders. Recent work with skin has shown promise. For example, elderly women with senile dementia of the Alzheimer's type (SDAT) show less sweat gland activity to intradermal injections of choline and carbachol than age matched controls (Eur.J.Clin.Pharm.24:1983). Also, skin fibroblasts from patients with SDAT have been reported to be hyperresponsive to beta adrenergic stimulation (Am.J.Hum.Genet.31:1979). We have used autopsied skin samples from human palm and sole to develop in vitro semi-quantitative autoradiographic techniques for analysis of muscarinic cholinergic and beta adrenergic receptors in human biopsy samples.

Skin was cut into 32-90um thick slices and thaw-mounted onto subbed slides. Tissue was incubated at 25°C for one hr with either (1) 1nM ^{3}H-scopolamine (muscarinic receptors) ± 10uM atropine or (2) 2nM ^{3}H-dihydroalprenolol(DHA; beta receptors) ± 20uM propranolol. The tissue was then exposed to tritium sensitive film for 8-12 weeks. Receptor binding was quantified using a computer-assisted densitometer and tissue was stained with cresyl violet in order to visualize sweat glands.

Specific binding of both scopolamine and DHA was localized to areas of the skin containing eccrine sweat gland tissue. The presence of an unlabeled competitor completely abolished this sweat gland localized binding.

In vitro autoradiography appears to be a useful method for measurement of neurotransmitter receptors in human skin. Biopsy samples from normal and SDAT subjects are presently being assessed.

42.9 PHARMACOLOGICAL TREATMENT OF A FOCUSED BRAIN STEM DISORDER IN MAN. K.A. Bonnet, Millnauser Laboratories, New York University School of Medicine, New York, N.Y. 10016.

A clinical condition consisted of episodic vomiting crisis occurring every 13 days from birth and having a duration of approximately three to five days each time. The individual also exhibited signs of retarded motor development and of facial hemiparesis. The individual had a single seizure at four months of age and was subsequently maintained for three years on phenobarbital and Dilantin. Neurological studies showed relatively little and treatment recommendations were not forthcoming from several major centers. The patient was examined by computerized EEG, plasma catecholamine biochemistry, fundoscope examination, and sinus-atrialarhythmia determination, at points during a well period and at points during a presentation of crisis. Through systematic overlay of the results from each of these investigations it was possible to determine that the primary disorder lay in the hypersensitivity of the afferent sympathetic branch of the vagus and in the brain stem nuclei. Systematic investigation of sphincter regulation confirmed hyperactivity of the pyloric sphincter which was activated at CCK-receptors effecting premature and prolonged closure. The gastric filling that resulted stimulated hypersensitive gastro-esophageal junction receptors triggering the onset of emesis. Systematic investigation of the nuclei in the brain stem medicating this response permitted a selection of a compound for treatment. The receptors for this compound were four-fold more sensitive than the same receptors for this compound in other areas of the brain. Use of the compound at 8 micrograms per day permitted discontinuation of Dilantin, phenobarbital, and released the individual to exhibit a neurological, skeletal and muscular growth spurt that began to approach age-appropriate levels.

Crisis prevention or crisis arrest by this strategy has permitted cognitive growth that was unexpected and has permitted an increase in vocabularly, for example of from 2 to 500 words in a period of only a few months. This type of integrated study and strategy development can be effective in the detection, localization, and systematic focal treatment of brain stem disorders. Supported by Courtney Block Fund for Brain Research.

43.1 ADENYLATE CYCLASE ACTIVITY IN AN ANIMAL MODEL OF DEPRESSION, D.J. Anderson*, J.O. Johnson, and F.A. Henn. Dept. of Psychiatry and Behavioral Science, SUNY/Stony Brook, Stony Brook, NY 11794-8101.

Previous studies have shown that rats exposed to inescapable intermittent foot shock develop behavioral deficits which can be reversed with antidepressant drugs and ECS (Sherman and Petty, 1980). Concurrent with the behavioral deficits is an upregulation of beta-adrenergic receptors in the hippocampus of these rats (Johnson and Henn, 1983). One of the major theories of antidepressant action proposes that all antidepressants cause deamplification of noradrenergic receptor-adenylate cyclase systems (Vetulani and Sulser, 1975). The present study investigates the coupling of upregulated beta-adrenergic receptors with a possible supersensitivity of adenylate cyclase in an animal model of depression.

Male rats (200-250g) were subjected to randomized, uncontrollable foot shock (0.8 mA x 40min). Twenty-four hours later the rats were tested for escape responding in a bar-press paradigm. Approximately one-third of the animals were response deficient (RD, 10-15 failures) and one-third were nondeficient (ND, 0-4 failures). A group of controls was tested without prior shock (C, 0-5 failures). A fourth group of naive controls (N) received no shock.

Two to three hours after testing the hippocampus (HPC), anterior neocortex, and hypothalamus were dissected from individual animals. Each region was sliced 0.26x0.26mm and placed in oxygenated Krebs-Ringer buffer. Adenylate cyclase responsiveness to norepinephrine (NE) was assayed according to Baudry et al. (1976). Basal and stimulated cyclic AMP levels were measured using the protein binding assay of Gilman (1970) in kit form as provided by Amersham, Inc.

Percent maximal response over basal levels were measured in hippocampal slices of the above groups (N's in parentheses):

	RD (5)	ND (5)	C (5)	N (5)
Response %	234±74*	146±36	145±16	119±26

Adenylate cyclase activity in hippocampal slices from response deficient rats was found to be significantly different from the other groups when analysed by a two-tailed Student's t-test and by a random block design ANOVA.

These preliminary data coupled with previous findings of elevated hippocampal beta-adrenergic receptor density in response deficient rats indicate that an amplification of the noradrenergic receptor-adenylate cyclase system may be linked to the behavioral changes seen in this animal model of depression.

43.2 MODULATORY ROLE OF 5-HT ON BETA-RECEPTORS IN AN ANIMAL MODEL OF DEPRESSION, E. Edwards, and F.A. Henn. Dept. of Psychiatry & Behavioral Science, SUNY/Stony Brook, Stony Brook, NY 11794

Rats exposed to forty minutes of intermittent inescapable shock develop a transient learning deficit when later tested on a shock escape paradigm. This behavioral deficit has been shown to be correlated with an up regulation of hippocampal beta-adrenergic receptors (Johnson and Henn, 1983). Serotonergic mechanisms have also been implicated in the medication of the effects of inescapable shock on subsequent behavior (Edwards et al, 1984). The present study examined a possible modulatory role for 5-HT on the regulation of beta-adrenergic receptors after inescapable shock.

Rats were pre-treated with the potent serotonin depletor, p-chlorophenylalanine (PCPA, 300mg/kg i.p). Regardless of inescapable shock exposure, PCPA-treated rats demonstrated significantly less failures than saline controls in a shock escape test (3.8 ± 1.7 failures PCPA-rats vs 11.3 ± 1.5 failures, deficient rats). Concomitant with the blockade of the behavioral deficit, PCPA treatment also resulted in a significant decrease of beta-adrenergic receptors. These results lead to the conclusion that the beta-adrenergic receptor can be controlled by serotonergic mechanisms as suggested by Janowsky et al (1982).

Chronic administration of a specific serotonin uptake inhibitor, Fluvoxamine (12mg/kg i.p x 5 days) resulted in a reversal of the shock induced deficit and a down regulation of hippocampal beta receptors. This is consistent with our finding that most antidepressant treatments down regulate hippocampal beta receptors, even those compounds such as mianserin and fluvoxamine which do not appear to act on beta receptors directly. These serotonergic compounds seem to exert their action by chronic down regulation of 5-HT input to the hippocampus. This may be a multisynaptic pathway and need not involve direct 5-HT action in hippocampus.

All our results suggest that a normal level of 5-HT activity is necessary to maintain beta receptor levels in the hippocampus and a chronic decrease in 5-HT levels will cause down regulation of beta receptors. An understanding of this circuit provides a rational explanation for the mechanism of action of all known classes of antidepressants.

43.3 SELECTIVITY OF THE NOVEL ANXIOLYTICS BUSPIRONE AND TVX Q 7821 FOR 5-HYDROXYTRYPTAMINE$_{1A}$ RECEPTORS. B. C. Hiner*, P. J. Ison* and S. J. Peroutka. (Sponsor: M. Weinrich) Department of Neurology, Stanford University Medical Center, Stanford, California 94305

The exact mechanism of action of the novel anxiolytics buspirone and TVX Q 7821 remains unknown. Unlike diazepam, buspirone has no effect on the benzodiazepine/GABA receptor complex as studied by radioligand techniques. Buspirone does display weak neuroleptic-like activity although its effects on central dopamine systems is not believed to be related to its anxiolytic effects. 5-Hydroxytryptamine (5-HT) receptors have been proposed as the target site for both buspirone and TVX Q 7821 despite the fact that buspirone was initially reported to be inactive at 5-HT$_1$ receptors. Recently, the availability of selective radioligands has allowed 5-HT$_1$ binding sites to be differentiated into 5-HT$_{1A}$ and 5-HT$_{1B}$ subtypes. As a result, the present study analyzed the interactions of buspirone and TVX Q 7821 with 5-HT$_{1A}$ and 5-HT$_{1B}$ sites as well as with a series of eight other receptor binding sites in bovine brain membranes.

Buspirone (IC_{50} = 24 ± 4 nM) and TVX Q 7821 (IC_{50} = 9.5 ± 2 nM) are most potent at 5-HT$_{1A}$ binding sites labeled by ^{3}H-DPAT. Buspirone is 16-fold weaker at dopamine (D_2) sites labeled by ^{3}H-spiperone in striatal membranes (IC_{50} = 380 ± 70 nM) and 58-fold less potent at alpha-adrenergic$_1$ sites labeled by ^{3}H-WB 4101 (IC_{50} = 1,400 ± 500 nM). By contrast, TVX Q 7821 is 6-fold less potent (IC_{50} = 58 ± 10 nM) at alpha-adrenergic$_1$ sites and more than two orders of magnitude less potent at dopamine (D_2) sites (IC_{50} = 3,000 ± 300 nM). Both buspirone and TVX Q 7821 display moderate affinity (i.e., IC_{50} values between 1,000 - 10,000 nM) at 5-HT$_2$ sites labeled by ^{3}H-spiperone in cortical homogenates, histamine (H_1) sites labeled by ^{3}H-pyrilamine and alpha-adrenergic$_2$ sites labeled by ^{3}H-yohimbine. Both drugs are also similar in that they are essentially inactive (i.e., IC_{50} values greater than 10,000 nM) at 5-HT$_{1B}$ sites in the corpus striatum labeled by ^{3}H-5-HT, calcium channel antagonist sites labeled by ^{3}H-nitrendipine, muscarinic cholinergic sites labeled by ^{3}H-QNB and benzodiazepine binding sites labeled by ^{3}H-flunitrazepam.

The major finding of the present study is that buspirone and TVX Q 7821 are potent and selective inhibitors of 5-HT$_{1A}$ binding sites in brain membranes. These two novel anxiolytics share both structural and pharmacological properties. The drugs display moderate affinity for 5-HT$_2$ sites but are essentially inactive at 5-HT$_{1B}$ binding sites. In addition, buspirone and TVX Q 7821 are inactive at benzodiazepine binding sites. These findings suggest that the anxiolytic effects of buspirone and TVX Q 7821 may be mediated by an interaction with a specific subpopulation of 5-HT receptors in the central nervous system.

43.4 MODULATION OF SYNAPTIC TRANSMISSION IN THE HIPPOCAMPUS PRODUCED BY NOVEL ANXIOLYTICS (BUSPIRONE, TVX-Q 7821 & DPAT). M.D. Mauk, P.J. Peroutka & J.D. Kocsis. Deptartment of Neurology, Stanford Medical Center and VA Medical Center, Palo Alto, CA 94304.

Unlike diazepam, the novel anxiolytics buspirone and TVX-Q 7821 possess very little affinity for benzodiazapine/GABA binding sites. However, these compounds have recently been shown to display potent and selective affinity for 5-HT$_{1A}$ binding sites (Hiner, et al, this volume). Beyond this, little is known about the CNS actions of these compounds. Two observations; 1)that serotonin (5-HT) affects the amplitude of population spikes in hippocampal slice and 2)that the hippocampus is a rich source of 5-HT$_{1A}$ binding sites, suggested to us that further characterization of the CNS actions of buspirone and TVX-Q 7821 could be accomplished using in vitro hippocampal slice.

Hippocampal slices (400u) were prepared with a vibratome using tissue derived from female Wistar rats. Slices were placed in a submersion chamber and were superfused with a continuous flow of modified Krebs and maintained at 33-34°. Field potentials elicited by monopolar stimulation of Schaffer collaterals were recorded in the pyramidal layer of CA-1. When the field potentials had been stable for at least 20 min., the slices were superfused with Krebs containing various concentrations of the compounds under study. Dose-response curves were obtained by applying increasing concentrations of the compounds every 30 min. until complete abolition of the population spike was observed. Reversal of the effect was then assessed by washing the slices in normal Krebs solution.

Application of buspirone, TVX-Q 7821 and DPAT as well as diazepam produced a dose dependent and reversible reduction of the population spike. Effective concentrations were 25-100 uM. In one experiment, K^+-sensitive electrodes were used to monitor the field potential and extracellular K^+ concentration. Application of buspirone (100uM) produced a complete abolition of the population spike and was accompanied by an increase in extracellular K^+.

Previous experiments have shown that an increase in K^+ conductance and a decrease in membrane resistance are responsible for the effects of 5-HT on population spike amplitude. The present data indicate that the action of buspirone is similar to that of 5-HT suggesting that buspirone, TVX-Q 7821 and DPAT are 5-HT$_{1A}$ agonists in the hippocampus. Diazepam produces a similar effect on the amplitude of the population spike. However, on the basis of previous binding data and physiological characterization it seems likely that diazepam and buspirone affect the hippocampus via different ionic mechanisms. The similarity of action suggests, but our data do not demand, that modulation of hippocampal synaptic transmission may mediate the anxiolytic actions of diazepam, busbirone and TVX-Q.

Supported in part by the NIH and the Medical Service of the VA.

43.5 ANGIOTENSIN RECEPTOR BINDING IN DEVELOPING SPONTANEOUSLY HYPERTENSIVE AND NORMOTENSIVE RATS. B. Salaymeh* and J.A. Weyhenmeyer, College of Medicine, University of Illinois, Rockford, IL 61107, and Department of Anatomical Sciences, University of Illinois, Urbana, IL 61801

Although the peripheral renin-angiotensin system is considered to play an important role in blood pressure regulation and extracellular fluid volume homostasis, recent physiological and pharmacological data have indicated that the biologically active end product of the RAS, ANG II, can exert a profound neuromodulatory influence in the CNS. These central effects include an increase in arterial blood pressure, an increase in fluid intake, and a release of pituitary hormones. Although the role of ANG II in the development of hypertension remains as yet unresolved, Okuno et al. (Hypertens. 5:653, 1983) have demonstrated that chronic blockade of the angiotensin system prevents the development of hypertension in the young spontaneously hypertensive (SH) rat. The purpose of this study was to investigate the binding characteristics of ANG II receptors in the developing SH rat and its normotensive control, the Wistar Kyoto (WKY) rat.

Age-matched 4-, 8-, 12- and 16-week SH and WKY rats were sacrificed by decapitation while under CO_2 anesthesia. Brains were rapidly removed at 4°C and the hypothalamus-thalamus-septum-midbrain region was microdissected. Tissues were homogenized in 50 mM Tris containing 150 mM NaCl and 5 mM EDTA and centrifuged at 50,000 g for 30 min. The resulting pellets were suspended in Tris containing 5 mM dithiothreitol and 0.2% BSA. The homogenates were subsequently incubated in the presence of 0.003 to 1.0 nM ^{125}I ANG II in the presence (blocked) or absence (unblocked) of 4 μM ANG II for 30 min at 25°C and filtered under vacuum. The filters were washed with cold Tris and counted in a gamma counter with 75% effiency.

Our results demonstrate that although ANG II receptor levels decrease in both SH and WKY rats during development, there are significant differences in the ANG II binding capacities between the two strains. At 4 weeks of age, the ANG II receptor levels in the SH rat are significantly higher than in its normotensive control (WKY). At 8, 12 and 16 weeks of age, no significant differences were observed in the receptor levels of SH and WKY rat. These data indicate that ANG II receptor down regulation is greater in the developing SH rat than its normotensive (WKY) control, and suggest that the ANG II receptor may play a role in the pathogenesis of hypertension.

43.6 ANGIOTENSIN II LEVELS IN MICRODISSECTED BRAIN AND BRAINSTEM NUCLEI FROM SPONTANEOUSLY HYPERTENSIVE AND WISTAR KYOTO RATS. J. M. Meyer, D. L. Felten, and J. A. Weyhenmeyer, Neural and Behavioral Biology Program and College of Medicine, University of Illinois, Urbana, IL, 61801; Department of Anatomy, University of Rochester School of Medicine, Rochester, NY, 14642.

Angiotensin II (ANG II), a naturally occuring brain peptide, has been implicated in the CNS regulation of blood pressure, fluid intake, sodium intake and hormone release. Hoffman et al. (Am. J. Physiol., 232:H4426, 1977) demonstrated that the intraventricular administration of ANG II results in a more significant pressor response in the spontaneously hypertensive (SH) rat than its normotensive control, the Wistar Kyoto (WKY) rat, suggesting an increased ANG II sensitivity in the SH rat. The purpose of this study was to quantitate ANG II levels in microdissected nuclei of SH and WKY rat brain and brainstem, including the paraventricular nucleus of the hypothalamus (PVH), A1 region, nucleus of the solitary tract (NTS), and locus coeruleus (LC). Each of these nuclei has previously been shown to contain ANG II-like immunoreactivity (Weyhenmeyer and Phillips, Hypertens. 4:514, 1982) and has been implicated in cardiovascular regulation.

Twelve-week old male SH and WKY rats, recorded for blood pressure and weight, were anesthetized and perfused transcardially with ice cold phosphate buffered saline. Nuclei were microdissected over dry ice, rapidly frozen and stored at -90°C. Tissues were homogenized in 0.1N HCl, boiled for 5 min and centrifuged at 30,000 g for 30 min at 4°C. The supernatant was collected and the pellet re-extracted with 0.1N HCl. Supernatants were pooled and purified on Sep Pak cartridges according to the method of Raizada et al. (Am. J. Physiol., 247:C115,1984). Samples were analyzed by high performance liquid chromatography using a reverse phase C18 column and by a competitive inhibition radioimmunoassay using a specific ANG II antibody.

Preliminary evidence indicates that both SH and WKY rats contain picomolar levels of ANG II in the microdissected nuclei under study. However, significantly higher levels of ANG II were found in the PVH, NTS, and LC of the SH rat as compared to its normotensive control. These data suggest neurochemical differences between the genetically predisposed hypertensive rat and its normotensive counterpart and support previous findings that suggest a down regulation of ANG II receptor levels in adult SH rats.

43.7 EVIDENCE OF A ROLE FOR CATECHOLAMINES IN THE EVOLUTION OF INFARCTION IN ISCHEMIC HIPPOCAMPUS J. Weinberger, J. Nieves - Rosa. Dept Neurology, Mt. Sinai Sch of Med, N.Y., N.Y. 10029

The striatum and hippocampus are brain regions with a selective vulnerability to ischemic infarction. Previous studies in our laboratory have demonstrated an increased sensitivity of catecholamine nerve terminals to ischemic damage and have implicated catecholamines in the evolution of infarction in ischemic striatum. In the present study, the hippocampi of Mongolian gerbils with stroke due to unilateral carotid artery ligation were examined by the Falck-Hillarp technique to determine if there was a relationship between vacuolization of the neuropil and the presence of catecholamine derived fluorescence as seen in striatum. Brains were removed from stroke animals at 2, 4, 7, 12 and 16 hours after carotid artery ligation, freeze dried at -35°C for 48 hours and incubated with paraformaldehyde to form fluorescent isoquinolines. Specimens were examined with a Leitz transmission fluorescence microscope employing BG12 excitation filters and a K510 barrier filter. Morphologic damage to the neuropil was assessed by the Nissl technique, employing a cresyl violet stain.

At 2 (n=3) and 4 (n=3) hours after stroke, no vacuolization was seen in the ischemic hippocampi. Fluorescence of the nerve terminals was similar in the ischemic and control hippocampi. At 7 hours (n=3) and 12 hours (n=3), severe vacuolization of the neuropil was present adjacent to the granular cell layer of the CA_1 region and in the pyramidal cell layer of the dentate gyrus. Large concretions of fluorescence were seen in these vacuoles, probably representing swollen catecholamine nerve terminals. This fluorescence could be removed by washing the sections with a 0.1% solution of sodium borohydrate in 95% isopropanol and could be restored by reincubation with paraformaldehyde, confirming that the fluorescent material was derived from catecholamine. By 16 hours (n=3), fluorescence had faded, and there was no progression of vacuolization of the neuropil compared to 7 hours after stroke.

To further explore whether there was relationship of catecholamines to ischemic vacuolization, catecholamines were depleted by pretreating gerbils with a-methyl-p-tyrosine (AMPT) 400mg/kg i.p. 6 hours prior to carotid ligation. In these treated animals, ischemic vacuolization and associated fluorescence were not seen 7 hours after stroke (n=7), but appeared 16 hours after stroke (n=7).

There is a temporal and spatial coincidence of catecholamine derived fluorescence with vacuolization of the neuropil in the ischemic hippocampus. These changes can be delayed by depleting catecholamines with AMPT. The results suggest that catecholamines may play a role in the evolution of ischemic infarction in the hippocampus similar to that seen in the striatum.

43.8 EFFECTS OF LOW CONCENTRATIONS OF Cd^{++} ON THE BASAL RELEASE OF CATECHOLAMINES. A. Obeso*, S. Fidone and C. Gonzalez. Dept. of Physiology, School of Medicine, U. of Utah, Salt Lake City, Utah.

It is well documented in animal models that acute administration of Cd^{++} produces hypertension and that chronic exposure to this cation results in hypertension comparable to human essential hypertension. The pathogenic effects of Cd^{++} in producing hypertension in animal models is dose dependent; only moderate levels of Cd^{++} produce hypertension while high levels are ineffective. These findings in laboratory animals agree with epidemiological studies in humans. In these latter studies, a positive correlation was found amongst the Cd^{++} levels (moderate) in the tissues, increased blood catecholamine levels and the presence of hypertension. On the other hand, people living in Cd^{++} polluted areas have a normal incidence of hypertension despite high tissue levels of Cd^{++}. These well documented facts, the mechanism(s) involved in the genesis of hypertension induced by Cd^{++} is unknown.

In the present experiments, we found that low Cd^{++} concentrations (2-7 μM) induced a moderate but significant (≈ 20%) increase in the basal release of ^{3}H-DA (synthesized in vitro from ^{3}H-tyrosine) from the rabbit carotid body. In two vascular preparations (rabbit common carotid artery and rat aorta) preloaded with ^{3}H-NE (0.25 μM; 30 min), we found that 5 μM Cd^{++} in the superfusion fluid (air-equilibrated Tyrode's) produced a significant increase in the basal release of ^{3}H-NE, with minor effects on the release evoked by high K^+_o. The same effect was also observed with 2 μM and 7.5 μM Cd^{++} in the superfusion media. At higher concentrations (>20 μM), Cd^{++} produced inhibition of both the basal and the high K^+_o evoked release.

Since the concentrations of Cd^{++} that resulted in increased release of ^{3}H-catecholamines are within the range of those found in association with hypertension in animal models, our data, although preliminary, provide a possible explanation for the association between moderate levels of Cd^{++}, high blood catecholamine levels and hypertension.

Supported by USPHS grants NS12636 and NS07938 and a grant from the C.A.I.C.T. from Spain.

43.9 PROLACTIN-A CLUE TO THE MECHANISM OF HALOPERIDOL-INDUCED ACUTE DYSTONIA? D.D. Miller*, L.A. Hershey, B.M. Arafah*, J.P. Duffy* and D.J. Greenblatt*. Depts. of Psychiatry, Neurology and Medicine, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106 & Div. of Clin. Pharmacol., Tufts U. Sch. of Med., Boston, MA. 02111.

Although acute dystonia (AD) is a common adverse effect of antipsychotic agents, its pathophysiologic mechanism is unknown. Some investigators have suggested that a central imbalance of dopaminergic and cholinergic activity is involved. To better understand this reaction, we examined 21 acutely psychotic inpatients before and during their treatment with haloperidol (HDL) without prophylactic anticholinergics. We analysed various factors, looking for a difference between patients who developed AD (n=12) and those who did not (n=9). All patients whose AD was severe enough to have a rating of 2 or more on the scale of Chien et al (AJP,1974) had blood drawn within 30 minutes of developing this reaction (prior to administration of benztropine). Those patients who did not develop AD had blood drawn at similar times for comparison. Serum samples were analysed for HDL concentrations using the GLC method of Abernethy et al (J Chromatogr, 1985). Anticholinergic activity in serum was measured utilizing the QNB binding assay of Tune & Coyle (Arch Gen Psych, 1980). Prolactin (PRL) concentrations were measured by radioimmunologic assay. The technicians running these assays were unaware of whether or not the patients had developed AD. When pretreatment PRL concentrations were subtracted from those measured at the time of the drug reaction, the AD group showed a significantly larger increase in PRL than those who never experienced AD ($p<0.05$). Since serum PRL is a peripheral measure of central dopaminergic blockade, our findings suggest central dopamine antagonism as the basis for drug-induced AD. Since QNB is only a peripheral measure of anticholinergic activity, we cannot rule out the possibility of a central imbalance of dopaminergic and cholinergic activity. It will be important to examine whether stress might explain the increase in PRL concentrations in AD patients. We plan to measure serum cortisol and growth hormone levels in these serum samples in order to provide some insight into this question.

43.10 **A COMPARISON OF SUBSTANCE P AND SEROTONIN-IMMUNOREACTIVE NERVE TERMINALS IN SPINAL CORDS OF RATS AND GUINEA PIGS WITH ACUTE EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS (EAE).** **D. Vyas*, D. Bieger, and S.R. White. Fac. of Med., Memorial Univ. of Newfoundland, St. John's, NFLD., Canada, A1B3V6 and Dept. of VCAPP, Col. Vet. Med., Washington State Univ., Pullman, WA 99164**

Adult male Lewis rats and juvenile female Hartley guinea pigs were inoculated for EAE with hindfoot injections of homozoic spinal cord emulsified in complete Freund's adjuvant (CFA). Control animals of each species were injected with CFA only. EAE animals developed paraplegia 11-17 days post inoculation, at which time they were anesthetized and perfused with 4% paraformaldehyde in PBS. CFA animals, matched with paraplegic EAE animals for time since inoculation, were treated in an identical manner. Spinal cords were removed and stored in fixative for at least 48 hours. Sections from cervical, thoracic and lumbar spinal cord (40 µm thick) were stained for serotonin (5HT)-and substance P (SP)-like immunoreactivity using the peroxidase-antiperoxidase method. 5HT and SP antisera were purchased from ImmunoNuclear.

Grossly distorted 5HT-positive axons were observed in the ventral and lateral funiculi at cervical, thoracic and lumbar spinal cord levels in both rats and guinea pigs with acute EAE. However, EAE-induced changes in the morphology of 5HT-positive terminals in the spinal cord gray matter differed for the two species. Depletion of 5HT-immunoreactive fibers and terminals in gray matter was striking in EAE guinea pigs; lumbar gray matter was almost completely denuded of 5HT-positive staining. In EAE rats, 5HT-positive staining was still evident in spinal cord gray matter, but marked alterations in the morphology of stained fibers and terminals compared to those of CFA controls were observed. 5HT-immunoreactive varicosities were enlarged in EAE rats compared to controls and intervaricose segments which were clearly visible in CFA rats were absent in the EAE rats in lumbar and thoracic gray matter.

Although some distorted SP-positive axons could be observed in the dorsolateral funiculus of the spinal cords of EAE rats and guinea pigs, there was not a marked or consistent change in morphology or density of SP-immunoreactive terminals in spinal cord gray matter of either species. The extensive damage to bulbospinal 5HT-immunoreactive axons and terminals occurring during acute EAE appeared to be associated with relative sparing of SP-immunoreactive neurons. The effects of the disease on those axons and terminals which contain co-localized 5HT and SP are currently being examined.

43.11 GLYCINE RECEPTOR IN SPINAL CORD OF THE MUTANT MOUSE SPASTIC: EVIDENCE FOR NORMAL RECEPTOR STRUCTURE Cord-Michael Becker*, Irmgard Hermans*, Bertram Schmitt*, Heinrich Betz. Institute for Neurobiology, ZMBH, University of Heidelberg, D-6900 Heidelberg, FRG.

The glycine receptor from spinal cord is an M_r = 246K glycoprotein composed of three polypeptides of 48K, 58K, and 93K (Pfeiffer et al.; J. Biol. Chem. 257:9389; 1982). Homozygotes of the mutant mouse "spastic" are characterized by a specific reduction of ^{3}H-strychnine binding to homogenates from various regions of the CNS as compared with unaffected controls (White, W.F. and Heller, A.H.; Nature 298:655; 1982).

Scatchard analysis of ^{3}H-strychnine binding to crude synaptic membranes revealed a single binding site with a B_{max} of 267 ± 62 fmol/mg protein and 864 ± 220 fmol/mg protein for spastic homozygotes and control animals, respectively. K_D values were not significantly different with 7.68 ± 0.95 nM for spastic and 7.46 ± 0.85 nM for control mice. Competitive binding assays with glycine revealed K_i values of 22.2 ± 2.4 µM for spastic mice and 19.0 ± 1.7 µM for controls. Also, inhibition of ^{3}H-strychnine binding by glycinergic ligands was the same with mutant mice and control animals.

SDS-PAGE revealed the same polypeptide pattern for glycine receptor purified from spastic mice and controls, each consisting of three polypeptides of M_r = 48K, 58K, and 93K. Also, monoclonal antibodies directed against different subunits of the receptor protein produced an identical ELISA reaction pattern with glycine receptor purified from spinal cord of rat, normal, and spastic mice.

Immunofluorescent staining of sections from mouse spinal cord with monoclonal antibodies showed the same patchy distribution of fluorescence on the cell membrane of anterior horn neurons for both spastic and control mice.

These results strongly suggest that the pharmacology and the structure as well as the synaptic location of glycine receptors is unaltered in spastic homozygote mice. The reduction of Bmax for ^{3}H-strychnine binding observed in the mutants appears to result from a regulatory rather than a structural effect of the mutation on glycine receptors.

43.12 DECREASED PLATELET [^{3}H]IMIPRAMINE BINDING SITES IN DOWN'S SYNDROME. S.W. Tang, J. Bruni*, J. Berg*, and A. Davis. Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Ontario, Canada M5T 1R8.

Defective accumulation and storage of serotonin (5-HT) in blood platelets is one of the many metabolic abnormalities discovered in Down's syndrome (DS). Platelets are known to accumulate, store, and transport 5-HT in a similar fashion to that of serotonergic neurons in the central nervous system (CNS). A defect in platelet 5-HT storage, as seen in DS, may therefore reflect abnormal 5-HT metabolism in the CNS. This may in turn contribute to the mental deficiency observed in DS. In order to investigate the nature of the 5-HT problem in DS, radioactively labelled imipramine ([^{3}H]IMI) was used. Imipramine, a tricyclic antidepressant, appears to label the 5-HT uptake mechanism on both platelets and serotonin nerve terminals.

Subjects with a previously established diagnosis of DS (n=12, age 27 ± 5, mean ± S.E.) were recruited from the Metro Toronto Association for the Mentally Retarded (MTAMR). Two control groups also took part in the study. The parents of the Down's individuals comprised one group (n=16, age 63 ± 9). One or both parents were assayed on the same day as their child in order to control for possible assay and seasonal variation. The other control group consisted of individuals assayed independently and of comparable age (n=33, age 32 ± 7) to the Down's group in order to control for the possible influence of age. Platelet [^{3}H]IMI binding was performed according to the method of Raisman et al. (Europ. J. Pharmacol.,61:373, 1980) with slight modification. Scatchard analysis was performed to calculate the receptor density (B_{max}) and affinity constant (K_d) for [^{3}H]IMI binding.

Results show no significant difference in K_d values between Down's subjects and controls. However, Down's syndrome subjects had significantly lower B_{max} values for [^{3}H]IMI binding than controls. The observed B_{max} values were 630 ± 132 (mean ± S.D.) fmol/mg protein for the Down's platelets, 942 ± 190 fmol/mg protein for the parental controls, and 1009 ± 190 fmol/mg protein for the younger control group. The difference in B_{max} values between the Down's group and both control groups is significant ($p < .001$) as analyzed by either the two-tailed Student's t-test or by the paired t-test.

In conclusion, our results indicate a significant decrease in platelet [^{3}H]IMI binding in Down's syndrome. This finding may help us understand the 5-HT deficiency observed in DS platelets. Further, this demonstrates the usefulness of [^{3}H]IMI binding as a probe to further investigate the molecular mechanism of 5-HT transport across cellular membranes in both normal and pathological states.

(Supported by the Hospital for Sick Children Foundation. Our thanks to the MTAMR.)

43.13 EVIDENCE THAT THE BENZODIAZEPINE ANTAGONIST CGS-8216 COUNTERACTS THE SYMPTOMS OF HEPATIC ENCEPHALOPATHY. M. Baraldi. Inst. of Pharmacology, Modena University, Via Campi 287, 41100 Modena, Italy.

The CNS derangement which occurs during the developement of hepatic encephalopathy (HE) due to fulminant hepatic failure induced in rats by Galactosamine has been associated with a denervation supersensitivity phenomenon of GABA receptors (Science, 216:427, 1982) and of Benzodiazepine recognition sites (Clin. Sci.,67:167, 1984). This finding prompted us to test the potential usefulness of the Benzodiazepine antagonist CGS-8216 to counteract the CNS generalized depression which characterizes HE. The acute injection of CGS-8216 temporally wakes up the rats from the comatose state, normalizes the pattern of visual evoked potential recordings and down regulates the Benzodiazepine binding sites labelled by ^{3}H-Diazepam. CGS-8216 has been classified as a Benzodiazepine antagonist with inversive-agonist properties which may explain the above mentioned results. On the other hand, this agent seems to interact also with the purinergic system in the brain. In this context it is likely to mention that Adenosine receptor agonists are potent CNS-depressants whereas Adenosine receptor antagonists are potent CNS-stimulants. To test whether CGS-8216 counteracts the symptoms of HE not only by antagonizing the Benzodiazepine receptor supersensitivity but also by blocking the Adenosine receptors, we performed binding experiments in vitro and behavioral studies in vivo. CGS-8216 displaces Adenosine agonist (|-|N^{6}-phenylisopropyl-^{3}H-adenosine and 5'-N-ethylcarboxamido-^{3}H-adenosine) and antagonist (1-3-diethyl-8-^{3}H-phenylxantine) binding to brain membranes with an IC_{50} of 5-10 uM wich is very similar to that of theophylline but higher than that of |-|N^{6}-phenylisopropyl-adenosine (0.08 uM). From these data and from behavioral experiments (CGS-8216 counteracts in vivo the sedative effects of adenosine derivatives) one can surmise that CGS-8216, like methylxantines, is an adenosine receptor antagonist. Finally, by studying the characteristics of Adenosine receptors in HE, we found that during the developement of the coma there is no change of ^{3}H-PIA binding while there is an increased affinity of the antagonist ligand ^{3}H-DPX. All these data taken together seem to indicate that CGS-8216 has antagonistic properties on Adenosine receptors and that its usefulness in counteracting the CNS depression of HE could be due to the antagonistic effect on both Benzodiazepine and Adenosine receptors.

43.14 TYROSINE HYDROXYLASE ACTIVITY IN EXPERIMENTAL DIABETES MELLITUS. R.W. Hamill, F.K. Northington*, S. Banerjee, Dept of Neurology, CBR & Pharmacology, Univ Roch Med Ctr/Monroe Community Hospital, Rochester, NY 14624

Autonomic dysfunction in man is a common manifestation of diabetes mellitus (DM); frequently experienced disabilities include orthostatic hypotension, sweating abnormalities, bladder dysfunction, impotence, and altered gastrointestional motility. Experimental DM in rats is also associated with autonomic abnormalities: streptozotocin (STZ), a B-cell cytotoxic agent, treatment results in altered cardiovascular and gastrointestional function and is associated with ultrastructural and biochemical changes in sympathetic innervation. In order to examine the neurochemical aspect of experimentally induced DM, tyrosine hydroxylase (TH), the rate limiting enzyme in catecholamine biosynthesis, was examined in peripheral sympathetic ganglia following induction of the diabetic state.

In initial studies STZ (65mg/kg) or vehicle was injected intravenously and 8 weeks later animal weight, blood sugar and stellate ganglion TH activity were determined in 8 control and 8 experimental animals. Diabetic animals exhibited blood sugars of 415+/-130mg/dl compared to control values of 200+/40mg/dl and a 23% weight loss. Stellate ganglion (SG) TH activity was reduced by 35% (control-4483+/-362pmoles/gang/hr; diabetic-2990+/-283 pmoles/gang/hr.p<0.01). In order to determine whether these effects might be a direct toxic effect of STZ, TH activity was examined within 72 hrs. of induction of glycosuria. Enzyme activity was unchanged. The effect of experimental DM on the sympathetic axis was evaluated by examining TH activity in the superior cervical (SCG), stellate(SG) and hypogastric (HG) ganglia for 12 weeks following induction of DM:

Tyrosine Hydroxylase Activity (pmoles/gang.hr)

	Control	Diabetic	Insulin Rx'd
SCG	2522±293	2145±332	2968±450
SG	3659±289	1702±234	2742±258
HG	1685±200	1417±243	2054±253

(Insulin Rx'd was initiated one month prior to sacrifice)

These studies indicate that STZ induced DM effects neurotransmitter synthesizing enzymes in specific peripheral ganglia and short term insulin treatment appears to partially reverse these effects. (Supported in part by Univ of Rochester/MCH Research Fund and NIA grant AG03234).

43.15 EFFECTS OF PARASYMPATHETIC DECENTRALIZATION ON AUTONOMIC RECEPTOR FUNCTIONS AND ON THE NON-CHOLINERGIC CONTRACTILE RESPONSE TO ELECTRICAL FIELD STIMULATION IN CAT URINARY BLADDER. K.-E. Andersson*, A. Mattiasson*, C. Sjögren*, M. Atta* and A. ElBadawi. Dept. Obst. Gyn., Univ. of Toronto, Canada, Dept. Urol., Univ. of Lund, Sweden and Dept. Pathol., SUNY-Upstate Med. Ctr. Syracuse, New York 13210.

Previous investigations have shown that parasympathetic decentralization of the lower urinary tract in cats is associated with morphological changes in the autonomic innervation and receptor functions. The aim of the present study was to investigate in vitro whether the contractile response to electrical field stimulation remaining after muscarinic receptor blockade, the responses to α-adrenoceptor agonists and antagonists, and the muscarinic receptor functions on the adrenergic nerves were changed after parasympathetic decentralization.

Male cats were parasympathetically decentralized by means of ventral sacral root division. The animals were killed for investigation after three weeks (n=6) and ten weeks (n=6) after decentralization and the results obtained were compared to those of normal controls (n=6). Strips of detrusor muscle (mucosa removed) were dissected and mounted in organ baths maintained at 37° C, and isometric tension was recorded. Pieces of tissue from the bladder muscle were pre-incubated with ^{3}H-noradrenaline, and the release of ^{3}H in response to electrical stimulation was investigated.

The results showed that the non-cholinergic part of the electrically induced contraction decreased in amplitude after parasympathetic decentralization, and maximum was reached at lower frequencies of stimulation than in controls. The non-cholinergic part of the contraction was not decreased by α-adrenoceptor blockade. Both before and after decentralization there was a weak and inconsistent response to α-adrenoceptor stimulation with phenylephrine and noradrenaline (>10^{-5} M), but never to clondine. In the release studies muscarinic receptor stimulation with carbachol concentration-dependently decreased the electrically induced release of ^{3}H by 19±4% (10^{-7} M) and 51±5% (10^{-6} M). Corresponding figures after decentralization were 41±5% and 73±3%. No differences were found between cats investigated three and ten weeks after decentralization.

The results suggest that no changes in post-junctional α-adrenoceptor functions occur after parasympathetic decentralization in cats. However, there seems to be a pre-junctional supersensitivity of the muscarinic receptors controlling noradrenaline release, similar to the post-junctional supersensitivity previously demonstrated to occur on bladder smooth muscle.

43.16 *EXPERIMENTAL AUTO-IMMUNE MYASTHENIA GRAVIS AND MYASTHENIA GRAVIS : COMPARISON OF SOME IMMUNOLOGICAL RESULTS.* *M. Geffard, M.L. Souan*, and C. Gouyou-Beauchamps*. IBCN-CNRS, 1 rue Camille Saint-Saëns, 33077 Bordeaux cedex, France.*

Myasthenia gravis (MG) is an auto-immune disease with a breakdown in the self-recognition of the acetylcholine receptor (ACh-R) due to the production of anti-ACh-R antibodies. The consequent loss in the ACh-R activity leads to a characteristic muscular weakness. Though the humoral and cellular mechanisms of this disease have extensively been studied, the triggering mechanism of the auto-immune process has not been elicited yet. Animal models have therefore been studied by using two main procedures : (i) injection into animals of purified ACh-R to raise antibodies and study the structure and function of the receptor complex; (ii) immunization of matched allotypic animals with antibodies directed against an ACh-agonist in order to raise anti-idiotypic antibodies. From Jerne's network theory, we developed a more direct route : we induced an experimental auto-immune myasthenia gravis (EAMG) by injecting into rabbits an acetylcholine-conjugate which both mimicked the molecular structure and the biological activity of acetylcholine. After six months of immunization, the rabbits developed severed symptoms of MG. The EAMG mechanism was analyzed at the immunological and clinical levels : (a) Injections of an ACh-conjugate into rabbits induced the development of both idiotypic and anti-idiotypic antibodies. Using a modified ELISA method, competition experiments allowed to determine for anti-ACh antibodies the self-displacement which occurred between 10^{-8} and 10^{-6} M, indicating a quite high antibody affinity. After purification, the auto-anti-idiotypic antibodies recognized (i) the antigen combining site of the idiotypic antibodies and (ii) the ACh-R, as demonstrated by competition with |^{125}I|-α-bungarotoxin vis a vis the purified receptor.

(b) The rabbits were examined throughout the immunization period. Signs of muscular weakness were noticed within the first few weeks. At the end of the immunization period, the rabbits showed marked signs of respiratory distress and electromyographic disturbances : increased jitters, neuromuscular blockings ....

This type of model allowed to further understand the mechanisms involved into the human myasthenia gravis. Using a modified ELISA method, serum from MG patients was found to contain an antibody that recognized the ACh determinants of our ACh-conjugate. The presence of anti-ACh antibodies in MG sera suggests a possible pathophysiologic mechanism involving the idiotypic/anti-idiotypic regulation.

43.17 ANTIIDIOTOPIC MODIFICATION OF THE IMMUNE RESPONSE IN EXPERIMENTAL AUTOIMMUNE MYASTHENIA GRAVIS. M.A. Agius, C.G. Geannopoulos and D.P. Richman, (SPON: J.W. Crayton). Department of Neurology, University of Chicago, Chicago, Illinois 60637

The maintenance of tolerance and immune regulation in autoimmune diseases involves idiotypic-antiidiotypic network interactions. To modify the anti-acetylcholine receptor response in chronic experimental autoimmune myasthenia gravis, we have injected female Lewis rats with two purified syngeneic anti-idiotopic monoclonal antibodies (HC-4A and HC-29), that are directed against an anti-acetylcholine receptor antibody capable of inducing experimental myasthenia gravis. One of the anti-idiotopic antibodies (HC-4A) recognizes a crossreactive (public) idiotope on six other anti-acetylcholine receptor monoclonal antibodies. Injections of each antiidiotopic monoclonal antibody, or a control monoclonal antibody, were made intraperitoneally; for each antibody a one-half milligram per kilogram and a one-half microgram per kilogram dose was used. Animals were actively immunized two weeks later with acetylcholine receptor and assessed four months later. All animals had elevated total serum anti-acetylcholine receptor antibody titers despite absence of weakness or decremental electromyographic findings. The anti-acetylcholine receptor titers were significantly lower in the animals treated with high doses of antiidiotopic antibody (0.6 ± 0.10 micromoles per liter, mean ± SEM), compared with animals treated with low doses or controls (1.33 ± 0.26, $P < 0.05$). In addition acetylcholine receptor content analysis by immunoprecipitation revealed normal levels of free receptor (total receptor content minus receptor complexed to antibody) for the high dose anti-idiotope group (13.5 ± 2.0 picomoles of alpha-bungarotoxin binding sites per gram of extracted membrane protein) while the other groups had amounts reduced to thirty percent of normal (4.1 ± 1.0, $P < 0.005$). These results show that pretreatment with high doses of antiidiotopic antibody suppresses the myasthenic immune response in Lewis rats.

43.18 HUMAN x HUMAN HYBRIDOMAS FROM LYMPHOCYTES OF A PATIENT WITH MYASTHENIA GRAVIS SECRETE MONOCLONAL ANTIBODIES TO ACETYLCHOLINE RECEPTOR. D.A. Blair* and D.P. Richman* (SPON: R. Rosenberg). Dept. of Neurology, University of Chicago, Chicago, IL 60637

Peripheral blood lymphocytes from a patient with myasthenia gravis (MG) were fused with polyethylene glycol to a hypoxanthine phosphoribosyl transferase-deficient non-immunoglobulin-secreting variant of the human lymphoblastoid line, GM4672. Fused cells were cultured in selective media. Four weeks after fusion, resultant human x human hybridoma cells were screened for anti-acetylcholine receptor (AChR) activity with an ELISA assay (Mihovilovic and Richman, Journal of Biological Chemistry 259:15051, 1985). The antibodies produced were studied in this assay for their ability to bind to membrane-bound AChR from Torpedo californica as well as purified solubilized AChR from the same source. Several cell lines have been cloned by limiting dilution; these lines have been carried for six months and are stable in their monoclonal antibody production. For the five lines in which we have determined immunoglobulin class, all are IgM.

Thirteen cell lines have been studied for their ability to bind AChR. Results of a typical ELISA assay are as follows: OD_{450}

Cell line	Solubilized AChR	Membrane-bound AChR
MIL 11	.141	.597
MIL 12	.127	.598
MIL 13	.131	.556
MIL 16	.310	.470
MIL 19	.146	.368
MIL 20	.107	.431
11A-3	.079	.323
11A-4	.199	.529
8A-2	.214	.391
8B-2	.138	.153
16B-5	.047	.208

(For 238 unreactive supernatants, including GM4672 culture supernatant, x ± S.D. = .004 ± .01.)

In addition, two of our cloned lines, 11A-4 and 8A-2 have exhibited saturation kinetics with membrane-bound Torpedo AChR when tested with this assay.

To our knowledge, this is the first production of human x human hybridomas secreting anti-AChR monoclonal antibodies. These data suggest that the concept of restricted species cross-reactivity of antibodies present in MG deserves re-evaluation.

43.19 RADIONUCLIDE IMAGING OF DENERVATED SKELETAL MUSCLES IN LIVE ANIMALS AND MEASUREMENT OF THE DEGRADATION RATE OF THEIR EXTRA-JUNCTIONAL ACETYLCHOLINE RECEPTORS. A. L. Politoff, F. Silva* and C. G. Nascimento*. Neurophysiology Lab., Rush Medical College, Chicago, ILL 60612 and Univ. of P. R. Medical School, San Juan, PR 00936.

Visualization of denervated skeletal muscles in live animals has been achieved by gamma camera radionuclide imaging after an intravenous bolus injection of a non-paralyzing dose (20 μg/Kg) of radioiodinated α-Bungarotoxin (131-I-α-BuTX), with a specific activity of approximately 10^4 Ci/Mol (Politoff et al., J. Cell Biol., 97:240a, 1983). The rationale of the procedure is that α-BuTX binds with high specificity and in an essentially irreversible manner to skeletal muscle acetylcholine receptors in vitro and in vivo, after systemic injection. In the present experiments, rabbits with a 6-7 day old unilateral muscle denervation and contralateral sham operation were injected 131-I-α-BuTX as before and imaged 24 hours later through a gamma camera. General anesthesia (Na penthobarbital) was required to eliminate movement artifacts. Sequential images were obtained at 5 min intervals throughout at least one hour. At the end of each sequence the surfaces containing the orthogonal projections of the denervated and sham operated regions of the legs were enclosed by identical rectangles and counts in each rectangle were integrated over time and area (C_{TA}). The time course of C_{TA} at each side was plotted: C_{TA} was always larger and decreased faster over the denervated than over the sham operated region. Slight movements of the animal caused large shifts in C_{TA}: Complete, bilateral C_{TA} curves were obtained only in 3 anesthetized animals. The difference in C_{TA}'s (denervated minus sham operated region) was not abolished by pretreatment with cold iodide nor mimicked by injection of a radioactively equivalent dose of 131-INa. Furthermore, monoiodotyrosine is not incorporated into proteins. Thus, the difference is consistent with and can be attributed to denervation-induced increase in extrajunctional acetylcholine receptors. The difference C_{TA} curve was best fitted to an exponential function: The time constant ranged between -2.28 and -2.59 x 10^{-3} per min ($p < 0.006$), equivalent to half lifes between 4.5 and 5.1 hours. These values are slightly shorter than those found in the literature, all of which were obtained using invasive and destructive methods for the quantification of the receptors, in contrast with our in vivo conditions. It is suggested that the addition of iso-rate constant contour maps to the images will enhance current radionuclide detection of denervated muscles in vivo.

Supported by MDA and NIH (DRR, Prophet System and MBRS).

43.PO EVIDENCE FOR INVOLVEMENT OF CENTRAL GABA MECHANISMS IN AMYGDALOID KINDLED SEIZURES IN THE RAT. W.S. Schwark and W. Löscher*. New York State College of Veterinary Medicine, Cornell University, Ithaca, NY 14853 and School of Veterinary Medicine, Free University of Berlin, West Berlin, West Germany.

The role of central GABAergic systems in the amygdaloid kindling model of epilepsy in the rat was studied using drugs which modulate GABAergic activity and by examination of neurochemical aspects of GABA function in specific brain regions. Two inhibitors of GABA uptake from the synaptic cleft, N-(4,4-diphenyl-3-butenyl) guvacine (SKF 100330-A) and N-(4,4-diphenyl-3-butenyl) nipecotic acid (SKF 89976-A), produced profound inhibitory effects on all examined parameters of kindled seizure activity, including seizure severity, seizure latency, seizure duration and after discharge duration. In contrast to diazepam, which produced marked sedation and ataxia at ED50 dosages (0.0067 mmol/kg ip), ED50's of SKF 100330-A and SKF 89976-A (0.014 and 0.045 mmol/kg ip, respectively) resulted in no CNS depressant or other side effects. Other GABAmimetic drugs, including the specific GABA receptor agonists muscimol, progabide and THIP (gaboxadol), either had no inhibitory effect on kindled seizures or exhibited anticonvulsant action only in dosages which resulted in sedative effects.

Parameters relating to central GABA dynamics, including activity of the key GABA synthetic enzyme glutamic decarboxylase (GAD, EC4.1.1.15), GABA levels and postsynaptic [^{3}H]GABA binding, were examined in brain regions of sham-operated controls and fully kindled rats in which at least 1 week elapsed since the last kindled seizure. Of the 12 brain areas studied, i.e., olfactory bulb, frontal cortex, corpus striatum, hippocampus, right (kindled) amygdala, thalamus, hypothalamus, tectum, substantia nigra, pons, medulla oblongata and cerebellum, significant changes were localized to the amygdala, corpus striatum and substantia nigra. Evidence for reduced GABAergic function in the substantia nigra of kindled rats (control GAD activity 286±23.2 nmol/hr/mg protein vs. 161±8.9 in kindled rats; control GABA level 13.1±2.8 nmol/mg protein vs. 8.0±1.5 in kindled rats; control [^{3}H]GABA binding 385±67.5 fmol/mg protein vs 213±47.8 in kindled rats) is in agreement with several recent reports which indicate that the substantia nigra is an important regulatory site of seizure initiation and propagation. The present data suggest that alterations in central GABAergic systems may play an important role in the pathogenesis of seizures in the kindling model of eiplepsy.

Supported by a grant from the Fogarty Senior International Fellowship program (F06 TW00920-01).

43.PO Neuropeptide Y Levels in a Gene Mutation Causing Central Noradrenergic Hyperinnervation. Jeffrey L. Noebels, M. Flint Beal, Joseph B. Martin, V.R. Holets Whittemore, and Tomas Hokfelt. Departments of Neurology, Massachusetts General Hospital, Boston, MA., and Histology, Karolinska Institutet, Stockholm, Sweden.

Neuropeptide-Y (NPY) interneurons and fibers are present throughout the CNS and the peptide coexists in particular with tyrosine hydroxylase-containing cell bodies in the locus coeruleus (LC). NPY interacts at noradrenergic synapses and intraventricular exposure increases cortical synchronization. A single gene mouse mutation, tottering (tg), causes a striking and selective proliferation of LC (A6) axon terminals with a 100-200% increase in forebrain and cerebellar noradrenaline (NE) levels. The mutant expresses a neurologic syndrome of ataxia and absence seizures with spike-wave synchronization in cortex and hippocampus which can be corrected by denervation of the LC projection. To evaluate whether the tg gene co-regulates NPY levels in the LC fibers, and if altered, whether NPY might share a role with NE in disease expression, 4 tg/tg homozygotes were examined by immunohistochemistry for regional NPY innervation patterns, and 6 tg/tg were analyzed by RIA to quantify regional NPY levels. Each group was compared with age-matched +/+ control mice.

Neuroanatomical examination revealed no certain difference in NPY immunofluorescence innervation patterns between mutant and wild type mice. RIA assays of NPY content in selected brain areas showed a 20% decrease in frontal cortex (mean 41.9 pg/mg wet weight vs 52.2 pg/mg, $p<.04$) and a 60% decrease in hippocampus (9.5 pg/mg vs 24.5 pg/mg $p<.001$) in the mutants. The striatum (36.6 pg/mg vs 35.3 pg/mg) and brainstem (6 pg/mg vs 5.2 pg/mg) were unchanged. Cerebella in both genotypes contained unmeasurably low levels of NPY.

These studies identify lowered cortical and hippocampal NPY levels as a second neurochemical abnormality in the tottering mutation, and suggest that NPY probably co-localizes with only a small subgroup of LC neurons which do not hyperinnervate the tottering CNS. Whether the highly selective decrease in regional NPY levels is a cause or effect of noradrenergic hyperinnervation and inherited absence seizures, or an unrelated pleiomorphism of the tottering gene requires further study.

44 SYMPOSIUM. BEHAVIORAL FUNCTIONS OF CHOLECYSTOKININ IN THE CENTRAL NERVOUS SYSTEM. J.N. Crawley, NIMH (Chairperson); J.-J. Vanderhaeghen*, Free University of Brussels; B.G. Hoebel, Princeton University; Ph. De Witte*, Universete de Louvain; C.A. Baile, Washington University; E. Stellar, University of Pennsylvania.

Cholecystokinin (CCK) is an eight amino acid peptide which was discovered in mammalian brain by Jean-Jacques Vanderhaeghen in 1975. While the functions of gastrointestinal CCK in digestive processes and feeding behaviors have been well documented, the functional significance of central CCK opens a new field of investigation. In the brain, CCK satisfies many of the criteria for a neurotransmitter, i.e. neuronal localization, synthesis and metabolism within central neurons, neuronally stimulated release, postsynaptic receptors, and neurophysiological actions. This symposium will explore the behavioral functions of central CCK, by presenting the most recent studies on the actions of intracerebrally administered CCK on motor behaviors, feeding, self-administration, and self-stimulation.

Dr. Vanderhaeghen will introduce the session with an overview of the anatomical localization of central CCK in mammalian brain, including coexistences of CCK with other transmitters and peptides. Dr. Crawley will present evidence that picogram concentrations of CCK potentiate dopamine-induced hyperlocomotion and apomorphine-induced stereotypy in the mesolimbic pathway, where CCK and dopamine co-exist, but not in the nigrostriatal pathway, where CCK and dopamine are found in separate neurons. Dr. Hoebel will describe new studies on self-administration of CCK into the nucleus accumbens, and evidence for CCK-induced satiety in the paraventricular nucleus of the hypothalamus. Dr. De Witte will discuss findings suggesting that CCK attenuates brain stimulation reward in the hypothalamus after both peripheral and central administration, an effect not blocked by vagotomy, and a comparison of CCK actions with those of other neuropeptides and neurotransmitters in a drug discrimination paradigm. Dr. Baile will present information on changes in hypothalamic CCK concentrations after a meal, after a fast, or after chemically modulated feeding in normal rats, Zucker obese rats, and in sheep. Dr. Stellar will present new data showing that nanogram doses of CCK, administered into the third ventricle, inhibit runway performance and consumption of a food reward.

These studies suggest that CCK localized in central nuclei has discrete behavioral actions, which are functionally distinct from the actions of peripherally localized CCK. Time will be allocated for discussion of additional new research from other laboratories. Questions from the audience will be encouraged.

45 WORKSHOP. COMPUTER-ASSISTED ANALYSIS OF AUTORADIOGRAPHS: APPLICATIONS TO THE 2-DEOXUGLUCOSE METHOD. D. L. McEachron, Drexel Univ. (Chairperson); C. R. Gallistel, Univ,. of Penn.; N. R. Adler, Univ. of Penn.; C. Chu*, Drexel Univ.; O. J. Tretiak*, Drexel Univ.

The ^{14}C-2-deoxy-D-glucose (2-DG) method has been used extensively in recent years to visualize and locate changes in neurophysiology resulting from specific stimuli. Concurrently, computer-assisted analysis of the resultant autoradiographs is enjoying an increasing popularity. A number of questions remain concerning both the 2-DG method itself and the power and limitations of computer analysis. Most prominent of these are: What are the potential sources of error in the various applications of the 2-DG technique? Are normalized data valid or should local glucose utilization always be used? What are the assumptions inherent to the analysis of autoradiographs and what influence do these assumptions have on the choice of image processing hardware? What statistical methods should be used and in what way does the 2-DG technique influence the choice?

Dr. Gallistel will review the history and development of the 2-DG method with special emphasis on the assumptions involved in its application including questions of normalized data. Dr. Adler will discuss the utility of the 2-DG method as an interface between behavior and neurophysiology, commenting on what 2-DG uptake really measures neurophysiologically and how that effects data interpretation. Dr. Tretiak will examine the problems of data acquisition and interpretation from an engineering point of view once an autoradiograph has been generated. Dr. Tretiak will focus upon some of the intrinsic physical limitations involved in image analysis using the 2-DG method as an example and how this is applicable to other imaging problems. Dr. Chu will then present a particular solution to problems of computer imaging of autoradiographs in the form of a microcomputer - based image analysis system developed at Drexel University. Dr. Chu will discuss both the hardware and the software development in detail. Dr. McEachron will examine problems of standardization and statistical evaluation both as a question in the development of a computer imaging system and how these problems influence experimental designs. Dr. McEachron will discuss both practical and theoretical issues created by using the 2-DG method, including issues such as pattern recognition, which have yet to be resolved. The Drexel University microcomputer-based system (DUMAS) will be available for examination and demonstration at the workshop.

46.1 EVALUATING SPECIFICITY IN IN SITU HYBRIDIZATION HISTOCHEMISTRY. M.E. Lewis, S. Burke, T.G. Sherman, and S.J. Watson. Mental Health Res. Inst., University of Michigan, Ann Arbor, MI 48109.

In situ hybridization histochemistry is a valuable technique for anatomically localizing and quantifying changes in specific mRNA. In immunocytochemistry, controls have been devised to avoid "false-positive" staining; similarly, we have explored several procedures for evaluating the specificity of hybrids detected in situ. In these studies, we have used synthetic oligonucleotide or cloned cDNA probes complementary to different regions of proopiomelanocortin (POMC) mRNA. (1) Peptide-mRNA colocalization: Using 4% formaldehyde-perfused tissue, it has been possible to demonstrate cellular colocalization of POMC peptide (e.g. ACTH) immunoreactivity and POMC probe hybrids. (2) Competition studies: Prehybridization of pituitary mRNA with unlabeled alpha-MSH oligonucleotide appropriately attentuates the intermediate lobe (IL) oligonucleotide hybridization signal. However, when the alpha-MSH probe is prehybridized to an equimolar amount of message sense oligonucleotide before tissue incubation, both specific IL and nonspecific (posterior lobe; PL) signals are completely eliminated. Thus, the "preadsorption control," commonly used in immunocytochemistry, is logically inappropriate for in situ hybridization histochemistry. (3) Colocalization of multiple probes: Using adjacent thin sections, probes complementary to different regions of the same mRNA should hybridize to the same cells. We are presently exploring this procedure with multiple POMC as well as dynorphin oligonucleotide probes. (4) Thermal stability of hybrids: Since base-pair mismatches reduce the thermal stability of DNA-RNA hybrids, determination of the Tm (temperature at which 50% of hybrids dissociate), compared to the calculated theoretical Tm value, provides an index of specificity. We have confirmed the usefulness of this measure by showing excellent agreement between obtained and theoretical Tm values (69^{o}C) for hybridization of the alpha-MSH probe to IL. The nonspecificity of low level "hybridization" to PL was confirmed by the much lower apparent Tm (50^{o}C). (5) Northern analysis: The identity of an apparent mRNA target of a probe in situ should be confirmed by demonstrating that the probe hybridizes to an extracted RNA of appropriate size. Using this procedure, we have confirmed that the alpha-MSH oligonucleotide and a much longer POMC cDNA both hybridize to a single pituitary RNA species of a size previously determined for POMC mRNA (1230 nucleotides). These multiple controls provide important, complementary information for evaluating the specificity of hybrids found in situ. Furthermore, for several of these controls, synthetic oligonucleotides and other constant length probes have clear advantages over nick-translated cDNA probes.

46.2 BRATTLEBORO RAT TRANSCRIBES VASOPRESSIN mRNA IN HYPOTHALAMUS: EVIDENCE FROM IN SITU HYBRIDIZATION. J.T. McCabe, J.I. Morrell, H. Schmale*, R. Ivell*, D. Richter*, and D.W. Pfaff. The Rockefeller University, New York, N.Y. 10021 and The University of Hamburg, Hamburg, Federal Republic of Germany

Hereditary diabetes insipidus exhibited by the Brattleboro rat is caused by an inability to synthesize detectable amounts of vasopressin (VP) hormone in the neurohypophyseal system. Gene sequence analysis of genomic and cDNA libraries from Brattleboro rats indicate that the nucleotide sequence encoding VP hormone is normal, but that there is a single base-pair deletion in the region encoding the neurophysin moiety attached to the carboxyl end of VP (Schmale & Richter, 1984, Nature, 308: 705). This deletion base-pair in the Brattleboro's neurophysin segment of the VP gene, downstream to a normal VP sequence, appears to block synthesis of a normal VP-neurophysin-glycoprotein molecule.

Tritiated- and 35-sulphur-labelled (35-S) probes, generated from genomic and cDNA libraries of normal rats, were hybridized to fresh-frozen, cryostat-cut 6 μ sections, that were subsequently fixed (3:1 ETOH:Acetic acid), deproteinated (1 μg/ml pepsin in 2xSSC:Acetic acid, pH 3.5) and air-dried before prehybridization and probe application (method: McCabe et al., 1985, J Histochem Cytochem, submitted). An 18-hr hybridization period was followed by ammonium acetate:ETOH dehydration steps and standard autoradiographic procedures.

Tritiated probes encoding the 3' sequence of the neurophysin region of the VP gene, labelled magnocellular neurons in the supraoptic (SON) and paraventricular (PVN) nuclei of normal and Brattleboro rats. Comparable with immunocytochemical descriptions in normal rats, VP probes labelled magnocellular neurons in the lateral subnucleus of the PVN and ventral portions of the SON. Cell grain counts over SON neurons indicated the mean number of grains per cell for Brattleboro rats were approximately 25% the number seen in the normal rat. In situ hybridization with 35-S labelled probes also labelled magnocellular neurons in the Brattleboro hypothalamus, but with higher background levels. Prolonged (sixty-day) autoradiographic exposure periods with 35-S probes decisively demonstrated VP-gene transcription in the Brattleboro rat. The present results are congruent with recent Northern Blot analyses and transfection studies that show the defective VP gene is transcribed in Brattleboro rats (Schmale, et al., 1984, EMBO J, 3: 3289). This in situ hybridization analysis provides neuroanatomical confirmation that the defective VP gene is transcribed in cells which ordinarily synthesize VP hormone.

46.3 STIMULATION OF DYNORPHIN AND VASOPRESSIN mRNA EXPRESSION IN THE BRATTLEBORO RAT WITH CHRONIC INTERMITTENT OSMOTIC CHALLENGE. T.G. Sherman, O. Civelli*, J. Douglass*, E. Herbert* and S.J. Watson. M.H.R.I., University of Michigan, Ann Arbor, MI 48109, and *Dept. of Chemistry, University of Oregon, Eugene, OR 97403.

The coexistence of prodynorphin peptides within vasopressin magnocellular neurons of the rat hypothalamus has prompted several studies in our laboratory into the regulation of the expression of each of these peptide hormone mRNAs. Previously we have shown that with chronic osmotic challenge (salt-loading), these mRNAs are coordinately stimulated to levels 8-10 fold higher for vasopressin and 3-4 fold higher for dynorphin. Despite the inability of homozygous diabetes insipidus rats of the Brattleboro strain to synthesize AVP under most conditions, these animals continue to synthesize, process and secrete prodynorphin. Examination of their hypothalamic content of prodynorphin mRNA, in fact, revealed that they contained nearly twice as much prodynorphin mRNA as control Long Evans rats, with heterozygotes containing an intermediate amount. Furthermore, a 24 hour dehydration of these animals failed to elicit a further increase in this RNA as it did in controls. Longer dehydration or salt-loading experiments were difficult, for these animals would fail to survive even moderate salt-administration for more than 24 hours. To investigate whether homozygous animals expressed a dynorphin mRNA which was regulated differently than normals, we developed a means by which these rats could be chronically dehydrated without severe body weight loss or death. Animals were provided with 2% saline for 18 hours per day (from 4pm to 10pm), and with water for the remaining 6 hours. Body weights of homozygotes weighing 280-300 grams would lose up to 50-60 grams in an 18 hour dehydration, only to regain that and more in the hydration period. Control and heterozygote animals under this regiment fluctuated less widely. After a six day course of this treatment, individual PVN, SON and SCN areas were punched, and their isolated poly(A)RNAs examined by Northern analysis. Very little or no change in dynorphin mRNA content was recorded in the PVN and SCN areas, whereas, each group of normals, homozygotes, and heterozygotes had 2-3 fold increases in SON dynorphin mRNA levels. This finding is substantiated by in situ hybridization analysis for both dynorphin and AVP mRNAs with oligonucleotides. Work is continuing on estimating the total change in vasopressin mRNA in these nuclei, and whether or not changes can be detected between the expressionn of the normal versus the aberrant vasopressin mRNAs in heterozygotes.

46.4 QUANTITATIVE IN SITU HYBRIDIZATION STUDIES OF VASOPRESSIN AND SOMATOSTATIN mRNA DISTRIBUTIONS AND DYNAMICS. G.R. Uhl. Department of Neurology and Howard Hughes Medical Institute, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

Study of neuropeptide gene expression may provide a means for monitoring functional activities of peptidergic neuronal groups. In situ hybridization can allow quantitative detection of peptide-specific mRNAs with good anatomic resolution and can complement studies of mRNA populations in tissue extracts.

We have used a chemical/enzymatic "synprobe" technique to synthesize homogeneous single-stranded ^{3}H- and ^{35}S-radiolabeled cDNAs of 1500 and 12,000 Ci/mMole respectively. These probes can specifically recognize vasopressin and somatostatin mRNAs in brain sections.

Several physiologic conditions altering region-specific peptidergic activity alter mRNA hybridization in parallel fashion. Dehydration of rats doubles vasopressin hybridization in the supraoptic and paraventricular nuclei. Vasopressin releases related to hypoxia and to diurual cycles are also associated with regional mRNA level changes in preliminary studies. Conversely, vasopressin mRNA levels appear normal in hypothalamic nuclei of genetically vasopressin-deficient Brattleboro rats given free access to water.

Cells in different peptidergic neuronal groups may express substantial differences in peptide mRNA populations. Studies of somatostatin-hybridizing cells suggest that positive cells in the periventricular hypothalamus may express more than four times the hybridizable preprosomatostatin mRNA levels found in positive cells in the cerebral cortex or striatum. Levels of vasopressin hybridization in hypothalamic nuclei are substantially greater than levels found in extrahypothalamic zones thought to contain vasopressin-immunoreactive neurons.

Could these studies be applied to human brain tissue obtained postmortem? Using the rat (Spokes-Koch) model of the human postmortem process, we have found substantial stability of hypothalamic vasopressin mRNA up to twelve hours postmortem. Hybridization techniques can thus conceivably provide information about peptide mRNA variations related to involvement of peptidergic neurons in different brain circuits or different physiologic, genetic, and pathologic processes.

46.5 QUANTITATION OF VASOPRESSIN AND OXYTOCIN mRNA : AN IN SITU HYBRIDIZATION HISTOCHEMICAL STUDY OF NORMAL, ADRENALECTOMIZED AND BRATTLEBORO RATS. W. Scott Young, III*, Eva Mezey, and Ruth Siegel, Lab. of Cell Biol., NIMH, Bethesda, MD 20205

The levels of vasopressin (VP) and oxytocin (OT) in the supraoptic (SON) and paraventricular (PVN) nuclei change under various physiological stimuli. In contrast, VP is not detected in the brain of the Brattleboro rat. We have used in situ hybridization histochemistry to measure the mRNA levels in normal, adrenalectomized and Brattleboro rats to determine how they relate to peptide levels.

Sprague-Dawley rats were adrenalectomized (Adx) and perfused 2 weeks later with 4% paraformaldehyde and 10% sucrose. Some received colchicine 2 days prior to perfusion. Brattleboro rats were perfused similarly. Twelve micron thick frozen sections were hybridized with 48-base synthetic oligonucleotides directed toward the glycopeptide region of VP and N-terminus of OT. The probes were kinased with γ-^{35}S ATP. Sections and ^{35}S-impregnated brain-paste standards then were apposed to emulsion-coated coverslips for 4 days.

VP and OT mRNA-containing cells were found in the expected subdivisions of the SON and PVN. No labelling was seen with a VP probe of mRNA sense. In magnocellular neurons, we detected 7000 and 5200 VP mRNA copies in the SON and PVN, respectively. Adx raised the levels to 12,000 and 7000. Oxytocin mRNA levels were 8400 and 7300 with only a slight reduction, if any, after Adx. The parvocellular PVN contained about 10% of VP mRNA of the magnocellular PVN (by regional volume). Colchicine reduced levels of VP mRNA in all 3 areas before and after Adx with the exception of the Adx parvocellular PVN where levels increased, indicating a confounding effect of colchicine. Heterozygous Brattleboro rats had 8700 and 7300 copies of VP per SON and PVN magnocellular neuron, respectively. Homozygous rats had 30 to 50% fewer copies.

This study emphasizes the sensitivity of in situ hybridization histochemistry which will permit more detailed examinations of mRNA levels at steady state and after various stimuli. For example, our results show that Adx produces larger increases in the magnocellular than the parvocellular VP mRNA in the PVN.

Although magnocellular VP and OT mRNA levels are abundant, other mRNA species in lower amounts should be amenable to similar study. We do not know at present what percentage of the message we are detecting and this will likely be the limiting factor in absolute quantitation.

W.S.Y. is a Pharmacology Research Associate of NIGMS.

46.6 GLUCOCORTICOID SENSITIVE STIMULATION OF VASOPRESSIN mRNA SYNTHESIS IN THE PARAVENTRICULAR NUCLEUS. Frank Baldino,Jr. Betty Wolfson*, Rene Arentzen*, Robert W.Manning*, Jan Reid* and Leonard G. Davis. Central Research and Development, E. I. du Pont de Nemours and Co., Wilmington, DE 19898

Immunocytochemical studies have shown that adrenalectomy produces changes in the content and distribution of arginine-vasopressin (AVP) immunoreactivity in the paraventricular nucleus (PVN) of the hypothalamus. The purpose of this study was to determine whether glucocorticoids mediate the adrenalectomy-induced transcription of AVP mRNA within this region. In situ hybridization methodology with synthetic oligodeoxynucleotide probes and immunocytochemistry was used to detect the distribution of AVP-immunoreactive perikarya, AVP mRNA and alpha-tubulin mRNA. Probe specificity was determined by Northern blot hybridization against a rat AVP cDNA clone. The hybridization signal was detected with autoradiography on X-ray film or with photographic emulsion and quantitated with scanning densitometry. The results show that AVP mRNA is co-distributed with AVP immunoreactivity in the posterior magnocellular subdivision of the PVN and its accessory nuclei, the supraoptic nucleus (SON) and the suprachiasmatic nucleus (SCN). In adrenalectomized rats (7 days) the density of the hybridization signal is increased in the PVN and SON. Moreover, the distribution of AVP mRNA is altered in the PVN; a 3 fold increase in the area comprising the signal was observed. At the cellular level autoradiographic grains were detected in CRF-immunoreactive neurons throughout the medial parvocellular subdivision of the PVN. No changes were noted in the distribution of AVP mRNA in the SON or SCN. Although without effect in control animals, treatment with dexamethasone (240 µg/day for 7 days) prevented the increase in AVP mRNA produced by adrenalectomy. On the other hand, adrenalectomy did not influence the density or distribution of the hybridization signal produced by a probe for alpha-tubulin mRNA indicating that not all mRNA species are affected by this treatment.

These results demonstrate, at the cellular level, that adrenalectomy induces a glucocorticoid sensitive stimulation of AVP mRNA synthesis in the PVN. Thus considerable plasticity in gene expression is retained in the hypothalamus of the adult rat.

46.7 ANALYSIS OF PROOPIOMELANOCORTIN GENE EXPRESSION DURING RAT PITUITARY DEVELOPMENT BY IN SITU HYBRIDIZATION. D.I. Lugo and J.E. Pintar*. Dept. Anatomy and Cell Biology, Columbia Univ., P&S. New York, NY 10032.

The proopiomelanocortin (POMC) gene codes for a variety of peptide hormones which may have important functions during embryogenesis as well as post-natally. POMC gene expression has been detected as early as embryonic day 13 (e13) by hybridization of isolated nucleic acid to radiolabelled POMC probe. Moreover, POMC is synthesized at this stage and the pattern of POMC proteolytic cleavage resembles that of the adult intermediate lobe; it is not until e18 that peptides characteristic of the adult anterior lobe first appear. Although these data suggest that the intermediate lobe begins synthesis of POMC before the anterior lobe, immunocytochemical studies have shown that POMC peptide accumulation in the anterior lobe precedes the intermediate lobe by at least one day. Therefore, it is of interest to determine when and where in the pituitary POMC mRNA is first synthesized and whether changes in the relative amounts of POMC mRNA in the anterior versus the intermediate lobe coincide with specific developmental events. Since in situ hybridization can be used to determine both the cellular sites of specific mRNA and relative levels of a particular mRNA, we have used this approach to investigate POMC gene expression in the fetal and neonate rat pituitary gland.

Pregnant Sprague-Dawley rats were decapitated and the fetuses from day 12 (e12) to e20 were dissected. Young fetuses (less than e17) were fixed by immersion in 4% paraformaldehyde pH7 while older fetuses as well as neonate rats (post-natal day 1 (p1) to p17) were intracardially perfused; the pituitaries were then dissected, embedded and sectioned using a cryostat. The sections were hybridized with either P^{32}-labelled POMC cDNA and subsequently exposed to X-ray film or with H^3-labelled POMC cDNA and subjected to autoradiography. Experiments with P^{32}-labelled probe demonstrated higher film exposure over the intermediate lobe compared to other pituitary regions as early as e17. After 3.5 week exposure of sections hybridized with ^{3}H-labelled probes, most cells of the intermediate lobe and a few cells in the anterior lobe of e20 fetuses appeared labelled. Thus, by e20 the pattern of silver grains over the pituitary gland following in situ hybridization with POMC cDNA resembles that of the adult pituitary gland. Longer exposure times of sections from yonger embryos should prove effective in identifying sites of POMC gene expression at earlier ages. In addition, semi-quantitative comparison of grain densities over different pituitary cells from embryos of varied ages will provide an indication of the relative POMC mRNA levels and their variations during development.

Supported by HD-18952.

46.8 QUANTITATION OF POMC GENE EXPRESSION IN THE RAT PITUITARY AT THE LEVEL OF THE INDIVIDUAL CELL BY IN SITU HYBRIDIZATION. JL Roberts and JN Wilcox*, Center for Reproductive Sciences, Columbia Univ., College of Physicians and Surgeons, New York, NY 10032

The great advantage of in situ hybridization is its ability to resolve cDNA:mRNA hybrids at the level of the individual cell. This has many uses in localizing cells synthesizing an mRNA of interest. Perhaps the greatest potential of the technique is the possibility of quantifying specific mRNAs in individual cells. If the amount of cDNA in the hybridization reaction is saturating, then the amount of cDNA probe hybridized will be related to the amount of complementary mRNA in that cell. The number of silver grains over an individual cell should be related to the amount of radioactive cDNA probe hybridized, thus providing an estimate of mRNA levels in that cell. To demonstrate the potential of using this technique to study gene regulation at the cellular level we have used as a model the effect of glucocorticoids and dopamergic compounds on proopiomelanocortin (POMC) mRNA levels in individual cells of the rat pituitary.

In the present series of experiments we have been able to document changes in POMC gene expression in pituitary sections and in cell cultures by quantifying silver grains after in situ cDNA:mRNA hybridization. Female rats were injected ip with 1mg Bromocryptine (BROMO) per day for 1 or 3 days, the animals sacrificed and the pituitaries processed for in situ hybridization to a [3H] labelled POMC cDNA probe. After developing the slides the number of silver grains per cell were determined and paired with the cell area using a computer based grain counting system (Bioquant II, R&M Biometrics). A comparison of the grain densities (grains/pixels per sq mm) over individual cells of the intermediate pituitary indicated that there was a significant reduction in silver grain density to 50% and 26% of control after 1 or 3 days of BROMO treatment respectively.

In a separate experiment the effect of dexamethasone (DEX) was analyzed on cells in culture in which POMC mRNA levels are down-regulated by glucocorticoids. AtT20 cells were grown for 2 days in media containing 10^{-9}, 10^{-8}, 10^{-7}, or 10^{-6}M DEX. The slides were then fixed in ETOH:HAc and hybridized to a [3H] labelled POMC cDNA probe. Comparison of silver grain densities over individual cells treated with various concentrations of DEX indicated that there was a significant decrease in POMC mRNA to 65% of controls in cells treated with 10^{-6}M DEX.

Results from these experiments parallel known changes in POMC mRNA levels as previously determined by dot blot analysis and suggest that we can see significant changes in grain densities after in situ hybridization when mRNA levels differ by more than 2 fold.

46.9 LOCALIZATION OF POMC mRNA IN RELATED NEURONS FUNCTIONALLY DEFINED BY THEIR AXONAL PROJECTIONS: COMBINING IN SITU HYBRIDIZATION WITH FLUORESCENT AXONAL TRACING. J.N. Wilcox*,B.M. Chronwall, T.L. O'Donohue and J.L. Roberts. Center for Reproductive Sciences, Columbia Univ. P&S, New York, NY 10032 and NINCDS, NIH, Bethesda, MD 20205.

In situ cDNA:mRNA hybridization is a technique that has been developed for the visualization of cDNA:mRNA hybrids in individual cells. Recently this technique has received considerable attention as a method by which regulation of gene expression might be measured at the level of the individual neuron. However, to use this technique to study regulation of gene expression in the brain when the cell population under study does not respond uniformly, it will be necessary to divide hybridizing cells into functional subgroups that can be located in experimental and control tissues. Secondary techniques must be employed to define related cell types if there are no clear anatomical distinctions. With this problem in mind we have developed a procedure by which hybridizing cells may be classed according to their axonal projections by combining the techniques of in situ hybridization with retrograde axonal tracing of neurons using the fluorescent tracer Fast Blue (FB) on the same tissue section.

Cell bodies synthesizing proopiomelanocortin (POMC) mRNA are located in the periarcuate region of the rat hypothalamus. FB is injected by stereotaxic implant into the preoptic nucleus, a terminal field of the POMC system where it is taken up by axon terminals and fibers of passage. Animals are sacrificed 3 days after injection, 10 micron sections taken on a cryostat, and the tissue processed for in situ hybridization. Arcuate cells remain strongly labelled with the FB dye after in situ hybridization to a [3H] labelled POMC cDNA probe. By alternately viewing the slide under fluorescence or polarized light epilumenescence illumination it is possible to identify cells containing both FB and POMC mRNA. We estimate that about 10% of the POMC neurons detected by in situ hybridization in the medial arcuate region also project to the preoptic nucleus. Thus, this procedure sharply deliniates a small population of cells that project to the preoptic nucleus. Using these techniques it now becomes possible to measure mRNA regulation in functional subsets of neurons defined by their axonal projections.

46.10 LOCALIZATION OF CELLS CONTAINING PREPROENKEPHALIN mRNA IN THE RAT FOREBRAIN BY IN SITU HYBRIDIZATION. R.E. Harlan, B.D. Shivers*, G.J. Romano*, [1]R.D. Howells* and D.W. Pfaff. The Rockefeller University, New York, NY 10021 and [1]The Roche Institute for Molecular Biology, Nutley, NJ 07110.

Methionine enkephalin is cleaved from preproenkephalin, whose mRNA has recently been cloned and sequenced. Using a 435 bp cDNA complementary to mRNA coding for amino acids 56 through 200 of the rat preprohormone (Howells et al. PNAS 81:7651, 1934), we have localized cells in the rat brain containing this mRNA. The cDNA was nick translated to a specific activity of about 10^8 cpm/μg for ^{32}P or 10^7 cpm/μg for ^{3}H.

Cryostat sections of either paraformaldehyde-perfused brains soaked in sucrose containing 0.02% diethyl pyrocarbonate (DEP), or fresh-frozen, sectioned brains postfixed in paraformaldehyde containing 0.02% DEP were incubated in prehybridization buffer, followed by hybridization buffer (including 0.6 M NaCl and 50% formamide) containing labeled cDNA (50,000-125,000 cpm/20 μl for ^{32}P; 10,000-30,000 cpm/20 μl for ^{3}H) for 3 days at room temperature or 37 C. Sections were rinsed twice, ten minutes each in 2X SSC (1X SSC = 150 mM NaCl, 15 mM Na citrate) including 0.05% inorganic pyrophosphate, followed by 36-48 h of 0.5X SSC, 0.05% inorganic pyrophosphate, all at room temperature. Following dehydration, the sections were dipped in emulsion, and exposed at 4 C for 10-30 days for ^{32}P and 14-51 days for ^{3}H. Autoradiograms were developed and the sections stained with fast green and cresyl violet.

Controls: Sections incubated in hybridization buffer:formamide without probe, or pretreated with RNase before hybridization contained no labeled cells.

In the forebrain, well-labeled cells were located in: anterior olfactory nucleus (especially medial); frontal cortex; piriform cortex; caudate/putamen (especially in lateral aspects); nucleus accumbens; olfactory tubercle; diagonal bands of Broca; lateral septum; preoptic area (medial and lateral); bed nucleus of the stria terminalis; amygdala (especially the central nucleus); paraventricular nucleus; anterior hypothalamus; perifornical region; ventromedial hypothalamic nucleus (especially ventrolateral); dorsomedial hypothalamic nucleus (especially caudal part of ventral division); lateral hypothalamus; arcuate nucleus; premamillary nuclei (dorsal and ventral); medial mamillary nucleus and lateral geniculate. Analysis of midbrain, hindbrain and spinal cord is in progress.

In most cases, these results correlate well with those based on immunocytochemistry, although in situ hybridization revealed many more labeled cells. In situ hybridization has not demonstrated, to date, neurons that can synthesize preproenkephalin in the hippocampus or some cortical areas, as suggested by immunocytochemistry.

46.11 LOCALIZATION OF CELLS CONTAINING LHRH-LIKE mRNA IN RAT BRAIN. B.D. Shivers*, R.E. Harlan, [1]J.F. Hejtmancik*, [2]P.M. Conn*, and D.W. Pfaff. The Rockefeller Univ., NY, NY 10021, [1]Baylor College of Medicine, Houston, TX 77030, [2]Univ. of Iowa, Iowa City, IA 52242.

The purpose of this study was to localize neurons in the rat brain which synthesize the reproductive peptide, luteinizing hormone-releasing hormone (LHRH) by in situ hybridization. Rat brain sections were probed with two synthetic, radiolabeled oligomers complementary to different portions of the human LHRH mRNA sequence (Seeburg and Adelman, Nature 311: 666, 1984), and the formation of hybrids was detected autoradiographically.

Probe 1 was a 59-mer complementary to the sequence coding for amino acids -5-20 of the proposed human LHRH preprohormone which includes the region coding for the decapeptide. Probe 2 was a 60-mer complementary to a sequence in the open reading frame of human LHRH mRNA coding for amino acids 33-52. These oligomers were end-labeled with either (γ-^{32}P)ATP and T4 polynucleotide kinase, or (^{3}H)CTP and terminal transferase. Sections received 50,000-150,000 cpm/20μl for ^{32}P oligomers, or 12,000 cpm/20μl for ^{3}H oligomers.

Following incubation in prehybridization buffer:50% formamide to reduce nonspecific binding, 10μm sections of frozen, paraformaldehyde-fixed, diethyl pyrocarbonate-treated female rat brains (n=8) were hybridized for 3 days in a buffer which included 0.6M NaCl and 50% formamide and then rinsed two times, ten minutes each in 2xSSC (1xSSC= 0.15M NaCl; 15mM Na citrate) including 0.05% inorganic pyrophosphate followed by two rinses, in 48 hours, of 0.5xSSC, 0.05% inorganic pyrophosphate, all at room temperature. Sections were then dehydrated, dipped in emulsion, exposed at 4 C, the autoradiograms developed, and the sections stained with fast green and cresyl violet.

Autoradiogram exposures of 3-4 weeks for ^{32}P-labeled probe 1, and 60 days for ^{3}H-labeled probe 1 yielded labeled cells distributed in forebrain regions shown previously to contain immunoreactive LHRH cell bodies (Shivers et al. Neuroendocrinology 36: 1, 1983). The majority of probe 1-labeled cells were in the diagonal bands of Broca and the medial preoptic area. Some labeled cells were observed in the anterior hypothalamic area and were often found immediately dorsal to the supraoptic nuclei. Occasionally a labeled cell was observed in the medial basal hypothalamus. Labeled cells often appeared fusiform in shape.

Sections incubated in hybridization buffer:formamide without probe, or pretreated with RNase before hybridization, or hybridized with probe 2 contained no labeled cells.

Additional studies will be required to characterize the LHRH-like mRNA contained in these cells, and to determine whether its message level is regulated by steroids.

46.12 LOCALIZATION OF GLUTAMATE DECARBOXYLASE (GAD) MRNA IN MOUSE BRAIN BY IN SITU HYBRIDIZATION. C.W.Wuenschell*[1], R.S.Fisher[2], and A.J.Tobin[1] (SPON: N.Wexler). [1]Dept. of Biology and Molecular Biology Institute, and [2]Mental Retardation Research Center, Univ. of California, Los Angeles, CA 90024.

We are using in situ hybridization to locate specific mRNAs in individual cells in mouse brain in order to assess gene expression during development. In this initial report, adult mouse brain revealed GAD mRNA-containing cells in all the major brain regions known to contain cells positive for the GAD enzyme.

We have subcloned our GAD cDNA into the transcription vector pSP65 in both orientations with respect to the viral-specific promoter. Transcription from these two templates by the sp6 viral polymerase produces either "antisense" RNA molecules complementary to the mRNA, which can be used as a hybridization probe for mRNA, or RNA identical in sequence to the mRNA which serves as a negative control.

In situ hybridization was performed on 10 um frozen sections fixed with 4% paraformaldehyde. RNA probes were labeled with ^{35}S to specific activities of 3-5 X 10^8cpm per microgram. Hybridizations were performed overnight at temperatures ranging from 42° to 50° in 50% formamide, 750 mM NaCl. Following hybridization, non-specifically bound probe was removed by treatment with ribonuclease A, followed by washing at 43° in 0.1 X SSC and defatting with xylene. Autoradiographic detection was performed with Kodak NTB2 emulsion.

The antisense hybridization probe labeled many scattered cells throughout the globus pallidus, caudate-putamen, and the inferior and superior colliculi. In the cerebral cortex, stellate neurons appeared to be labeled, as did a sparse population of basket cells in the hippocampus. The negative control probe gave randomly distributed silver grains in all of these areas. Purkinje cells of the cerebellum and, to a lesser extent, granule and periglomerular cells of the olfactory bulb appeared to be labeled more heavily by the antisense than by the negative control probe.

47.1 3-D ANALYSES REVEAL SUBPOPULATIONS OF LHRH NEURONAL CELL BODIES FOLLOWING GONADECTOMY. King, J.C., G. Kugel*, D. Zahniser*, K. Wooledge* and D.A. Damassa. Department of Anatomy and Cellular Biology and the Image Analysis Laboratory, Tufts-New England Medical Center. Boston, MA 02111. Neuronal cell bodies capable of synthesizing LHRH are widely dispersed over several nuclear groups of the basal hypothalamus. If only some LHRH neurons, and not the entire population, increase secretion following gonadectomy, this change in activity might not be detected by RIA. It was the purpose of this study to specify subpopulations of LHRH cells identified by immunocytochemistry in male and female rats, one day, six days and three weeks after gonadectomy. The immunoreactive species of LHRH detected within neuronal cell bodies did not change in any endocrine condition. Only antisera capable of binding extended forms of decapeptide detected LHRH within neuronal perikarya and not antisera requiring either the amidated Gly C terminal or both amidated Gly C terminal and cyclicized Glu N terminal. Populations of LHRH cells were reconstructed in three dimensions across the basal forebrain using computer assisted techniques. Comparisons between populations were made by simultaneous viewing two or more color-coded reconstructed populations. We have previously reported sex differences in changes in the size of LHRH populations following gonadectomy. Further analyses indicate that variations in populations occurred largely in subgroups of neurons that surrounded a central core of neuronal cell bodies in which LHRH was detected in both males and females regardless of the endocrine condition. The core subgroup consisted of cells in several preoptic nuclei, the rostral preoptic area, periventricular preoptic and ventral preoptic areas. Peripheral subgroups layered in an onion-skin fashion about this central core and extended into the diagonal band of Broca, lateral preoptic and anterior hypothalamic regions and medial septal nucleus. We suggest that subgroups receive different types of afferent input and that changes in afferent stimulation to peripheral, but not core, subgroups are induced by gonadectomy. This work was supported by NSF PCM8402540.

47.2 IMMUNOLOCALIZATION OF THE TRH PROHORMONE IN THE RAT CENTRAL NERVOUS SYSTEM. R.M. Lechan, Ping Wu*, Serene Forte* and Ivor M.D. Jackson. Divisions of Endocrinology, Tufts-New England Medical Center, Boston, MA 02111 and Brown University, Rhode Island Hospital, Providence, R.I. 02902.

To study the distribution of the TRH prohormone in the rat CNS, we raised an antiserum (342) against a synthetic, cyclic decapeptide, cys-lys-arg-gln-his-pro-gly-lys-arg-cys (ProTRH-SH), based on the deduced amino acid sequence of the frog skin TRH precursor (Richter et al, EMBO, J. 3, 617, 1984). Brain tissue was fixed with 4% paraformaldehyde by intracardiac perfusion and sectioned on a vibratome. All immunocytochemical studies were performed by the indirect peroxidase-antiperoxidase technique using antiserum #342 at a final dilution of 1:750 containing 0.2% Triton X-100.

Immunoperoxidase was present predominantly within the cytoplasm of neuronal perikarya, closely juxtaposed to the nucleus, and conspicuously absent from axon terminals. Similar to the distribution of the tripeptide, TRH, in rat brain (Lechan and Jackson, Endocrinology, 111, 55, 1982), neurons immunoreactive for proTRH were present in the hypothalamus, preoptic area and medullary raphe. In addition, immunoreactive proTRH was present in neurons in the glomerular and external plexiform layers of the olfactory bulbs, caudate-putamen complex, hilus of the dentate, amygdala, central gray, pontine nuclei, dorsal raphe, cochlear nuclei, nucleus solitarius and flocculus of the cerebellum. Unique to the cerebral cortex, the soma of some neurons in layer II were observed to contain immunoreactive material within a large, cytoplasmic inclusion, often extending into first order dendrites or the axon hillock. All immunoreaction product was abolished by preincubation with Pro-TRH-SH at 10^{-6}M but not TRH at 10^{-5}M.

These studies support the belief that TRH biosynthesis in the mammalian CNS occurs by posttranslational cleavage of a larger precursor protein and indicates that processing of the prohormone occurs primarily within the neuronal cell body. In addition, immunoreactive proTRH appears more widely distributed than TRH. This raises the possibility that the prohormone could be processed to intermediate forms that would not be recognized by an antiserum specific for p-glu-his-pro-NH_2, TRH.

47.3 ELECTRON MICROSCOPIC LOCALIZATION OF ANGIOTENSIN AND ANGIOTENSIN CONVERTING ENZYMES IN THE RAT SUBFORNICAL ORGAN. V.M. Pickel, J. Chan*, D. Ganten[1] and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021 and [1] German Institute of High Blood Pressure Res., Univ. of Heidelberg, Heidelberg, Germany.

The octapeptide, angiotensin II (AgII) is a circulating hormone and a putative transmitter in neural circuits involved in drinking and blood pressure regulation. The humoral and neural pathways containing AgII overlap in regions of the central nervous system (CNS) which are outside the blood-brain barrier including the subfornical and certain other circumventricular organs. Immunocytochemical labeling with the peroxidase-antiperoxidase method alone or combined with immunocolloidal gold was used to examine the ultrastructural localization of angiotensin and angiotensin converting enzyme (EC 3.4.15.1), generously supplied by Dr. R.J. Soffer, Cornell Univ. Med. College, in the subfornical organ of adult male rats. The antisera (CE and DE) to angiotensin cross-reacted most extensively with Ag II and III. Angiotensin-like immunoreactivity (AGLI) was diffusely localized in the extracellular spaces near blood vessels, in a few perikarya and dendrites and in numerous axon terminals. The axon terminals contained small clear and large dense core vesicles and made synaptic contacts principally with dendrites. In addition to the diffuse cytoplasmic labeling, pinocytotic and multivesicular bodies in dendrites, perikarya and terminals also contained AGLI. The immunoreactivity for angiotensin converting enzyme was found on the luminal surface of blood vessels, the apical and basal surfaces of certain ependymal cells, the plasmamembranes of intrinsic neurons, and througout a few small axon terminals. In dual localization studies employing peroxidase and colloidal gold markers, AGLI and the converting enzyme were associated with a few neuronal perikarya and processes. We conclude that the humoral and neuronal afferents containing AGLI coverage on neurons in the subfornical organ and that the converting enzyme has a localization compatible with a role in generation of angiotensin II in the cerebrospinal fluid, in the extracellular spaces from plasma constituents and within neurons in the subfornical organ. (Supported by NIH grants HL18974 and MH00078.)

47.4 **LOCALIZATION OF IMMUNOREACTIVE MET-ENKEPHALIN IN WIDELY DISPERSED INDIVIDUAL VESICLES IN THE GLOBUS PALLIDUS.** H. D. Coulter. Dept of Anatomy, Univ of Minn, Minneapolis, MN 55455.

The purpose of this study was to determine the subcellular location of immunoreactive met-enkephalin in tissue not treated with aqueous fixatives and dehydration media. Globus pallidus from rats was frozen at liquid helium temperature, dried in a freeze-drying apparatus, fixed with osmium tetroxide vapor, and embedded in epoxy resin. 25-100 nm thick serial sections were placed on glass slides for light microscopy and on grids for electron microscopy. Sections on slides were treated with alcoholic NaOH to remove resin, 3% hydrogen peroxide, anti-met-enkephalin (R451 from Immunonuclear at 1:100), and FITC-labeled sheep anti-rabbit IGG. Grids were stained with anti-met-enkephalin at a dilution of 1:30,000 followed by goat anti-rabbit IGG labeled with colloidal gold. For control experiments, serial sections were treated with antisera pre-absorbed with 0.1 mM met-enkephalin. Fluorescence images were obtained with a silicon-intensified-tube television camera. Photographs were taken directly from the television monitor, and printed at a final magnification of 7500 X. Electron microscopic negatives were printed at the same magnification for direct comparison.

Staining was represented in the light microscope by scattered 200-400 nm areas of fluorescence. The positive staining represented flaring of much smaller structures, because fluorescence images in serial experimental sections could not be correlated with one another except in sections thinner than 50 nm. In the electron microscope, colloidal gold was found associated with 80-100 nm vesicles, of average electron density, widely dispersed in the neuropil. Usually one and no more than four vesicles were found in profiles of individual neuronal processes. Adjacent absorption control sections were negative both in the light and electron microscope.

In immunocytochemical studies carried out with pre-embedding staining, immunoreactivity for enkephalin is widely dispersed throughout the cytoplasm of positive cells, with staining found on mitochondria, neurotubules, vesicles of various types, nuclei, and background cytoplasm. In contrast, this approach utilizes post-embedding staining of ultrathin sections of frozen-dried tissue. It reveals precise subcellular localization of immunostaining in a peculiar class of vesicles, overlooked until now, that are found primarily in axonal processes. Supported by NSF grant BNS 80-21004 and NIH grant RO1 NS 18428.

47.5 DIFFERENTIAL PROJECTIONS OF LOCUS COERULEUS NEURONS CONTAINING TYROSINE HYDROXYLASE AND NEUROPEPTIDE Y AND/OR GALANIN. V.R. Holets[1], T. Hökfelt[1]*, L. Terenius[2]* and M. Goldstein[3]. Dept. of Histology 1, Karolinska Institute, Stockholm, Sweden, Dept. of Pharmacology[2], Uppsala Univ., Uppsala, Sweden and Neurochem. Res. Lab.[3], New York Univ. Medical Center, New York, NY.

Populations of locus coeruleus (LC) neurons contain the peptides neuropeptide Y (NPY) and/or galanin (GAL) together with noradrenaline. In the present study, we investigated the projections of these populations of LC neurons to the cerebral cortex (CTX), hypothalamus (HYP) and spinal cord (SC) using retrograde tracing combined with immunohistochemistry.

Rats (n=4 for each group) were injected with Fast Blue (1% in distilled water) 3 days before receiving an intraventricular injection of colchicine. The following injections were made: simultaneous injections into 5 sites in the right CTX, a unilateral injection into the paraventricular and dorsomedial nuclei of the HYP and bilateral injections into the T6 segment. The animals were perfusion fixed 24-36 hr after the colchicine injection. The LC and the injection sites were sectioned (10 µm serial sections) and photographed for Fast Blue labeling. Adjacent sections were then processed for immunohistochemistry using antisera raised against NPY, tyrosine hydroxylase (TH) and GAL. Photographs of the sections were compared to the photographs of the Fast Blue labeling. The number of Fast Blue neurons labeled, the number of TH-, NPY- and GAL-immunoreactive neurons and the number of neurons which contained TH-, NPY- or GAL- immunoreactivity and Fast Blue were counted.

99.17% ± 0.37 (S.E.M.) of the LC neurons contained TH immunoreactivity. Of the total population of TH neurons in the LC, 25.45% ± 2.04 contained NPY and 83.55% ± 0.74 also contain GAL. Following injections into the HYP: 16.07% ± 2.69 of the NPY immunoreactive neurons, 14.21% ± 2.97 of the TH immunoreactive neurons and 15.93% ± 2.47% of the GAL immunoreactive neurons also contained Fast Blue. Following injections into the CTX: 3.20% ± 0.16 of the NPY neurons, 13.82% ± 0.66 of the TH neurons and 4.37% ± 0.32 of the GAL neurons were also retrogradely labeled. Following injections into the SC: 7.97% ± 0.70 of the NPY neurons, 14.51% ± 2.26 of the TH neurons and 5.07% ± 0.55 of the GAL neurons were also retrogradely labeled.

A differential projection to the CTX, HYP and SC of those LC neurons which contain NPY versus those which contain GAL was observed. This may point out functional divisions in the LC based on the peptide contained within the neurons and their afferent projections.

Supported in part by a Fogarty International Fellowship from the S.M.R.C. (V.R.H.) and S.M.R.C. Grant 04X-2887 (T.H.).

47.6 COLOCALIZATION OF NEUROPEPTIDES IN AFFERENT PATHWAYS TO THE URINARY BLADDER AND COLON: DEMONSTRATION WITH DOUBLE COLOR IMMUNOHISTOCHEMISTRY IN COMBINATION WITH AXONAL TRACING TECHNIQUES. M. Kawatani, M.B. Houston*, M. Rutigliano*, S. Erdman*, and W.C. de Groat, Dept. Pharmacology, Univ. of Pittsburgh, Pittsburgh, PA, 15261.

A major part of the afferent innervation to cat urinary bladder and colon originates in the sacral dorsal root ganglia (DRG) and is carried in the pelvic nerve (PN). Previously we have shown that a large percentage of visceral afferent neurons projecting to the PN contain neuropeptides (eg., VIP 42%, leucine enkephalin (LENK) 30%, substance P (SP) 27%, and CCK 23%). The total percentage of cells containing individual peptides exceeded 100% indicating that some of these visceral afferent neurons must contain more than one peptide.

This possibility was examined using axonal tracing methods (fluorescent dyes; fast blue and diamidino yellow) in combination with immunohistochemical techniques to identify two peptides on the same section. Different dyes were injected into the bladder or colon wall 7-20 days prior to sacrifice. Colchicine (5 µg) was injected into sacral DRG 31-48 hrs before sacrifice to increase peptide levels. Peptide immunoreactivity was examined using two techniques: (1) a double staining technique in which two antisera prepared in different species were applied to the same sections, then processed with bridge antibodies linked to different fluorochromes (FITC and TRITC) or (2) application of one antiserum to a series of individual thin (6 µm) cryostat sections, where DRG cells could be identified on multiple sections.

Bladder afferent neurons (BA) and colon afferent neurons (CA) which were small to medium size (<40 µ m) were present in the S1-S3 DRG with the largest numbers in S2. BA exceeded the number of CA by 50-100%. Dye injected into the colon also labeled 1-2% of BA. Approximately equal proportions of BA and CA contained SP (32% vs 27%) and LENK (10% vs 12%), however, VIP was present in a considerably higher percentage (50% vs 12%) of BA. Somatostatin was present in a low percentage (<1%) of BA and CA.

Double color immunohistochemistry revealed that 20% of BA contained both VIP and SP. Other combinations of peptides, eg., VIP-LENK, SP-LENK were present in less than 10% of BA and CA. This is in contrast to the more prominent colocalization noted in the general population of sacral DRG cells eg., VIP-SP 60-80%, LENK-SP 40-65%, VIP-LENK 20-40%.

In summary the present results indicate that several types of neuropeptides are present in sacral afferent pathways to the colon and bladder. VIP was most prominent in bladder afferents whereas other peptides were present in both afferent pathways. Certain peptides (VIP-SP, VIP-LENK) were colocalized in these pathways.

47.7 GABAERGIC, SUBSTANCE P-IMMUNOREACTIVE NEURONS IN MONKEY CEREBRAL CORTEX E.G. Jones and S.H.C. Hendry Dept. of Anatomy, University of Calif., Irvine, Irvine, CA 92717

Using immunocytochemical methods, we have discovered a large population of substance P immunoreactive neurons in the monkey cerebral cortex. Sections from monkeys (Macaca fascicularis) perfused with 2% paraformaldehyde and 0.1% glutaraldehyde were incubated in a rat monoclonal antibody to substance P. The anti-substance P antibody was localized with either the avidin-biotin method, using 3,3'-diaminobenzidine HCl as a chromogen, or with an FITC-conjugated goat anti-rat IgG. Control experiments were done using anti-substance P antibody adsorbed with an excess of substance P, bombesin, caerulein, somatostatin, neuropeptide Y and cholecystokinin. The staining was blocked only after substance P adsorption. Substance P positive neurons are exclusively non-pyramidal cells and are present in all areas of the monkey cerebral cortex. The stained cell bodies and processes form two populations: 1) a minority of cell bodies are intensely stained and give rise to long prominently beaded processes. In each area of the cortex, these cells are widely scattered throughout the layers but are most numerous in the subcortical white matter. 2) The majority of substance P positive cell bodies are lightly stained and seldom give off stained processes. They are, instead, embedded in a neuropil that contains numerous, small punctate profiles that are also lightly stained. A marked difference exists among areas of the cerebral cortex in the density and laminar distribution of the lightly stained cell bodies and profiles. They are most numerous in areas of the prefrontal and temporal cortex, in areas of the superior parietal cortex and in area 18 of the occipital cortex. In these areas the cells are clustered in layers IV and V. Relatively few of the cells are found in the granular sensory areas (area 17 and areas 3b,1 and 2) or in the precentral motor area (area 4); there they occur mainly in layers II-III and VI. Using methods for simultaneous detection of two antigens by immunofluorescence, we have found the cell bodies and punctate profiles lightly stained for substance P to be also immunoreactive for GABA. The intensely stained substance P cell bodies and processes display no GABA immunoreactivity but they are also stained for neuropeptide Y. Numerous GABA and NPY immunoreactive are not stained for substance P. We conclude that two populations of substance P neurons exist in the monkey cerebral cortex; one is also GABA positive, gives rise to numerous punctate profiles and varies markedly in density and distribution among areas. The other is also neuropeptide Y positive, gives rise to long beaded processes and in each area consists of neurons present mainly in the subcortical white matter. Supported by NIH Grant NS 21377.

47.8 **INNERVATION OF FOREBRAIN STRUCTURES BY VENTRAL MESENCEPHALIC NEURONS CONTAINING BOTH CHOLECYSTOKININ-AND TYROSINE HYDROXYLASE-LIKE IMMUNOREACTIVITIES: A FLUORESCENT TRIPLE-LABELING STUDY.** K.B. Seroogy, K. Dangaran, S. Lim, and J.H. Fallon. Department of Anatomy, University of California, Irvine, CA 92717.

The distribution and forebrain projections of dopamine-containing cells in the midbrain substantia nigra-ventral tegmental area (SN-VTA) have been thoroughly described. Recent work from our laboratory has demonstrated the forebrain projection patterns of cholecystokinin (CCK)-containing neurons in this same region. CCK and tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine synthesis, have been co-localized within subpopulations of these mesencephalic neurons. The purpose of this study was to describe the forebrain projections of those neurons of the SN-VTA containing both CCK and TH and to determine if these projections are distinct from those of neurons containing TH or CCK alone.

The technique of indirect immunofluorescence for two antigens combined with fluorescence retrograde tracing was used. Adult female albino rats received .04-.15 ul injections of the fluorescent dyes Fast Blue or Stilbene Gold into the prefrontal cortex (PFC), caudate-putamen (CP), nucleus accumbens (NAC), or amygdala (AMY). Four to six days later, colchicine was injected intracerebroventricularly and locally near the SN-VTA. After one or two days, the animals were perfused and cryostat tissue sections immunocytochemically processed for the simultaneous localization of TH and CCK using sheep anti-TH (supplied by J. Haycock, Rockefeller Univ.) and rabbit anti-CCK (Immunonuclear Corp.).

The distribution of cells in the SN-VTA containing only TH, only CCK, or both TH and CCK immunoreactivities was similar to previous reports although a higher incidence of co-localization was observed in this study. In all cases following tracer injection into each of the forebrain areas, neurons in the SN-VTA were found to be triple-labeled with both CCK and TH immunoreactivities plus the retrogradely transported dye. With the injection of tracer into the PFC or NAC, triple-labeled neurons were primarily located in the middle VTA. After dye injection into various loci of the CP, triple-labeled neurons were mainly found in the medial SN, with relatively fewer observed in the lateral VTA and middle SN. Following tracer injection into the AMY, the majority of triple-labeled cells were located in the SN pars lateralis and lateral SN. Generally, cells double-labeled for CCK immunoreactivity and dye were located more dorsally in the SN-VTA, whereas cells double-labeled with TH immunoreactivity and dye were found more ventrally throughout this region. These results indicate that CCK projections of the SN-VTA parallel the ascending dopaminergic projections of this area. Particularly noteworthy is the presence of dye-labeled, CCK immunoreactive neurons with or without TH immunoreactivity following injection placement in the CP which suggests that CCK is more significantly involved in the nigrostriatal pathway than previously thought. (Supported by NSRA 5F31MH09090 from NIMH to K.B.S. and NIH grant NS 15321 to J.H.F.)

47.9 LIGHT AND ELECTRON MICROSCOPIC CHARACTERIZATION OF SOMATOSTATIN IMMUNOREACTIVE NEURONS IN RAT VISUAL CORTEX. D. L. Meinecke* and A. Peters. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

Results of studies using antisera to somatostatin (SOM), a potential neuromodulator, to examine the types and distribution of SOM immunoreactive neurons in the rat visual cortex have been conflicting. Some authors report these neurons belong to certain non-pyramidal classes, while others include non-pyramidal neurons and some pyramidal neurons. To better identify the types of SOM immunoreactive neurons in the rat visual cortex, and to resolve whether or not they include pyramidal neurons, we used antisera to SOM (Dako) to examine immunoreactive neurons in the light and electron microscope. Adult Sprague-Dawley rats were anesthesized and perfused with buffered solutions of 4% paraformaldehyde for light microscopy, or 5% acrolein for electron microscopy. Blocks of visual cortical areas were cut into 20-40 um slices on a vibratome, reacted with SOM antisera, and immunostained with the Avidin/Biotin system (Vector). SOM immunoreactive neurons were present in all layers of the visual cortex, but were concentrated in layers II/III and V/VI. We could identify bipolar, multipolar, bitufted, horizontal, and subcortical white matter cells. SOM immunoreactive bipolar neurons were present in equal numbers in layers II/III and V/VI and measurements of their sizes revealed they included both the small and large varieties described by Peters and Kara (J. Comp. Neurol. 234:242-263, 1985). Ultrastructurally both large and small bipolar neurons had clefted nuclei, and the large bipolars had prominent stacks of ER at both poles of their cell bodies. Immunoreactive multipolar neurons were also present in layers II/III and V/VI and had rounded cell bodies with several randomly oriented dendrites. Some of these neurons had thin dendrites while others had two or more stout dendrites which tapered as they left the cell body. In the EM, multipolar neurons had folded nuclei and made asymmetric and symmetric axosomatic synapses. Some immunoreactive neurons resembled pyramidal cells because they had a thick, tapering ascending dendrite which soon branched and other prominent dendrites extending from the base of the cell body. These proved to be non-pyramidal neurons, for when examined in the EM their somas possessed asymmetric synapses, and their dendrites lacked spines. Consequently, we suggest that they belong to the population of multipolar neurons with stout dendrites. These results demonstrate SOM immunoreactive neurons all belong to non-pyramidal neuronal classes, some of which use GABA, and others acetylcholine as their putative neurotransmitter.

47.10 **PROOPIOMELANOCORTIN-DERIVED NEUROPEPTIDE IMMUNOREACTIVE CELLS OF THE VENTROMEDIAL ARCUATE NUCLEUS ESTABLISH DIRECT SYNAPTIC CONNECTIONS WITH LH-RH NEURONS OF THE MEDIAL PREOPTIC AREA IN THE RAT** Leranth, Cs., MacLusky, N.J. and Naftolin, F. (SPON: W. Collins) Section of Neuroanatomy and Dept. of Obstetrics and Gynecology, Yale University Medical School, New Haven, CT 06510

Pharmacologic evidence suggests that hypothalamic opioid peptide-containing neurons are involved in the control of LHRH release. The present studies were performed to determine whether direct synaptic connections exist between cells in the arcuate nucleus which contain proopiomelanocortin (POMC)-derived peptides (ACTH, β-endorphin, α-MSH) and LHRH-containing neurons in the preoptic area. To establish whether axons from POMC peptide-containing cells form synapses in the preoptic area, rats were pretreated with colchicine (Sigma; 80μg into the lateral ventricle) 24h prior to sacrifice then perfusion fixed (Somogyi and Takagi, Neuroscience 7:1779, 1982). The brains were sectioned on a Vibratome and immunostained for POMC-derived peptides using the peroxidase ABC technique (Hsu et al, J. Histochem. Cytochem. 29:577, 1981). Immunoreactive axo-dendritic synapses were observed most frequently in the medial and ventrolateral parts of the preoptic area. In the medial preoptic area, the synaptic contacts were primarily on dendritic shafts, while in the ventrolateral region they were on dendritic spines. To determine whether some of these synapses might terminate directly on LHRH-immunoreactive cells, we used a recently developed pre-embedding double-label electron microscopic immunostaining procedure in which peroxidase and avidin-ferritin serve as contrasting electron-dense markers (Leranth et al, Histochemistry 82:165, 1985). Direct synaptic connections were observed in the medial preoptic area between axons immunoreactive for the POMC-derived peptides and the dendritic shafts of LHRH neurons. To study the origin of these axons, a combination of immunocytochemical and retrograde horse radish peroxidase (HRP) tracing techniques was employed. Animals were injected with HRP in the medial preoptic area. Two days later, Vibratome sections through the arcuate nucleus were immunostained for ACTH and reacted for HRP using the diaminobenzidine-glucose oxidase method (Zaborszky et al Neuroscience Letters 52:219,1984). The majority of ACTH-immunoreactive perikarya were HRP-negative. HRP-labeled ACTH-immunoreactive neurons were observed primarily in the ventromedial arcuate nucleus, close to the third ventricle. HRP-labeled but ACTH immunonegative neurons were observed distributed throughout the arcuate nucleus. These studies suggest that a subpopulation of POMC neurons in the ventromedial arcuate nucleus may modulate the activity of LHRH cells in the preoptic area through a direct synaptic connection. (Supported by grant HD13587 from NIH, NICHHD and the A. Mellon Foundation.)

47.11 SUBSTANCE P-, CALCITONIN GENE-RELATED PEPTIDE-AND CHOLECYSTOKININ/GASTRIN-LIKE IMMUNOREACTIVE TRIGEMINAL GANGLION CELLS SUPPLY THE EYE: QUANTITATIVE EVALUATION USING IMMUNOHISTOCHEMISTRY AND RETROGRADE TRACING. Y.Kuwayama*, R.A.Stone, G. Terenghi*[1], and J.M.Polak[1]. Department of Ophthalmology, University of Pennsylvania School of Medicine, Scheie Eye Institute, Philadelphia, PA. 19104; and [1]Department of Histochemistry, Hammersmith Hospital, London W12 OHS, U.K.

Using immunohistochemical techniques, substance P (SP), calcitonin gene-related peptide (CGRP) and cholecystokinin/gastrin (CCK) have been localized to peripheral ocular nerve fibers; these nerves are believed to originate in the trigeminal ganglion. In the present study, the combination of immunohistochemistry and retrograde axoplasmic tracing not only confirmed the trigeminal origin of these nerves but also established their quantitative relationship.

Under general anaesthesia, guinea pigs received intraocular injections of the cholera toxin B subunit conjugated to fluorescein isothiocyanate (B-FITC). Two days later, the animals were perfused under pentobarbital anaesthesia with Zamboni's fixative. Sequential cryostat sections of trigeminal ganglia were stained by an indirect immunofluorescence technique with primary antisera to SP, CGRP, and cholecystokinin-octapeptide and with a rhodamine-conjugated secondary antiserum.

Within the entire trigeminal ganglion, the comparative ratio of immunoreactive nerve cells was SP:CGRP:CCK=1:3:0.2. Retrograde labelling of neurons by B-FITC was seen only in the anteromedial region of the ipsilateral trigeminal ganglion. Approximately 5-10% of all B-FITC labelled cells were immunoreactive for SP; 20%, for CGRP; and less than 1%, for CCK.

47.12 THE ORIGIN OF CALCITONIN GENE-RELATED PEPTIDE (CGRP)-IMMUNOREACTIVE NERVES IN THE URINARY TRACT. J. Wharton*, H.C. Su*, T. Katagiri*, M.A. Ghatei*[1], P.K. Mulderry*[1], J. Ballesta*, S.R. Bloom[1] and J.M. Polak. Department of Histochemistry and [1]Medicine, Royal Postgraduate Medical School, London W12, U.K.

We report here the distribution and origin of CGRP- immunoreactive (CGRP-IR) afferents in the urinary tract by combined immunocytochemistry and retrograde labelling with True blue. Adult rats and guinea pig were used (200-300 gm) and anaesthetised with Diazepam (10 mg/kg^{-1} i.p.) and Hypnorm (5 mg/kg^{-1} i.p.). True blue (5% w/v) was injected at 2 - 3 sites (1-6μl total volume) in the rat kidney (hilum), ureter, bladder (dome and trigone), and upper urethra. All injections were on the left side and 4 rats were used per area. Seven days after injection they were perfused transcardially with phosphate buffered saline (PBS) and 4% paraformaldehyde. Animals were also treated with capsaicin, either as neonates (rats; 50 mg kg^{-1} s.c. on the 2nd and 3rd day after birth) or adults (guinea pigs; stepwise over 5 days with 25, 50, 100, 200 and 400 mg kg^{-1} s.c. or i.p.). Controls received vehicle alone (10% alcohol, 10% Tween 80 and 80% saline). Tissues were collected up to 3 months later and fixed in 4% paraformaldehyde or 0.4 benzoquinone in PBS (w/v). After washing in PBS containing 15% sucrose the tissues were processed either as cryostat sections or whole mounts and immunostained with fluorescent or PAP techniques. A specific antiserum was raised in rabbits against synthetic rat CGRP (1-37) conjugated to bovine serum albumin by glutaraldehyde and used at a dilution of 1/200-1/2000.

Numerous CGRP-IR nerves were found distributed throughout the urinary tract, from the renal pelvis to urethra, running in the adventitia, muscle and sub-epithelial layers and in association with blood vessels. No immunoreactive cell bodies were identified in these tissues. The CGRP immunostaining of nerve fibres was almost totally abolished in capsaicin treated rats and guinea pigs, as was substance P immunostaining. The injection of True blue resulted in the retrograde labelling of neuronal cell bodies in specific dorsal root ganglia, the level of which was dependent on the site of injection. Although labelling was also noted in the pelvic, inferior mesenteric and coeliac ganglia, CGRP-IR perikarya were only demonstrated in dorsal root ganglia. These occurred in all the levels examined (T_5-S_2) and were mainly of the smaller type. In those ganglia possessing True blue labelled cells a sub-population of CGRP-IR cells was identified which contained both substances. The results demonstrate that the urinary tract of the rat and guinea pig receives CGRP-IR afferent nerve fibres from perikarya in dorsal root ganglia, the distribution of which is organ-specific.

48.1 AXONAL CONTRIBUTION TO SUBTHRESHOLD CURRENTS IN APLYSIA BURSTING PACEMAKER NEURONS. Richard H. Kramer (Spon. I. Levitan) Dept. of Physiology-Anatomy, Univ. of California, Berkeley, CA 94720.

Voltage-clamp studies of molluscan somata have revealed an assortment of ionic conductances which generate the bursting pacemaker cycle. The cell bodies of bursting neurons have been used because of technical advantages (size and identifiabilty) and because they can retain bursting activity following isolation. However, recent evidence suggests that bursts can continue in the absence of voltage changes in the soma, and that spikes during spontaneous bursts are initiated in the axo-dendritic tree (Treistman, Brain Res. (1980) 187:201-205). In this study, the role of the axon in the generation of bursting activity was investigated by using two electrode voltage clamp in Aplysia bursting cell somata in conjunction with intra-axonal recordings. The results demonstrate directly that the axon contributes significantly to the subthreshold currents which underlie bursting pacemaker activity.

Experiments were done on bursting cells L2-L6 of the Aplysia abdominal ganglion. Two electrodes in the soma were used for voltage-clamp; a third electrode containing 6-carboxyfluorescein was used to iontophoretically pass dye into the cell so that the axon could be visualized with a fluorescence microscope. Dye-filled axons were impaled 300-500 uM from the cell body. Depolarizing voltage-clamp pulses in the soma resulted in uncontrolled regenerative responses in the axon. A component of the axonal response was resistent to block by TTX, but was blocked by Ca^{2+} channel blockers (Co^{2+} or Mn^{2+}). The axonal Ca^{2+} spike did not produce noticeable current "notches" in the cell body, although they did distort the time course and magnitude of inward currents generated in response to the somatic voltage-clamp pulse.

Spikes were generated selectively in the axo-dendritic tree by voltage clamping the soma to a constant value (-40 mV) while passing depolarizing current into the axon. Axon spikes were followed by a depolarizing afterpotential (DAP), and bursts of spikes were followed by a long (>10 sec) post-burst hyperpolarization (PBH). As in the soma (Kramer & Zucker, J. Physiol., June, 1985) the PBH was blocked by Ca^{2+} channel blockers, was unaffected by external tetraethylammonium, and did not reverse at E_K; hence the axonal PBH is not due to Ca-activated K^+ current.

The axonal afterpotentials contribute to slow currents resulting from somatic voltage clamp pulses. In some L2-L6 cells, elimination of axonal activity (by axonal hyperpolarization, or by axotomy) blocks the slow currents. In other L2-L6 cells, elimination of axonal activity reduces the slow currents by less than 50%. Hence, the axonal contribution to subthreshold bursting currents is quite variable in different cells. Supported by NSF grant BNS 82-02416 and NIH grant NS 15114.

48.2 PHYSIOLOGIC IMPLICATIONS OF INITIAL SEGMENT STRUCTURE IN FROG SPINAL GANGLION CELLS. J. Rosenbluth, E. Matsumoto* and A. Blight. Depts. Physiology and Rehab. Medicine, New York University School of Medicine, New York, NY 10016

Intracellular recordings from frog spinal ganglion cells have demonstrated an "NM" spike, thought to originate in the non-myelinated initial segment (IS), preceding the "S" spike, thought to originate in the soma (Ito, 1957, Jap. J. Physiol. 7: 297). The threshold for the NM spike is significantly lower than that for excitation of the soma (Ito, 1959, Jap. J. Physiol. 9: 20), suggesting electrophysiological similarities between the initial segment and the node of Ranvier. Morphological examination of the initial segment and axon hillock (AH) regions of frog spinal ganglion cells shows both similarities to and differences from nodes of Ranvier. In freeze-fracture replicas both display unusually high concentrations of E-face intramembranous particles, but at the node these are restricted to a ~ 1 μm band between collars of paranodal axoglial junctions. Additional particles are found under the myelin sheath in the paranodal axolemma and in the juxtaparanodal portion of the internode, but these are isolated by the overlying myelin lamellae and by the extensive paranodal axoglial junctions at both ends of each internode. In the AH and IS, in contrast, E-face intramembranous particles are distributed over a much broader area without obvious boundaries. Moreover, in thin sections the sheath overlying the IS displays multiple interruptions with no evidence of paranodal-type axoglial junctions that might restrict current flow to portions of the axolemma. As a result, much larger numbers of axolemmal particles are accessible to current fluxes during the action potential than is the case at the node of Ranvier. If the E-face particles in the AH and IS plasma membrane represent voltage-sensitive sodium channels, as has been proposed for nodal E-face particles, the morphological findings suggest the presence of much larger overall numbers of sodium channels in the AH and IS than at a typical node, inasmuch as the total area is at least an order of magnitude greater and the particle density comparable. The morphological observations are therefore compatible with very large sodium currents in the AH and IS regions. Our in vitro studies confirm that S and NM spikes are both eliminated by low concentrations of tetrodotoxin before the nodal (M) spike, deeper in the ganglion, is noticeably affected. None of these components is significantly reduced by replacement of calcium with manganese or cadmium. Local amplification of the action potential current in the AH and IS regions would serve to discharge the large somatic membrane capacitance to threshold rapidly. A delayed action potential in the soma could reactivate the axon, as is in fact observed when depolarization of the soma is slowed by shunting of its membrane resistance. Supported by grants from the NIH (NS 07495) and Muscular Dystrophy Association.

48.3 **CONDUCTION IN DEMYELINATED NERVE MEASURED BY CHANGES IN LIGHT ABSORPTION OF POTENTIAL-SENSITIVE DYES.** P. Shrager, S.Y. Chiu*, J.M. Ritchie*, D. Zecevic, and L.B. Cohen. Dept. of Physiology, University of Rochester Medical Center, Rochester, NY 14642 and Depts. of Physiology and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

Frog sciatic nerves were focally demyelinated by injection of 1% lysolecithin 5-15 days prior to the experiment. Desheathed nerves were soaked in Ringer's solution containing a pyrazoxonol dye (RH155), kindly supplied by Amiram Grinvald and Rina Hildesheim, 1 mg/ml, for 1-2 hours. The optical path was placed between pairs of Pt wires for external stimulation and recording. A Leitz Ortholux II microscope formed a real image of the nerve on a photodiode array oriented with rows of elements parallel to the axons. The incident light was filtered at 705 nm. Absorption changes were recorded from control regions of the nerve following moderate stimuli. Conduction velocities were measured by calculating the time to peak change in light intensity. In control segments these velocities were in excess of 5 m/sec, values typical of A and B myelinated fibers in this preparation. In the demyelinated zone optical signals decreased in amplitude, generally reaching minimum levels of detection 0.5-1 mm beyond the transition region. These signals 're-emerged', however, at the distal end of the 2-3 mm demyelinated zone indicating that the decrease in amplitude was not due to conduction block in increasing numbers of fibers. Conduction velocities in the demyelinated area (measured near the boundary) were 0.4-0.8 m/sec, significantly lower than in control segments.

4-Aminopyridine (4-AP), a K^+ channel blocker, has been shown to widen the frog myelinated nerve action potential about 2-fold. Optical signals, which represent the summed changes in many fibers with a spectrum of conduction velocities, doubled in amplitude after addition of 2.5 mM 4-AP. Optical records also showed that after K^+ channel block action potentials were markedly enhanced in the demyelinated zone and conduction could be followed throughout this region.

Thus, optical techniques can be used to monitor accurately electrical excitability in demyelinated nerve. This method may ultimately be of value in studies of the central nervous system, in regions in which conduction is not readily followed electrophysiologically.

48.4 VOLTAGE-DEPENDENT ION CHANNELS IN GLIAL CELLS. B.A.Barres, L.L.Y. Chun*, and D.P.Corey. Program in Neuroscience, Harvard Medical School, Neuroscience Group, Howard Hughes Medical Institute and Department of Neurology, Massachusetts General Hospital, Boston, Ma. 02115.

The traditional notion that glial cells have passive membranes permeable only to potassium has been revised by recent patch-clamp studies of cultured mammalian glial cells that reveal voltage- and ion-dependent ion currents (Chiu et al., Nature 1984; Quandt and MacVicar, Soc. Neurosci. Abstr. 1984). We have used the postnatal rat optic nerve preparation developed by Raff and coworkers to prepare neuron-free cultures of each of three glial cell types (type 1 and type 2 astrocytes and oligodendrocytes). Each type can be positively identified by a unique surface antigenic phenotype, which correlates with a specific morphology in culture. For studies with freshly dissociated cells in suspension, cells were labelled with antibodies and observed with a fluorescence microscope during electrophysiological study. Because pretreatment with antibodies was time-consuming and subject to the possibility that it might change physiologic properties of the cell studied, we further developed a Percoll density gradient separation technique with which we can rapidly separate out greater-than-90% pure populations of each glial subtype.

Ionic currents were studied in cultured glial cells using the whole cell and cell-attached patch-clamp recording configurations. These reveal a voltage-sensitive sodium current in type 2 astrocytes which has a voltage-dependent inactivation and is blocked by TTX. This conductance differs quantitatively from mammalian neuronal sodium conductance in its timecourse and voltage-dependence. We have also identified a voltage-dependent calcium current in these cells which is blocked by cobalt and is characterized by a strong voltage-dependent inactivation. There is also a TEA-sensitive potassium current.

In contrast, oligodendroglial cells were not observed to have sodium or calcium conductances but exhibit a large voltage-sensitive potassium permeability that is different in its characteristics from that of the type 2 astrocyte. Whole cell and single channel recording reveal it to be inactive only at large negative potentials, and to pass inward current better than outward current (Corey, Barres and Chun, this meeting).

Two important issues are unresolved: First, at what point do the electrophysiological characteristics of the oligodendrocyte and the type 2 astocyte diverge in development, since these arise from a common progenitor cell, the O2A? Second, are these ion channels normally present in glial cells in vivo, or are they artifacts of the tissue culture environment? These questions are now being studied by recording from cells in suspension immediately after optic nerve dissociation.

48.5 AN INWARDLY RECTIFYING POTASSIUM CHANNEL IN OLIGODENDROGLIA. D.P.Corey, B.A.Barres, and L.L.Y.Chun*. Neuroscience Group, Howard Hughes Medical Institute and Department of Neurology, Massachusetts General Hospital, and Program in Neuroscience, Harvard Medical School, Boston, Ma. 02114

Oligodendroglial cell membranes have been shown to be exclusively permeable to potassium (Kettenman et al., J. Neurosci., 1983) and this permeability has been thought to be passive, that is, not voltage-sensitive. To determine whether there is a voltage dependence to the potassium permeability in oligodendroglia, we have used the patch-clamp recording technique to study oligodendroglia cultured from postnatal rat optic nerve with the procedure developed by Raff and coworkers.

Oligodendroglia were first studied with the whole cell patch-clamp recording configuration, using the following solutions (in mM). Outside: 20 KCl, 100 TMA-Cl, 2 Ca; inside: 120 K aspartate, 10 EGTA, and no added Ca. In all cells studied under these conditions we observed a large current at potentials more positive than about -110 mV, which reversed near the potassium equilibrium potential. Inward current was increased when external potassium was raised. The current-voltage relationship showed marked inward rectification: outward current was much less than inward current even with these solutions. This current was completely blocked by barium but was not blocked by 20 mM TEA or 1 mM 4-AP.

Preliminary experiments were done with single channel recording in the cell-attached configuration, using a 130-mM KCl solution in the micropipette. In one case a channel was observed which activated at 50 mV below resting potential, and was almost always open at resting potential or above. The single channel conductance at negative potentials was 140 pS at 21°C in this solution. The single channel current-voltage relation demonstrated marked inward rectification, with little current flow in an outward direction.

This channel differs from many inward rectifiers that have been studied in that it is positively activating, but it is very similar to an inwardly rectifying potassium channel recently observed in cultured hippocampal neurons (Sullivan and Cohen, Biophys. J., 1985). It differs from channels observed in cultured mouse spinal cord oligodendroglia (Kettenman et al., Pflugers Arch., 1984) primarily in its large conductance and in its rectifying current-voltage relation. The difference could be explained by a heterogeneity of oligodendroglia, but more likely reflects the low external potassium concentrations used in the spinal cord studies.

This channel may play an important role in the ability of oligodendroglia to accumulate and spatially buffer potassium.

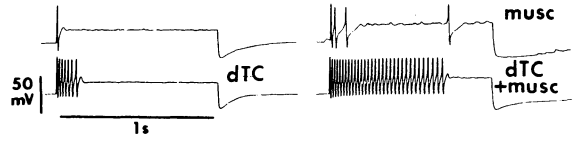
48.6 MODULATION OF REPETITIVE FIRING IN BULLFROG SYMPATHETIC GANGLION CELLS BY TWO DISTINCT K CURRENTS, I_{AHP} AND I_M. P.Pennefather†, S.W. Jones and P.R.Adams. Dept. Neurobiology, SUNY Stony Brook, NY 11794 Fac. Pharmacy, Univ. of Toronto, Toronto, Ont, M5S 1A1†.

I_{AHP} is a voltage insensitive K current that is evoked by Ca influx during an action potential (Pennefather et al. P.N.A.S. 1985 in press). I_M is a voltage sensitive K current that is half maximally activated at -35 mV. At potentials near threshold for action potential generation (-40 to -30 mV) both I_M and I_{AHP} show exponential kinetics with time constants in the hundreds of milliseconds. Both currents are small (1-3 nA at -40 mV) compared to K currents responsible for spike repolarization but, because of their slow kinetics, modulate repetitive firing.

Maximal activation of receptors for muscarine, LHRH or ATP cause a 90% inhibition of I_M and a 30% inhibition of I_{AHP}. Apamin and the neuromuscular blocking agents d-tubocurarine (dTC) and pancuronium inhibit maximally 80% of I_{AHP} without affecting I_M. We have used 10 μM muscarine and 200 μM dTC (10X their half maximal blocking concentrations) to investigate the influence of I_M and I_{AHP} on repetitive firing.

Membrane currents and membrane potential were measured by repeated switches between single electrode voltage and current clamp (hybrid clamp). Cells, with resting potential $<$-45 mV and input resistance $>$70 MΩ, were manually clamped to -60 or -55 mV. Depolarizing current steps of 1-2 nA typically evoked 1-3 spikes after which the membrane potential settled to a new level of around -45 mV, i.e. a potential where sufficient I_M is activated to balance the injected current. In the presence of dTC this step evoked a burst of spikes for about 100 ms after which the potential settled to a level similar to that in the absence of dTC. The duration of the discharge reflects the the time needed to develop sufficient I_M. When I_M is inhibited by muscarine the current step causes a greater steady depolarization. There are a few more spikes early in the step and spikes occur irregularly thereafter. Muscarine and dTC together have a synergistic effect on repetitive firing. Yet, even when both I_M and I_{AHP} are inhibited, repetitive firing is not maintained.

Supported by NS 20751 to S.W.J. and NS 18579 to P.R.A., P.P. is a Career Scientist of the Ontario Ministry of Health.



2nA step, holding potential -60 mV, AP's clipped by chart recorder

48.7 COMPUTER SIMULATION OF BULLFROG SYMPATHETIC GANGLION CELL EXCITABILITY. C. Koch and P. R. Adams. The Center for Biological Information Processing, Massachusetts Institute of Technology, Cambridge, Mass., 02139 and Department of Neurobiology & Behavior, State University of New York, Stony Brook, N.Y., 11794.

Using conventional microelectrodes and patch clamp techniques, seven distinct voltage-dependent currents have been characterized in type B bullfrog sympathetic ganglion cells. We have now modeled the electrical behavior of these cells under current-clamp conditions in terms of a fast sodium current (I_{Na}), a calcium current (I_{Ca}), a transient K^+ current (I_A), a non-interacting muscarine-sensitive K^+ current (I_M), a large sustained delayed rectifying K^+ current (I_K), a fast Ca^{++}-dependent K^+ current (I_C), a slow Ca^{++}-dependent K^+ current (I_{AHP}), intracellular calcium buffering and diffusion, extracellular potassium accumulation, membrane pumps and nicotinic, muscarinic and peptidergic -induced synaptic conductance changes. The underlying equations for these processes were developed using either experimental data or literature values. This interactive and graphic computer program accounts for the electrical behavior of the cell under a variety of conditions (e.g. voltage-clamp). In particular, the model satisfactorily reproduces the waveform of individual action potentials, both before and after inhibiting Ca^{++}-dependent potassium currents, and for a wide variation of input impedances. The model reveals that under normal conditions, an action potential leads to a large transient increase in I_C, which is replaced by a similar increase in I_K if calcium influx is blocked. In agreement with experimental data (see Pennefather, Jones and Adams, this volume), the model predicts that maintained repetitive firing during depolarizing current steps will only be seen if both I_M and I_{AHP} are inhibited at the same time. These two currents both subtract from the stimulus current, and hence act cooperatively, albeit in response to different stimuli (i.e. voltage or calcium).

48.8 DIFFERENTIAL EFFECTS OF Co^{++} AND TEA ON SPIKES OF FROG DORSAL ROOT GANGLION NEURONS. S. D. Stoney, Jr., Dept. of Physiology, Medical College of Georgia, Augusta, GA 30912.

Four types of neurons are distinguishable in frog dorsal root ganglia (DRG) based on shape of the somatic spike, orthodromic conduction velocity (CV) and least conduction interval (LCI) for pairs of orthrodromic impulses at their intraganglionic axon branch point (Hershberger and Stoney, Neurosci. Abstr. 10:109, 1984). I have attempted to determine the causes for different spike shape by superfusing DRG neurons with solutions containing Co^{++}, Co^{++} & TEA, TEA, TEA & Co^{++}, or excess Ca^{++}. 10mM Ca^{++} caused the appearance or accentuation of a hump on the spike falling phase for all neurons tested, suggesting that a Ca^{++}-sensitive outward current contributes to repolarization. Co^{++} (10mM, 3-5 mins) followed by Co^{++} & TEA (10mM each, 3-5 mins) had significantly different effects on the repolarization phases of different types of neurons. Spikes of F neurons (CV≈20 m/sec; LCI≈1.7 msec; brief & smooth) were slightly affected by Co^{++} alone and greatly affected by the addition of TEA. The maximum rate of repolarization (-dv/dt) was decreased by 39% by Co^{++} alone and an additional 243% by TEA. Spike duration at 50 mv (D50) was increased by 70% and 174% by the two treatments. In contrast, H1 neuron spikes (CV, etc., the same as F neurons) were strongly affected by Co^{++} and by TEA. D50 was increased by 130% and 120% while -dv/dt was decreased by 59% and 57% by Co^{++} and Co^{++} & TEA, respectively. Spikes of H2 neurons (CV ≈ 7 m/sec; LCI≈2.2 msec; broad with slight hump on falling phase) were more strongly influenced by Co^{++} than by TEA. D50 was increased by 73% and 28% while -dv/dt was decreased by 60% and 28% by the two treatments. Spikes of H3 neurons (CV≈7 m/sec; LCI≈4.8 msec; very broad with marked hump on falling phase) were reversibly blocked by Co^{++}. Other neurons were treated with 10mM TEA followed by TEA & Co^{++} (10mM each). Co^{++} caused a lengthening of F, no change in H1 and a shortening of H2 neuron TEA spikes. These results suggest that differences in spike shape among different types of frog DRG neurons are due to quantitative differences in the extent to which g_{Ca}, $g_{K(Ca)}$ and $g_{K(V)}$ are activated during the spike. The importance of g_{Ca} and $g_{K(Ca)}$ in spike electrogenesis appears to be graded across neuron types H3>H2>H1>F. This is nearly identical to the way CV (H3<H2<H1 = F) and LCI grade across neuron types (H3>H2> H1 = F). Supported by BRSG # 2S-07-RR-05365-23.

48.9 EXPRESSION OF IONIC AND SYNAPTIC MECHANISMS UNDERLYING ELECTRICAL EXCITABILITY IN DEVELOPING PURKINJE NEURONS. D.L. Gruol and C.L. Franklin*, Div. of Preclin. Neurosci. and Endocrin., Scripps Clinic and Research Foundation, La Jolla, CA 92037

The Purkinje neuron (PN) of the cerebellum exhibits characteristic patterns of electrical activity generated by synaptic input and endogenous, voltage-sensitive mechanisms. Similar patterns of activity are express by mature PNs derived from fetal rat tissue and differentiated in culture (Gruol, Brain Res., 263, 1983). In culture, PN activity typically consists of regular patterns of simple spikes, generated by pacemaker potentials, with intermittent bursts events similar to complex spikes (CS). We have investigated the expression of these mature electrophysiological characteristics during the course of PN development using the cerebellar culture system as a model. Initially, immunohistological techniques were used to identify the immature PNs in culture and extracellular recordings were used to characterize the activity patterns (Franklin and Gruol, Neurosci. Abst, 1984). We have now used intracellular recordings to examine the underlying membrane and ionic mechanisms, as a first step in establishing the timing and sequence in expression of the specific ion channels mediating the activity. The cultures are prepared from 20 day rat embryos (1 day before birth) and earliest culture age at which PNs could be identified was 4 DIV (DIV= days in vitro). At this age, the majority of PNs were silent. However, the excitatory transmitter glutamate could evoke action potentials (APs) in some of the silent PNs, indicating that this age represented a transition period in development of electrical excitability. By 6 DIV, which is well before the main period of synaptic and dendritic development, the majority of PNs displayed slow, spontaneous activity consisting of synaptic events and APs. In some of these PNs, the APs were soley generated by the synaptic events, which tended to occur in intermittent patterns. In other PNs, the endogenous mechanisms were the predominant triggering factor and patterns were more regular. Both the synaptic and endogenous mechansism evoked doublet spikes of full amplitude, as opposed to the single and complex type spikes typical of later stages. Na+, Ca++, and K+ channel blockers significantly altered the activity patterns and current evoked APs of these young PNs, indicating that a variety of ion channels had been expressed by this early developmental stage. These data indicate that both synaptic and endogenous mechanisms are expressed early in PN development, that chemical excitability and synaptic input mediate the first patterns of spontaneous activity and that expression of the ionic mechanisms underlying AP generation precede expression of the endogenous mechanisms responsible for maintaining the activity. (supported by NIH grant NS21777)

48.10 ELECTROPHYSIOLOGICAL CHARACTERIZATION OF IDENTIFIED, INTRINSIC CORTICAL NEURONS IN DISSOCIATED CELL CULTURE. J.M. Nerbonne[1], A. Burkhalter[2] and J.E. Huettner[3], Depts. of Pharmacology[1] and Neurosurgery[2], Washington Univ. Sch. of Med., St. Louis, MO 63110 and Neurobiology[3], Harvard Med. Sch., Boston, Mass. 02115.

It is likely that the membrane properties of individual cortical neurons are functionally as important as the attributes of their interconnections. Characterizing these properties should, therefore, contribute to the understanding of the mechanisms underlying cortical information processing. Using the whole-cell patch-clamp recording technique, we have determined the properties of voltage-activated currents in callosal projecting neurons in dissociated cell culture.

Neonatal Long-Evans rats were injected at postnatal day 3-5 with rhodamine labelled beads, a retrograde tracer suitable for in vitro visualization of neurons (Katz et al., Nature, 310: 498 (1984)). Injections were made into primary visual cortex (area 17) of the left hemisphere. Histological examination after 2-5 days, revealed bead labelled cells distributed throughout the contralateral area 17, in layers 3-5. For the preparation of cultures, tissue pieces from this area were dissociated (Huettner and Baughman, Soc. Neurosci., 165 (1984)). A large number of labelled cells are obtained; these cells retain beads and survive for several weeks in culture. Lucifer Yellow injections of labelled cells revealed extensive process outgrowth and functional synaptic contacts are formed.

In the whole-cell recording configuration, with 140 mM Na^+ and 5mM Ca^{++} in the bath and 140 mM K^+ in the pipette, depolarizations from holding potentials -30 to-80 mV, revealed inward and outward currents. In all cells studied under these conditions, a fast TTX-sensitive inward Na^+ (I_{Na}) current and an outward K^+ (I_K) current, resembling the delayed rectifier, were seen. With 140 mM Cs^+ in the recording pipette, K^+ currents were blocked and depolarizations revealed a second (slow) inward current, carried by Ca^{++} and blocked by Co^{++} (I_{Ca}). When I_{Na} and I_{Ca} were blocked (1uM TTX and 5 mM Co^{++}), two components of outward current were distinguished: a fast transient K^+ current (I_A) and the slower, non-inactivating I_K. With Ca^{++} in the bath, it is evident that at least one component of outward current is Ca^{++}-dependent.

Using this methodology, we have identified voltage-activated currents suggested previously by intracellular recordings in cortical slices. These currents are recorded from cells within hours after isolation and most likely are present in vivo. In addition, their properties are not altered in vitro, as similar results are obtained 6 hr. to 2 wk in culture. Employing this approach, we anticipate that we shall similarly be able to study transmitter modulation of ionic currents in identified cells.

48.11 VOLTAGE-DEPENDENT CURRENTS IN EMBRYONIC CULTURES OF DROSOPHILA NEURONS. Lou Byerly, Section of Neurobiology, Department of Biological Sciences, University of Southern California, Los Angeles, California 90089.

Patch clamp studies are being performed on Drosophila neurons in cultures prepared by disaggregating whole gastrulating embryos as described by Seecof et al. (Exp. Cell Res 69:161, 1971). Neuroblasts differentiate in vitro during the first 24 hr into neurons that can form functional neuromuscular junctions with the myocytes in the culture (Seecof et al., Proc. Natl. Acad. Sci. USA 69:566, 1972). The nerve cell bodies (3-8μm in diameter) are usually found in clusters from which radiate bundles of nerve processes, but isolated nerve cell bodies are also present. Tight seals of 5-20GΩ readily form between the membrane of these nerve cell bodies and patch clamp electrodes. Frequently spontaneous biphasic currents (5-15pA in amplitude) are recorded from these on-cell patches, indicating the presence of action potentials in the neuronal somas. When the patch electrode contains an extracellular solution (125mM Na^+, 6mM K^+, 5mM Ca^{2+}, 5mM Mg^{2+} and 10mM HEPES, pH 7.4), outward single-channel currents are observed during depolarization of the patch. These single-channel currents are probably carried by K^+ and indicate single-channel conductances of several sizes, the largest being about 40 pS. Before characterizing the single-channel currents, a study of the macroscopic currents of the Drosophila nerve cell body is being undertaken, using whole-cell voltage clamp studies. Although seals to the membrane are formed equally well when the patch electrode contains an intracellular solution (144mM K^+, 10mM HEPES, 5mM EGTA, pH 7.3), pulses of negative pressure tend to break the seal instead of the patch membrane. When a whole-cell clamp is successfully established, the total resistance is 5-10GΩ. With 144mM K^+ in the patch electrode only net outward currents are evoked by depolarizing voltage pulses, when the cell body does not have processes. These currents activate rapidly (fully activating in 5ms at 0mV) and then slowly inactivate (decaying about 30% in 100ms at 0mV). This conductance is first activated about -30mV and reaches 5nS at 0mV (50 times larger than the conductance at -60mV). Repetitive transient inward currents are frequently recorded during depolarizing pulses in neurons with processes, probably indicating Na currents from regions of the membrane where the voltage is not controlled.

48.12 COMPLEMENTATION ANALYSIS OF SHAKER MUTANTS IN DROSOPHILA. L. C. Tinpe*(SPON: L. Y. Jan). Howard Hughes Medical Institute and the Dept. of Physiol., Univ. of Calif., San Francisco, San Francisco, Calif. 94143

Previously described mutations of the Shaker locus either eliminate a transient potassium current, the A current, or alter its inactivation kinetics (Salkoff and Wyman, Nature 293: 228-230, 1981). Using intracellular recording and voltage clamp techniques I have examined the phenotypes of sixteen additional Shaker mutants, and have used complementation tests to study the genetic complexity of the locus. Ten of the sixteen mutants have no detectable A current in pupal indirect flight muscle. Measurement of A current peak amplitudes in Sh^{null}/Sh^+ heterzygotes shows that while some of the null mutations are almost completely recessive, others are partially dominant. Crosses between different members of the null class give progeny which likewise have no A current. These ten null mutations therefore identify a single locus required for the presence of normal A current.

In four of the remaining mutants A current is present, but the peak amplitude is reduced compared to its level in wild type. One of the four, B55, is an X:Y chromosomal translocation with a breakpoint in or near Shaker. Male pupae of the genotype Sh^{null}/proximal B55 have A current, demonstrating that Shaker is proximal to the B55 breakpoint.

The two mutants of a final class have close to normal A current in pupal muscle, but have the same severely mutant phenotype of synaptic transmission at the larval neuromuscular junction as do the null mutations. These mutations map to the Shaker region by recombination. Tests against null alleles show non-complementation of the abnormal phenotype at the neuromuscular junction. Since altered synaptic transmission at the larval neuromuscular junction is thought to be due to a defect in a neuronal potassium channel (Jan, Jan and Dennis, Proc. R. Soc. Lond. B. 198: 87-108, 1977), these mutations seem to identify a region of the Shaker locus necessary for the expression of the A channel in nerve but not in muscle.

49.1 NEUROCHEMICAL PROFILE OF FENGABINE, A NEW ANTIDEPRESSANT DRUG. B. Scatton, T. Dennis*, B. Zivkovic*, K.G. Lloyd, S. Arbilla, S.Z. Langer and G. Bartholini*.(SPON : B. Onteniente). Biology Department, LERS, Paris 75013, FRANCE.

FENGABINE (SL 79.229) [2-(butylimino)(2-chlorophenyl) methyl -4-chlorophenol] is a new GABA-mimetic agent which possesses marked therapeutic properties in patients with major depression. However, its neurochemical profile in animals differs from that of tricyclic antidepressants. Thus, fengabine does not inhibit the re-uptake of cerebral norepinephrine or serotonin ; whilst, after acute and chronic treatment, this agent increases the turnover of cerebral norepinephrine in the rat as indicated by the increased utilization rate of norepinephrine and the rise in 3,4-dihydroxyphenylethyleneglycol and normetanephrine levels in the hypothalamus, septum and nucleus accumbens (ED_{50}=50-75 mg/kg i.p.). Fengabine (100 or 200 mg/kg i.p., b.i.d.) given repeatedly for two, but not one, weeks, caused a strong desensitization of isoprenaline-stimulated adenylate cyclase in slices of the septum and cerebral cortex. This desensitization seems to be due to an uncoupling of the enzyme from the β-receptor as repeated treatment with fengabine neither decreases basal activity of the enzyme nor down-regulates the β-adrenergic recognition site. No desensitization of the adenylate cyclase stimulated by dopamine (striatum) or by sodium fluoride (septum) occurred under these conditions. Furthermore, chronic treatment with fengabine failed to change the density of cortical α_1 and α_2-adrenoceptors. However, the compound given repeatedly for 6-18 days enhanced $GABA_B$ binding in the rat frontal cortex as do classical antidepressants. The effects of fengabine on noradrenergic transmission are relatively selective as neither acute nor repeated administration of this drug influences serotonin-related parameters and diminishes slightly striatal acetylcholine and dopamine turnover. Moreover, chronic treatment with fengabine did not affect the density of ^{3}H-spiperone binding to 5-HT_2 receptors in the frontal cortex. Finally, in agreement with its GABA mimetic activity, fengabine decreases cerebellar cyclic guanosine 3',5'-monophosphate levels upon acute treatment in the rat. In conclusion, the acceleration of cerebral norepinephrine turnover by fengabine suggests that this compound increases the amine concentrations in the synaptic cleft as do the classical antidepressants, although by a different mechanism (probably via an increase in the firing rate of noradrenergic neurons). Activation of central noradrenergic transmission may be involved in the antidepressant action of the compound.

49.2 PUMILIOTOXIN B: A POTENTIAL BIOCHEMICAL TOOL FOR THE STUDY OF PHOSPHATIDYLINOSITOL METABOLISM. F. Gusovsky*, E.B. Hollingsworth* and J.W. Daly. Laboratory of Bioorganic Chemistry, NIADDK, NIH, Bethesda, MD 20205.

Pumiliotoxin B (PTX-B), an alkaloid from the skin of the neotropical frog Dendrobates pumilio, possesses marked myotonic and cardiotonic activity (Mensah-Dwumah and Daly, Toxicon, 16:189, 1978; Albuquerque et al., Mol. Pharmacol., 19:411, 1981; Daly et al., J. Med. Chem., 28:482, 1985). The molecular mechanism for these actions of PTX-B are poorly defined, but may involve effects on the mobilization of calcium that is required for excitation-secretion coupling at synaptic terminals and excitation-contraction coupling at postsynaptic sites.

Biochemical actions of PTX-B now have been investigated with respect to phosphatidylinositol (PI) turnover in guinea pig cerebral cortical synaptoneurosomes and mouse atrial preparations. PI turnover was measured as accumulations of [^{3}H]inositol phosphates in the presence of 10 mM LiCl in preparations prelabeled with [^{3}H]-inositol. Effects on PI turnover, in particular the formation of inositol triphosphate, which is known to release calcium from internal storage sites, was considered as one possible basis for the pharmacological actions of PTX-B.

PTX-B was found to significantly increase PI turnover in brain preparations as do a variety of biogenic amines and muscarinic agonists. In synaptoneurosomes, PTX-B elicits significant PI turnover at concentrations as low as 0.5 μM with maximal accumulation of [^{3}H]inositol phosphates (140 to 170 percent of control) occurring at concentrations of 5 to 10 μM. The effects of PTX-B are not blocked by muscarinic or α-adrenergic agonists and are, therefore, not mediated via such receptors. Phorbol-12-myristate-13-acetate prevents both PTX-B-elicited PI turnover and PI turnover elicited by muscarinic and α-adrenergic agonists in synaptoneurosomes. PTX-B also elicits accumulations of [^{3}H]inositol phosphate in mouse atria and, therefore, may represent a biochemical tool for investigation of PI turnover and its role in physiological functions in a variety of cells and tissues.

49.3 GABA-MEDIATED SYNAPTIC INHIBITION IN RAT SUPRAOPTIC NUCLEUS (SON) NEUROSECRETORY NEURONS IN VITRO. J.C.R. Randle, C.W. Bourque and L.P. Renaud. Neurosciences Unit, Montreal Gen. Hosp. Res. Inst. and McGill University, Montreal, Canada H3G 1A4.

Intracellular recordings of rat SON neurons in perfused explants of hypothalamus (cf. Bourque & Renaud, J. Neurosci. Methods 7:203, 1983) reveal a high frequency of spontaneous hyperpolarizing post-synaptic potentials (psps). These spontaneous psps rise to peak in 3-5 msec; their decay is roughly exponential with a mean time constant of 16.8 msec, 1.6-fold longer than the cell time constant for decay of a hyperpolarizing pulse. These may arise from the anteroventral third ventricular (AV3V) region where focal stimulation evokes graded hyperpolarizing psps that peak in 3-10 msec and decay exponentially with a mean time constant of 32.9 msec. Both spontaneous and evoked psps are reduced or abolished by tetrodotoxin (10^{-6} M) or 15mM $MgCl_2$. In recordings with potassium acetate (KAc)-filled electrodes the mean psp reversal potential (Epsp) is -72mV. Reversal potentials for spontaneous and evoked psps agree within 1 mV. Recordings obtained with KCl electrodes reveal a mean Epsp of -45mV and replacement of medium NaCl with Na Glucuronate induces a positive shift of Epsp indicating a chloride dependence of the psps. Conductance changes associated with spontaneous psps are consistently near 0.65 nS. Maximal conductance values for evoked psps vary widely between cells (range 1.5-20 nS). Bicuculline methiodide (BMI, 10^{-6} -10^{-4} M) reversibly abolishes both spontaneous and evoked psps. Pentobarbital (10^{-4} M) prolongs both spontaneous and evoked psps, increasing the time constant of decay 2-3 fold.

These data suggest that the majority of this spontaneous synaptic activity is inhibitory (ipsps) and may be mediated by a GABA-activated chloride conductance. GABA (10^{-5} -10^{-3}M) induces 5-20nS increases in input conductance in SON neurons. In about 60% of cells recorded with KAc electrodes, GABA induces a membrane hyperpolarization (reversal potential near -75 mV, in agreement with Eipsp) which, at high doses of GABA can be followed by a depolarization (reversal potential near -50 mV). In the remaining cells recorded with KAc electrodes, and in all cells recorded with KCl electrodes, GABA induces a membrane depolarization with a reversal potential near -40mV. These effects of GABA are blocked by BMI and mimicked by muscimol, properties of a GABA-A receptor-mediated process.

We conclude that in the hypothalamic explant, GABA-mediated ipsps form the majority of spontaneous synaptic activity. In vivo, synchronization of this powerful inhibitory input may have an important influence on SON neuronal firing patterns. Supported by the MRC and FRSO.

49.4 EFFECTS OF CHRONIC ETHANOL ADMINISTRATION ON SYNAPTIC MEMBRANE NA^+-CA^{2+} EXCHANGE ACTIVITY. E. K. Michaelis, M. L. Michaelis, E.W. Nunley*, and N. Galton*. Dept. of Human Development and Center for Biomedical Research, Univ. of Kansas, Lawrence, KS 66046.

We have recently reported that ethanol and other short chain alcohols inhibit the activity of the Na^+-Ca^{2+} exchange system in brain synaptic plasma membrane vesicles. This transport system is sensitive to ethanol at low concentrations (IC_{50}≈ 15 mM) when the activity is measured at physiological temperatures.

The present studies were undertaken to determine whether chronic ethanol administration leads to alterations in this Na^+-Ca^{2+} antiporter system that might be indicative of an adaptive response to alcohol. Sprague Dawley rats were maintained for 3 weeks on a diet that contained 8% ethanol or sucrose substituted for ethanol in controls. Following the drug treatment, animals were sacrificed, the brains removed, and highly purified synaptic plasma membranes isolated as described earlier (J. B. C. 258, 6101, 1983). The Na^+-dependent Ca^{2+} transport activity in the two plasma-membrane fractions obtained was measured at various Ca^{2+} concentrations. Membrane vesicles (≈10-20 μg protein) were loaded internally with 150 mM NaCl and diluted 20-fold into an incubation medium containing either 150 mM KCl ($+Na^+$ gradient in → out) or 150 mM NaCl ($-Na^+$ gradient), plus the indicated concentrations of isotopically-diluted $^{45}CaCl_2$. Incubations were carried out for 8 sec at 24°C. Membranes from each pair of control and ethanol-treated animals were processed and tested together. Results of these experiments revealed that the 3-week ethanol regimen brought about a significant increase in the Na^+-dependent Ca^{2+} transport activity only in the membrane fraction enriched in synaptic junctional complexes. These membranes showed a near doubling in the specific activity of the antiporter in alcohol-treated compared to the control animals. The kinetic constants determined from computer fitting of the data to the Michaelis-Menten equation were: K_{act} for Ca^{2+} = 28 μM and 31 μM and the V_{max} = 3.1 and 4.3 nmol/mg protein for control and alcohol-treated animals respectively. Changes in the kinetic parameters were reversible as the Na^+-Ca^{2+} exchange activity in these membranes from animals maintained on alcohol for 3 weeks and then withdrawn for 1 week was indistinguishable from that of membranes from control animals. Thus it appears that this Ca^{2+} antiporter which is quite sensitive to the presence of ethanol in vitro is also sensitive to the chronic in vivo presence of this agent, and treated animals make a reversible adaptation in their neuronal cell membranes to compensate for its effects. 49.5 MODULATION OF EVOKED SYNAPTIC POTENTIALS BY ADENOSINE AND CAFFEINE. R.W. Greene* and H.L. Haas* (SPON: D. Weinreich). Neurochirurgische Universitätsklinik, CH 8091 Zürich, Switzerland.

Adenosine and caffeine affect the same neuronal membrane properties but in the opposite manner. These include membrane potential and resistance, the long lasting after hyperpolarization and accommodation of firing. The adenosine dose-response curve of the population EPSP is shifted to the right by caffeine (Haas & Greene, Pflügers Arch. 402,244; Greene et al., Brit. J. Pharm., 1985; J. Physiol., 1985). We have now examined the effects of adenosine and caffeine on the intracellularly recorded EPSP-IPSP evoked by stimulation of the stratum radiatum in CA 1 neurones in rat hippocampal slices. Adenosine (20 µM) reduced this compound potential by 50% with less than a 2 mV hyperpolarization of the membrane potential, in confirmation of Siggins & Schubert (1981) and Segal (1982). This could result in part from an adenosine evoked increase in gK (Ca) which may reduce conduction of the EPSP from dendrites to soma. Caffeine (50 µM) increased the EPSP 15-28% with less than a 1 mV depolarization of the membrane potential. The time course of the EPSP-IPSP sequence was unchanged. These observations are consistent with a mechanism of action for caffeine as an antagonist of adenosine, which is normally present in the CSF in an electrophysiologically active concentration. A late potassium dependent IPSP component follows stimulation of the stratum radiatum. We found this component insensitive to caffeine (100 µM), in contrast to the adenosine actions. Therefore, adenosine is unlikely to be the transmitter mediating this IPSP. The late IPSP was not enhanced by adenosine.

49.6 PHARMACOLOGY OF RABBIT LUMBAR SYMPATHETIC GANGLIONIC TRANSMISSION; AN INTRACELLULAR ELECTROPHSYIOLOGICAL STUDY. W.H. Percy* and J. Krier, Department of Physiology, Michigan State University, East Lansing, Michigan 48824.

Experiments were performed to investigate synaptic transmission in, and the pharmacological and electrophysiological properties of, cells in a mammalian lumbar sympathetic ganglion. The lumbar sympathetic chain from above the L3 ganglion to below the L5 ganglion with associated inferior splanchnic nerves (ISN) and rami communicantes (RC) was removed en bloc from rabbits killed by cervical fracture. Intracellular electrophysiological recordings were made in vitro from the L4 ganglion. Stimulating electrodes were positioned on any of RC or ISN above, below or entering the ganglion or on the lumbar chain above or below L4. The mean transmembrane potential (TMP) was 55.4 ± 2.3 mV (n=30). No cells studied exhibited spontaneous action potentials. Fast EPSPs with or without associated action potentials were seen following electrical stimulation of the chain above (n=15), RC (n=11), chain below (n=5) and ISN (n=3). These responses were abolished by superfusion of the ganglion with either hexamethonium (10^{-4} M) or tetrodotoxin (5×10^{-6} M) but were unaffected by atropine (10^{-6} M). Slow EPSPs of 3-12 mV amplitude and 2-30s duration were seen following stimulation of the chain above (n=6), RC (n=3), ISN (n=2) and chain below (n=1). These responses were atropine (10^{-6} M)-resistant. In 2 cells slow EPSPs led to spontaneous firing of action potentials. Antidromic action potentials were recorded from 5 cells and occurred without correlation to the locus of electrical stimulation. McNeil A-343 (5×10^{-6} M), an M1 agonist, caused an 8 mV depolarzation with action potential discharge in 2 cells. Substance P (5×10^{-6} M) caused depolarization ranging between 4 and 20 mV in 8 cells. In 2 cells this was associated with action potential discharge. In conclusion, cells in the rabbit L4 ganglion receive synaptic input consisting of either or both fast and slow EPSPs following electrical stimulation of axons in the lumbar sympathetic chain, ISN and WR. Cells have nicotinic, muscarinic M1 and substance P receptors, but only the role of the former in physiological function has been deduced. (AM 29920)

49.7 ACTIONS OF PHORBOL ESTERS ON SYNAPTIC TRANSMISSION AND MEMBRANE CURRENTS IN HIPPOCAMPAL CA1 PYRAMIDAL NEURONS. R.A. Nicoll, D.V. Madison, R.C. Malenka and R. Andrade. Depts. of Pharmacology and Physiology, University of California, San Francisco, CA. 94143.

Protein kinase C (PKC) is a calcium and phospholipid-dependent kinase which has been implicated in the transduction of extracellular signals at a variety of receptors, and is selectively activated by phorbol esters. We have examined the actions of 4β-phorbol-12, 13-dibutyrate (PDBu), which directly activates PKC, to determine what effects this kinase might exert on synaptic transmission and on membrane currents in the hippocampus. We have used standard extra- and intracellular recording and single-electrode voltage clamp techniques in the in vitro hippocampal slice preparation.

PDBu had marked effects on synaptic potentials evoked by orthodromic electrical stimulation in the slice. Using extracellular recording of field potentials we observed that PDBu caused increases in both the population spike, recorded at the pyramidal cell layer, and in the population EPSP, recorded in the stratum radiatum. Intracellular recording revealed that PDBu caused large increases in the amplitude of the fast monosynaptic EPSP, but had little consistent effect on the fast IPSP. Both the slow IPSP, which may result from activation of $GABA_B$ receptors (Newberry and Nicoll, J. Physiol 360, 161,1985), and the slow muscarinic EPSP, elicited by repetitive electrical stimulation in stratum oriens (Cole and Nicoll, J. Physiol. 352, 173, 1984), were reduced by PDBu. These effects could be accounted for by a postsynaptic action, since the hyperpolarizing action of the selective $GABA_B$ agonist, baclofen, and the depolarizing action of carbachol, were reduced during PDBu application. In some cells in the presence of PDBu, epileptiform bursts and presumed spontaneous EPSPs were observed.

We have also examined the effects of PDBu on a number of membrane currents in pyramidal cells. The slow afterhyperpolarization (AHP) and its underlying current (I_{AHP}) were blocked by PDBu, resulting in a decrease in accommodation. I_M and I_Q were unaffected by PDBu. In conditions designed to block K^+-currents, we have identified a slowly activating current which is turned on by hyperpolarizing commands from holding potentials of less than -50mV. This current is carried primarily by Cl^- ions and is abolished by PDBu.

Analogs of phorbol, which have in other systems been shown to be ineffective in activating PKC, produce none of the effects described above.

Supported by MH 38256, MH 00437 and the Klingenstein Fund to R.A.N.; NS 07495 and The Scottish Rite Schizophrenia Research Program, NMJ, USA to R.C.M.; and MH 09180 to R.A.

49.8 SYNAPTIC ACTIONS OF DIMETHYLSULFOXIDE. J. G. McLarnon*, D. M. J. Quastel, and D. A. Saint*. Department of Pharmacology & Therapeutics, The University of British Columbia, Vancouver, B. C., Canada, V6T 1W5.

At mouse and frog neuromuscular junctions concentrations of dimethylsulfoxide (DMSO) in excess of 1% have actions, completely reversible upon withdrawal, resembling those of alcohols and acetone, to increase the frequency and amplitude of miniature end-plate potentials (MEPPs). Using a two electrode point voltage-clamp at the mouse junction the subsynaptic action is seen to consist in a prolongation of miniature end-plate currents in association with a reduction in maximum size of the currents. Presynaptically, the increase in frequency of MEPPs (f-MEPP) occurs either in 5 mM K^+ or when control f-MEPP is raised using 10 or 15 mM K^+; the multiplication of f-MEPP by a given concentration of DMSO is similar whether or not base-line f-MEPP is raised, and remains when Ca^{2+}-dependent release of transmitter is blocked using Cd^{2+} (0.5 mM). DMSO differs from acetone and alcohols in that it does not block conduction of action potentials and end-plate potentials can be recorded in the presence of up to at least 10% DMSO. In raised Mg^{2+}/low Ca^{2+} solution, DMSO causes a parallel multiplication of quantal content of end-plate potentials (EPPs) and of f-MEPP. Facilitation phenomena are apparently unaffected by DMSO; the multiplication of f-MEPP by DMSO reduces the number of iterations needed for study of stimulus-evoked modification of spontaneous transmitter release. At junctions blocked using d-tubocurarine the increase in EPP amplitude is associated with an increase in "early tetanic rundown" in keeping with an increase of fractional release of available transmitter. These results are consistent with an effect to increase quantal transmitter release without alteration of Ca^{2+} influx into nerve terminals, perhaps by increasing the effectiveness of internal Ca^{2+}, and inconsistent with the notion that spontaneous and stimulus-evoked quantal release are governed by different mechanisms.

49.9 CALCIUM-INSENSITIVE QUANTAL ACETYLCHOLINE RELEASE AT THE NEUROMUSCULAR JUNCTION. M.T. Lupa* and N. Tabti*. (SPON: R.K. Josephson). Dept. of Pharmacology, University of Lund, S-223 62 Lund, Sweden.

Del Castillo and Katz (J. Physiol., 124:560, 1954) based their explanation for quantal acetylcholine (ACh) release, the vesicle hypothesis, on the close correspondence in both amplitude and rise time between the spontaneous miniature end-plate potentials (mepps) and the nerve-evoked end-plate potentials seen in conditions of low ACh release. In 1957, Liley (J. Physiol., 136:595, 1957) observed that there were occasional mepps which were much larger and slower-rising than the normal "fast" mepps, could also be blocked by curare, and which did not fit into the Gaussian amplitude and rise-time distributions of the normal population. Molgó and Thesleff (Proc. Roy. Soc. Lond. B., 214:229, 1982) noticed that this type of release dominated at botulinum toxin (BoTx) poisoned muscles, and was insensitive to many procedures which increase intracellular Ca^{2+} concentrations, such as 20 mM K^+, 8 mM Ca^{2+}, and 0.2 mM ouabain. This type of ACh release could be selectively increased in both normal controls and BoTx-poisoned muscles by the drug 4-aminoquinoline (4-AQ), without affecting the normal "fast" population.

Kim et al. (Kim, Y., Lömo, T., Lupa, M.T. and Thesleff, S., J. Physiol., 356:587, 1984) called these Ca^{2+}-insensitive mepps "slow" mepps for their long rise time, and found that they were released at a rate of 0.04 Hz at normal untreated endplates, accounting for 5% of the total mepp population, with variability between fibres. 1-2 days after BoTx poisoning, the "fast" mepps disappear, and about 5-10 days later the "slow" mepp frequency increases dramatically to approximately 0.5 Hz. As the muscle recovers and the epps become larger the "fast" mepps gradually reappear and the "slow" mepps gradually decrease to control values. Interestingly, the frequency of "slow" mepps reached higher values in partially paralysed than in completely BoTx-paralysed muscles.

We have concluded that the "slow" mepps represent a type of discrete spontaneous ACh release which is not stimulated by increased intracellular Ca^{2+}, and therefore cannot contribute to nerve-evoked release and synaptic transmission. It is a type of release present at normal neuromuscular junctions, and prominent in many pathological conditions of the neuromuscular junction (BoTx poisoning, murine muscular dystrophy, regenerating synapses). Speculatively, it may have a role in recovery of normal synaptic transmission, or function in maintenance of a trophic relationship at the synapse.

49.10 GLUTAMATERGIC SYNAPTIC RECEPTOR-SPECIFIC AFFERENT PATHWAYS TO SECOND ORDER VESTIBULAR NEURONS IN THE FROG. S.L. Cochran and W. Precht*. Brain Research Institute, University of Zürich, CH-8029 Zürich, Switzerland.

Glutamatergic synaptic receptors are thought to consist of at least two types: those activated best by N-methyl-D-aspartic acid (NMDA) or by kainic (KA) and quisqualic (QUIS) acids. This classification is based on demonstrations of differential blockade of acidic amino acid-induced excitations by various 'glutamate' antagonists. We find that each of these two receptor types is selectively activated by different afferent pathways to second order vestibular neurons of frogs (Rana temporaria). EPSP's (recorded in vitro) in these neurons appear to be exclusively 'glutamate'-mediated in that high concentrations of kynurenic acid (KENYA; 1-5 mM) in the bath totally and reversibly block the chemically-mediated component of these EPSP's, regardless of their source of origin. Lower concentrations (0.05-0.25 mM) of KENYA, however, have a differential effect on these EPSP's: EPSP's evoked from electrical stimulation of the contralateral VIIIth nerve and from spinal stimulation, the longer latency component of EPSP's evoked from ipsilateral VIIIth nerve stimulation, and bicuculline-induced rhythmic excitations of these cells are abolished. Similarly, depolarizations of these neurons induced by bath-applied NMDA are reduced. The short latency component of EPSP's evoked by ipsilateral VIIIth nerve stimulation and QUIS-induced depolarizations are resistant to these low concentrations. γ-D-glutamylaminomethylsulfonic acid (GAMS; ∿1 mM), which is reported to be a more effective KA/QUIS than NMDA receptor antagonist, more strongly reduces short latency, ipsilateral VIIIth nerve-evoked EPSP's, while only slightly reducing the contralaterally-evoked EPSP's or the rhythmic excitations. On the other hand, D-2-amino-5-phosphonovaleric acid (APV; 50 μM), a relatively specific NMDA receptor antagonist, reversibly abolishes the contralateral input, the long latency ipsilateral input, and the rhythmic excitations. These findings support the NMDA vs. KA/QUIS receptor classification scheme and indicate that polysynaptic pathways which mediate excitation from the ipsilateral VIIIth nerve, the pathways mediating commissural excitation, and many other excitatory synapses on these cells act through NMDA receptors. VIIIth nerve afferents mediate excitation, however, through KA/QUIS receptors. Because VIIIth nerve afferents terminate largely on the cells' somata and principal dendrites, while commissural afferents terminate on the more peripheral dendrititure, it is speculated that KA/QUIS receptors are somatic and proximal dendritic, while NMDA receptors are peripheral dendritic in location.

49.11 **ABAMECTIN BLINDS THE EYES OF THE BOLLWORM MOTH WHILE OTHER SENSORY SYSTEMS ARE UNAFFECTED.** **H. R. Agee* (SPON: C. Leonard), Insect Attractants, Behavior, and Basic Biology Research Lab, ARS, USDA, Gainesville, Florida 32604.**

It was discovered by electrophysiological techniques that the compound eye of the bollworm moth, Heliothis zea (Boddie), was totally blinded by abamectin (common name for avermectin) when 0.1 microgram of abamectin in a saline solution was injected into the abdomen of the moth or when the moth feeds ad lib. on a 5% sucrose-water containing 200 micrograms of abamectin per ml. Abamectin (#MK-936) is a product of Merck Sharp and Dohme Co., Edgerton et al. (Antimicrob. Agents. Chemother. 15:369, 1979). Injected moths were toally blind, as measured by the electroretinogram, within 2 hours. Sixteen hours after ingestion of the abamectin, the moths were blind. The compound eyes of these nocturnal moths have secondary pigment cells that move to shield the receptors from excessive light during the day and move to expose the receptors to maximum light at night. After introduction of abamectin into the moths, the shielding pigments move to and remain in the day-adapted position, regardless of the light conditions.

Abamectin is a GABA agonist that blocks action potential transmission across the neuromuscular junctions (Friz et al., Proc. Natl. Acad. Sci, USA, 76:2062, 1979. With higher dosages, abamectin also causes total paralysis of skeletal muscles, which makes it an especially useful tool for immobilizing insects when inserting microelectrodes and making stable single-cell electrophysiological recordings. However, sensory inputs from the acoustic, olfactory, chemoreception, and mechanoreceptor systems remain fully functional. Sensory and motor traffic in the central nervous system of abamectin-treated moths appear identical to that of normal moths, except for the absence of visual inputs. The heart continues to beat with a lower volume and rate for 2-4 days after moths are treated with abamectin.

50.1 KAINIC ACID NEUROTOXICITY IN THE DEVELOPING RAT HIPPOCAMPUS. T. M. Cook and K. A. Crutcher, Dept. of Anatomy, Univ. Utah Sch. Med., Salt Lake City, Utah, 84132.

Kainic acid (KA), an excitatory neurotoxin, produces a specific pattern of neuronal death in the adult rat hippocampal formation (HF). The CA3/CA4 pyramidal cells are most sensitive followed by CA1, the dentate granule cells and CA2. Several studies, however, have failed to obtain significant pyramidal cell damage in developing rats following IP or ICV injections of KA (Ben-Ari et al., Dev. Brain Res., 1984; Nitecka et al., Neurosci., 1984; Wolf and Keiloff, Dev. Brain Res., 1984). In a study examining the aberrant ingrowth of mossy fibers into CA1 (Cook and Crutcher, in press) we also observed that 1.0 ug of KA did not produce significant CA3/CA4 pyramidal cell loss (target cells of the granule cell axons) in five day old (PN5) rats. Higher doses however, did destroy pyramidal cells. Since the vulnerability of neurons differs markedly between CNS regions and doses of KA required to produce cytotoxicity may approach the LD50 dose for KA (1-5 ug), we sought to determine the susceptibility of developing hippocampal neurons to intra-hippocampal injections of KA. Sprague-Dawley rats were injected with KA (1.0, 2.5, 5.0 or 7.5 ug) on PN days 3-7 or 9. The injections were made via a microdispenser directly into the dorsal hippocampus. The animals were sacrificed at survival times ranging from 9-30 days. Serial transverse (16 um) sections were taken through the HF and stained for Nissl substance. The CA3 pyramidal cells were counted on a single section through the middorsal HF at the level of the injection site. The mean CA3 cell count for noninjected controls (PN30) was 601. The lowest dose of KA (1.0 ug) produced little CA3 cell loss ($\bar{X}$=580) in PN5 pups. This same dose, however, produced a 40% loss of CA3 cells in the PN 6, 7 and 9 pups. Greater than 50% CA3 cell loss was observed following 2.5 ug KA at PN 5-9. At 5 ug PN3 and 4 pups exhibited greater than 50% CA3 cell loss. The 5.0 ug, dose produced an increasingly greater loss of CA3 pyramidal cells in the PN5 (65%), PN6 (69%), PN7 (80%) and PN9 (100%) animals. None of the pups survived the 7.5 ug dose. These results indicate that KA cytotoxicity is observed in the HF of developing rats, but at doses significantly higher than required in adults. The extent of pyramidal cell loss as a function of age and dose indicates that two factors are probably involved in KA neurotoxocity. One factor is the direct cytotoxicity on the pyramidal cells, presumably mediated by postsynaptic receptors. The second factor is the development of excitatory (presumably mossy fiber) innervation to the CA3 subfield. The interaction of KA with an excitatory input has previously been proposed to account for the selective toxicity of KA. Our results support this hypothesis and clarify the parameters needed for producing pyramidal cell loss in the developing rat HF. Supported by NIH Grant #NS17131.

50.2 DESTRUCTION OF PERIPHERAL SYMPATHETIC NEURONS IN MACAQUE MONKEYS TREATED WITH GUANIDINIUM ADRENERGIC NEURON BLOCKING AGENTS. M.A. Palmatier*, R.E. Schmidt*, and E.M. Johnson, Jr. (SPON: H.B. Clark) Depts. of Pharmacology and Pathology, Wash. Univ. Sch. of Med., St. Louis, Mo. 63110.

Guanadinium adrenergic neuron blocking agents, the prototype being guanethidine, have been used extensively in the treatment of clincial hypertension. Guanacline, another guanadinium antihypertensive agent, was used clinically in the late 1960's. Some of the patients who received guanacline developed severe orthostatic hypotension and remained hypotensive for at least 18 months after guanacline treatment was stopped. There have been no reports of the subsequent clinical status of these patients nor papers describing the histology of their peripheral sympathetic ganglia. We have synthesized guanacline and the saturated analog of guanacline. We are using these three guanadinium compounds in an attempt to elucidate the mechanism by which the functional sympathectomy was produced by guanacline in the hypertensive patients.

Monkeys, (Macaca fasicularis or Macara nemestrina) were treated with 20 mg/kg guanacline, guanethidine, or the saturated analog of guanacline for 30 days or 12 weeks. The peripheral sympathetic ganglia, examined at the LM and EM level, from monkeys treated with guanacline, guanethidine or the saturated analog of guanacline for 30 days show neuron loss when compared to sympathetic ganglia from untreated control monkeys. There is also a perivascular and parenchymal infiltrate of heterogeneous mononuclear cells including lymphocytes, and immunoblastic and plasmacytoid cells in the sympathetic ganglia of treated monkeys. Peripheral sympathetic ganglia from 12-week-treated monkeys have a similar histologic appearance to the ganglia from 30-day-treated monkeys, although the neuron loss is more severe. A dose of guanacline comparable to that used clinically (2 mg/kg) for 30 days or 12 weeks also resulted in the loss of sympathetic neurons and a similar mononuclear infiltrate. No histologic changes are seen in dorsal root or nodose sensory ganglia or the adrenal medulla of monkeys treated with these guanadinium compounds.

The histologic appearance of the peripheral sympathetic ganglia from the treated monkeys is identical to the appearance of sympathetic ganglia from rats treated with guanacline, guanethidine, or the saturated analog of guanacline. The sympathetic neuron loss in rats treated with these compounds has been shown to be immune-mediated. We propose that the sympathetic neuron loss in guanadinium compound-treated monkeys is also immune-mediated and speculate that the functional sympathectomy produced by guanacline in patients reflected a similar process resulting in the loss of sympathetic neurons. (Supported by NIH grants HL-20604, AM-19645 and 5T32GM07805-04).

50.3 TWO MECHANISMS UNDERLYING GLUTAMATE NEUROTOXICITY IN CORTICAL CELL CULTURE. D. W. Choi. Department of Neurology, Stanford University School of Medicine, Stanford, CA 94305.

The central neurotoxicity of glutamate (glu) is a possible link in the pathogenesis of several diseases including Huntington's disease and epilepsy, but its mechanism is unknown. One possibility, first proposed by Olney, is that this toxicity is a direct consequence of neuroexcitation ("excitotoxicity"), perhaps due to intracellular volume overload (NaCl/water influx). More recently, evidence has been accumulating that an influx of extracellular Ca may serve as a common pathway in the injury of several cell types by several toxins; however, as reported by Rothman (Neurosci. Abstr. 10:24) and by Olney et al. (ibid.), glutamate can kill neurons in the absence of extracellular Ca.

The phenomenon of glu neurotoxicity was examined in dissociated mouse cortical cell culture. Brief (5 minute) exposure of mature cortical cultures to 0.5 mM glu was followed immediately by neuronal swelling and increased granularity (phase-contrast microscopy), and over the next day by widespread neuronal disintegration. Replacement of extracellular Na or Cl attenuated the early neuronal swelling, but resulted in only minor reduction in the late neuronal loss. Exposure of cultures to 100 mM K produced immediate neuronal swelling similar to that produced by glu.

Removal of extracellular Ca, on the other hand, did not block early swelling, but did markedly reduce ultimate neuronal loss; elevation of extracellular Ca accentuated the loss produced by threshold (.05 mM) concentrations of glu. Exposure of cortical cultures to the Ca ionophore A23187 (10-70 microM) produced little in the way of immediate morphological changes, but was followed by widespread late disintegration of neurons (and many non-neuronal cells). Increasing the time of glu exposure to 30 minutes increased late neuronal cell loss in cultures exposed to glu in the single absence of either Na or Ca; however in the absence of both Na and Ca, cultures were largely intact even after such prolonged exposure.

These observations are consistent with the hypothesis that the toxicity of glu on cortical neurons can be separated into two components that can be distinguished by differences in time course and in ionic dependence. The first component occurs early, is dependent on extracellular Na or Cl, can be mimicked by high K, and is thus possibly "excitotoxic". The second component occurs late, is dependent on extracellular Ca, and is possibly mediated by a transmembrane influx of Ca through glu-activated channels and/or voltage dependent channels. While either component alone is ultimately capable of producing irreversible neuronal injury, at lower exposures to glu the Ca-dependent mechanism predominates. (Work supported by BRSG RR5353 and by a grant from the Wills Foundation).

50.4 ENHANCEMENT OF MPTP NEUROTOXICITY BY METABOLISM TO MPP AND MPPYRIDONE. R. D'Amato*, J. Nye, C. Pronsky* and S.H. Snyder. Johns Hopkins Univ. Sch. of Med., Dept. of Neuroscience, Baltimore, MD 21205.

Metabolic studies of liver microsomes have demonstrated the production of MPP+ and MPPyridone (N-Methyl-4-Phenyl-2-Pyridone) when MPTP is incubated in the presence of NADP (Biochemical and Biophysical Research Communications, 125, No. 2, 1984). We have synthesized the MPPyridone from MPP+ and ^{3}H-MPP+ to study the toxic effects of this compound and to investigate its binding or uptake properties. Preliminary results in mice reveal that the pyridone metabolite is neurotoxjc as measured by loss of dopamine uptake (^{3}H-mazindol binding) sites and tyrosine hydroxylase activity in the striatum. Further studies in PC12 cells using enzyme markers (LDH, tyrosine hydroxylase), mazindol binding and dopamine uptake have demonstrated that MPP+ is 100 times more neurotoxic than MPTP. The pyridone also shows enhanced neurotoxicity. Both MPP+ and its metabolite MPPyridone are taken up by catecholamine neurons which may explain their enhanced selective toxicity. Ongoing studies examine the effects of inhibitors of MAO and amine uptake on the toxicity of the metabolites.

50.5 CHARACTERIZATION OF COVALENT BINDING OF AN MPTP METABOLITE TO RAT, MOUSE AND MONKEY BRAIN IN VITRO. S. Pintus, A. Bocchetta, M. Del Zompo* and G.U. Corsini. Section on Immunopharmacology, NINCDS, NIH, Bethesda, Maryland 20205. *Clinical Pharmacology, University of Cagliari, Cagliari, Italy, 09100.

We have recently demonstrated that MPTP is converted by MAO in vitro to a reactive intermediate which binds covalently to one or more proteins in rat and monkey brain. Different lines of evidence support the concept that the generation of the covalently bound metabolite in rat, mouse and monkey brain tissue homogenates is enzymatic. When [methyl-^{3}H] -MPTP was incubated at 37°C with rat brain homogenates, an increasing amount of radioactivity was recovered in tissue proteins after exhaustive extraction with organic solvents. At 10^{-5}M MPTP the time course of formation was linear for 2 hours, reaching the amount of 71 picomoles bound per milligram of protein. The rate of formation was of 22.88 pmoles/mg protein/min. The enzyme activity was greatly reduced at 0°C and was virtually absent in preboiled homogenate or under nitrogen. There was a variation in enzyme activity in different subcellular fractions and brain regions. The highest activities were seen in the P_2 fraction and in the frontal cortex, hypothalamus and caudate, while the P_1 and S_2 fractions, the pons, midbrain and cerebellum exhibited the lowest activities. MAO inhibitors almost completely prevented covalent binding of radioactivity. Deprenyl and pargyline were the most potent, while clorgyline was far less. Incubations with [methyl-^{14}C]-MPTP and [2,6-$^{3}H_2$]-MPTP resulted in the formation of similar amounts of binding, indicating that neither the ^{3}H label nor the N-methyl group was lost during the metabolic oxidation. If the tissue homogenate was incubated with [methyl-^{14}C]-MPP^{+}, the final product of MAO dependent MPTP metabolism, no radioactivity was recovered after exhaustive extraction indicating that the intermediate which binds covalently to tissue proteins is generated during the MPTP oxidation. We suggest that the finding of a chemically reactive metabolite of MPTP in brain might play a role in its neurotoxicity.

50.6 CYTOTOXIC CHANGES IN CULTURED DOPAMINE NEURONS TREATED WITH MPP+. C. Mytilineou, Dept. of Neurology, Mount Sinai Sch. of Med., New York, N.Y. 10029.

The parkinson inducing agent, MPTP, can be metabolized in vivo by monoamine oxidase to 1-methyl-4-phenylpyridine (MPP+) which could be responsible for MPTP induced toxicity. We have shown that MPTP treatment results in degeneration of dopamine (DA) neurons in cultures of embryonic rat midbrain. We, therefore, examined whether MPP+, is also toxic to DA neurons in explant and dissociated cell cultures. The toxicity of MPP+ was assessed by measuring the 3H-DA uptake by the cultures, as well as by catecholamine (CA) histofluorescence and tyrosine hydroxylase (T-OH) immunocytochemistry. Cultures were established from the ventral midbrain area of rat embryos between the 14th and 16th day of gestation. On the 7th day in vitro MPP+ was added to the feeding medium. After 7 days of treatment with 10 uM MPP+, uptake of 3H-DA was reduced to 4% of control values, while 2.5 uM MPP+ caused a reduction to 35% of control (Mytilineou et al., Neurosc. Lett., in press). Histofluorescence, after loading the CA neurons with alpha-methylnorepinephrine, demonstrated a complete absence of fluorescing neurons and fibers 7 days after treatment with 10 uM MPP+. With the lower concentration (2.5 uM), most of the fluorescing axonal outgrowth had degenerated, but some fluorescing neurons and processes remained within the main explant. The higher susceptibility of neuronal processess to the toxicity of MPP+ is consistent with recent evidence indicating that MPP+ uses effectively the amine uptake pump. In order to visualize the entire DA neuron during the analysis of MPP+ toxicity, we used dissociated cultures stained with antibodies against T-OH. Treatment with 10 uM MPP+ for 24 hours, which produces a 34% reduction in 3H-DA uptake, resulted in morphological changes to the T-OH positive neurons, which could be grouped in 3 general categories. (1) Neurons almost entirely devoid of axonal or dendritic processes; (2) trunkated neurons with short processes restricted to the immediate vicinity of the soma and (3) neurons with appearance indistinguishable from the controls. In general, the fibers present were smooth with less prominent varicosities. In addition to these changes, which could be considered as events leading to neuronal degeneration, several neuronal somata had lost the normally smooth appearence of their membrane and exhibited many filopodia-like protrusions. The possibility of an attempt for new growth by the MPP+-damaged neurons is of interest, in view of the extensive amounts of large fluorescent varicosities present in the vicinity of the substantia nigra of monkeys treated with MPTP. (Supported by NIH grant NS 18979).

50.7 PROTON MAGNETIC RESONANCE STUDIES OF BRAIN AND SPINAL CORD OF DEVELOPING RABBITS INTOXICATED WITH TRIETHYL TIN. A.V. Lorenzo, F.A. Jolesz*, J.K. Wallman* and P.W. Ruenzel*. Dept. of Neurosurgery and Radiology Children's, and Brigham and Woman's Hosp and Physiology and Biophysics, Harvard Med Sch, Boston, MA 02115.

Myelinogenesis and tissue dehydration are characteristic features that occur concomitantly during perinatal brain development in most mammalian species. Coincident with these changes there is in the developing postnatal rabbit brain a marked reduction (approx 50%) in the proton MR average relaxation times, T_1 and T_2. It is not clear if these changes in proton MR parameters are attributable to myelin accumulation or dehydration.

To resolve this issue groups of rabbits, 1 to 90 days of age, were injected ip with 1mg/kg/day triethyl tin (TET) or saline. At day 5 they were killed, the brains removed and weighed. Cortex, white matter, midbrain, pons-medulla, cervical and lumbar spinal cord, and multifidus muscle were sampled. These were placed in tared vials and dessicated to constant weight to determine water content, or in test tubes to measure relaxation times with an IBM PC 10 Minispec at 10 MHz. T_1 was determined with an inversion recovery pulse sequence; and a 20 spin echo CPMG sequence was used to determine T_2. Some animals were perfused with aldehydes and tissues were processed for light and electron microscopy.

As early as 24 hours hind limb weakness, poor planting reflex and tremor were evident in TET treated younger but not older animals. Weight gain was slower and brain weights lower in TET treated than in normal littermate controls. Both in control and TET treated animals tissue water content decreased with age. However, except for cortex and muscle, water content was significantly higher in TET treated than in control animals. Interestingly, the highest content was observed in white matter, pons-medulla, cervical and lumbar spinal cord of the youngest animals whose brains were least myelinated. Light and electron microsocopy revealed extensive vacuolation of myelinated areas and splitting of myelin interlaminal sheaths by large fluid filled vacuoles.

At all ages and for all tissues, except cortex and muscle, T_1 and T_2 were of longer duration in TET treated animals than in respective controls. As with water content these changes were most prominent in spinal cord segments followed by white matter, pons-medulla and midbrain obtained from the youngest animals. In older TET treated rabbits MR relaxation times were most prolonged in white matter and less so in spinal cord segments. The close regional and temporal relationship between the proton MR relaxation times and the pathologic increase in tissue water of brain suggests that alterations in proton MR parameters during development are related to changes in content and/or mobility of brain water. Supported in part by NIH Grant HD15304, Valleley Family Fund, and The Ingraham Fund.

50.8 ATTENUATION OF TMT INDUCED NEUROTOXICITY BY CHRONIC, CONTINUOUS ADMINISTRATION OF SCOPOLAMINE AND MUSCIMOL J.J. Kinsora*, M.E. Smith*, J. French, D.G. Robertson* and J.G. Marriott (Spon:D.Boyd). Warner-Lambert/ Parke-Davis, Pharmaceutical Research, Ann Arbor, MI 48105

Trimethyltin (TMT) selectively damages the CA1 and CA4 pyramidal cell layers of the hippocampus. EEG studies have shown that the developing neuronal injury is correlated with a persistant increase in hippocampal 4-6 Hz theta activity. The anticholinergic scopolamine and the GABA agonist muscimol can block the appearance of TMT induced increases in hippocampal theta. Chronic, continuous administration of scopolamine and muscimol were evaluated for their effects on TMT related pyramidal cell loss.

Adult male, Long-Evans rats (240 gm) received either chronic scopolamine(n=6) or muscimol(n=6) at 0.1 mg/kg/day via osmotic minipumps implanted subcutaneously in the nape of the neck. Another 6 rats were sham operated. After 24 hr recovery, all rats received TMT (3 mg/kg PO) daily for 3 consecutive days. Fourteen days post TMT, all rats were anesthetized and perfused fixed with formalin. Coronal sections through the hippocampus were cut at 50 u or 5 u and stained with either cresyl-violet or iron-hematoxylin, respectively. The number of cells in the pyramidal layers were estimated by light microscopy (50X).

Animals treated with TMT showed body weight, temperature and behavior changes characteristic of previous reports. Rats given TMT alone lost 85-90 % of the hippocampal CA1 pyramidal cells with some evidence of CA4 injury. Two of the 6 rats given TMT and chronic scopolamine demonstrated comparable neuronal damage. The remainder of the TMT/chronic scopolamine rats and all of the TMT/chronic muscimol rats showed only 5-10 % CA1 cell loss with no apparent damage to the CA4 region.

Chronically administered scopolamine and muscimol protected hippocampal neurons from typical TMT damage. Since these agents attenuate TMT induced increases in hippocampal theta, the present data support the contention that the prolonged occurrence of theta activity following TMT, may have excitotoxic consequences in hippocampal neurons.

50.9 VENTRAL ROOT AXONOPATHY ASSOCIATED WITH THE NEUROFIBRILLARY DEGENERATION OF LOWER MOTOR NEURONS IN EXPERIMENTAL ALUMINUM ENCEPHALOMYELOPATHY. L.C. Triarhou, J. Norton*, O. Bugiani* and B. Ghetti. Depts. of Pathology, Psychiatry, and Medical Genetics, Indiana University Med. Ctr., Indianapolis, IN 46223, and Istituto Neurologico 'C. Besta', 20133 Milano, Italy.

When metallic aluminum (Al) is injected intracisternally in adult rabbits, lower motor neurons of the spinal cord undergo neurofibrillary degeneration. It has been previously reported that the PNS of rabbits injected with Al may also show pathologic changes (Bugiani, O. and Ghetti, B., Neurobiol. Aging, 3: 209, 1982). In the present study, we examined the ventral roots that originate in the cervical enlargement and the corresponding motor neurons in Al-treated animals to clarify the modality and extent of axonal pathology, and to relate the latter to the severity of perikaryonal involvement. Eight rabbits received 0.15 ml of a 1% Al slurry each into the cisterna magna. They were perfused through the heart with aldehydes at 14-62 days post-injection. Spinal cords and spinal roots were processed, embedded in Epon, and examined by qualitative and quantitative morphological methods.

In animals that developed a rapidly progressing motor weakness, neurofibrillary degeneration was widespread in the spinal cord, involving the lateral motor nucleus as well, and the incidence of ventral horn neurons with neurofibrillary tangles was 66-81%. In the remaining animals, motor signs were mild and developed slowly, and the lateral motor nucleus was relatively spared. In the former group, a severe axonopathy of the ventral spinal roots was observed. The axonopathy was characterized by neurofilamentous axonal swellings and myelin attenuation. At the C6 level, the overall fiber-diameter distributions in animals with axonopathy differed significantly from the average distribution in controls ($P<0.0001$). Using individual comparisons, a significant excess or shortage was detected in several fiber-size classes ($P<0.05$). However, in one animal with severe qualitative changes in the roots, the distribution of fiber diameters did not differ significantly from controls. The variability of histograms could be better understood through the analysis of individual axons in serial sections, which showed that axons that appeared normal at a given level showed signs of axonopathy several micrometers distally. Moreover, there was a highly significant difference between the variability of diameter in fibers traced serially in treated animals and controls ($P<0.0005$). The presence of myelin of normal thickness proximally to the axonal swellings supports the view that the peripheral axonopathy is unifocal or multifocal. The findings of this study demonstrate that PNS changes in the Al-induced encephalomyelopathy are related to the axonopathy of motor neurons. Our observations may be relevant to the pathophysiology of lower motor neuron disease in humans.

50.10 THE SUSCEPTIBILITY OF VARIOUS INTERMEDIATE FILAMENTS TO AGGREGATION BY 2,5-HEXANEDIONE: PARALLELS WITH THEIR SUSCEPTIBILITY TO AGGREGATION SECONDARY TO DISRUPTION OF MICROTUBULES. H.D.Durham*. (SPON: G.Karpati). Dept. Neurology & Neurosurgery, Montreal Neurological Inst. & McGill University, Montreal, Canada, H3A 2B4.

2,5-hexanedione (2,5HD), the neurotoxic metabolite of n-hexane and methyl n-butyl ketone, induces both focal accumulation of neurofilaments (NF) in axons and juxtanuclear aggregates of intermediate filaments (IF) of the vimentin-type in cultured human skin fibroblasts. It has been proposed that 2,5HD prevents the association of IF with microtubules (MT), thereby disrupting NF transport. If this is correct, only IF-subclasses which depend on MT for their cellular distribution should be affected and the IF-aggregates formed should resemble those induced secondary to depolymerization of MT in the presence of colchicine. Therefore, the effect of 2,5-HD was investigated in PTK1 cells, which contain two distinct networks of IF: vimentin-IF whose distribution is colchicine-sensitive and keratin-IF which are insensitive to colchicine. The distribution of both networks of IF was examined in the same cell by double-label immunohistochemistry using antisera specific against vimentin and keratin. In cultures exposed to 6mM 2,5HD for 15 days, aggregates of IF were observed which were labeled by anti-vimentin, but not by anti-keratin. No aggregation of keratin-IF was observed even after exposure of the cells to 2,5HD (2 to 8 mM) for up to 8 weeks.

PTK1, a cell line derived from marsupial kidney, was approximately 3-fold less sensitive to 2,5HD than were human skin fibroblasts. Also, IF pathology in non-neuronal cells was not reported in studies of 2,5HD on organotypic cultures of mouse spinal cord-DRG-skeletal muscle (Veronesi et al. J. Neuropathol. exp. Neurol. 42:153, 1983), although the concentration and duration of exposure which induced focal accumulation of NF in these neurites was similar to that which aggregated IF in cultured human skin fibroblasts (Durham et al. Muscle & Nerve 6:631, 1983). We have confirmed this species difference between human and mouse, i.e. in the susceptibility of IF distribution in non-neuronal cells in culture to alteration by 2,5HD, using human and mouse skin fibroblasts, fibroblast-like cells from mouse spinal cord and 3T3, a cell line derived from mouse fibroblasts. Differences between human and mouse cells were also observed in the response of their IF to depolymerization of MT. IF aggregates were found in human skin fibroblasts, but not in 3T3 cells, after 24 hr exposure to colchicine (5uM).

50.11 FINE STRUCTURE OF CAT CNS AFTER SOMAN EXPOSURE K.C. Sikora-VanMeter, W.G. VanMeter and R.C. Wierwille. Dept. Pharmacol. and Exptl. Therap., Sch. Med., Univ. Maryland, Baltimore, MD 21201; USAMRICD, APG, MD 21010 and Dept. Vet. Physiol. and Pharmacol., Iowa State Univ., Ames, IA 50011

Male or spayed female cats weighing 2.0 to 3.5 kg were given single subcutaneous injections of 5 µg, 10 µg, 15 µg, 17.5 µg, 18.75 µg or 20 µg/kg SOMAN. Cats treated with 5 µg or 10 µg/kg failed to show convulsions for 24 hours at which time they were anesthetized with DIAL (80 mg/Kg ip.), and fixed by whole body perfusion with 5% phosphate buffered glutaraldehyde. Selected tissue samples were taken from the brain and spinal cord, postfixed in OsO_4, dehydrated and embedded in Poly-Bed 812/Araldite mixture. Neuronal as well as glial elements of supraoptic nucleus (SON), hippocampus (HPC), caudate nucleus (CN) and the anterior horn of lumbar segment 7 (L-7) of the spinal cord were examined for changes in fine structure. Cats receiving the other doses were anesthetized either on the appearance of convulsions or after 60 minutes, in the absence of convulsions. These animals as well as the controls were then processed as described above. All animals showed effects of treatment. However, these effects are dependent on dose, duration of exposure and vary with the selected sites. Thus, the SON and HPC of all treated animals show invaginations of the nucleus, vacuolization of nuclear membrances and multiple nucleoli in neuronal nuclei. Neurons in the SON, HPC and L-7 of cats given 15 µgm/Kg or larger doses of SOMAN show increased amounts of rough endoplasmic reticulum and well developed Golgi complexes which indicates increased metabolic activities in these neurones. Also, HPC CA3, and L-7 neurones show increases in mitochondria and lysosomes. On the other hand, changes in fine structural elements of the CN were not observed. A rank ordering of the selected sites according to degree of change and dose shows the SON most effected followed by HPC, and L-7. Finally, the influence of the duration of exposure is demonstrated in an initial increase of metabolic acitivity followed by early signs of degeneration such as dense lamellar bodies, vacuolization, accumulation of mitochondria and increase in electron density in neuronal as well as some glial elements.

Supported in part by U.S. Army Medical Research & Development Command Contract Nrs. DAMD 17-80-C-0106, DAMD 17-81-C-1279 & DAMD 17-85-C-5117.

50.12 AMINO ACID ANALYSIS AND HPLC CHARACTERIZATION OF THE ISOFORMS OF THE METALLOTHIONEIN-LIKE PROTEIN IN RAT BRAIN. M. Ebadi, D. Babin*+ and S. Swanson*. Dept. of Pharmacology, Univ. of Nebraska College of Medicine and Dept. of Biochemistry*+, Creighton University School of Medicine, Omaha, Nebraska 68105.

Previous studies from our laboratory identified in rat brain a metallothionein-like protein whose synthesis was stimulated by Zn^{2+} and Cu^{2+}, but not by Cd^{2+}. The zinc-stimulated protein incorporated a large quantity of S^{35} cysteine and was blocked by actinomycin D.

The zinc-stimulated metallothionein-like protein was further purified by ion exchange chromatography on DEAE Sephadex A-25 columns. The proteins, which were separated with a linear gradient using Tris acetate buffer (0-200 mM, pH 7.5), produced two isoforms, eluting at 75 mM and 137 mM, respectively. The comparative HPLC profiles of zinc-treated rat hepatic metallothionein and metallothionein-like proteins from rat brain are very similar (Fig. 1).

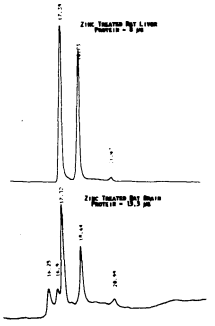

Fig. 1. Comparative HPLC profiles of Zn^{2+}-stimulated hepatic metallothionein and metallothionein-like protein from rat brain.

Metallothionein-like protein isoform I possesses a Mr of 6200, consists of 60 residues of 12 cysteine and no histidine, arginine, leucine, tyrosine, or phenylalanine. Metallothionein-like protein isoform II possesses a Mr of 6300, consists of 61 residues of 3 cysteine and no histidine, arginine, leucine, tyrosine, or phenylalanine. The function(s) of metallothionein-like protein in the brain is not clear and remains to be determined. The lack of binding of Cu^{2+} and Cd^{2+} may be interpreted to indicate that the metallothionein-like protein in the brain is not involved in metal detoxification. Since zinc in physiological concentrations stimulates a number of pyridoxal phosphate-dependent reactions, and in pharmacological doses inhibits an extensive number of SH-containing enzymes and receptor sites for neurotransmitters, we postulate that the metallothionein-like protein in the brain may have function(s) associated with zinc homeostasis and perhaps events related to synaptic functions. (Supported in part from a grant from USPHS-NS-08932).

51.1 **FORMATION OF PRESYNAPTIC SPECIALIZATION INDUCED BY LATEX BEADS IN SPINAL CORD CULTURES.** **H. Benjamin Peng, D.R. Markey, W. Muhlach and E. D. Pollack.** Dept. of Anatomy and Inst. Study Dev. Disabilities, Univ. of Illinois at Chicago, Chicago, Illinois 60612.

The development of the synapse is initiated by an interaction of the pre- and the postsynaptic elements. In the development of the neuromuscular junction (NMJ), the postsynaptic differentiation is triggered by the nerve-muscle contact. Recently we showed that basic polypeptide-coated latex beads can also induce the postsynaptic development in cultured Xenopus muscle cells. Previously, R.W. Burry (Brain Res. 184:85, 1980) showed that Sepharose beads coated with poly-basic compounds also cause the formation of apparent presynaptic elements in cultures of rat cerebellum neurons. In this study, we examined whether a similar presynaptic differentiation can be elicited in spinal cord cultures. Explant cultures were prepared from spinal cords isolated from the lumbar region of Nieuwkoop and Faber stage 50 tadpoles or from stage 22 embryos. After the neurite outgrowths were established, latex beads (1-4.5 μm in diameter) coated with polyornithine were applied to the cultures. Following an incubation period of 1-2 days, the cultures were fixed and processed for light and electron microscopy (LM and EM). For LM, we permeabilized the neurites with saponin and labeled them with a monoclonal antibody (mab 48) specifically against the synaptic vesicles (Matthew et al., J. Cell Biol. 91:257, 1981; a gift from Drs. W. Matthew and R. Burry). Immunofluorescence showed that the mab 48 antigens were concentrated at 60% of the bead-neurite contacts. The rest of the neurite showed very little labeling. Cultures treated with negatively charged (polycarboxylate) beads did not show labeling at the bead contacts. However, labeling was also detected at varicosities along the neurites cultured on polylysine substrate. EM studies revealed the following features: (1) Clusters of 50-60 nm clear vesicles were prominent at the neurite-bead contacts. The vesicles were densely packed at the contact and larger clusters were often composed of smaller 0.1-0.5 μm subclusters. (2) A class of large (90-100 nm) dense-cored vesicles was also seen in the bead-induced terminal, although they were not concentrated at the immediate contact area. (3) Basement membrane did not form at the bead-neurite contact. This is in contrast to our previous observation that this structure does form at the bead-muscle contact. (4) Coated pits were occasionally seen at the contact area.

Our LM study with mab 48 strongly suggests that the vesicles at the neurite-bead contacts are synaptic vesicles. These results thus indicate that basic polypeptide-coated beads can induce a presynaptic-type specialization along the neurite. This offers a model system to study the differentiation of the nerve terminal in the NMJ formation. (Supported by NIH grant NS-16259 and MDA)

51.2 APPARENT CONVERSION OF THE GATING PROPERTIES OF ACETYLCHOLINE RECEPTORS AT RAT SOLEUS ENDPLATES IN VITRO. S.M. Schuetze and S. Vicini*. Dept. Biol. Sci., Columbia Univ., New York, NY 10027 and Fidia Research Laboratories, 35031 Abano Terme (Pd), Italy.

The apparent mean channel open time (τ) of acetylcholine receptors (AChRs) decreases 4- to 5-fold at developing rat endplates. During the first three weeks after birth, ACh-activated channels are converted from a slow, embryonic type (τ=5 msec at 21°C) to a fast, adult type (τ=1.2 msec). Individual endplates contain both types of AChRs during this transition period, and as a result they have miniature endplate currents (MEPCs) with doubly-exponential decay phases. The relative amplitudes of the fast and slow exponential components indicate the relative activities of adult-type and embryonic-type AChRs.

We have used MEPC analysis to see if channel conversion occurs at endplates in neonatal muscles maintained in vitro. Using soleus muscles taken from 5 to 15 day old rats, we followed the kinetics of MEPC decays at 97 individual endplates for 2-24 hr each. On the average, the size of the slow decay component decreased from 49.5% of total MEPC amplitude initially to 36% of total MEPC amplitude 6.6 hr later. The fast and slow time constants did not change. Noise analysis studies revealed a similar progressive decrease in the relative amount of slow channel activity in perijunctional regions. There was no indication that these changes were due to deterioration of the preparation. Since the overall amplitude of the MEPCs remained roughly constant, it is unlikely that slow, embryonic-type AChRs simply become silent with time. A conversion of AChR channel properties seems more likely.

The frequency and extent of this apparent channel conversion varied with the initial state of the endplate. Endplates that had virtually all embryonic-type or all adult-type AChRs at the start of the experiment rarely showed channel conversion. Endplates that started with a mixture of channel types, suggesting that they had already initiated channel conversion in vivo, were most likely to show changes in MEPC decays in vitro. The major difference between channel conversion in vivo and apparent channel conversion in vitro is that the latter process is about 10-20 times faster. This in vitro system should prove useful in investigating the mechanism of channel conversion. Preliminary experiments indicate that high concentrations of sugars (200 mM dextrose or sucrose) inhibit the process, but we do not yet know whether this is a direct effect of the sugars or an indirect effect of the increased osmolarity.

51.3 THE ANEURAL DEVELOPMENT OF THE ACETYLCHOLINE RECEPTOR IN THE PRESENCE OF AGENTS WHICH BLOCK PROTEIN SYNTHESIS AND GLYCOSYLATION. C.G. Carlson*, R.J. Leonard and S. Nakajima. Dept. of Biological Sciences, Purdue University, West Lafayette, IN 47907.

Cultured muscle from Xenopus embryos offers an ideal preparation for the developmental analysis of the acetylcholine receptor (AChR) since (1) two classes of receptor (high and low conductance) with different mean open times develop in the absence of neural influence, and (2) the open time of the low conductance class decreases by about 50% between developmental Stages (St) 22 and 35. In addition, the proportion of high conductance events ('junctional' type) gradually increases between St 28 and 43. In an attempt to determine whether these changes occur before or after translation or insertion of the AChR into the plasma membrane, muscle cultures from myotomes dissected from St 15-18 embryos were treated with cycloheximide (Cy-100 μg/ml) or Tunicamycin (TM-5 μg/ml) at St 22 to 29. The physiological properties of the two classes of receptor were then examined at St 35-42 utilizing the cell-attached patch clamp technique.

When Cy was added to cultures as early as St 24 or as late as St 28, the proportion of high conductance events subsequently examined at St 37 to 43 was reduced from control levels of about 50% to between 5 and 12%. Many cells appeared to completely lack high conductance events. Neither the developmental change in open time nor the conductance of the low conductance event were altered by Cy. Similar results were obtained with TM which, when added as early as St 22, blocked the appearance of the high conductance event, but left unaltered the developmental change in the open time of the low conductance event. Since Cy is known to block protein synthesis at the translation stage and TM blocks protein glycosylation and insertion of the receptor into the plasma membrane (Rotundo and Fambrough, Cell, 22: 595-602, 1980), these data suggest that no post translational or post-insertional mechanism exists for the conversion of low conductance to high conductance events. Nevertheless, the possible development of a converting enzyme which could act on receptors in the plasma membrane has not been excluded. The failure of TM to block the developmental reduction in open time of the low conductance event, however, suggests that this reduction normally occurs subsequent to protein glycosylation, or after insertion of the AChR into the plasma membrane. (Supported by NIH grants NS08601 and T-32-GM-07211, and an MDA grant).

51.4 THE LOCALIZATION OF ACETYLCHOLINE RECEPTORS ON MUSCLE CELLS CONTACTED BY SINGLE NEURONS IN CULTURE. M.W. Cohen and E. Wilson*. Dept. of Physiology, McGill Univ., Montreal, Quebec.

Previous studies have indicated that competent spinal cord (SC) neurites which innervate muscle cells in culture induce the development of sites of high acetylcholine receptor (AChR) density along the path of contact. However, the capacity of a single competent neuron to interact with muscle cells in this way has not been assessed since the possibility of polyneuronal innervation of the muscle cells was previously not excluded. In the present study cultures prepared from dissociated SC and myotomal muscle cells of Xenopus embryos were analyzed for only those cases where the muscle cells were contacted exclusively by the neuritic arborization originating from a single soma. SC cells were added to 2-3 day old muscle cultures and the cultures were examined for AChR localization up to 6 days later by combined phase contrast and fluorescence microscopy after staining with tetramethylrhodamine-labelled α-bungarotoxin.

So far eight competent SC neurons, containing neuritic arborizations 400-1200 μm in total length, have been analyzed. Each neuron contacted four to seven muscle cells, and on each of these muscle cells AChRs were localized along the path of contact. For each neuron the length of contact exhibiting AChR localization was 20-40% of the total length of contact. The neuritic arborization of individual neurons contained as many as seventeen segments (the portions of neurite between the soma and a branch point, between two branch points, or between a branch point and the end of the neurite). These neuritic segments varied in length from 5 μm to more than 100 μm. More than 85% of them exhibited AChR localization along their path of contact with muscle. Likewise more than 85% of the contacts formed by terminal neuritic segments had sites of high AChR density. In addition, 75% of the ends of terminal neuritic segments also exhibited AChR localization at their sites of contact with muscle.

These results indicate that all muscle cells in this culture system can interact with competent SC neurons to localize AChRs at the sites of contact and that most, if not all, of the neuritic segments are capable of participating in this interaction. The absence of AChR localization at contacts formed by a few of the neuritic segments does not necessarily mean that these segments were incapable of inducing AChR localization. Rather individual muscle cells may have a limited capacity to develop sites of high AChR density and in the case of some terminal neuritic segments the contact may have been too immature for AChR localization to be detected. The fact that AChR localization occurred at the great majority of contacts involving terminal segments, and even their end points, suggests that the capacity to induce AChR accummulation is a feature of the entire neuritic arborization to the limit of its growth. (Supported by MRC).

51.5 **AChR/AChE-AGGREGATING FACTOR FROM TORPEDO ELECTRIC ORGAN IS ANTIGENICALLY SIMILAR TO MOLECULES CONCENTRATED IN THE SYNAPTIC CLEFT AT NEUROMUSCULAR JUNCTIONS.** Noreen E. Reist, Ralph M. Nitkin, Justin R. Fallon, Bruce G. Wallace, U.J. McMahan. Dept of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

Molecules tightly adherent to the synaptic cleft basal lamina in skeletal muscle direct the aggregation of acetylcholine receptors (AChRs) and acetylcholinesterase (AChE) on regenerating muscle fibers. As part of a series of studies aimed at characterizing the AChR- and AChE-aggregating molecules, we have extracted a factor from a basal lamina fraction of Torpedo californica electric organ, which causes both AChRs and AChE to form aggregates on cultured myotubes. Thus far we have purified the factor several thousand fold and have made two different monoclonal antibodies (6D4 and 2F6) against it. In the study described here, we sought to determine if the antibodies recognize molecules at the neuromuscular junction of skeletal muscles, as would be expected if the electric organ factor were similar to the AChR- and AChE-aggregating molecules in the synaptic basal lamina.

We used muscles from electric rays and observed the distribution of molecules recognized by the antibodies by indirect immunohistochemistry. In frozen cross sections fluorescence microscopy revealed that both monoclonal antibodies heavily stained the neuromuscular junctions. Staining was also observed along axons and in the walls of muscular arteries. Thus, the monoclonal antibodies recognize molecules associated with more than one tissue component in muscle, but on muscle fibers such molecules are concentrated at neuromuscular junctions. To learn whether or not epitopes recognized by 6D4 are extracellular, intact muscles were fixed, incubated with the antibody, and examined in whole mounts. Under such conditions the antibodies could interact only with the extracellular matrix and the external surface of plasma membranes. Fluorescence microscopy revealed that all of the structures labeled in cross sections were also stained in the whole mounts, including neuromuscular junctions. Some whole muscle preparations incubated with 6D4 and HRP-conjugated second antibody were sectioned and examined by electronmicroscopy to determine the distribution of 6D4 epitopes at neuromuscular junctions. HRP reaction product occupied much of the synaptic cleft, including the synaptic portion of the myofiber basal lamina; no labeling was detected beyond the synaptic cleft. Thus, epitopes recognized by 6D4 at neuromuscular junctions are concentrated in the synaptic cleft and are a part of or adjacent to the synaptic basal lamina.

51.6 METAMORPHIC TURNOVER OF TRIGEMINAL NEUROMUSCULAR CONTACTS IN RANA PIPIENS. K. Alley. Dept. of Oral Biology, Ohio State Univ., Columbus, OH 43210.

During metamorphic climax the cranial architecture of larval anuran amphibians is dramatically changed to the adult form. As part of this adaptive process the larval jaw apparatus, used in an aquatic filter-feeding habitat, is retooled to accommodate the predatory life style of the adult. Gross changes in cranial morphology are accompanied by a complete degeneration of the larval myofibers and the regeneration of a replacement population during a second wave of myogenesis. Moreover, previous investigation has shown that the same trigeminal motoneurons innervate both the pre- and postmetamorphic musculature (Alley and Barnes, J. Comp. Neur. 218: 395, 1983).

This investigation analyzed the morphologic and molecular events associated with the rewiring of the preterminal axons during the transition from larval to adult myofibers. A combination of ^{125}I-α-bungarotoxin autoradiography, light and electron microscopy was used to assess the reactivity of the pre- and postsynaptic components of the myoneural junctions in the adductor jaw muscles of metamorphic leopard frogs. Specifically, I wanted to determine whether the entire end plate complex is destroyed with the larval myofiber, or if the preterminal axon is separated from the muscle prior to the onset of myodegeneration and recycled to innervate the adult myofibers.

Both light and electron microscopic observations indicate that the presynaptic component of the NMJ remains in contact with the larval myofibers throughout the entire degenerative process. In fact, axon terminals were frequently observed contacting the empty basal laminar tubes long after the sarcoplasm was digested. These contacts exhibited many of the characteristics of normal myoneural junctions. Bungarotoxin labeling of acetylcholine receptors (AChR) provides further support for the stability of the larval NMJs. The distribution and number of AChRs remains unchanged even in myofibers undergoing degenerative changes.

Although the ultimate fate of the preterminal axon is still unknown, the current observations suggest the following conclusions: 1). innervation of the newly formed adult myotubes is by sprouting of the trigeminal axons and not recycling of the larval terminals, 2). the basal lamina of the larval myofibers is capable of maintaining the synaptic ending in the absence of the postsynaptic receptors, and 3). a stable neurotrophic relationship does not prevent the degeneration of the larval muscle fibers.

51.7 REGULATION OF THE STABILITY OF SYNAPSES. D.G.Puro. Bascom Palmer Eye Institute, University of Miami, Miami,FL

The turnover of synapses appears to play an important role in the development of specific neural circuits. Here, I report the use of a cell culture system in which it is possible to quantitate the on and off rates of synapse formation, to identify transient and stable synaptic pairs and to influence the stability of synapses.

Striated muscle cells were used as postsynaptic targets for cholinergic retinal neurons. Rat myoblasts were cultured in 35mm dishes for 5 days under conditions which limited fusion and, thus, myotube length. Retinal cells from embryonic day 8 chicks were trypsin-dissociated; $5x10^4$ cells were added to a muscle culture. By plating a low density of retinal cells onto short myotubes, innervated myotubes received synaptic input from only one neuron. Neuron-muscle synapses were detected by the presence of spontaneous synaptic input demonstrated by intracellular recordings from muscle cells.

Between 12 and 36 hrs of coculture, the percent of randomly sampled muscle cells with synaptic input increased from 0 (0/280) to 7.6 (26/342). For the next 24 hrs, the overall percent ofinnervated muscle cells remained stable. However, a significant turnover of synapses was discovered during this time. Specifically, of the myotubes shown to be innervated at 36 hrs of coculture, only 67% (14/21) of these myotubes remained innervated 8 hrs later.Conversely of 60 muscle cells found to be without innervation at 36 hrs of coculture, 6 became innervated within 12 hrs. Thus, despite a constant net percent of innervation, synapses were turning over.

Not all retina-muscle synapses were turning over at the same rate. Although a third terminated within 8 hrs, the other two-thirds remained for at least 16 hrs. This suggested two populations- one of transient synapses, the other of stable synapses. In a search for a functional correlate for this difference, the potency of glutamate-evoked transmission across retina-muscle synapses was assessed at 36 hrs of coculture. Responses were classified as weak (2-3 fold increases in the frequency of psp's) or strong (≥5 fold increase). Over an 8 hr period, none (0/10) of the muscle cells with weakly evocable input remained innervated. In contrast, 90% (9/10) of the muscle cells with strong evoked input remained with synapses. Thus, a stable and a transient population of synapses could be identified.

Attention was also directed to the period in culture, 60 to 96 hr, when the net percent of innervation decreased from 7.6 (25/326) to 1 (1/110). Could this termination be regulated? When cocultures were exposed to 50 μM glutamate from 48 hrs of coculture, 6.7% (6/90) of the sampled myotubes were innervated at 96 hrs of coculture. Glutamate exposure did not influence the on rate of synapse formation. Rather, glutamate appeared to maintain a population of synapses.

In summary, the turnover of synapses can be quantiated and regulated in a cell culture system.

51.8 SYNAPSE FORMATION BETWEEN JUVENILE AND ADULT APLYSIA NEURONS IN VITRO. S. Schacher and M. S. Flaster. Center for Neurobiol. & Behav., Dept. of Anat. and Cell Biol., Columbia Univ., College of P&S, and N.Y.S. Psychiatric Instit., New York, NY 10032.

We are interested in examining whether adult CNS neurons can re-establish their normal chemical connections in vitro. We have previously shown that both juvenile and adult neurons isolated from the abdominal ganglion of Aplysia regenerate extensive neuritic processes in cell culture (Schacher, S. & Proshansky, E., J. Neurosci., 3:2403, 1983). Juvenile cells reliably form appropriate chemical synapses (Camardo et al., J. Neurosci., 3:2614, 1983). Here, we report that adult cells form chemical connections reliably only in the presence of juvenile cells.

The cholinergic interneuron L10 and target cells L2-L6 (LUQ cells) were isolated with portions of their original axons from juvenile (1-3 gm) and adult (30-50 gm) animals, co-cultured in various combinations, and assayed for the presence of chemical synapses using standard intracellular recording methods. As described previously (Camardo J. et al., J. Neurosci., 3:2614, 1983), when both pre- and postsynaptic cells were derived from juvenile animals, the typical dual component IPSP was recorded in over 85% of the cultures (13 of 15). The PSP amplitude averaged 5 mV (2-10 mV range) and the properties of the PSP were identical to that seen in the intact ganglion. In contrast, adult-adult cultures formed the dual component IPSP in only 1 of 10 cultures and had an amplitude of 1 mV. In two other cultures only repetitive firing in L10 produced a small response in the target cells.

Chemical connections by adult cells are greatly enhanced in the presence of juvenile cells. Adult L10-juvenile LUQ cultures formed dual component IPSPs in all cases (5 of 5) with an average amplitude of 5 mV (2-10 mV range). Juvenile L10-adult LUQ cells formed normal connections in 2 of 3 cultures (1.5 mV average). In the presence of juvenile LUQ cells, adult L10 cells formed appropriate chemical connections with adult LUQ cells in all cases (N=3) with an average amplitude of 3 MV. Preliminary evidence suggests that smaller cell body input resistance in adult LUQ cells compared to juvenile cells cannot account for the reduced level of connectivity in adult cells. In addition, ACh sensitivity on isolated juvenile and adult LUQ cell bodies and distal neurites revealed no significant differences. We tentatively conclude that there is a deficit with regard to some aspect of synapse formation in adult presynaptic and/or postsynaptic cells that is overcome in the presence of juvenile cells. We are now studying the role played by cell-cell interactions in the enhancement of synapse formation in older cells.

51.9 CHEMICAL NEUROTRANSMITTERS CAN INDUCE AND STRENGTHEN ELECTROTONIC SYNAPSES. D.C. Spray, J.C. Saez, M.V.L. Bennett, J.A. Kessler+. Depts. Neuroscience and Neurology+, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Cultured superior cervical ganglion (SCG) neurons from fetal or neonatal rats form electrotonic synapses when cultured in a defined medium (DM) but do not in ordinary serum containing medium (Higgins and Burton, J. Neurosci. 7: 2241, 1982; Kessler et al., PNAS 81: 6235, 1984). The coupling is partially attributable to components uniquely present in DM (insulin and selenium). However, coupling is also induced by membrane permeant cAMP derivatives; endogenous cAMP is suppressed by serum which accounts for its inhibitory effect on electrotonic synapse formation (Kessler et al., ibid.). Further work has shown that expression of electrotonic synapses in insulin-containing medium is blocked by the protein synthesis inhibitor cycloheximide (2 ug/ml) and the mRNA synthesis inhibitors actinomycin D (1 ug/ml) and camptothecin (2 ug/ml). Dopamine and the cholinergic agonist carbachol induce electrotonic synapse formation within 12 hrs of application (dopamine and acetylcholine are prominent neurotransmitters in SCG). For dopamine at concentrations of 10 nM to 10 uM the lowest dose is most effective, perhaps due to receptor down-regulation or desensitization. For carbachol, the effect increases with increasing doses over a similar concentration range. Incidence of coupling induced by 10 uM carbachol is similar to that induced by 1 mM db-cAMP; when both drugs are added together the incidence is unchanged. Junctional conductances (g_j) measured in carbachol or db-cAMP treated coupled pairs are similar; g_j is approximately doubled when both drugs are present. Presumably carbachol and db-cAMP act upon the same subpopulation of neurons. We conclude that chemical neurotransmitters normally present in sympathetic ganglia can induce formation of electrotonic synapses and strengthen coupling between cells. Supported in part by McKnight Foundation Development Award (DCS).

51.10 **EXPERIMENTAL REDUCTION OF SEROTONIN CONTENT DURING EMBRYOGENESIS ALTERS MORPHOLOGY AND CONNECTIVITY OF SPECIFIC IDENTIFIED HELISOMA NEURONS.** **I.I. Goldberg* and S.B. Kater. (SPON: G.J. Mpitsos). Dept. of Biology, University of Iowa, Iowa City, IA 52242.**

In this investigation, we begin to test the hypothesis that during embryogenesis, neurotransmitters play a role in regulating development of the nervous system. 5,7-dihydroxytryptamine (5,7-DHT) was used to experimentally reduce the serotonin content of embryos during a defined window of embryogenesis. The developmental consequences of this embryonic perturbation were subsequently assessed in developed snails.

To reduce levels of serotonin, embryos staged between 45% and 60% of total embryonic development were incubated in 0.5 mM 5,7-DHT for 24 hours, and then returned to normal rearing conditions for the remainder of development. HPLC with electrochemical detection was performed to determine the magnitude and timecourse of a 5,7-DHT - induced change in serotonin content. Whole embryo serotonin levels were lowered by 42% within 3 days following treatment. This decrease was transient, with no difference between treated and untreated embryos by 6 days post-treatment (embryonic stage 95%) nor upon maturing into adult snails. In addition, the cerebral neuron C1, the only serotonergic neuron which innervates the buccal ganglion, survived the embryonic treatment and was physiologically normal in the adult. Thus, the perturbation of serotonin levels was achieved during an embryonic window spanning the latter half of embryonic development.

Mature snails were examined morphologically and electrophysiologically to assess the effects of embryonic perturbations in serotonin levels. The morphology of buccal neuron 19 (B19), as determined by Lucifer Yellow injection, was grossly abnormal in 3 of 14 animals treated with 5,7-DHT, while normal in all of the controls. In addition, 7 of the 14 experimental B19's were aberrantly dye-coupled to one or several neighboring somata, in comparison to 1 case of aberrant dye-coupling in control B19's. The morphology of buccal neuron 4, which was also examined as a test of specificity, appeared normal in all of the 5,7-DHT - treated and control preparations. Furthermore, only a single example of aberrant dye-coupling was observed in the treated preparations, while the controls had none. Electrotonic coupling measurements were taken to more precisely determine whether the observed changes in frequency of dye-coupling represented changes in synaptic connectivity. In treated preparations, the electrotonic coupling coefficient for bilateral pairs of B19 was 52% greater than that recorded in control preparations. This effect was neuron-specific as the same treatment did not affect the strength of the electrotonic synapse between bilateral buccal neuron 4's. Therefore, both morphological and electrophysiolgical data demonstrate that a transient reduction in serotonin concentrations during embryonic development evokes a neuron-specific increase in electrical synaptic connectivity.

Supported by Alberta Heritage Foundation for Medical Reasearch and NIH grants NS18819 and NS15350.

51.11 **THE FORMATION OF TRANSIENT CHEMICAL SYNAPTIC CONNECTIONS BY IDENTIFIED NEURONS OF HELISOMA.** **P.G. Haydon and S.B. Kater. Department of Biology, University of Iowa, Iowa City, IA 52242.**

The nervous system of Helisoma exhibits extensive neuroplastic capabilities that can be studied in detail and with great precision due to the ability to identify as individuals its component neurons. A reliable experimental perturbation, axotomy, evokes neurite outgrowth and subsequently the formation of novel electrical synaptic connections (Bulloch and Kater, Science. 212: 79, 1981). Such changes in connectivity are transient. The nervous system forms a series of novel electrical synaptic connections and then by selection processes the majority of these electrical connections are broken. We now report that normally unconnected identified neurons will also form transient chemical synaptic connections during such neuroplastic periods. The esophageal nerve trunks were crushed in vivo in order to axotomize identified neurons 4 and 5 of the buccal ganglia. Such animals were allowed to recover and were maintained for up to 8 days following surgery. Subsequently, buccal ganglia were acutely isolated and the connectivity of the test neurons was determined by pairwise intracellular recording. Identified neurons 4 and 5 of the buccal ganglia are not synaptically interconnected in the mature, unperturbed nervous system. Axotomy, however, evoked the growth of new neurites from these neurons and the reliable formation of a transient excitatory chemical synapse from neuron 5 to neuron 4. Shortly after its formation this chemical synapse was broken and neurons 4 and 5 returned to their normal unconnected state. The elimination of this chemical synaptic connection does not reflect a generalized withdrawal of chemical synaptic inputs to neuron 4. Previously characterized extant excitatory chemical inputs to neuron 4 were maintained during the same time period that the excitatory input from neuron 5 was broken. Thus these data demonstrate that neurons not normally interconnected are, in fact, capable of forming chemical synaptic connections with one another, and that after sampling such a connection the nervous system is capable of selectively eliminating synapses in order to restore its preferred connectivity.

For further examination of the mechanisms involved in the initial formation and subsequent elimination of chemical synapses, the resolution afforded by cell culture is required. We therefore isolated as individuals neurons 4 and 5 and plated them as pairs into cell culture. Here they extended neurites and formed an excitatory chemical synapse from neuron 5 to neuron 4. Thus neurons that will form chemical synaptic connections in vivo will form the same specific synapse in cell culture where we can study with a high degree of resolution those mechanisms involved in synaptogenesis.

Supported by NIH grant NS18819.

51.12 EXTENT OF MULTIPLE INNERVATION OF CEREBELLAR PURKINJE CELLS BY CLIMBING FIBERS IN ADULT RATS AFTER DIFFERENT SCHEDULES OF POST-NATAL X-IRRADIATION. J. Mariani, P. Benoit*, M.D. Hoang* and N. Delhaye-Bouchaud*. Dep. de Biologie Moléculaire, Institut Pasteur, and Lab. Neurophysiologie Ontogénétique, Univ. P. et M. Curie, Paris, France.

The multiple innervation of cerebellar Purkinje cells (PCs) by climbing fibers (CFs), that exists transiently in the normal developing rats, can be experimentally maintained in adult rats the cerebellum of which has been degranulated by repetitive postnatal X-irradiation between birth and postnatal day 14 (see review in Benoit et al., Dev. Brain Res., 14, 310, 1984). It has been previously shown (Delhaye-Bouchaud et al., Neurosci. Lett., 9, 51, 1978) that irradiation restricted to the first postnatal week was sufficient to prevent most of the CF-PC synapse elimination; since the latter occurs essentially between postnatal days 5 and 10 and given that postirradiation effects last 2-3 days, the question arose to know whether it is possible to further delimit a "critical period" of irradiation within the first week.

A quantitative estimate of the extent of multiple innervation of PCs was made in adult rats that had been irradiated according to 4 different schedules :
In group 1, rats received 200r on day 0 (birth) 4,5,6,7 and 150r on day 3 (total dose 1150r).
In group 2, rats received 200r on day 0, and 150r on days 3,4,5,6,7 (total dose 950r).
In group 3, rats received 200r on days 4,5,6,7 (total dose 800r).
In group 4, rats received 200r on days 1,2,3 (total dose 600r).
The rats were anesthetized, paralysed, artificially respired, and the CF pathway was electrically stimulated at the level of the inferior olive or in the cerebellar white matter. Intracellular recordings of spontaneous and evoked PC responses were performed in the medial part of lobules VI, VII and VIII. The number of afferent CFs was estimated by the number of steps in the CF postsynaptic excitatory potential. The location of all the recorded cells was ascertained on sagittal histological sections.

The mean number of CFs impinging on a given PC was similar in group 1 (0 → 7 days, n = 124 cells) and in group 3 (4 → 7 days, n = 102) ie 3.1 ± 0.1 (sem). By contrast, in group 4 (1 → 3 days, n = 174), the mean number of CFs was only 1.27 ± 0.04. These results strongly suggest that the critical period of irradiation is from postnatal day 4 to day 7. In group 2, the mean number of CFs per PC was significantly lower than in group 1 (m = 2.25 ± 0.11, n = 113), which is similar except for lower doses between days 4 to 7, suggesting that the dose delivered should also be taken into account. These results establish that a close correlation exists between the elimination of supernumerary CF-PC synapses and the settlement of granule cells during a limited period of time.

51.13 CEREBELLAR AXON DEVELOPMENT: FEATURES OF THE EXUBERANT STATE. E. Gregory and C.A. Mason, Dept. of Pharmacology, New York University School of Medicine, New York, NY 10016.

During cerebellar development, climbing fibers (CF) branch exuberantly onto multiple Purkinje cells and then, after withdrawal of excess branches, focus on single Purkinje neurons. A second type of cerebellar axon exuberance and synapse elimination is the transient projection of mossy fiber (MF) branches into the Purkinje cell zone. These branches have the form of CF branches and contact both Purkinje and granule neurons (Mason and Gregory, 1984). To study the developmental histories of these different exuberant afferents in cerebellum, and to compare their projection, form, and fine structural relationships, axons were labeled by inserting a HRP-coated microelectrode into fiber tracts in fresh slices of mouse cerebellum. After brief rest periods, sections of slices were processed with DAB for light and electron microscopy. At postnatal day (P)6-8, axons with CF-like branches (fine with small tapered endings) project over many adjacent Purkinje cells. The growing tips associate with Purkinje cell somatic spines and insert themselves into the soma, forming simple synapses. By P9-12, 'nids' or perisomatic nests are common. Nids occur on axons at the over-branched stage, but single CF's support only one nid. Conversely, individual Purkinje cells can be contacted by multiple CF's during the over-branched stage, but never by more than one nid. Nid terminals contact Purkinje somatic spines but do not insert themselves into the soma. Axons with primarily MF features at P6-8 have large growth cone-shaped boutons that are central to synaptic glomeruli. MF boutons give off filopodial branches, many of which reach up to Purkinje cells and have small CF-like growing tips. These tips make elementary synapses and adherent junctions onto Purkinje cells; profiles apposed to these filopodial branches commonly have coated vesicles. By P14-21, MF terminals have few short filopodia and are confined to the granule layer. Thus, while axon exuberance is mainly observed in the Purkinje cell zone, CF and MF branching patterns and cell-cell contacts differ. The nature of synapses made by exuberant branches may indicate 'acceptance' by the postsynaptic cell of the appropriate input. (Supported by NIH Grant NS15182 and Irma T. Hirschl Foundation).

ENDOCRINE EFFECTS ON DEVELOPMENT AND BEHAVIOR

52.1 STEROID-INDUCED CHANGES IN ACTION POTENTIAL WAVEFORMS OF AN ELECTRIC ORGAN. A.H. Bass and S.F. Volman. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

We are interested in the effects of gonadal steroid hormones on the generation of action potential (spike) waveforms by excitable cells. We now report that steroids induce dramatic changes in the duration of spikes produced by the cells (electrocytes) of the electric organs of the mormyrid fishes of Africa.

For some mormyrids, androgenic steroids induce changes in the Electric Organ Discharge (EOD) waveform of females and juveniles that mimic the changes natural males undergo during sexual maturation. Specimens of Brienomyrus (sp. 2) undergo a 2-3 fold increase in EOD duration when treated with 17α-methyl-testosterone. Cholesterol has a weak, though non-significant, effect. Testosterone-induced changes in EODs are accompanied by nearly a two-fold increase in the duration of spikes generated by the electrocytes excitable membrane.

All cells were studied from intact fish. Following anesthetization, animals were spinalectomized, turning off the EOD-generating mechanism and immobilizing the trunk. The tail, which contains the electric organ, was isolated in a Ringer's-filled chamber and the electrocytes were exposed. The animal was revived and cells were impaled with two intracellular 3M KCl-filled microelectrodes. Each electrode was used alternately as a stimulating and then a recording electrode, so that spikes were often recorded from more than one position in the cell.

Our study includes 9 Testosterone (T)-treated (11-28 days), 3 Cholesterol (C)-treated (10-18 days) and 12 Untreated (U) specimens. We recorded 206 individual spikes from 138 cells (76-T, 26-C, 36-U). Duration is measured at 50% of peak-to-peak amplitude. The average spike duration is 0.370 ms (n=117, SE=0.009 ms) for T-, 0.187 ms (n=42, SE=0.007 ms) for C-, and 0.137 ms (n=47, SE=0.004 ms) for U-treated animals.

Mormyrid electrocytes are wafer-shaped cells with well-defined anterior and posterior faces (see Bennett and Grundfest, Bioelectrogenesis, 1961). In 16 cells, the intracellular spike could be split into two spikes, each one probably representing the spike generated by each face; their duration is also about two-fold greater in T-treated, compared to C- and U-treated animals.

Together with morphological and biochemical data (see Bass et al., Neurosci. Abstr., 1984), these new physiological results emphasize that mormyrid electric organs have evolved a sensitivity to gonadal steroid hormones. While changes in spike duration may relate in part to the electrocyte's passive electrical properties, it seems more likely they also depend on changes in ionic conductances.

52.2 DEVELOPMENT OF ANDROGEN ACCUMULATION IN A FOREBRAIN NUCLEUS THAT MEDIATES SONG LEARNING IN ZEBRA FINCHES. S.W. Bottjer & A.P. Arnold, Dept. of Psychology & Lab. of Neuroendocrinology, UCLA, CA 90024.

MAN (magnocellular nucleus of the anterior neostriatum) is a forebrain nucleus that is uniquely involved with the development of learned song behavior in zebra finches (Bottjer et al., 1984, Sci.). The normal ontogeny of this nucleus includes the loss of half of its original contingent of neurons; this loss occurs during the time juvenile birds are learning the motor pattern of song production (Bottjer, et al., 1985, J. Neurosci). In adult males, a large proportion of cells in MAN accumulate androgens (Arnold et al., 1976, JCN), thereby raising the possibility that hormones are importantly involved in song learning and in cell loss from MAN.

The purpose of this experiment was to examine the characteristics of androgen accumulation in MAN during song development. 7 juvenile male zebra finches with a mean age of either 24 (n=5) or 60 (n=2) days were gonadectomized; 24 hours later they were injected intramuscularly with equal molar doses of tritiated dihydrotestosterone (^{3}H-DHT; 20ng/g body weight, specific activity = 123-135uCi/mmole). 90 minutes later the animals were killed and the brains were processed for thaw-mount autoradiography. Sections were stored for 4 to 8 weeks in dessicated boxes at 4°C, developed, fixed, and stained with thionin. A Poisson criterion was used for quantitative assessment of cell labeling.

Data in Table 1 show that a much lower percentage of cells in MAN accumulate DHT or its metabolites in juvenile birds that are just beginning to produce song-related vocalizations (24 days) than in older birds in which the basic motor pattern of song is typically established (60 days). However, because the number of neurons in MAN is approximately twice as large in younger birds (Bottjer et al., 1985) these results suggest that (1) 24-day males may possess the full complement of androgen-accumulating cells in MAN that will be preserved into adulthood, and (2) a population of cells that does not accumulate androgens may be selectively lost from MAN during vocal development. Table 1 also shows that the intensity of labeling (density ratio of labeling in cells relative to background) is much higher in older than in younger males, indicating that the ability of these cells to concentrate androgen increases during this phase of song learning. This result suggests that the number of androgen receptors are increasing, that receptors are better able to bind hormone, or that there is a developmental change in steroid metabolism. In any case, the increase in cellular concentration of DHT that occurs while birds are learning to produce song is compatible with the notion that androgens influence song learning.

TABLE 1 ($\bar{X}$ ± S.D.)

age	% labeled	density ratio	size labeled cells
24 days	21.4 ± 4.6	2.5 ± 0.3	241.0 ± 20.4 um^2
60 days	52.5 ± 7.8	5.8 ± 1.3	235.5 ± 7.8 um^2

52.3 ANDROGEN-INSENSITIVE SNB MOTONEURONS CAN BE SPARED BY ANDROGEN FROM DEATH DURING DEVELOPMENT. S. Marc Breedlove. Department of Psychology, University of California, Berkeley, CA 94720.

The bulbocavernosus and levator ani (BC/LA) muscles of male rats are innervated by the spinal nucleus of the bulbocavernosus (SNB). Both the BC/LA and the SNB are present in newborn female rats, but without androgen both motoneurons and targets die. We have eliminated supraspinal neural afferents as a site of androgen action for sparing the SNB system (Soc.Neurosci.Abstr. 10 453 '84), and have shown that neonatal androgen can spare the BC/LA following complete removal of the lumbo-sacral spinal cord containing SNB motoneurons (R.B.Fishman, this volume). We now report that in mice, androgen need not act upon SNB motoneurons themselves in order to spare them from death during development.

Testicular feminization (tfm) is a recessive mutation on the X chromosome which, when combined with a paternal Y, produces a fetus with testes and testosterone, but which develops a female external phenotype because its tissues lack androgen receptors. Male carriers of the sex-reverse (Sxr) mutation produce sperm with an X chromosome which has an attached Y fragment. Embryos from such sperm develop testes because of the Y fragment, and testicular secretions produce a mouse with a normal male phenotype, despite an XX genotype.

We bred tfm carrier mice with Sxr carrier males. Some of the offspring clearly carried both traits: coat color markers indicated an XX genotype, yet they had an enlarged clitoris, hypospadias and abdominal testes. Such an intersex phenotype is never seen with tfm or Sxr mutations alone, and can be explained as an XX mouse with the Sxr mutation, which develops testes and testosterone, but only partially responds to the hormone due to the tfm gene. These mice, with a tfm gene on one X, are partially androgen-insensitive because of random-X inactivation. In the developing blastocyst of XX individuals, each of the cells which will give rise to the somatic tissues begins to express only 1 X chromosome. Thereafter, all cells clonally derived from these cells continue to express only that particular X chromosome. Thus a proportion of the cells in these mice expressed the X with tfm and were therefore androgen-insensitive. Because they were partially androgen-insensitive, these mice only partially responded to their own testicular androgen: hence the intersex phenotype.

Two tfm/Sxr mice retained BC/LA muscles into adulthood and had more SNB cells than do normal females. If androgen spares SNB cells by interacting with motoneuron receptors, then one would expect these SNB cells to be androgen-responsive. But if androgen acts at some other site to spare SNB cells, then some SNB cells could be androgen-insensitive, i.e. tfm. In fact, androgen autoradiography with 3H-methyltrienolone revealed a total of 132 SNB cells, none of which accumulated hormone, even though other nearby motoneurons did. Apparently androgen can spare dying motoneurons to form the SNB even if the cells are themselves incapable of interacting with the hormone. Androgen must interact with another cell population, perhaps the muscles, to spare the SNB system.

52.4 DEVELOPMENTAL CHANGES IN THE PULSATILE LH PATTERNS OF OVARIECTOMIZED, IMMATURE GUINEA PIGS. M.D. Loose* and E. Terasawa, Neurosciences Training Program & Wisconsin Reg. Primate Research Center, University of Wisconsin, Madison, WI 53715-1299.

Our previous finding that pulsatile LHRH infusion into immature female guinea pigs resulted in precocious vaginal opening and first ovulation (Biol. Reprod. 30; Suppl. 1:71, 1984), suggests maturational changes in LHRH release occur prior to puberty. To examine this possibility, the ontogenic pattern of pulsatile LH release, which presumably reflects developmental changes in LHRH release, was investigated in ovariectomized female guinea pigs. Three groups of females at 46.6±0.3 days (47D, n=7), 32.7± 0.3 days (33D, n=7), and 24.3±0.6 days of age (24D, n=7) were evaluated, since first vaginal opening and ovulation of female guinea pigs in our colony are usually seen at 45-60 days of age. All animals were ovariectomized 12 days prior and received a jugular catheter 2 days prior to the experiment. Blood samples (0.4ml) were collected through the catheter at 5 min intervals for 180 min and equal volumes of red blood cells and a plasma protein fraction were infused after samplings. Plasma LH estimated with RIA is expressed in ng/ml. Either LHRH (20ng) or saline was injected through the catheter after sampling at 120 min and 150 min. Results are: 1) Basal LH levels in the 24D group (212±27) were lower than those in the older age groups (33D, 382±37, $p<0.01$; 47D, 322±35, $p<0.05$); 2) the mean LH level during the first 120 min in the 24D group (326±65) was much lower than that in the 33D (672±67, $p<0.01$) and 47D (642±77, $p<0.05$) groups; 3) the number of LH pulses during the first 120 min in the 24D group (2.6±0.8) was significantly smaller ($p<0.05$) than that in the older groups (33D, 4.7±0.3; 47D, 4.3±0.3); 4) peak value of LH pulses in the 24D group (862±76) was lower ($p<0.05$) than that in the 33D group (1154±105), but not in the 47D group (1190±148); 5) there was a positive correlation ($r=0.899$, $p<0.01$) between peak LH values and body weights in the animals of the 24D and 33D groups; 6) the amplitude of the LH pulses was not different between groups (24D, 640±91; 33D, 710±85; 47D, 742±128); 7) LH release induced by LHRH injection was similar in all groups (24D, 1027±190; 33D, 1045±195; 47D, 940±248). The results indicate that 1) an elevation of mean LH, due to increases in basal LH, LH pulse frequency and peak LH, occurs during the early pubertal phase, approx. between 24 and 33 days of age, and it remains high through the midpubertal phase, 2) increased release of LHRH from the hypothalamus may be responsible for this elevated LH release during the early phase of puberty, since the changes are independent of the ovary, and the pituitaries of the youngest females respond to LHRH in a similar manner as that of older females. It is concluded that an increase in LHRH release may occur during the early pubertal stage, several weeks prior to the age at first ovulation. (Supported by NIH grants RR00167 and HD11355).

52.5 MANIPULATION BY GONADAL STEROIDS OF THE SEXUALLY DIMORPHIC MET-ENKEPHALIN FIBER POPULATION IN THE ANTERIOR PORTION OF THE PERIVENTRICULAR NUCLEUS. R.E. Watson, Jr., G. Hoffman and S.J. Wiegand. Department of Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

We have recently identified a distinct sexual dimorphism in the density of methionine-enkephalin (m-ENK) immunoreactive (ir) fibers in the anterior portion of the periventricular nucleus (Pea) (Bleier et al., JCN 212:116, 1982) in the rat (Watson and Hoffman, Anat. Rec. 211:211A). This region exhibits a cytoarchitectonic sexual dimorphism as well in which the density of cellular packing is greater in the female than in the male (Bleier et al., 1982). Immunoperoxidase studies performed upon tissue from male-female pairs of rats revealed that in the female there exists a dense band of m-ENK ir fibers, approximately 100 um wide, over the Pea. This dense fiber plexus is apparent over the anterior-posterior interval between the medial preoptic nucleus (Bleier et al., 1982) and the sexually dimorphic nucleus of the preoptic area (Gorski et al., Brain Res. 148:333, 1978) and is present at all stages of the estrous cycle. In contrast, in the male, the density of m-ENK ir fibers is not appreciably increased over that present in more laterally situated regions in the preoptic area.

Gonadal steroids exert both an organizational and activational effect upon the presence of the m-ENK dimorphism. Administration of testosterone propionate (200 ug/day s.c. on postnatal days 2,3,4,5) to genotypic female rats resulted in the elimination of the m-ENK band at adulthood. This response appears to be a function of the action of aromatizable androgen since comparable dosing with dihydrotestosterone (and vehicle alone) produced no alteration in the typical dense band of m-ENK ir. Castration of the male rat on the day of birth with subsequent treatment on days 2,3,4,5 with testosterone (200 ug/day), dihydrotestosterone (200 ug/day), or vehicle alone (0.05 ml/day) resulted in the typical male m-ENK distribution pattern.

Regarding the expression of activational effects of the gonadal steroids, ovariectomy of the young adult female resulted in the elimination of the m-ENK ir band within 2 weeks post surgery while castration of the male rat produced no discernable alteration of m-ENK ir in the region. Replacement of estradiol in the female via Silastic capsules implanted s.c. brought about re-expression of the m-ENK ir band within 2 weeks. Estradiol implants in the male castrated at adulthood were without effect. Thus, the sexual dimorphism of m-ENK fibers in the Pea requires activation by estrogen in order to be expressed. These observations are of significance in the context of opiate effects upon various sexually differentiated functions, including, particularly, the regulation of gonadotropin secretion.

52.6 AN OVARIAN-INDEPENDENT AFTERNOON EPISODE OF PROLACTIN (PRL) SECRETION OCCURS DURING FEMALE SEXUAL DEVELOPMENT: AMPLIFICATION BY ESTRADIOL-17β. H.F.Urbanski* and S.R. Ojeda* (SPON: N. McArthur). Dept. of Physiology, Univ. Texas Hlth. Sci. Ctr., Dallas, Texas 75235.

Previous investigations have demonstrated that mean plasma PRL levels increase during sexual development of the female rat and that the changes occur preferentially in the afternoon. The aims of the present study were (a) to characterize the nature of this enhanced level of secretion and (b) to determine the extent to which it is controlled by a central, ovarian-independent, mechanism. Animals were maintained under a 14L:10D photoperiod (lights on from 05:00 to 19:00h) and blood samples collected every 5 min for 4h via an intraatrial cannula. The preovulatory PRL surge occurred at approximately 15:30h, reaching peak plasma levels of 600ng PRL-RP-3/mL When juvenile rats were ovariectomized and PRL secretion examined 2 days later a similar midafternoon episode of PRL release was detected but this was considerably smaller (ca. 1/10th) than that observed in the intact animals at first proestrus. Administration of estradiol -17β (E_2) at different doses (s.c., via Silastic capsules) at the time of ovariectomy greatly enhanced the PRL secretory episode. This effect was produced even by small E_2 doses which generated preovariectomy plasma E_2 levels. More significantly, when a separate group of rats was ovariectomized neonatally and subsequently bled every 5 min for 5h either 20, 30 or 40 days later, the PRL mini-surge persisted in the majority of these animals regardless of the length of the postovariectomy period.

The results suggest that the increase in plasma PRL levels observed in the afternoons of prepubertal development reflect an episode of secretion which is initiated by a centrally-originated, ovarian-independent, mechanism. They further suggest that the preovulatory PRL surge itself is initiated by this central mechanism and that the signal strength is markedly amplified by ovarian E_2. The ovarian independence of the underlying primary signal is emphasized by the finding that mid-afternoon PRL mini-surges persisted even 40 days after ovariectomy.

52.7 BEHAVIORAL EFFECTS OF NEONATAL AND ADULT EXPOSURE TO GONADAL HORMONES IN A MARSUPIAL. B.H. Fadem* (SPON: H. Edinger). Dept. of Psychiatry, UMDNJ-NJ Med. Sch., Newark, NJ 07103.

Gonadal hormones present during development and in adulthood affect a variety of behavioral patterns associated with reproduction in mammals. One of these is scent-marking behavior which is sexually dimorphic in many species. In these studies, the effects of gonadal hormones administered neonatally and in adulthood on scent-marking and related behavior were examined in the gray short-tailed opossum (Monodelphis domestica). The gray opossum is a small, South American marsupial which is a practical species for laboratory research (Fadem et al., Lab. Anim. Sci. 32:405, 1982).

Scent-marking in gray opossums occurs with greater frequency in males (Fadem & Cole, Anim. Behav., 33:730, 1985) and only males possess a suprasternal scent gland. High levels of scent-marking were induced in ovariectomized adult females with both estradiol benzoate (EB) and testosterone propionate (TP). Scent-marking behavior was not eliminated although scent gland size was significantly reduced eight weeks following castration of adult males.

Because the reproductive system is in an undifferentiated stage at birth, marsupials are a particularly good model for studying the effects of early exposure to gonadal hormones on mammalian sexual differentiation. As evidence for the sensitivity of the newborn marsupial to gonadal hormones, EB administered on days 1 and 3 of postnatal life, blocked testis development and resulted in feminized genitalia in genetic male gray opossums (Fadem & Tesoriero, Anat. Rec. 211, 1985). Similar sensitivity of the developing marsupial brain and hence behavior to early hormone treatment is therefore likely. Studies of scent-marking and related behavior in neonatally hormone-treated gray opossums will be discussed.

52.8 MATING BEHAVIOR IN HYPOGONADAL FEMALE MICE WITH GNRH CELL-CONTAINING BRAIN GRAFTS. M.J.Gibson,G.Kokoris,A.J.Silverman and E.A.Zimmerman.Dept.Med.,Mt.Sinai Sch.ofMedicine,New York,NY10029 and Columbia College Phys.&Surgeons,New York,NY 10032.

Due to a genetic deficiency in hypothalamic GnRH, the hypogonadal (Hpg) mutant adult female mouse is sexually immature and infertile. When GnRH cell-containing implants,from normal fetal preoptic area(POA),are placed in the IIIrd ventricle of Hpg females, the mice respond with increased LH and FSH, ovarian and uterine development,and continuous vaginal estrus. 7 of 10 such mice became pregnant when housed overnight with normal males (Science225:949'84).

This study examined the characteristics of Hpg/POA mice in mating tests with normal males. The females were compared with normal females in proestrus(PE), for their ability to elicit mounting from males,and in their lordosis response. In addition,blood samples from the orbital plexus were obtained at various times before and after mating in Hpg/POAs and on days of the cycle in normals. Mice were housed in 12L:12D(lights off:1200hr). Two-hr mating tests were conducted in the male's home cage during 1300-1700hr.

			Latency (in minutes) to:		
Group	N	#♂ mounts	1st♂ mount	♀ lordosis	♂ ejaculation
Normal	15	33.5±8.5 (n=13)	20.4±5.2 (n=13)	45.5±10.5 (n=10)	77.2±8.7 (n=5)
Hpg/POA	21	19.8±5.3 (n=20)	18.2±4.0 (n=20)	21.9±3.1 (n=10)	47.8±10.8 (n=10)

The Hpg/POAs appear to elicit the male's first mount attempt as effectively as the PE normal mice, although males mounted more frequently with normal females. The 10 of 21 Hpg/POAs that showed lordosis were responsive sooner than the normals that responded in the 2-hr tests. Furthermore, the males ejaculated sooner with the responsive Hpg/POAs than with normal PE females. Plasma levels in normal females at 1200hr were: on diestrus(n=7) 1.22±0.21ng/ml; on PE(n=10) 16.82±4.78ng/ml, and on estrus(n=8), 1.44±0.33ng LH/ml. In Hpg/POAs in constant estrus, LH levels at 1200hr were 0.87±0.09 ng/ml(n=10).Following the male's ejaculation,LH levels in Hpg/POAs were:at 30 min(n=6) 1.18±0.17ng/ml; at 60 min(n=4) 1.05±0.17ng/ml and at 120 min(n=7), 0.94±0.09mg/ml.

Hpg females with successful POA grafts appear to show normal or increased receptivity in restricted behavioral tests. However, we have not yet been able to detect significant increases in plasma LH following mating in the constant estrus females. An LH rise is expected, since our previous finding of pregnancy following one overnight mating session implied reflex ovulation. Additional time points will be studied.

Supported by NIH Grant HD 19077 to MJG.

52.9 BRAIN REGION SPECIFICITY IN ANTIESTROGEN INHIBITION OF LORDOSIS IN FEMALE RATS. R.L. Meisel, G.P. Dohanich, B.S. McEwen, and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

Prior studies have demonstrated that estradiol stimulation of neurons in the ventromedial nucleus of the hypothalamus (VM) is a sufficient estrogen treatment condition for the display of sexual receptivity (i.e. lordosis) in female rats (Rubin & Barfield, Endocrinology, 106:504). In the present experiments, we tested the possibility that the interaction of estradiol with its receptors in VM neurons is necessary for lordosis in female rats.

In the first experiment, ovariectomized female rats were bilaterally implanted with cannulae aimed at the VM, preoptic area (POA), or medial amygdala (AMY). All females received subcutaneous implants of 5mm Silastic capsules containing a 5% mixture of estradiol diluted with cholesterol, followed 48 h later by an injection of 500 ug progesterone. Behavioral testing was conducted 4-5 h after progesterone, and a lordosis quotient (LQ), the percentage of male mounts that elicited lordosis, was calculated. A 1% crystalline dilution of the high affinity antiestrogen monohydroxytamoxifen (TAM) was delivered to the VM, POA, or AMY 24 h prior to estradiol treatment with matched groups of control females receiving empty implants. An additional group of VM females received TAM implants 12 h after estradiol. We also tested the effects of VM implants of a second antiestrogen, LY 156758 (LY). Application of TAM or LY to the VM 24 h prior to estradiol significantly reduced lordosis responding compared with control females (TAM - LQ = 46 vs. 89; LY - 50 vs. 90). TAM had no effect on lordosis when delivered to the POA or AMY 24 h prior to estradiol. TAM applied to the VM 12 h after estradiol was also without effect.

In a second experiment, we again found that VM implants of 1% TAM (LQ = 52) significantly reduced lordosis responsivity relative to control females (LQ = 85). Increasing the concentration of TAM to 10% essentially eliminated lordosis responding. Furthermore, even at this higher concentration of TAM, we found evidence of site specificity in that TAM-treated females with both cannula tips in or adjacent to the VM had lower levels of lordosis (LQ = 15) than did TAM-treated females with one or both cannulae outside the VM (LQ = 68), or control females (LQ = 85). A recovery test was given the following week, and the females previously treated with 10% TAM showed normal levels of lordosis (LQ = 75).

Thus, selectively blocking estradiol receptors specifically in VM neurons can reversibly antagonize the effects of systemically-delivered estradiol on lordosis behavior.

[Monohydroxytamoxifen was the generous gift of Dr. A.H. Todd of ICI Ltd. LY156758 was the generous gift of Dr. J. Clemens of Lily Research Laboratories.]

52.10 ATTENUATION OF THE PERIOD OF SEXUAL BEHAVIOR IN FEMALE GUINEA PIGS BY THE PROGESTIN RECEPTOR ANTAGONIST, RU 486. T.J. Brown* and J.D. Blaustein (Spon: Paul Herron). Div. of Neuroscience and Behavior, Dept. of Psychology, Univ. of Massachusetts, Amherst, MA 01003.

In estrous-cycling guinea pigs, as well as in many other rodent species, the sequential secretion of estradiol and progesterone activates a period of sexual behavior (heat) of a limited duration. Although the activation of sexual behavior by estradiol and progesterone, characterized by the lordosis response, is thought to be mediated by mediobasal hypothalamic (MBH) intracellular progestin receptors, little is known of the mechanism by which the behavior terminates. Previously we have hypothesized that the termination of sexual behavior results from the loss of progestin receptors from MBH cell nuclei. We have shown that hormonal manipulations that delay heat termination also delay loss of MBH nuclear progestin receptors. In order to determine if accelerated nuclear receptor loss results in attenuation of the period of sexual behavior, we tested the effect of RU 486, a progesterone antagonist, on heat termination. We have shown previously that RU 486 prevents the initiation of sexual behavior when administered at the time of progesterone, and acts to decrease the concentration of available progestin receptors in MBH cytosol. Ovariectomized guinea pigs were treated with 10 ug estradiol benzoate. Forty h later, animals received 100 ug progesterone followed 4 h later by an injection of RU 486 or vehicle. A third group was treated identically except that RU 486 was given at the time of progesterone treatment. Animals were tested hourly for presence of the lordosis response. RU 486 injected along with progesterone prevented the initiation of sexual behavior, and when injected 4 h after progesterone, caused heat termination to occur 3-4 h earlier than in vehicle-injected animals.

We have found that RU 486 administration to estradiol-treated guinea pigs causes accumulation of progestin receptors in the nuclear extract; however, this accumulation can be detected only when assay conditions are used that promote exchange of RU 486 progestin receptor complexes (15 °C incubation rather than 0 °C). Therefore, we can use our routine assay conditions (at 0 °C) to measure primarily receptors that are occupied by progesterone. In order to confirm that RU 486 decreased (progesterone-occupied) nuclear progestin receptor levels when injected 4 h after progesterone, animals treated as in the behavioral experiment were killed 6 or 10 h after progesterone injection (2 or 6 h after RU 486), and nuclear progestin receptor levels were measured. RU 486 treatment resulted in lowered nuclear concentrations of MBH progestin receptors at both times, a finding that was confirmed by Scatchard analysis. These results support our hypothesis that the termination of the period of sexual receptivity in female guinea pigs is the result of loss of progestin receptors from MBH nuclei.

Supported by NIH grant NS 19327 (to JDB).

52.11 FACILITATION OF MATING BEHAVIOR IN THE FEMALE RAT BY AN LHRH FRAGMENT, AC-LHRH 5-10: SITE SPECIFICITY AND ONSET OF ACTION. C.A. Dudley and R.L. Moss. Dept. Physiol. UTHSCD Dallas, TX 75235

Third ventricular infusions of Ac-LHRH 5-10 had previously been shown to facilitate mating behavior in the estrogen (EB) primed, ovariectomized (OVX) female rat (Neuroendocrinol. 86: 486, 1983). The present study assessed CNS-site specificity of this behavioral effect, and compared the magnitude and onset latency of the lordotic enhancement produced by Ac-LHRH 5-10 with that obtained by the entire LHRH decapeptide. Female rats were OVX and cannula were bilaterally implanted in the ventromedial hypothalamus (VMH; n=20), the midbrain central gray (MCG; n=20), the medial preoptic area (MPOA; n=15), or the cerebral cortex (CC; n=14). Animals were injected with EB (1-3µg at 0hr) and infused with either Ac-LHRH 5-10 (100ng/0.5µl saline/side) or saline (0.5µl/side) at 46hr. Mating behavior tests were conducted at 15, 45, 90,and 180 min post-infusion. The same procedure was followed for testing LHRH (100ng/0.5µl saline/side), except that the LHRH trials were counterbalanced and that LHRH was not tested in the CC.

MPOA	.24/.42	.38/.30	.35/.32	.37/.37

*difference between peptide and saline L/M <.05; two-tailed t test.

In both the VMH and MCG, Ac-LHRH 5-10 significantly enhanced mating behavior at 90 and 180 min post-infusion. LHRH infused into the VMH produced a more rapid (45min) enhancement of lordotic responding than the fragment, however the LHRH effect was detected only at this one time point. Infusion of LHRH into the MCG quickly facilitated behavior (15 min) and maintained a significant elevation throughout the testing period. In the MPOA, Ac-LHRH 5-10 facilitated sexual receptivity at 45, 90, and 180 min whereas LHRH failed to enhance mating at this site. No change in mating behavior was observed in the CC following infusion of Ac-LHRH 5-10. An overall index of the magnitude of lordotic enhancement was obtained by summing the differences between the mean L/Ms obtained following drug and saline treatment. This manipulation revealed that Ac-LHRH 5-10 and LHRH were equally effective in the VMH; LHRH produced enhancement superior to that of Ac-LHRH 5-10 in the MCG; and Ac-LHRH 5-10 was more effective than LHRH in the MPOA. Supported by HD11814.

52.12 EFFECTS OF CASTRATION AND TESTOSTERONE REPLACEMENT ON TRAINED CIRCLING BEHAVIOR AND BRAIN DOPAMINE IN THE MALE RAT. P.C. Doherty, J. Lin* and M.J. Baum. Dept. of Nutrition and Food Sci., Massachusetts Institute of Technology, Cambridge, MA 02139.

Previous studies have shown that concentrations of dopamine (DA) in the nucleus accumbens and septum are decreased in male rats castrated for 30 days or more (Alderson and Baum, Brain Res. 218:189, 1981). The present studies were undertaken to determine if these deficits in DA content could be related to functional deficits in dopaminergic activity. Thus, the effects of castration or castration and testosterone (T) replacement on the ability of male rats to display trained circling behavior, an activity involving both the mesolimbic and nigrostriatal DA pathways, were assessed according to the methods of Yamamoto and Freed (Nature 298:467, 1982). Adult male Long-Evans rats that had been castrated or sham-castrated for thirty days or longer were deprived of water for 24h and trained for 7 days to circle in a clockwise or counterclockwise direction to receive a 10% sucrose solution on a continuous reinforcement schedule. The animals were subsequently retrained for 6 days and on the seventh day were allowed to circle for 0, 20 or 70 minutes. Castrated animals displayed significantly less circling behavior at both the 20 and 70 min time periods than did sham-operated controls. To determine if these differences could be ascribed to an effect of castration on the acquisition of the circling behavior, adult male Sprague-Dawley rats were trained to circle and subsequently were castrated, castrated and given a T implant or sham-castrated. Beginning 24 days later, the animals were retrained and thirty days after castration, the animals were allowed to circle for 0 or 20 min after which time the animals were sacrificed and the caudate, accumbens, septum and preoptic area-anterior hypothalamus (POA-AH) were removed for analysis of DA and dihydroxyphenylacetic acid (DOPAC) levels using HPLC with electrochemical detection. No significant effects of castration or T replacement were observed on the rate of circlng or DA concentations in these animals. Concentrations of DA and DOPAC were increased in the caudate in response to circling, as were DOPAC concentrations in the septum and accumbens; however, there were no significant effects of gonadal status or circling on lateralization of DA or DOPAC levels in any of these areas. Interestingly, there were also no significant differences in DOPAC/DA ratios in the POA-AH in these animals. This area has been reported to be sensitive to the effects of castration and T replacement on the rate of decline of DA concentrations afer α-methyl-p-tyrosine treatment. These results show that while castration may affect the acquisition of trained circling behavior, it has no significant effects on the display of this behavior, nor on the lateralization of DA within the central nervous system. (Supported by MH-00392 and HD-06333).

52.13 ANDROGEN RECEPTORS IN THE CEREBRAL CORTEX OF FETAL FEMALE RHESUS MONKEYS. S.A. Sholl* and S.M. Pomerantz. Wisconsin Regional Primate Res. Ctr., University of Wisconsin, Madison, WI 53715.

Previously, we demonstrated the presence of androgen receptors in the brain of the fetal rhesus monkey (Pomerantz et al., *Endocrinology* 116:83, 1985). The present study extends this finding by characterizing and comparing binding activities of both dihydrotestosterone (DHT) and methyltrienolone (R1881) in the fetal female cerebral cortex (Day 125-135 postconception). Cytosolic extracts were prepared in a buffer consisting of 10 mM Tris-HCl, 1.5 mM EDTA, 10% (v/v) glycerol, 1 mM mercaptoethanol and 25 mM $NaMO_4$ (pH 7.4). Extracts were incubated with 0.075-16 nM ^{3}H-DHT or ^{3}H-R1881 at 4°C for 16 hr. Separation of receptor-bound and free hormone was achieved on Sephadex LH-20 columns. A computer-fit of Bound/Total versus Total-ligand binding curves for ^{3}H-R1881 yielded a $K_a \approx 4.3 \times 10^9$M (n=4) and a receptor concentration of 5.5×10^{-15} moles/mg protein (n=2). Competition with DHT (2×10^{-6} M) or triamcinolone (TA, 10^{-5} M) reduced binding by 85% and 86%, respectively. Computer analysis of ^{3}H-DHT binding curves yielded a similar K_a ($\approx 7.0 \times 10^9$ M) and receptor concentration (1.7×10^{-15} moles/mg protein) (n=1). Competition with R1881 (10^{-6} M) was greater than 99%. In a separate series of experiments, the competition obtained when ^{3}H-R1881 was incubated with DHT (2×10^{-6} M) was greater than that observed when ^{3}H-R1881 was incubated with DHT when both the DHT-competed and uncompeted samples contained additional TA (10^{-5} M). This reduced competition suggests that TA may interfere with the binding of R1881 to the androgen receptor. Further analysis of receptor-binding on DEAE cellulose columns (KCl gradient) revealed multiple peaks (0.05-0.3 M KCl) with either ^{3}H-R1881 or ^{3}H-DHT as ligand. Similar elution profiles were obtained for the two ligands. Throughout the KCl-gradient competition with either R1881 or DHT significantly reduced ^{3}H-DHT binding while TA had no effect. In contrast, ^{3}H-R1881 binding was reduced by all three competitors. In summary, the findings verify the existence of a specific androgen receptor(s) in the cerebral cortex of female rhesus monkeys. Its presence may be important in terms of the influence of potential teratogenic agents or for normal developmental change.

53.1 TEMPERATURE COMPENSATION IN THE NERVOUS SYSTEM OF THE GRASSHOPPER, SCHISTOCERCA AMERICANA. C.I. Miles*(SPON: R.B. Pinter). Dept. of Zoology, University of Washington, Seattle, Wa. 98195.

Small terrestrial ectotherms like grasshoppers experience wide variations in body temperature as they move through thermally complex environments. Such variations can affect the performance of the nervous system, as individual insect neurons are known to be sensitive to temperature.

The temperature sensitivities of mechanosensory hair neurons were examined in an earlier study (Miles, C.I., J. exp. Biol. in press). Of these neurons, wind-sensitive head hairs were by far the most temperature sensitive. These mechanoreceptors occur in five fields on each side of the head, on its dorsal surface. Their sensory neurons have inputs to an identified interneuron in the brain, the Tritocerebral Commissure Giant, (TCG). Inputs from four of the fields are excitatory to the TCG, while those of one are inhibitory (Bacon & Mohl, J. comp. Physiol. 150:439-153, 1983).

Temperature differences of up to 5°C were recorded between the head cuticle near the wind-sensitive hairs and the brains of animals placed in thermally complex environments. The effects of such differences on the response of the TCG to stimulation of the head hairs were examined. If the temperatures of head hairs were increased while that of the TCG did not change, TCG output showed little sensitivity to temperature. Thus, in spite of great increases in the firing frequencies of its inputs, the TCG's output remained essentially constant. If, however, the temperature of the TCG itself increased while that of its inputs did not change, the interneuron's output in response to stimulation of either excitatory only or both excitatory and inhibitory inputs was dependent on its temperature.

When temperatures of both the TCG and its mechanosensory inputs increased together, the TCG's output displayed a sensitivity to temperature when only the excitatory inputs were stimulated. While substantial, this sensitivity was not as great as that of the sensory neurons themselves. If, however, both excitatory and inhibitory inputs to the TCG were stimulated, the temperature dependence of the interneuron's output was greatly reduced. Reducing the strength of stimuli applied to its excitatory inputs alone had a similar effect.

There are thus at least two levels of information processing in the head hair/ TCG system where temperature compensation occurs: One is at the level of receiving sensory inputs; temperature induced increases in inhibitory input can counteract increases in excitatory input. Another involves the generation of interneuronal output; if the temperature of the TCG does not change, its output remains constant despite marked increases in its inputs. The neuronal basis for these compensations is under investigation.

53.2 GABA-MEDIATED INHIBITION IN THE ANTENNAL LOBES OF THE MOTH *MANDUCA SEXTA*. T.A. Christensen, B.R. Waldrop and J.G. Hildebrand. Dept. of Biol. Sci., Columbia Univ., New York, NY 10027.

Electrophysiological studies of neurons in the primary olfactory centers, the antennal lobes (ALs), in the brain of *Manduca sexta* have revealed that inhibitory synaptic interactions play a prominent role in the processing of olfactory information in this species. Projection neurons (PNs), which relay information from the ALs to higher centers in the protocerebrum, generally show a biphasic inhibitory/excitatory response when the antennal nerve (AN) is stimulated by electrical shock [Harrow & Hildebrand, *Soc. Neurosci. Abstr. 8*:528 (1982)]. Many of these cells, including the male-specific, pheromone-responsive PNs, are inhibited synaptically when the ipsilateral antenna is stimulated with natural odors.

The ALs synthesize and contain relatively large amounts of γ-aminobutyric acid (GABA)[Maxwell *et al., Comp. Biochem. Physiol. 61C*:109 (1978); Kingan & Hildebrand, *Insect Biochem.*, in press], which is known to be a major inhibitory neurotransmitter in many species of invertebrates and vertebrates. Moreover, recent immunocytochemical studies in our laboratory have shown that GABA is present in many intrinsic, local interneurons (LNs) in the ALs of *Manduca* [Hoskins *et al., Soc. Neurosci. Abstr. 10*:688 (1984)]. We are studying PNs to test the hypothesis that the observed synaptic inhibition is GABA- and chloride-mediated.

Injection of hyperpolarizing current reverses the IPSP evoked by shocking the AN, suggesting that the IPSP may be due to an increased conductance for chloride or potassium ions. Treatment of the preparation with picrotoxin or bicuculline reversibly blocks the IPSP. Preliminary results indicate that injection of GABA into the AL neuropil can hyperpolarize the PNs and that the response to GABA reverses near the apparent resting potential. We are assessing the role of chloride ions in the IPSP in PNs by means of chloride-substitution experiments. If the IPSP is mediated by chloride, then a decrease in the chloride concentration gradient across the cell membrane will shift the reversal potential of the IPSP in a depolarizing direction. To perform such experiments, we inject chloride (using KCl-filled electrodes) into test PNs or superfuse the preparation with low-chloride saline solution. In still other experiments, we examine the simultaneous effects of application of GABA and alteration of chloride concentration gradients.

These electrophysiological studies, together with the aforementioned neurochemical investigations, promise to advance our limited understanding of GABA-mediated synaptic inhibition in the insect central nervous system.

Supported by NIH grant AI-17711 and by a research contract from the U.S. Army Research Office, as well as by NIH Postdoctoral Fellowships to T.A.C. and B.R.W.

53.3 HEARING IN A PRAYING MANTIS. D. Yager* and R. Hoy. Section of Neurobiology & Behavior. Cornell University, Ithaca, NY 14853.

To observe the prominent eyes of the praying mantis is to acknowledge the obvious: it is a highly visual animal. Only recently, however, has the almost complete dominance of vision in the mantis's sensory world begun to be questioned. We now report that the mantis, Mantis religiosa, possesses an acute and well-developed auditory sense. Ours is the first report of hearing in this group of insects.

We demonstrated an auditory capability in the mantis by making electrical recordings from its ventral nerve cord. First, extracellular recordings from the connectives between the pro- and meso-thoracic ganglia revealed, 1) as many as four action potential classes that responded to sound, 2) that the auditory response encompasses a broad frequency range from 10 to 80 kHz, and 3) that, as in crickets and some moths, mantids are by far most sensitive (55-60 dB SPL) at frequencies between 25 and 45 kHz. Second, intracellular recordings were made from two types of auditory neurons whose physiological properties paralleled those described from extracellular recordings. The anatomy of one of these neuronal types was revealed by lucifer yellow staining.

Perhaps the most surprising aspect of hearing in mantises is the ear itself. Contrary to the usual pattern of paired, laterally placed acoustic receptors, the mantis possesses a single, midline ear. Externally the ear appears as two membranes facing each other within a groove situated between the metathoracic legs. Internally, each membrane is backed by a large tracheal sac; the sacs behind the two membranes are connected to each other. Associated with each sac is a small receptor organ which is connected to the metathoracic ganglion by a nerve root containing about 20 axons, 3-5μ in diameter. As might be suggested by the anatomy of the ear, we have found no indication that the mantis auditory system can distinguish right from left at frequencies as high as 40 kHz.

In summary, the praying mantis can hear. It does so using an unorthodox single ear located in the animal's midline. The auditory system is almost exclusively sensitive to the ultrasonic frequencies of hearing. Thus far, the behavioral significance of audition in mantids remains a mystery.

53.4 THE INFLUENCE OF SOUND DIRECTION ON ENCODING OF STIMULUS TEMPORAL PATTERN IN THE CRICKET TELEOGRYLLUS OCEANICUS. G.S. Pollack. Dept. Biol., McGill Univ., Montreal, Quebec, Canada H3A 1B1.

Crickets are able to recognize the calling song of a conspecific using the temporal pattern of the stimulus as a cue. Teleogryllus oceanicus orients towards a song model with the temporal pattern of the conspecific song in preference to a model of heterospecific song when both stimuli are presented simultaneously from loudspeakers on opposite sides of the animal. The ability to discriminate between simutaneously presented patterns implies that they are represented separately within the nervous system. This might be made possible by the directional characteristics of the auditory system. The present work examines the relationship between sound direction and the fidelity with which temporal patterns are encoded in the central nervous system.

Recordings were made from omega neurons (ON), a pair of interneurons in the prothoracic ganglion which have been implicated in the processing of directional information. Each ON is most sensitive to sound on its soma-ipsilateral side, although it can also be excited by soma-contralateral sound. Responses were recorded to presentation of conspecific and heterospecific song models from opposite sides of the animal, both one at a time and simultaneously. The fidelity with which ON encoded the temporal pattern of the song on the soma-ipsilateral side was determined by cross-correlation analysis of the PST histogram describing its spiking response. ON faithfully encoded both song models when they were presented one at a time. Encoding of the soma-ipsilateral song was only minimally disturbed by simultaneous presentation of the soma-contralateral song when the broadcasting loudspeakers were at angles of 90°, 60° or 30° to the left and right of the midline, but was severely disrupted when the speakers were at 15°.

Preliminary behavioral experiments accord well with these findings. In a tethered flight assay, crickets stimulated simultaneously with both patterns reliably oriented towards the conspecific pattern when the loudspeakers were at angles of 90°, 60° or 30°. This ability deteriorated when the speakers were at 15°, even though crickets could reliably orient towards the stimulus when it was presented alone from this angle.

Considerable attention has been focused on the directional properties of the cricket's auditory system. This work has been concerned primarily with the problem of how the cricket is able to locomote to the sound source. The present findings suggest that another important behavioral role of directionality may be to permit the cricket to distinguish stimulus temporal patterns under less than ideal, but perhaps not unnatural, acoustic conditions. Supported by the Natural Sciences and Engineering Research Council of Canada.

53.5 IDENTIFICATION AND CHARACTERIZATION OF INHIBITORY INPUTS IN THE CRICKET CERCAL AFFERENT SYSTEM. G.A. Jacobs, C. Redfern* and J.P. Miller. Dept. of Zoology, UC Berkeley, Berkeley, Ca. 94720

The directionally sensitive response properties of wind sensitive interneurons in the terminal abdominal ganglion of the cricket result from a combination of monosynaptic excitatory inputs and polysynaptic inhibitory inputs. At present, these inhibitory interneurons are unidentified. We have undertaken a series of experiments aimed at identifying these neurons and characterizing their effects on identified wind sensitive interneurons in the cricket cercal afferent system. Interneuron 10-3 receives polysynaptic inhibitory inputs which can be activated by stimulating selected classes of sensory afferents on either cercus. The ion that mediates the IPSP is most likely chloride since the IPSP recorded in the cell body reversed near the resting potential of the interneuron and injection of chloride ions eliminated the IPSP evoked by wind stimuli. As a first step in the anatomical identification of these inhibitory interneurons, we have stained the terminal ganglion with a commercially available antibody directed against γaminobutyric acid (GABA) (Immunonuclear) which is the putative inhibitory transmitter. Terminal ganglia were fixed, embedded in paraffin and serially sectioned at 10 microns. The sections were incubated in the antibody at a dilution of 1:1000 and processed using a modified PAP technique. This technique revealed approximately 80 neurons that exhibited GABA-like immunoreactivity in the terminal ganglion. The cell bodies of these neurons fall into two size classes: those with soma 80-100 microns in diameter and 20-50 microns in diameter. The cells are arranged in bilaterally paired clusters that are located on both dorsal and ventral surfaces of the ganglion. We are currently using a double label technique to identify individual putative GABAergic neurons by injecting wind sensitive neurons with lucifer yellow followed by sectioning and staining for GABA-like immunoreactivity. (Supported by NSF Grant BNS 82-02416 to JPM.)

53.6 MORPHOLOGICAL AND PHYSIOLOGICAL EXAMINATION OF A PAIRED DORSAL GROUP OF INTERNEURONS IN THE THORACIC GANGLIA OF THE COCKROACH. A.J. POLLACK* AND R.E. RITZMANN. Dept. of Biology, Case Western Reserve Univ., Cleveland, OH 44106.

Several insect circuits clearly employ many interganglionic interneurons to integrate sensory information and direct motor behavior. In an attempt to understand complex orientation behavior in the cockroach, we are conducting a long term study directed at characterizing important groups of interganglionic interneurons in that animal.

Cobalt backfills were performed on the thoracic T2-T3 connectives. Most of the somata filled in the metathoracic ganglion were ventral (67%) and in specifically located, reproducible groups. Two bilateral groups with dorsal somata were also filled. One of these, the dorsal posterior group (DPG), could be easily located by backfilling only the lateral 1/2 to 1/3 of the connective, which contains the more lateral and dorsal tracts of axons travelling through the thoracic ganglia (Gregory, 1974). In T3 these DPG cells emerged as two distinct groups. DPG-I cells were more anterior but still posterior to the ganglion A-P midline. DPG-II cells were even more posterior; in fact, they appeared in the first abdominal ganglion which is fused to the third thoracic ganglion. In addition to grouped somata, the DPG cells all had neurites that crossed the midline in common tracts and axons restricted to two longitudinal tracts; the lateral dorsal and dorsal intermediate tracts (LDT and DIT, respectively).

More specific morphological information was obtained by intracellular penetration of DPG cells with dye-filled microelectrodes. Lucifer yellow fills showed fine detail in wholemounts and sections, and an overlay-template system of grids for soma and tract positions allowed cell-to-cell comparisons of location and reproducibility. The detailed morphology of five cells in DPG-I and at least one in DPG-II have been documented. At least three of these cells have large axons in the connectives, making them useful targets for further intracellular analysis.

Numerous physiological recordings were made while the intracellular electrodes were in place. All T3 DPG cells were found to be activated by wind directed at the cerci and by tactile stimulation of the metathoracic legs. In addition, in double penetrations of a GI and a DPG, vGI stimulation caused DPG excitaton while dGI stimulation did not. Upon intracellular stimulation of the DPG cells, weak but definite excitation of motor neurons was often seen. This work is being continued to determine if the DPG's play a role in integrating wind information from the GI's and directing activity to appropriate motor neurons for the wind mediated escape behavior.

This work was supported by NIH grant 1 R01 NS17411-01 to R.E.R..

53.7 CHARACTERIZATION OF THORACIC INTERNEURONS IN THE COCKROACH: PHYSIOLOGICAL AND MORPHOLOGICAL ANALYSIS. M. Murrain and R.E. Ritzmann. Dept. of Biology, Case Western Reserve Univ., Cleveland, OH 44106.

A large array of sensory structures are located on the leg of the cockroach. These relate information about leg position and movement to the central nervous system, and are used in a variety of ways to help coordinate and fine-tune many behaviors. Of particular interest to us is how this information is used to help coordinate the walking behavior. Macmillan and Kein (Proc. R. Soc. Lond. 218:287,1983) have demonstrated specific reflexes from different leg sensory structures in the locust, which help to time the different phases of walking.

In order to further understand the cellular mechanisms involved in processing of leg sensory information we have begun a study of thoracic interneurons which are sensitive to leg sensory structures. The structures tested were those which have been determined to be involved in intra- and intersegmental coordination and fine tuning of walking (Macmillan and Kien,1983; Wong and Pearson J Exp. Biol. 64:233, 1976). Individual cells were impaled intracellularly, and the responses to stimulation of individual sensory structures analyzed. A group of interneurons, both intra- and intersegmental have been identified by morphology. Also, the arborization patterns of the sensory cells have been determined by a cobalt backfilling technique similar to that used by Hustert, et. al. (Cell Tiss. Res. 216:97,1981).

One of the questions that we would like to ask about these interneurons is whether they have common morphological loci, and, can we match those common loci with the morphological location of the sensory neurons themselves. This gives us predictive capabilities in two situations: if we only know the morphology of a given cell, we can predict whether this cell has a chance of getting input from a specific sensory structure. Also, if we know that a given cell recieves input from a sensory structure, we can predict from its morphology whether this cell gets this sensory input directly or from an intervening interneuron. We have employed a computer system to compile morphological data from many cells, and to aid in finding overlap in three dimensions.

The computer system we developed involves digitizing the morphological data into a computer and reconstructing the cell and ganglion in three dimensions. The system then partitions the ganglion into many small cubes. The cell data is then run through these partitions and counted. Each cube can be analyzed for total number of cells that go through the cube, and those cells that go through with specific physiological charictaristics. Several areas of the ganglion have been found to be common loci for groups of cells, and some of these have been correlated with backfill data. Supported by NIH grant NS17411-01 to R.E.R.

53.8 PHYSIOLOGICAL CHARACTERISTICS OF SENSORY CELLS OF DROSOPHILA WING CORRELATE WITH CENTRAL PROJECTIONS AND DEVELOPMENTAL TIMING. M. H. Dickinson and J. Palka, Department of Zoology, University of Washington, Seattle, WA 98195.

Campaniform sensilla are common sensory structures of insect appendages; they respond to small deformations of the cuticle. Eight such sensilla, appearing identical under light and scanning electron microscope, are found in specific locations on the wings of Drosophila. The single sensory cells associated with these identified sensilla send axons into distinct branching regions and tracts in the CNS. Their projection patterns correlate not with the topographic distribution of the sensilla on the wing, but with the time in development when the neurons differentiate (Wigston, et al., Abst. Soc. Neurosci. 10, 139). We have now found that certain physiological characteristics of the sensory neurons also correlate with the central projections.

We monitor the action potentials (AP's) elicited by deformational stimuli using a high impedance AC amplifier, recording differentially along the length of the wing veins in which the axons lie. Stimuli are delivered by a fine glass probe mounted on a piezoelectric bender. Transverse cuts through the wing and ablations of individual sensilla allow extracellular recordings of single neurons. With these techniques we can unambiguously determine the responses of 7 of the 8 sensory neurons to reproducible stimuli. Three of the neurons are phasic, firing short bursts of AP's at the onset and/or offset of wing deformation. Their axons all project medially. The other four neurons respond to apparently identical stimuli with tonic trains of AP's, and their axons all project laterally. Thus, the projection of these wing campaniform sensilla is organized according to sub-modality. The sensilla presumably function during flight, courtship song, grooming and other behaviors during which strains are set up in the wing cuticle. The phasic cells act as accelerometers, encoding rapid changes in wing deformation, while the tonic cells monitor the magnitude and duration of strain. Their signals are delivered to at least partially segregated regions of the CNS.

As demonstrated previously, the medially projecting neurons differentiate and extend axons early during metamorphosis; we now see that they carry phasic information. The laterally projecting neurons arise during a second wave of cell birth and differentiation; they carry tonic information. The causal factors generating these strict correlations remain to be established.

53.9 MORPHOLOGY OF THE EYE OF THE GIANT DEEP-SEA ISOPOD *BATHYNOMUS GIGANTEUS*. S. C. Chamberlain, V. B. Meyer-Rochow*, and W. P. Dossert*. Inst. for Sensory Research, Syracuse University, Syracuse, NY 13210 and Dept. of Biological Sciences, University of Waikato, Hamilton, New Zealand.

Bathynomus giganteus is the largest known isopod species. We have examined the eyes of four specimens recovered from depths of 500 to 600 meters near the edge of the continental shelf off Key West, FL. The triangular compound eyes face forward and slightly downward and appear to have significant overlap in visual fields. Each eye contains about 3,500 ommatidia independent of animal size over a range of body lengths from 22.5 cm to 37.5 cm. The packing of ommatidia is not uniform across the retina, but is nearly hexagonal in the central, central dorsal, and medial regions and nearly square in the ventral and lateral regions.

The optical elements for each ommatidium consist of a laminar cornea which is flat externally and convex internally and a bipartite crystalline cone. Seven or eight retinular cells closely appose the cone internally and bear the microvilli of the rhabdom. Below the rhabdom the retinular cells form thin pillars near the periphery of the ommatidium and the central portion along the optic axis is occupied by interstitial cells which contain massive arrays of clear vesicles thought to serve as reflective elements. The arhabdomeral segments of the retinular cells and the interstitial cells sit on a basal limiting membrane. Each ommatidium has two unusual apical extensions of the limiting membrane, each with a cylindrical central core and thin sheets of dense material and collagen fibers which occupy spaces between adjacent interstitial cells up to the level of the rhabdom. Arrays of pigment cells separate adjacent ommatidia, but have relatively weak light screening properties.

Animals were fixed (a) within a week after being brought from depth and exposed to daylight and (b) after two months of maintenance in constant darkness following such daylight exposure. In both cases, the microvilli of the rhabdom were severely disrupted and the retinular cytoplasm contained numerous multivesicular bodies. Exposure to natural daylight appears to cause irreversible structural damage to the photoreceptors of these animals.

53.10 **INTRACELLULAR RECORDINGS OF OPTIC LOBE INTERNEURONS IN THE COCKROACH PERIPLANETA AMERICANA: COLOR OPPONENCY AND POLARIZATIONAL SENSITIVITY.** **K.M. Kelly* and M.I. Mote* (SPON: S. McElligott). Dept. of Biology, Temple U., Phila., Pa. 19122**

Intracellular recordings from spontaneously active optic lobe interneurons were made while stimulating the ipsilateral eye with brief broadfield flashes of monochromatic light from 370-703 nm over a 6 log unit range of intensity. Recorded cells were then injected with Lucifer yellow to reconstruct their anatomy. Response patterns were analyzed by applying the known differences in the spectral sensitivity functions as well as the waveform and timecourse of the receptor potential in the ultraviolet (UV) and green (G) receptor groups in the animal's dichromatic retina. Determining which receptor groups were responsible for input to a recorded cell allowed use of a classification system adopted by Kien and Menzel (1977) which categorizes response properties according to the number of receptor groups involved and the type of input. 70 responses fell into one of the categories of broadband, narrow band and color opponent.

Broadband responses result from either excitatory or inhibitory input from both UV and G receptors. Response magnitudes indicate convergence of the UV and G input at short wavelengths where there is broad overlap in the sensitivity functions of the two receptor groups. This usually occurred with high to intermediate intensity stimulation. Narrow band responses result from either excitatory or inhibitory input from only one color receptor group. Narrow band properties were seen in cells receiving predominantly single channel input with evidence of some antagonistic interactions or single channel input at high intensities and dual channel input at lower intensities.

Color opponent responses result from antagonistic input from more than one color receptor group. Opponency was seen only as UV inhibition and G excitation. In some cases, responses to a fixed wavelength were dominated by one receptor group at low intensities and by the other group at high intensities.

Polarizational sensitivity was tested in 30 neurons by a stationary polarizing filter inserted into the light path and rotated between successive flashes of monochromatic light or rotated through a 90° arc in a clockwise, then counterclockwise, direction during constant monochromatic illumination. There was no apparent change to the stationary e-vector orientation, however, 2 cells appeared to change in firing rate by being inhibited by rotation in one direction and excited by rotation in the reverse direction. **Supported by NIH grant EY00784 to MIM.**

53.11 PROCESSING OF COLOR IN BUTTERFLY VISUAL SYSTEM. G.A. Horridge (SPON: E.E. BALL). Dept. of Neurobiology, Australian Natl. Univ. P.O. Box 475, Canberra. ACT 2601, Australia.

Intracellular recording reveals four types of photoreceptors in the retina of Papillo and other butterflies, but in order to measure the properties of the primary photoreceptors as transducers the indifferent electrode must be immediately outside the cell recorded. With a single electrode and indifferent electrode below the basement membrane of the eye, hyperpolarizations can be recorded with an off-axis stimulus, or at some wavelengths on axis. Whether this negative coupling between primary receptors is significant in vivo has been investigated by repeating the experiments but with intracellular recording from the second-order cells (laminar monopolars). Also several behavioral responses have been tested for color opponency and color-specific behavior. The second-order neurons of the lamina, and the behavioral responses are color-coded, but show no sign of color vision in individual neurons or responses. Color vision is defined as the ability for a neuron or behavior pattern to make a response to wavelength irrespective of contrast or intensity. The second-order neurons can have extremely sharp spectral sensitivity curves but as yet it is impossible to locate the exact origin or the behavioral significance of color-opponency neurons already long known in the protocerebrum of butterflies.

53.PO THE MOST DIRECT PATHWAY FROM PHOTORECEPTORS TO EYE MUSCLE MOTONEURONS IN DAPHNIA IS THROUGH ONE INTERNEURON. T.R. Consi, S.J. Sims*, N. Necles*, K.C. Smith* and E.R. Macagno. Dept. of Biological Sciences, Columbia University, New York, NY 10027.

Computer reconstructions from serial electron micrographs of the Daphnia magna compound eye visual system have revealed that at least two classes of interneurons in the optic ganglion receive direct chemical synaptic contacts from photoreceptor terminals in the lamina. The LS neurons, one of these two classes, have dendrites only in the lamina and send unbranched axons which bypass the medulla and enter the supraesophageal ganglion (SEG) (see Sims & Macagno, J. Comp. Neurol. 233:12, 1985). We have now traced these axons for a few of the LS cells (those which have particularly large axons) and have discovered that they travel to and branch in the same area of SEG neuropil where the eye muscle motoneurons branch. We have also found that at least one of these LS interneurons, ml5, is presynaptic to the pair of motoneurons which are connected to the contralateral ventral eye muscle (see Consi et al., Am. Zool. Abs. 21:956, 1981). Cell ml5 branches in the dorsal half of the laminar neuropil and extends across the midplane, making synaptic connections with similar subsets of photoreceptors within each of the optic cartridges which it innervates. Thus, our anatomical observations reveal that the most direct pathway from the compound eye photoreceptors to the motoneurons which innervate the muscles that rotate the eye is through individual LS interneurons.

Several reasons lead us to propose that this is probably the most important neural pathway mediating the eye flick response (see Consi & Macagno, J. Comp. Physiol. A156:135, 1985). 1. The eye flick is always a ventral rotation, independent of the position of the stimulus in the visual field, and it must therefore utilize the ventral motoneurons. 2. The LS cells that branch in the motoneuron neuropil of the SEG are those with the largest axons and are therefore best suited to produce a fast reflex like eye flick. 3. Cell ml5 receives synaptic inputs from photoreceptors of different spectral classes (see Schehr & Macagno, Soc. Neurosci. Abs. 9:325, 1983), which is necessary in order to explain the complex spectral dependence of the eye flick. Current efforts are addressing the question of whether the spectral sensitivities of the photoreceptors known to connect to ml5 provide sufficient information to explain the wavelength dependence of the eye flick. (Supported in part by NIH Grant NS-14946.)

54.1 MPTP PRODUCES CLASSIC PARKINSONIAN SYNDROME IN AFRICAN GREEN MONKEYS. D.E. Redmond, Jr., R.H. Roth, and J.R. Sladek. Psychiat. & Pharmacol., Yale Sch. Med., New Haven, CT 06510, Dept. Anatomy, Univ. Rochester Sch. Med., Rochester, NY 14642.

MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) in humans, rhesus, and squirrel monkeys produces selective neurotoxicity of the substantia nigra and a syndrome almost identical to Parkinson's disease. Rather than the characteristic resting tremor of parkinsonism in humans, one difference in monkeys has been that, if tremor was observed, it appeared to be a postural or action tremor. The present study was undertaken to characterize simultaneous behavioral, biochemical, and histopathological effects in African green monkeys two months after treatment with MPTP at a time when acute pharmacologic and non-specific neurotoxic effects have diminished.

Three male monkeys were treated with 5 doses of 0.25 mg/kg MPTP over 5 days. Four monkeys served as controls. Two MPTP treated monkeys developed mild tremor acutely after the third or fourth dose; the monkey which was most severely affected was successfully treated with Sinemet (25 mg/kg per day) to overcome the effects of motor deficits on food and water intake. Daily observations were made of each monkey over the entire period. Videotapes were made in a variety of semi-natural conditions to demonstrate deficits and their similarities to idiopathic parkinsonism. The severity of deficits in the three monkeys was correlated with changes in brain determined in several ways. After sacrifice under deep anesthesia, the brains were rapidly removed, chilled, blocked, and sliced into 5 mm sections. Monoamine enzymes, transmitters, and metabolites were measured in brain regions dissected by micropunch from one side of the brain, and the opposite side was freeze dried and prepared for dopamine histofluorescence.

The three MPTP animals showed varying degrees of deficits. One animal was more severely impaired, showing bradykinesia, freezing, and difficulty in initiation of movement; a resting tremor of the head and arms was intensified by stress and certain activities but eliminated by other types of movement. All deficits improved after exercise. The other animals showed much more subtle changes. Videotapes of behavioral effects will be shown. Biochemical and histopathological measures showed changes that were consistent with the motor and behavioral deficits, supporting reports that MPTP produces a close approximation to idiopathic parkinsonism.

54.2 THREE-DIMENSIONAL COMPUTER ANALYSIS OF MPTP-INDUCED AMINERGIC CELL LOSS IN THE MONKEY. D.M. Bowden, M.F. Dubach*, R. Snyder*, S. Askari*, & D.C. German. Regional Primate Res. Cntr., and Dept. of Psychiat., Univ. of Washington Sch. of Med., Seattle, WA. 98195 and Depts. of Physiol. and Psychiat., Univ. of Texas Health Sci. Cntr., Dallas, TX. 75235.

The meperidine analogue, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP), has been reported to induce a parkinsonian syndrome in both human and non-human primates (see Burns et al., Proc. Natl. Acad. Sci., 80:4546, 1983). In the monkey, the syndrome was accompanied by a depletion of neostriatal dopamine (DA) but not of nucleus accumbens DA, and a reduction in substantia nigra zona compacta neurons. Norepinephrine (NE) in locus coeruleus (LC) neurons appeared normal.

The purpose of the present experiment was to quantify regional catecholamine-containing cell loss in the monkey produced by MPTP. Four adult male Macaca fascicularis monkeys were used for this experiment, two controls and two treated with MPTP. Both monkeys received 5 consecutive daily injections of MPTP (0.35 mg/kg, i.v.). Monkey 1 survived for 45 days and Monkey 2 for 21 days. Monkey 1 had a more severe parkinsonian syndrome (akinesia, tremor, etc) than did Monkey 2. A computer graphics system was used to reconstruct the 3-dimensional pattern of DA cell loss in the midbrain (nuclei A8, A9 and A10) and NE cell loss in the LC. A tyrosine hydroxylase (TH) immunohistochemical staining procedure was used to identify these neurons. The midbrain DA neurons were found to have a rostral-caudal extent of 6-7 mm, and the A8 and A9 cells are multipolar and measure up to 18 X 30 μm. The A10 cells are round/oval and measure up to 13 μm in diameter. These cell sizes were smaller in the MPTP-treated animals. The midbrain DA cell complex has an estimated 250,000 cells in the normal animal. The LC has a rostral-caudal extent of 2.5-3.0 mm and the oval multipolar cells measure 20-30 μm in diameter. MPTP produced a severe loss (> 70%) of DA cells in Monkey 1 and primarily spared cells in the A10 and substantia nigra pars lateralis. Monkey 2 had less DA cell loss than Monkey 1, and predominantly in the substantia nigra zona compacta. LC cell loss was minimal in both monkeys, however, the TH staining intensity was more prominent in the MPTP-treated vs. control animals. This latter observation suggests that MPTP, like reserpine, may induce TH activity in the LC. Further examination of the present brain tissue will be conducted to quantitatively determine specific regions of DA cell loss and whether the loss is confined to a particular morphological cell type. 54.3 ALZHEIMER DISEASE RELATED ANTIGEN PRESENT IN TANGLES, PLAQUES AND MORPHOLOGICALLY NORMAL NEURONS. B. L. Wolozin*, A. Pruchnicki*, and P. Davies* (SPON: C. Raine). Albert Einstein College of Medicine, The Bronx, NY 10461.

Alzheimer's disease is a neurodegenerative disorder whose pathology is defined by the presence of neuritic plaques and neurofibrillary tangles. We have generated a monoclonal antibody, called Alz-50, which recognizes an antigen present in plaques and tangles, as well as in neurons from Alzheimer brains which are normal by thioflavine immunocytochemistry.

An ELISA assay was used to compare the binding of the antibody to Alzheimer and normal brain homogenates. Using 5% nonfat milk as a blocking agent, Alz-50 recognized an antigen that was present in Alzheimer brain and absent from normal brain or present in much lower amounts. Immunocytochemistry on formalin-fixed tissue showed that the antigen is present in both plaques and tangles in Alzheimer brain. In addition, many pyramidal neurons of the hippocampus and large neurons in the frontal cortex were stained. Only an occasional neuron was stained in sections of normal human brain.

Tissue sections were double-stained with thioflavine and Alz-50 followed by rhodamine-labelled or peroxidase-coupled secondary antibody. This protocol revealed neurons in Alzheimer brains that were stained with antibody but not stained with thioflavine. There were also tangles that were stained with thioflavine but were not stained by Alz-50. Biochemical studies show that the antigen recognized by Alz-50 is not strongly coupled to neurofibrillary tangles. Unlike tangle antigens, this antigen is partially soluble in saline, fully soluble in 5% SDS, and is sensitive to both trypsin and neuraminidase. Preliminary studies suggest that the antigen has a molecular weight of 50kd. These results suggest that formation of plaques and tangles might not represent the only changes in the cell biology of neurons in Alzheimer's disease.

This investigation was supported by NIH training grant T32 GM7288 from the National Institute of General Medical Sciences, and a grant from The McKnight Foundation.

54.4 GLUCOSE AND GLUTAMINE OXIDATION, DNA AND PROTEIN SYNTHESIS IN FIBROBLASTS FROM YOUNG, AGED AND ALZHEIMER DONORS. C.Peterson and J.E.Goldman, Dept.Pathology (Neuropathology) Albert Einstein College of Medicine, Bronx, N.Y. 10461

Cultured skin fibroblasts provide a convenient model to study human aging and age-related disorders, such as Alzheimer's disease (N.Engl.J.Med. 312:1063 (1985)). The present study examined the oxidation of glucose and glutamine, the incorporation of leucine into protein and thymidine into DNA in four different cell lines from young, aged and Alzheimer donors. Fibroblasts were seeded (day 1) in glass scintillation vials (20,000 cell/vial) in Dulbecco's modified Eagles medium supplemented with 15% fetal bovine serum. The media was replaced on day 4 by one that was serum-free and any confluent cultures were discarded. On day 5, the cells were incubated, for the indicated times, in serum-free media that contained either ^{14}C-glucose (4 hr), ^{14}C-glutamine (4 hr), ^{14}C-leucine (4 hr) or ^{3}H-thymidine (24 hr). To terminate the incubation for $^{14}CO_2$ collection the vials were acidified. For protein and DNA synthesis, the media was removed and the cells were washed three times with serum free media before acidification. Protein was determined in the acid insoluble precipitate. All conditions were examined in triplicate at three different passages between 5 and 10.

	YOUNG	AGED	ALZHEIMER
Age (years)	23.2±1.1	63.5±2.1	61.7±3.0
Glucose	100±2	85.5±4.9*	72.9±3.8*
Glutamine	100±3	68.9±2.0*	53.9±3.0*
Thymidine	100±3	52.2±2.3*	69.3±2.3*
Leucine	100±3	78.4±3.2*	102 ±1.1

Values are expressed as percent of young.
*Denotes difference (P<0.05) from young control.

Thus, during Alzheimer's disease oxidative processes may be depressed while biosynthetic ones are slightly elevated when compared to normal aging. These findings suggest that at the cellular level Alzheimer's disease may have some systemic alterations.

Support in part by grant AG05386.

54.5 SOMATOSTATIN LOSS PREDOMINATE IN HYPOMETABOLIC BRAIN REGIONS IN ALZHEIMER'S DISEASE, C.A. Tamminga, K. Tanimoto*, S. Kuo*, A. Kask*, T.N. Chase, Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205 and Maryland Psychiatric Research Center, Baltimore, MD 21228

Several cortical neurotransmitter systems have been identified as abnormal in Alzheimer's Disease, with little evidence to indicate which, if any, may be causally related to the dementia. The use of positron emission tomography with fluorodeoxyglucose (PET-2DG) in the study of human brain disease has provided an opportunity to localize areas in CNS of dysfunctional neural activity in the human patient. Using PET-2DG in subjects with Alzheimer's Disease, maximal decreases in glucose utilization have been identified in posterior parietal cortex, whereas frontal, occipital, and anterior temporal areas are significantly less affected. Therefore, we have analyzed postmortem brain samples from parietal cortex (Brodmann areas 39 and 40) for concentrations of various cortical neurotransmitters and compared them to concentrations in frontal areas (Brodmann areas 9 and 10) from Alzheimer and control brains. Cerebral material was obtained at autopsy from 10 individuals with histologically confirmed Alzheimer's Disease and an equal number of normal controls matched for age and sex. Tissue was kept at -70° C and dissected at -20° C from regions corresponding to Brodmann areas 9, 10, 7, 39, and 40. Analysis of choline acetyltransferase (CAT) was carried out according to the radioenzymatic technique of Bull and Oderfeld-Nowak (J. Neurochem. 18:935,1971). Somatostatin levels were determined using a double antibody radioimmunoassay with a ^{11}Tyr-somatostatin tracer. Catecholamines and their metabolites were quantified using reverse phase high pressure liquid chromatography. The activity of CAT in Alzheimer brain was diminished by a mean of 40% relatively uniformly throughout cortex, with decreases in frontal regions indistinguishable from reductions in parietal areas. Levels of catecholamines and metabolites in Alzheimer tissue including NE, DA, and HVA were unchanged from control levels. Somatostatin concentrations, unlike any of the other transmitters quantified, were similar to normal values in the relatively spared frontal cortex (102% of normal values), whereas levels were significantly reduced in parietal samples (45% of normal values). Thus, we propose that this selective loss of somatostatin in the parietal cortex may underlie not only the reduction in glucose utilization predominantly localized to this area, but symptoms of the dementia as well. Treatment of Alzheimer's disease with somatostatin or an active analogue should be considered.

54.6 THIAMIN-DEPENDENT ENZYMES IN BRAINS AND PERIPHERAL TISSUES FROM ALZHEIMER PATIENTS. G.E. Gibson, K.-F.R. Sheu*, J.P. Blass, A. Baker*, K.C. Carlson*, J. Dale*, B. Harding*, P. Perrino*. Cornell Univ. Med. Coll., Burke Rehabilitation Ctr., White Plains, NY 10605.

Thiamin deficiency is a major etiological factor in the mental impairment that accompanies Wernicke-Korsaff syndrome, which, like Alzheimer's disease, is accompanied by severe recent memory loss and neuronal cell loss in the nucleus basalis. Furthermore, decreases in the activities of the thiamin-dependent enzymes, pyruvate dehydrogenase (PDHC), transketolase (TK) and 2-ketoglutarate dehydrogenase (KGDH) accompany behavioral deficits during experimental thiamin deficiency. Thus, the activities of these enzymes were determined in the brains from patients that died with Alzheimer's disease, in cultured skin fibroblasts and in various blood elements from living patients diagnosed as having Alzheimer's disease. In brains from Alzheimer patients compared to controls (% decrease; n of control, n of Alzheimer, respectively) TK declined in frontal cortex (-51%; 8,9), caudate (-54%; 3,5), occipital cortex (-50%; 6,7) or midtemporal cortex (-51%; 4,3). The decreases in KGDH were larger: frontal cortex (-87%; 9,8), caudate (-75%; 3,5), occipital cortex (-92%; 6,7) and midtemporal cortex (-100%; 4,3). Studies with mouse brain demonstrated that TK was stable for two days at room temperature, whereas KGDH declined by approximately one-third. Previous studies demonstrated decreases in PDHC in Alzheimer brains that correlated with deficits in choline acetyltransferase. Alterations in cultured skin fibroblasts or various blood cells were considerably less. In cultured skin fibroblasts (7 control lines; 6 Alzheimer lines at 4 different passage numbers), TK declined 15% ($p<0.05$) and KGDH declined 23% ($p>0.05$). Variable decreases (0-50%) of PDHC occurred in fibroblasts. Analysis of blood platelets revealed no change in the activity or heat denaturation curves of TK or KGDH. In red blood cells, basal and methylene-blue-stimulated flux through the pentose shunt, which utilizes TK, was normal. In conclusion, three thiamin-dependent enzymes decreased substantially in the brain of Alzheimer patients; these enzymes were much less reduced in peripheral tissues.

54.7 PICK DISEASE: PURIFICATION OF NEURONAL PICK FIBRILS. D.R. Sparkman*, K. Hammon*, S. Johnson*, P. Allison* and C.L. White, III* (SPON: R. Tindall) Depts. of Neurology, Pathology and Internal Medicine, Univ. of Texas Hlth. Sci. Ctr., Dallas, TX 75235.

Pick disease is a rare form of degenerative dementia which resembles Alzheimer disease clinically, but is distinctively different in microscopic pathology. A prominant feature is the presence of numerous swollen neurons which contain an intracytoplasmic inclusion or Pick body. Ultrastructurally this inclusion is composed of numerous fibrils in random orientation, with no limiting membrane. These fibrils were isolated from frozen Pick disease brain tissue, and were found to be insoluble in boiling SDS, even in the presence of a reducing agent. They were isolated by sucrose gradient centrifugation of the SDS insoluble material. Negative staining with uranyl acetate and electron microscopy revealed two types of Pick fibrils (PF). Studies to date suggest that Type I is a 14-16 nm fibril composed of two 6-8 nm protofilaments tightly twisted so as to appear as a straight fibril. Type II is a 28 nm twisted fibril where the two protofilaments had relaxed or were hydrated due to the SDS treatment, and reveal obvious twisting with a periodicity of about 165 nm. Various intermediate stages have also been observed. This study demonstrates that PF may be isolated from Pick disease brain by a method similar to that employed for isolation of paired helical filaments (PHF) from Alzheimer brain, but their ultrastructural morphology is distinct from that of PHF. This work was supported in part by ADRDA research grant 84-1482.

54.8 PHENYLETHANOLAMINE N-METHYLTRANSFERASE IN NORMAL AND ALZHEIMER'S DISEASE BRAINS. W. J. Burke, G. L. Marshall* and H.D. Chung*. St. Louis Veterans Administration Med. Center and St. Louis Univ. Med. Sch., St. Louis, MO. 63125

We have recently developed a highly sensitive and specific assay for phenylethanolamine N-methyltransferase (PNMT) in brain. The sensitivity of the assay is due to the use of high specific activity adenosyl-L-methionine S-[methyl-^{3}H] (^{3}H SAM) as substrate coupled with the use of reineckate precipitation of [^{3}H]SAM after the reaction and with the adsorbtion and elution of [^{3}H] epinephrine product from alumina to attain low blank values. The assay has a sensitivity of 30 f moles. When coupled with small homogenizing volumes and removal of naturally occurring inhibitors in the tissue by dialysis, the assay achieves a sensitivity of 50 times that of other brain PNMT assays. With this assay we were able to demonstrate PNMT activity in regions of brain where it had been reported absent or present in only trace amounts. These areas include frontal cortex 39.3 ± 1.8 pmole/h/g; amygdala 50.5 ± 3.1; hippocampus 25.7 ± 2.5; cerebellar cortex 40.9 ± 1.9. In an autopsy proven case of Alzheimer's disease (A.D.), there was a 96% decrease in PNMT in the right and a 67% decrease in PNMT in the left locus coeruleus compared to controls. These results indicate a wider distribution of PNMT in human brain than previously reported and suggest a deficiency of this enzyme in A.D.

54.9 **IMMUNOREACTIVITY OF ANTISERUM TO ALZHEIMER PAIRED HELICAL FILAMENTS IS NEUTRALIZED BY ABSORPTION WITH PICK DISEASE BRAIN.** C. L. White, III*, P. Allison*, J. M. Gause*, S. A. Johnson*, and D. R. Sparkman* (SPON: J. B. Mullen). Depts. of Pathology and Neurology, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

Alzheimer disease (AD) and Pick disease (PD) are two forms of degenerative dementia with distinct pathological features. Light microscopic cellular changes in AD include widespread intraneuronal accumulation of neurofibrillary tangles (NFT) in the hippocampus, neocortex, and subcortical and brainstem nuclei. Classical PD is characterized by the presence of ovoid cytoplasmic Pick bodies (PB) in neurons of the temporal and frontal cortex. Ultrastructurally, the NFT consists of paired helical filaments (PHF), whereas the PB consists of straight fibrils morphologically distinct from PHF. In this study, unfixed brain tissue was obtained at autopsy from a patient who died with pathologically documented AD. PHF protein was isolated from the frontal cortex by the method of Ihara et al. (Nature 1983; 304:727-730). Anti-PHF antiserum was obtained from a New Zealand white rabbit after immunization with purified PHF and Freund's adjuvant, diluted, and applied to paraffin sections of formalin-fixed hippocampus from 5 AD cases, one PD case, and normal control brains. All of these cases had had histopathological documentation of the respective diagnoses. The sections were then developed using the avidin-biotin immunoperoxidase method. Neuronal perikarya in the 5 AD cases showed immunoreactivity in NFT, and the PD case showed immunoreactivity in PB. Morphologically normal neurons showed no immunoreactivity. Absorption of the anti-PHF antiserum with unfixed brain tissue homogenates from either AD or PD cases eliminated the immunoreactivity in both NFT and PB in subsequent staining of tissue from the same regions. Absorption with normal control brain tissue did not affect staining of NFT or PB. We conclude that the structural components of Alzheimer NFT and of Pick bodies have antigenic similarities despite the differences in morphological changes between AD and PD.

54.10 Olfactory Pathways in Alzheimer's Disease (AD): Neuropathological Studies. P.F.Reyes*,G.T. Golden, R.G. Fariello, L.Fagel*, M. Zalewska*,(Spon: R.M. Benjamin). Neurology & Research, VAMC Coatesville PA 19320 and Neurology & Psychiatry , Thomas Jeff. Med. College, Phil. PA 19107.

Dementia of the Alzheimer type (DAT) is the most common cause of progressive dementia among middle-aged and the elderly. Alzheimer's disease (AD) is characterized pathologically by the development of numerous argophilic neuritic plaques (NP) and neurofibrillary tangles (NFT) within the brain.

We have examined formalin-fixed brain obtained at post-mortem from four patients with clinical diagnosis of AD. In all cases, light microscopic examination of serial hematoxline-eosin, luxol fast blue-cresylviolet and Bodian's silver stained tissues demonstrated increased NFTs and NPs in neocortex and hippocampus showing a classical histopathologic morphology and argrophilia. In addition, we examined the olfactory regions including olfactory bulb and tract, anterior olfactory nucleus, prepiriform cortex and amygdala. In one case, NPs and NFTs counts were determined in the prepiriform cortex, amygdala, hippocampus and frontal cortex using a BH-2 Olympus light microscope with 10X microscopic fields the center of which contained the highest concentration of either NPs or NFTs. The density of NPs and NFTs in the prepiriform cortex and amygdala was higher than that observed in the frontal cortex. In all cases studied NFTs and extensive neuronal loss were found in olfactory bulb anterior olfactory nucleus and amygdala. The prepiriform cortex showed NFTs, NPs, extensive neuronal loss and granulovacuolar degeneration.

These changes clearly demonstrate that the olfactory sensory pathway is significantly affected pathologically in Alzheimer's disease. The absence of high concentrations of NPs and NFTs in the frontal cortex suggest that the frontal lobe may not be the optimal site for brain biopsy in all cases of AD. Supported by VA funds.

54.11 ALUMINOSILICATES AND THE GENESIS OF SENILE PLAQUES. J.A. Edwardson*[1], A.E. Oakley*[1], J. Klinowski*[3], R.H. Perry*[1], E.K. Perry*[2] and J.M. Candy*[1]. (SPON: E.T. Hedley-Whyte). MRC Neuroendocrinology Unit[1] and Department of Pathology[2], Newcastle General Hospital, Newcastle upon Tyne NE4 6BE; Department of Physical Chemistry[3], University of Cambridge, Cambridge CB2 1EP.

Using energy dispersive X-ray microanalysis (EDAX) we have shown that aluminium and silicon are co-localized in the central core region of senile plaques, one of the major neuropathological features of Alzheimer's disease. Coincident distribution of these elements was observed in plaque cores isolated from cerebral cortex using protease digestion, treatment with 2% sodium dodecyl sulphate to solubilize proteins, treatment with 4M hydroxylamine to remove collagen, and final purification on a sucrose gradient. Such cores appeared as spherical particles (8-20μm diameter) with a fibrillary ultrastructure and the staining properties of plaque amyloid in situ. However, the protein content was relatively small (<5%) in comparison with the content of Al (4-19%) and Si (6-24%) as measured by EDAX analysis of thin epon-embedded sections. Co-localization of Al and Si was also observed in plaque cores present in formalin-fixed, silver-stained cryostat sections of cortex and in foci of similar dimensions and elemental composition observed in unfixed, unstained tissue.

The close correlation between the distribution of Al and Si suggested the presence of aluminosilicates and this has been confirmed using solid state ^{27}Al NMR with magic angle spinning to analyse plaque cores isolated from Alzheimer brain. The co-localization of Al and Si is a constant feature of senile plaques from both senile and presenile cases of Alzheimer's disease and of the more sparsely distributed plaques from non-demented, aged individuals. Aluminosilicates are a highly reactive class of substances and these findings raise the possibility that their focal deposition may be involved in the genesis or early development of senile plaques.

Abnormalities of calcium homeostasis have been implicated in the accumulation of Al associated with neurofibrillary tangles in the Parkinsonian-dementia complex of Guam and the possibility of such changes being a contributory factor in the deposition of aluminium as aluminosilicates and the development of Alzheimer type pathology is being investgated.

54.12 ALZHEIMER'S DISEASE: MAZE LEARNING DEFICITS AND NEUROPATHOLOGY RESULTING FROM CHRONIC INFUSION OF HEMICHOLINIUM INTO NUCLEUS BASALIS MAGNOCELLULARIS OF THE RAT. B. J. Hurlbut*, J. F. Lubar, R. Switzer, J. Dougherty, M.E. Eisenstadt.Univ. of Tenn., Knoxville, TN 37996-0900

Alzheimer's Disease is characterized by progressive dementia correlated with an insidious loss of acetylcholine (Ach) producing cells in the Nucleus Basalis of Meynert (Mnb). Experimental studies with monkey, cat, and rat have demonstrated a reduction in cortical Ach correlated with lesions in Mnb. Methods utilized to destroy Mnb include electrolyticlesions and acute injection of kainic acid or ibotenic acid. These methods are non-specific to Ach-rich cells, involving the destruction of fibers of passage or all cell bodies at the site of involvement.

In this study, 12 mature male Sprague-Dawley rats were chronically, bilaterally implanted with 30-gauge cannuli terminating in Nucleus Basalis Magnocellularis (Mnm), the homolog of Mnb. The cannuli were connected to two independent Alzet miniosmotic pumps subcutaneously located on the flanks of each animal. Each pump was filled with 214 ul of hemicholinium (HC-3) and 0.9% saline. Over fourteen days, 385 ug/hr of HC-3 were delivered to each Mnm. HC-3 is an agent which interferes with the uptake of choline thus preventing the production of Ach by an affected cell. Twelve control rats were fitted with cannuli and pumps filled with 0.9% saline solution in the same fashion as the rats recieving HC-3. Each HC-3 and control rat was tested in a series of composite T-mazes prior to receiving implants. Learning curves were generated for each rat, and for the HC-3 and saline groups. After receiving an implant, each rat was again tested.

HC-3 rats receiving implants demonstrated a significant deficit in maze-learning ability compared with individual and group performances before receiving the implants. In saline rats there was no significant difference in maze-learning ability before and after receiving implants. The HC-3 group receiving implants demonstrated a significant deficit in maze-learning ability compared with the saline control group. Serial sections through Mnm from 8 control and 8 HC-3 rats were treated with thionine for confirmation of infusion site and cell body destruction; with the cupric silver method of de Olmos for extent of damage in Mnm and concurrent terminal field loss in cortex; and with thioflavin-S for the formation of plaques. All cannuli were located within Mnm. In cupric silver sections, differences in the extent of terminal field degeneration and Mnm cell loss were more apparent in HC-3 animals. However, some damage resulting from cannula insertion interfered with analysis. Plaque formation was not evident in control or HC-3 animals.

55.1 CLASSIFICATION AND LOCALIZATION OF NONCOMPETITIVE INHIBITOR SITES BASED ON TIME-RESOLVED PHOTOLABELING OF THE NICOTINIC ACETYLCHOLINE RECEPTOR BY QUINACRINE AZIDE. M. DiPaola*, P.N. Kao*, R.N. Cox* and A. Karlin. Departments of Biochemistry and Neurology, Columbia University, New York, NY 10032.

We have photolabeled the receptor in membrane from Torpedo californica electric tissue with the photolyzable local anesthetic [3H]quinacrine azide (QA), using a continuous-flow, rapid-mixing device and millisecond-duration irradiation (Cox, R.N. et al. J. Biol. Chem., 260:xxx, 1985). Membrane was mixed with QA and effectors and, 20 ms to 200 ms later, irradiated for 2 ms. Agonists, but not competitive antagonists, induced a transient state of the receptor in which the alpha and beta chains were specifically susceptible to photolabeling by QA. We define specific photolabeling by QA as that obtained in the presence of 1 mM acetylcholine and 0.4 mM hexamethonium minus that obtained in the presence of 0.4 mM hexamethonium, alone. QA concentration was varied from 0.75 uM to 10 uM. The agonist-enhanced labeling of the alpha and beta chains was blocked in the presence of other noncompetitive inhibitors (NCIs) such as proadifen, bupivacaine and histrionicotoxin. Proadifen (50 uM) blocks at least 90% of the specific labeling by 3 uM QA. Saturating concentrations of the NCIs, histrionicotoxin and bupivacaine, however, blocked at most 50% of the specific labeling by 3 uM QA. In contrast, at lower concentrations of QA (1 uM and lower), 100 uM histrionicotoxin blocked 80% to 90% of the specific incorporation. We infer that there are two classes of sites that are specifically (as defined above) photolabeled by QA: both classes bind proadifen, but only one class binds histrionicotoxin and bupivacaine. These NCIs differ in that proadifen is a much more potent promoter of receptor desensitization than either histrionicotoxin (Boyd, N.D., and Cohen, J.B., Biochem., 23:4023, 1984) or bupivacaine (Ikeda, S.R., et al., Molec. Pharmacol., 26:293, 1984). HPLC maps of the CNBr fragments of the alpha chain labeled with QA in the presence and absence of these various NCIs will be presented. Supported by research grants from NIH and MDA and a fellowship to M.D. from The N.Y. Heart Association, Inc.

55.2 LOCALIZATION OF THE CHLORPROMAZINE BINDING SITE ON THE SEQUENCE OF ACETYLCHOLINE RECEPTOR δ-SUBUNIT FROM TORPEDO MARMORATA. J. Giraudat*, M. Dennis*, T. Heidmann*, J.Y. Chang* and J.P. Changeux. (SPON:J. Hirsch). Institut Pasteur, Paris, France; and Ciba-Geigy, Basel, Switzerland.

The permeability response to acetylcholine (ACh) is blocked by a group of compounds referred to as non-competitive blockers (NCBs). Binding experiments with several radioactive NCBs have revealed two types of sites on acetylcholine receptor (AChR)-rich membrane fragments : a) a unique high affinity site, present in one copy per AChR oligomer and common to all NCBs tested; and b) a series of low affinity sites. The high affinity site can be labeled by a variety of photoactivable NCBs. In particular ^{3}H-chlorpromazine (CPZ) covalently attaches to all AChR—subunits; this labeling is prevented in the presence of the NCB phencyclidine (PCP), which binds almost exclusively to the high affinity NCB site.

The availability of complete cDNA sequence for all AChR subunits opens the way for direct identification of the amino acids forming the high affinity NCB binding site using protein chemical techniques. In the present study, the amino acids of the δ-subunit involved in this site were probed with ^{3}CPZ.

AChR rich membranes treated at pH 11 to remove extrinsic proteins were equilibrated with 1mM carbamylcholine, 2.5 μM ^{3}H-CPZ and then U.V. irradiated. Addition of 200 μM PCP reduced CPZ incorporation in the δ-subunit by 80%. AChR subunits were purified by preparative polyacrylamide gel electrophoresis. After reduction and carboxymethylation, the δ-subunit was cut into peptides by a combination of enzymatic and chemical cleavages. On initial analysis by reversed-phase HPLC, 70-75% of the injected radioactivity eluted as a very broad peak. Further purification in several HPLC systems enabled us to resolve four distinct radioactive components. Incorporation of ^{3}H-CPZ in these four peaks was inhibited by the presence of 200 μM PCP during the labeling. Gas phase automated sequencing permitted identification of the labeled peptides by their N-terminal amino acid sequence and provided sequence position of radioactive residues.

55.3 IDENTIFICATION OF THE α-BUNGAROTOXIN BINDING SITE ON THE PRIMARY AMINO ACID SEQUENCE OF THE α SUBUNIT FROM THE TORPEDO ELECTRIC ORGAN ACETYLCHOLINE RECEPTOR. P.T. Wilson*, T.L. Lentz and E. Hawrot. Depts. Cell Biology and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

We previously described the binding of α-bungarotoxin (BTX) to proteolytic fragments of the α subunit of the acetylcholine receptor (PNAS 81:2553, 1984). We have now mapped the BTX binding site with respect to Asn 141, the site of N-linked glycosylation. BTX-binding proteolytic fragments that contain Asn 141 bind concanavalin A (Con A) and, after treatment with endoglycosidase H (endo H), demonstrate an increase in electrophoretic mobility during SDS-PAGE consistent with the removal of one N-linked oligosaccharide chain. We therefore tested BTX-binding fragments for sensitivity to endo H. In general, for all proteases used, fragments larger than 30 kd were endo H sensitive and those smaller than 15 kd were endo H resistant. Two large BTX-binding fragments (28 kd: papain; 27 kd: chymotrypsin) were endo H resistant. Since the largest possible endo H resistant fragment residing within the amino terminal side of Asn 141 cannot exceed 16 kd (140 a.a.), the existence of much larger endo H resistant fragments indicates that the BTX binding site must lie on the carboxyl side of Asn 141. The smallest endo H sensitive fragment that binds BTX, a 12 kd (∿103 a.a.) fragment produced by digestion with papain, indicates that the BTX binding site must be within ∿103 a.a. of Asn 141. V8 protease generates a 19 kd BTX-binding triplet that does not bind Con A, and hence does not contain Asn 141. The first V8 cleavage site past Asn 141 is Glu 161. Thus the BTX binding site resides between a.a. 161 and 244. To narrow further the a.a. sequence containing the BTX binding site, a synthetic peptide of 32 a.a. comprising a.a. residues 173-204 and containing the cysteines that are labeled with MBTA (Kao et al. JBC 259:11662, 1984) was tested for its ability to bind ^{125}I-BTX. ^{125}I-BTX bound to the peptide both in a dot-blot assay and after electrophoretic transfer onto positively charged nylon filters. In contrast, no binding of ^{125}I-nerve growth factor to the peptide was detected. Similar to the results obtained with isolated, immobilized α subunit, ^{125}I-BTX binding was competed by BTX and by d-tubocurarine with IC_{50} values of 0.1 μM and 0.1 mM respectively. No binding of ^{125}I-BTX was detected to either insulin or β-endorphin in dot-blot assays. We conclude, therefore, that the major determinant of the BTX binding site resides between Ser 173 and His 204, most likely including a negative subsite near Cys 192. (Supported by NIH GM32629, the PMA Foundation, and NSF 82-03825.)

55.4 PHOTOAFFINITY LABELING OF MAMMALIAN NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS. H. Siegel and R.J. Lukas. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

The curaremimetic neurotoxin, alpha-bungarotoxin (Bgt), was extensively purified and used to determine the molecular composition of the putative nicotinic acetylcholine receptor (nAcChoR) from rat brain. Bgt was covalently modified with the photoaffinity reagent, 4-fluoro-3-nitrophenylazide (Hucho, FEBS Lett. 103: 27, 1979), radiolabeled with iodine-125 and chromatographically repurified. In a related procedure, Bgt or previously purified iodine-125-labeled, monoiodinated Bgt (I-Bgt) was covalently modified with Allison's photoaffinity reagent (Lewis et al., Biochemistry 16: 5650, 1977) and subjected to further purification. Photoaffinity labeled toxin (PAL-Bgt) preparations each exhibited characteristic spectroscopic properties that were sensitive to illumination in the near ultraviolet. Analysis of PAL-Bgt binding to membranes from Torpedo californica electric organ or from rat brain prior to or following photoactivation demonstrated specific, high-affinity, nicotinic interaction at the binding site for Bgt or I-Bgt. The covalent nature of the specific interaction with photoactivated PAL-Bgt and membrane components was shown by comigration of radiolabel with high molecular mass (> 40,000 daltons) material on column chromatography in the presence of sodium dodecyl sulfate (SDS).

Specific binding sites for photoactivated PAL-Bgt were further characterized by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and autoradiography. PAL-Bgt was found to be covalently attached to polypeptides from Torpedo with masses of ca. 40, 50, 60 and 70 kilodaltons, which are comparable to the masses of the subunits of the Torpedo nAcChoR. A similar profile is obtained for polypeptides from rat brain membranes or detergent extracts that are labeled with PAL-Bgt. The PAL-Bgt labeling pattern is also expressed by toxin binding components from either tissue that have been purified by curaremimetic neurotoxin affinity chromatography using carbamylcholine as a specific elutant.

In conclusion, PAL-Bgt conjugates can be used for examination of the molecular composition of neuronal binding sites for curaremimetic neurotoxins. These nAcChoR-like sites appear to express a presumptive subunit pattern that is characteristic of the authentic nAcChoR from peripheral tissues.

55.5 ALPHA-BUNGAROTOXIN, BROMOACETYLCHOLINE AND ANTI-NICOTINIC ACETYLCHOLINE RECEPTOR ANTIBODY BINDING SITES ON THE HUMAN MEDULLOBLASTOMA LINE, TE671. R.J. Lukas. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Presumptive nicotinic acetylcholine receptor (nAcChoR) sites on the human medulloblastoma clonal cell line, TE671, have been characterized with respect to their interactions with three classes of specific probes. The properties of these sites are compared to previously described characteristics of toxin binding sites and nAcChoR from other tissues.

TE671 cells in proliferative growth phase express a single class of high affinity binding sites for alpha-bungarotoxin at a site density of 30 fmol per million cells with a dissociation constant on the order of 0.3 nM. The toxin binding site has a distinctive nicotinic cholinergic pharmacology, but exhibits comparatively high affinity for the nicotinic ligand, decamethonium. Consequently, the features of this site are similar to nAcChoR from the electroplax of Torpedo californica. and to toxin binding sites from rat brain, but are different from the toxin binding sites on the rat pheochromocytoma clonal line, PC12.

The nicotinic cholinergic affinity reagent, bromoacetylcholine, reversibly inhibits toxin binding to unmodified TE671 cell membranes. Bromoacetylcholine also irreversibly blocks toxin binding to membranes that have been treated with dithiothreitol. Nicotinic agonists, but not antagonists, block irreversible labeling of toxin binding sites with bromoacetylcholine if they are applied prior to disulfide cleavage and reduction. These interactions of bromoacetylcholine with the TE671 cell toxin binding site are comparable to those with nAcChoR from Torpedo and with toxin binding sites from rat brain and PC12 cells.

Two different polyclonal antisera raised against nAcChoR from the electric tissue of Electrophorus electricus have been tested for their interactions with toxin binding sites. Each of these antisera inhibit binding of toxin to TE671 cells. The potency of this blockade is similar to that for antiserum-mediated inhibition of toxin binding to nAcChoR from Torpedo electric tissue and to toxin binding sites from rat brain or PC12 cells. Each of the antisera also precipitate at least 50% of detergent-solubilized toxin binding sites from TE671 cells. By contrast, under the same conditions these antisera precipitate 0-4% of liganded toxin binding sites from rat brain or PC12 cells, but 100% of nAcChoR from Torpedo.

On the basis of these data, it is suggested that presumptive nAcChoR from a variety of tissues exhibit immunological and pharmacological heterogeneity. The genetic or post-translational bases of this heterogeneity and its functional manifestations are being subjected to further study.

55.6 BIOCHEMICAL CHARACTERIZATION OF TWO NICOTINIC RECEPTORS FROM THE OPTIC LOBE OF THE CHICK. M. Schneider*, C. Adee*, H. Betz*, and J. Schmidt. (SPON: I. Spector). Dept. of Biochem., State Univ. of New York at Stony Brook, Stony Brook, NY 11794 and Zentrum für Molekularbiologie, Univ. Heidelberg, 6900 Heidelberg, West Germany.

We have studied nicotinic receptors in the optic lobe of the newborn chick, using ^{125}I-α-bungarotoxin, a specific blocker of acetylcholine receptors in the neuromuscular junction, and [^{3}H]-acetylcholine, a ligand which in the presence of atropine selectively labels nicotinic binding sites in rat brain cortex (Schwartz, R.D. et al., Mol. Pharmacol. 22:56, 1982). We observed that [^{3}H]-AcCh binds reversibly to a single class of high-affinity binding sites (K_D = 2.2x10^{-8} M; B_{max} = 5.7 picomoles/g). 60% or more of these binding sites are solubilized with Triton X-100, sodium cholate, or CHAPS. Solubilization increases the affinity for AcCh and several nicotinic drugs from 1.5 to 7 fold.

The acetylcholine-binding macromolecule ('agonist receptor') in optic lobe resembles the receptor for α-bungarotoxin (toxin receptor) present in the same tissue with respect to subcellular distribution (both receptors are enriched in the synaptosomal fraction); hydrodynamic properties (mobility on Sepharose-4B and velocity sedimentation); lectin affinities (retention on immobilized concanavalin A, wheat germ agglutinin, peanut lectin, and Ulex europaeus agglutinin). Pharmacologically, the two receptors share a nearly identical rank order for nicotinic agonists.

Several fundamental differences however exist between the two receptors: The agonist receptor has a markedly lower affinity for nicotinic antagonists; it is thermally denatured with a T_m of 49°, compared to a T_m of 70°for the toxin receptor; and in a Triton X-114 biphasic system (Bordier, C., J. Biol. Chem., 256:1604, 1981), the agonist receptor prefers the detergent-rich phase while the toxin receptor partitions approximately equally between the detergent-rich and aqueous phases. Complete physical separation of the binding activities was achieved through incubation with agarose-linked acetylcholine; by affinity chromatography on immobilized α-cobrotoxin; and by precipitation with a monoclonal antibody to chick optic lobe toxin receptor (Betz, H. and Pfeiffer, F., J. Neurosci., 4:2905, 1984).

55.7 REGULATION OF ACETYLCHOLINE RECEPTORS ON CHICK CILIARY GANGLION NEURONS IN CELL CULTURE. J.F. Margiotta, D.K. Berg, and V.E. Dionne . Div. of Pharm. and Dept. of Biol., UCSD, La Jolla, CA 92093.

Chick ciliary ganglion neurons possess functional nicotinic acetylcholine receptors (AChRs) in cell culture. Pressure application of 100 µM ACh induces a large increase in membrane conductance which is blocked by 25 µM d-tubocurarine. The ACh sensitivity of the cells can be regulated by the K^+culture conditions: neurons grown in medium containing elevated K^+ concentrations have four-fold lower levels of ACh-induced conductance (tested under standard conditions) than do neurons grown in normal medium. We have examined the time course of the K^+ effect, shown that it is Ca^{++}-dependent, and determined that it does not involve changes in either the open time or conductance of single AChR channels.

The time course of the K^+ effect on ACh-induced conductances was determined by switching cultures from normal medium (containing 5.4 mM K^+) to medium supplemented with K^+ (25 mM final concentration). After 2-72 hrs the elevated K^+ medium was removed by rinsing, and ACh-induced conductances were examined with intracellular recording techniques. The peak ACh response decreased exponentially with a half-time of 10 hr after switching to elevated K^+ medium. The K^+ effect was Ca^{++}-dependent. Omission of Ca^{++} from the K^+-supplemented medium resulted in ACh responses that were identical to those of neurons grown in normal medium.

Results obtained with intracellular recording were confirmed in voltage clamp studies using the whole-cell recording configuration of the patch clamp technique. After 5-7 days in culture, application of 10 µM ACh to neurons grown in normal medium induced sustained inward currents of 52 +/- 10 pA (mean +/- SE, n=9), but only 15 +/- 2 pA (n=9) in neurons grown in elevated K^+ medium. These currents correspond to whole-cell ACh-induced conductances of 800 +/- 100 pS and 200 +/- 40 pS, respectively. Noise spectra obtained by analysis of ACh-induced current fluctuations from the neurons grown in either medium were well-fit by single Lorentzian functions, suggesting that the cells possess a single population of functional AChRs under both growth conditions. The spectra revealed no differences in the burst duration (ca. 5 ms) or single channel conductance (ca. 30 pS) for neurons grown in either condition. Preliminary single AChR channel data from outside-out patches support these conclusions. The mean channel open time (ca. 1.5 ms) and single channel conductance (ca. 40 pS) were indistinguishable for neurons grown with or without elevated K^+ concentrations.

The absence of an effect of K^+ on single channel parameters suggests that chronic exposure to elevated K^+ concentrations regulates ACh sensitivity by reducing the number of functional AChRs on the neurons. (Supported by NS 15344 and NS 12601.)

55.8 CHOLINERGIC MODULATION OF AN ACETYLCHOLINE RECEPTOR-LIKE ANTIGEN ON CHICK CILIARY GANGLION NEURONS IN CELL CULTURE. D.K. Berg, M.A. Smith, J.F. Margiotta, and J.M. Lindstrom. Dept. of Biol., UCSD, La Jolla, CA. 92093; and Salk Institute, S.D., CA. 92138.

The neuronal nicotinic acetylcholine receptor (AChR) has remained elusive due to lack of suitable probes. Recent work has shown that monoclonal antibodies (mAbs) to the "main immunogenic region" (MIR) of AChR alpha subunit from muscle and electric organ crossreact with a membrane component on chick ciliary ganglion neurons. The MIR-like component in the ganglion has the surface distribution and biochemical properties expected for the neuronal AChR. It is clearly distinct from the alpha-bungarotoxin binding component in the ganglion which previous work has shown to be different from the synaptic AChR on the cells. Since anti-MIR mAbs do not block AChR function either in muscle or neurons, we have sought additional evidence for the relationship of the MIR-like component to the neuronal AChR by testing cholinergic agents for modulation of the component on the neurons in culture.

Exposure to Bgt 3.1, a protein neurotoxin known to reversibly inhibit AChR function on the neurons, causes a 50% reduction in the number of MIR-like sites on the cells after 1 hr, and an 80% reduction after 5 days without competing with anti-MIR mAbs for binding to the component. Cholinergic ligands including d-tubocurarine, nicotine, trimetaphan, carbachol, and ACh protect the MIR-like sites against modulation by Bgt 3.1 both in short- and long-term exposures. Moreover, long-term exposure to carbachol alone induces a 30% decrease in the number of MIR-like sites. Alpha-bungarotoxin has no effect on the number of sites or on the Bgt 3.1-induced modulation. These findings demonstrate that the MIR-like component is subject to modulation through a cholinergic site on the neurons.

ACh sensitivity is altered in parallel with the changes in number of MIR-like sites following chronic exposure to Bgt 3.1, while GABA sensitivity remains unchanged. Co-modulation of ACh sensitivity and the MIR-like component is also seen for trimetaphan protection against the Bgt 3.1 effect, and for carbachol treatment. An exception to co-modulation, however, is observed for neurons grown in elevated K^+ concentrations: the cells express 4-fold lower levels of ACh sensitivity (tested under standard conditions) than do control neurons, and yet have no difference in the number of MIR-like sites.

Previous biochemical and ultrastructural studies, and the co-modulation results described here suggest that the MIR-like component on ciliary ganglion neurons represents the neuronal AChR. While the exception cited above to co-modulation of ACh sensitivity and MIR-like sites does leave questions about the identification, it can also be taken to imply that growth conditions regulate the fraction of neuronal AChRs that are functional. (Supported by NS 12601, NS 11323, MDA, Amer. Heart Asso.)

55.9 SURFACE AND INTRACELLULAR DISTRIBUTION OF AN ACETYLCHOLINE RECEPTOR-LIKE ANTIGEN IN CHICK CILIARY GANGLION NEURONS. M.H. Jacob, J.M. Lindstrom, and D.K. Berg. Dept. of Biol., UCSD, La Jolla, CA. 92093; and The Salk Institute, S.D., CA. 92138.

Ultrastructural studies with monoclonal antibodies (mAbs) to the "main immunogenic region" (MIR) of nicotinic acetylcholine receptor (AChR) alpha subunit from muscle and electric organ have identified a crossreacting component on the surface of ciliary ganglion neurons that is located predominantly in synaptic membrane. Biochemical studies have shown that the MIR-like component in the ganglion has a number of properties expected for the nicotinic AChR on the neurons, and that the component is distinct from the alpha-bungarotoxin binding component in the ganglion. Moreover, cholinergic agents can modulate the number of MIR-like sites on the neurons in cell culture, and in most instances ACh sensitivity is modulated in parallel. Immunohistochemical staining of frozen ganglion sections indicates that a substantial proportion of the MIR-like sites is intracellular. In the present study we show that the intracellular sites are associated with organelles known to be part of the biosynthetic and regulatory pathways for cell surface membrane proteins.

Ciliary ganglia from 15-17 day chick embryos were lightly fixed, saponin-permeabilized, incubated with anti-MIR mAb followed by horseradish peroxidase-labeled secondary antibody, reacted for peroxidase activity, and examined by electron microscopy. Deposits of reaction product were present on most of the rough endoplasmic reticulum, some Golgi complexes, portions of the nuclear envelope, a few coated vesicles, some vacuoles, some multivesicular bodies, the specialized synaptic membranes, and small portions of the pseudodendrite surface membranes. No labeling was associated with other organelles or found in the cytoplasm. The labeling was specific since substitution of nonimmune serum or other mAbs for the anti-MIR mAb failed to generate reproducible labeling in the ciliary ganglion. Also, no labeling was found with anti-MIR mAb in dorsal root ganglion neurons which lack AChRs.

The surface distribution of MIR-like sites was again confined primarily to synaptic membrane on the neurons. The intracellular distribution of the MIR-like component observed here is similar to the biosynthetic pathway described for a number of surface membrane components including the AChR of muscle. Intracellular MIR-like component may represent neuronal AChR undergoing intracellular processing and/or transport to the cell surface. (Supported by NS 12601, NS 11323, The Muscular Dystrophy Association, and The American Heart Association.)

55.10 STRUCTURE OF CHICKEN GENES ENCODING THE NICOTINIC ACETYLCHOLINE RECEPTOR SUBUNITS AND THEIR VARIANTS. A. Mauron*, P. Nef*, C. Oneyser*, R. Stalder*, C. Alliod* and M. Ballivet*. (SPON: B.W.Fulpius) Dept. of Biochemistry, University of Geneva, CH-1211 Geneva, Switzerland.

The nicotinic acetylcholine receptor (AChR) present at the neuromuscular junction of vertebrates is still the receptor of neurobiological interest whose molecular genetics is best understood. The cDNAs encoding its individual subunits α, β, γ and δ have been cloned first in Torpedo, then in a variety of other organisms and this laboratory has focused on the study of the AChR genes of chicken. We recently published the structure and nucleotide sequence of the γ and δ genes (Nef et al. 1984. Proc. Natl. Acad. Sci. U.S.A. 81, 7975). They were found to be related to each other as well as to the corresponding Torpedo genes. Furthermore, they are very closely linked in the chicken genome. Both coding sequences comprise 12 exons which encode homologous protein domains. A gene encoding the α subunit was obtained as well, whose sequencing now approaches completion. Although it has only 9 exons, these can be derived by exact excision from the 12 exon pattern that obtains for the γ and δ genes.

By screening the same chicken genomic library, a variant α gene, named α2, was discovered and sequenced. It shows more sequence similarity to known α genes than to any other AChR subunits and shows α-specific features, including 4 cysteine residues which are thought to form a box-like structure presumably involved in the binding of cholinergic ligands. The α2 gene has 7 exons: as compared to the α gene, two introns were again excised, thus forming a large exon which encodes the first three putative transmembrane domains. The α2 sequence shows none of the characteristic features of a pseudo-gene and probably represents a functional gene. Transcriptional studies are in progress to determine the function of this variant gene. It is not clear at this point whether the α2 gene encodes an embryonic form of the AChR or one of the several nicotinic AChR-like molecules which have been described in the CNS.

PAIN: CENTRAL PATHWAYS I

56.1 NOCICEPTIVE LAMINA I NEURONS HAVE AXONS THAT ASCEND IN THE DORSOLATERAL FUNICULI (DLF) AND TERMINATE IN THE PARABRACHIAL AREA. J.L.K. Hylden, H. Hayashi*, G.J. Bennett and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

We have physiologically and anatomically characterized a population of lamina I neurons that projects to the parabrachial area (PBA; n. cuneiformis and parabrachial n.). Extracellular recordings were made from 89 lamina I PBA projection neurons in the lumbosacral enlargement of chloralose-anesthetized cats. Half of the cells (44) were antidromically activated from the contralateral PBA; the other half projected to the ipsilateral PBA (40) or to both sides (5). In addition, 8 PBA projection neurons were also activated from the contralateral thalamus. The majority of physiologically characterized projection neurons responded exclusively to noxious stimulation of their cutaneous receptive fields (92%); only a few wide-dynamic-range neurons were observed. Conduction velocities for antidromic activation from the PBA ranged from 1 to 18 m/s.

Following physiological characterization, several neurons were impaled and injected with HRP. Intracellularly stained PBA projection neurons (n=14) had a mean cell body diameter of 13 to 30 μm and extensive dendritic arbors which were oriented in the rostrocaudal axis (850-1900 μm in length) and either remained within lamina I or extended dorsally into the white matter. Nine cells had well stained axons and 5 of these had at least one collateral.

Projection neurons were also labelled following an injection of wheat germ agglutinin-HRP (0.2 μl, 25%, 72h) into the PBA. Many lamina I neurons were retrogradely labelled, bilaterally, in all spinal segments. Bilateral lesions of the DLF at T11 resulted in an 86-94% decrease in the number of labelled lamina I cells below the lesion. Injection of colchicine (6 μl, 1%) into thoracic spinal cord allowed visualization of small and large HRP-containing axons bilaterally in the DLF and ipsilaterally in the anterolateral funiculus.

Our data indicate that there is a large population of nociceptive lamina I neurons with projections through the DLF to the PBA of the midbrain. The similar physiology (Craig and Kniffki J. Physiol., (Lond.), in press) and DLF pathway (Jones et al., Soc. Neurosci. Abstr., 1984) of cat spinothalamic lamina I neurons suggests that a significant number of PBA projection neurons may also project to the thalamus.

56.2 FURTHER EVIDENCE THAT THE ACTIVITY OF WIDE-DYNAMIC-RANGE BUT NOT NOCICEPTIVE-SPECIFIC NEURONS CORRELATES WITH THE ABILITY OF MONKEYS TO DETECT SMALL INCREASES IN NOXIOUS TEMPERATURE. W. Maixner, D.R. Kenshalo, Jr., J.-L. Oliveras, M.C. Bushnell and R. Dubner. Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Previous reports from this laboratory (Bushnell et al., J. Neurosci., 1985, in press) have demonstrated that both monkeys and humans detect small increases in noxious heat. The activity of medullary dorsal horn wide-dynamic-range (WDR) but not nociceptive-specific (NS) neurons predicted the monkey's ability to detect near threshold increases in noxious temperature (Kenshalo et al., Neurosci. Abstr. 10:798, 1984). In the present series of studies, we have obtained additional evidence which indicates that the activity of WDR but not NS neurons is correlated with monkeys' ability to detect small increases in noxious temperature.

Two rhesus monkeys were trained to perform a noxious thermal detection task. Monkeys initiated a trial by depressing an illuminated panel button. Following button press, a contact thermode that was positioned on the upper lip increased in temperature from a baseline of 38°C to a noxious (45° or 46°C) temperature (T1). After a random 3 to 9 sec foreperiod (time between button press and onset of T2), the thermode increased an additional 0.2°C to 1.5°C (T2). Monkeys received a fruit juice reward for releasing the button within 2.4 sec of the onset of T2. Single unit activity was recorded from WDR (N=18) and NS (N=9) medullary dorsal horn neurons during the performance of the task. In addition, the median detection latency (MDL) to the onset of T2 was determined.

The MDL was inversely related to the magnitude of T2 irrespective of the preceding T1 temperature. The MDL was also inversely related to the magnitude of peak neuronal discharge produced by the various T2's presented from the two different T1's for both WDR and NS cells. When MDLs and peak neuronal discharge were directly compared, equivalent MDLs were associated with similar peak neural discharge rates for WDR neurons (N=6). In contrast, NS (n=4) neurons did not demonstrate such a strong relationship. In addition, the MDL for a 0.2°C T2 presented from a preceding T1 of 46°C decreased as the foreperiod increased. The peak neuronal discharge response to the 0.2°C T2 was also increased as a function of hold time for WDR (N=18) but not for NS (N=9) neurons.

These data demonstrate that the magnitude of discharge of WDR neurons is a more accurate predictor of MDL than the magnitude of discharge of NS neurons. We conclude that WDR neurons are the critical medullary dorsal horn neuronal population which provides the minimal information required to make fine discriminations in the 45° to 46°C noxious heat range.

56.3 RESPONSE PROPERTIES OF NEURONS IN THE LATERAL CERVICAL NUCLEUS (LCN) OF THE ANESTHETIZED OR DECEREBRATE-SPINALIZED (D-S) CAT. K.C. Kajander and G.J. Giesler Jr., Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

A large number of electrophysiological studies have shown that the majority of neurons at the origin of the spinocervical tract (SCT) respond differentially to noxious cutaneous stimuli. Surprisingly, studies of the LCN, the nucleus in which the SCT terminates, have uniformly failed to find more than a very small percentage of nociceptive neurons. Since these previous studies of the LCN have all been performed in anesthetized animals, the purpose of the present experiments was to compare the response properties of cat LCN neurons in anesthetized and D-S states.

Cats were either anesthetized with urethane or decerebrated and spinalized at the C1-medullary junction. Extracellular single unit recordings were made within the LCN between caudal C1 and C3. Electrical stimulation of the ipsilateral C5 dorsolateral funiculus (DLF) was used as a search stimulus. The criteria for identification of an LCN neuron were: 1) inability to follow reliably DLF stimulation at greater than 50 Hz, 2) action potentials with shape and polarity characteristic of somatic recordings, 3) anatomical localization of recording point within the LCN. On some occasions, successful attempts were made to activate LCN neurons antidromically from either the ventral posterior lateral nucleus of the thalamus (anesthetized cats) or the contralateral C1 ventral funiculus (D-S cats). Responses of each neuron were determined to hair movement, pressure and noxious pinch. In addition, all nociceptive neurons were examined for their responses to a series of ascending innocuous and noxious thermal stimuli.

Receptive fields on the distal portion of the limbs were smaller than those on the proximal aspect of the limbs and trunk in both anesthetized and D-S cats. The sizes and locations of receptive fields were indistinguishable from those previously reported. In anesthetized cats, 25 LCN neurons were examined; only one (4%) responded to noxious stimuli. In D-S cats, 44 LCN neurons have been examined. Of these, 21 (47%) responded either differentially or exclusively to noxious stimuli. The remaining 23 (53%) responded only to innocuous mechanical stimuli. In several nociceptive LCN neurons, responses to noxious stimulation were temporarily blocked by small doses of sodium methohexital, a short-acting barbiturate. It appears that anesthesia importantly affects the capability of LCN neurons to respond to noxious mechanical and thermal stimuli. These findings support a role for the spinocervicothalamic system in nociception in the cat.

56.4 RESPONSES OF SPINOMESENCEPHALIC TRACT (SMT) CELLS TO THERMAL STIMULI. R.P. Yezierski, H. Hirata and N.A. Olson*. Department of Anatomy, University of Mississippi Medical Center, Jackson, Mississippi 39216.

Recent studies in our laboratory have demonstrated that cat SMT cells can be classified based on their excitatory and/or inhibitory responses to varying intensities of mechanical stimuli. Two classes of SMT cells, i.e. wide dynamic range (WDR) and high threshold (HT), were found to respond best or exclusively to noxious stimuli. The purpose of the present study was to evaluate the responses of these two classes of cells to innocuous and noxious thermal stimuli.

Recordings were made from 25 identified SMT cells located in laminae I and V-VIII of the cat lumbosacral spinal cord. Cells were activated antidromically from stimulating electrodes positioned in the contralateral midbrain. Animals were anesthetized with alpha-chloralose (60mg/kg) and sodium pentobarbital (2mg/kg/hr); expired CO2 and body temperature were maintained within normal limits. Responses to thermal stimuli were recorded while heating/cooling the skin with ascending (35-55°C) or descending (35-5°C) sequences of 20-30 second thermal pulses produced by a Peltier thermal stimulator. The effects of repeated heating and/or cooling on thermal evoked responses were also evaluated.

The results of the present study have shown that WDR and HT SMT cells respond to heating and/or cooling of glabrous skin with thermal thresholds of 50°C and 25°C, respectively. Maximal responses to heating were obtained between 52-55°C and those to cooling between 5 and 15°C. The most consistent responses to thermal stimuli were excitatory although five cells inhibited by mechanical stimuli were observed to have similar responses to noxious heating of the receptive field(s) on the ipsi- and/or contralateral hindlimb. One cell was inhibited by heating the ipsilateral receptive field and excited by the same stimuli applied to the contralateral hindlimb. Two cells were excited by heat stimuli of 50°C and inhibited by stimuli of 52 and 55°C. Four cells were excited by both noxious heating (50-55°C) and cooling (5-25°C). Sensitization was observed for three cells following repeated applications of a series of thermal pulses which increased in a stepwise fashion from 45-55°C.

In conclusion the results of the present study have shown that cat SMT cells can be excited and/or inhibited by heating/cooling the skin within a narrow range of temperatures. The present results will be discussed in relation to the role of the SMT in thermal nociception.

56.5 **URINARY BLADDER MODULATION OF T_3-T_5 SPINAL NEURONS IN THE CAT.** **T.J. Brennan*, U.T. Oh* and R.D. Foreman. (Spon, R. Person) Dept. of Physiol., Univ. Okla. HSC., Okla. City, OK 73190.**

We have previously demonstrated that feline upper thoracic spinal neurons with somatic receptive fields in the triceps and chest region receive convergent excitatory input from cardiopulmonary (CP) sympathetic afferent fibers innervating the heart. In addition, we have observed that gall bladder distension excited 25% of these cells, inhibited 14%, and had no effect on the remaining neurons. Thus, abdominal input from the gall bladder can influence these upper thoracic spinal neurons.

The purpose of the present study was to determine if the urinary bladder could affect the activity of T_3 to T_5 spinal neurons. Experiments were performed on 8 cats anesthetized with α-chloralose and paralyzed with pancuronium. The upper thoracic segments were searched with microelectrodes for single neurons with somatic receptive fields in the chest and arm region which were excited by the CP sympathetic fibers. Of the 16 cells located in the T_3 to T_5 segments, 15 received convergent excitatory input from the chest and arm and CP sympathetic afferent fibers while 1 cell was inhibited by these stimuli. Urinary bladder distension (UBD) ranging from 30 to 150 cmH_2O inhibited the activity of 8 cells, excited 2 cells, excited then inhibited 1 neuron and had no effect on the remaining 5 cells. Phasic inhibition was usually observed during the onset of small distensions (20-60 cmH_2O) while tonic inhibition occurred with higher distending pressures (30-150 cmH_2O). UBD inhibited excitatory input produced by noxious pinch of the somatic field (n=8), electrical stimulation of CP sympathetic afferent fibers (n=5), and intracardiac injection of the algesic chemical bradykinin (n=3). In 2 experiments, spinal cord transection at the L5-L6 level greatly reduced or eliminated inhibition produced by UBD, suggesting that this inhibition occurs largely via pelvic parasympathetic afferent fibers.

In summary, upper thoracic spinal neurons with input from the chest, arm, and CP sympathetic afferent fibers also received convergent input from the urinary bladder. In contrast to the previously observed input from the heart and gallbladder, stimulation of a more distant visceral organ, the urinary bladder, inhibited (50%) or did not affect (31%) most cells. These results may provide an explanation for the specificity of visceral input to the spinal cord and may also suggest possible mechanisms for localization of visceral pain. (Supported by NIH grant HL22732, HL27260, and HL07430).

56.6 PONTOMEDULLARY RAPHE NEURONS: INTRACELLULAR RESPONSES DURING THE TOOTH PULP-EVOKED JAW OPENING REFLEX, P. Mason, A. Strassman*, and R. Maciewicz (SPON: W.H. Sweet). Pain Physiology Lab, Neurology Service and Dept of Neuroscience, Mass General Hosp and Harvard Med School, Boston MA 02114.

Several lines of evidence suggest an important role for the pontomedullary raphe in modulation of central pain pathways. To determine how raphe cells are activated during a nociceptive behavior, the intracellular responses of raphe neurons were studied during the jaw opening reflex (JOR) elicited by tooth pulp shock in nonparalyzed, lightly anesthetized cats.

Tooth pulp stimulation produces reflex EMG activation of the digastric muscle at a latency of 7-9msec, resulting in jaw opening. Tooth pulp shock that elicits the JOR also produces an EPSP in a subset of raphe neurons. This EPSP consists of an early small depolarization at a latency of 10-12ms followed by a larger depolarization at a latency of 20-30ms. In all cases the EPSP follows digastric EMG activation. These cells also show oligosynaptic EPSPs in response to electrical stimulation of the four paws. No raphe neurons are inhibited by either tooth pulp or peripheral paw shock.

Electrical train stimulation of the midbrain periaqueductal gray region (PAG) suppresses the JOR. Single shock stimulation at the same PAG sites that suppress the JOR evokes monosynaptic EPSPs in the large majority of raphe neurons recorded. In all cases, the threshold for EPSP is below the threshold for suppression of the JOR. The EPSP amplitude is a direct function of PAG stimulus intensity and there is temporal summation of EPSPs evoked by paired PAG shocks. At conditioning-test intervals of 40-90ms, train stimulation of PAG suppresses the tooth pulp-evoked EPSP in raphe neurons. The threshold for EPSP suppression occurs at a PAG stimulation intensity below that required for suppression of the JOR.

The location and morphology of studied neurons were determined by intracellular injection of either HRP or ethidium bromide. Most recordings were made from large or medium-sized raphe neurons in nucleus raphe magnus or rostral nucleus raphe obscurus. Large raphe cells are multipolar in shape with average somatic diameters of 50-90um, and most medium-sized neurons are fusiform in shape with average somatic diameters of 30-40um. The axons of stained cells typically course laterally through the paramedian white matter tracts, then turned caudally to descend through the ventromedial medullary reticular formation to cervical levels.

Immunohistochemical processing of ethidium bromide-labeled cells revealed that few of the electrophysiologically-characterized raphe neurons responding to PAG or tooth pulp shock colocalize serotonin-like immunoreactivity.

56.7 COLLATERAL PROJECTIONS FROM THE PERIAQUEDUCTAL GRAY TO THE THALAMUS AND MEDULLARY RETICULAR FORMATION: A RETROGRADE DOUBLE LABEL FLUORESCENCE STUDY IN THE RAT. C.M. Pechura*, L. Chang* and R.P.C. Liu* (SPON: G.J. Bennett). Dept. of Anatomy, Uniformed Services Univ. of the Health Sciences, Bethesda, MD 20814-4799.

Both the ascending and descending efferent projections of the midbrain periaqueductal gray (PAG) have been proposed to subserve certain components of stimulation-produced and opiate analgesia. Of particular importance are the midline and intralaminar thalamic nuclei and the medullary reticular formation (MRF). It is not known whether these PAG projections are completely independent of each other or whether some are via axon collaterals which ascend and descend to innervate multiple targets. In order to determine the presence and location of any PAG cells which project to both the thalamus and MRF via axon collaterals, retrograde double label fluorescence techniques were utilized. The tracers 5% Fast Blue (FB) or 2% Diamidino Yellow Dihydrochloride (DY-2HCl) were pressure injected via glass micropipettes into either the medial thalamus or MRF. The thalamic injections were centered in the mediodorsal nucleus and included the central lateral, central medial and habenular nuclei. Reticular formation injections were centered in the n. reticularis gigantocellularis and included n. reticularis magnocellularis. The animals were sacrificed 5-7 days after injections. Frozen, transverse sections (25μ) through the injection sites and serial sections through the PAG were viewed with epifluorescent microscopy. The locations of all double labeled cells were plotted on cross sectional drawings with the use of a microprojector. The distributions of single labeled FB or DY-2HCl cells were plotted in the same manner.

Double labeled cells were located throughout the rostrocaudal extent of the PAG. The heaviest concentration of such neurons was found at intercollicular levels. The vast majority of double labeled cells were observed ipsilateral to the injection sites and were located in the lateral, lateroventral and ventral portions of the PAG. In more caudal regions, double labeled cells were found in the lateral dorsal tegmental nucleus. Few double labeled neurons were seen in the dorsal raphe nucleus.

These data demonstrate the presence of PAG neurons which project to both the medial thalamus and MRF via axon collaterals. Thus, an anatomical substrate exists for simultaneous input from the PAG to both the inhibitory reticulospinal system and the thalamic nuclei proposed to mediate emotional and affective components of pain perception. Such divergent projections from single neurons in the PAG underscore the importance of considering both ascending and descending pathways in the functional sequelae of stimulation-produced or opiate analgesia. (Supported by NSF Graduate Fellowship (CMP) and DoD Grant No. R07058.)

56.8 DIFFERENTIAL EFFECTS OF CORDOTOMIES UPON THALAMIC NEURONAL RESPONSIVENESS IN HEALTHY RATS AND IN AN EXPERIMENTAL MODEL OF CHRONIC PAIN. G. Guilbaud, M. Peschanski, A. Briand and M. Gautron, INSERM U. 161, 2 rue d'Alésia 75014 Paris, France.

Numerous neurons responding to noxious cutaneous stimulation can be recorded in the ventrobasal complex of the thalamus (VB) of healthy rats. In contrast, in an experimental model of chronic pain (arthritic rats), most VB neurons are activated by movement or pressure of the inflammed joints. Changes observed in the spinal neuronal responsiveness in arthritic rats are too limited to explain the striking difference at the thalamic level. The present experiment was therefore designed to test another hypothesis, that afferent ascending pathways involved in the genesis of VB neuronal responses might differ according to the experimental conditions.

Electrophysiological characteristics of the same VB neurons were studied before and after localized lesions of the spinal cord. VB neurons responding to pinches or joint movements of both hindlimbs were recorded extracellularly using glass micropipettes in moderately anesthetized healthy (n = 15) and arthritic (n = 18) rats. Successive lesions of the dorsal columns (DC) of one dorsolateral funiculus (DLF) then of half the spinal cord were performed at the level of prepared laminectomies of C2, C4 and C6 vertebrae. Histological controls of the lesions were systematically done.

In the two experimental conditions, DC and DLF lesions did not modify the receptive fields of the VB neurons. In contrast, hemisection - i.e. essentially the addition of the lesion of one anterolateral quadrant (ALQ) - produced differential effects :

. in healthy animals, it eliminated the receptive field located on the hindlimb contralateral to the lesion. Noxious inputs are therefore conveyed, in healthy rats, by and ascending pathway located in the ALQ and completely crossed, most probably the direct spinothalamic tract.

. in arthritic rats, the effects of the ALQ lesion was more complex ; indeed, a lesion on the side of the thalamic recording failed most often to modify the receptive field of the VB neurons; in contrast the lesion of the ALQ opposite to the recording site did eliminate the responses elicited from the hindlimb ipsilateral to the recorded neuron. This shows that in this experimental model of chronic pain, afferent inputs involved in some VB neuronal responses are subserved by a pathway located in the ALQ, with both a crossed and a direct components. This pathway is probably a part of the spinoreticular system.

These observations are discussed with reference to the results of therapeutic unilateral cordotomies, in particular to some paradoxical results with elimination of sensori-discriminative aspects of acute pain and failure of a consistant effect upon chronic pain.

56.9 CLUSTER ANALYSIS OF SOMATOSENSORY NEURONS. J.M. Chung, D.J. Surmeier, K.H. Lee*, L.S. Sorkin, C.N. Honda, Y. Tsong* and W.D. Willis. Marine Biomedical Institute, Departments of Anatomy, Physiol. & Biophys. and Office of Academic Computing & Biostatistics, Univ. Texas Med. Branch, Galveston, TX 77550.

An attempt is made to classify primate spinothalamic tract (STT) cells and neurons of the caudal part of the ventral posterior lateral nucleus (VPLc) of the thalamus using a cluster analysis of the responses of these cells to graded mechanical stimulation of the skin.

Data were collected from a total of 75 young monkeys (1.8-3.0 kg; Macaca fascicularis). Animals were anesthetized with an initial dose of α-chloralose (60 mg/kg), and then sodium pentobarbital (4 mg/kg/hr) was infused throughout the experiment to maintain a constant level of anesthesia. Single unit activity of STT cells antidromically activated from the contralateral VPLc thalamus were recorded with a microelectrode in the lumbosacral enlargement of the spinal cord. For thalamic unit recording, a microelectrode was driven slowly into the VPLc nucleus while applying electrical search stimuli to the sciatic nerve. A k-means clustering analysis, a non-hierarchical cluster technique, was done based on the relative responsiveness of the cells to graded mechanical stimuli applied to their receptive fields.

For 128 STT cells, a classification scheme with 3 clusters was found statistically to be the best. This yielded groups of 22, 57 and 49 cells in clusters 1, 2 and 3, respectively. Response characteristics of cells in each cluster showed that cluster 1 cells are activated best by low threshold mechanical stimuli whereas cluster 3 cells are activated mostly by nociceptive stimuli. Cluster 2 cells had intermediate characteristics. When the classification scheme based on the cluster analysis was compared with the conventional classification of low threshold (LT), wide dynamic range (WDR) and high threshold (HT) cells, cluster 1 cells were divided into LT and WDR cells whereas cluster 2 and 3 cells included WDR and HT cells. For 110 thalamic neurons, a classification scheme with 5 clusters was found statistically to be the best. Clusters 1-5 contained 25, 34, 17, 10 and 24 cells, respectively. Response characteristics of cells in each group indicated a gradual change in sensitivity to higher threshold peripheral input from cluster 1 to 5. When this classification scheme was compared with the conventional classification, cluster 1 cells belonged to LT group, clusters 2 and 3 split into LT and WDR cells, and clusters 4 and 5 included WDR and HT cells.

Classification schemes based on a cluster analysis of the responses of cells may provide an objective and functionally meaningful categorization for somatosensory neurons. 56.10 CLUSTER ANALYSIS OF THE RESPONSES OF PRIMATE SPINOTHALAMIC NEURONS TO NOXIOUS THERMAL STIMULATION. D.J.Surmeier, C.N.Honda and W.D. Willis. Marine Biomed. Inst., Univ. Texas Med. Br., Galveston, TX 77550.

A k-means cluster analysis was performed on the responses of spinothalamic (STT) neurons to graded mechanical and thermal stimulation in an attempt to ascertain whether functional subdivisions within the STT population could be resolved.

Macaque monkeys (M. fascicularis) were initially anesthetized with α-chloralose (70 mg/kg) and maintained by continuous intravenous infusion of sodium pentobarbital (5 mg/kg/hr). Recordings from antidromically-identified STT neurons in the L7-S1 segments of the spinal cord were made with glass microelectrodes. The majority of cells were isolated within laminae IV-VI. Thermal stimulation was performed with a servo-controlled Peltier stimulator. Thirty second thermal pulses were delivered to the skin in ascending, two degree steps from 43 to 55°C.

The responses to a standard series of mechanical stimuli were used to classify neurons according to the scheme proposed by Chung et al., 1985. A cluster analysis was also performed on the responses evoked by noxious thermal stimulation. Four well-defined clusters of STT neurons were found when the analysis was based upon the alteration in discharge rate in the stimulation and post-stimulation periods. No clustering was evident based upon only the alteration in rate during stimulation. Members of the 'A' class (35/56) had relatively poor thermal responses and were either suppressed following stimulation or exhibited no change in rate. Members of the 'B' class (8/56) had relatively large thermal responses and were suppressed following stimulation. Members of the 'C' class (2/56) possessed the largest responses to thermal stimuli and had mixed post-response activity patterns. Members of the 'D' class (11/56) had intermediate thermal responses and a post-response afterdischarge. The clustering was independent of the type of skin stimulated. The mechanical and thermal responsivity of the four classes strongly covaried.

The STT population's pattern of discharge to thermal stimuli was also examined with multidimensional scaling (MDS) techniques. The across-neuron pattern of discharge has been correlated with the quality of sensation in other sensory systems (Smith et al., J. Neurophysiol., 50: 541-558, 1983). The MDS analysis revealed that STT neurons are capable of qualitatively ordering stimuli from 45-55°C in an intuitively reasonable manner. In addition, the across-neuron pattern derived from hairy skin was found to undergo a marked change between 47-49°C, whereas that from glabrous skin underwent a similar change near 51°C. An MDS analysis of the mechanical type 2 and 3 subgroups suggest that although their coding capacities differ, each is essential to the coding of thermal quality in the 45-55°C range.

Supported by NIH grants NS07216, NS07574, NS09743 and NS11255.

56.11 CORTICAL NOCICEPTIVE RESPONSES AND BEHAVIORAL CORRELATES TO TOOTH PULP STIMULATION IN THE MONKEY. E.H. Chudler*, W.K. Dong and Y. Kawakami*. Departments of Anesthesiology and Psychology and Multidisciplinary Pain Center, University of Washington, Seattle, Washington 98195.

The location and function of cortical mechanisms that subserve trigeminal nociception are uncertain. To investigate such mechanisms, we characterized the distribution of tooth pulp-evoked potentials (TPEPs) in the sensory and motor cortices of anesthetized and unanesthetized monkeys. In lightly anesthetized monkeys (n = 5), bipolar electrical tooth stimulation elicited components P23 and N44 over the primary somatosensory cortex (SI), P26 and N72 over the primary motor cortex (MI) and P72, N161, P280, N420, P561 and N662 over the secondary somatosensory cortex (SII). Anesthetics attenuated TPEPs in SII more than TPEPs in SI and MI. TPEPs were not contaminated by extradental input and muscle artifacts because pulpectomy of the stimulated tooth eliminated all TPEPs and neuromuscular blocking agents had no effect on TPEPs, respectively. Compound action potential recordings from the trigeminal ganglion indicated that the shorter latency TPEPs recorded from SI and MI required the activation of only A-beta nerve fibers while the longer latency TPEPs recorded from SII required the additional recruitment of A-delta nerve fibers. Intracortical recordings revealed polarity reversals of P23 and N44 in cytoarchitectonic area 3b, P26 and N72 in area 4 and P72 to N662 in the superior bank of the lateral sulcus (SII/r).

The relationships between nociceptive cortical events and behavioral indices of pain were determined in monkeys trained on a simple escape task or an appetitive-tolerance escape task. An array of epidural or subdural electrodes to record TPEPs was placed over SI, MI and SII in four monkeys. Long latency components were found exclusively in SII when TPEPs were recorded from the pial surface. These late TPEPs recorded from SII required the recruitment of A-delta nerve fibers and were correlated with high rates of escape and short mean escape latencies. At low stimulus intensities, few escapes occurred and only short latency TPEPs were observed. Administration of morphine (2-4 mg/kg, s.c.) significantly increased escape threshold and latency and selectively reduced the amplitude of only the longer latency potentials recorded over SII.

These results support the assumption that a large population of nociceptive neurons exists in SII. The noninvasive measurement of nociceptive evoked potentials over the SII region may provide a useful tool in assessing the efficacy of pharmacological, electrical, and surgical manipulations that modulate nociception.

This research was supported by National Institute of Dental Research Grant DE 05130.

56.12 DO ELECTRICALLY INDUCED PAIN AND THERMALLY INDUCED PAIN SUM? A. C. Brown, A. C. Kloka*, R. W. Fields*, W. J. Beeler*, and A. P. Hainisch*. Physiol. & Biophysics SD, Oregon Health Sci. U. and VA Md. Center, Portland, OR 97201.

The purpose of these experiments was to ascertain whether tooth pain and detection (pre-pain) thresholds determined from electrical stimulation were altered by the simultaneous application of heat. Stimuli were applied to maxillary central incisors of normal human volunteers. All teeth used were free of restorations or had at most one small composite restoration, were free of disease, and gave normal responses to standard clinical tests (percussion, heat, cold, vitalometer). Stimuli were applied through a custom-molded acrylic splint applied to the maxillary anterior teeth. A 2.5 mm hole through the splint on the lingual surface was filled with conducting paste for delivery of electrical pulses (0-100 uamp, 1 msec duration, repeated at 2 sec intervals). Heated air was circulated through a chamber on the labial surface and tooth surface temperature monitored with a thermocouple. The subject indicated sensation intensity (pre-pain, brief pain, continuous pain) by pressing a pushbutton. Stimulus amplitude was determined by a computer-controlled stimulator which was used to implement staircase and threshold tracking algorithms. The experimental design was to use electrical stimuli to determine pain and detection thresholds, starting at a tooth surface temperature of 35C, and then raising surface temperature in 5C increments until the subject reported continuous pain. Each temperature was maintained for a two-minute "epoch" while electrical thresholds were tested; every few epochs, temperature was returned to the 35 C baseline and electrical stimulation withdrawn for two minutes to reduce the possibility of adaptation or sensitization. We found that increasing temperature produced no significant effect on either detection or pain electrical thresholds, even when the temperature was raised to a level which caused thermally induced continuous pain (50-55 C in most subjects). From this lack of interaction, we conclude the following: First, pain due to electrical stimulation and pain due to heat stimulation are mediated by separate neural pathways. Possibly electrical stimulation activates tooth pulp A-beta and A-delta axons, while heat activates C-fibers. Second, there is no significant convergence or summation of the two pathways in relation to sensation. Supported by NIDR grant DE-05895.

PROCESS OUTGROWTH: GROWTH CONES

57.1 DISTRIBUTION OF NCAM IN THE CHICK HINDLIMB DURING AXON OUTGROWTH AND THE ESTABLISHMENT OF MATURE NERVE-MUSCLE RELATIONSHIPS. K. Tosney, M. Watanabe, L. Landmesser, U. Rutishauser. Division of Biology, Univ. of Michigen, Ann Arbor, MI 48109, Anatomy & Developmental Genetics, Case Western Reserve Univ., Cleveland, OH, 44106, Depts. of Physiology and Neuroscience, Univ. of Connecticut, Storrs, CT 06268, Anatomy & Developmental Genetics, Case Western Reserve Univ., Cleveland, OH, 44106.

Motoneurons in the chick lumbosacral spinal cord have been shown to interact with the developing limb bud to form a stereotyped gross anatomical nerve pattern and a precise pattern of specific connections with muscles. Adhesive interactions between the neuronal growth cone and limb components would be expected to play an important role in these processes. We therefore determined the distribution of NCAM (a molecule known to mediate neural adhesion) in this system from the initiation of axon outgrowth through hatching using both immunocytochemistry and SDS-Page gel immunoblots of microdissected limb components.

NCAM staining was intense on neurites throughout development. At early stages, weak to moderate NCAM staining was also always found on mesenchyme cells in advance of growing nerves, suggesting that it may play at least a supportive role in axon elongation. However, no differences were detected in NCAM levels between regions where axons grow and adjacent regions (i.e., the anterior vs. posterior half of each somite; nerve pathway vs. surrounding mesenchyme) suggesting that the pathways these axons follow are not delineated by NCAM.

However, axon invasion of developing muscles was temporally correlated with the onset of intense NCAM staining of developing myotubes. Axons enter muscle at st 28, but do not ramify within muscle until st 31-32 (Tosney & Landmesser, J. Neurosci., in press). Between st 28-32, the intensity of NCAM staining increased in all thigh muscles. The onset of NCAM staining in muscle was not triggered by nerves or nerve-evoked activity, since it also occurred in aneural limbs.

While NCAM increased in amount during st 28-32, it did not alter in form. NCAM in nerves (plexus and sciatic nerve) and muscle was similar with an apparent molecular weight ranging smoothly between 140-250Kd at each stage.

Muscle NCAM remained high between st 34 and 40, when large numbers of myotubes are added and synapses formed, but declined sharply around hatching, as mature contacts become stabilized and polyneuronal innervation is removed. These results suggest that high levels of NCAM may facilitate formation and rearrangement of synapses. Since NCAM staining declined earlier in fast than in slow muscles, nerve-mediated activity patterns, which differ between fast and slow muscles, may play a role in reducing NCAM expression.

In summary, the distribution of NCAM is not correlated with pathfinding in this system. However, dynamic changes in the levels of NCAM seem to be associated with the subsequent interaction of these neurons with their targets.

57.2 RELATIVE RECEPTOR INDUCING ACTIVITY ALONG NEURITE. J.M. Dubinsky, M. Morgan*, G.D. Fischbach. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Mo.

Accumulation of acetylcholine receptors occurs on cultured myotubes soon after contact by a cholinergic growth cone. Several neurites issue directly from neuron cell bodies and each of them is capable of inducing several receptor patches within a few hours of coculture. We have searched for a gradient of receptor inducing activity along neurites by examining receptor patches as a function of distance from the cell body. Acetylcholine receptor patches were identified by labelling all receptors in cocultures of chick neurons and myotubes with Rhodamine-conjugated alpha-Bungarotoxin (R-BTX). Neurites were visualized by injection of Lucifer Yellow or 5,6 Carboxyfluorescein into individual ciliary ganglion neurons or spinal cord motorneurons. Images of neurites and individual neurite-associated AChR patches (NARPs) were digitized using a Dage SITCAM connected to a Grinnell Image processor and PDP 11/44 computer. The entire neuritic arbor was traced and the locations of muscle contact and NARPs were noted. For each NARP the maximum receptor density within a cluster was judged by fluorescence intensity of the cluster relative to the background intensity of the adjacent muscle membrane. Total area of the NARP was measured by calculating the number of pixels above a threshold value. We also made note of variations in fluorescence intensity within individual NARPs. These values were compared for all NARPS along a given process. A total of 33 neurons were studied, between 4 hours and ten days after plating. 360 NARPs were analyzed along 80 neurites contacting 22,656 micrometers of muscle surface. The mean incidence of NARP occurrence was 1.6 per 100 um of muscle contact (cf. Role et al Nsci Abst. 9:1179, 1983). While several neurites had only one or two NARPs, some neurites induced up to 30 NARPs along their length with the avarage range being 8-15 per neurite. Most NARPs along a given neurite fell within a relatively narrow intensity range with the exception of one or two NARPs of up to ten-fold greater intensity. These bright NARPs were usually located at an intermediate position along the course of the neurite rather than at the extreme proximal or distal positions. The area of individual NARPs varied significantly (from 2 to 20 μm^2) with one or two NARPs up to 10 times larger than others along the same neurite. As observed with the most intense NARP, the largest ones were usually found midway along the neurite, although the largest NARPs were not necessarily the brightest. Based on these parameters, no gradient of receptor induction by the neurites was apparent. We are currently using time-lapse techniques to study the formation, organization, and stability of NARPs at different times after the initial neurite-muscle contact is formed. Supported by USPHS 5 T32 NS07057-07.

57.3 **NEURITE-PROMOTING ACTIVITY OF A LAMININ-RELATED POLYPEPTIDE FROM MUSCLE-CONDITIONED MEDIUM IS INCREASED BY DENERVATION.** T.N. Stitt*, (Spon.: M. Gurney). Committee on Neurobiology, Univ. of Chicago, 947 E. 58th St., Chicago, IL 60637.

The composition of the substrate to which neuronal growth cones adhere in large part determines the extent of outgrowth of neuronal processes. It may be postulated that postsynaptic tissues supply substrate-bound factors which influence neuron-target interactions. This report is a preliminary characterization of a polypeptide secreted into muscle-conditioned medium which promotes neurite outgrowth from embryonic spinal cord cells.

Rat hemidiaphragm, denervated 3 days in vivo, was organ cultured as a source of serum-free conditioned medium (Ddia CM). When bound to polyornithine-coated tissue culture plastic, a component of the Ddia CM promoted neurite outgrowth from 25% of cells from dissociated 5-day embryonic chick neural tube. A 190 gm/L ammonium sulfate-precipitable fraction of the Ddia CM (190 gm AS) was 10-fold more active (half max. activity = 10 µg/ml using 0.3 ml to coat 16 mm wells) than the Ddia CM and the percentage of cells responding increased to 50%. In comparison, laminin, an extracellular matrix glycoprotein purified from mouse EHS sarcoma, had a half-maximal activity of 2 µg/ml in the assay. The effects of denervation on neurite-promoting activity was examined by comparing the activity of Ddia CM with medium conditioned by muscle placed into culture without prior in vivo denervation (Ndia CM). Dose-response curves of 190 gm AS fractions from 24-hour cultures of Ndia CM and Ddia CM indicated that 3-day prior denervation increased neurite-promoting activity 2-fold.

The active component of the Ddia CM may be laminin or a laminin-related polypeptide. The activity of the Ddia CM was removed by precipitation with antisera to laminin. Laminin antisera blocked the neurite-promoting activity of laminin but not that of the Ddia CM material. On Western blots of Ddia CM proteins electrophoresed on reduced, SDS-polyacrylamide gels, laminin antisera reacted with a doublet of approx. 210 kilodaltons and a faint band at 400 kd, corresponding to the molecular weights of the subunits of laminin. These results suggest three non-exclusive possibilities: 1) the neurite-promoting functionality of the muscle-derived material is in some way masked such that it is inaccessable to antibody, 2) the laminin-related polypeptide acts as a carrier for the neurite-promoting activity, or 3) the Ddia CM polypeptide is antigenically related to laminin but contains regions which differ from laminin in function and primary structure. Currently, work is being done to map both the laminin-related polypeptide from muscle and authentic laminin using proteolytic enzymes.

57.4 PATTERN AND GROWTH RATES OF NEURITES IN PERIPHERAL NEURONAL CULTURES ARE MOST PRONOUNCED ON EXTRACELLULAR MATRIX PREPARATIONS OBTAINED FROM SCHWANN CELL-NEURON CULTURES. Carson J. Cornbrooks Dept. of Anatomy & Neurobiology, University of Vermont Burlington, Vermont 05405

Neuronal regeneration within the peripheral nervous system (PNS) is promoted when the proximal and distal portions of the injured nerve are in close apposition. This indicates that the cellular components distal to the site of injury are required for the promotion and continuation of the initial sprouting response. To date, the cellular source and the molecular nature of neurite promoting factors remain unclear although adequate evidence suggests that extracellular matrix (ECM) components, Schwann cell membrane molecules and molecules secreted by nonneuronal cells may facilitate PNS neuronal regeneration.

In order to characterize neurite promoting factors in peripheral nerve tissue, pure populations of neurons from embryonic superior cervical ganglia (SCG) and dorsal root ganglia (DRG) were prepared in culture. Neurons from embryonic day (E) 21 SCG and E15 and E18 DRG were grown in vitro, subjected to axotomy and transplanted to a second dish with modified substrata. Substrates consisted of untreated collagen (control), detergent extracted collagen, pure populations of Schwann cells, and ECM prepared by detergent extraction of mature Schwann cell-neuron cultures. Growth rates of the transplanted neurons were constant for at least 5 days after the axotomy and varied with respect to age and neuron type (E21 SCG > E15 DRG > E18 DRG). Neurite growth on untreated collagen (E21 SCG 13um/hr; E15 DRG 10um/hr; E18 DRG 5um/hr) was approximately equal to the growth rates on detergent treated collagen. Surprisingly, neurons transplanted onto Schwann cells extended highly fasciculated neurites at the same approximate rate as neurons grown on collagen (E15 DRG 9um/hr;E18 DRG 4um/hr). In contrast neurons placed on preparations of ECM maintained growth rates which were consistently 2 to 3 fold higher than those calculated with collagen substrata (E21 SCG 34um/hr;E15 DRG 21um/hr;E18 DRG 14um/hr). Neurites regenerating on ECM substrata grew without fasciculation and faithfully oriented within the matrix channels. Neurons grown on Schwann cell cultures for 1 week increased their growth rates at least 3 fold when transferred to ECM cultures, but neurite growth decreased to control rates when the paradigm was reversed.

These observations indicate that components of the ECM produced in mature Schwann cell-neuron cultures contain neurite promoting factors which facilitate regeneration of PNS neurons.

57.5 COMPARISON OF LAMININ AND NEURONECTIN (A CONDITIONED MEDIUM-DERIVED NEURITE EXTENSION FACTOR) USING RADIATION INACTIVATION ANALYSIS. M.D. Coughlin, A.K. Grover* and C.Y. Jung*+. Department of Neurosciences, McMaster University, Hamilton, Ontario, L8N 3Z5, Canada, and +Biophysics Lab., Veterans Administration Medical Center, SUNY, Buffalo, New York, 14215.

Neurite outgrowth from a wide variety of peripheral neurons is stimulated and may be directed in culture by a substrate-binding factor derived from medium conditioned over numerous types of cells. We shall refer to this factor as neuronectin by reason of its ability to serve as an adhesion molecule for neurons. The extracellular matrix molecule laminin (M_r-900 kDa) possesses a similar capacity for eliciting neurite extension (Baron van Evercooren et al., J. Neurosci. Res. 8: 179, 1982), and some studies suggest that laminin and neuronectin may be identical (Lander et al., Soc. Neurosci., 10: 40, 1984).

To obtain an estimate of the molecular weight of neuronectin and to compare it with laminin, both laminin and the partially purified neuronectin were subjected to target size analysis using radiation inactiviation. This method makes use of the finding that biologically active proteins exposed to high energy radiation are rendered inactive by direct "hits" occurring within the volume of the molecule possessing activity. The degree of inactivation at any radiation dose is proportional to the size of the target (i.e., its M_r), regardless of the state of purification or non-covalent association.

Partially purified neuronectin was frozen in thin layers in aluminum trays, as similarly laminin and enzyme standards, and exposed to a graded series of radiation dosages from 0.2 to 8 Mrads. The activity remaining in each sample of neuronectin or laminin was determined by the standard dissociated cell bioassay using dose-response curves of dilutions either preincubated in culture dishes or added directly to the culture medium.

Comparison of the activity decay slope of neuronectin with those of enzyme standards indicates that the M_r of neuronectin is 352 ± 21 kDa. By the same method, the size of laminin as assayed by its neurite-promoting properties has been confirmed to be ~900 kDa. Moreover, unlike neuronectin, laminin gives rise to toxic or inhibitory products when exposed to high energy radiation. These results indicate clear differences between laminin and neuronectin and suggest that the neurite-promoting activity from conditioned medium is distinct from laminin. The existence of multiple neurite-promoting factors suggests a mechanism for the formation of specific axonal pathways during embryogenesis.

57.6 INDUCTION OF PROCESS OUTGROWTH BY A 2-ACETYLPYRIDINE THIOSEMICARBAZONE IN INSECT AND RAT CLONAL CELL LINES. G.M. Carrow and R.G. Van Buskirk*. Marine Biological Laboratory, Woods Hole, MA 02543 and Dana-Farber Cancer Institute, Boston, MA 02115.

Cells of the embryonic line Kc of Drosophila melanogaster respond to the insect molting hormone, 20-OH-ecdysone, by ceasing proliferation and elaborating processes (Cherbas et al., 1977, Science 197:275). Similarly, cells of the rat pheochromocytoma line PC12 elaborate processes in response to nerve growth factor (NGF) and Bt_2cAMP (Greene and Tischler, 1976, PNAS 73:2424). Induction of process outgrowth in both neuron-like cell lines is highly specific. We have now found that a 2-acetylpyridine thiosemicarbazone, one of a class of antineoplastic agents, blocks proliferation and induces process outgrowth in Kc and PC12 cells.

The [1-(2-pyridinyl)ethylidene]hydrazide of 1-pyrrolidinecarbothioic acid was dissolved in dimethyl sulfoxide and added to cultures of Kc or PC12 cells; the cells were incubated for several days and scored for the fraction of cells showing processes. The thiosemicarbazone at 10^{-6} M to 10^{-5} M blocked Kc cell proliferation and induced process elaboration equivalent to about 75% of the response to 10^{-6} M 20-OH-ecdysone. Notably, cells of a mutant subclone of the Kc line that was selected for lack of a morphological response to 20-OH-ecdysone did elaborate processes in response to the thiosemicarbazone. Finally, the compound did not induce process outgrowth in cells of an unrelated embryonic cell line, Schneider's 2, that do not extend processes when treated with 20-OH-ecdysone. The 2-pyridyl moiety was found to be essential for the process promoting activity of the thiosemicarbazone.

PC12 cells exposed to 10^{-6} M to 10^{-5} M of the thiosemicarbazone elaborated processes if they adhered to the culture dish. The response was similar to that evoked by 1 mM Bt_2cAMP. Remarkably, cells of a mutant subclone of PC12 that do not elaborate processes in response to either NGF or Bt_2cAMP did grow processes in response to the thiosemicarbazone.

These data suggest that the 2-acetylpyridine thiosemicarbazone initiates differentiation of neuron-like cells derived from diverse species. Its mode of action may be downstream or distinct from that of the factors that have been previously shown to regulate process outgrowth in these cell lines.

We thank K. Wing for discussions and providing the thiosemicarbazones and P. Cherbas for providing the Drosophila cell lines. Supported by a Grass Foundation Fellowship to G.M.C., NIH Fellowship AM0722 to R.G.V.B., and NSF grant PCM-8215638.

57.7 CONTACT MEDIATED AVOIDANCE BETWEEN SPECIFIC PAIRS OF GROWTH CONES AND NEURITES IN CULTURE. J.A. Raper, J.P. Kapfhammer*, and E.B. Grunewald*. Max-Planck-Institut für Entwicklungsbiologie, D-7400 Tübingen, West Germany.

Experiments in invertebrates suggest that growth cones distinguish between and crawl upon reproducible sequences of particular axons, implying that axons possess specific labels on their surfaces. Bray, Wood, and Bunge (Exp.Cell.Res.130:241,1980) describe a tissue culture system in which embryonic rat SCG neurites grown on collagen will not mix with retinal neurites, while SCG neurites mix with SCG neurites, and retinal neurites mix with retinal neurites. We have replicated their results using embryonic chick sympathetic and retinal tissues grown on laminin. We have also made a time lapse study of the behavior of growth cones as they approach and touch like and unlike neurites.

Retinal tissue was taken from 6 day embryos, sympathetic and dorsal root (DRG) ganglia from the lumbar region of 8 day embryos. Non-neuronal cells spread poorly on laminin, and were suppressed by the addition of anti-mitotics to the culture medium. Consequently, we were able to observe neuron-neuron interactions without their interference.

After 5-7 days in culture, the neurites from adjacent sympathetic and retinal explants form two nearly exclusive interdigitating territories, separated by a mostly axon free zone. In contrast we see no signs of exclusive territoriality when the following pairs are explanted together: retina-retina, sympathetic-sympathetic, DRG-DRG, or DRG-sympathetic. Ambiguous results are obtained when DRGs confront retinae.

Time lapse examination of these cultures 1-2 days after explantation show that, upon contact, sympathetic growth cones retract from retinal axons (23 retractions/24 encounters), but less often from sympathetic axons (8/29). Retinal growth cones retract from sympathetic axons (30/38), but not from retinal axons (1/44). The probabilities that retinal or sympathetic growth cones are incapable of distinguishing between retinal and sympathetic neurites are less than .001 . Similar data collected for DRG-sympathetic confrontations yielded no evidence that either DRG or sympathetic growth cones distinguish between DRG or sympathetic neurites in this assay.

These results demonstrate that the growth cones of vertebrate neurons can distinguish between particular neurites in a cell specific manner. Since contact appears to be required, tissue specific cell surface labels may be involved. Finally, our results highlight the role active avoidance might play in growth cone navigation.

57.8 USE OF VEC-DIC MICROSCOPY AND HVEM-IMMUNOLOCALIZATION TO STUDY ADHESIVE INTERACTIONS BETWEEN NEURONAL FILOPODIA H-C. T. Tsui, and W.L. Klein. Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201

Observation of cultured chick retina neurons with VEC-DIC microscopy showed that the motile filopodia of growth cones were extremely adhesive. Motile filopodia that contacted each other often became attached at their tips, remaining attached despite drastic movements of the filopodia. Attached filopodia were seen to push or pull on each other, move laterally together, or stretch tightly and undergo small vibratory movements. Attached filopodia separated slightly at times, but within seconds re-attachment occurred at the original position. If one filopodium moved away, another from the same cell often became attached to the same region of the stable filopodium. These observations are consistent with the hypothesis that adhesive molecules are specifically localized within filopodial membranes. We therefore studied the distribution of adheron molecules (J. Cell Biol. 96:990-999) on neuron surfaces using immunogold labeling of whole mounts of cultured neurons. Treated cells were then critical-point-dried and examined with the high voltage electron microscope (HVEM). Antibodies were located primarily on membranes at the edges of neurites, growth cones, and filopodia, regions where the cells were attached to the substratum. In addition, particularly high concentrations of antibodies were present at areas where filopodia contacted each other. The HVEM immuno-labeling data are consistent with the possibility that adherons were responsible for the localized adhesive interactions of filopodia observed with VEC-DIC microscopy.

57.9 GROWTH CONE FORM CHANGES WITH AGE AND POSITION ALONG THE EMBRYONIC MOUSE RETINAL AXON PATHWAY. P. Bovolenta and C.A. Mason. Department of Pharmacology, New York University School of Medicine, New York, NY 10016.

In vivo studies of the mammalian CNS have never asked whether growth cone form varies with growth cone behavior, or with features of the environment. It is also not known how these two factors in turn relate to differential adhesion to the surfaces on which axons grow. To address these questions, we have been studying the morphological changes which growth cones undergo along the mouse retinal axon pathway. This system offers the advantage of a relatively homogenous population of axons which pass through microenvironments with different cellular organizations (optic nerve or neuroepithelium, chiasm, tract and target tissue). Retinal axon growth cones were visualized along the entire pathway by inserting HRP-coated micropipettes into mouse retina at embryonic day (E)11 to E15 and into the chiasm at E14-E19; injections were made in whole embryos or fresh isolated brains kept *in vitro* for several hours. Vibratome sections were reacted with DAB both for light and electron microscopy. Between E11 and E15, growth cones in the optic nerve consist of flattened irregular expansions up to 50 μm long, often having wing-like extensions but rarely bearing filopodia. In general the growth cones that are found further along the optic nerve are larger and more expanded than the followers. Moreover, in older embryos growth cones along the nerve are simpler and more fusiform. Between E13-E16 growth cones reach the chiasm, where they are shorter (20 μm), more broad and three-dimensionally complex; most of them bear filopodia. As in the nerve, the shapes vary somewhat and simpler forms are more common in older embryos. Finally, growth cones enter the optic tract between E14-E19, where they are much smaller and more sleek. They do not have expansions or filopodia, but give off small spines along their length. When near their first target (lateral geniculate nucleus), the main axon extends branches that end in growth cones with filopodia and shapes similar to the ones in the chiasm.

These results suggest that simple growth cone forms are prominent when axons follow a well defined pathway, and that more elaborated forms appear at "choice points". Since growth cones are actively involved in the guidance of the axons, it is conceivable that the complexity of growth cones correlates with a more active role in recognition. EM analysis is in progress to determine the interactions between various growth cone forms and axonal and glial processes in their microenvironments.

57.10 Ca^{2+} MEASUREMENTS USING THE FLUORESCENT INDICATORS QUIN 2 AND FURA 2 COMBINED WITH DIGITAL IMAGING IN MAMMALLIAN CNS CELLS. John A. Connor, Dept. Mol. Biophys., AT&T Bell Laboratories, Murray Hill, NJ 07974.

Cells in two types of culture were examined, trypsin dispersed cells from embryonic rat diencephalon (E17,18), and cerebellar explants (P3,8). In the explants, granule cells were the predominant type studied. Cells were loaded with indicator by bathing them (30 min., T=36°C) in defined media containing either 60 μM quin 2 or 8 μM fura 2. After loading and a 2 hr. post-load incubation, cells growing on #1 thickness coverslips were mounted on the stage of an inverted microscope and viewed through a 40X objective (1.3 N.A., glycerine). U.V. illumination was provided by a 100 w, short-arc Hg lamp. A charge coupled device (CCD) photometer was mounted at the 35 mm camera port of the microscope in the image focal plane. The CCD had 320 x 512 pixels, though generally, pixel binning was employed to reduce thermal noise variance (operating temperature -40 °C). Experimental procedure was to obtain sequential images (340 and 360 nm excitation for quin, 340 and 380 nm for fura) and then to form the ratio of the two images. The value of this ratio gives a measure of spatially resolved Ca^{2+} concentration independent of indicator concentration and cell geometry to a first approximation. Exposure times of .15 to .25 s were employed for each image and a temporal separation of about 1 sec was required to change the excitation filter. In dispersed cultures 5 to 15 cells could be included in a given field, while for small, densely packed granule cells from explants, the number was often greater than 20.

In the dispersed cultures there were large differences in the ratio images of the various cells in a given field (>100%), while there was uniformity to within a few percent in granule cell populations. Exposure to high K saline (25 mM) produced measurable increases in Ca^{2+} within 30 sec to 1 min. Only a fraction of the cells in diencephalon cultures responded to high K. Addition of TTX (.3 μM) to high K saline caused a rapid decrease in Ca^{2+} indicating that the increase was due in some cases to enhanced action potential firing. Nitrendipine and nifedipine (10 μM) caused a decrease in Ca^{2+} in subpopulations of the diencephalon cells, but the cell types affected have not been worked out at this time. Cells new in culture (growing) showed higher levels of Ca^{2+} than cells of more mature cultures. Examples of growth cones with extended filapodia have been observed. In these cases, Ca^{2+} in the cone was generally higher than in the soma. Where filapodia were not evident the ratio image was nearly uniform throughout the cell.

57.11 PRESENCE OF REGENERATING PROCESSES IS ASSOCIATED WITH PROLONGED BURSTING OF CALCIUM-ACTIVATED NONSELECTIVE CATION CHANNELS. Stuart A. Lipton. Dept. of Neurology, Children's Hospital and Harvard Medical School, Boston, MA 02115.

Calcium-activated channels that are permeable to multiple cations were first described in heart muscle and neuroblastoma. In the present study, conductances with similar permeation selectivity have been found in cultured neurons from the mammalian CNS, and the degree of channel activity was different in cells regenerating processes from those without processes.

Patch-electrodes were sealed to the soma of 65 rat retinal ganglion cells that had been cultured and identified as described previously (Leifer, Lipton, Barnstable, and Masland, Science 1984;224:303-6). In culture, ganglion cells were found as solitary cells or within small clusters of other retinal cells, and many of the solitary ganglion cells regenerated long processes within 1 to 3 days (ibid). Each cell-attached patch exhibited bursts of inward currents at rest (about -60 mV). Judged from continuous records lasting 5-30 minutes, solitary ganglion cells with processes displayed longer bursts of channel openings than cells without processes. In patches with comparable numbers of channels the mean burst duration was 1.3 sec (± S.D. 0.6 sec, n= 25 patches) for cells lacking processes vs 1.2 min (± S.D. 0.45 min, n=12) for cells with one or more processes. Because of the long duration of the bursts in cells with processes, the mean interburst interval could not be accurately determined in these recording sessions. For cells both with and without processes at least 4 conductance levels were encountered (30, 85, 165, and 300 pS at rest, 36°C). Inward channels of similar amplitudes were observed in the same patch of membrane after excision from the cell to the inside-out configuration. The conductance levels were little affected by varying monovalent cations, including Na, K and Cs, or by substituting the relatively impermeant anion MES for Cl. These findings support the notion that the current is carried by cations rather than by anions. For inside-out patches the current-voltage relation of the smallest conductance exhibited some degree of inward rectification. In these patches, channel activation was only slightly affected by varying the membrane potential from -60 to +60 mV. However, raising Ca^{2+} on the internal side of the membrane patch from 10 nM to 18 micromolar increased the activity of the conductances. Thus, the bursting activity of these channels may reflect variations in the level of an internal messenger such as Ca^{2+}, especially in cells that are regenerating processes, but rapid measurement of intracellular Ca^{2+} will be necessary to test this hypothesis.

57.12 **GENERATION OF ACTION POTENTIALS SUPPRESSES NEURITE ELONGATION IN ISOLATED IDENTIFIED NEURONS.** C.S. Cohan and S.B. Kater. Department of Biology, University of Iowa, Iowa City, Ia 52242.

The dynamic actions of the neuronal growth cone are well documented but little understood. Growth cones are thought to be intimately involved in the process of neurite outgrowth and may play an important role in determining final neuronal morphology. Elucidation of the cellular events which regulate growth cone properties may provide a better understanding of the organizing principles underlying architecture and connectivity in the nervous system.

We recently suggested (J. Neurosci. Res. 13:285 1985) that voltage sensitive ion channels may influence growth cone motility. The growth cone membrane of isolated *Helisoma* neurons possesses a 70 pS ion channel. In excised patches in isotonic saline this channel mediates an inward current at negative membrane potentials, which is not blocked by TTX (100 μM) and shows little inactivation during maintained depolarizations. Our ability to distinguish morphologically between growth cones that are actively elongating and those that have ceased elongating has enabled us to demonstrate further that the activity of this ion channel is correlated with growth state. Growing growth cones contain active ion channels whereas nongrowing growth cones contain masked channels which are in a nonactivatible state. This physiological difference suggests that ion channel activity may play a role in growth cone movement and neurite elongation.

In the present series of experiments we show that the generation of action potentials suppresses neurite elongation. Gigohm seals were obtained with patch pipettes on the somata of isolated *Helisoma* neurons 5 and 19 which were in an active state of outgrowth. After setting a holding potential of -50 mv, the membrane patch was ruptured to gain access to the intracellular compartment as in whole cell clamps. Photographs were taken at 15 minute intervals to monitor neurite outgrowth. Neurite elongation was analyzed after the experiment by measuring the advance of each growth cone from the photographed neuron at each 15 min. time point. During periods in which the patch pipette was at the holding potential, neurite elongation proceeded at a constant rate (15.5 μm/h, n=14). Similarly, during hyperpolarizing pulses, neurite elongation was unchanged. However, when depolarizing pulses which produced overshooting action potentials were used, neurite elongation stopped. This occurred within 15 min. of the onset of the stimulus pulses and was accompanied by a change in growth cone morphology. Growth cones which had ceased elongating showed some additional outgrowth over the following 12 h. (nonstimulated) after the patch pipette was removed. These experiments demonstrate that the generation of action potentials within an actively outgrowing neuron can inhibit neurite elongation. Furthermore, they suggest that electrical activity may be one mechanism for regulating neuronal morphology as neurons grow, interconnect, and form spontaneously active circuitry.

FEEDING AND DRINKING III

58.1 SALT APPETITE EVOKED BY SODIUM DEPLETION IS ABOLISHED BY CONCURRENT INTERFERENCE WITH ENDOGENOUS ANGIOTENSIN II AND ALDOSTERONE R.R. Sakai*, A.N. Epstein & S. Nicolaidis*, University of Pennsylvania, and Collège de France.

During sodium deficiency, angiotensin II (ANG II) and aldosterone (ALDO) are produced and cause renal sodium conservation. Epstein (Peptides, 3, 493, 1982) has suggested that the behavioral counterpart to sodium conservation, sodium appetite, is aroused by the same two hormones in the sodium deplete rat. Moe et al (AJP. 247, R356, 1984) have demonstrated that blockade of endogenous ANG II formation with captopril, an angiotensin converting enzyme antagonist, suppresses but does not abolish sodium appetite induced by sodium depletion

The role of ALDO in the expression of sodium appetite was studied by giving RU 28318 (Roussel-UCLAF), an anti-mineralocorticoid, either systemically or directly into the brain ventricles of rats that were sodium depleted by combining a natriuretic drug, furosemide (10 mg/rat, SC), with removal of ambient sodium (home cage washed, removal of 3% NaCl, and food replaced with a sodium deficeint diet). At least 18 hours after the beginning of the depletion 3% NaCl was returned for 2 hours and the rats expressed a sodium appetite.

Peripheral ALDO receptors were blocked in sodium deficient rats (N=6) by giving RU 28318 in their drinking water (1 mg/ml, PO) and by SC injection (5 mg/kg, BW) 15 minutes before furosemide and at 2 hours and at 30 minutes before 3% NaCl access the following day. There was no suppression of the volume of 3% NaCl drunk during the 2 hour access period (veh 6.8 ± 0.6 ml, RU 7.5 ± 0.5 ml).

Central ALDO receptors were blocked in other rats (N=5/group) receiving RU 28318 (0.5, 5 and 25 μg/hr) by continuous intracerebroventricular (cICV) infusion during the depletion through an indwelling cannula. Their sodium appetite was suppressed in a dose related fashion by RU 28318 (veh 8.2 ± 0.6 ml, 0.5 μg/hr 5.6 ± 0.8 ml, 5 μg/hr 4.2 ± 0.9 ml, 25 μg/hr 2.2 ± 0.7 ml).

In a final group, rats (N=6) were treated with both cICV RU 28318 (25 μg/hr) and captopril (CAP) (SC, 50 mg/kg/BW, and PO, 0.1 mg/ml), during the depletion. By interfering with the actions of both ANG II and ALDO, sodium appetite was abolished. In all experiments, the drug treatments did not reduce water intake and did not affect sodium excretion during the depletion (veh 1.6 ± 0.09 mEq, RU + CAP 1.67 ± 0.24 mEq). These data are strong support for the idea that ANG II and ALDO are essential for both the arousal and expression of sodium appetite.

Supported by NS 03469-24 and T32 MH 17168-01

58.2 THE ENDOCRINE CONSEQUENCES OF SODIUM DEFICIENCY PREPARE THE BRAIN FOR SALT APPETITE A.N. Epstein, R.R. Sakai*, and W. Fine*, (SPON. J. Sprague). University of Pennsylvania.

A salt appetite is aroused in the sodium replete rat by endogenous aldosterone (ALDO) and angiotensin II (ANG II) acting in synergy (Neurosci. Abstracts, 10, 1984, 1010) and the appetite of the sodium deplete rat can be abolished by preventing the actions of endogenous ALDO and ANG II (Neurosci. Abstracts, 11, 1985).

We now report 1) that a single sodium depletion enhances the salt appetite that is expressed after a second and subsequent sodium depletions, 2) that this enhancement does not depend on the drinking of salt after the first depletion, and 3) that it can be produced by the actions of ALDO and ANG II on the brain in the absence of sodium depletion.

1) Rats (N=5) living in their home cages with water, 3% NaCl, and Purina pellets freely available were depleted of sodium by combining pharmacological natriuresis (furosemide, 10 mg/rat, SC) with removal of sodium (Na deficient diet, removal of the 3% NaCl, and thoroughly washed cage). Eighteen to 20 hours later they expressed a reliable salt appetite (latency of 10 seconds and 6.8 ± 0.5 ml volume drunk) when the 3% NaCl was returned for 2 hours of access. When depleted a 2nd time 1 week later, they drank more rapidly (0 latency) and nearly twice as much (10.5 ± 1.3 ml). Total sodium loss was the same after the 1st and 2nd depletions. There was no further enhancement. Latencies and volumes drunk after a 3rd and 4th depletion were the same as after the 2nd.

2) Other rats (N=17) were depleted overnight but were not permitted to drink 3% NaCl the next morning. Their appetite after a 2nd depletion was enhanced and was indistinguishable from that of rats that drank after both their 1st and 2nd depletions. The same result was obtained whether or not the animals were repleted of sodium (by SC injection) after the first depletion.

3) A third group of rats (N=11) were treated while sodium replete with systemic ALDO (40 μg/day) for 5 days and with a pulse intracerebroventricular injection of ANG II on day 5 which, as we have shown (Neurosci. Abstracts, 10, 1984, 1010), arouses a robust sodium appetite. But these animals were not offered salt. One week later they were depleted and allowed to drink salt. Their appetite was indistinguishable in latency and volume drunk from the enhanced appetite of animals that were depleted twice and were expressing an appetite for the 2nd time.

When the levels of hormones of sodium deficiency, angiotensin II and aldosterone, are raised by a rat's first sodium depletion they not only cause a salt appetite, but they also leave a long-lasting trace in the animal's brain that prepares it for more rapid and more vigorous expression of the appetite in response to future depletions. Supported by NS 03469-24 and T32 MH 17168-01.

58.3 HEPATIC-PORTAL NaCl INFUSION ATTENUATES SALT APPETITE. M.G. Tordoff, J. Schulkin* and M.I. Friedman*. Monell Chemical Senses Ctr., and Dept. Anatomy, Univ. PA, Philadelphia, PA 19104.

We investigated the possibility that sodium-sensitive elements in the liver or hepatic-portal vein can mediate the satiation of salt appetite in sodium-depleted rats. All experiments used male Sprague-Dawley rats (300-350 g) given hepatic-portal or jugular catheters. NaCl consumption was measured in 30-min two-bottle tests (0.5 NaCl vs. water). A sodium deficit was induced by providing a low-sodium diet 48 hr before, and injecting furosemide (5 mg, sc) 24 hr before tests were conducted. Infusions were of 1 ml volume given over 30 min, starting 15 min before access to the two bottles. Infusions were given in counterbalanced order with at least 6 days between tests. Nine rats with hepatic-portal catheters received 0, 0.15, 0.6 and 1.2 M NaCl. All three doses of NaCl significantly suppressed NaCl intake relative to the 0 condition (mean ± SEM [ml/30 min] 0 = 7.1 ± 0.71, 0.15 M = 5.5 ± 0.69, 0.6 M = 5.7 ± 0.49, 1.2 M = 4.4 ± 0.83). Note that the suppression of NaCl intake was probably not due to an osmotic effect of the infusate because 0.15 M (isotonic) NaCl significantly suppressed NaCl intake. Water intakes during the same period were not significantly altered, although there was a trend for the 0.6 and 1.2 M infusions to increase water consumption (0 = 1.3 ± 0.48, 0.15 M = 0.6 ± 0.22, 0.6 M = 2.7 ± 0.73, 1.2 M = 3.4 ± 1.35). On the other hand, 10 rats given jugular infusions of 1.2 M NaCl did not decrease NaCl intake (0 = 6.0 ± 1.10, 1.2 M = 5.2 ± 1.05) but did significantly increase water intake relative to the 0 condition (0 = 1.9 ± 0.41, 1.2 M = 5.0 ± 0.83).

The reduction of salt appetite produced by hepatic-portal NaCl infusion is apparently mediated by the vagus nerve: NaCl solution consumption was measured in seven rats before and after selective hepatic vagotomy. Before vagotomy, hepatic-portal infusion of 1.2 M NaCl significantly reduced NaCl intake relative to intake in response to distilled water infusion. However, after vagotomy the suppressive effect of 1.2 M NaCl was abolished.

Thus, the results support the existence of a vagally mediated porto-hepatic mechanism that can modulate NaCl appetite. This may be a function of brainstem components of the visceral-taste pathway, which have been shown by electrophysiological and anatomical methods to integrate afferent information from the liver and oral cavity.

58.4 THE "VASCULAR HYPOTHESIS" FOR INITIATION OF THIRST AT THE SUBFORNICAL ORGAN. R.G. Blasberg*, P.M. Gross and J.D. Fenstermacher, Department of Neurological Surgery, SUNY at Stony Brook, NY 11794 and Department of Nuclear Medicine, NIH, Bethesda, MD 20205.

The subfornical organ (SFO) is a midline tubercle in the third ventricle having a dense, highly permeable capillary bed that makes this structure a primary target for circulating hormones. One hypothesis (1) for stimulation of thirst and hormonal responses during dehydration is that vasoactive hormones, such as angiotensin II and vasopressin (whose plasma concentrations are elevated during dehydration), cause contraction of the blood volume and reduced blood flow to circumventricular organs, including the SFO; such vascular effects then lead to behavioral, cardiovascular and endocrine responses to restore fluid balance ("vascular hypothesis" for thirst). We comprehensively evaluated this hypothesis in the SFOs of conscious rats that were normally hydrated or severely dehydrated (5 days of water deprivation). Using quantitative autoradiographic methods and computerized image processing, we determined in the SFO local blood flow (14C-iodoantipyrine), microvascular plasma volume (125I-albumin), microvascular erythrocyte volume (51Cr-erythrocytes), and tissue glucose utilization (14C-deoxyglucose) (Reference 2).

	Control	Dehydration
Blood flow (ul/g/min)	1010±160(5)	1520±190(6)
Plasma volume (ul/g)	42± 10(5)	44± 7(6)
Erythrocyte volume (ul/g)	12± 1(5)	8± 1(4)
Glucose utilization (umoles/g/min)	0.47±.05(8)	0.81±.04*(8)

Means ± SE; Number of animals in parenthesis; *p<0.05.

The results do not support the "vascular hypothesis" for initiation of thirst through microvascular adjustments in the SFO. Capillary blood flow and total vascular volume (plasma + erythrocyte volumes) in the SFO were not altered by severe dehydration. Glucose utilization, however, was substantially increased, both by the conditions of chronic dehydration and by direct intravenous administration of angiotensin II (3). The findings suggest that the vasodilatatory effects of increased metabolism, both from angiotensin II itself and from metabolic products such as H+, effectively oppose the actions of any circulating substances that may cause vasoconstriction. There appears to be no significant net effect of these antagonistic stimuli on the SFO microcirculation.

58.5 MONOSODIUM L-GLUTAMATE LESIONS: EFFECTS ON NOREPINEPHRINE STIMULATED FEEDING AND INSULIN SECRETION IN THE RAT. J. Steves Sims and J. F. Lorden, Dept. Psych., Univ. of Alabama at Birmingham, Birmingham, AL 35294.

Neonatal treatment with monosodium L-glutamate (MSG) produces lesions of the medial basal hypothalamus in rodents. Relatively little is known about the cause of the resulting obesity syndrome. MSG obesity is distinguished from other hypothalamic obesities by the absence of hyperphagia but may be associated with altered carbohydrate metabolism. Therefore, we examined the feeding response of MSG-treated rats to norepinephrine (NE) stimulation and studied the dependence of the MSG obesity on vagal function.

Litters of 8-10 rats were injected on postnatal days 2 and 4 with 4 mg/g of MSG or isotonic saline. In adulthood, 10 saline and 10 MSG-treated rats were implanted with bilateral cannulae aimed at the paraventricular nucleus of the hypothalamus (PVN). After recovery, the rats were given sweetened condensed milk for 1 h each day. Intake was measured and a fresh supply given for a second hour. After 10 days training, rats received bilateral injections of either saline (.5 ul) or NE (20 nM) through the PVN cannulae immediately prior to the second hour. For rats treated neonatally with saline, milk intake was 18.4 ml ± 4.0 (M ± SD) during the first hour. Following a saline injection, milk intake was 4.4 ml ± 2.2 and following NE, 10.6 ± 2.7. In the MSG group, rats drank 13.7 ± 3.1 ml prior to the injections. Consumption following saline injections was 3.2 ml ± 1.3 and following NE, 4.2 ± .9. Thus, the MSG-treated rats consumed less milk overall and showed a significant attenuation of NE-induced feeding. It is possible that the reduced responsiveness of the MSG rats to stimulating effects of NE contributes to their hypophagia.

In the second study, adult female MSG and saline treated rats from the same litters used in the first study were given either complete subdiaphragmatic vagotomies (Vx) or sham surgery (SVx). Animals were monitored for 180 days. At that time, all rats were fasted overnight, anesthetized and implanted with venous catheters. A fasting blood sample was drawn, .3 cc of 2 M glucose injected and additional blood samples drawn 5, 10 and 15 min later. Blood glucose levels were similar in all groups. SVx MSG-treated rats were obese and showed a significant fasting hyperinsulinemia in comparison with SVx Saline-treated rats. Vagotomy produced a complete reversal of both the obesity and hyperinsulinemia of the MSG group, suggesting that MSG obesity depends on vagal function. (Supported by NINCDS grant 14755.)

58.6 CHOLINERGIC AFFERENTS TO THE SUBFORNICAL ORGAN IN RATS. David A. Wheeler and John B. Simpson. Department of Psychology, University of Washington, Seattle, WA 98195.

Acetylcholine is involved in the central regulation of body fluid balance. Intraventricular injection of cholinergic agonists stimulates water ingestion, raises blood pressure, increases vasopressin secretion, induces natriuresis, and suppresses sodium appetite. Some of these effects may be mediated by the subfornical organ (SFO)— an area of the brain involved in angiotensin II body fluid regulation. Direct application of cholinergic agonists into the SFO in quantities smaller than are required by intraventricular injection produce water ingestion, elevated blood pressure, and increased vasopressin secretion.

There is also anatomical evidence which suggests that the SFO receives cholinergic afferents. Acetylcholine, the synthetic enzyme, choline acetyltransferase (ChAT), and the degradation enzyme, acetylcholinesterase (AChE) have been found there. Electron microscopy reveals vessicles in nerve terminals which appear to contain acetylcholine. Lewis and Shute (Brain, 90:521, 1967) suggested that the SFO receives cholinesterase containing axons originating from the area of the dorsal fornix but the specific neurons were not identified. The study presented here uses modern neuroanatomical tract tracing techniques to identify the nuclei which send afferents to the SFO.

The retrogradely transported molecules wheat germ aggultinin, cholera toxin subunit-B, or succinylated concanavalin-A were injected directly into the SFO in rats through stereotaxically implanted cannulas and they were visualized using the Vectastain ABC immunohistochemical method. Initially, possible cholinergic neurons were identified using AChE histochemistry in diisopropylflourophosphate treated rats. Once possible cholinergic afferents were identified, adjacent sections were stained using a monoclonal antibody against ChAT (Immunonuclear). Neurons which contained both the retrogradely transported tracers and choline acetyltransferase were considered to be likely cholinergic afferents to the SFO.

To confirm that these nuclei projected to the SFO and not to adjacent tissue, they were injected with the anterogradely transported phaseolus vulgaris leucoagglutinin (PHA-L). Nuclei were considered to be the source of cholinergic afferents to the SFO only when the PHA-L provided confirmation of the projection to the SFO.

Preliminary results suggest that the medial septum is the source of cholinergic afferents to the SFO.

58.7 HISTAMINERGIC AND VAGAL CONTROL OF GASTRIC ACID SECRETION BUT NOT DRINKING IN ANTICIPATION OF EATING IN THE RAT. F.S. Kraly, S.M. Specht*, L.A. Coogan*, J.E. McOsker* and S. Geasey*. Dept. of Psychology, Colgate Univ., Hamilton, NY 13346.

Male Sprague-Dawley rats (n = 10), surgically equipped with stainless-steel gastric cannulas, were tested in a paradigm similar to that used by Weingarten and Powley (Physiol. Behav., 27: 217, 1981) to achieve conditioning of cephalic phase gastric acid secretion in the rat. After 24-hr food deprivation, each rat was prepared for testing by having its fistula opened, its stomach washed with .9% NaCl, and a collecting tube attached to the cannula. On Test 1 (Baseline), no food was offered, but water intake and gastric acid secretion (through the fistula) were measured for 60 min. For Tests 2-6, rats were offered sweetened milk to sham feed with open fistula for 60 min. On Test 7 rats were not offered milk (though they should have expected it), and water intake and gastric acid secretion were again measured. Subsequent tests evaluated the ability of atropine methyl nitrate (AMN; 1 mg/kg i.p.) or combined antagonism of H_1 and H_2 receptors using dexbrompheniramine (DXB; 1 mg/kg i.p.) and cimetidine (C; 16 mg/kg i.p.) to affect water intake and acid secretion when rats expected to eat but were not offered food.

		Anticipation of eating		
	Test 1	Test 7		
	Baseline	.9% NaCl	DXB + C	AMN
Water intake (ml)	0.6 ± 0.4	6.9 ± 2.5	5.6 ± 1.4	5.7 ± 2.0
Gastric acid (μEq H^+)	61 ± 20	155 ± 38	28 ± 10	12 ± 7

(Scores are means ± SE for 60-min tests)

Rats appeared to have been successfully conditioned to anticipate eating in the experimental paradigm; gastric acid secretion ($p < .02$) and water intake ($p < .05$) on Test 7 were greater than baseline scores. Combined antagonism (DXB + C) of peripheral H_1 and H_2 receptors inhibited ($p < .01$) cephalic phase gastric acid secretion, such that it was not different ($p > .10$) from baseline, but failed to affect water intake ($p > .20$). Blockade (AMN) of peripheral cholinergic vagal efferents inhibited cephalic phase gastric acid secretion ($p < .01$), bringing it below baseline ($p < .05$), but failed to affect water intake ($p > .20$). This dissociation between drinking and acid secretion in anticipation of eating was further supported by the failure to find correlations (all $ps > .05$) between 60-min water intake and acid secretion for each experimental treatment.

These results suggest no vagal histaminergic mediation of drinking elicited by the anticipation of eating, in contrast to evidence for histaminergic control of drinking elicited by pregastric food-contingent stimulation in the rat (Behav. Neurosci., 98: 349, 1984).

58.8 FUNCTIONAL COUPLING BETWEEN TRANSIENTS IN BLOOD GLUCOSE AND FEEDING BEHAVIOR:. TEMPORAL RELATIONSHIPS. F.J. Smith* and L.A. Campfield (SPON: C. Enroth-Cugell) Depts. of Physiology and Engr. Sci., Northwestern University, Chicago and Evanston, Il. 60611 and 60201.

A premeal decline in blood glucose (BG) has been recently shown to be causally related to meal initiation in free-feeding rats (Brandon, Smith, Campfield, Soc. Neurosci. Abstr. 10, 534,1984). In order to assess the degree and time course of the functional coupling between declines in BG and meal initiation, access to food was prevented by covering the food cup prior to and throughout declines in BG, followed by restoration of access to food 5 minutes after BG returned to baseline. The latency to feeding and the next decline in BG were measured. 200 gm female Wistar rats implanted which chronic cardiac cannulas were allowed to recover for 7 days prior to experiments. Powdered chow and water were available, except when the food cup was covered. Continuous blood withdrawal (25μl/min) for BG monitoring was initiated 45 minutes after the IV administration of 200 U heparin. The food cup was then covered and the rat was returned to its home cage and remained undisturbed throughout the rest of the experiment. In five experiments across the light/dark transition, declines in BG, similar to those described previously under free- feeding conditions, were observed. Food seeking behavior (moving to food cup, sniffing, try to remove cover) occurred in each experiment with an average latency of 10 ± 1.4 minutes after the beginning of the fall in BG. (This compares with the average latency to meal initiation of 12.1 ± 1.7 minutes after the beginning of the decline in the free-feeding condition.) After the food cup was uncovered, no food seeking behavior and no feeding was observed until after another similar decline in BG occurred. Meal initiation following the second decline occurred an average of 88.5 ± 5.2 minutes after the food seeking behavior following the first decline in BG.

In preliminary studies, a novel food (orange slice, cookies) was introduced 30 minutes after the food cup was uncovered. No significant decrease in BG occurred following food presentation. The food was eaten with a very short latency but without a prior decline in BG.

Therefore, we conclude that transient declines in BG strongly signal food seeking and meal initiation but this functional coupling between BG and feeding behavior is of short duration. The transient nature of this coupling requires a second decline in BG to initiate feeding if the rat is unable to eat within a narrow temporal window. In addition, transient declines in BG appear to be an endogenous cue for food seeking and meal initiation that is not strongly influenced by sensory cues.

58.9 SELECTIVE ALTERATIONS IN OPIATE-INDUCED FEEDING FOLLOWING NALOXONAZINE PRETREATMENT. P.E. Mann, R.J. Bodnar, M.T. Romero*, L.S. Truesdell and G.W. Pasternak. Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367 and George C. Cotzias Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Ctr. and Depts. of Neurology and Pharmacology, Cornell Univ. Medical Ctr., New York, NY 10021.

Naloxonazine, a selective and irreversible antagonist of mu-1 opioid binding sites and naloxone, a short-acting antagonist which interacts with a number of opiate receptor sub-types, inhibit food intake in freely feeding and food-deprived rats. Yet, 2-deoxy-D-glucose hyperphagia is reduced by naloxone and potentiated by naloxonazine. The present study evaluated the effects of long-term (24 h) pretreatment with naloxonazine and short-term (5 min) pretreatment with naloxone upon feeding induced by the mu receptor agonist, morphine (MOR) and the kappa receptor agonists, ethylketocyclazocine (EKC) and dynorphin (DYN). First, food intake of 14 mildly-deprived (5 h) rats was assessed 4 h following MOR (5 mg/kg, SC) alone or following naloxonazine (10 mg/kg, IV) or naloxone (10 mg/kg, SC) pretreatment. MOR hyperphagia was completely blocked by naloxone, yet was significantly potentiated by naloxonazine. Second, MOR (1-10 mg/kg) hyperphagia was absent in 15 rats neonatally treated with monosodium glutamate which destroys medial-basal hypothalamic cells which contain beta-endorphin and met-enkephalin. Third, food intake of freely-feeding rats was assessed 4 h following EKC at doses of 5 mg/kg (n=19, SC) or 2 mg/kg (n=13, SC). While neither naloxone nor naloxonazine blocked EKC (5 mg/kg) hyperphagia, naloxone, but not naloxonazine blocked EKC hyperphagia at the 2.5 mg/kg dose. Fourth, food intake of 12 freely-feeding rats was assessed 1 h following DYN (10 ug, ICV). Again, naloxone, but not naloxonazine blocked DYN hyperphagia. These data indicate that both mu and kappa receptor subtypes are involved in the short-term opioid-induced increases in feeding behavior. Further, the mu-1 binding site appears to differentially modulate various forms of feeding paradigms. (Supported by NIDA Grant DA002615 and PSC/CUNY Grant 6-64187.)

58.10 (^{14}C) 2-DEOXYGLUCOSE UPTAKE IN THE NUCLEUS TRACTUS SOLITARIUS INCREASES IN RESPONSE TO GASTRIC DISTENTION. M. F. Gonzalez, F. R. Sharp and J. A. Deutsch*. V. A. Medical Center, Department of Neurology, San Francisco, CA 94121 and University of California, San Diego, Department of Psychology, La Jolla, CA 92093.

The presence of fibers in the vagus nerve that respond to gastric distention has been extensively documented. However the areas where this information projects in the brain are still not well established. The present work mapped these areas using the (^{14}C) 2-deoxyglucose (2DG) method.

Under urethane anesthesia (1.5g/kg body weight) the left cervical vagus was severed and intragastric balloons were implanted in six, food and water deprived, Sprague-Dawley rats. An injection of 2DG (167μCi/kg body weight dissolved in 0.3 ml sterile saline) was injected as a bolus into each rat's tail vein. Immediately following this injection, the intragastric balloons of three subjects were inflated with 20 ml of warm water to produce stomach distention. In the other three subjects, a nondistending volume of 2 ml was injected into their balloons. 45 min after the 2DG injection the rats were sacrificed, and their brains removed, frozen, sectioned, and autoradiographed as previously described (Sharp and Evans, J. comp. Neurol., 208:255, 1982).

Gastric distention induced increases of 2DG uptake in the right nucleus tractus solitarius (NTS), contralateral to the vagotomized side. This effect was confined to the medial aspects of the NTS and extended from the most caudal, commissural end of the nucleus to the level of appearance of the fourth ventricle. The locus of maximal activation was at the level of the area postrema. A nonparametric Mann Whitney U test comparing the optical densities of the activated sites in the right NTS to those of the contralateral, non-activated NTS was significant at the $p<0.05$ level. A significant left versus right difference in 2DG uptake was not found in control subjects or in other brain stem structures. The present results confirm the notion that gastric distention information travels to the brain, at least partially, through the vagus nerve. They are also compatible with our knowledge of neural connections between the stomach and the brain.

58.11 ESTROGENIC CONTROL OF FEEDING BEHAVIOR AND BODY WEIGHT REGULATION IN RATS WITH KAINIC ACID LESIONS OF THE LATERAL SEPTAL AREA. T.R. KING* AND D.M. NANCE. Department of Anatomy, Dalhousie University, Halifax, N.S., Canada, B3H 4H7 (SPON: D.A. Hopkins).

Extrahypothalamic control of feeding behavior and body weight (BWt) regulation is well documented. We have suggested that the lateral septal area (LS) may have a primary role in the hormonal control of energy balance (Nance P.B.&B., 18:605, 1983). In support of this, we have shown that rats with kainic acid (KA) LS lesions exhibit a systematic increase in BWt and an attenuation in the anorexic effects of estrogen on energy balance. However, it is not known whether these changes are correlated to alterations in feeding behavior. We examined the short term effects of KALS lesions on food intake (FI) and BWt regulation in female rats. In addition, the effects of ovariectomy and exogenous estrogen treatment on these parameters were determined. Using a microsyringe, KA [2µg/µl] was infused bilaterally (total volume 1.0 µl) into the LS at a rate of 0.1 µl/minute and the needle left in place for an additional 10 minutes. In all animals KA lesions of the LS produced major cell loss in the LS, however the extent of damage to the LS was variable. Associated with KALS lesions was the concurrent loss of CA3-CA4 cell groups in the hippocampus which was comparable for all lesioned animals. The extent of septal damage was quantified morphometicaly using a Zeiss IBASS Image Analyzer and correlated with changes in FI and BWt. The significant effects of the KALS lesions, relative to the controls were: 1) an increase in percent BWt gain from baseline which was significant 22 days following brain surgery. 2) an increase in percent food intake which was significant by day 6 post surgery, 3) an attenuation in the anorexic effects of estrogen on FI and BWt, and 4) a decrease in the percent days of vaginal estrus. Moreover, the anorexic effects of estrogen were inversely correlated with the extent of LS damage, but not the amount of hippocampal damage. The present study has confirmed that there is an increase in BWt following KALS lesions and further indicates that a sustained period of increased FI precedes the increase in BWt. These results verify that cells in the LS are involved in the estrogenic control of energy balance and further suggest that the increase in FI and BWt following KA lesions of the LS is attributable to the concurrent reduction in the anorexic effects of estrogen. Finally, the morphometic analysis of the brain lesions further suggest the ventral and/or intermediate subdivisions of the LS as the location of the cell bodies mediating the estrogenic control of feeding behavior. Supported by MRC of Canda.

58.12 CONCENTRATION DEPENDENT SUCROSE INTAKE IN CHRONIC DECEREBRATE RATS. F.W. Flynn, G. Acevedo* and H.J. Grill. Dept. Psychol. and Inst. Neurol. Sci. University of Pennsylvania, Philadelphia.

In neurologically intact rats, the volume of sucrose solution ingested increases with concentration up to a maximum. Further increases in concentration are accompanied by decreases in intake. These data are interpreted as evidence that taste and post-ingestional feedback interact in determining the amount ingested. Previously, Grill and Norgren provided evidence that chronic decerebrate rats show normal discriminative oromotor responses to taste stimuli. The volume of the taste stimulus infused into the rats' mouths (50µl) did not allow the quantification of the interaction of taste and postingestional feedback. In the present study, the interaction of taste and postingestional feedback in determining the amount of sucrose solution ingested was measured.

Brains of Sprague-Dawley rats were transected in the supra-collicular plane using a 2-stage procedure. Decerebrate (N=6) and pair-fed control rats (N=8) were implanted with intraoral cannulae and were maintained by intragastric feedings (4, 8ml meals/day). Intraoral intake tests began 10 days postsurgery. One hour following the morning meal, a taste stimulus-filled tubing was attached to the intraoral cannula and the rat was placed in a clear plastic chamber. A syringe mounted on an infusion pump maintained a constant rate of intraoral stimulus delivery (0.8ml/min). Intraoral infusions continued until the stimulus was expelled from the rat's mouth. The amount consumed was then computed by multiplying the rate of infusion x time spent ingesting. On alernate days, rats were given the following order of stimuli: water, 0.03M, 0.1M, 0.3M, 1.0M, 1.3M, 2.0M sucrose.

The volumes of the stimuli consumed showed the same concentration dependent relationship for control and decerebrate rats. For both groups, the amount of water and 0.03M sucrose consumed were not significantly different. The amounts consumed by control and decerebrate rats significantly increased when sucrose concentration was increased to 0.1M, and again when increased to 0.3M ($p<.05$). Intake of 0.3M, 1.0M, and 1.3M was similar. Both groups significantly decreased their intake when sucrose concentration was increased to 2.0M. Overall, control rats ingested more of all the stimuli than did decerebrate rats. The concentration dependent function in decerebrate rats shows that caudal brainstem mechanisms are sufficient for the detection of taste and postingestional feedback, and their integration to control the ingestion of orally-delivered sucrose solutions.

58.13 MEDULLARY AND CEREBELLAR DEGENERATION AND CYTOLOGIC CHANGE FOLLOWING THERMAL ABLATION OF THE AREA POSTREMA. Jon N. Kott, Nancy J. Kenney, and L. E. Westrum. Departments of Psychology and Neurological Surgery, University of Washington, Seattle, WA 98195.

The area postrema and underlying caudal-medial portion of the nucleus of the solitary tract (AP/cmNTS) have received a great deal of attention from researchers in the areas of food-intake and body-weight regulation, fluid and electrolyte balance, blood-pressure regulation and food aversion. Much of the research dealing with the function of the AP/cmNTS has utilized a thermal method for ablation of this region. Considering the rapid rate at which these studies are accumulating, it seems appropriate to examine the extent to which nearby structures may be damaged by the ablation procedure. We are undertaking a limited series of studies utilizing a modified Fink-Heimer degeneration technique, as well as, critical cytological staining to examine any ancillary damage resulting from thermal ablation of the AP/cmNTS.

Preliminary examination of material stained for degneration shows little advanced cell-body degeneration beyond the area that is carbonized and removed by the cautery tip. Cells within the dorsal motor nucleus of the vagus and the hypoglossal nucleus appear normal using this technique. However, critical cytologic examination may still reveal subtle changes.

Degenerating fibers and terminals appear more widespread; both are often seen in the gracile, cuneate and external cuneate nuclei. Lobule X of the cerebellum shows degeneration that may be both axonic and dendritic. As the Xth cerebellar lobule lies immediately dorsal to the AP, damage to this structure might be attributable to heat rising from the cautery tip at the time of lesioning. However, it seems more likely that both the dorsal column and the cerebellar damage may be attributable to the mechanical manipulation necessary to dry the medullary surface and to elevate the cerebellum or simply from exposure of these surfaces to the air.

Thus, while cell-body degeneration is quite limited around the lesion site, degenerating fibers, terminals and, possibly, dendrites, appear more widespread than might be predicted from the connectivity of the area.

59.1 EVIDENCE FOR DYNAMIC ELECTROTONIC COUPLING IN MAMMALIAN INFERIOR OLIVE IN VIVO. K. Sasaki* and R. Llinás (SPON: J. A. Gruner). Dept. of Physiology & Biophysics, New York Univ. Med. Ctr., New York, NY 10016.

Anatomical and physiological studies have demonstrated that the inferior olive (I.O.) neurons are electrotonically coupled by dendro-dendritic gap junctions at the I.O. glomerulus (Llinás et al. & Sotelo et al.: J. Neurophysiol. 37, 1974; Llinás & Yarom: J. Physiol. 315, 1981). The possibility that the functional organization of this nucleus may be modulated by the dynamic decoupling of neuronal groups was suggested some years ago (Llinás: Physiologist 17, 1974). In order to investigate this question, we recorded complex spikes from 32 Purkinje cells simultaneously using extracellular micropipettes in the cerebellar cortex of the rat (Crus IIA) as a variance of a technique developed in this laboratory (Bower & Llinás: Soc. Neurosci. Abst., 1982, 1983). Rats were anesthetized with Nembutal or Ketamine. Recording micropipettes were individually placed 250 μm from each other and were arranged in a 4x8 matrix in a rostrocaudal and mediolateral direction, respectively. The degree of electrotonic coupling between the I.O. neurons (the origin of the climbing fibers) was determined by the normalized degree of cross-correlation of Purkinje cell complex spikes. This spontaneous oscillatory firing of complex spikes occurred at a frequency of 8-12 Hz. The synchronous firing was observed in rostrocaudal bands which would cover most of the rostrocaudal span of a folium but which had a mediolateral span of 250-500 μm. I.O. reflexes (Eccles et al.: J. Physiol. 182, 1966) evoked from direct white matter stimulation also demonstrated the rostrocaudal organization of complex spikes, indicating that such arrangement is not dependent on co-activation of I.O. cells by common afferent inputs. Physiological stimulation of the trigeminal nerve produced responses in three rostrocaudal bands separated by two corridors of nonresponse bands. A similar spatial organization of cross-correlation was observed after injection of harmaline which increased the level of cross-correlation but does not modify the spatial organization of the climbing fiber input. Blockage of GABA inhibition by systemic application of picrotoxin induced clear cross-correlation throughout Crus IIA. Similarly following this pharmacological treatment, previously well defined trigeminal responses became widespread. These results suggest that the global organization of the I.O. can be changed through modulation of electrotonic coupling between neurons mediated by the activation of GABAergic inhibitory terminals on the I.O. glomerulus. [Supported by USPHS grant NS13742 from NINCDS]

59.2 NON-ISOCHRONOUS GENERATION OF PURKINJE CELLS DESTINED FOR SINGLE CEREBELLAR CORTICAL ZONES: A TRITIATED THYMIDINE AUTORADIOGRAPHIC STUDY IN THE CAT. B.L. Brown. Department of Anatomy, Emory University School of Medicine, Atlanta, Georgia 30322.

Considerable evidence (Voogd, 1969, Neurobiol. of Cerebellar Evol. and Devel.) suggests that the cerebellar cortex can be subdivided into a series of roughly longitudinally oriented strips, or zones, which constitute fundamental units of cerebellar cortical organization. Purkinje cells in each zone receive climbing fiber input from a single subdivision of the inferior olivary complex and send their output to a single deep cerebellar nucleus. The question arises as to how this precise pattern of connectivity is achieved during prenatal development. A simple hypothesis states that differences in connectivity between zones are related to differences in time of cell generation in neurons destined for those zones. Furthermore, this hypothesis requires that there is an orderly temporal sequence of neuron generation in cerebellar cortical zones and the deep nuclei and inferior olivary subdivisions to which they are related, coupled with an orderly sequence of axon outgrowth and synapse formation. Accordingly, the earliest-generated inferior olivary subdivision would form connections with Purkinje cells in the earliest-generated cerebellar cortical zone. To test this hypothesis, cat fetuses were exposed to tritiated thymidine (^{3}H-TdR) in utero at ages ranging from embryonic day 22 (E22) to E51 and sacrificed postnatally. Following tissue processing by standard autoradiographic techniques, the distribution of heavily labeled Purkinje cells was plotted on drawings or photographs of the cerebellum. Heavily labeled Purkinje cells were present in cerebella which had been exposed to ^{3}H-TdR on embryonic days 22 through 29, with peak Purkinje cell generation occurring around embryonic days 25-26. In cats injected with ^{3}H-TdR between E22 and E29, heavily labeled Purkinje cells are scattered across the cerebellar cortex, rather than being confined to a single cerebellar cortical zone. Since recent studies (Hickey et al., 1983, J. Neurosci. Meth. 8, 139-147) show that ^{3}H-TdR is available for approximately 4h after administration in cat fetuses, this scatter cannot be attributed to limitations of the method as applied to cats. These data therefore refute the simple hypothesis stated above by showing that individual cerebellar cortical zones are not made up of a single population of isochronously generated Purkinje cells.

The author wishes to thank Drs. Terry Hickey, Carla Shatz, and Ed Polley, who provided much of the tritiated thymidine autoradiographic material. Supported by the Sloan Foundation, the Emory University Research Fund, and NIH RR5364.

59.3 AUTORADIOGRAPHIC STUDY OF THE OLIVOCEREBELLAR PROJECTION IN ADULT NORMAL AND WEAVER MUTANT MICE. G.J. Blatt and L.M. Eisenman. Daniel Baugh Institute, Jefferson Medical College, Philadelphia, PA 19107.

The organization and topography of the olivocerebellar projection was studied in normal mice (+/+) and in weaver (wv/wv; wv/+) mutant mice. The weaver cerebellum is characterized by reduced numbers and ectopia of Purkinje cells (PCs); the primary target for incoming climbing fiber (CF) afferents. This study was designed to address the following questions: (1) will the organization of olivocerebellar afferents be altered in weaver due to the PC abnormalities? and (2) in the normal animal, does the olivocerebellar projection terminate in a series of parasagittal zones alternating with zones devoid of CF input or do CFs supply all regions of the molecular layer (ML)? To investigate these questions, single injections of ^{3}H-L-leucine were made into the inferior olivary complex (IO) in normal and weaver mice. In addition, some normal mice received either multiple injections of ^{3}H-leucine directly in the IO or multiple injections around, but not in, one side of the IO to label all or most IO cells by diffusion. The results from nine cases in +/+ mice demonstrate that olivocerebellar afferents end in terminal bands oriented orthogonal to the long axis of the folia. Many labeled bands extend across all cerebellar lobules but in some areas the label was restricted to one or a few lobules leaving other lobules devoid of label. More extensive CF terminal labeling was seen in cases where the injections were placed around the IO. A comparison of similar sections from different cases (of multiple injections) indicates that in one or another case there is label present in all parts of the ML. Unlabeled areas in individual cases appear to be the result of either cell death at the injection site or the insufficient labeling of some IO cells.

Tritiated leucine injections in wv/+ mice yielded similar results to +/+ mice. In wv/wv, single injections into the IO resulted in many band-like areas of label. The topographic organization of CF terminals was similar in all three types of mice: the caudal medial accessory olive projects to the contralateral vermis; the dorsal accessory olive projects to the contralateral paravermis; and the rostral medial accessory olive and principal olive send a projection to the opposite hemisphere and paraflocculus.

These findings suggest that (1) CFs project to PCs in all regions of the cerebellum, and (2) in the weaver mutant, exact target cell position and number do not appear to be important factors in determining the organization and topography of CF terminals.

59.4 DISTRIBUTION PATTERN OF INFERIOR OLIVE AXON COLLATERALS WITHIN CAT CEREBELLAR STRIPS. A.Rosina* and L.Provini* (SPON: European Neuroscience Association), C.N.R., Ist. Fisiol. Centri Nervosi , Via Mario Bianco, 9, 20131 Milano, Italy.

While it is now generally accepted that the olivocerebellar axons distribute over the cerebellar cortex along parasagittally oriented strips, it is still largely obscure how the collaterals (10 on the average in the cat) of single inferior olive(IO)axons distribute within the strips.

One way to address this problem is to ascertain whether climbing fiber (CF) collaterals sustain any relation between somatotopically homologous areas of cerebellar cortex. Along this line it was shown (Rosina and Provini,Brain Res.,289:45-63,1983) that single IO neurons supply CF collaterals to pairs of face-forelimb (FL) related areas in the pars intermedia of the anterior lobe (PIAL), lobulus simplex, crus II and paramedian lobule (PML), within strips C_1 to D_2.While this mosaic type of interlobar branching involves the majority of IO neurons in each pertinent olivary subdivision, it only accounts for 2 of the 10 estimated collaterals. The residual branches could therefore distribute within a single folium and/or adjacent folia within each somatotopically homogeneous cerebellar area.The questions we then addressed were: a)do CFs branch over contiguous folia?, and b)how do these interfolial branches relate to the interlobar collaterals? To this end two spectrally different fluorescent tracers, Fast blue (2%,w/v) and Diamidino yellow (1%, w/v), were microinjected into single adjacent folia (V_b and $V_{c,d}$) of PIAL. In the same animal a third fluorescent tracer (Evans blue, 10%, w/v) was microinjected into the FL folia of PML.

The results showed that a number of IO neurons do give off branches directed to contiguous folia of V-PIAL as well as to the FL folia of PML. These data suggest that in the FL areas of strips C_1 to D_2,IO neurons give two interlobar collaterals which further split into branches directed to adjacent folia; finally a few (two to three) branches would be given within each folium. CF input from single IO neurons might thus sustain the replication of the same peripheral receptive field according to this distribution pattern.

59.5 THE GRACILE NUCLEUS PROJECTION TO THE INFERIOR OLIVE: AN ELECTRON MICROSCOPIC STUDY. H.H. Molinari. Department of Anatomy, Albany Medical College, Albany, N.Y. 12208.

The gracile nucleus is one of several sources for the inferior olive of cutaneous feedback from the hindlimb. The present study defined the mode of termination of gracile axons in the dorsal accessory portion of the cat inferior olive. The gracile terminals were labeled by anterograde transport of wheat germ agglutinin-horseradish peroxidase and visualized, after a 24 hr survival time, with tetramethylbenzidine (TMB). The tissue was prepared for electron microscopy following Carson and Mesulam (1982). Ultrathin and 0.25 µm thick sections were examined with either a JEOL 100CX or High Voltage (N.Y. State Department of Health) electron microscope. The labeling patterns were analyzed by scanning selected sections, photographing all labeled elements within those sections, and classifying the labeled elements using published ultrastructural descriptions of the inferior olive.

The TMB reaction product was largely confined to myelinated axons and synaptic terminals. Virtually all of the labeled terminals measured less than 2 µm in diameter, contained round synaptic vesicles, and formed asymmetric contacts with postsynaptic elements. Thus, in keeping with physiological data, the gracile terminals had the properties of excitatory synapses.

The majority of labeled gracile terminals contacted distal dendritic shafts. They did not participate in synaptic glomeruli. Despite this, only a third of the terminals formed isolated contacts. The majority terminated within loosely organized synaptic complexes termed dendritic thickets by Sotelo et al. (1974). The dendritic thickets were composed of three or four serially connected, distal dendritic shafts that received input from three or four different presynaptic elements. Only one presynaptic element per thicket contained TMB reaction product. The unlabeled terminals within the thickets resembled the gracile terminals in that they were also small, contained round synaptic vesicles, and formed asymmetric contacts with the dendritic shafts.

Dendritic thickets provide a means by which postsynaptic elements within the inferior olive might simultaneously receive input from a number of presynaptic elements and through which interactions between postsynaptic elements might occur. It is suggested that the convergence of somatosensory inputs in the inferior olive, demonstrated with physiological techniques by Oscarsson and Sjolund (1977), occurs within dendritic thickets.

59.6 ANATOMY AND PHYSIOLOGY OF DORSAL COLUMN AFFERENTS TO FORELIMB DORSAL ACCESSORY OLIVE. C. Weiss, M.L. McCurdy, J.C. Houk and A.R. Gibson. Neuroscience Program and Department of Physiology. Northwestern University, Chicago, Ill. 60611

The origin of forelimb afferents from the dorsal column nuclei to the dorsal accessory olive (DAO) has been elusive. Using WGA-HRP we have identified these cells as forming a narrow column, 0.6 mm wide, which extends from the dorsal caudal cuneate nucleus (CCN) to the rostro-ventral CCN. This region provides dense input to the DAO.

Using bipolar stimulation (.1ms pulses) of the forelimb DAO we located antidromically activated cells within the CCN. Only cells showing low threshold activation and collision were studied. Thus far we have data on 22 cells that have been histologically verified as being within the column of cells that project to DAO. They had a mean antidromic threshold of 17.8uA (SD=11.6uA) and a mean antidromic latency of 1.67ms (SD=.94ms). A majority of these cells(N=13) had zero spontaneous activity or the low irregular firing frequency characteristic of olivary neurons.

These cells were activated by stimulation of hairs(N=9) and by deep rapidly adapting(N=3) and slowly adapting(N=2) receptors, or they were inhibited(N=2). Six cells could not be driven. The majority of receptive fields(N=12) were on the distal paw, mostly the dorsal surface. The others were on the proximal forelimb, shoulder or back. The majority of cells had simple responses, a few had more complex properties such as prolonged excitation, post excitatory inhibition and surround inhibition.

We have also found a reciprocal connection between this narrow column of cells in the CCN and the forelimb area of the magnocellular red nucleus(RNm). To determine if input from the RNm mediates inhibition of olivary activity, which occurs during movement (Gellman et al., Soc. Neuro. Abs. 9:607,'83), we stimulated either the RNm or rubrospinal tract and looked at the effects on DAO unit activity. We found that 50-200ms trains of electrical stimuli (200-400Hz, .2ms), to either the nucleus or tract (within the brainstem), inhibited the DAO response to a peripheral stimulus delivered approximately 30ms later. All 16 rostral DAO cells were inhibited by this conditioning stimulation ($\bar{X}$=37.0uA, SD=24.8uA).

We conclude that the input from the dorsal column nuclei to the forelimb DAO arises from a restricted region of the caudal cuneate nucleus, and that the cells of this region demonstrate receptive field properties similar to DAO cells (Gellman et al., JCN 215: 228-243,'83). Input from the rubrospinal tract (probably via a collateral) to the vicinity of the DAO projecting cells, may provide the anatomical basis for electrophysiological as well as behavioral suppression of DAO responses.

59.7 MAPPING THE CLIMBING FIBER PROJECTION FROM THE BETA NUCLEUS TO THE UVULA-NODULUS OF THE CEREBELLUM OF THE RABBIT. N. H. Barmack and Y. Sato*. Neurological Sciences Institute, Department of Ophthalmology, Good Samaritan Hospital and Medical Center, Portland, OR 97209.

The beta nucleus comprises the caudal-medial aspect of the medial accessory olive; lying ventromedially to the dorsal cap of Kooy, the major source of visual climbing fiber projections to the cerebellar flocculus. The beta nucleus is of functional interest for two reasons: 1) It receives information of otolithic origin from the vestibular nuclei, and 2) It is the recipient of a major GABAergic projection, the origin of which is at present undetermined. Previous investigations have demonstrated a projection of the beta nucleus onto the nodulus and uvula of rat, cat and monkey. As a first step in understanding the significance of olivo-cerebellar circuitry mediating otolithic information, using retrograde tracers, we have studied the pattern of olivary projections in the rabbit onto the uvulo-nodulus; with the particular aim of describing the projections from the beta nucleus.

Small and large (40nl-120nl) pressure injections of HRP or fluorescent retrograde tracers (fast blue or 2,4-diamidino nuclear yellow) were injected into one or several folia of the uvula and nodulus in 20 rabbits at different medio-lateral locations. The topographic patterns of contralateral climbing fiber projections onto the cerebellar surface reveal longitudinally oriented, transfolial strips.

The caudal beta nucleus projects onto the most medial aspect of the uvula-nodulus. The rostral part of the beta nucleus projects more laterally. Together these strips comprise a longitudinal band which is approximately 1.3-1.4mm wide. Further laterally on the cerebellar surface is another longitudinal strip projection from the caudal-lateral medial accessory olive, an olivary area from which vestibularly-evoked activity has also been evoked. Still more laterally, about 2mm from the midline is a projection from the dorsomedial cell column. The ventral lamellae of the principal olive projects to a strip which is about 3.5mm from the midline, and the rostrolateral MAO projects to the most lateral region of the uvula-nodulus. These findings indicate the medial 1.5mm of the posterior cerebellar vermis may be involved in processing vestibular as well as other information mediated by climbing fibers.

59.8 LOSS OF GABAERGIC NERVE TERMINALS IN THE INFERIOR OLIVE OF CEREBELLECTOMIZED RATS. B. Nelson and E. Mugnaini. Lab. of Neuromorphology, Univ. of Conn., Storrs, CT 06268.

Nerve terminals immunoreactive for the GABA synthesizing enzyme, glutamic acid decarboxylase (GAD), are densely distributed throughout all subnuclei of the mammalian inferior olive (IO). In rat, small GABAergic nerve terminals (0.5-1.0 um) are present in principal olive (PO), dorsal accessory olive (DAO), and medial accessory olive (MAO). Large, densely stained GABAergic terminals (up to 2.5 um) are distributed in the ß nucleus, while dorso-medial cell column and caudal portion of DAO contain GABAergic terminals of intermediate size and density. One source of olivary GABAergic terminals are small neurons situated in the cerebellar nuclei (Nelson et al., 1984). The present study is an attempt to ascertain the extent of the GABAergic cerebello-olivary projection by the loss of GAD-immunoreactive nerve terminals induced by cerebellectomy. Sprague-Dawley rats (150-450 g b.w.) were divided into four groups: 1) unoperated rats; 2) totally cerebellectomized rats; 3) hemicerebellectomized rats; and 4) rats subjected to large cerebellar cortical ablations without damage to the cerebellar nuclei. Ablations were made without apparent damage to vestibular nuclei. After 4, 10, and 21 days survival, rats were perfused transcadially with a low pH zinc-aldehyde fixative. Serial sections of the brainstem were obtained on a freezing microtome. Sections were processed for GAD-immunoreactivity with the PAP method using sheep antiserum S3 of Oertel et al., 1981. Within 10 days, total cerebellectomy results in conspicuous bilateral reduction of GAD-immunoreactive nerve terminals in areas known to receive the cerebello-olivary projection, i.e., PO, DAO, and rostral MAO. This terminal loss is contralateral to the aspirated side in unilaterally cerebellectomized rats. A small reduction of GAD immunoreactive nerve terminals perhaps occurs in caudal MAO ipsilaterally. After 21 days the GAD immunoreactivity is partially recovered. The observed loss of GABAergic nerve terminals in the IO may be the result of the removal of the source nuclei of the GABAergic cerebello-olivary projection and/or of a retrograde olivary cell response to severance of the climbing fibers. Removal of large areas of cerebellar cortex without damage to the cerebellar nuclei fails to elicit loss of GAD immunoreactivity in IO, but climbing fiber collaterals projecting to the undamaged cerebellar and vestibular nuclei may prevent a retrograde effect. Complete bilateral cerebellectomy does not produce the same effect throughout IO. Beta nucleus, dorsal cap, and medial DAO remain unchanged in spite of an expectable retrograde effect. Experiments are in progress to further elucidate these observations, and to investigate the nature of the recovery of GAD-immunoreactivity observed 21 days after cerebellectomy.

59.9 GLUTAMIC ACID DECARBOXYLASE ACTIVITY IN THE DEEP CEREBELLAR NUCLEI FOLLOWING CLIMBING FIBER LESIONS OR IN DYSTONIA. G.A. Oltmans, J.F. Lorden and M. Beales*. Dept. of Pharmacology, Chicago Med. Sch., N. Chicago, IL 60064 and Dept. of Psychology, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

The inferior olive(IO)-climbing fiber(CF) input to the cerebellar cortex constitutes one of the two major excitatory inputs to the cerebellar Purkinje cell(PC). Activation of the IO-CF system by the drug harmaline produces increased complex spike activity in the PCs, an increase in cerebellar cGMP, and behavioral tremor. Removal of the CF input to the PCs by destruction of the IO with the toxin 3-acetylpyridine (3AP) results in an absence of complex spikes, a decrease in cerebellar cGMP, and a block of the behavioral responses to harmaline. The 3AP lesion also produces multiple motor dysfunctions.

Motor abnormalities similar in part to those found following 3AP lesion are seen in the genetically dystonic rat (genotype dt). This mutant also has decreased cerebellar cGMP levels and is refractory to the tremorogenic effects of harmaline (Lorden et. al., 1985, J. Neurosci.), suggesting a similarity to animals with CF lesions. The dt rat also has increased levels of glutamic acid decarboxylase (GAD) activity in the projection area of the Purkinje cells, the deep cerebellar nuclei (Oltmans et. al., 1984, Exp. Neur.,85:216). The purpose of the present study was to determine if lesions of the CF system in normal animals would produce a change in GAD activity in the deep cerebellar nuclei. In addition, GAD activity in specific cerebellar nuclei of the dt rat was measured to determine if this neurochemical change was localized to a specific site.

To produce CF destruction, normal 16-day old rats were injected wtih 65 mg/kg of 3AP. The animals were then killed 4 hr., 24 hr., 14 days, or 28 days later, and GAD activity determined in the cerebellar nuclei and vermis. There was a significant increase (115% of control) in GAD activity in the deep nuclei at 24 hr. post-treatment. This increase became larger with time, reaching 134% of control at day 28. A significant increase in GAD activity in the vermis was found only on day 28, and this increase was smaller (114% of control) than that found in the deep nuclei.

Analysis of GAD activity in specific cerebellar nuclei of the 16 day old dystonic rat was accomplished using a modification of the "punch" technique of Palkovits (Br. Res., 59:449, 1973). A significant increase in GAD activity was found only in the nucleus interpositus(125% of control). No significant change was found in either the lateral or medial cerebellar nuclei.

The results indicate the presence of increased GAD activity in the cerebellar nuclei of both dystonic rats and rats with CF lesions. Differences in their motor syndromes may be due to the specific sites of neurochemical change. (Supported by NS 18062).

59.10 ULTRASTRUCTURAL CHANGES OF THE NERVE TERMINALS IN THE CEREBELLAR NUCLEI FOLLOWING PURKINJE CELL DEPRIVATION OF THEIR CLIMBING FIBER INPUT. P. Strata, F. Rossi and D. Cantino (SPON: European Neuroscience Association). Inst. of Human Physiol. and Inst. of Human Anatomy, University of Turin, 10125 Turin, Italy.

It has been reported that following inferior olive lesion, Purkinje cell inhibitory function is reduced. This effect may be the consequence of a loss of a throphic factor carried along the climbing fiber input (Ito et al., Nature 277: 568-569, 1979) or the consequence of an increased Purkinje cell activity (Montarolo et al., J. Physiol. 332: 187-202, 1982; see Strata P. In: Cerebellar Function, Bloedel et al. Eds. Springer, Heidelberg, 1984). We examined the intracerebellar nuclei following inferior olive lesion, in order to recognize possible morphological changes in the Purkinje cell axon terminals.

The inferior olive of adult female Wistar rats was lesioned by means of 3-acetylpyridine and the cerebellum was processed for electron microscopy 3 days to 6 months after lesion. A quantitative analysis of the axon terminals exhibiting a series of ultrastructural changes was made in the dentate nucleus. For each animal, we counted the number of altered terminals in 10 squares, each measuring 90x90 μm, randomly chosen according to the method described by Weibel (Stereological methods, Academic Press, London, 1979).

We have counted the axon terminals characterized by the presence of i) clusters of vesicles, ii) large vacuoles, iii) elongated cysternae of the smooth endoplasmic reticulum, iv) whorled bodies. The number of altered axons for each class was remarkably higher than in control material and depended on the time interval from the lesion. Axon terminals of class i), ii) and iii) increased in number up to day 15, and decreased until 6 months. In contrast, those characterized by whorled bodies showed an increase up to 6 months.

These results will be discussed in relation to the functional modifications described above.

This research was supported by a M.P.I. grant.

59.11 EVIDENCE FOR ENKEPHALINERGIC CLIMBING FIBERS IN THE OPOSSUM'S CEREBELLUM J.S. King, R.H. Ho and G.A. Bishop. Department of Anatomy and Neuroscience Research Laboratory, The Ohio State University, Columbus, Ohio 43210.

Previous investigations suggest that climbing fibers contain an amino acid transmitter (likely aspartic acid) and arise from the inferior olivary complex. In the present study, adult opossums were perfused with Zamboni's fixative, and their brains serially sectioned on a freezing microtome in the transverse and sagittal planes. The sections were processed for the localization of enkephalin immunoreactivity using the indirect antibody peroxidase-antiperoxidase (PAP) technique. Enkephalin-like immunoreactivity is present in the cerebellum within axons that have the anatomical characteristics of climbing fibers. The parent fiber branches in the lower third of the molecular layer giving rise to fine beaded axons that either course at right angles or in parallel to the parent axon. Enkephalingeric climbing fibers are not present throughout the cerebellum, but are limited to restricted areas of cortex in vermal lobules II-VIII and X, the medial paramedian lobule, the paraflocculus and the flocculus. Brains of other animals were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde, sectioned on a vibratome at 60 um and processed for electron microscopic immunohistochemistry. Serial thin sections (90 nm) reveal enkephalinergic profiles that approximate Purkinje cell dendrites from the level of the Purkinje cell bodies to the area just beneath the pial surface. The labeled terminals contain clear synaptic vesicles and make multiple synaptic contacts on the thorns of Purkinje cells. In order to localize the cell bodies of origin for enkephalin positive axons, horseradish peroxidase (HRP) was injected into the cerebellum. After a survival time of 24-36 hours the animals received intraventricular injections of colchicine. Twelve to twenty-four hours later, the animals were perfused with 3.5% paraformaldehyde and their brains processed for HRP histochemistry followed by enkephalin immunohistochemistry. Neurons retrogradely labeled with HRP are located in all precerebellar nuclei as well as in several reticular and raphe nuclei. Enkephalinergic neurons are present primarily in the reticular formation rostral to the inferior olive, (gigantocellular and the parvicellular reticular nuclei), several raphe nuclei and the periaqueductal gray. In addition, a population of enkephalinergic neurons is located immediately lateral to the rostral dorsal accessory olivary nucleus, adjacent to the ventral brain surface. Neurons that are both retrogradely labeled with HRP and demonstrate enkephalin immunostaining have only been observed in this latter region and the nucleus reticularis gigantocellularis. To date, no enkephalinergic or double-labeled neurons have been seen in the inferior olivary complex although a dense plexus of enkephalinergic varicosities is present. These data in the opossum suggest that: 1) climbing fibers are not uniform in their (putative) transmitter content and 2) enkephalin which is inhibitory in other brain areas is present in cerebellar axon terminals which are well-characterized physiologically as excitatory. (Supported by NS-08798).

60.1 SELECTIVE EFFECT OF AMIFLAMINE, A REVERSIBLE MONOAMINE OXIDASE INHIBITOR, ON SEROTONERGIC NEUROTRANSMISSION. P. Blier, C. de Montigny and A.J. Azzaro. Université de Montréal, Canada and University of West Virginia, Morgantown, USA.

Amiflamine, a reversible type A monoamine oxidase inhibitor (MAOI), has been reported to exert a preferential effect on serotonin (5-HT)-containing neurons (Ask et al., Neuropharmacology 21: 299, 1982). Pilot observations suggest that amiflamine might be effective in major depression.

Male Sprague-Dawley rats received amiflamine (2 mg/kg, i.p.) twice daily for 2, 7 or 21 days. Biochemical determinations and electrophysiological experiments were carried out 2-6 h after the last dose of amiflamine. Whole brain concentrations of 5-HT and norepinephrine (NE) were increased respectively by 62% and 29% after 2 days, by 52% and 40% after 7 days, and by 89% and 40% after 21 days of treatment.

Unitary extracellular recordings of 5-HT and NE neurons were obtained from the raphe dorsalis and the locus coeruleus under chloral hydrate anesthesia (400 mg/kg, i.p.). The two-day amiflamine treatment markedly reduced the firing activity of 5-HT neurons. However, there was a partial recovery of their activity, after 7 days of treatment, and the recovery was complete after 21 days of treatment. This recovery was attributable to a desensitization of the 5-HT autoreceptor indicated by a decreased responsiveness of 5-HT neurons to LSD, a 5-HT autoreceptor agonist. In contrast, the firing activity of NE neurons was normal after 2 days of treatment but decreased progressively with the prolongation of the treatment. The responsiveness of NE neurons to the α_2 agonist clonidine was unchanged after 21 days of treatment, indicating that the NE autoreceptor had not desensitized.

The responsiveness of hippocampal pyramidal neurons to microiontophoretic applications of 5-HT and NE and the effect on the activity of these neurons of the electrical activation of the ventromedial 5-HT pathway and of the dorsal NE bundle were assessed in control rats and in rats treated with amiflamine for 21 days. The responsiveness of pyramidal neurons to exogenous 5-HT and NE was unchanged by the treatment. However, the efficacy of the stimulation of the ascending 5-HT pathway was increased by amiflamine, whereas that of the stimulation of the NE pathway was not modified.

These data confirm the preferential effect of amiflamine on 5-HT neurons resulting in a selective enhancement of 5-HT neurotransmission without any modification of the postsynaptic neuron responsiveness. Hence, should the antidepressant activity of amiflamine in major depression be confirmed, this would provide novel evidence supporting the hypothesis that an increase of 5-HT neurotransmission might contribute to the therapeutic activity of antidepressant treatments.

60.2 EFFECTS OF TRAZODONE ON ALPHA-2 ADRENOCEPTOR FUNCTION IN DEPRESSION. L.H. Price, D.S.Charney*, G.R.Heninger, Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT., 06508.

Based on preclinical findings, it has been hypothesized that antidepressant drugs may exert their therapeutic effects by reducing the sensitivity of alpha-2 adrenoceptors during long-term treatment. Clinical studies have demonstrated this property for the tricyclic antidepressants desipramine and amitriptyline. Mianserin, an atypical tetracyclic drug, lacked this effect. In the present investigation alpha-2 adrenoceptor function was measured before and during treatment with the atypical triazolopyridine antidepressant trazodone.

METHODS: 11 patients with DSM III major depression gave voluntary informed consent to participate. Alpha-2 adrenoceptor function was assessed by measuring the ability of the alpha-2 agonist clonidine to decrease plasma 3-methoxy-4-hydroxyphenylethyleneglycol (MHPG) and blood pressure, and to increase sedation and plasma growth hormone. After a minimum 2-week placebo period (at least 3 weeks psychotropic drug-free), patients underwent 2 double-blind test days. Placebo was given the first day and clonidine 5 ug/kg p.o. was given the second day. The test procedures were repeated after 4 weeks of active trazodone treatment. Clinical change was assessed with the use of rating scales. A gas chromatography mass spectrography method was used to measure MHPG and an RIA method to measure growth hormone.

RESULTS: Clonidine-induced changes in MHPG, blood pressure, sedation, and growth hormone were not significantly affected by trazodone. Trazadone treatment was associated with a small (.2 ng/ml) nonsignificant decrease in baseline plasma MHPG. There was no clear difference between the patients whose symptoms improved during trazodone treatment and the nonimproved patients on any of the measured variables or the effects of clonidine before or after trazodone treatment.

CONCLUSION: Long-term clinical treatment with trazodone has no clear effect on pre- and postsynaptic measures of alpha-2 adrenoceptor function. Since some patients improved during trazodone treatment this study suggests that trazodone, like some other atypical antidepressants, does not exert its therapeutic effects via changes in alpha-2 adrenoceptor sensitivity. Trazodone acts as an antagonist at serotonin receptors and one of its metabolities (m-chlorophenylpiperazine) acts as a serotonin agonist. The therapeutic mechanism of action of trazodone may therefore predominantly involve the serotonin system and not the noradrenergic system.

Supported by the State of Connecticut, MH25642, MH30929, and MH36229.

60.3 THE EFFECTS OF ANTIDEPRESSANTS, WHICH ATTENUATE CLINICAL ANXIETY ASSOCIATED WITH DEPRESSION, IN TWO ANTIANXIETY PROCEDURES IN RATS, D. Luttinger and P. A. Mason.* Dept. of Pharmacology, Sterling-Winthrop Research Institute, Rensselaer, NY 12144

Several antidepressants have been reported to alleviate anxiety associated with depression. In the present studies we examined the effect of five antidepressants, with purported antianxiety properties, in two operant procedures used to assess antianxiety activity in water deprived male Sprague-Dawley rats. One procedure was a metrazol drug discrimination procedure (Shearman and Lal, Neuropharmacol, 1980). In this paradigm rats are trained to discriminate between saline and metrazol (15mg/kg, i.p.). Antianxiety compounds such as chlordiazepoxide routinely inhibit metrazol discrimination in a dose related fashion. Mianserin (1-10 mg/kg), trazodone (0.1-30 mg/kg), amoxapine (3-30 mg/kg), maprotiline (1-10 mg/kg), and doxepin (0.1-10 mg/kg) injected i.p. did not affect metrazol discrimination, suggesting that these compounds do not produce demonstrable antianxiety activity in this procedure. This may be due, in part, to the observation that when the antidepressant was administered at the highest dose tested, with saline instead of metrazol, 25-50% of the rats choose the drug lever; suggesting that the antidepressants possess some metrazol like discriminable properties. The second procedure was a punishment procedure (Cook and Davidson, The Benzodiazepines, 1973) with water used as the positive reinforcer and electric footshock (0.6 mA) as the punishing stimuli. Mianserin (3-30 mg/kg), trazodone (0.1-30 mg/kg), amoxapine (0.3-10 mg/kg), maprotiline (3-30 mg/kg) and doxepin (0.1-10 mg/kg) were injected i. p. sixty minutes before testing. Trazodone, amoxapine, maprotiline and doxepin did not demonstrate any antianxiety activity in this procedure. Mianserin (3 mg/kg) tended to increase punished responding, suggesting antianxiety activity, though the magnitude of this effect was not as large as that observed with chlordiazepoxide.

In summary, in two procedures that detect antianxiety activity in rats, antidepressants with purported antianxiety activity were not active. Three possible reasons for the lack of effect of the antidepressants are a) anxiety reduced by these antidepressants may be associated with depression and distinct from the anxiety routinely treated with the benzodiazepines, b) these antidepressants may work by a unique mechanism for the alleviation of anxiety which is not detected by metrazol discrimination or punishment procedures, or c) these antidepressants may only work at reducing anxiety when administered on a chronic basis.

60.4 5-HYDROXYTRYPTOPHAN ALTERATION OF ENDOGENOUS OPIOIDS: IS IT RELATED TO THE CLINICAL EFFECTS OF THE DRUG ? E. Parati, G. Bussone*, A. Groppetti*, M. Parenti*. Inst. Neurol. "C. Besta", and Dept. of Pharmacol., Univ. of Milan, Milano, Italy.

Drugs affecting serotonergic neuronal activity are often used in the clinical treatment of migraine.

In our hands the administration of 5-hydroxytryptophan (5-HTP) to patients affected by common migraine ameliorated the clinical symptoms.

In the attempt to potentiate the therapeutic efficacy of 5-HTP, the peripheral catabolism of the drug was decreased by the concomitant administration of the inhibitor of L-aromatic aminoacid decarboxylase carbidopa (CAR). In fact, while only a modest raise of plasma 5-HTP levels was observed when the drug was given orally at the dose of 100 mg to normal or migraineous subjects, a dramatic increase of plasma drug concentrations (about 10 fold) occurred after treatment with 5-HTP plus CAR (10 mg). However the association induced a marked nausea and vomiting in all the subjects shortly after the treatment. The appearance of these side effects was significantly delayed by the slow intravenous infusion of naloxone (16 mg in an hour) but was not affected by the administration of the dopamine antagonist domperidone (20 mg in an hour) suggesting that endogenous opioids could be affected by 5-HTP. Indeed interactions between serotonergic and opioid neuronal systems have been already reported.

In this context we have found that, in rats, the i.p. administration of 5-HTP, in combination with CAR (25 mg/kg 5-HTP; 2.5 mg/kg CAR) strongly enhanced serotonin (5-HT) metabolism in different brain areas such as hypothalamus (see Table), striatum and brainstem. On the contrary met-enkephalin-like immunoreactive material (ME.IR) concentrations were decreased in all these regions.

Further investigations are needed to establish whether the clinical effects of 5-HTP are related to endogenous opioid modifications.

60.5 WY-45,030, A NEW ANTIDEPRESSANT, AND ZIMELIDINE DECREASE 5-HIAA LEVELS IN WHOLE RAT BRAIN. E.A. Muth and K.M. Cilmi*. Wyeth Laboratories, Division of Experimental Therapeutics, Philadelphia, PA 19101.

The novel antidepressant compound, Wy-45,030, possesses monoamine uptake inhibitory properties. The compound potentiates the behavioral actions of L-DOPA in rats, antagonizes reserpine in mice, is active in vitro vs. the rat brain synaptosomal uptake of norepinephrine (NE; IC50=0.64 μM), serotonin (5-HT; IC50=0.21 μM), and dopamine (DA; IC50=2.8 μM), but lacks affinity for alpha-1/alpha-2/beta adrenergic, muscarinic cholinergic, histaminic, or opiate receptors (Muth et al. and Moyer et al., Neuroscience Abstracts 10:261, 1984). In addition, the compound caused a rapid (24 h) beta noradrenergic subsensitivity in the pineal model (Moyer et al., ibid.)

In the present follow-up study, we compared the in vivo biochemical effects of Wy-45,030 to those of desipramine (DMI), imipramine (IMI), and zimelidine (ZIM). Each compound was administered at 10 mg/kg i.p. either acutely or once a day for 5 days (also b.i.d. for 18 days for Wy-45,030). Two hours after the last injection, rats were decapitated and monoamines and their major metabolites were measured by reverse-phase HPLC with electrochemical detection. In whole rat brain minus the cerebellum, neither IMI nor DMI, after acute or chronic dosing, caused any significant changes in the concentration of any of the neurochemicals monitored, although IMI had a tendency to decrease the concentration of the serotonin metabolite, 5-hydroxyindole acetic acid (5-HIAA). In contrast, both ZIM and Wy-45,030 decreased 5-HIAA levels by 31% after acute treatment and by 43% and 35%, respectively, after 5-day dosing. Wy-45,030 also decreased 5-HIAA content by 21% after the 18-day b.i.d. regimen. These results suggest that Wy-45,030 shares with ZIM the ability to slow the turnover of 5-HT without affecting NE metabolism, despite the fact that ZIM, but not Wy-45,030, is a specific 5-HT uptake inhibitor.

60.6 PR 903-574:BIOLOGICAL PROFILE OF A NOVEL NON-TRICYCLIC AS A POTENTIAL ANTIDEPRESSANT. S.McCreedy*, J.Blosser, J.M. Ordy, J. Frankenheim*, R.Griffith*, and B. Watkins* Depts. of Pharmacol., Chem., Pennwalt Corporation, Pharmaceutical Division, Rochester, NY 14623.

PR 903-574A, a halogenated isoquinoline derivative modeled after mianserin (Griffith et al., J. Med. Chem. 27:995, 1984), exhibited CNS and biochemical properties predictive of anti-depressant activity. Like most clinically active antidepressants, PR 903-574A antagonized tetrabenazine (TBZ) induced ptosis in mice; it exhibited a minimal effective dose (2 mg/kg) intermediate between that of mianserin (10 mg/kg) and imipramine (<0.5 mg/kg). The effect of PR 903-574A on adrenergic receptor function in rat frontal cortex following chronic (14 days) but not acute treatment was also indicative of antidepressant activity. PR 903-574A (30 mg/kg) as well as mianserin (30 mg/kg) and imipramine (15 mg/kg) decreased norepinephrine (NE) sensitive adenylate cyclase (AC) activity by 40-50%. Similar chronic treatment had little effect on β-adrenergic receptor number in rat whole cortex. PR 903-574A produced small (10%) decreases in receptor number as did mianserin (12%). This contrasted with imipramine treatment which produced marked reductions of 25-30%. There were no changes in receptor affinity. PR 930-574A demonstrated an affinity for histamine-2 receptor sites that was comparable to that of other tri- and tetracyclic agents including mianserin. EEG power spectra of PR 903-574A was consistant with that of other antidepressants. A 60 min analysis of EEG power (picowatts) time curves with respect to pretreatment baselines following 1 mg/kg iv dose in beagle dogs showed that imipramine increased total power maximally at 15 minutes while mianserin produced a lesser effect which was maintained over the entire period. Total power spectra of PR 903-574A exhibited elements of both reference agents; that is, a dose response characteristic of mianserin and a time response characteristic of imipramine. Certain aspects of the biochemical profile of PR 903-574A were dissimilar from other classes of anti-depressants. PR 930-574A did not inhibit total monoamine oxidase (MAO) or MAO-A activity in vitro or in vivo following acute or subacute treatment. Unlike many tricyclic agents, PR 903-574A weakly inhibited NE and dopamine uptake and had no effect on serotonin (5HT) uptake in vitro. Despite structural similarities with mianserin, PR 903-574A demonstrated very low affinity for α_2 adrenergic and 5HT-2 binding sites in vitro. Based on the antagonism of TBZ induced ptosis, the inhibition of NE sensitive AC following chronic treatment, and characteristic EEG spectra PR 903-574A appears to have potential as a new antidepressant agent. The lack of effect on amine transport and low affinity for α_2 adrenergic and 5HT-2 receptors suggest that its mechanism of action differs from that of tricyclic antidepressants and mianserin.

60.7 A NOVEL COMPOUND, AMPEROZIDE (FG 5606), ACTIVATES LOCUS COERULEUS NEURONS AND INHIBITS DORSAL RAPHE NEURONS IN VIVO. J.T. Haskins, D.E. Jones*, G.J. Zingaro* and E.A. Muth. Wyeth Laboratories, Inc., Dept. of Experimental Therapeutics, Philadelphia, PA 19101.

A novel compound, amperozide (Ferrosan FG 5606; 4-[4,4-bis(4-flurophenyl)butyl]-N-ethyl-1-piperazine carboximide, hydrochloride) has in vivo and in vitro activities indicating a diverse preclinical profile. Amperozide (AMPZ) has atypical neuroleptic activity including blockade of spontaneous exploratory behavior in mice and inhibition of conditioned avoidance response in rats, but no cataleptogenic activity and no effect on amphetamine-induced stereotypies.

AMPZ is also reported to be an antidepressant compound as a result of its inhibition of rat muricidal behavior, reduction of immobility in behavioral despair and moderate activity in blocking serotonin-dependent behavior in mice. The anxiolytic activity of AMPZ is reflected in its suppression of anxiety induced by an approach avoidance conflict test in rats and inhibition of aggression in isolated male mice.

Biochemically, we found AMPZ to be a ligand of only moderate affinity at limbic dopamine-2 receptors (Ki=190 nM). The compound was weaker in binding to alpha-1, serotonin-1 and alpha-2 receptors, with Ki's of 0.3, 2.7, and 3.5 μM, respectively. Interestingly, AMPZ was most potent vs. serotonin-2 binding, with a Ki of 43 nM. AMPZ is also a monoamine uptake inhibitor, with IC50's of 2.1 μM vs. norepinephrine and 0.7 μM vs. serotonin.

Considering the diverse biochemical and behavioral actions of AMPZ, it was of interest to determine the acute electrophysiological effects of AMPZ on noradrenergic and serotonergic neuronal activity. Neurons were recorded with a single-barreled electrode and observed during intravenous (lateral tail vein) or intraperitoneal administration of increasing doses of AMPZ. Intravenous administration of low doses of AMPZ (0.5 mg base/ml saline) resulted in a rapid acceleration of locus coeruleus (LC) neuronal activity. Cumulative doses of AMPZ up to 0.6 mg/kg produced increases in activity from 218 to 313% of predrug activity in all cells tested. Additional doses of AMPZ, up to 1.4 mg/kg, caused only minimal increases (approximately 20%) in LC firing rate. Intraperitoneal administration of AMPZ (10 mg/kg) caused a rapid reduction in serotonergic neuronal activity in the dorsal raphe nucleus. Neuronal firing rate was reduced to about 30% of baseline activity 8-9 minutes post-injection. By 25 minutes after the i.p. injection neuronal activity had usually dropped to less than 10% of baseline activity. In view of the behavioral, biochemical and electrophysiological actions of AMPZ, it seems likely that interactions with serotonergic and noradrenergic systems play an important role in its mechanism of action.

60.8 BUPROPION (WELLBUTRIN®) INHIBITS THE FIRING RATES OF NORADRENERGIC BUT NOT SEROTONERGIC NEURONS. V.K. Shea* and C.M. Wang* (SPON: J. L. Howard), Dept. of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Bupropion is a clinically effective antidepressant with novel neurochemical and neuropharmacological properties. While active in animal antidepressant models (ED_{50} ≈ 10 mg/kg i.p.), bupropion fails to inhibit monoamine oxidase and, compared to tricyclic antidepressants, is a weak inhibitor of norepinephrine (NE) uptake and a very weak inhibitor of serotonin (5-HT) uptake in vitro. Bupropion also weakly inhibits the uptake of dopamine (DA) in vitro and also in vivo at high doses (ID_{50} ≈ 45 mg/kg i.p.). Consistent with this weak inhibition of DA uptake, bupropion was found to suppress the firing rates of DA neurons at high doses (ID_{50} ≈ 45 mg/kg i.p.)(Shea and Wang, Neurosci. Abst., 1984).

Since tricyclic antidepressants and MAO inhibitors typically suppress the firing rates of 5-HT and/or NE neurons, we examined the effects of bupropion on 5-HT neurons in the dorsal raphe nucleus and on NE neurons in the locus coeruleus in the chloral hydrate anesthetized rat by conventional extracellular recording techniques.

Injection of bupropion did not alter the firing rates of 5-HT neurons up to a total cumulative dose of 12 mg/kg i.v., or when administered i.p. at a dose of 25 mg/kg. However, the firing rates of NE neurons were consistently suppressed by bupropion with an ID_{50} of about 4 mg/kg by the i.v. route. By the i.p. route, bupropion suppressed the firing rates of NE neurons in a dose-dependent manner with an ID_{50} of approximately 14 mg/kg. Suppression of NE neuronal firing rates by bupropion was rapidly reversed by yohimbine (0.25 - 1.0 mg/kg i.v.).

It is unlikely that bupropion's ability to suppress NE neuronal firing rates is secondary to inhibition of NE uptake because bupropion only weakly inhibits NE uptake in vitro and only slightly inhibits NE uptake at doses of 100 mg/kg i.p. in vivo (Ferris et al., J. Clin. Psychiat. 44:74-78, 1983). While bupropion's ability to suppress NE neuronal firing rates cannot be attributed to inhibition of NE uptake or MAO inhibition, the fact that suppression of NE firing rate occurred with a potency by the i.p. route comparable to bupropion's antidepressant potency suggests an unusual noradrenergic link in its antidepressant activity.

60.9 DISSOCIATION OF BEHAVIORAL AND BIOCHEMICAL INDICES OF CORTICAL $5HT_2$ RECEPTOR SENSITIVITY AFTER CONTINUOUS GEPIRONE (BMY 13805) TREATMENT. A.S. Eison and F.D. Yocca. Preclinical CNS Research, Pharmaceutical Research and Development Division of the Bristol-Myers Company, Evansville, IN, 47721.

Gepirone, known chemically as 4,4-dimethyl-1-[4-[4-(2-pyrimidinyl)-1-piperazinyl]butyl]-2,6-piperidinedione hydrochloride (BMY 13805) is a novel nonbenzodiazepine compound with activity suggestive of anxiolytic potential. Recent behavioral and electrophysiological studies have demonstrated that, acutely, gepirone interacts with brain serotonin systems. Gepirone induces a behavioral serotonin syndrome in rats and the drug's anticonflict activity is significantly attenuated in rats depleted of serotonin by the neurotoxin 5,7-dihydroxytryptamine (Eison et al., Soc. Neurosci. Abs. 9:436, 1983). Systemic administration of gepirone potently inhibits the activity of serotonin-containing dorsal raphe neurons (Eison et al., Soc. Neurosci. Abs. 10:259, 1984).

In addition to acute effects consistent with an anxiolytic preclinical profile, gepirone administered chronically induces behavioral and neurochemical alterations common to clinically-effective antidepressants. Both chronic (oral) and continuous (subcutaneous) administration of gepirone for 28 days decreased rat cortical $5HT_2$ receptors (Bmax) and reduced the frequency of head shakes induced by the serotonin agonist, quipazine (Eison et al., 1984; Eison and Yocca, Eur. J. Pharmacol., 1985, in press). Chronic administration of antidepressant drugs, which reduce the number of cortical $5HT_2$ receptors, also reduce the head shake response associated with $5HT_2$ receptors (Lucki et al., Soc. Neurosci. Abs. 10: 1067, 1984).

In the present study, the time course for gepirone's effects upon behavioral and biochemical reflections of cortical $5HT_2$ receptor sensitivity were examined following continuous treatment in the rat. Gepirone was administered via continuous pumping systems (Alzet minipumps) implanted subcutaneously to deliver a daily dose of 40 mg/kg. Minipumps were removed 24 hr. prior to behavioral testing with quipazine. Animals were sacrificed at the completion of behavioral testing and binding parameters were determined in cortical homogenates using [3H]-spiperone as ligand.

Following 3, 7 and 14 days of continuous administration, gepirone significantly decreased $5HT_2$ receptor density by 17%, 18% and 23%, respectively. In contrast, an enhanced behavioral response (head shakes) was observed after 3 and 7 days treatment (161% and 200% of control, respectively) with a return to control levels at 14 and 21 days. The time course of gepirone's actions will be compared to classical antidepressant agents (tricyclics and monoamine oxidase inhibitors).

F.D. Yocca is a Bristol-Myers Postdoctoral Fellow.

60.10 THE NONBENZODIAZEPINE ANTIDEPRESSANT-ANXIOLYTIC CANDIDATE, GEPIRONE, INHIBITS SEROTONERGIC DORSAL RAPHE NEURONS IN THE RAT BRAIN SLICE. G. Gehlbach and C. P. VanderMaelen, Preclinical CNS Research, Bristol-Myers Company, Evansville, IN 47721.

Preclinical testing of the nonbenzodiazepine compound, gepirone (MJ 13805, BMY 13805), indicates this compound may be potentially useful as an antidepressant-anxiolytic agent. Gepirone interacts with brain serotonin (5-HT) systems as exemplified by its ability to produce a behavioral 5-HT syndrome in rats. Its anticonflict action is reduced in animals depleted of brain 5-HT by 5,7-dihydroxytryptamine (Eison, et al., Soc. Neurosci. Abstr., 1983,9: 436). Chronic treatment of animals with gepirone down-regulates $5HT_2$ receptors (Eison and Yocca, Eur. J. Pharmacol., in press). Gepirone binds to $5HT_1$ receptors in the hippocampus with an IC_{50} of 471 nM (D.P.Taylor, personal communication). Systemic administration of gepirone inhibits the firing of 5-HT containing neurons in the dorsal raphe (DR) nucleus (Eison et al., Soc. Neurosci. Abstr., 1984, 10:259). The present study examined the effects of gepirone on the activity of these neurons in the rat brain slice.

Adult male albino Sprague-Dawley rats were anesthetized with chloral hydrate and allowed to breathe 100% O_2 for at least 5 min. Frontal sections 400 μm in thickness were cut through the DR nucleus and placed in a chamber through which 95% O_2, 5% CO_2 flowed. The slices were bathed in continuously flowing artificial CSF containing in mM: NaCl, 130; KCl, 5.0; $CaCl_2$, 1.25; $MgSO_4$, 1.25; $NaHCO_3$, 24; NaH_2PO_4, 1.25; d-glucose, 10.0. Phenylephrine (PE, 10 μm) was present to provide increased neuronal activity. Gepirone in concentrations of 50, 75, 100, 125, 200 or 400 nM was added to the bath and its effect on the firing of DR neurons observed using extracellular single unit recording techniques.

Gepirone inhibited the firing of DR neurons in a manner similar to that of 5-HT and 5-methoxy-N,N-dimethyl tryptamine. This inhibition was concentration-dependent with a calculated IC_{50} of 93.5 nM. The anxiolytic, buspirone, which is structurally related to gepirone, was 5 times more potent (IC_{50}=18.9nM) in inhibiting DR cells under similar, but not identical experimental conditions. Interestingly, buspirone is also 5 times more potent than gepirone in binding to $5HT_1$ receptors in the hippocampus (IC_{50}=95nM; Riblet et al., Psychopathology, 1984, Suppl. 3, 17:69). The fact that gepirone does not bind to α receptors combined with the observation that it inhibited spontaneously active DR neurons indicates that its inhibition of PE-activated DR cells was not simply due to antagonism of α receptors.

This study, combined with previous studies, suggests that the inhibitory effect of the antidepressant-anxiolytic candidate, gepirone, on DR neurons is due to a direct effect of this agent on these cells, and may involve an interaction with 5-HT receptors.

60.11 SYNTHESIS AND AMNESIA-REVERSAL ACTIVITY OF 1-AROYL-5-OXO-2-PYRROLIDINEPROPANOIC ACID DERIVATIVES: IDENTIFICATION OF CI-933 AS A POTENTIAL COGNITION-ACTIVATOR. D.E. Butler*, J.D. Leonard*, B.C. Caprathe*, R.E. Davis, J.G. Marriott, and F.M. Hershenson (Spon: R. Marriott). Depts. of Chemistry and Pharmacology, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

A number of simple pyrrolidone derivatives, including piracetam, aniracetam, and pramiracetam, have been reported to reverse ECS-induced amnesia in rodents, as well as exhibiting cognition-activating properties in other animal models. CI-911, 1, a pyrrolizinedione, was also recently identified to possess these biological features. It has also been discovered that CI-911 undergoes a rapid conversion in vivo to 5-oxo-2-pyrrolidinepropanoic acid, 2. As a result of this finding, the preparation of additional analogs of 2 was undertaken. Three structural variations were examined (see 3): (1) changes in the substituent, R, of the aroyl group on the pyrrolidine ring nitrogen, (2) alteration of the length (h) of the alkyl side-chain bearing the carboxylic acid, and (3) derivatization of the carboxylic acid moiety. These compounds were tested for their ability to reverse ECS-induced amnesia in mice and rats trained on a one-trial, inhibitory avoidance task. From these series, CI-933, 4, was found to exhibit the best profile of amnesia-reversal activity in mice and rats. On the basis of these results, CI-933 was selected for additional preclinical studies, and is currently in Phase 1 safety and tolerance trials in humans as a potential treatment of cognitive disorders.

60.12 ENHANCEMENT OF DELAYED-ALTERNATION PERFORMANCE IN RAT AND DELAYED-RESPONSE PERFORMANCE IN RHESUS MONKEY BY CI-933. J.G. Marriott, R.E. Davis, R.E. Voigtman*, and T. Tew*. Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

CI-933, (1-(4-methoxybenzoyl)-5-oxo-2-pyrrolidinepropanoic acid), was initially found to have potential cognition-activating properties in tests measuring reversal of ECS-induced amnesia in mice and rats. CI-933 administered over a broad dose range reversed the transient amnesia seen in this model of impaired memory. Additional studies were undertaken to determine if CI-933 would also improve performance in animal models of normal and impaired short-term memory (STM).

CI-933 was first tested for effects upon STM using an operant, delayed-alternation task in well-trained, drug-sophisticated Long-Evans rats. These discrete trial, correctional procedures required the animals to remember from one trial to the next which of two levers was correct. The correct response was always the opposite (or alternate) of that chosen on the previous trial. Groups of rats were tested twice a week under either drug or control conditions. CI-933 (0.1 to 32 mg/kg PO) was administered 30 min prior to the start of a 100 min test session.

Additional tests for effects upon STM were conducted using an automated delayed response task in young and old rhesus monkeys. In these procedures, recall of the spatial position of a stimulus within a 3 x 3 matrix is tested following retention intervals of various lengths. Animals were tested twice a week, once under control conditions and once 30 min following drug administration (0.32 to 10 mg/kg PO).

In the rat delayed-alternation task, CI-933 produced small, statistically significant improvements in performance at doses above 0.32 mg/kg in several replications of this test. This improvement was not related to the length of the retention interval. Similarly, CI-933 improved performance on the delay-response of both aged rhesus monkeys and poor performing adult monkeys. This improvement was most evident when no delay was interposed between the presentation of the correct stimulus and the opportunity to respond. On trials with retention intervals interposed, CI-933 produced only minimal improvement over control levels of performance.

Taken together, these results indicate that CI-933 has performance-enhancing effects in these tasks that do not appear to be due to direct effects upon short-term memory. Based on these findings, CI-933 may be useful in the treatment of human cognitive declines related to attentional, motivational, and/or learning disorders.

60.13 CI-933 REVERSES DIAZEPAM-INDUCED MEMORY IMPAIRMENTS IN YOUNG AND AGEND MONKEYS. R.E. Davis, T.F. Tew*, and J.G. Marriott, Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI 48105.

Besides their well known anxiolytic actions, certain benzodiazepines have been found to impair human memory. We have reported previously that diazepam produces a reliable short-term memory deficit in aged-rhesus monkeys performing a delayed response task. This memory impairment is similar to that produced in humans by this agent, suggesting that this may be an excellent animal model of human impaired cognition. In light of this and the finding that CI-933, 1-(4-methoxybenzyl)-5-oxo-2-pyrrolidine-propanoic acid, improves performance of monkeys in a delayed response task, CI-933 was studied for its ability to reverse diazepam-induced delayed response deficits in young and aged monkeys.

Performance on a delayed response task was measured in aged (>18 yrs old) and adult (<15 yrs old) rhesus monkeys using an automated testing apparatus. Monkeys were presented a stimulus in one of nine spatial locations in a 3 x 3 array on a CRT. Recall of the spatial position of the stimulus was tested following various retention intervals (0-30 secs). Diazepam (2.0 mg/kg, IM) or vehicle was administered 45 minutes prior to testing. Fifteen mins later CI-933 (0.32-10.0 mg/kg, PO) was administered. Monkeys were tested twice each week, once under drug and once as a control day.

Diazepam significantly decreased performance across all intervals tested in young and aged monkeys. CI-933 did not reverse the diazepam-induced deficits on nondelay trials. However, CI-933 significantly reversed this deficit on all delay trials in both age groups.

These data demonstrate that CI-933 antagonizes the memory impairing effects of diazepam. This occurs despite the fact that CI-933 does not interact with any known receptor including benzodiazepine receptors. Thus, CI-933 appears to antagonize the effects of diazepam through a novel mechanism. To the extent that diazepam induced memory impairments serve as a model of human cognitive dysfunction, these data suggest that CI-933 may be useful in treating congitive dysfunction in humans.

60.14 CI-933 REVERSES THE ANTINEOPHOBIC ACTIVITY BUT NOT THE SURVIVAL TIME ENHANCING PROPERTIES OF DIAZEPAM. R.E. Voigtman*, M. Smith*, R.E. Davis and J.G. Marriott (Spon: E. Gamzu). Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI. 48105.

CI-933, 1-(4-methoxybenzoyl)-5-oxo-2-pyrrolidine propanoic acid, possesses a broad spectrum of activity in animal models of cognition. Among its many behavioral properties, CI-933 antagonizes the ability of diazepam to impair short-term memory. It is not known whether this effect of CI-933 is selective for the memory-impairing effects of diazepam or is reflective of a general ability to antagonize most actions of benzodiazepines. To examine this question, CI-933 was tested for its ability to block the antineophobic and survival time increasing actions of diazepam.

CI-933 (0.32 - 100.0 mg/kg, PO) was tested in rats alone or in combination with diazepam (3.2 mg/kg, IP) or vehicle for effects on consumption of a novel milk solution in a novel environment. Diazepam, vehicle or CI-933 was administered 30 mins prior to testing and 15 mins before CI-933 or vehicle. Milk consumption was measured at 1/2 hr intervals for the next 2 hrs. Diazepam increases milk consumption in this model.

For survival time testing mice received diazepam (3.2 mg/kg, PO) 45 mins prior to testing. Fifteen mins later CI-933 (0.32-100.0 mg/kg, PO) or vehicle were given. At the time of testing, core body temperature was measured and the animals were immediately placed into a glass chamber containing 4.1% oxygen and 95.9% nitrogen. Time to respiratory arrest was measured for each animal. Diazepam increases survival time under these conditions.

CI-933 antagonized the ability of diazepam to increase milk consumption in a novel environment while having no effect when given alone. In contrast, CI-933 did not antagonize diazepam-induced body temperature decreases or survival time increases.

Insofar as antineophobic activity of diazepam in animals is related to its anxiolytic activity in man, these data suggest that CI-933 may block the therapeutic effects of benzodiazepines. Taken together with previous findings, these data indicate that CI-933 may possess a generalized ability to antagonize most effects of diazepam. The exception to this is that CI-933 did not block diazepam induced changes in survival time or body temperature. However, it should be noted that benzodiazepine antagonists such as BCEE and Ro 15-1788 also do not block these effects of diazepam.

60.15 THE EFFECTS OF CI-933 UPON ACQUISITION OF A WATER MAZE TASK IN INBRED MICE. J.P. Symons*, R.E. Davis, J. Kalanik*, and J.G. Marriott (Spon: F. Gullotta). Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI 48105.

CI-933 (1-(4-methoxybenzoyl)-5-oxo-2-pyrrolidinepropanoic acid) has been shown to reverse ECS-induced amnesia in rats and mice, enhance delayed response performance in young and aged monkeys and reverse diazepam-induced memory deficits in young and aged monkeys. The mechanisms responsible for these actions of CI-933 are not known. However, these studies suggested CI-933 influenced performance by altering non-mnemonic processes such as attention or motivation. If this is the case, then performance on a task requiring animals to attend to distal spatial cues might also be enhanced by administration of CI-933. This hypothesis was tested using a swim maze, a task in which an animal is required to locate the position of a hidden platform using spatial cues.

Inbred C57BL/10 mice, a strain deficient in the number of pyramidal cells of the hippocampus (Wimer, et al, 1980) and impaired in swim maze acquisition (Symons, et al, 1985), were trained and tested over two consecutive days. CI-933 (0.0, 0.1, 0.32, 1.0, 3.2, 10.0, 100.0 mg/kg, PO) was administered 30 mins prior to testing. Mice were given four trials in the maze each day. A trial consisted of placing the animal in one of the four corners of the pool and recording latency to locate the submerged platform (maximum of 2 min per trial). Results indicated that low doses of CI-933 enhanced acquisition and/or retention of this task. With doses levels less than 3.2 mg/kg there were significantly more trials in which the platform was located within the first 15 sec of each trial when compared to the higher dose levels and vehicle control.

CI-933 improved performance in hippocampally deficient mice on the spatial swim maze task. Taken together with previous results, these data support the hypothesis that CI-933 enhances performance by altering non-mnemonic processes such as attention or motivation.

60.16 ELECTROPHYSIOLOGICAL EFFECTS OF CI-933 IN THE AGED RAT. J. French, J.J. Kinsora*, M.E. Smith*, and J.G. Marriott, Warner-Lambert/ Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

CI-933, 1-(4-methoxybenzoyl)-5-oxo-2-pyrrolidine-propanoic acid, has been shown to enhance performance of learned behaviors in many animal models of cognition. The EEG changes produced by CI-933 in aged rats were studied to identify changes in the brain which might (1) correlate with the bioavailability of CI-933 and/or (2) suggest possible mechanisms underlying the performance-enhancing properties of CI-933.

Bipolar electrodes were implanted in the cortex and hippocampus of aged Fisher-344 rats (>24 months) since increased arousal or attention is often correlated with changes in electrical activity in these areas of brain. A computerized system for conducting power spectral density analyses of the EEG below a Nyquist frequency of 40 Hz was used to evaluate 6 rats over a 2 hr period. Rats were tested twice a week using a crossover design to test each dose of CI-933 and vehicle control once in every animal. CI-933 was administered 5 min prior to beginning the test session.

Oral doses of CI-933 increased the power seen in hippocampal 4-6 Hz theta and 16-40 Hz beta activities. Increases in beta activity (centered at 19 Hz) occurred at several doses, beginning immediately after dosing and becoming maximal after 60 minutes (68% increase over control levels at the most effective dose). A second peak in the 16-40 Hz activity occurred 95 minutes after dosing. Cortical changes consisted of increases in the 6-8 Hz band.

The most prominent electrophysiological effect of CI-933 was to increase hippocampal beta activity during the first two hours after dosing. Similar increases in hippocampal beta activity can be elicited by direct electrical stimulation of the brainstem reticular activating system. Taken together, these results suggest CI-933 may produce its effects on hippocampal beta by activation of brainstem mechanisms. Further, the unique performance-enhancing effects of CI-933 may be due to direct effects of this compound upon the brainstem reticular formation, which in turn have diffuse effects upon the hippocampus and cortex. The unique behavioral and EEG profiles of CI-933 in animal models and the absence of any side effects over a wide range of doses, support its use in clinical populations with arousal-related performance deficits.

60.17 **CI-933 INCREASES BRAIN FUNCTIONAL ACTIVITY IN DISCRETE BRAIN REGIONS.** H.E. Gompers*, R.E. Davis and J.G. Marriott (Spon: R. Richardson). Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI. 48105.

CI-933, 1-(4-methoxybenzoyl)-5-oxo-2-pyrrolidinepropanoic acid, has been shown to broadly affect cognitive performance in animals. This agent reverses ECS-induced amnesia in rodents, improves delayed response performance and reverses diazepam-induced memory impairments in monkeys. As part of a series of experiments to determine possible sites of action and mechanisms mediating these cognition enhancing effects of CI-933, we studied the ability of this agent to modulate functional activity of discrete brain regions as estimated by 2-deoxyglucose utilization. This technique was chosen since glucose utilization in the brain is sensitive to procedures and drugs which modulate cognitive performance in man and other animals.

Male albino rats were food deprived 24 hrs prior to initiation of the experiment. CI-933 (0.0, 1.0, 3.2 and 10 mg/kg PO) was administered 15 minutes before tail vein injection of [3H]- or [14C]-2-deoxyglucose (200 uCi/kg). Forty-five mins later these animals were decapitated and their brains were frozen in dry ice and prepared for apposition to LKB-ultrafilm or Kodak x-ray film. Brains were analyzed using videocapture microdensitometry.

CI-933 globally increased functional activity at all doses tested. In addition there were dose related increases in functional activity in most cortical areas and in regions receiving reticular formation input including most thalamic structures, the inferior colliculi and the dorsal but not ventral cochlear nuclei.

These data demonstrate that at behaviorally active doses, CI-933 increases functional activity in brain regions thought to be involved in cognitive performance. Among the most interesting are those seen in the inferior colliculi and the dorsal cochlear nuclei. Changes similar to these in magnitude and pattern are seen after strong electrical stimulation of dorsal reticular sites which also produces intense arousal or orienting reactions. This similarity suggests that CI-933 may influence behavior by driving reticular structures. This interpretation is consistent with studies indicating that CI-933 drives hippocampal EEG activity in the beta bandwidth and increases behavioral arousal or attention.

60.18 NEUROCHEMICAL ASPECTS OF CI-933: A NOVEL PERFORMANCE ENHANCING AGENT. R. D. Schwarz, T. A. Pugsley*, L. L. Coughenour* and S. F. Stewart*. Warner-Lambert/Parke-Davis Pharm. Research, Ann Arbor, MI 48105.

Alzheimer's disease, and other age-related disorders which show marked declines in cognitive function, are being diagnosed with greater frequency as the age of the general population increases. At present, no therapy exists which effectively treats this decline in mental ability. As part of an ongoing program to develop new therapeutic agents to treat cognitive dysfunction, a behavioral testing strategy has identified 1- 4-methoxybenzoyl)-5-oxo-2-pyrrolidinepropanoic acid CI-933) as an agent which enhances performance in certain animal models of cognition.

CI-933 was studied in a variety of biochemical assays in order to gain an understanding of its mechanism of action. There was no in vitro binding of CI-933 to any of the various receptors examined: adenosine A1 and A2, alpha and beta adrenergic, benzodiazepine, Ca^{++}, dopamine, glutamate, muscarinic or serotonin receptors. Brain monoamine functions have been shown to be involved in learning and memory. In examining monoamine metabolism CI-933 10 and 30 mg/kg) elevated DOPAC levels in rat mesolimbic, but not striatal areas. Serotonin metabolism was unaffected. Since a profound loss of short-term memory has been associated with a cholinergic deficit, CI-933 was tested for effects on cholinergic function. It failed to affect either spontaneous or K^+-stimulated release of ^{3}H-ACh from rat brain slices, did not alter in vitro Na^+-dependent high affinity choline uptake into hippocampal synaptosomes following in vivo administration, or alter choline acetyltransferase in vitro. A third neuronal system believed to impact short-term memory involves glutamate/aspartate asp) neurotransmission. CI-933 was found to decrease the Ca^{++}-dependent, K^+-stimulated release of ^{3}H-D-asp from rat hippocampal slices. This effect is similar to that of muscarinic agonists and certain other agents which positively improve cognitive function in rodent models. Since CI-933 appeared to antagonize some of the behavioral effects of diazepam, a biochemical correlate to this activity was examined. Like the known benzodiazepine antagonist, RO15-1788, CI-933 was able to inhibit the diazepam blockade of the chlorpromazine-induced rise in HVA and serum prolactin levels. Thus, CI-933 blocks certain effects of diazepam, while exhibiting no in vitro or in vivo affinity for rat brain benzodiazepine receptors.

In summary, CI-933 appears to be a novel agent which may show behavioral activity by one or more mechanisms. In addition to effects on neurotransmission mediated by monoamines and excitatory amino acids, it represents a unique compound in its ability to reverse the action of diazepam while not binding to the benzodiazepine receptor site.

60.19 PHARMACOKINETICS AND BIOAVAILABILITY OF CI-933, A NEW COGNITION ACTIVATOR, IN LABORATORY ANIMALS. A. Black and T. Chang (SPON: D. Lobstein). Warner-Lambert/Parke-Davis, Ann Arbor, MI. 48105.

CI-933 (I), 1-(4-methoxybenzoyl)-5-oxo-2-pyrrolidinepropanoic acid, is a new cognition activator currently undergoing phase I clinical evaluation. The pharmacokinetics and bioavailability of I were determined in beagle dogs and Wistar rats following 10 mg/kg intravenous and oral doses. A rapid and selective HPLC assay was develop for quantitation in plasma in which I and the internal standard (PD-116,312) are extracted from acidified plasma with methylene chloride. Separation was achieved on a Lichrosorb RP-8 column (5 micron; 250 x 4 mm) with a mobile phase of 0.0087M tetrabutylammonium sulfate in 0.05M phosphate buffer (pH 7.1):acetonitrile (75:25) at flow rate of 1 ml/min. Calibration curves are linear from 0.1 to 5 mcg/ml of plasma. Assay precision ranges from 0.7-5.6% (within-day) to 1.1-5.2% (between-day). Accuracy was determined by replicate analysis of spiked control plasma at low, medium, and high concentrations. The measured values differed from theoretical by 2.5% or less.

Following intravenous dosing, plasma concentrations of I declined monoexponentially. The kinetic parameters were: $t_{\frac{1}{2}}$, 0.45 and 0.35 hr, total plasma clearance, 9.7 and 8.5 ml/min/kg, and volume of distribution, 0.36 and 0.26 1/kg for dogs and rats, respectively.

Oral absorption of I was rapid with peak plasma concentrations being attained in 0.25-1 hr after dosing. The absolute systemic oral bioavailability was 82% in dogs and 72% in rats. Repeated oral administration (10 mg/kg/day) for 5 days resulted in no drug accumulation or evidence of autoinduction.

60.20 NEURAL ACTIVITY AND MYO-INOSITOL-1-PHOSPHATE LEVELS IN HIPPOCAMPAL SLICES EXPOSED TO LITHIUM AND A CHOLINESTERASE INHIBITOR. Rinaldi, P.C., Fairchild, M.D.*, Jenden, D.J. & Wasterlain, C.G.*, Neurosurgery Div., UCIrvine, 92717; Neurology Dept., V.A.Med.Ctr., Sulpulveda & Pharmacology Dept.,UCLA.

Lithium (Li) has been shown to stimulate cholinergic activity and alter D-myo-inositol-1-phosphate (MIP) levels in the CNS. This interaction in brain with inositol levels and associated modulation of receptor sensitivity may be part of the mechanism through which Li exerts its therapeutic effects. In addition, MIP levels were increased, behavioral seizures produced and limbic, cortical and thalamic morphological changes observed when Li treated rats were challenged with a cholinesterase inhibitor. We have begun investigations to determine whether these results can be studied in the in vitro hippocampal preparation.

In the present work extracellular field potentials and MIP levels have been studied in perfused hippocampal slices in response to LiCl substituted for NaCl in perfusion media and acetylcholinesterase inhibition following addition of edrophonium HCl to the media. Studies were conducted in the CA3 region which has been shown to be susceptible to epileptiform activity. A fast-slow (FS) potential reflecting both antidromic discharge and orthodromic synaptic activation of pyramidal cells was recorded in s.pyramidale in CA3 following fimbria stimulation. A portion of the FS complex is expected to represent activation of cholinergic elements since the septal-hippocampal pathway projects via the fimbria and innervates CA3.

Initially we determined that combined Li/edrophonium perfusion produced sustained paroxysmal bursting in CA3. Li alone (10 mM) would only occasionally produce such activity. Experiments have now been conducted in 51 hippocampal slices. After stabilization in normal media, slices were perfused for 30 min. in media with 10 mM LiCl or 150 μM edrophonium HCl or both. In several experiments atropine methylbromide (10 μM) was added to the Li/edrophonium combination. The FS potential was recorded during perfusion. At the end of perfusion, slices were collected for extraction and MIP levels for each slice were analyzed by GC-MS techniques.

The results (in μM/mg protein) indicated that neither Li ($\bar{x}$=0.116 ±0.015) nor edrophonium ($\bar{x}$=0.145 ±0.019) had a significant effect on MIP levels over control values ($\bar{x}$=0.102 ±0.017) while the combined perfusion of these two agents resulted in a substantial increase ($\bar{x}$=0.464 ±0.077). Neither Li nor edrophonium perfusion reliably produced abnormal neural activity. However, during combined administration spontaneous epileptiform discharges were observed and fimbria stimulation produced a sustained and recurring afterdischarge. The addition of atropine to the Li/edrophonium combination modified MIP levels ($\bar{x}$=0.311 ±0.035) but did not totally block the increase.

60.21 SULFONYL FLUORIDES: A STRUCTURE/ACTIVITY STUDY AS CNS SELECTIVE CHOLINESTERASE INHIBITORS. L.A. Rodriguez*, D.E. Moss and M.L. Camarena*. Psychobiochemistry Laboratory, Department of Psychology, University of Texas at El Paso, El Paso, Texas 79968.

A decline in CNS cholinergic function appears to be correlated with dementia in several disorders including senile dementia of the Alzheimer type (e.g., Whitehouse et al., Science 15, 1237-1239, 1982), Parkinson's disease (Nakano and Hirano, Ann. Neurol. 15, 415-418, 1984), and parkinsonism-dementia complex of Guam (Nakano and Hirano, Ann. Neurol. 13, 87-91, 1983). Because of this, there has been interest in enhancing CNS cholinergic function but these attempts have been limited by the peripheral toxicity of drugs that are not CNS selective. As one possible solution to this problem, a device for intracranial infusion of cholinergic drugs was tested in Alzheimer's disease (Harbaugh et al., Neurosurgery 15, 514-518, 1984). A more satisfactory approach to the problem of enhancing CNS cholinergic function without unacceptable levels of peripheral toxicity is to develop CNS selective drugs. Moss et al. (In: Senile Dementia of the Alzheimer Type, J.T. Hutton and A.D. Kenny (Eds.), Alan Liss, New York, 1985, in press) reported that certain sulfonyl fluorides show a high degree of selectivity as CNS cholinesterase inhibitors as compared to enzyme from several peripheral tissues. In fact, under certain circumstances, up to 90% inhibition of CNS cholinesterase could be inhibited with 30% or less inhibition of peripheral enzyme. In addition, some representatives of these compounds were relatively free from effects on extrapyramidal motor behaviors as compared with physostigmine (Moss, Rodriguez and McMaster, Pharm. Biochem. Behav. 22, 479-482, 1985).

In view of the potential therapeutic applications for CNS selective cholinesterase inhibitors, an additional 33 sulfonyl fluorides of widely varying structure were screened for reactivity against CNS and peripheral cholinesterases in vivo in rats. The tissues assayed included the forebrain, ileum, skeletal muscle and heart. The results showed that all of the larger molecular weight compounds and those with two or more rings were without effect at the standard test dose of 0.575 mmole/kg). Of all of the compounds tested, only 5 have shown significant activity against CNS enzyme as compared to peripheral enzyme. There was no clear structure/activity relationship observed by comparison of the various compounds. The mechanism responsible for inducing CNS selectivity is currently obscure.

Supported in part by NIMH and the MBRS Program of NIH (Grant No. RR08012), Alzheimer's Disease and Related Disorders Association (El Paso Chapter), and a gift from the Moss family.

CARDIOVASCULAR REGULATION

61.1 AUTORADIOGRAPHIC LOCALIZATION OF ATRIAL NATRIURETRIC FACTOR BINDING SITES IN THE PERIPHERY AND CENTRAL NERVOUS SYSTEM OF THE RAT AND GUINEA PIG. C.R. Mantyh*, N.C. Brecha, L. Kruger, and P.W. Mantyh Center for Ulcer Research and Education, VA Wadsworth, Bldg. 115, Room 217, L.A., CA., 90073 and Brain Research Institute, UCLA, L.A., CA., 90024

Specific high affinity atrial natriuretic factor (ANF) binding sites are localized and quantified in 20um cryostat sections of the nervous system and periphery of rats and guinea pigs using autoradiographic techniques and the radioligand ^{125}I-ANF$_{1-28}$ (Amersham). Specific binding is defined as that binding that was displaced in the presence of 1uM of ANF$_{1-28}$, but not by unrelated peptides, and is greater than 75% of the total binding.

In the periphery, the highest concentration of specific ANF binding sites is observed in the glomerular apparatus, collecting tubules, and small arteries of the kidney, the zona glomerulosa of the adrenal cortex, the smooth muscle of the aorta and gall bladder, the epithelium of the lung, the posterior lobe of the pituitary and the ciliary body of the eye.

ANF receptor binding sites in the brain are present in several neuroendocrine and circumventricular structures including the pituitary stalk and caudal neurohypophysis, subfornical organ, and in the subcommisural organ, pineal, medial habenular nucleus and the preoptic region of the organum vasculosum of the lamina terminalis. Within the brain one of the highest concentrations of receptors is present in the dendritic field of the olfactory bulb mitral cells extending along the entire axonal extent of the olfactory tracts but fails to penetrate the neuropil of the primary olfactory tract. The fasciculus retroflexus and its diencephalic terminations also reveal a moderate concentration of binding sites. A high concentration of binding sites is also present in the chorioid plexus epithelium, whereas the ependymal lining of the ventricles has a negligible concentration of binding sites. The leptomeningeal margins and expanded subarachnoid spaces also reveal a high concentration of binding sites.

Species differences are significant only in the presence of extensive ANF binding sites in the neuropil of the cerebellar cortex of guinea pigs but not in rat. The distribution of specific ^{125}I-ANF$_{1-28}$ binding sites is consistent with earlier physiological and pharmacological studies which suggest that ANF plays a functional role in the regulation of extracellular fluid volume, electrolyte concentration and blood pressure.

61.2 SUBDURAL INJECTION OF A SUBSTANCE P ANTIBODY ATTENUATES THE REFLEX PRESSOR RESPONSE TO STATIC MUSCULAR CONTRACTION. K.J. Rybicki*, G.P. Kozlowski*, and M.P. Kaufman* (Spon: G.A. Iwamoto). Dept. of Physiol., Univ. of Texas Health Science Center, Dallas, Texas 75235.

Static contraction of hindlimb muscles has been firmly established to reflexly increase mean arterial pressure, an effect initiated by the stimulation of group III and IV afferents. Although the specific neurotransmitters or neuromodulators released by these muscle afferents are not known, substance P is one candidate. Therefore, in chloralose anesthetized cats, we have examined the effect of injecting subdurally a substance P antibody on the reflex pressor responses to static contraction of the triceps surae muscles. This antibody was found not to cross-react (less than 0.01%) with neurotensin, met-enkephalinamide, or somatostatin. Before injection of the antibody, static contraction, induced by stimulating the tibial nerve (40 Hz; 2 times motor threshold), increased mean arterial pressure by 28±2 mmHg (n=6 cats). After injection of the substance P antibody, via a cannula whose tip was located at the entry point into the spinal cord of the L_7 and S_1 dorsal roots, contraction increased arterial pressure by 11±2 mmHg. Injections of equal volumes of normal rabbit serum, the vehicle containing the antibody, had no effect on the pressor response to contraction. In 2 cats, the pressor response to electrical stimulation of the posterior hypothalamic area was not decreased by injection of the substance P antibody, suggesting that the antibody was not directly inhibiting sympathetic outflow. Last, after waiting about 60 minutes or opening the dura and washing out the cerebral spinal fluid, the pressor response to contraction returned towards its pre-injection level (17±3 mmHg). Our results are consistent with the hypothesis that substance P functions as a neuromodulator in mediating the reflex cardiovascular responses to static muscular contraction. (Supported by HL06296 and HL30710.)

61.3 LHRH ANALOGUE ACTS AS SUBSTANCE P ANTAGONIST BY INHIBITING SPINAL CORD VASOMOTOR RESPONSES. Y. Takano*, W.B. Sawyer*, N.L. Sanders* and A.D. Loewy. Dept. Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Intrathecal injections of the LHRH analogue - D-pGlu^1, D-Phe^2, D-Trp^{3,6} LHRH caused dose-dependent decreases in mean arterial blood pressure in anesthetized rats similar to those seen with the substance P analogue D-Pro^4, D-Trp^{7,9}-substance P(4-11). Similarly, intrathecal injections of either peptide reversed the hypertension elicited by application of kainic acid on the ventral surface of the medulla oblongata. Both analogues had similar I.C.$_{50}$ values ($\sim 10^{-5}$M) for inhibition of specific [^{3}H]-substance P binding in tissue sections through the region of the intermediolateral cell column. LHRH had no effect on [^{3}H]-substance P binding in sections of rat spinal cord. Furthermore, no specific [^{3}H]-LHRH binding sites could be demonstrated in the spinal cord.

The LHRH analogue failed to block substance P-induced contractions of the isolated guinea pig ileum and did not affect tail-flick withdrawal time in a thermal nociceptive test, whereas the substance P analogue acted as an antagonist in both of these bioassays.

In conclusion, these results suggest that D-pGlu^1, D-Phe^2, D-Trp^{3,6} LHRH may act as an antagonist which can inhibit the sympathetic vasomotor outflow and potentially by a relatively specific substance P-physalaemin (SP-P) receptor antagonist in the central nervous system but without effect on peripheral SP-P receptors.

61.4 SINGLE NEURONS IN NUCLEUS TRACTUS SOLITARIUS PROCESS CONVERGENT AFFERENT INPUT FROM CARDIAC VAGUS, CAROTID SINUS AND RENAL NERVES. R.B. Felder, Department of Internal Medicine and Cardiovascular Center, University of Iowa, Iowa City, Iowa 52242.

Afferent nerves carrying cardiovascular sensory information from cardiac, aortic and carotid sinus receptors terminate centrally in the nucleus of the tractus solitarius (NTS). Renal afferent nerves have also been shown to influence neurons in the vicinity of NTS. Stimulation of sensory receptors in each of these regions can reflexly modify arterial pressure and heart rate, and a number of central interactions among these receptor groups have been described. Recent single unit recording studies have suggested that neurons in the NTS may integrate multiple sensory inputs rather than simply transmitting unaltered sensory signals to other centers involved in cardiovascular reflex regulation. In the present experiments, the influences of the cardiac branch of the right vagus nerve (CBVN), the right carotid sinus nerve (CSN) and the right renal nerve (RN) on NTS neurons were examined. In 5 alpha-chloralose anesthetized, paralyzed and artificially ventillated cats, microelectrode recordings were obtained from 11 single units in NTS excited by stimulation of CBVN. Peak response latencies to electrical stimulation of CBVN ranged from 9-64 msec. Seven of these units were also evoked by electrical stimulation of CSN at peak response latencies ranging from 5-51 msec. Two units evoked by both CBVN and CSN were also excited by stimulation of RN at peak response latencies of 33 and 39 msec. Recording sites marked by iontophoresis of Pontamine Blue were recovered histologically for 6 units, 3 of which had combined CBVN and CSN input. All were medial to tractus solitarius with 5 in dorsomedial or commissural subnuclei and 1 ventromedial to tractus. These results suggest that single neurons in medial NTS may integrate afferent signals from cardiopulmonary, carotid sinus and renal sensory receptors.

61.5 CENTRAL EFFECTS OF ADENOSINE AND ITS ANALOGS ON BLOOD PRESSURE AND HEART RATE IN THE RAT. E.P. Schoener, W. Richard Campbell*, R.A. Barraco and D.R. Marcantonio*. Departments of Physiology and Pharmacology, Wayne State University Medical School, Detroit, Michigan 48201.

Adenosine (ADO), its precursors and the enzymes involved in both its synthesis and degradation are ubiquitous to neural and other tissues. In the CNS, ADO and its analogs exert potent depressant effects on neural firing at many levels of the neural axis. ADO is released from neurons and synaptosomes following electrical stimulation and the notion that ADO acts as a synaptic modulator in the CNS is supported by demonstrations of its inhibitory effects on the presynaptic release of a number of neurotransmitters. Perhaps the best characterized effect of ADO at the biochemical level is its capacity to modulate adenylate cyclase activity through two separate purinergic receptors, A_1 and A_2. Male Sprague-Dawley rats with chronic indwelling cannulae were injected in the lateral cerebral ventricle with two adenosine analogs and their effects on blood pressure and heart rate were examined. NECA (5'-N-ethyl-carboxamidoadenosine) and L-PIA(L-phenyl-isopropyladenosine) produced dose-related reductions in blood pressure and heart rate. NECA exerted slighly more potent hypotensive action while L-PIA was more potent in depressing heart rate. These effects were antagonized by intraperitoneal injections of caffeine. In other experiments using the technique of push-pull perfusion, the nucleus tractus solitarius and adjacent brainstem regions were unilaterally perfused with adenosine or NECA. ADO produced diphasic effects in blood pressure, producing increases at nanomolar concentrations and decreases in micromolar concentrations. NECA, and A_2 specific agonist, produced mostly decreases in blood pressure. These studies on the central effects of ADO analogs on blood pressure and heart rate and their antagonism by caffeine suggest that the CNS areas involved in the control of cardiovascular function may be under the influence of endogenously released purines. (Supported by a grant from the American Heart Association of Michigan).

61.6 TRANSIENT HYPOTENSION FOLLOWING AREA POSTREMA LESIONS IN THE RAT. Skoog, K.M. and Mangiapane, M.L. Dept. of Pharmacology, University of Rochester, Rochester, NY 14642.

The dog literature suggests that the area postrema (AP) is an important site at which circulating angiotensin II acts to regulate arterial pressure. In contrast, some investigators have suggested that the rat AP is not involved in cardiovascular responses to AII. Recently, however, Mangiapane et al. (1985) have found that ablation of the AP renders the rat unable to sustain chronic angiotensin II hypertension (although pressor responses to acute AII are unaffected). In view of the proximity of the AP to the nucleus of the solitary tract (NTS), we examined in the present study the acute and chronic effects of AP ablation on resting arterial pressure, baroreflex control of heart rate, and lability of arterial pressure. Arterial pressure was recorded and analyzed via an IBM PC-based analog-to-digital data acquisition system. Rats were first given femoral arterial and venous catheters. Two days later, arterial pressure and heart rate were recorded for one hour, immediately after which the AP was ablated under very short-acting pentothal anesthesia. Immediately after the ablation, both sham and AP-ablated rats were replaced in their cages. Pressure and heart rate were recorded for the next 12 hours, and again one hour each day for the next seven days. Although pre-lesion pressures were the same in both groups, the AP-ablated rats had significantly ($p<.001$) lower arterial pressures in the 12 hour period following the lesion, and on each of the following two days. By the third post-lesion day, there was no difference in pressures between the two groups. Ablation of the AP also produced a significant ($p<.02$) bradycardia which was present in the first 12 hours following the lesion, and also on the third post-lesion day. Group differences were greatest during the 12 hr immediately following sham or AP lesions. During this period arterial pressure of the AP lesion rats dropped 15.9 $\pm$ 2.4 mm Hg vs. a drop of 2.0 $\pm$ 1.3 mm Hg in sham lesion rats. Heart rate decreased 38.7 $\pm$ 14.6 beats per min in AP lesion rats and increased 15.8 $\pm$ 11.5 beats per min in sham lesion controls during the same period. Baroreflex control of heart rate was not impaired in AP-ablated animals, nor was lability of arterial pressure increased. These results indicate that: (1) AP ablation produces a transient hypotension; (2) in spite of the proximity of the NTS, AP ablation does not impair the baroreflex, produce increased lability of arterial pressure, or cause neurogenic hypertension. We conclude that the antihypertensive effects of the AP lesion occur without significant damage to the baroreflex function of the NTS. (Supported by NIH grant HL32981.)

61.7 MECHANISM OF THE VENTRICULAR TACHYARRHYTHMIAS THAT OCCUR AFTER TOPICAL APPLICATION OF KAINIC ACID TO THE AREA POSTREMA OF THE CAT. R.A. Gillis*, J. Dias Souza* and P.J. Gatti* (SPON: D.A. Eagles), Dept. of Pharmacol., Georgetown Univ. Schls. of Med. & Dent., Washington, DC 20007.

We recently found that the neuroexcitotoxin, kainic acid, applied topically to the area postrema of chloralose-anesthetized cats causes ventricular tachyarrhythmias (Fed. Proc. 43: 699, 1984). These arrhythmias were associated with increases in sinus rate and arterial blood pressure. The cause of the arrhythmias was not clear but may be related to constriction of the coronary arteries since Somberg (Circulation 68, Suppl. III, 31, 1983) reported that electrical stimulation of the area postrema causes an increase in coronary vascular resistance. The increase in resistance was mediated by increased sympathetic activity as it was counteracted by alpha-adrenergic blockade. To determine whether ventricular tachyarrhythmias evoked by bilateral topical application of kainic acid (40 mM) were due to coronary constriction, we monitored blood flow from the left anterior descending coronary artery of 5 anesthetized cats.

We also monitored the ECG and the arterial blood pressure. Topical application of kainic acid produced an increase in coronary vascular resistance (43 + 13%, $P < 0.05$), S-T segment changes, and ventricular tachyarrhythmias. The increase in coronary vascular resistance was noted first (at 2.5 min after drug application) followed by changes in S-T segment (at 3.4 min) and arrhythmias (at 4.1 min). All of these effects were prevented by pretreating animals with the alpha-receptor blocking agent, phentolamine (n = 4). These results suggest that chemical excitation of area postrema neurons produces arrhythmias because of coronary constriction, and that this constriction is mediated by the sympathetic nervous system and alpha-adrenergic receptors on coronary vessels.

61.8 MICROINJECTION OF VASOPRESSIN OR VASOPRESSIN ANTAGONIST INTO THE AREA POSTREMA ALTERS BAROREFLEX FUNCTION IN THE ANESTHETIZED RABBIT. E.M. Hasser*, D.O. Nelson, J.R. Haywood, K.P. Undesser*, R.J. Applegate* and V.S. Bishop. Dept. of Pharmacology, Univ. of Texas HSC, San Antonio, TX 78284.

Arginine vasopressin (AVP) has been shown to augment arterial baroreflex inhibition of renal sympathetic nerve activity (RSNA), an action which is dependent upon an intact area postrema. Low level electrical stimulation of the area postrema also appears to inhibit RSNA and to enhance baroreflex inhibitory effects. This study was designed to examine the RSNA response to small volumes of AVP microinjected directly into the area postrema and to evaluate the effects of microinjection of the V_1 AVP antagonist $d(CH_2)_5TYR(ME)AVP$ (AVPX) on the AVP augmentation of baroreflex function. Rabbits were anesthetized with urethane and instrumented with arterial and venous catheters, and recording electrodes on the renal nerve to record RSNA. The brainstem was exposed, and a glass microelectrode containing artificial CSF, AVP or AVPX was visually inserted into the area postrema. Artificial CSF or AVP (4-10 ng) in a volume of 4-10 nl was injected via a micropressure injection system, and RSNA responses monitored. Following a recovery period, increasing doses of either AVP (2-50 mU/kg/min) or phenylephrine (PE) (0.5-10 µg/kg/min) were infused intravenously for one minute at each dose, and baroreflex curves relating arterial pressure (MAP) and RSNA were constructed for both drugs. AVPX (100 ng in 10 nl) was then injected into the area postrema and infusions of AVP and PE repeated. Microinjection of AVP into the area postrema resulted in a significant inhibition of RSNA, while the same volume of artificial CSF had no effect. Intravenous administration of AVPX (10-15 µg/kg) blocked the inhibitory effects of AVP microinjected into the area postrema. Effects of AVPX injected into the area postrema on baroreflex function are shown below.

SLOPES OF MAP-RSNA RELATIONSHIP

	AVP	PE
Control	9.6±1.2	4.4±0.3
AVPX	5.3±0.7	4.3±0.3

When given intravenously the slope of the MAP-RSNA curve was significantly greater for AVP infusions than for PE. Microinjection of AVPX into the AP normalized the slope of the MAP-RSNA relationship for AVP to that of PE without altering the baroreflex response to PE infusion. Intravenous administration of the same amount of AVPX did not alter the AVP curve. Results suggest that AVP acts at the area postrema to augment baroreflex inhibition of RSNA. This effect appears to be mediated via the V_1 AVP receptor. Supported by NIH grants HL12415-15 and HL32834-01, and AHA #G-581.

61.9 CARDIOVASCULAR FUNCTION IS MARKEDLY ALTERED BY PICOMOLES OF L-GLUTAMATE INJECTED INTO RAT BRAINSTEM. D.O. Nelson, J.L. Feldman, D.R. McCrimmon, and H.L. Cohen*. (SPON: R.E.W. Harrison). Department of Physiology, Northwestern University Medical School, Chicago, IL 60611.

The nucleus tractus solitarius (NTS) is a major brainstem site involved in integration of afferent signals related to the neural regulation of cardiovascular function. Several studies utilizing electrical stimulation or large injections of concentrated L-glutamate (GLU) have attempted to functionally map the NTS and surrounding structures. In our previous studies, injections of picomole quantities of GLU (0.2-10 nl) revealed an underlying functional heterogeneity of the NTS. This study investigated the effects of glutamate activation of discrete NTS subregions on the processing of cardiovascular-related information within this structure.

Urethane-anesthetized rats were instrumented to record arterial pressure (BP) and heart rate (HR). Multibarrel micropipettes, filled with 10mM GLU, 100mM glutamate diethyl ester (GDEE), saline or marking dye and connected to a micropressure injection system permitting 100pl resolution, were inserted into the NTS region. GLU injections (0.2-10nl) into the medial and lateral NTS caudal to the obex produced rapid, dose-dependent decreases in HR and BP. At discrete sites, 1nl injections routinely produced 40 mmHg decreases in BP and 50-150 bpm decreases in HR. At some sites effects on BP with no observed change in HR were elicited. Depressor responses increased with depth, beginning 300 um below the brain surface increasing to a maximum at approximately 800 um. At greater depths the responses rapidly attenuated. Marked dose- and site-dependent increases in BP and HR were produced following injections into the commissural nucleus. Maximal responses were obtained approximately 800 um below the brain surface in the medial and caudal aspects of this region. Responses to GLU were attenuated or blocked by simultaneous injection of GDEE.

Our results indicate that glutamate activation of neurons within discrete regions of the NTS markedly alters BP and HR. Further, we hypothesize a heterogenous organization of the NTS with respect to cardiovascular regulation.

61.10 DORSAL MOTOR NUCLEUS OF THE VAGUS: SELECTIVE MU- AND KAPPA-OPIOID RECEPTOR MEDIATED CARDIOVASCULAR RESPONSES. A.H. Hassen. Dept. Physiology, West Virginia School of Osteopathic Medicine, Lewisburg, West Virginia 24901.

Previous studies have described the selective cardiovascular responses elicited by mu- and kappa-opioid receptors in the nucleus of tractus solitarius (NTS) and nucleus ambiguus (NA) regions of the rat hindbrain; mu-agonists increased mean arterial pressure (MAP) and heart rate (HR) following microinjection into either region whereas kappa-agonists depressed MAP following NA microinjection. The present study describes the unique cardiovascular responses elicited by receptor-selective opioid agonists following microinjection into another nucleus which is important in cardiovascular regulation, the dorsal motor nucleus of the vagus (DMN).

Male Sprague Dawley rats were anesthetized with urethane, the trachea intubated to permit artificial ventilation and the femoral artery and vein cannulated. MAP, HR and blood gas were monitored by standard recording devices. Each animal was placed in a stereotaxic device and the obex was exposed by removing the medial portion of the occipital bone. A pulled glass capillary (OD 14-42u) filled with either 0.9% NaCl (vehicle) or opioid solution was stereotaxically inserted into the DMN (AP: obex, L: 0.5 mm; V: 0.8 mm below the dorsal surface of the brainstem) or the commissural nucleus of the NTS (AP: obex, L: 0.5 mm; V: 0.3 mm below the dorsal surface of the brain stem). Each animal was monitored for 15 minutes prior to a single microinjection (100 nl) of vehicle or opioid solution. Naloxone was administered 15 min. after the microinjection and the animal was observed for an additional 10 min. Fast green was used to mark the injection site which was identified by microscopic examination of frozen sections.

The mu-agonist DAGO elicited a dose-related (3 pmol-3 nmol) increase in blood pressure following DMN microinjection (+1±2 - +28±2 mmHg). Although the high dose did not change HR, the lower dose tended to decrease HR (-23±11 BPM). Animals pretreated with atropine methyl nitrate (ATMN) exhibited a greater increase in MAP accompanied by tachycardia (+56±15 BPM) following DAGO injection into the DMN. This contrasts with the lack of effect by ATMN on the tachycardia elicited by DAGO microinjected into the NTS. The kappa agonist U50,488H (30 nmol) lowered HR (-54±10 BPM) without affecting MAP following DMN microinjection; the bradycardia was attenuated by pretreatment with ATMN. It is concluded that mu- and kappa-receptors in the DMN increased vagal activity to the heart.
