Reserpine treatment of cultured bovine adrenal chromaffin cells has been shown to increase the production of low molecular weight met^5-enkephalin-immunoreactive peptides (Eiden et al, PNAS 81, 3439, 1984). We have used antisera directed toward six different portions of the proenkephalin molecule to examine the processing rates and patterns of proenkephalin-derived peptides in chromaffin cell cultures. Gel filtration was used to separate multiple molecular weight forms of immunoreactive peptides. Reserpine (10^{-6}M, three days) increased the production of not only low molecular weight met^5-enk, but also met^5-enk-arg^6-gly^7-leu^8, met^5-enk-arg^6-phe^7, and leu^5-enk in a parallel fashion. Immunoreactivity corresponding to intermediate-sized enkephalin-containing peptides (such as the 5.3 kDal peptide and Peptide B) was decreased, supporting the notion that increased processing of these intermediates occurs in the presence of reserpine. These results suggested that reserpine is able to increase the general activity of trypsin-like enzymes within the chromaffin granule. We therefore investigated the effect of reserpine treatment on the production of two amidated opioid peptides in order to ascertain whether activation of amidation also occurred in the presence of reserpine. Reserpine treatment produced profound effects on the levels of metorphamide and amidorphan; these peptides increased ten and five-fold, respectively, after three days of treatment. The effect on the amidated peptides was rapid, with a 70-80% increase occurring within the first 12 hours after exposure to reserpine. Only one molecular weight form of each amidated peptide was observed in control and treated cultures. The ratio of two Peptide E-derived peptides, leu^5-enk and metorphamide, decreased from 50 to 8 in response to reserpine treatment, reflecting a disproportionate increase in the content of metorphamide. These results indicate that activation of amidation occurs in the presence of reserpine, and suggest that reserpine may be capable of altering not only the extent but also the pattern of proenkephalin processing.

116.4 **PROJECTION-SPECIFIC PROCESSING OF PROENKEPHALIN IN THE RAT CNS.** J.D. White, C.M. Gall[1] and J.F. McKelvy, Dept. of Neurobiology and Behavior, SUNY Stony Brook, NY 11794 and [1]Dept. of Anatomy, U.C. Irvine, CA 92717

Several recent studies have suggested that post-translational proteolytic processing of the precursor proteins to the opiate peptides occurs in a tissue-specific and, perhaps, a projection-specific manner. The implications of these findings are that the prohormones contain an array of potential biologically active peptides and that different neuron systems differentially use specific peptides to facilitate intercellular communication. The present studies were designed to directly test this hypothesis using dynamic measurements in three distinct, anatomically well-defined, enkephalin projections in the rat brain.

The biosynthesis and processing of proenkephalin was studied in vivo using our previously described methods (White et al., J. Neurosci., 4:1262), i.e. radiolabeled amino acid was delivered to the cell bodies of interest through stereotaxically implanted cannulae using an osmotic mini-pump delivery system. Radiolabeled peptides were harvested from the terminal fields and purified to constant radiochemical specific activity, in the presence of carrier peptides, through three sequential HPLC steps and two chemical modification steps. For these studies we chose to examine the biosynthesis of six Met-enkephalin containing peptides: Met^5-, Met^{5}Arg^{6}Gly^{7}Leu^8-, Met^{5}Arg^{6}Phe^7-enkephalin (MENK, MERGL, MERF), metorphamide, Peptide E and BAM 18 P. The three projection systems we studied were the caudate putamen to the globus pallidus, the paraventricular nucleus of the hypothalamus to the median eminence and the mossy fiber system of the granule cells of the hippocampus. In all cases 500 µCi of ^{35}S-Methionine was delivered over a 4 hour period followed by artificial extracellular fluid for an additional two hours to allow for synthesis, processing and transport of the peptides to the terminal field. To facilitate comparison of the data between animals and projection systems, the amount of each peptide was expressed as a ratio of radioactivity with the amount of radioactivity present in MERF for each animal arbitrarily set equal to one.

We were able to reach several conclusions regarding proenkephalin processing using this approach. (a) Neither metorphamide nor Peptide E contributed substantially to the pool of Met-enkephalin peptides in any of the three terminal fields. In all cases the amount of radioactivity present in these peptides was less than 10% of that present in MERF. (b)The ratio of MENK:MERGL:MERF was virtually identical in the hypothalamic and hippocampal projections, i.e. 3.4:0.5:1. (c) This ratio was significantly different in the striatal projection, i.e. 4.3:0.9:1. (d) Both the hypothalamic and hippocampal projections produced substantial amounts of BAM 18 P, roughly equal to the molar amount of MERGL, however, this peptide was virtually absent in the globus pallidus, i.e. less than 10% of MERF.

These data demonstrate that projection-specific processing of proenkephalin occurs in the rat CNS. Furthermore, the data demonstrate that the post-translational processing of proenkephalin is not solely directed by the location of paired basic amino acids. We are currently investigating the processing of proenkephalin in the mossy fiber system during hippocampal seizures in a model in which enkephalin biosynthesis dramatically increases to investigate the coordination of enkephalin synthesis and processing. Additionally, we are exploring the mechanisms by which this diversity of enkephalin-containing peptides is generated in these projection systems. 116.5 AGONISTS INHIBITORY TO ADENYLATE CYCLASE STIMULATE PROENKEPHALIN SYNTHESIS IN NG-108 CELLS. Joan P. Schwartz. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

The neuroblastoma-glioma hybrid cell line NG-108 contains three receptors which are coupled to the adenylate cyclase (AC) in an inhibitory mode, the opiate, the α_2-adrenergic and the muscarinic receptors. Growth of the cells in the presence of an agonist for any one of these receptors has been shown to result in an initial inhibition of AC and decrease of cyclic AMP content, which is followed by an increase in AC activity such that the cyclic AMP content is restored to control levels. Recent reports have demonstrated that the cells contain enkephalin peptides (Glaser et al., Eur. J. Pharm. 65: 319, 1980) and that their content is regulated by cyclic AMP (Braas et al., J. Neurosci. 3: 1713, 1983). Using a cDNA probe for proenkephalin (PE), we have detected the PE mRNA in the cells and find that it has the same size, 1400 bases, as has been found in brain and adrenal. Growth of the cells in 10^{-7}M etorphine had no effect on the content of PE mRNA for the first three days: by day 5, the content had increased 2-3 fold. Morphine has the same effect and the action of both drugs is blocked by naloxone. The EC_{50} for etorphine is ~1 nM, similar to that for morphine. Although both etorphine and morphine can inhibit forskolin-stimulated AC 50% acutely, an effect which is also blocked by naloxone, neither opiate agonist changes the cyclic AMP content of the cells following a five-day treatment period. Exposure to either 10^{-6}M carbachol or 10^{-7}M clonidine inhibits forskolin-stimulated AC activity (over a 30 minute incubation) and leads to a 50-100% increase of PE mRNA after five days exposure. Forskolin ($5x10^{-6}$M) alone, which produces a 10-20 fold increase of cyclic AMP content, also increases PE mRNA 2-3 fold, a response which is not additive with that of etorphine. The results therefore suggest that PE synthesis in NG108 cells can be regulated by two different mechanisms, one involving cyclic AMP while the other, yet to be determined, is common to opiate, muscarinic and α_2-adrenergic receptor stimulation. The two mechanisms may converge prior to stimulation of PE mRNA content in NG-108 cells.

116.6 Ca^{++} CHANNEL ANTAGONISTS ALTER MORPHINE HYPERTHERMIA. N.P. Pillai* and D.H. Ross. Div. Molecular Pharmacology, Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284.

The action of opiates on body temperature has been shown to depend on both dose and route of administration. Morphine (15 mg/kg, s.c.) produces hyperthermia (30 - 120 min) in unrestrained rats, while producing biphasic responses in restrained rats. Opiates in vitro and in vivo have been shown to alter Ca^{++} content, binding and transport, and Ca^{++}-dependent transmitter release from synaptosomes. These effects correlate well with analgesia tolerance and physical dependence. Temperature regulation has previously been shown to be affected by hypothalamic movement of Ca^{++} ions and it is believed that Ca^{++} ions may act to control the temperature set point in this specific brain region. Ca^{++} antagonists such as lanthanum and EGTA are known to block the effect of Ca^{++} in reversing opiate analgesia. We have therefore studied the effects of organic Ca^{++} channel antagonosts, the 1,4-dihydropyridines, on morphine hyperthermia and Ca^{++}-ATPase activity in brain regions and subcellular fractions. Morphine (15 mg/kg, s.c.) produced hyperthermia (+ 1.5°C) at 2 hrs. Ca^{++}-ATPase in synaptic membranes from whole brain was inhibited 24%. Morphine hyperthermia and Ca^{++}-ATPase inhibition was reversed by pretreatment with naloxone (2 - 5 mg/kg). Ca^{++}-ATPase activity was decreased in P_2 fractions from hypothalamus (18%) and cortex (20%) $P < 0.05$, but not in cerebellum. Nimodipine (1 mg/kg), verapamil (10 mg/kg) or diltiazem (5 mg/kg) reversed inhibition of Ca^{++}-ATPase, while nimodipine was most effective in reversing hyperthermia. The Ca^{++} channel agonist BAY K 8644 (3 mg/kg) produced hypothermia (-2.2°C) and increased Ca^{++}-ATPase activity (28%) in hypothalamus but not cortex or cerebellum. Nimodipine blocked the BAY K 8644 hypothermia and increase in Ca^{++}-ATPase. Naloxone (2 - 5 mg/kg) was ineffective in antagonism of BAY K 8644. These results suggest that activation of opiate receptors may alter thermoregulatory mechanisms by interferring with Ca^{++} transport in the hypothalamus. While opiate inhibition of ATPase was seen also in cortex, no effects were demonstrated in cerebellum. Specific changes in hypothalamic ATPase following BAY K 8644 and antagonism by nimodipine suggest that Ca^{++} movement in hypothalamus may be differently regulated by opiate and dihydropyridine receptors. The actions of opiates to alter temperature may be coupled to Ca^{++} transport.

116.7 OPIOID TOLERANCE IN SYMPATHETIC PREGANGLIONIC NEURONS DUE TO LOSS OF ADENYLATE CYCLASE INHIBITION. Donald N. Franz and Lewis C. Miner* (SPON: J.H. Petajan). Department of Pharmacology, University of Utah, Salt Lake City, Utah 84132.

Chronic exposure of neuroblastoma X glioma hybrid cells (NG 108-15) to opioids produces tolerance to opioid-induced depression of adenylate cyclase (Klee et al., Life Sci. 16:1869, 1975). We have previously shown that both opioids and clonidine markedly depress the excitability of sympathetic preganglionic neurons (SPGNs) by respective actions on opioid and alpha-2 receptors (Science 215:1643, 1982). These depressions appear to be mediated by negative receptor coupling to adenylate cyclase because both opioids and clonidine prevent the marked increases in descending transmission to SPGNs that are produced by phosphodiesterase (PDE) inhibitors (Soc. Neurosci. Abstr. 9:797, 1983: 10:713, 1984). The present study was designed to assess the ability of SPGNs to become tolerant to opioids.

Sympathetic discharges, recorded from upper thoracic preganglionic rami, were evoked by stimulation (0.1 Hz) of descending excitatory pathways in the cervical dorsolateral funiculus of unanesthetized spinal cats and were analyzed by signal averaging. Theophylline (50 mg/kg), IBMX (1 mg/kg), or RO 20-1724 (1 mg/kg) rapidly enhanced transmission to about 175% of control levels. Morphine (2 mg/kg) or methadone (1 mg/kg) rapidly depressed transmission by 60-90% and prevented the typical enhancement by the PDE inhibitors. Naloxone (20 ug/kg) then rapidly reversed the opioid depression and restored enhancement by the PDE inhibitors. A second series of experiments was conducted on cats pretreated with increasing doses of methadone HCl for 3 weeks; implanted Alzet minipumps delivered 5 mg/kg/day during the 3rd week. Plasma levels averaged 1.5 ug/ml on the final day. In these cats, 1 mg/kg of methadone produced only a transient 25% depression, but 1 mg/kg of IBMX rapidly enhanced transmission to the same level as in untreated cats (175%). Naloxone produced further enhancement. The depressant effect of clonidine (25 ug/kg) was unaltered by the tolerant state.

The markedly reduced depression of intraspinal transmission by methadone and its failure to prevent enhancement by IBMX after chronic methadone treatment indicates that SPGNs and their adenylate cyclase develop tolerance to opioids. The mechanism may involve an impaired ability of the negative regulatory proteins to couple opioid receptors to adenylate cyclase.

116.8 THE DESIGN AND TESTING FOR ANALGESIA OF SOME ENKEPHALIN-LIKE COMPOUNDS IN THE RAT. M.A. Khaled* and J.M. Beaton, Neurosciences Program and Departments of Nutrition Sciences and Psychiatry, Univ. of Alabama at Birmingham, B'ham., AL 35294.

Although many opiate-like peptides have been isolated from either brain or pituitary gland, the enkephalins remain the smallest active peptides. These pentapeptides, H-Tyr-Gly-Gly-Phe-Met-OH(Met-enkephalin) and H-Tyr-Gly-Gly-Phe-Leu-OH(Leu-enkephalin) are only briefly active in the CNS after central administration. Structure activity relationship studies have shown that the Tyr moiety is the most critical one in the peptides and modifications to this amino acid result in decreased opiate like activity. Studies on dipeptides with Tyr at the N-terminus amino acid have also shown some activity. Horn and Rodgers (Nature, 260, 795, 1976) theorized that the amino group of Tyr and the hydroxyl of its side chain adopt a distance (ca. 7A) similar to one between the tyramine and hydroxyl groups in morphine. In order to verify this fact experimentally we synthesized some small molecules with tyrosine.

H-Tyr-D.Lys was synthesized first following the usual solution method for peptide synthesis. D.Lys was used in the hope of slowing enzymatic degradation. Next, two other compounds with Tyr covalently linked to long lipophilic hydrocarbon chains were synthesized. They are Tyr-$(CH_2)_6$-NH_2 and Tyr-$(CH_2)_{12}$-NH_2. The purity of the compounds was checked using thin layer chromatography and nuclear magnetic resonance.

Behavioral testing was carried out in groups of rats at several doses for each compound. The compounds were dissolved in distilled water and injected subcutaneously immediately prior to testing in a flinch-jump apparatus. Morphine was used for comparison. Five trials of an ascending, followed by a descending series of 0.75 sec foot shocks, delivered at 15 sec. intervals were carried out. The initial shock was 0.05 mA and was altered in 0.05 mA increments. The flinch and jump thresholds were noted. The trials were repeated at 10 minute intervals. The average jump thresholds, in mA, after 4 mg/kg, are shown below.

	Jump Threshold (mA)						
Time (Min)	0	10	20	30	40	50	60
Compounds							
Tyr-D.Lys	1.95	1.85	1.23	1.30	0.95	0.90	0.90
Tyr-$(CH_2)_6$-NH_2	1.80	1.50	1.80	1.00	0.90	0.90	0.85
Tyr-$(CH_2)_{12}$-NH_2	1.63	1.83	1.40	1.55	1.30	1.15	0.95
Morphine	1.45	1.50	2.50	2.50	2.25	2.50	2.25

These results indicate that all three of the synthesized compounds have analgesic properties after subcutaneous administration. Ongoing studies are examining the ability of naloxone to block these effects. Planned studies are to synthesize and test compounds in which the side chain of tyrosine is further constrained to maintain the distance between the amino group and the side chain hydroxyl as discussed above. (Supported in part by grants from NIH SO7-RR05349 and Alabama Consumer Research Fund).

116.9 MORPHINE AND OTHER OPIATES FROM BOVINE HYPOTHALAMUS AND ADRENAL. R.W. Barrett*, C.J. Weitz*, L.I. Lowney* and A. Goldstein. Addiction Research Foundation, Palo Alto, CA 94304.

We have recently reported the presence of six substances (Peaks 1-6) from bovine hypothalamus and adrenal, which are recognized by antisera to morphine. One of these (Peak 1) was identified as morphine by 500 MHz proton NMR after purification to homogeneity (Proc. Natl. Acad. Sci. USA, in press). Peaks 4 and 5 were not present in sufficient amount, but the other peaks have now been purified to homogeneity using polystyrene resin adsorption, anion and cation exchange, and reverse-phase HPLC. The criterion for purity is that both immunoreactive and UV-absorbing material is adsorbed to and recovered from a morphine antibody affinity resin but not a control immunoglobulin resin.

Peaks 2, 3 and 6 were inactive in the guinea pig ileum bioassay at doses (IR-morphine equivalents) 10 times higher than morphine. They are better recognized by an antiserum raised against a BSA-3-ethylamine-morphine conjugate ("937" antiserum) than by an antiserum raised against a BSA-N-carboxymethyl-normorphine conjugate. Titration experiments with "937" antibody affinity resin against a fixed amount of ir-equivalents revealed that Peaks 2 and 6 had higher affinity than morphine. Peak 3 and morphine had equivalent affinities.

Peaks 2, 3 and 6 are likely to be structurally related. Peak 6 is converted to Peaks 2 and 3 in NH_4OH. Since the isolation procedure included exposure to NH_4OH, it is not clear if Peaks 2 and 3 are present in tissue. However, the isolation procedure does not convert morphine or normorphine into other immunoreactive compounds.

Their HPLC behavior shows that Peaks 2, 3 and 6 are not any of the known major biosynthetic precursors or metabolites of morphine. Their structures are currently being determined.

116.10 LOCALIZATION OF NEUTRAL METALLOENDOPEPTIDASE (ENKEPHALINASE) ACTIVITY IN RAT BRAIN BY FLUORESCENT HISTOCHEMISTRY. Stephen A. Back and Charles Gorenstein. Department of Pharmacology, University of California, Irvine CA 92717.

We have histochemically localized neutral metalloendopeptidase (enkephalinase) in rat brain. Nitrosalicylaldehyde (NSA) was used to fluorescently localize the enzyme product resulting from cleavage of the substrate, glutaryl-Ala-Ala-Phe-4-methoxy-2-naphthylamide.

Rats were perfused with a low formaldehyde concentration which achieved maximal preservation of tissue morphology while retaining enzyme activity. Vibratome sections were incubated with 0.5 mM substrate and 0.5 mM NSA in the presence of microsomal leucine aminopeptidase at neutral pH. The yellow fluorescent precipitate formed in the tissue was observed using a Zeiss fluorescent microscope.

The enzyme was highly localized and displayed a unique pattern of distribution. Intense staining was observed in striate cortex with little or no staining in the adjacent globus pallidus. A number of other brain regions stained positively including the olfactory bulb, nucleus accumbens, anterior commissure, hippocampus, substantia nigra, and superior colliculus. The brain stem and spinal cord stained relatively lightly. No activity was detected in cerebellum. The pia and blood vessels throughout the brain showed considerable staining.

Following colchine injection into the lateral ventricle (100ug), fluorescent reaction product within cell bodies was found to be localized in punctate structures. That the staining pattern observed is due to "enkephalinase" is suggested by staining done in the presence of the enkephalinase inhibitor, thiorphan, at concentrations ranging from 3 nM to 30 nM. 30 nM thiorphan completely inhibited all staining throughout the brain. By contrast, the staining pattern obtained in the presence of the angiotensin converting enzyme inhibitor, captopril, did not appear different from control.

The distribution pattern of the enzyme and its selective response to thiorphan support a role for the enzyme in the metabolism of enkephalin. This technique provides a sensitive method to assess the extent to which the distribution of the enzyme correlates with the distribution of opiate peptides and opiate receptors in the brain and peripheral tissues.

Supported by NIDA grant DA03131, NIDA predoctoral PHS fellowship DA05255, and funding from Hoffman LaRoche.

116.11 ANTIBODIES TO THE MU OPIATE RECEPTOR PURIFIED FROM RAT BRAIN.
R. Maneckjee*, R.S. Zukin and S. Archer# (SPON: J.W. Holaday). Department of Biochemistry, Albert Einstein College of Medicine, Bronx, NY 10461 and Department of Chemistry, Cogswell Laboratory, Rensselaer Polytechnic Institute, Troy, NY 12181

Active opiate receptors have been solubilized from rat neural membranes and purified approximately 5000-fold using a specific affinity column (Affigel 401 to which "hybromet", a newly synthesized opioid ligand with high affinity for the μ receptor, had been attached) and hydroxylapatite column chromatography. A potent and specific antibody to the purified μ receptor was produced in rabbits. The specificity of the antiserum was demonstrated by immunoprecipitation studies, as well as by the specific displacement of ^{3}H-opioid ligand binding. Immunological titration of opiate binding activity from rat brain showed that the antibody was able to effectively displace specific ^{3}H-etorphine and ^{3}H-dihydromorphine binding, but was ineffective against the binding of ^{3}H-ethylketocyclazocine, ^{3}H-D-Ala^{2}-D-Leu^{5}-enkephalin or ^{3}H-phencyclidine. The antibody was able to precipitate the M_r 94,000 component of the ^{125}I-labeled affinity purified receptor, suggesting the possibility that this subunit represents the μ opioid recognition component. By indirect immunofluorescence, the antibody was shown to specifically bind to the plasma membranes of NCB-20 neuroblastoma X chinese hamster brain hybrid cells and NC41A neuroblastoma cells, both of which revealed high affinity ^{3}H-etorphine and ^{3}H-dihydromorphine binding activity. The observed fluorescence in the neuroblastoma cells was prevented by pre-adsorption of the antibody with solubilized extracts of rat brain. These results indicate that the rabbit antibody to the purified receptor is μ-specific and will prove valuable in the precise localization of the μ receptor subtype in the central and peripheral nervous systems using immunohistochemical procedures.

116.12 BETA-ENDORPHIN AND DYNORPHIN A IMMUNOREACTIVITY IN THE PLASMA AND CSF OF RHESUS MONKEYS.
D.E. Gmerek*, M. Knobloch*, J.H. Woods and H. Akil. Department of Pharmacology and the Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109-0010.

The purpose of these studies is to detect changes in levels of endogenous opioid peptides in the plasma and CSF of rhesus monkeys associated with chronic administration of receptor-type selective opioid agonists. This report presents the results from preliminary studies. Radiommunassay of plasma and CSF samples proceeded as reported previously (Cahill et al., J. Clin. Endocrinol. Metab. 56: 992, 1983). Plasma and CSF were withdrawn from monkeys anesthetized with pentobarbital (28 mg/kg, i.v.). The acidified samples were extracted on Sep-Pak C18 cartridges. The samples were resuspended in 150 mM $NaPO_4$ buffer for beta-endorphin assays and MeOH:0.1 N HCl (1:1) for dynorphin assays. The antibodies used for the beta-endorphin assays recognize positions 17-27 of beta-endorphin (1-31). The antibodies used for the dynorphin assays recognize the COOH-terminus of dynorphin A (1-17) or the COOH-terminus of dynorphin A (1-8) (Dores et al., Neurosci. Abstr. 9: 586, 1983). The samples were incubated in buffer (150 mM $NaPO_4$, pH 8.2 or 50 mM $NaPO_4$ with 0.1 % Triton, pH 7.6) in the presence of antibody for a minumum of 24 hrs before addition of the trace (iodinated human beta-endorphin (1-31), dynorphin A (1-17), or dynorphin A (1-8), respectively). The assays were separated 24 hrs later by immunoprecipitation with goat antirabbit immunoglobulin G. Quantification was based on concurrently assayed standard curves of the appropriate cold ligand.

The amounts of beta-endorphin-like immunoreactivity in normal rhesus monkey plasma (n=5) of 26 ± 5 fmole/ml were in agreement with previous studies in our lab (Cahill, doctoral thesis, 1983). The amount of beta-endorphin-like immunoreactivity detected in normal rhesus CSF, which should reflect the peptides released from brain rather than pituitary, was 15 ± 4 fmoles/ml. Dynorphin A (1-17)-like immunoreactivity was detected in normal rhesus plasma (10-15 fmole/ml). Dynorphin A (1-8)-like immunoreactivity was also found in normal rhesus plasma in lesser amounts (approx. 3 fmole/ml). Dynorphin A (1-17) could not be detected consistantly in rat plasma. These results reflect the observations that rat posterior pituitary contains twice as much dynorphin A (1-8) as dynorphin A (1-17) (Dores et al., Neuropeptides 5: 501, 1985); whereas in rhesus, dynorphin A (1-17) is by far the dominant form (Dores, et al., unpublished observations). Supported by USPHS Grant 00254.

LIMBIC SYSTEM: DEVELOPMENT AND PLASTICITY I

117.1 THE MODULATION OF LONG TERM POTENTIATION BY DELTA-9-TETRAHYDRO-CANNABINOL IN THE IN VITRO RAT HIPPOCAMPAL SLICE.
Alexander V. Nowicky, Richard M. Vardaris, and Timothy J. Teyler, Neurobiology Program, Kent State Univ., and Northeastern Ohio Universities College of Medicine, ROOTSTOWN, OH 44272.

Delta-9-Tetrahydrocannabinol (THC), the major psychoactive cannabinoid in marihuana, causes an increase in neuronal excitability in the CA1 region of the in vitro Hippocampal slice,(Foy, et al, Brain Res. Bull., 1982, 8(4):341-45). The increase in excitability is seen with THC doses ranging from 10^{-12} to 10^{-10} M., and occurs within 15 min. after onset of drug incubation. Other work with the cannabinoids has shown that they cause membrane fluidity perturbations in synaptosomes, probably due to their high lipophilicity. However, doses necessary to obtain these effects are in excess of 10^{-6} M. Because the excitability effects in slices occurs at much lower doses, we have suggested that THC may be acting through specific receptors and/or the modulation of endogenous neurotransmitter systems. Recently, a THC binding study on brain tissue indicated the Hippocampus contained the highest level of THC binding, (Essman and Das, Fed. Proc., 1984, 43:951). We wondered whether THC might modulate Long Term Potentiation (LTP) in the CA1 region of the Hippocampus. LTP, which is a form of synaptic plasticity, is found in the Hippocampus, and has been suggested as a model of synaptic change underlying the mechanisms of memory.

Briefly, Hippocampal slices were obtained from adult, male, Long Evans rats by standard means, (Teyler, Brain Res. Bull., 1980, 5: 391-40). Evoked population responses were obtained from the stratum radiatum--CA1 pyramidal cell region of slices. Data collection involved recording 2 mV. population responses before, and 30 min. after control, 10 or 100 picomolar (pM) THC exchanged with the bathing media. Following the exchanges, LTP was induced by a tetanizing train of 260 Hz., .25sec., repeated 4 times. The stimulus intensity which evoked the original response was used to tetanize and then monitor the responses throughout the experiment. Data was collected to 100 min. post-tetanus. All response amplitudes were normalized to pretetanus baseline levels for analysis.

There were no significant differences between the control and 10 pM THC groups, with respect to early, post-tetanus LTP magnitude. Both groups showed an average of 200% increase over baseline levels at 15 min. However, whereas the control group exhibited the same magnitude increase of LTP at 100 min., the 10 pM THC group showed a significant decay to a magnitude of 50% increase over baseline. Thus the 10 pM THC treated sliced showed a significant decrease in the time constant of LTP. The 100 pM THC treated slices exhibited a more rapid decrease, such that at 100 min. LTP magnitude had decayed to 50% below baseline levels. We have shown that an acute pretreatment of slices with THC has no apparent effect on induction or magnitude, but significantly increases the rate of LTP decay.

117.2 NONLINEAR CHARACTERISTICS OF HIPPOCAMPAL PERFORANT PATH-DENTATE SYNAPTIC TRANSMISSION ARE DEPENDENT ON THE INTENSITY OF STIMULATION.
J.R. Balzer*, R.J. Sclabassi and T.W. Berger. Depts. of Psychology, Psychiatry and Neurosurgery, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Random impulse trains of electrical stimulation delivered to the perforant path (PP) effectively reveal nonlinear characteristics of synaptic transmission to the hippocampal dentate gyrus (DG) as measured by amplitude of the granule cell field potential population spike (Berger et al., Soc. Neurosci. Abstr., 1983). In the experiments reported here, we tested the effects of varying intensity of stimulation on nonlinear properties of PP-DG synapses while maintaining a constant mean frequency (λ) of stimulation. Varying stimulation intensity will change the number of presynaptic PP fibers and postsynaptic DG cells included in the system response.

Experiments were conducted using chronically implanted rabbits while animals were awake and mildly restrained. A computer generated random interval train (Poisson distribution, λ=500 msec, range-1/msec-1/5 sec) was used to determine the sequence of 4,064 single shock (0.1 msec duration) stimulations applied to the PP. Intensities used were those that produced 5%, 10%, 20%, 30%, 50%, and 100% of maximum spike amplitude; one 4,064 impulse train at one intensity was given each day.

First order kernels, which reflect the averaged population spike response to each impulse in the train, increased 300-400% as a function of intensity, reflecting the fact that average spike amplitude increased with increasing intensity. Second order kernels, which reflect the modulatory influence of a previous impulse on the activity evoked by the current stimulus whether or not other impulses occur between the two, also revealed significant changes as a function of intensity. The most prominent changes involved short-interval inhibition and longer-interval facilitation. For example, at 5% intensity inhibition to the second impulse of a pair of impulses was observed for inter-impulse-intervals up to approximately 40 msec. At 100%, inhibition lasted up to approximately 60 msec. Facilitation decreased in magnitude and occured at longer intervals as intensity was increased. At 5%, an average facilitation of 50-60% (at approximately 70 msec) was observed. At 100%, an average facilitation of 15-20% (at approximately 100 msec) was observed. Third order nonlinearities, which reflect the modulatory influence of any pair of preceding intervals on the activity evoked by the most current stimulus, also decreased as a function of intensity. Once intensity reached 30%, no more than a 10% deviation was observed in third order kernel values, whereas at 5% intensity, deviations as great as 60% were observed. In summary, hippocampal perforant path-dentate synaptic transmission becomes more linear as intensity is increased. Supported by The Whitaker Foundation.

117.3 NONLINEAR CHARACTERISTICS OF HIPPOCAMPAL PERFORANT PATH-DENTATE SYNAPTIC TRANSMISSION ARE DEPENDENT ON THE MEAN FREQUENCY OF STIMULATION. G.B. Robinson, J.L. Eriksson*, R.J. Sclabassi and T.W. Berger. Depts. of Psychology, Psychiatry and Neurosurgery, Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

We are utilizing random impulse train stimulation and nonlinear system analysis techniques to characterize synaptic transmission in the rabbit perforant path-granule cell (PP-GC) circuit (Berger et al., Soc. Neurosci. Abstr., 1983). Population spikes were recorded from the GC layer of awake rabbits with stimulation intensity adjusted to produce a response 10-15% of the maximum. Random interval trains (Poisson distribution) were presented at mean frequencies (λ) of 0.5, 1.0, 2.0, 3.3, 5.0, 6.7 and 10.0 Hz. Kernels were computed by cross-correlation of the random input with the amplitude of the PP-GC population spike.

Second order kernels, which represent the response to the second stimulation of an impulse pair embedded within the random train, exhibited nonlinearities that depended on λ. Briefly, increasing λ from 0.5 to 10.0 Hz had the following effects: 1) decreasing the magnitude of maximum facilitation (from 80% to 5%) and 2) increasing the duration of inhibitory interactions (from 35 ms at 0.5 Hz to 60 ms at 10.0 Hz). Regardless of λ, the second order kernels were approximately linear for interstimulus intervals greater than 300 ms. Third order kernels, which represent the response amplitude following the final impulse of a triplet of impulses embedded within the random train, also depended on λ. Generally, increasing λ resulted in a decrease of both the third order facilitative and inhibitory effects. That is, the third order kernel values approached zero. Regardless of λ, the largest facilitative effects (up to 70%) were observed when the third impulse occurred 20-40 ms after an impulse pair of less than 30 ms. Generally the largest inhibitory effects (up to 60%) occurred when the two intervals were approximately 40-70 ms. At 2.0 Hz, for example, if the third impulse occurred 50 ms after an impulse pair of 50 ms, then the response following that third impulse was approximately 60% smaller than would have been predicted from the linear summation of the responses to two 50 ms intervals. These results suggest that the output of the dentate gyrus GCs approaches linearity as their frequency of activation by the PP increases. Supported by The Whitaker Foundation and the Natural Sciences and Engineering Research Council of Canada.

117.4 **IMMUNOCYTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN SEPTAL NEURONS TRANSPLANTED TO THE RAT HIPPOCAMPUS.** K.J. Anderson, R.B. Gibbs, P.M. Salvaterra, and C.W. Cotman. Dept. of Psychobiology, Univ. California Irvine, Irvine CA 92717 and Div. of Neurosciences, City of Hope Research Institute, Duarte CA, 91010.

Septal neurons have been used extensively in transplant studies to replace cholinergic deficits when the intrinsic innervation has been lost or compromised. It is not known, however, whether these neurons form synapses with, or receive synapses from, the host. We have studied transplanted cholinergic neurons with electron microscopic immunocytochemical techniques using a monoclonal anitbody to choline acetyltransferase (ChAT). We demonstrate that transplanted ChAT positive neurons form asymmetric synapses with the host tissue and receive non-cholinergic synapses.

Ten days following a bilateral transection of the fimbria-fornix, adult rats received an injection of dissociated embryonic (E18) septum into the rostral hippocampus. Animals were allowed to survive for 30 days and killed by vascular perfusion. Sections from the entire hippocampal formation were processed for ChAT immunocytochemistry by the PAP method and then prepared for electron microscopy. At the light microscopic level, ChAT positive neurons from the transplants were identifiable by their large size (35-50 μm in diameter) and location in the hippocampus. Immunoreactive neurons were seen within the hippocampus itself and often formed clumps on the ventricular surface. Plastic embedded sections containing transplanted septal neurons were mounted and thin sections were cut on face for electron microscopy. At the electron microscopic level, ChAT positive neurons were identified by electron dense precipitate that associated with cytoplasmic organelles such as mitochondria, Golgi apparatus, microtubules and endoplasmic reticulum. These neurons were seen to receive axosomatic synapses from non-cholinergic axon terminals. Both asymmetric and symmetric synapses were observed terminating on immunoreactive neurons. ChAT positive dendritic processes arising from transplanted neurons were seen receiving non-immunoreactive synapses on both spines and shafts that were largely asymmetric. Myelinated axonal processes were observed arising from several ChAT positive neurons. Serial sections of immunoreactive axonal processes revealed that they made synaptic contacts with small dendritic processes and dendritic shafts of non-immunoreactive neurons. Axon terminals from ChAT positive neurons were round to oval in shape, contained small clear vesicles and formed asymmetric contacts.

117.5 PARTIAL RECOVERY OF PERFORMANCE ON A DRL OPERANT SCHEDULE IN HIPPOCAMPAL-DAMAGED RATS GIVEN POST-LESION IMPLANTS OF EMBYRONIC HIPPOCAMPUS. Michael L. Woodruff, Ronald H. Baisden, Dennis L. Whittington, and Amy E. Benson*. Department of Anatomy, Laboratory for Neurobehavioral Science, Quillen-Dishner College of Medicine, East Tennessee State University, Johnson City, TN 37614.

Several published reports have indicated that implantation of fetal neural tissue into the site of a brain lesion in an adult animal can produce some recovery of function on "cognitive" tasks. For example, spatial alternation deficits usually observed to follow destruction of the medial frontal cortex in rats were attenuated by implantation of embryonic frontal cortical tissue into the lesion site in the adult brain (Labbe et al. Science 221, 1983), and Dunnett et al. (Brain Res. 251, 1982) found that implants of fetal septal tissue into the cavity produced by a fimbria-fornix lesion significantly reduced the deficit in performance of rewarded alternation usually produced in the rat by such lesions. However, the possibility that behavioral recovery might be produced by implantation of fetal hippocampal tissue into the site of a hippocampal lesion produced in an adult animal has not yet been tested. We now report that partial recovery of function on one behavioral measure can be produced by such an implant. Ten rats served as unoperated controls and ten as cortically damaged controls, while ten rats were given bilateral aspiration lesions of the hippocampus. The final ten rats were given the same type of lesions, but received implants of fetal hippocampus. The embryonic anlage of the hippocampus was dissected from embryos removed from ketamine-anesthetized mothers 13 days after conception. Care was taken to free the neural tissue from all connective elements. It was then transferred to a Hams F10 nutrient medium before being placed into the lesion cavity of the host. Six months were allowed for recovery after which all rats were food deprived and tested on a DRL 20 sec operant schedule for 50 days. Bilateral hippocampal damage is known to produce deficits in the ability of rats to perform efficiently on this task. Histological evaluation conducted after behavioral testing indicated that the implants had indeed developed and resembled those described by Kromer et al. (J. Comp. Neurol. 218, 1983). Analysis of the behavioral data from the present experiment revealed that rats receiving implants of fetal hippocampus were significantly better at the DRL task than the rats receiving only hippocampal lesions. However, both groups were inferior to the control groups. The enduring deficit usually produced in performance of the DRL task by hippocampal lesions can, then, apparently be attenuated, but not completely reversed, by development of embryonic tissue within the lesion cavity.

117.6 **TRANSPLANTATION OF SEPTAL NEURONS MAINTAINED IN LONG-TERM CULTURES** Robert B. Gibbs, Sarah Pixley and Carl W. Cotman Department of Psychobiology, U. C. Irvine, Irvine, CA. 92717

Postnatal CNS tissues do not readily survive transplantation to the brain. In the present study, we examined whether embryonic central neurons could be maintained in culture for a long period of time and then successfully transplanted to the adult CNS. Cells transplanted from culture were compared with non-cultured cells taken at comparable developmental stages.

Adult, male Sprague Dawley rats (~200 g) received bilateral transections of the fimbria to remove the native septal cholinergic input to the hippocampus. Ten days later, transplants of; (1) 18 day embryonic septal cells (E18) maintained in dissociated cell culture with 10% FCS for 1 week (n=10), 2 weeks (n=13), or 4 weeks (n=13); (2) non-cultured E18 septal cells in suspension (n=10); or (3) solid septal grafts from postnatal day 4 (P4) (n=7) or postnatal day 13 (P13) (n=7) neonates, were injected unilaterally into the host hippocampus. All grafts were examined 30 days after transplantation.

Transplants of embryonic septal cells contained many acetylcholinesterase (AChE) -positive neurons which innervated the host hippocampus in a pattern comparable to that of the native cholinergic input. A similar pattern of innervation was observed using transplants of 1-week septal cultures and P4 septal tissues; however the P4 grafts had considerably fewer surviving cells. In contrast, there was no evidence of transplant survival in grafts from 2-week or 4-week septal cultures or from P13 neonates.

To control for the trauma of removing the cells from culture, aliquots of cell suspensions prepared from 2-week and 4-week septal cultures were replated under conditions identical to those used above. All primary and secondary cultures contained cells which bound antibodies against neurofilament proteins and which stained for AChE within 1-2 weeks after plating.

We conclude that embryonic septal neurons maintained for a short period in culture can be successfully transplanted to the adult CNS, but that prolonged culturing under our conditions is incompatible with transplantation. The ability of cultured cells to survive in the brain parallels the survival of grafts of neonatal tissues taken at comparable developmental stages.

117.7 IMMUNOCYTOCHEMISTRY OF DEVELOPMENT IN THE OLFACTORY CORTEX OF POSTNATAL RATS. R.E Westenbroek[*1], L.E. Westrum[1], A. Hendrickson[2], M.C. Beinfeld[*3], and J.Y. Wu[4]. Depts. of Biological Structure[1], Neurological Surgery[1], and Ophthalmology[2], Univ. of Washington, Seattle, WA 98195 and Dept. of Pharmacology[3], St. Louis Univ., St. Louis, MO 63108 and Dept. of Physiology,[4] Pennsylvania State Univ., Hershey, PA 17033.

Although conventional microscopic studies have provided considerable information about the organization and development of the olfactory cortex (area 51), the immunocytochemistry of this area of cortex is generally lacking. Cholecystokinin (CCK), a neuropeptide, and gamma aminobutyric acid (GABA), a neurotransmitter, have been shown to be present in the olfactory cortex. Using anti-CCK serum prepared by M.C. Beinfeld and anti-GAD (glutamic acic decarboxylase), prepared by J.Y. Wu, and the indirect peroxidase anti-peroxidase technique of Sternberger, the immunoreactivity of the olfactory cortex during development is being investigated. Light microscopic (LM) studies of this cortical region at several known "critical periods" between postnatal (PN) day 0 (day of birth) and PN 30 have revealed distinct changes in the immunoreactivity of cells, fibers, and terminal puncta. Anti-CCK reactivity shows labelled cells present especially in layer II in both subareas 51a and 51b at PN 0. The relative numbers of labelled cells appears to double by PN 9, remains the same at PN 13 but increases dramatically by PN 21. Little or no change occurs thereafter. CCK-cells are also present in small numbers in layer Ib and in layer III in the younger animals. Labelled CCK-fibers are virtually absent from the lateral olfactory tract (LOT) until PN 13 after which they appear to double by PN 21, especially in sublayer Ib. Terminal puncta are rare at PN 0-3, gradually increases between PN 6 and PN 13 and thereafter are densely distributed within layer II with fewer found in the deeper part of layer I and in III. LM studies of anti-GAD reactivity reveal that labelled cells are seen as early as PN 2 in layer Ib and in layer III. GAD-positive terminal puncta are also present at PN 2 and are basically of uniform size being most numerous in the superficial part of Ia and the deeper part of Ib. They are extremely rare in layer II. This pattern of distribution persists through PN 13. By PN 30 terminal puncta are large and densely distributed subadjacent to the LOT and in layer Ia but decrease in size and numbers in deeper Ib, while remaining rare in layer II. The results show that there are complementary patterns of cellular and terminal immunoreactivity for the two antisera and that the "critical periods" of immunoreactivity are different during development for each of them. Also, the presence of labelled cells suggest as origins for the fibers and terminals, nearby, possibly intracortical cells.

117.8 NEUROGENESIS IN THE SUBNUCLEI OF THE INTERPEDUNCULAR NUCLEUS (IPN) AND IN THE MEDIAL HABENULA (MH) OF RAT. N.J. Lenn and S.A. Bayer, Dept. of Neurology, Univ. of Virginia, Charlottesville, VA 22908 and Dept. of Biology, Indiana-Purdue Univ., Indianapolis, IN 46223.

Development of the habenulo-interpeduncular system is of interest because of its adult structure, including 7 subnuclei of IPN, localization of synapses of different types and MH sites of origin within the subnuclei, and different localization of neurochemicals amongst the subnuclei. To further investigate the mechanisms controlling these features, the birthdays of IPN and MH neurons were reinvestigated. Autoradiographs from groups of rats whose mothers had been injected with ^{3}H-thymidine on embryonic days (E) 12+13, 13+14, ... 18+19 were studied. Counts of 30,000 labeled and unlabeled cells from the 7 subnuclei of IPN at 4 uniform coronal levels of the nucleus were expressed as % labeled cells for each 24 hr interval. All IPN neurons were formed on E12-16. Birthdays varied for the subnuclei of IPN, with the earliest being those of the serotonin-containing apical subnucleus and the latest being those of the rostral subnucleus ($p<.001$; sign test). Rostral lateral and lateral subnuclei were approximately simultaneous with apical. The intermediate and central subnuclei, related to each other in a number of ways, had simultaneous birthdays earlier than the rostral and later than the other subnuclei. Neurons at the caudal levels of the central, intermediate and lateral subnuclei were formed latest, and at their middle levels earliest ($p<.021$ to $.0001$).

In these autoradiographs, MH consisted of 3 regions. Medial and lateral regions of equal size occupy the rostral ½ of MH, and medial ventral and lateral ventral portions caudal to the exit of the fasciculus retroflexus. The dorsal region is only present in the caudal ½ of MH. Neurons in these regions undergo their final mitoses on E15-16, 16-17 and 17-18, respectively.

It is possible to relate the subdivisions of MH and IPN, the neuronal birthdays of these subdivisions, and the localization of neurochemicals. The dorsal region of MH contains substance P immunoreactive cell bodies which have early neuronal birthdays, as do the neurons of their target, the lateral subnucleus of IPN. The cholinergic cell bodies in MH are located in the lateral and medial portions of MH. The birthdays of these MH cells are in the middle to late part of the range of MH birthdays, E16-18. They project to the intermediate and central subnuclei where they terminate as crest and S synapses on cells which have birthdays in the middle and late part of the range for IPN. For the opiate related regions, there is less complete data.

These findings provide additional support for the validity of the subnuclei as currently delineated. They further suggest mechanisms of development which involve early interactions between specific groups of MH neurons and specific groups of IPN neurons.

METABOLIC STUDIES

118.1 ANOXIA WITH AND WITHOUT CALCIUM ON HIPPOCAMPAL SLICE MACROMOLECULAR SYNTHESIS. K.M. Raley*, and P. Lipton, Dept. of Physiology, Univ. of Wisconsin, Madison, WI 53706.

We are using an in vitro hippocampal slice preparation to investigate the irreversible brain damage caused by a brief period of anoxia. Two questions are being asked: (i) is the irreversible damage seen with anoxia due to a disruption of macromolecular synthesis--namely protein and RNA synthesis?; ii) what might be the role of calcium in mediating such effects on synthesis?

To answer these questions, we incubated transverse slices of hippocampus from ~90 day old rats in a 95%O_2-5%CO_2-buffered modified Ringers solution at 36°C. Experimental slices were exposed to 10' of anoxia(95%N_2-5%CO_2) and allowed to recover for 30' or 3 hr in reoxygenated buffer. To test the involvement of calcium, some slices were placed in a Ca-free buffer during and 5' following the anoxic period. 30' of ^{14}C-lysine(0.1mCi/ml) and ^{3}H-uridine (1mCi/ml) incorporations into PCA insoluble material were used to measure protein and RNA synthesis.

10' of anoxia caused a decrease (to 47-51% of control) in the incorporation of ^{14}C-lysine into protein both 30' and 3 hr post-anoxia.

When slices were placed in Ca-free medium during the anoxia and allowed to recover for 30', protein synthesis was 69% of control rates. In contrast, when slices were allowed to recover for 3 hr, protein synthesis was not inhibited at all. These results suggest that the long-term damage to protein synthesis involves a Ca influx during or immediately following the anoxia. In support of this, it was found that there is an approximate 20% increase in net Ca influx into hippocampal cells during 10' of anoxia. Anoxia did not inhibit ^{14}C-lysine incorporation into tRNA.

Anoxia affected the incorporation of ^{3}H-uridine into RNA somewhat differently. 30' following anoxia, RNA synthesis rates were the same as those found in control slices. However, following 3 hr recovery, RNA synthesis rates were 42% of control rates. These results suggest that the damage to RNA synthesis progresses with time.

When slices were exposed to Ca-free medium during anoxia and allowed to recover for 3 hr, RNA synthesis rates were 42% of control. However, slices exposed to a Ca-free medium for 20' and allowed to "recover" in normal buffer for 3 hr exhibited a decrease in RNA synthesis to 45% of control levels.

These data support the following conclusions:1) 10' anoxia inhibits protein and RNA synthesis 3 hr post-anoxia, in a Ca-dependent manner; 2) the Ca-dependent inhibition develops with time.

We are currently investigating the following questions:1) How is Ca exerting its damaging effect on protein and RNA synthesis during anoxia? 2) Is the inhibition of protein synthesis a global effect or does it involve a specific group of proteins?

118.2 GAMMA-HYDROXYBUTYRATE EFFECTS ON CEREBRAL SEROTONIN METABOLISM AND TURNOVER. Y. Ueki*, B. Djuricic*, K. Kumami* and M. Spatz (SPON: H.G. Wagner). LNNS, NINCDS, NIH, Bethesda, MD 20205

Gamma-hydroxybutyrate (GHB), the naturally occurring central nervous system depressant affects various cerebral metabolic pathways in normal and pathological conditions. In ischemia, GHB has a beneficial effect as a preventive and therapeutic agent. Preischemic GHB treatment of gerbils reduces the development and progression of edema, spares the energy metabolism, stabilizes the 5-HT metabolism as well as increases the survival rate of the affected animals. On the other hand, the late post-ischemic GHB treatment has no significant effect on the energy metabolism but decreases the progression of edema, reduces the increased BBB permeability and the mortality rate of the gerbils. Since the improvement in the recovery of the ischemic GHB treated animals could not be directly related to the carbohydrate and energy metabolism, we investigated the influence of postischemic GHB treatment on the metabolism of 5-HT which has been implicated as one of the main factors involved in development and progression of ischemic edema.

Bilateral cerebral ischemia was induced in gerbils by clipping of common carotid arteries for 15 min. only or with clip release for 4 hours. GHB (500 mg/kg b.w.) was injected intravenously 1 hour prior to the termination of the experimental period (4 hrs. after clip release). For the 5-HT turnover studies p-chlorphenylalanine [(PCPA) 300 mg/kg b.w.] were given intraperitoneally just before removal of the clips. Similarly treated sham operated animals served as controls. The gerbils were sacrificed by microwave irradiation and the acid-soluble metabolites were extracted from each dissected brain structure with perchloric acid. Tryptophan, 5-HT and 5-hydroxyindole acetic acid (5-HIAA) were determined by high pressure liquid chromatography (HPLC) using electrochemical detection.

The overall responsiveness of the 5-HT metabolism and turnover to GHB shows regional differences in the brain of sham operated gerbils. Particularly, GHB decreases the 5-HT turnover in the hippocampus while increases 5-HT turnover in the striatum and does not affect the cortex. On the other hand, GHB reverses the observed increased turnover time and decreased turnover rate (decreased 5-HT release and synthesis) at 4 hours reflow after the ischemic insult in the cortex hippocampus and partly in the striatum. However, 5-HIAA accumulation is unaffected by GHB treatment.

The results indicate that GHB effects on the 5-HT metabolism of sham operated controls is distinctly different from those seen in the brains of gerbils recovering from ischemia. Moreover, these findings suggest that the reported beneficial manifestations of the postischemic GHB treatment may be related to 5-HT synthesis which appears to be enhanced in the treated as compared to the untreated ischemic animals.

118.3 DIFFERENTIAL DISTRIBUTION OF LYSOSOMAL ENZYMES IN THE BRAIN AND INCREASED ACTIVITY OF DPP II AFTER CHRONIC EXPOSURE TO LEUPEPTIN. M.Kessler, G.Ivy, C.Gorenstein, M.Baudry and G.Lynch. CNLM and Dept. of Pharmacology, University of California, Irvine CA 92717.

Several of us have reported that the thiol protease inhibitor leupeptin and the general lysosomal enzyme inhibitor chloroquine cause the accumulation of ceroid-lipofuscin in brain cells (Ivy et al., Science 226:985,1984). This led us to propose that the lipofuscin which accumulates during aging and in certain disease states results from defects in lysosomal enzymes. We thus decided 1) to examine the brain distribution of different lysosomal enzymes and 2) to see if leupeptin treatment caused any changes in enzyme activity. We have employed histochemical techniques and computerized densitometry to compare the distribution of dipeptidyl aminopeptidase II (DPP II) and acid phosphatase (AP) in control and leupeptin treated animals.

Six rats each were implanted with miniosmotic pumps filled with saline (0.9%) or leupeptin (40 mg/ml) and 6 rats were untreated.The rats were perfused with buffered formalin. Sections were cut on a Vibratome at 50 μm and processed histochemically for DPP II or AP.

First, we have extended the findings of Gorenstein et al.(J.Neurosci., 1:1096, 1981) on the differential brain distribution of these two lysosomal enzymes. While both DPP II and AP are often co-localized, the relative distribution of the enzymes among neuronal populations differs. In addition, AP is commonly found in glia whereas DPP II is not. Computerized color contrast enhancement showed that DPP II staining is most dense in cerebellar granule and Purkinje cells, hippocampal regions CA3 and CA4, dentate gyrus granule cells and layer V of neocortex. AP is most concentrated in cerebellar granule cells, brainstem and layer VI of neocortex. We did not find any changes in the relative distribution of the enzymes after leupeptin or saline treatment.

Second, selected cell populations were analyzed for staining density in leupeptin and saline treated and untreated rats. Leupeptin treatment caused an increase in DPP II staining in hippocampal areas CA3 and CA4, in dentate gyrus granule cells and in deep cerebellar nuclei by a mean of approximately 20% over saline treated rats. AP levels were not affected by leupeptin treatment. Saline treatment caused a small decrease in both DPP II and AP levels. Studies are in progress to determine the significance of this effect.

In summary, we have found that lysosomal enzymes are not homogeneously distributed throughout the brain and that levels of DPP II but not AP are affected by leupeptin treatment. It is interesting to speculate that the differential distribution of lysosomal enzymes may underlie various pathological phenomena which are restricted to certain brain regions. Supported by NIA AG 00538 (G.L.).

118.4 PHOSPHOLIPID METABOLISM DURING NORMAL AND DYSTROPHIC AVIAN PECTORAL MUSCLE CELL DIFFERENTIATION IN CULTURE. E.L. Hogan and K.C. Leskawa* (SPON: L.D. Middaugh). Department of Neurology, The Medical University of South Carolina, Charleston, SC 29425

The biosynthesis of phospholipids during the differentiation of normal and dystrophic muscle cells (i.e., myogenesis) was studied in vitro using [32P] added to the culture medium. The course of myogenesis was divided into several phases: (1) a replicating stage, when single myoblasts actively divide, (2) a stationary phase brought about by the addition of EDTA to the medium, when myoblasts exit the cell cycle and align in parallel arrays, (3) an initial fusion stage, when opposing muscle cell membranes fuse together, (4) a late fusion stage, when over 70% of the total cell nuclei are contained within multinucleated, contractile myotubules, and (5) a final phase where functional myotubules are isolated by the addition of cytosine arabinoside to the culture medium. At each phase, 160 uCi [32P] was added to the medium and cultures incubated at 37o C for 3 hr. After extracting and partitioning, labeled phospholipids were separated by two-dimensional thin-layer chromatography, exposing the plates to HCl vapors between solvents to cleave the alk-1-enyl bonds. Chromatograms were visualized by autoradiography and spots comigrating with standards were scraped from the support and radioactivity determined by liquid scintillation spectrometry.

Incorporation of label into plasmalogens (ethanolamine or choline) did not vary during myotubule formation, and no differences were observed between normal and dystrophic cultures at any stages of differentiation, which is in disagreement with in vivo studies (Kester & Privitera, 1984, Biochim. Biophys. Acta, 778:112).

A sharp decrease in phosphoinositide labeled was observed as myoblasts first achieved cell contact and recognition. PI labeling continued to decline slowly as myotubules developed. Others have suggested that phosphoinositides act to block fusion (Wakelam & Pette, 1984, Ciba Found. Symp., 103:100), and a decrease in membrane PI content may promote proper conditions for myoblast membrane fusion to occur. More dramatic was the labeling of phosphatidylcholine during myogenesis -- from 18.4% of the total labeled phospholipids in myoblasts to 48.6% of the total myotubule phospholipid. The gradual increase in PC labeling during differentiation roughly corresponded to the shape of a cell fusion curve. This increase in PC labeling may reflect development of the sarcoplasmic reticulm during the differentiation of muscle fibers, since PC is known to be enriched in the sarcoplasmic reticulum, where it is essential for ATPase activity and Ca++ uptake (Martonosi, 1963, Biochem. Biophys. Res. Comm., 13:273).

Supported by grant NS1057 from the NIH.

118.5 PHORBOL ESTERS STIMULATE PHOSPHATIDYLCHOLINE METABOLISM IN NG108-15 CELLS. M. Liscovitch*, A. Freese*, J. K. Blusztajn* and R.J.Wurtman. (SPON: J. D. Milner). Department of Applied Biological Sciences. Massachusetts Institute of Technology, Cambridge, MA 02139.

The effects of tumor-promoting phorbol esters on phosphatidylcholine (PtdCho) metabolism were investigated in the NG108-15 neuroblastoma x glioma hybrid cell line. After one hour of incubation of 12-O-tetradecanoylphorbol-13-acetate (TPA, 100 nM) with cells that were prelabelled with [^{3}H]choline for 24 hours, the release of radioactivity into the medium was stimulated by 158±24% (Mean±S.D., N=9). This effect was dose-dependent (ED_{50}=10 nM) and was observable as early as 5 min after exposure to TPA. The TPA-induced release of radioactivity into the medium was accompanied by a small and variable increase in the radioactivity associated with cellular, acid-soluble choline metabolites (mainly [^{3}H]phosphorylcholine) and a corresponding decrease in [^{3}H]PtdCho. 4β-phorbol-12,13-didecanoate (PDD), another biologically active phorbol ester, had a similar effect, while its non-tumor-promoting isomer 4α-PDD had no effect. When NG108-15 cells were labelled with [^{3}H]choline in the presence of either TPA or PDD (at 100 nM), the incorporation of [^{3}H]choline to PtdCho was stimulated by 180±33% (N=4). In a pulse-chase study cells were labelled with [^{3}H]choline for 1 hour and then chased for up to 8 hours in growth medium that did not contain radiolabelled choline, in the absence or presence of phorbol esters. PDD (100 nM) enhanced the transfer of radioactivity from [^{3}H]phosphorylcholine to [^{3}H]PtdCho, causing a 30% increase in [^{3}H]PtdCho and a corresponding decrease in [^{3}H]phosphorylcholine after 2 hours of chase. However, no difference between control and PDD-treated cells was noted after 8 hours of chase. As phorbol esters were shown to activate the Ca^{2+}-, phospholipid -dependent protein kinase C, we have also investigated the effects of a Ca^{2+} ionophore on PtdCho metabolism. A23187 (at concentrations up to 2 μM) did not significantly affect the release of radioactivity from [^{3}H]choline-labelled cells nor did it affect the incorporation of [^{3}H]choline to the phospholipid fraction. In addition, A23187 did not affect the response of the cells to PDD (100 nM) at any of the concentrations tested. Under pulse-chase conditions, however, A23187 stimulated the accumulation of intracellular [^{3}H]glycerophosphocholine and [^{3}H]choline by 200 to 300%, in a time-dependent manner.

These findings show that phorbol esters can cause a rapid stimulation of PtdCho metabolism in a neuronal cell line and may suggest the possible involvement of protein kinase C in the regulation of PtdCho metabolism. Increased PtdCho degradation induced by the phorbol esters may be due to stimulation of phospholipase C activity, which may also trigger the enhanced incorporation of choline into this phospholipid.

118.6 HYPERGLYCEMIA INHIBITS THE DEVELOPMENT OF ALTERATIONS IN BRAIN MITOCHONDRIAL FUNCTION DURING ANOXIA. K.R. Wagner and R.E. Myers. Research Service, VA Medical Center, Cincinnati, Ohio 45220 and Department of Neurology, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

Exposure of hyperglycemic animals to anoxia/ischemia causes severe brain injury. In contrast, saline infused animals identically exposed remain brain intact. Thus, we hypothesized that alterations in brain mitochondria occurring during anoxia in hyperglycemic animals would importantly influence development of injury. We tested this hypothesis by exposing normo- (5 mM) and hyperglycemic (50 mM) cats to anoxia by respiring them with 100% nitrogen. Brain mitochondria were isolated after 8 minutes of anoxia as described by Clark and Nicklaus (1970). Mitochondria from saline infused cats showed 30-50% inhibition of state 3 respiration with NAD-linked substrates glutamate or pyruvate (both plus malate). Addition of the uncoupler FCCP maximally stimulated respiration, indicating that alteration of adenine nucleotide translocase or inner membrane ATPase, not inhibition of substrate transport or oxidation was present. State 3 respiration with succinate (plus rotenone) was not inhibited. Mitochondrial respiratory control ratios were decreased while ADP/O ratios were unchanged. In contrast, hyperglycemic cats showed no such inhibition of state 3 respiration with NAD- or FAD-linked substrates. No differences were present between saline and glucose infused controls. At the end of exposure, hyperglycemic cats showed significantly higher brain tissue lactate concentrations but similar reductions in ATP and phosphocreatine versus saline infused cats. Thus, decreased energy state alone did not account for inhibition of state 3 respiration in saline infused cats. In conclusion, hyperglycemia inhibits the development of dysfunction of mitochondrial inner membrane properties during anoxia. Since hyperglycemic cats develop brain edema, severe neurologic injury and altered brain mitochondrial function by 5 hours after exposure (Soc. Neurosci. Abs. 10:120, 1984), processes taking place following reoxygenation are responsible for the development of mitochondrial dysfunction and brain tissue injury in hyperglycemic cats exposed to anoxia. Furthermore, since saline infused animals will recover neurologic function and show no or minimal brain pathology, brain mitochondrial dysfunction which develops during anoxia in saline infused cats is reversible following reoxygenation. 118.7 AMINO ACID TRANSPORT IN ASTROCYTE CULTURES. E. Stöcklin*, S.C. Quay*, Y-L. Lee* and L.F. Eng. Dept. Path., Stanford Univ. Sch. of Med. and Veterans Admin. Med. Cen., Palo Alto, CA 94304.

In other systems (Quay and Oxender, In: Biological Regulation and Development, R.F. Goldberg, ed., Plenum Press, New York, 1980, pp. 413-436) the study of amino acid transport in mammalian tissue cultures has provided insight into the process of cell differentiation and the response of the cell to injury, proliferation, and senesence. We report here the study of amino acid transport in rat astrocytes grown on Millipore filters. Secondary astrocyte cultures were prepared from newborn rat brains according to McCarthy and deVellis (J. Cell Biol. 85:890-902, 1980). One ml aliquots of primary astrocytes (5 x 10^5 cells per ml) were plated on 13 mm Millipore filters, placed in 24 well culture plates and maintained in serum supplemented medium until the cells were confluent (5-10 days). Some filters were immunocytochemically stained for glial fibrillary acidic protein and vimentin, some were analyzed for total protein and the remaining were used for transport studies.

The filter discs containing astrocytes (typically 70 µg protein/disc) were washed free of serum-containing medium and incubated with tritium-containing α-amino isobutyric acid, a non-metabolizable substrate for the mammalian amino acid transport system designated the A system (Christensen H.N.: Biological Transport, Benjamin, Inc., 1975, pp. 435-437). The uptake was time dependent, reaching a steady state in 6-10 min. The concentration dependence was examined and indicated a single independent uptake system with a Km of 4.55 mM and a V_{max} of 48 nmoles/min/mg protein. Finally, the system exhibited its typical sodium-ion dependence, since substitution of choline for sodium lead to a dramatic loss in uptake capacity. With the fundamental parameters of this system established, we are now exploring the effect of physiological or pathological manipulation of the cell culture on the transport system.

118.8 CA UPTAKE DURING ANOXIA IN THE RAT HIPPOCAMPAL SLICE. Peter Lipton, Cynthia Hurtenbach, and Ira S. Kass (Spon: D. Gilboe), Dept. of Physiology, University of Wisconsin, Madison, WI.

Irreversible anoxic damage to hippocampal slices depends on extracellular calcium. Thus, prolonged (at least 3 hrs) inhibition of synaptic transmission following 10 minutes of anoxia is prevented if the buffer during anoxia contains 10 mM Mg/OmMCa (Kass & Lipton, J. Physiol., 1982); a similarly induced inhibition of protein and RNA synthesis is prevented if the buffer during anoxia contains OmMCa (Raley & Lipton, these meetings). These results suggest that an anoxic induced increase in Ca uptake may be causing irreversible damage to these processes. Prolonged inhibition of transmission is more sensitive to anoxia in CA1 than in the dentate granule cell (DG) region.

Ca uptake was measured by incubating hippocampal slices with 45-Ca (10µCi/ml) for different periods of time and measuring intracellular accumulation.

Anoxia increased 45-Ca accumulation in both DG and CA1. The increased accumulation was about twice as great in CA1 as in DG and, via a kinetic analysis of uptake, appeared to result from a decrease in unidirectional efflux and not an increase in unidirectional influx. The analysis showed that ten minutes of anoxia should increase exchangeable Ca in CA1 by 30% and in DG by 15%.

The presence of 2 mM Cobalt during anoxia prevents transmission damage. It did not prevent the increase in Ca accumulation during anoxia at all in DG and inhibited it by only 35% in CA1. This is consistent with the conclusion that inhibition of efflux is the major cause of excess Ca accumulation during anoxia.

Pre-incubation with creatine strongly protects the tissue against anoxic transmission damage, maintaining ATP and K/Na levels during anoxia. This pre-incubation reduces the anoxic increase in Ca influx by about 50% in both CA1 and DG.

Ouabain, at a dose which increases cell Na/K more than anoxia, does not increase Ca uptake. This suggests that decreased Na gradient driven Ca efflux does not account for the anoxic increase in Ca uptake.

Thus, 1) there is an anoxia-associated increase in Ca uptake which is larger in CA1 than in DG; CA1 is more sensitive to anoxic transmission damage than is DG; 2) Treatments which strongly protect against anoxic transmission damage (Cobalt & Creatine) also strongly attenuate net Ca influx during anoxia. These data are consistent with the conclusion that increased Ca influx during anoxia participates in irreversible anoxic damage. The increase appears largely due to an inhibition of the efflux Ca-ATPase but, in CA1, is partially due to an increase in influx through depolarization-sensitive channels.

118.9 SIGNIFICANT INTRACELLULAR ZINC ACCUMULATION IN CARDIAC AND SKELETAL MUSCLES OF DYSTROPHIC HAMSTERS WITH HYPERTROPHIC CARDIOMYOPATHY. A.J. Crawford and S.K. Bhattacharya. Surgical Research Laboratory, University of Tennessee Medical Center, Memphis, TN 38163.

In previous investigations, we have quantitatively established the presence of excessive intracellular calcium accumulation in BIO-14.6 strain dystrophic hamsters (DH) and C57BL/6J-dy^{2J} strain dystrophic mice, in patients with Duchenne muscular dystrophy (DMD), in patients with other neuromuscular disorders, and in prenecrotic muscle from male human fetuses at risk of DMD (Neurology,34:1436, 1984). The tissue zinc (Zn) content in muscular dystrophy (MD), however, has not been extensively characterized. Recently, zinc has been shown to play important roles in protein synthesis, cardiac malfunctions, cellular necrosis, collagen cross-linking, and wound healing. In a study of striated muscle, Zn has also been shown to act much like UO_2^{2+} on the membranes by prolonging the action potentials and muscle contraction times. Since all of these process are intricately associated with the dystrophic lesions, we measured the Zn content in cardiac and skeletal muscles of 7-month-old male DH and age and sex matched BIO-F1B normal hamsters (NH). The atomic absorption spectrophotometric technique of Bhattacharya et al. (Analytical Letters,17:1567,1984) was employed for Zn determinations in the nitric acid extracts of the tissues.

Zinc Contents in mg/kg Fat-Free-Dry Tissue (Mean ± SEM)

Group(N)	Myocardium	Diaphragm	Rectus Femoris
NH (10)	81.17±3.25	125.16±3.39	72.14±5.14
DH (8)	105.20±15.30	153.25±7.25	131.11±12.84
Significance	p<0.002	p<0.005	p<0.001

The tissue Zn contents of the myocardium, diaphragm, and rectus femoris were significantly elevated in DH compared to NH. This excessive intracellular Zn accumulation is physiochemically compatible with the increased protein synthesis in the diaphragm and heart, the significant ventricular hypertrophy, the characteristic electrocardiographic and mechanophysiologic abnormalities, and the histological changes observed in DH. These observations suggest a possible physiologic role of Zn in MD and perhaps implicate an accelerated effort by the cellular system(s) to repair the tissues damaged by the dystrophic processes.

118.10 CHANGES IN THE RATE OF OXIDO-REDUCTION OF THE NADH IN THE RESPIRATORY CHAIN IN TOAD RETINA INDUCED BY CADMIUM IONS. Carlos Rodríguez-Estrada. Cátedra de Fisiología, I.M.E., Facultad de Medicina, U.C.V., Caracas, Venezuela.

In a recent review G.P.Cooper et.el. (Cellular and Molecular Neurotoxicology, Raven Press,N.Y.1984) postulated an anabolic effect of heavy metals as a partial explanation to the released of neurotransmitters by the impairment of energy production. In this work it has been studied the oxido-reduction change of nicotinamide adenine dinucleotide (NADH) of mitochondrial respiratory chain. Fluorometric determinations were performed in several preparation (13) as previously described. Each isolated preparation was placed in a gas circulated chamber at a constant temperature (298K). A full reduction of NADH was obtained after a period of anoxia, i.e. 5 minutes of circulating moistened nitrogen. Subsequently this gas (nitrogen) was replaced by oxygen. A 5 minute period in oxygen was allowed before a drop of Ringer solution with 10 micro-Mole of cadmium chloride was placed on top of the preparation. Then a second period of anoxia was repeated followed by oxygen. The rate of change of oxidation was measured timing it from the largest reduction to half oxidation of NADH ($t_{1/2on}$). The mean value after cadmiun ions was 7.679 seconds (SD =3.735, SEM =1.078) and the control, (i.e. preparation Cd ions-free) was 3.228 seconds (SD= 1.549, SEM= 0.447), P less than 0.001 (Student test =7.1; Underwood,B.J. et.al. Elementary Statistics) was obtained. These results indicated an action of cadmium ions on the respiratory chain, and supports the postulated anabolic effect as a partial explanation of the effect of heavy metals to the released of neurotransmitters.

118.11 EFFECT OF INTRACEREBROVENTRICULAR INSULIN ON METABOLIC SUBSTRATES OF HYPOTHALAMIC-LESIONED RATS. E.C. Lotter and L.L. Bernardis. Univ. of Rochester, Sch. of Med., Rochester, NY 14610 and Vet. Administration Medical Center, Buffalo, NY 14215.

Recently, we have reported that insulin infused into the cerebrospinal fluid (CSF) of normal and ventromedial hypothalamic lesioned rats (VMNL) resulted in a significant decrease of plasma epinephrine (E) and norepinephrine (NE) with no significant change in plasma insulin or glucose. The present study, extends the previous findings and examines plasma glycerol, free fatty acids, triglycerides and plasma protein of VMNL rats.

Weanling male Wistar rats (n = 10) received bilateral electrolytic lesions of the VMN; sham-operated animals served as controls. At maturity, free-moving unanesthetized VMNL rats (832 ± 25 g) and controls (420 ± 11 g) were infused with artificial rat CSF or CSF plus rat insulin (100 μU/15 μl) into the left lateral ventricle for 1 h.

Infusion of CSF alone had no reliable effect on plasma E and NE or glucose. Infusion of insulin resulted in a significant decrease of E and NE ($p < 0.05$). No change in plasma glucose was observed, thus replicating our previous findings. Mean baseline plasma glycerol (VMNL: 8.5 ± 1.78; C: 4.7 ± .28 mg%); free fatty acid (VMNL: 1438 ± 537; C: 890 ± 49.5 μM/L); triglycerides (VMNL: 136.9 ± 68; C: 32.9 ± 6.2 mg/dl) were significantly different between the VMNL rats and their controls. No significant difference in plasma protein was observed between the two groups.

These data suggest that CSF insulin infusions may have a direct effect on plasma E and NE of normal and obese rats and may account for the observed reduction of food intake and body weight.

FUNCTIONS OF GLIA II

119.1 SYNERGISTIC ACTION OF FIBROBLAST GROWTH FACTOR AND DEXAMETHASONE ON ASTROGLIAL CELL MITOGENESIS. Douglas A. Kniss and Richard W. Burry, Dept. of Anatomy and Neuroscience Research Laboratory, The Ohio State University, College of Medicine, Columbus, OH 43210.

Astroglial cell proliferation is an important component of CNS ontogeny. In addition, marked astroglial hyperplasia is a common feature of CNS trauma. We have used a primary cell culture model in an effort to understand the putative signal molecules governing glial cell cycle activity.

Primary astrocyte cultures were prepared from 2-d rat cerebellum. After 9-10 d in vitro cells were subcultured into 24-well plates at $1x10^5$ cells per well with 10% fetal calf serum (FCS). Glial cells were growth arrested with 0.25% FCS and, after 2-4 d growth in low serum, were stimulated with test substances and labeled with ^{3}H-TdR for 24 h. DNA synthesis was assessed by liquid scintillation counting of trichloroacetic acid-insoluble radioactivity to serve as a measure of cell proliferation.

Initial experiments tested several peptide growth factors (Epidermal Growth Factor, Fibroblast Growth Factor, Platelet-derived Growth Factor, and insulin) for their ability to stimulate DNA synthesis in serum-free medium. Only bovine brain FGF induced a significant enhancement of astroglial cell DNA synthesis. Half-maximal stimulation occurred at 2-3 ng FGF per ml.

Previously, we reported that dexamethasone (DEX) arrested the growth of astrocytes cultured in FCS-containing medium (Kniss and Burry, Soc. for Neurosci. Abstr. 10 (1984) 764). In another experiment, we examined whether similar growth arrest could occur when DEX was presented to cells stimulated by FGF (a brain tissue-derived mitogen). When DEX and FGF were presented simultaneously to growth arrested astrocytes there was a potent synergistic effect on DNA synthesis. That is, cells were stimulated almost 2-fold over levels seen in FGF alone or in FGF plus 5% FCS. Moreover, DEX alone caused a 50% growth arrest in serum-stimulated astrocytes. These results suggest that FGF-induced mitogenesis is potentiated by DEX, while serum-stimulated mitogenesis is inhibited by DEX.

FGF, PDGF, and EGF were generously provided by D. Gospodarowicz, W.J. Pledger, and S. Cohen, respectively. 119.2 PROLIFERATION AND DIFFERENTIATION OF ASTROCYTES IN RESPONSE TO NEURAL TRAUMA. B.T. Faddis and V.K. Vijayan. Dept. of Human Anatomy, School of Medicine, Univ. of Calif., Davis, CA 95616.

By contributing to glial scar formation, astrocyte proliferation may play a key role in both the functional recovery of damaged neural systems and the successful integration of neural transplants with host tissue. Previous studies of neural trauma using pulse injections of ^{3}H-thymidine have shown labelling of 1-2% of GFA-reactive astrocytes in the rat cortex (Dev. Biol., 72:381, 1979). Combining autoradiography and GFA immunohistochemistry with plastic embedding, we examined trauma-induced proliferation of astrocytes in the cortex and hippocampal neuropil of the rat brain to determine: (1) whether a greater magnitude of astrocyte proliferation could be demonstrated with repetitive intralesion injections of ^{3}H-thymidine, and (2) whether the morphologically distinct stages of astrocyte differentiation observed in vitro (J. Neuroimmunol., 2:235, 1982) could be identified in vivo during the course of astrocyte proliferation.

Adult, male Sprague-Dawley rats received unilateral needle wounds through cortex and hippocampus (N=4). They received daily intralesion injections of 10.0 μCi ^{3}H-thymidine at 24,48,72, and 96 hours postlesion. Control rats (N=6) did not receive lesions or thymidine. Rats were sacrificed by vascular perfusion with buffered 4% paraformaldehyde one hour after the last injection. Seventy μm slices through the lesion were stained immunohistochemically for GFAP, flat embedded in methacrylate, and sectioned at 1.0 μm for autoradiographic processing.

In control rats, astrocytes showed a regional difference in their numerical densities. Density in the cortex (2.2 per oil immersion field) was less than that of the hippocampal neuropil (3.0 per field) ($P < .02$). Repetitive injections of thymidine resulted in labelling of 40% of astrocytes in both cortex and hippocampus at three days postlesion. Although the hippocampal astrocyte population showed no increase over control numbers, those of the cortex demonstrated an increase of 200% ($P < .01$). Several stages of astrocyte differentiation were apparent in "stabbed" tissues. An astroblast stage with little or no GFA staining and immature processes characterized the earliest form detected. A ring of GFA-staining cytoplasm then appeared around the nucleus followed by vacuolation of the cytoplasm which lead to the formation of thicker processes and development of the mature astrocyte.

We have shown that substantial astrocyte proliferation occurs within three days of neural trauma. Reactive astrocyte proliferation is associated with astrocyte differentiation similar to what has been shown in culture. These studies suggest that neural trauma will prove to be an ideal model for the in vivo testing of various factors known to affect astrocyte behavior in culture.

119.3 POST-ISCHEMIC CHANGES IN PERINEURONAL GLIA. C.K. Petito, Department of Pathology, New York Hospital-Cornell Medical Center, New York, N.Y. 10021.

The response of perineuronal (PN) glial cells to cerebral ischemia and to the presence of ischemic neuronal necrosis was studied by electron microscopy (EM) and by quantitative estimates of cell size and number. Ischemia was produced in rats by permanent occlusion of the vertebral arteries and 30 minute occlusion of the common carotid arteries. This insult produces severe and consistent ischemic neuronal damage in the dorsolateral striatum (Stroke 10:267-72, 1979) and is associated with early proliferative changes in astrocytes. Animals were sacrificed by perfusion-fixation following post-ischemic (P-I) intervals of 3, 15, 30, 120, and 180 min and pieces of dorsolateral striatum were prepared for EM . Dark oligodendrocytes (oligos) represented 35.5% of control PN glia and showed no significant post-ischemic changes in cell size or morphology although a relative increase (65% of all PN glia) was noted at 180 min. Medium oligos represented 55% of control PN glia and showed a significant mild and persistant increase in cell size by 3 min after ischemia and a marked decrease in number to 6.5% of all PN glia at 180 min. Astrocytes represented 11% of control PN glia. A significant increase in size occurred at 120 min and an increase in number to 23% of all PN glia at 180 min; morphologic changes included mitochondrial alterations as previously reported (Ann Neurol 11:510-18, 1982) and microtubule proliferation; intermediate filaments were present but sparse. Transitional PN glia appeared first at 15 min P-I and showed characteristic EM features of oligos as well as of astrocytes (dispersed nuclear chromatin) or microglia (myelin figures and lipid inclusions). Well-differentiated microglia were seen at 180 min, contained lipid inclusions, myelin figures, and long wavy endoplasmic reticulin cisterns, and represented 8.5% of all PN glia. These results suggest that the PN glia identified by EM criteria as medium oligos are transformed into reactive astrocytes or into microglia in areas of ischemic neuronal necrosis. The current data is insufficient to determine if medium oligos seen in controls actually represent oligos, intermediate glia, or true astrocytes and microglia unidentifiable as such by EM criteria alone.

119.4 ASTROCYTIC REACTION IN CULTURE FOLLOWING ISCHEMIA. W.J.Goldberg J.R.Connor and J.J. Bernstein. Lab. CNS Injury and Regeneration, Veterans Administration Medical Center, Washington, DC. 20422 and Depts. of Physiology and Neurosurgery, George Washington University School of Medicine, Washington, DC. 20037.

Reactive astrocytes are observed in response to injury to the CNS. Such cells are morphologically characterized by fibrillogenesis and an increase in the density of staining reaction with anti-GFAP. We report here the appearance of astrocytes with altered morphologies and increased reaction with anti-GFAP in primary cultures of rat spinal cord following 4 hours of ischemia and 24 hours recovery. Dissociated cultures of spinal cord cells from day 14 gestation rat embryos were maintained for 3 weeks in nutrient medium supplemented with a survival factor isolated from horse serum (Kaufman and Barrett, Science 220:1394,1983). Ischemia was induced by removal of oxygen and glucose from the culture medium (Goldberg et al. Neurosci. Abstr. 9:855,1983) for a period of 4 hours. 24 hours after the return to normal culture medium the cells were fixed in 3.7% buffered formaldehyde and stained immunohistochemically for GFAP (GFAP antiserum provided by Dr. L.F. Eng, VA, Palo Alto) using the peroxidase-antiperoxidase reaction for visualization. In control cultures the majority of GFAP-positive cells had an unreactive nucleus and 2 major processes leaving from the soma which divided into many fine processes at the terminus. Following ischemia 2 new classes of staining reaction were observed. The predominant reaction was more intense than that observed in control cultures and the astrocytes had an altered morphology. The soma became more prominent and now had many short, broad processes which were less branched than those observed in control cultures. Some astrocytes were observed which had increased reaction product density but not the morphological alterations. In some regions of the ischemic cultures normal and reactive glial cells were observed in the same photographic field. In experiments involving shorter periods of ischemia these intensely staining astrocytes were not observed. When spinal cord cultures were subjected to a similar period of anoxia (removal of oxygen from the culture medium and surrounding atmosphere) no increase in the density of reaction product with anti-GFAP was observed but the morphological alterations previosly described were wide-spread. The appearance of intensely GFAP-positive astrocytes with altered morphology seems to be related to the extent of the damage suffered by the culture, as measured by loss of neurons and neuronal processes, and resembled reactive astrocytes observed in vivo following CNS insult.
Supported by the Veterans Administration.

119.5 MORPHOLOGICAL CHARACTERIZATION OF REACTIVE ASTROCYTES IN EXPLANT CULTURES OF GLIAL SCARS. Patricia A. Trimmer. Department of Neurological Surgery, School of Medicine, University of Virginia, Charlottesville, VA 22908.

Astrocytes become reactive and form a glial scar in response to a variety of pathological conditions which induce axonal degeneration in the CNS. A number of questions on the subject of reactive astrocytes and their role in axonal sprouting and regeneration in the CNS remain unanswered. Glial scars derived from rat optic nerve were used in this study to establish and characterize the morphology of reactive astrocytes in vitro. Glial scars were formed in 5-7 day-old rat pups by unilateral enucleation. The unoperated control optic nerves and glial scars were excised 14 days later using sterile techniques. The dural sheath was removed and the tissues were cut into 1-2 mm segments. The explants were grown on poly-D-lysine coated glass chamber slides in media consisting of Eagle's basal metabolic medium with Earle's salts supplemented with 10% fetal calf serum, 0.1% glutamine and 0.6% glucose. During the first week in culture, both polygonal and process-bearing cells grew out of the glial scar and optic nerve explants. The outgrowth of cells from the explant proper slowed down and after about 2 weeks appeared to stop. Examination of explants processed for electron microscopy revealed that the glial scars were composed of a homogeneous population of hypertrophied astrocytes whose cell bodies and processes contained large numbers of densely-packed intermediate filaments. Other prominent features of these reactive astrocytes were irregularly-shaped euchromatic nuclei, microtubules, and wide-bore cisternae of rough endoplasmic reticulum. The ultrastructural morphology of reactive astrocytes in culture closely resembled the morphology of reactive astrocytes in vivo. However, reactive astrocytes in vitro did not contain the large quantities of glycogen normally found in reactive astrocytes in vivo. Explants of normal optic nerve underwent degeneration in culture. In general, astrocytes in the central portion of optic nerve explants also became reactive and formed a glial scar. These observations illustrate that reactive astrocytes can be maintained in culture and that cultured reactive astrocytes exhibit ultrastructural features comparable to reactive astrocytes in vivo. Furthermore, astrocytes in normal optic nerves which degenerate in vitro can become reactive and form a glial scar. These findings suggest that explant cultures of rat optic nerve and glial scar can be useful models for future studies of the causes, characteristics and consequences of the reaction of astrocytes to CNS injury.
Supported by NIH Training Grant NS07199.

119.6 IMMUNOHISTOCHEMICAL CHARACTERIZATION OF NORMAL AND REACTIVE GLIA IN THE ADULT FROG SPINAL CORD. F.J. Liuzzi and R.H. Miller*, Dept. of Anatomy, Case Western Reserve Univ., Cleveland, Oh. 44106

Recent studies (Sah and Frank, J. Neurosci. 4:2784, 1984 and Liuzzi and Lasek, J. Comp. Neurol. 232:456, 1985) have shown that dorsal root axons regenerate into the spinal cord of adult frogs. This suggests that the amphibian glial response does not impede axonal regeneration. In this study we used immunohistochemical techniques to characterize the glia of the normal frog spinal cord and to study their response to axonal degeneration within the cord subsequent to dorsal root section.

Previous studies have shown that the adult frog spinal cord contains only one morphological type of astrocyte (Sasaki and Mannen, J. Comp. Neurol. 198:13, 1981). These radial glial cells have their somata within the gray matter and have long processes that extend through the white matter to the cord surface where their endfeet form the glia limitans. In addition, Dahl and Bignami (Brain Res. 61:279, 1973) have demonstrated GFAP positive elements in the adult frog spinal cord. However, they did not describe the detailed distribution of the protein in the gray and white matters.

In transverse sections of normal adult frog spinal cord, we have found that GFAP immunofluorescence reveals radially oriented processes within the white matter. There are, however, no GFAP positive cell bodies within this region. By contrast, within the gray matter, the processes of the radial glial cells were either weakly GFAP positive or negative. Similar patterns of immunofluorescence were obtained with vimentin antibody.

Following dorsal root section, the intensity of GFAP and vimentin immunofluorescence increased dramatically in the white and gray matters. Moreover, within the dorsal funiculus, there appeared to be a breakdown of the radial orientation.

These results suggest that in the normal frog spinal cord, both GFAP and vimentin appear to be preferentially localized within those regions of the radial glial processes that extend through the white matter. In response to axonal degeneration, the radial glial cells become reactive showing increased GFAP and vimentin immunofluorescence. Changes in the glia may contribute to the support of axonal regeneration in the adult frog spinal cord.

119.7 **Interleukin like molecules in normal and injured brain.**
M. Nieto-Sampedro, K.G. Chandy*, M. Berman*, C.I .Sandborg*, C.W. Cotman, S. Gupta* and G.J. Friou*. Dept. of Psychobiology and Dept. of Immunology, University of California, Irvine, CA 92717.

The mitogenic activity of extracts of rat brain on purified astrocytes in culture increased up to 3-fold in the tissue surrounding a brain injury. Maximal activity occurred 6 days postlesion and was still twice the basal level 20 days later.

Rat brain also contained molecules capable of promoting thymidine incorporation into phytohemoagglutinin stimulated mouse thymocytes. Such IL-1 like activity increased about 10-fold following brain damage, and its increase postlesion paralleled or slightly preceeded that of astrocyte mitogens. Brain "IL-1" behaved in a Sephacryl S-200 column as authentic IL-1 did, giving peaks at apparent molecular weights of 30,000, 15,000 and 5,000. The most abundant species in brain was that of 15,000 molecular weight. Monoclonal antibodies to human IL-1 inhibited 60 to 70 % of the brain mitogenic activity on astrocytes and thymocytes and more than 90% that on fibroblasts.

Purified brain astrocytes in culture secreted in their growth medium at least 5-times as much IL-1 like activity as similar numbers of peripheral monocytes. However, in the case of astrocytes the most abundant species was that of mol.wt. 5,000 (about 70%) followed by mol.wt. 15,000 (ca. 30%). The high molecular weight species was barely detectable.

Brain injury caused a 7-10 fold increase in the activity of a mitogen promoting thymidine incorporation in IL-2-specific CTLL cells. In a hplc sizing column, this mitogen had an apparent molecular weight of 23,000 whereas under identical conditions murine IL-2 had a mol.wt.of 15,000.

Brain interleukin-like molecules could play a regulatory role in glia proliferation and hypertrophy after CNS injury. In normal brain, IL-1 may control hypothalamic pituicyte swelling, thereby contributing to thermoregulation and regulation of water intake.

119.8 IMMUNE RESPONSES IN BRAIN. L.L.Y. Chun* and A. Rao*. (SPON:K.J. Sweadner). Dept. Neurology, Massachusetts General Hospital, Boston, MA 02114 and Div. of Immunopathology, Dana Farber Cancer Institute, Boston, MA 02115.

The central nervous system (CNS) has classically been thought to be outside the surveillance of the immune system because it is protected by the blood brain barrier and lacks lymphatic drainage. Recent evidence, however, suggests that endogenous brain cells may play a role in the generation of immune responses in the CNS. Two aspects of these responses which appear to mediated by astrocytes are reported here. In these studies we dissociated tissue from early postnatal mouse brain and prepared cultures which were at least 90-95% astrocytes as judged by immunofluorescent staining with antibodies to glial fibrillary acidic protein (GFAP).

We studied the ability of these dissociated cells to present antigen to T helper lymphocytes. T cell clones specific for ovalbumin or p-azobenzenearsonate co-cultured with astrocytes exhibited increased proliferation as measured by ^{3}H-thymidine incorporation. This effect was antigen specific and major histocompatibility restricted (MHC). Similar results were obtained when T cell activation was measured by interleukin-2 production. In double-label immunofluorescent experiments with antibodies to GFAP and I-region associated antigens (Ia), we found that at least a subpopulation of astrocytes activated by T cell clones expressed Ia, whereas astrocytes cultured alone did not. These data suggest that one role the astrocyte may play in brain immune responses is that of an antigen presenting accessory cell.

We have also studied the ability of astrocytes to mediate target cell lysis in vitro. Co-cultures of astrocytes and T helper cell clones exhibited the ability to kill P815 tumor cells. The ability of the astrocytes to be activated to cytotoxicity was antigen specific and MHC restricted. In addition, cells from several CNS areas were competent, whereas cells obtained from several different ganglia in the peripheral nervous system were not. It is not yet known whether the ability to present antigen and the ability to mediate target cell lysis reside in the same cell.

The finding that astrocytes can actively participate in immune responses may have important implications where there is acute injury to the brain or in certain neurologic diseases such as multiple sclerosis, where there is evidence of lymphocyte infiltration into the CNS. Whether these mechanisms also play a role in other types of brain pathogenesis is unclear.

119.9 GLIA RESPOND TO SYSTEMIC IMMUNE DISEASE. L. Lonsberry* and W.S.T. Griffin. Univ. of Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235.

Graft-vs-host-disease (GVHD) is a systemic immune disease characterized by high serum titers of factors produced by activated lymphocytes (Grebe, S. & Streilein, W., Adv Immunol., 22:119, 1976), increased cortisol levels (Hoot, G., et al., Transplant., 35:478, 1983), increased gamma interferon (IFN-) levels (Zawatsky, R., et al., Can Fed Biol Sci., 22:415, 1979), and lymphocytic infiltration of many organs, but not brain. Lymphocytic infiltration is associated with increases in class II antigens, suggested infiltration targets (Suitters, A. & Lampert, I., Transplant., 38:194, 1984). In vitro, either cortisol or soluble factors from activated lymphocytes stimulates astrocyte proliferation, RNA synthesis, and elaboration of growth-factor-like products (Fontana, A., J Neurosci Res., 8:443, 1982), and IFN- induces class II antigens (Ia) (Wong, G., et al., Nature, 310:688, 1984). We have investigated whether or not experimentally-induced GVHD 1) mimics in vitro responses to immune factors and cortisol, i.e., proliferation of glial-fibrillary-acidic-protein (GFAP) immunoreactive astrocytes and 2) induces Ia expression in the absence of infiltrating lymphocytes. Brain tissue was collected from FI rats with GVHD induced on the day of birth by intravenous injection of DA rat lymph node cells, as well as from rats with adult-onset GVHD. Uninjected littermates were controls. One-half of each brain was fixed in Bouin's, embedded in paraffin, and stained with antibody to GFAP using a peroxidase-anti-peroxidase technique, while the other half was mounted in OCT (Miles) and frozen at -70C. After sectioning, frozen tissue was acetone fixed and immunoreacted with antibodies to GFAP and Ia. There was an age-related, progressive increase in GFAP immunoreactivity in rats with neonatally-induced disease compared to their littermates. Moreover, rats with adult-onset GVHD had a similar increase in GFAP immunoreactivity, signifying that the blood brain barrier does not exclude GVHD-induced, astrocyte stimulating factors. Compared to controls, there were more GFAP-immunoreactive cells and more immunoreactive product in individual astrocytes. This gliosis was not associated with an induction of Ia, suggesting that other facets of GVHD, such as increased titers of immune factors and/or alterations in hormone levels are responsible for the GVHD-induced gliosis in neonatal as well as adult rats. The lack of Ia induction in the brain during GVHD may be related to the absence of lymphocytic infiltration in brain. This non-cell mediated gliosis is reminiscent of that in Alzheimer's and other dementing disorders, suggesting immune involvement in neuropathologies. We propose GVHD as a model for studying factors generated during the immune response and their varied effects on the brain. This work was supported by AI 14663 and AG 05537.

119.10 INHIBITION OF ASTROCYTE VOLUME CONTROL BY CIRCULATING FACTORS ASSOCIATED WITH REYE'S SYNDROME. J.E. Olson, R. Sankar, and D. Holtzman. Dept. Psych. and Neurol., Tulane Univ. Sch. of Medicine, New Orleans, LA 70112

Reye's Syndrome is an acute childhood illness with severe intracellular brain edema. The brain pathology is characterized by large, swollen astrocyte cell bodies and foot processes with little apparent change in extracellular volume (Partin et al., J Neuropath Exp Neurol 34:425-444, 1975). Serum factors; including elevated levels of short chain fatty acids such as octanoate, prolonged elevation of NH_4^+, and the presence of salicylates; have been implicated in the pathogenesis of brain edema in Reye's Syndrome. To investigate potential mechanisms of cellular brain edema, we have measured the effects of Reye's Syndrome serum factors on energy metabolism and volume control in primary cultured rat cerebral astrocytes.

Astrocytes suspended in hypo-osmotic medium swell initially and then shrink toward the volume of cells maintained in iso-osmotic medium. This regulatory volume decrease is energy-dependent and tightly coupled to (Na,K)-ATPase activity (Olson et al., Biophys J 47:475a, 1985). The astrocyte regulatory volume decrease is completely inhibited with 1-4 mM octanoate, concentrations observed in the serum of Reye's Syndrome patients. Very high NH_4^+ (15 mM) or salicylate (10 mM) concentrations do not affect the astrocyte regulatory volume decrease. At these concentrations, octanoate, but not salicylate, inhibit basal oxygen consumption in astrocytes. Salicylate, more than octanoate, increases respiration in cells previously exposed to oligomycin (an inhibitor of oxidative phosphorylation). Octanoate (0.4 mM) also reduced by 30% the component of astrocyte oxygen consumption inhibited by ouabain, suggesting a direct effect on (Na,K)-ATPase activity. Thus, in Reye's Syndrome, elevated serum levels of octanoate, but not NH_4^+ or salicylate, could produce cellular brain edema by interfering with astrocyte volume control. This effect is not related to uncoupling of mitochondrial electron transport, but may be a result of direct inhibition of astrocyte (Na,K)-ATPase.

119.11 REVERSIBILITY AND SODIUM INDEPENDENCE OF MONENSIN-INDUCED GOLGI SWELLING. A.F. Boyne, P. Yarowsky, R. Wierwille* and N. Brookes. Dept. of Pharmacol. & Exp. Therap., Univ. of Md. Sch. of Med., Balt. MD 21201.

The sodium-selective ionophore, monensin, is well known to cause swelling of Golgi cisternae and block of normal Golgi function in several cell types. This effect is generally thought to result from sodium loading of the cytoplasm. We have shown that in mouse cerebral astrocytes monensin causes a large, rapidly reversible increase in glucose use, measured by tritiated 2-deoxy-glucose uptake, in addition to causing marked Golgi swelling and vacuole formation. Whereas monensin-stimulated glucose utilization was abolished in a Na-free solution, the Golgi effect was still apparent.

Cell cultures of mouse cerebral astrocytes were exposed to 5 μM monensin in Tris-buffered balanced salts solution (BSS) at 35°C for 20 min. The cultures were prepared for EM study by quick freezing or by aldehyde fixation. Golgi swelling increased in the cis-trans direction across the stack, with spherical vacuoles appearing to arise from the trans cisternum. A similar pattern was present in cultures exposed to monensin in Na-free (choline substituted) solution. Astrocyte Na-loading by 20 min exposure to zero K^+ caused relatively selective swelling of the trans Golgi cisternum and small vacuole formation.

Morphometric analysis of aldehyde fixed cultures showed that the effects of 5 μM monensin and zero K^+ solution were additive, together producing 10 ± 0.9% (SE, 25 cells) vacuolization, as a fraction of the total non-nuclear cytoplasmic area. Morphologic recovery was rapid on returning these cultures to normal BSS at 35°C. By 10 min after washing, vacuoles occupied 7 ± 0.8% (7 cells) and by 20 min they had reverted to the control level of 2.4 ± 0.4% (16 cells).

Thus, monensin-induced swelling of astrocyte Golgi is at least partially independent of Na-loading. The rapidity with which the swelling reverses on washing suggests that the ionophore moves readily in and out of cell membranes. It further suggests an ability to penetrate directly to the Golgi. Swelling may then occur by exchange of Golgi protons (which are not osmotically active) for cytoplasmic Na. Further active H^+ pumping and passive Cl^- entry would give rise to osmotically active salt accumulations, and visible swelling.

119.12 Ca-CONTROLLED, REVERSIBLE STRUCTURAL TRANSITION IN MYELIN

A. E. Blaurock* and J. L. Yale* (SPON: J. E. Wilson)
Department of Biochemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514

The myelin in goldfish spinal cord, originally compact, swells spontaneously when excised cord is kept in physiological saline at 23°C without any fixation. As studied by X-ray diffraction, this myelin initially has a 150 Å repeating distance (from one major dense line to the next), but it gradually converts to a slightly swollen, although equally regular, form having a 175 Å repeat. No intermediate repeat is detected (A. E. Blaurock, J. L. Yale and B. I. Roots, Trans. Am. Soc. Neurochem. 16, 183 [1985]).

We now report that Ca is required in the saline for swelling to occur in goldfish spinal-cord myelin and that, after an initial swelling phase, swelling can be reversed by removing Ca. First, about half the myelin converts to the swollen form after one day in the normal saline, but none of the swollen myelin is detected after a day in saline lacking Ca. Second, 6.5 mM NaCN in the saline speeds up the rate of swelling about four-fold, but there is no swelling if Ca is omitted from the saline containing NaCN. Other agents that accelerate swelling when added to the normal saline (colchicine, β lumi-colchicine, A23187, high pH) also fail to have any effect in the absence of Ca. Third, when a NaCN-treated cord is treated subsequently with Ca-free and NaCN-free saline containing 10 mM EDTA, about half of all the myelin converts back to the normal, compact form; however, if NaCN is present in the Ca-free saline, there is no recovery and more of the compact myelin swells. Fourth, myelin first swollen in saline without NaCN also tends to recover in Ca-free saline, but to a lesser extent than after swelling in saline containing NaCN. Regarding specificity for Ca, only a trace of the myelin swells when Ba or Sr is substituted for Ca in the saline. A similar cycle of swelling and recovery has been induced in human oculomotor-nerve myelin but not in human optic-nerve myelin.

These results demonstrate that some kinds of myelin are bistable. They are consistent with the hypothesis that in some cases active metabolism maintains normal, compact myelin by keeping down Ca concentration within the sheath. Although the swelling here is pathological, it would appear possible for a limited region of a normal internode to swell due to a local influx of Ca *in vivo*, as a precursor to large-scale opening of the interbilayer spaces, e.g. in Schmidt-Lantermann clefts. Finally, our results suggest a new basis for myelin pathology similar to the failure of heart muscle cells due to excessive free Ca inside them.

We thank Drs. J. E. Wilson and R. V. Wolfenden for helpful discussion. Supported by the Biomedical Research Support Grant Program at UNC-CH.

DEVELOPMENTAL DISORDERS I

120.1 TRISOMY 16 IN MOUSE AS A MODEL OF DOWN'S SYNDROME IN HUMANS: ELECTROPHYSIOLOGICAL PROPERTIES OF NEURONS MAINTAINED IN CULTURE. C. Orozco* C.J. Epstein* S. Smith* and S.I. Rapoport (SPON: Ch. Edwards). Lab. of Neurosciences, NIA. Bethesda MD 20205 and Dept. of Pediatrics. School of Medicine. Univ. of Cal. San Francisco.

Alterations in the electrical membrane properties of neurons have been postulated to cause mental retardation in subjects with Down syndrome (DS)(Scott, et al. 1982. Dev Brain Res. 2: 257-270). Trisomy 16 in mice is considered as to be a model of trisomy 21 in humans (Epstein et al. 1984. In: Research Perspectives in Cytogenetics. Sparks & de la Cruz Eds. Univ. Park Press. Baltimore). The purpose of this study was to characterize the electrical membrane properties of normal and trisomic neurons from mice embryos to correlate with the alterations seen in human neurons.

The experimental embryos were obtained by breeding normal females C57BL/6N with heterozygous males with double Robertsonian translocation from the strains 32Lub/2H or 9Rma/32Lub. 10% of the embryos are trisomic and have 2 metacentric chromosomes. The rest of the embryos with normal numbers of chromosomes and only 1 metacentric chromosome, were taken as controls. Dorsal root ganglia neurons taken from 12-14 days old embryos were dissociated and maintained in culture up to 3-4 weeks. A bridge amplifier (WPI model M-707) was used for intracellular recording and stimulation with single micro-electrodes filled with 3M KCl. The pipet resistance varied from 40 to 120 megaohms.

Control neurons showed a resting membrane potential (Vm) -48.2 ± 1.1 mV (S.E.M.)(n=59). They could conduct spontaneous and evoked action potentials whose amplitude and duration were 84.4± 2.1 mV (n=20) and 3.0± 0.1 msec (n=24). The magnitude of the after-hyperpolarizing potential was 13.4± 1.0 mV (n=24). The maximal rate of rise of the action potential was 120.0± 1.5 V/sec meanwhile the time required for repolarization from the peak of the spike to 25% of the spike height was 3.9± 0.2 msec (n=15). The threshold of excitation at 50 msec of duration pulse was 1.8±0.3 nA (n=20). These values are similar to published values for normal cells (Ransom et al. 1977. J. Neurophysiol. 40: 1132-1150) and have showed that the translocation of one chromosome had no effect in the neuronal electrical membrane properties.

In 29 trisomic neurons Vm was similar to that in the controls, -48.4± 2.9 mV. Action potentials were also similar. Differences were found in the duration of the repolarization; however, due to the small number of cells sampled (n=7) additional experiments are required to support the suggestion that the trisomic cells posses altered electrical membrane properties. One clear difference was a lower survival of the trisomic cells in culture.

120.2 DEVELOPMENT OF CAUDAL AND SCIATIC NERVE CONDUCTION IN THE TWITCHER MOUSE AND HETEROZYGOUS AND NORMAL LITTERMATES. S. D. Lavine,* K. E. Burrell* and Ch. E. Olmstead.(Spon: G. C. Galbraith) UCLA School of Medicine, Mental Retardation Research Center Group at Lanterman State Hospital, Pomona, Ca. 91769.

The murine mutant "twitcher"(C57Bl/6J-twi) is an enzymatically authentic model for human globoid cell (Krabbe's) leukodystrophy (Suzuki & Suzuki, Am. J. Pathol, 1984, 111). This recessively transmitted genetic deficiency is for galactosylceramidase. We have previously (Soc. Neurosci. Abstr., 1983, 1984) described the neurological and neurobehavioral development of the mutant twitcher and its littermates. In addition to the progressive debilitation of the affected animal we have described some subtle differences between the normal and the heterozygote during development that suggest that this mutant may also be an excellent model for heterozygote risk for subtle neurological disease during life span development. The studies described here were carried out to develop a better understanding of the functional pathophysiology of this demyelinating disease in both the homozygously affected and heterozygous carriers.

Enzyme Assays. Between 5 and 8 days of age, lengths (<0.5cm) of tail were clipped and galactosylceramidase was determined by an assay adapted from Suzuki (Meth. Enzymol., 1978, 50). Tail and sciatic nerve conduction velocities (NCV) were performed under Nembutal anesthesia with the mouse immobilized on a temperature controlled (38 °C) platform.. Tail stimulation and recording was via needle electrodes inserted into the tip of the tail and at two points along the tail, respectively. For the sciatic the nerve was surgically exposed and elevated on silver hook electrodes in a warmed pool of mineral oil. Stimulation was to the pad of the foot through needle electrodes. Results of in vitro recordings from excised, desheathed sciatic nerve will also be reported.

The three genotypes were clearly different on the basis of tail NCV by 21 days of age with Normal > Heterozygote > Affected. The tail NCV of the affected mouse decreased from a median of 11.2 m/s at 21 days to 6.8 m/s at 36 days and was not elicitable at 42 despite the fact that a tail pinch still elicited a behavioral response. The sciatic showed a similar pattern in the affected animal showing a high of 12.0 m/s at 21 days decreasing to 6.5 m/s at 30 to 35 days of age and it was unmeasurable by 42 days. Generally this decline was accompanied by severe, observable, edema, but a hind limb withdrawal response remained. The tail NCV difference between the normals and the heterozygotes(22.5 versus 13.2 m/s) was clearly present at 21 days and both groups showed a consistent increase in velocity with aging. They were still significantly different (26.8 m/s vs 17.7 m/s) after 50 days of age. Similar findings will be reported for the sciatic nerve.

120.3 **SLOWED LOCOMOTOR RECOVERY FOLLOWING SCIATIC NERVE CRUSH IN MICE HETEROZYGOUS FOR GALACTOSYLCERAMIDASE DEFICIENCY (C57bl/6j-twi "Twitcher")** Ch. E. Olmstead. UCLA School of Medicine, Mental Retardation Research Center Group at Lanterman State Hospital, Pomona, Ca. 91769

The murine mutant "twitcher"(C57Bl/6J-twi) is an enzymatically authentic model for human globoid cell (Krabbe's) leukodystrophy (Suzuki & Suzuki, Am.J. Pathol,1984,111). This recessively transmitted genetic deficiency is for galactosylceramidase. We have recently developed evidence that this mutant may also be an excellent model for heterozygote risk for subtle neurological disease during life span development. The studies described here were carried out to develop a better understanding of the functional pathophysiology of this demyelinating disease in both the homozygously affected and heterozygous carriers.

Enzyme Assays. Between 5 and 8 days of age, lengths (<0.5cm) of tail were clipped and galactosylceramidase was determined by an assay adapted from Suzuki (Meth. Enzymol.,1978,50) Affected homozygotes(twi/twi), heterozygous carriers and normal animals were readily identified and were assigned to groups based on sex and genotype.

Sixty to 80 day old heterozygous and normal mice received crush or sham lesions of the left sciatic nerve under Nembutal anesthesia. Locomotor recovery was evaluated by a modification (Sugarman & Olmstead, Soc. Neurosci. Abstr., 1983) of the footprint technique of de Medinaceli, et al. (Exp. Neurol. 1982) and Hruska, et al. (Life Sci. 1979). Myelin turnover was estimated by the 24hr uptake into sciatic, spinal cord and brain of i.p. ^{35}S(1mCi ^{35}S $NaSO_4$/100g).

All of the mice with crushed sciatics showed significant disruption of the left leg gait that persisted until 8 to 12 days post-lesion. After that time the normal animals and a few of the heterozygotes showed a progression to complete recovery by thirty days. Significantly fewer heterozygotes showed complete recovery by 30 days post-lesion and those that did recover did so at slower rates than the normal controls. In addition there were subtle differences between the normals and heterozygotes on selected gait parameters during the recovery process. When studied at 40 days post-lesion the heterozygotes showed greater incorporation of ^{35}S into both the crushed and normal nerves when compared with the homozygous normals. This is consistent with other data from this laboratory demonstrating that during development myelin turnover remains high in heterozygotes. These data present both functional and biochemical evidence for slowed recovery of function in mice heterozygous for a demyelinating disease and suggest that carriers for such disease might be at increased risk for subtle neurological disease.

120.4 SPATIAL ABILITY IN A MURINE MODEL OF KRABBE'S DISEASE. R. N. Shull and C. E. Olmstead, UCLA Mental Retardation Research Center Group at Lanterman State Hospital, Pomona, CA 91769.

In the recessively transmitted Krabbe leukodystrophy, evidence indicates that adult carriers perform abnormally on some intelligence subtests, including spatial cognition (Christomanou et al., Hum. Genet. 1981, 58). The twitcher mouse (C57BL/6J-twi) is an anatomically and enzymatically correct model of this disease (Suzuki & Suzuki, Am. J. Pathol. 1983, 111). In order to test for higher-order behavioral abnormalities in heterozygotic murine carriers, two groups of normals and carriers (one per sex/4-6 months of age) were tested in an eight-arm radial maze similar to that described by Pick and Yanai (Int. J. Neurosci. 1983, 21). Genotype determinations were made on the basis of galactosylceramidase activity levels as determined by homogenized tail assays (Olmstead, Soc. Neurosci. Abstr. 1984, 8). Subjects were food deprived to 80% body weight and run one trial per day for 3-4 weeks. No significant genetic differences were found in either group regarding choice accuracy as measured by the number of non-repeated arm entries made during the first eight choices in the food baited maze. Both groups showed a rapid decline over trials in time spent in each arm while also showing a marked tendency to enter the arm closest to the last arm previously entered in a sequential pattern, although several times the subjects did alter this pattern to enter previously missed arms. In groups of aged animals (>20 months) this sequential pattern has not been seen, regardless of sex or genotype. There was also a definite bias in the female carriers for clockwise maze rotation/arm entry with counterclockwise movement seen in the female normals, a situation opposite to that seen in the male group. None of the groups showed significant performance deficits when tested in the dark under red-light conditions. In the female group, both atropine sulfate (0.5-4.0 mg/kg) and scopolamine HBR (0.5-2.0 mg/kg) produced a dose-dependent reduction in choice accuracy, with a larger reduction in number of pellets eaten, and a dose-dependent increase in time spent in each arm. Similar results were seen in the male group with scopolamine (0.5-4.0 mg/kg) alone. Scopolamine methyl bromide (4.0 mg/kg) produced similar results, although choice accuracy was somewhat less reduced Physostigmine salicylate (.05-0.4 mg/kg) in the male group did not produce any apparent decrease in choice accuracy but did, at the higher doses, increase time spent in each arm while reducing the number of pellets eaten. These results would indicate that simple choice accuracy as measured in a radial maze may not be adequately sensitive, at least under these conditions, to determine higher-order behavioral abnormalities in a genetically compromised murine CNS and that mice in such an environment may use different sensory cues from those of other mammalian species to negotiate the maze effectively.

120.5 DISPROPORTIONS IN NUMBER OF AFFERENT AND TARGET NEURONS FOLLOWING TEMPORAL EFFECT OF METHYLAZOXYMETHANOL ACETATE. S. Chen and D.E. Hillman, Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Methylazoxymethanol acetate (MAM) is ideal to selectively reduce the number of specific types of neurons undergoing active cell division at the time of administration. A single 20 mg/kg dose of MAM was injected peritoneally into pregnant rats at gestational day (G) 11 through 21 or subcutaneously into neonatal rats from postnatal (P) day 0 through day 5. All liters were limited to 8 pups and sacrificed at 60 days of age. The brains were first dissected into 4 parts: brainstem, cerebellum, olfactory bulbs, and cerebrum together with the thalamus and tectum. The hippocampus was dissected from the cerebral mass following separation from the thalamus and tectum. The parts were weighed, and light microscopy done on all regions to determine the cellular distribution.

Weight reduction for each brain region over the developmental period supports the contention that prenatal injections can differentially reduce the number of specific types of macroneurons while postnatal injection, in rat, affects only specific groups of microneurons.

Following G13 or 14 injections, the cerebellum was moderately decreased in weight and had a decrease in the number of Purkinje cells. For G13 to 17 (especially G15) injections, there was clearly a large deficit in the number of pyramidal cells of cerebrum and hippocampus. This was accompanied by a deficit in mitral cells of the olfactory bulb. Postnatal administration produced size reductions in the cerebellum, hippocampus and olfactory bulb due to the effect on granule cell proliferation in these three regions. These were most severe on day P0 and gradually improved until P5. The size of olfactory bulbs was reduced more than was the cerebellum. The hippocampus had only a mild change. The brainstem weight was virtually unaffected at any of these times.

Histological examination of the pre- and postnatally injected preparations revealed hypoplasia in the cerebrum, hippocampus, olfactory bulbs and cerebellum. The most severely affected hippocampus occurred prenatally with occasional disruption of the CA^{1-3} layer. The olfactory bulbs from P0 had very small glomeruli and mitral cells were in multilayers. Ectopic neurons in the cerebella were as described by others. MAM injection coinciding with the birthdate of neurons altered the proportion of Purkinje cells and granule cells of the cerebellum, mitral cells and the granule cells of the olfactory bulb, or pyramidal cells (entorhinal and CA^{1-3}) and the granule cells of the hippocampus. [Supported by USPHS grant NS-13742 from NINCDS]

120.6 **EARLY POSTNATAL EXPOSURE TO PHENYLACETATE INCREASES RESISTANCE TO EXTINCTION IN ADULTHOOD.** A.Rabe, Y.H. Loo*, P.Wang*, and R. Fersko*. NY State Office of Mental Retardation and Developmental Disabilities, Institute for Basic Research in Developmental Disabilities, Staten Island, NY, 10314.

Phenylacetate (PA), a major metabolite of phenylalanine, may be the primary cause of brain dysfunction associated with sustained hyperphenylalanemia. This hypothesis has found support in biochemical (Loo et al., Life Sci, 1980, 27, 1283), morphological (Robain et al., Acta Neuropathol., 1983, 61, 313) and behavioral (Fulton et al., Life Sci, 1980, 27, 1271) studies. In a series of experiments we sought to determine the nature of the behavioral changes resulting from early postnatal exposure to PA. Two aspects of these experiments are described here: responding on operant timing schedules and during subsequent extinction.

The offspring of Sprague-Dawley rats were injected with PA twice daily. The injections were given subcutaneously in the following doses as umol/g body wt: days 2-3, 2.5, days 4-16, 3.0, and days 17-22, 3.5. The control litters were injected with corresponding volumes of saline. As adults (70-120 d), the rats were deprived of water for 22.5 hr daily and shaped to press a lever for water reward on a continous reinforcement schedule. Subsequently, the animals received extended training (at the rate of 30 min/day) on one of three operant schedules; extinction, or responding in the absence of reinforcement, concluded each experiment. (1) Control (n=8) and PA-treated (n=8) groups were trained for 24 d on a fixed interval schedule with a 60 sec delay. There were no differences between the groups in either the total responses or in the distribution of responses. During 60 min of extinction, the PA animals made more median responses (297) than the controls (243). This difference was not statistically significant. However, the PA-treated rats had a significantly ($p<.05$, two- tailed U-test) smaller (56) drop in responses from reinforced to unreinforced responding than the controls (102). (2) Other control and PA-treated groups (n=6 in each) were trained for 24 d on a differential reinforcement for low rates (DRL) schedule with a 12 sec delay, then shifted to DRL 20 sec for 6 d. There were no significant differences between the two groups in total responses, the reinforcements received, and the percent of rewarded responses. During 90 min of extinction, however, the PA group emitted significantly ($p<.04$) more responses (376) than the controls (261). (3) A third pair of control (n=8) and PA groups (n=16) was trained on DRL 20 sec for 24 d and then shifted to DRL 30 sec for 9 d. There were no differences between the two groups. During 100 min of extinction, the PA rats again made significantly ($p<.02$) more responses (282) than the controls (196). (Supported in part by NIH grants 1 R01 16153 and 06843).

120.7 DEFECTS OF THE GLIAL SLING IN MOUSE FETUSES WITH HEREDITARY ABSENCE OF CORPUS CALLOSUM. D. Wahlsten, Dept. of Psychology, Univ. of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

About 20% of adult BALB/c inbred mice have serious deficiency or total absence of the corpus callosum (CC), whereas mice of the inbred C57BL/6J strain and the hybrid B6D2F2/J cross never show defects of CC. The defect seen in adult BALB/c mice seems to be specific to the CC, because the hippocampal and anterior commissures are of normal size in all BALB/c adults.

Prenatal development of the CC was examined using H & E staining in normal C57BL/6J and B6D2F2/J fetuses ranging in age from 16.0 to 18.0 days ($\pm$ 2 hr.) from conception, and comparisons were made with BALB/c fetuses matched for overall degree of morphological maturity or developmental age determined from whole body size. Principal findings were as follows.

1. Growth of the anterior commissure relative to whole body size was similar in all three strains.

2. Growth of the hippocampal commissure of BALB/c fetuses was mildly retarded in comparison with C57 and F2 fetuses, but that structure eventually reached normal size in BALB/c adults.

3. Growth of the corpus callosum of BALB/c mice was very retarded compared to the other strains. Every C57 and F2 fetus which weighed more than 0.46 gm (less than 16.0 days developmental age) had some CC axons crossing midplane, whereas no BALB/c fetus less than 0.60 gm had a CC at midplane, which amounted to retardation by at least 1 day.

4. At 18.0 days chronological age when BALB/c body weights averaged 0.79 gm, there were still many BALB/c fetuses with no CC at midplane (34 of 102 with no CC), but at 19.0 days only 7 of 103 BALB/c fetuses lacked a definite CC ($z=4.6$, p 0.0001).

5. In all BALB/c fetuses with no CC at 18.0 days, the glial sling (Silver, et al., J. Comp. Neurol., 1982, 210, 10-29) was either absent or grossly deficient. The sling was also defective in many BALB/c fetuses with a small CC at 18.0 days.

6. The frequency of an abnormal glial sling in 18.0-day BALB/c fetuses was similar to the frequency of abnormal shape or deficient size of CC in adult BALB/c mice.

These results indicate that axons of the CC in BALB/c mice are sometimes able to traverse the region between the cerebral hemispheres in the absence of a normal glial sling. However, when this occurs, evidently the shape of the CC in the adult mice is quite unusual, being shorter but thicker at midplane than in C57 or F2 mice.

Supported in part by Grant A4878 from the Natural Sciences and Engineering Research Council of Canada. Technical assistance of Kathryn Blom, Barbara Bulman-Fleming and Marilyne Reese is acknowledged with thanks.

120.8 BRAIN ANOMALIES AND AUTOIMMUNITY IN MICE. G.F. Sherman, P.O. Behan*, and A.M. Galaburda. Neurological Unit, Beth Israel Hospital and Harvard Medical School, Boston, MA 02215; Southern General Hospital, Glasgow, Scotland.

The NZB strain of autoimmune mice exhibits cerebrocortical anomalies of developmental origin that are similar in type to those seen in human dyslexic individuals (Sherman et al., Soc. Neurosci. Abs., 9:939, 1983; Galaburda et al., Ann. Neurol., in press). Furthermore, non-righthandedness, dyslexia, and autoimmunity have been shown to cluster together (Geschwind and Behan, PNAS, 79:5097, 1982). Because the anatomical findings in a single mouse strain (NZB) cannot answer the general question of whether autoimmunity and developmental neuropathology are linked, we examined the brains of several other strains of immune-defective mice.

The mice were perfused, and their brains removed, embedded in celloidin, sectioned at 30μ, and every tenth section stained for Nissl substance. The inbred autoimmune strains examined were additional NZB (n=84), as well as BXSB (n=68), and MRL (n=45). All three strains are considered models of human lupus erythematosus, although the disease in NZB and BXSB (characterized by B-cell lymphoproliferation) differs from that of MRL (T-cell proliferation). We also studied the following crossbred strains: BXSB/NZB (n=46), MRL/NZB (n=20), MRL/BXSB (n=12), NZB/NZW (n=209), BXSB/NZW (n=71), and MRL/NZW (n=21), and the inbred strains NZW and C57Bl/6, and the CFW outbred strain. The mice ranged in age from 10-90 days and the data were collapsed over these ages, as no age differences were present.

Twenty-six percent of the NZB, 32% of the BXSB, and 20% of the BXSB/NZB and MRL/NZB had cortical anomalies consisting of ectopic clusters of neurons in layer I of the cerebral cortex. The MRL, NZW, and the remaining crosses had low rates of abnormality (less than 5%) and no anomalies were seen in the CFW controls. Eight females of the 64 C57Bl/6 had anomalies. Interestingly, there is evidence indicating that there are immunological abnormalities in this strain (Shirai and Mellors, PNAS, 68:1412, 1971).

The localization of anomalies differed significantly in the two strains that had the highest incidence of ectopias (NZB and BXSB): Anomalies were present mostly in the somatosensory cortex in NZB and in the frontal and motor cortices in BXSB ($X^2=17.27$, $df=2$, $p < 0.001$). When asymmetry of location was examined over all strains, it was seen that anomalies were usually present in the left frontal and motor cortices and in the right somatosensory cortex ($X^2=5.42$, $df=1$, $p<0.02$).

Thus, this study shows that brain anomalies are present in high numbers in at least two pure strains of autoimmune mice (B-proliferative NZB and BXSB) and in some crossbreeds. They are not, however, seen in large numbers in the T-proliferative MRL strain. The anomalies differ in architectonic localization and hemisphere involved among the strains. (Supported by NIH grants 14018 and 19819).

120.9 VISUAL PROSTHESES: PRELIMINARY REPORT OF USE BY INFANT MACAQUES. B. J. Sonnier, E. R. Strelow,* D. H. Warren* and A. H. Riesen. Dept. of Psychology, Univ. of California, Riverside, CA 92521.

We are examining the behavioral and neural development of infant stumptail macaques (M. Arctoides) reared from birth to three months with electronic sonar sensory substitution devices to assess correlations between spatial-motor behavior and auditory, motor and visual cortical development. Groups of four animals are reared as follows: 1) experimental group without vision but with the Trisensor Aid (TSA) in continuous use (the TSA is an advanced experimental version of a blind travel aid, the Sonicguide), control groups without vision but with 2) silent, dummy versions of the device, or 3) with a sound-making but non-functional device, and 4) normal, colony-reared animals.

We are exploring the advantages that the TSA provides for blind infant monkeys in early development. Behavioral observations and tests are being made throughout the three-month period, including cage observations and tests of auditory perception and locomotor behavior. After 90 days of in the experimental conditions all animals are sacrificed, and Golgi-Cox and computerized morphometric (Bioquant II) techniques are used to examine cortical development.

Preliminary behavioral results show that the first experimental animal was able to discriminate objects using the TSA: It showed a marked drop in general motor activity in its home cage when the device was turned off for 24 hrs and recovery of activity levels when the device was turned back on. A control animal showed markedly less motor activity overall. Neuroanatomical analyses are currently in progress for an experimental and two normally-reared control animals. Although cell orientation patterns may change, we expect to find few numerical differences in primary auditory and motor cortex in the three animals as the experimental animal engaged in as much or more motor activity as the normally-reared ones. However, we expect to see differences in association or secondary motor and auditory cortex. Finally, if visual cortex is in some sense a "spatial cortex," then the visual cortex of an animal reared with a working device should develop more normally than in an animal reared with control devices.

This research addresses questions which are important to blind human infants but which are difficult to answer with human subjects. Behavioral and cortical changes after prolonged early use of a sensory prosthesis could be of considerable importance to their eventual use by humans. The TSA is a potentially important research tool, for it allows the study of novel questions of intermodal organization via the sensory substitution paradigm. Correlations of behavioral and neuroanatomical evidence are necessary to understand the role of sensory information in the ontogeny of development.

121.1 RESPONSES OF POPULATIONS OF DSCT NEURONS TO ANKLE MOVEMENT. C.E.Osborn and R.E. Poppele, Lab. of Neurophysiol.,Univ. of Minnesota, Minneapolis, MN 55455.

The wide convergence of muscle afferents onto DSCT neurons reported earlier (Osborn & Poppele,Neurosci.Abs.10:744) suggested that the DSCT provides information on parameters of limb movement, rather than the state of single muscles. From the eariler study it was also likely that this information was encoded in the relative occurrence of a small number of distinct types of response within the total DSCT population. We have now recorded the behavior of 127 DSCT units in cats during randomly generated ankle flexions and extensions in an intact and otherwise immobile hindlimb. A population response for DSCT was derived from the average of the recorded changes in discharge probability in single units. Significant responses were found in 60% of the units; 43% of the units responded to extension, 53% to flexion and 37% to both (Fig. 1). The responses had a long time course (ave. >50 ms) which did not follow the time course of the imposed movement. There were 4 types of response: excitatory (E), inhibitory (I; Fig. 2A), and two types of mixed responses (Fig. 2B). One type of mixed response, EI, was excitatory for the first 20 ms after the stimulus, but was inhibitory after 30 ms. The other type (IE) was nearly the mirror image of the EI response. The proportions of the E and I responses did not change with the direction of the movement (38% and 21% respectively), but the proportions of the mixed responses did. IE responses were twice as common as EI during extension (26% vs. 13%), but the opposite was true for flexion (13% vs. 26%). Individual units often changed their response when the movement direction changed, but this also was more prominent among units with mixed responses. 92% of the units with EI or IE response to extension had a different type of response during flexion, compared to only 42% of the units with E or I responses.

121.2 ENHANCEMENT OF TONIC VIBRATION AND STRETCH REFLEXES IN THE DECEREBRATE CAT BY SEROTONIN. J. S. Carp and W. Z. Rymer. Dept. of Physiology, Northwestern Univ., Chicago, IL 60611.

In the tonic vibration reflex (TVR), high frequency longitudinal muscle vibration elicits a massive discharge of primary spindle afferents and an increase in electromyographic activity (EMG) and force. Upon cessation of vibration, afferent discharge rapidly returns to the prestimulus level, but motor output subsides over a much slower time course, such that force and EMG may take several seconds to reach the previbration levels. While this apparent discrepancy between sensory input and motor output has previously been attributed to afterdischarge of spinal interneuronal networks, it has recently become apparent that spinal motoneurons might contribute directly to this phenomenon. Hounsgaard et al. (Exp. Brain Res. 55:391, 1984) have described a serotonin (5HT) dependent property of spinal motoneurons in which brief depolarizing current injections into these neurons resulted in a prolonged depolarization and repetitive discharge which long outlasted the duration of the current input. While this behavior may be a significant determinant of motoneuronal function on the cellular level, its role in regulating motor output across the motoneuron pool is as yet unclear. In order to assess the functional significance of this intrinsically mediated behavior of spinal neurons, we have evaluated the effects of pharmacological manipulations of 5HT on segmental reflex mechanisms.

Force, EMG and primary spindle afferent discharge rate recorded during the TVR and the stretch reflex in unanesthetized decerebrate cats were compared before and after administration of the 5HT reuptake blocker fluoxetine (FLU, n=6), the 5HT precursor 5-hydroxytryptophan (5HTP, n=3) and the 5HT receptor antagonist methysergide (MS, n=4). The degree to which motor output continued to be elevated above control levels one second after cessation of vibration was increased by FLU and 5HTP to approximately 230% and 160% of control, respectively, and was reversed by subsequent administration of MS. Administration of MS alone decreased the postvibration motor output to approximately 50% of control. In addition, both mean dynamic and static stretch reflex stiffnesses were increased by FLU and 5HTP to approximately 150% and 200% of control, respectively, and were reversed by subsequent administration of MS. MS alone decreased mean stretch reflex stiffness to approximately 75% of control. These powerful effects on the tonic vibration reflex and the stretch reflex could not be explained by drug-induced alterations in primary afferent discharge. These data support the hypothesis that a 5HT dependent intrinsically mediated behavior of spinal neurons is an important factor in determining motor output.

121.3 SUPRASPINAL CONDITIONING OF SHORT-LATENCY CUTANEOUS PATHWAYS TO LUMBAR MOTONEURONS. J.W. Fleshman, P. Rudomin and R.E. Burke. Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Supraspinal control of pathways for low threshold cutaneous input to spinal α-motoneurons was examined using a conditioning-testing paradigm and intracellular recording techniques in six barbiturate-anesthetized cats. A monopolar stimulating electrode was placed in the red nucleus (RN) and, in two experiments, a second bipolar electrode was placed in the medullary pyramidal tract (PT). A special effort was made to study the short latency excitatory pathway from the superficial peroneal nerve (SP) to flexor digitorum longus (FDL) motoneurons described by Fleshman et al. (Exp. Brain Res. 54: 133, 1984).

Conditioning stimuli to either RN or PT (typically 4 pulses, 50-100 μA, 500 Hz, 10-30 ms C-T interval) increased the amplitude and decreased the latency of EPSPs in FDL cells produced by single pulse stimulation of low threshold (<3xT) SP afferents. The mean onset latency of the earliest EPSP, measured from the negative peak of the first afferent volley at the dorsal root entry zone, decreased from 1.96 to 1.56 ms (n=12). Due to the confluence of early excitatory and later inhibitory components, amplitude changes could not be measured, though both components were clearly larger. The late IPSPs also decreased in latency. In a mixed sample of other extensor and flexor motoneurons with initial depolarizing responses to SP stimulation, conditioning stimulation decreased segmental latencies from 2.24 to 1.77 ms (n=15).

The finding that supraspinally conditioned EPSPs from low threshold cutaneous afferents in some hindlimb motoneurons may have segmental latencies in the 1.5-2.0 ms range raises a question as to the synaptic linkage of this pathway. Similar latencies in group Ib and group II pathways have been taken as evidence for a disynaptic linkage. Illert et al. (Exp. Brain Res. 26: 521, 1976) have described a supraspinally facilitated disynaptic cutaneous pathway to forelimb motoneurons with latencies in the same range. Our results suggest that some cutaneous excitatory reflex pathways in the cat hindlimb may also have a disynaptic component. The identity of the premotor interneurons in this pathway and their target motor nuclei requires further study.

121.4 SPECIFIC AND UNSPECIFIC MECHANISMS INVOLVED IN THE GENERATION OF PAD OF CUTANEOUS FIBERS. I. Jiménez*, M. Solodkin* and P. Rudomin (SPON: F.J. Alvarez-Leefmans). Dept. Physiol. & Biophys. C. Res. and Adv. Studies IPN, México, 14 D.F. México.

In a recent publication (J. Neurophys. 52 (1984): 921-940) we have showed that tetanic stimulation of group I fibers from the biceps posterior and semitendinosus (PBSt) nerve produces presynaptic depolarization (PAD) of group Ia muscle afferent fibers ending in the intermediate nucleus of the lumbo-sacral spinal cord, without significantly increasing the potassium concentration ([K+]). On the other hand, tetanic stimulation of the sural (SU) nerve increased the [K+], particularly in the dorsal horn, and could depolarize neighboring Ia afferent fibers but not fibers ending in the intermediate nucleus. It is therefore possible that unspecific mechanisms are more important in the generation of PAD of cutaneous than of Ia fibers. The aim of this study was to relate the negative DC potential shifts (which are proportional to changes in [K+]) with the changes in the PAD of single cutaneous fibers. The experiments were made in cats anesthetized with pentobarbital (35 mg/kg), paralyzed and artificially respired. PAD of single fibers was inferred from changes in their activation threshold. DC shifts were recorded intraspinally with the same microelectrode used for excitability testing. In 9 SU fibers, a single 2 xT stimulus to the superficial peroneus (SP) or to the SU nerve produced large threshold decrements (mean 83.1±10.7 % and 83.0±9.1 %, respectively) without significantly changing the DC potentials. On the other hand, graded stimulation of the SP nerve (1-10 xT) with high frecuency trains (100 Hz for 10-20 sec) decreased the threshold of SU fibers and produced a parallel increase of the negative DC shifts (correl. coef.=0.92, n=5). Graded stimulation of the SU nerve produced a dual effect. With low stimulus strenghts (1.2-2.5 xT) the fiber threshold was decreased without significant changes in the DC potentials. However, with stronger stimuli (>4 xT) the threshold decrements were highly correlated with DC potential shifts. Stimulation of the brain stem reticular formation reduced the activation threshold of 12 cutaneous fibers (mean 86.1±9.7 %) located in the dorsal horn without producing noticeable DC potential shifts at the site of excitability testing. It is suggested that the PAD of low-threshold cutaneous fibers produced by cutaneous inputs is due to both specific and unspecific mechanisms, whereas the PAD produced by reticulo-spinal inputs is predominantly due to activation of specific neuronal pathways in which the first order interneurons appear to be located in the intermediate nucleus or in more ventral regions of the spinal cord.

121.5 **PATTERNS OF PRIMARY AFFERENT DEPOLARIZATION AND HYPERPOLARIZATION OF GROUP Ia AND Ib FIBERS PRODUCED BY SEGMENTAL AND DESCENDING INPUTS.** P. Rudomin, M. Solodkin* and I. Jimenez*. Dept. Physiol. & Biophys. CINVESTAV, Mexico 14 D.F. Mexico.

It is generally accepted that stimulation of cutaneous nerves produces primary afferent depolarization (PAD) of Ib fiber terminals, and inhibits the PAD of Ia fibers. These PAD response patterns were used as operational criteria to differentiate Ia from Ib fibers and it was concluded that stimulation of reticulo-spinal, rubro-spinal and cortico-spinal pathways have the same actions as cutaneous inputs on Ia and Ib fibers. However, in some group I fibers stimulation of the brain stem reticular formation produced PAD although cutaneous volleys had inhibitory actions. We assumed that these were Ia fibers in which the brain stem stimulation activated, in addition, descending pathways with excitatory actions (J. Neurophysiol 50 (1983): 743-769). However, contrary to the accepted views, they could be Ib fibers in which the PAD was inhibited by cutaneous inputs. Experiments were made on cats anesthetized with pentobarbital (35 mg/kg), paralyzed and under artificial respiration. Changes in membrane polarization of afferent fibers were inferred from alterations in the activation threshold of single group I fibers from the posterior biceps and semitendinosus (PBSt) nerve where Ia and Ib fibers have different peripheral thresholds and conduction velocities. Twenty four out of 44 single group I PBSt fibers ending in the intermediate nucleus were depolarized by stimulation of group I afferents from the PBSt or deep peroneous nerves but not by cutaneous or by reticulo-spinal inputs, both of which inhibited the PAD elicited either by group I muscle volleys or by vestibulo-spinal stimulation. The conduction velocities of these fibers (Type A) varied between 78 and 118 m/sec (mean + SD = 100.5 + 13.6 m/sec) and their electrical thresholds in the periphery between 1.01 and 1.56xT (1.23 + 0.17xT), which are in the Ia fiber range. The other 20 fibers were depolarized by all the tested descending inputs. Cutaneous volleys produced PAD in 6 of these fibers (Type B) and inhibited the PAD in 14 fibers (Type C). Fibers with type B and C PAD response patterns had overlapping conduction velocities and electrical thresholds in the peripheral nerve, which varied between 68 and 90 m/sec and between 1.47 and 2.16xT, respectively. The mean conduction velocities and peripheral thresholds of the Type B and C fibers were 76.2 + 4 m/sec and 1.8 + 0.15xT and 77 + 5.3 m /sec and 1.75 + 0.19xT, respectively, clearly in the Ib range. These results indicate that cutaneous fibers have a dual action in the pathways mediating the PAD of Ib fibers. They produce PAD in one set of fibers and inhibit the PAD in another set.

121.6 ANALYSIS OF STEADY-STATE SYNAPTIC CURRENTS GENERATED IN CAT MOTONEURONS BY HOMONYMOUS IA AFFERENTS. C.J. Heckman* and Marc D. Binder. Dept. of Physiology & Biophysics, Univ. of Wa. Sch. of Med., Seattle, WA 98195.

Although it is known that the amplitudes of aggregate homonymous Ia EPSPs vary over an approximately 10-fold range within the cat triceps surae motoneuron pools, recent anatomical analyses indicate that all of these motoneurons generally receive about the same number of synaptic contacts from homonymous Ia afferents (Lev-Tov et al. J. Neurophys. 50: 1983). If one assumes that all Ia synapses have equivalent efficacies and that they are all "physiologically active", then the total Ia synaptic current should be equal in all motoneurons and the observed variation in EPSP amplitude should be largely attributable to differences in the intrinsic properties of the motoneurons (e.g. membrane surface area, membrane resistance, etc.), which together determine input resistance. Alternatively, it is possible that not all Ia synapses on all motoneurons are active (Henneman et al. J.Physiol. 352: 1984) or that Ia synapses display a range of efficacies and thus, the variation in Ia EPSP amplitudes within a motoneuron pool may be produced in part by differences in Ia synaptic current. To address this issue, we have devised a simple technique to measure synaptic current that is based on the established equivalence of synaptic and injected currents with respect to the generation of repetitive firing in cat motoneurons (Schwindt and Calvin. Brain Res. 59: 1973). Steady-state, homonymous Ia EPSPs were generated in cat MG motoneurons by subjecting the triceps surae muscles (lateral gastrocnemius-soleus nerve cut) to longitudinal vibration (150 μ, 200 Hz) for 1-2 sec. We then determined how much current the Ia afferents generated in the somata of the same cells by increasing the magnitude of 1 sec current pulses passed through the microelectrode until they produced a membrane depolarization equal to that observed during the vibration. In our initial results (n=30) steady-state homonymous Ia EPSPs had a 10-fold range in amplitude (0.5-6.7 mV) that was very strongly correlated with motoneuron input resistance ($r=0.89; p<.001$) which varied over a 5-fold range (0.4-2.2 MΩ). In addition, however, we have found that the EPSP amplitude was also systematically related to Ia synaptic current ($r=.77; p<.001$) which varied over a 4-fold range (0.8-3.1 nA). Taken together, these results suggest two conclusions: 1. that the variation in the amplitudes of homonymous Ia EPSPs observed within a pool of motoneurons must be ascribed both to differences in the intrinsic properties of the motoneurons and to the magnitude of the Ia synaptic currents generated in them; and 2. that Ia synaptic current must covary with one or more motoneuronal intrinsic properties. (Supported by NSF grant BNS82-06223)

121.7 VARIANCE OF SINGLE FIBER EPSPs REVEALS LONG LATENCY CONNECTIONS TO HOMONYMOUS MOTONEURONS. L.M. Mendell & W.F. Collins III, Dept. of Neurobiol. & Beh., SUNY, Stony Brook, NY 11794 & Dept. ObGyn, Yale Sch. of Med., New Haven, CT 06510

The variance of intracellularly recorded membrane potential measured in repeated trials during accumulation of an averaged EPSP has been shown to increase in conjunction with the EPSP (Rudomin et al., J. Neurophysiol. 38; Jack et al., J. Physiol. 321). This increase in variance during the EPSP has been attributed to the fluctuation in EPSP amplitude associated with non uniform release of transmitter. Single fiber EPSPs and the associated variance increases were studied in medial gastrocnemius (MG) motoneurons of deeply anesthetized cats using electrical stimulation of MG Ia fibers impaled in dorsal roots (Honig et al., J. Neurophysiol. 49). Standard stimulation conditions consisted of 400-1000 trials at 18 Hz. In 12 out of 25 cases the rising phase and initial fall of the variance trace was similar to that of the mean voltage trace although variance trace peaked before the mean in 6/12. At 5 connections with relatively small EPSPs, no increase in variance was observed. In others (8 out of 25) the variance trace was clearly different from the mean voltage trace reaching its peak earlier (6/8) and/or falling more quickly (8/8) to baseline values. At 6 connections, clearcut secondary components were superimposed on the falling phase of the variance trace which was associated with a deflection in the mean voltage trace. These secondary components could have latencies 2-3 ms longer than that of the initial response. Examination of single sweeps revealed that these responses could be intermittent in contrast to the short latency ones which fluctuated in amplitude but were present in all trials. The presence and amplitude of these long latency variance components was highly dependent on the frequency of stimulation usually disappearing at rates 100Hz. In contrast, the short latency increases in variance were virtually unchanged even when mean EPSP amplitude was induced to change (e.g., during high frequency burst stimulation (Collins et al., J. Neurophysiol. 52). The finding that peak of the variance trace often occurs during the rising phase of the mean voltage trace suggests either that latency fluctuations of EPSPs (Cope & Mendell, J. Neurophysiol., 47) may play an important role or that more distal synapses contribute less to the variance than proximal ones. The finding of frequency sensitive, long latency components suggests the possibility that polysynaptic pathways to homonymous motoneurons can be activated under these conditions (single fiber/barbiturate anesthesia) which may be of considerable importance in normal function. Supported by NIH NS 16996 and NS 14899 (LMM) and NS 21875 and a grant from ALSSA (WFC).

121.8 **POTENTIATION OF COMPOSITE EPSPs IN MOTONEURONS.** B.M. Davis, R.E. Druzinsky, L.M. Mendell. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY, 11794.

In studies of potentiation of motoneuron EPSPs produced by stimulation of single Ia fibers with repeated short high frequency bursts (32 shocks, 167Hz), we observed that the maximal amount of potentiation occurred within 200ms after the burst, and that a relationship existed between motoneuron rheobase and maximal potentiation. Furthermore, we found the greatest amount of potentiation at connections with small EPSPs (typically large rheobase motoneurons) while the duration of potentiation was greatest at connections with large EPSPs (small rheobase motoneurons) (Davis et al., Soc. Neurosci. Abstr. 10:742, 1984). These results suggested that the properties of potentiation was determined by the motoneuron. Here, we have examined potentiation of composite EPSPs to see if the amount and duration of potentiation are correlated with motoneuron rheobase when a large population of afferents is activated. We have also compared potentiation produced by short high frequency bursts to that produced by long high frequency trains used by others (Luscher et al., J. Neurophysiol, 49:269; Lev Tov et al., J. Neurophysiol. 50:379).

Recordings were made from triceps surae motoneurons in Nembutal anesthetized cats. Rheobase was determined using depolarizing current injections of 50ms duration. The heteronymous muscle nerve was then stimulated (3 times Group Ia threshold) at 18Hz to evoke a "control EPSP". Each connection was tested repetitively (every 2s) with a 32 shock burst (167Hz) followed by a single interburst test shock delivered 50-1250ms after the burst (64 or 128 trials). Finally, the EPSP produced by 1.8Hz stimulation (32 or 64 trials) was recorded. The nerve was then stimulated at 500Hz for 20s followed by a 10s pause; an EPSP produced by 1.8Hz stimulation was again recorded (this EPSP was averaged during the approximate period of maximal potentiation).

The maximal amount of potentiation produced by short bursts was seen 50-150ms after the burst. Potentiation then decayed slowly and at 2sec. often remained elevated above control values. The amount of potentiation observed 100ms after the burst was positively correlated with motoneuron rheobase ($p<.05$). The duration of potentiation was inversely correlated with motoneuron rheobase ($p<.05$). These results are very similar to that obtained with single fiber burst stimulation and suggest that even during activation of a large number of afferents, the parameters of potentiation are determined by factors intrinsic to the motoneuron. Polysynaptic EPSPs and IPSPs were reduced or abolished following short bursts at times when the monosynaptic EPSP was potentiated.

Of the 15 connections at which potentiation was elicited using both the short repetitive burst and the 500Hz train, the amount of maximal potentiation produced by both techniques was similar (1.68±.04, short burst; 1.68±.08, 500Hz). However, potentiation produced by the 500Hz train was accompanied by a large shift in latency (mean shift 126± 17μs (SEM)) compared to the potentiated EPSP elicted by repetitive bursting (Δlatency 26±6μs). The potentiated EPSPs in both paradigms exhibited changes (both positive and negative) in their rise time (10-90%), but there was no systematic relation between the amount of potentiation and the change in rise time. The independence between magnitude of potentiation and changes in latency and rise time suggests that the mechanisms involved in the shifts in latency and time to peak are not crucial for potentiation. Supported by NS16996 (LMM) and NS07319(BMD).

121.9 FACTORS INFLUENCING THE SHAPE AND AMPLITUDE OF EPSPs EVOKED IN MOTONEURONS BY IMPULSES IN SPINDLE AFFERENT FIBERS, Elwood Henneman, Hans-R. Luscher and H. Peter Clamann, Institute of Physiology, University of Zurich, CH 8057, Zurich, Switzerland.

A recent study (Clamann et al., J. Physiol. 358: 483,1985) of the projections of large numbers of spindle-afferent fibers to homonymous motoneurons has revealed that the sizes of the motoneurons, the diameters of the afferent fibers and the numbers and locations of the synaptic boutons they form on the individual motoneurons, all influence functional connectivity in these monosynaptic reflex arcs. Data from the experiments cited were analyzed to determine how these same factors affect the shape and amplitude of the "single fiber" EPSPs used to establish functional connectivity.

Five dorsal rootlets, each shown to contain 1-5 active spindle afferents, were placed in continuity on pairs of silver electrodes. An expanded version of spike-triggered averaging (STA) permitted us to average out the EPSPs evoked by the impulses in each active fiber from the other synaptic noise recorded in the same motoneuron. From 6 to 11 single-fiber EPSPs were elicited in a single motoneuron and 6 to 24 motoneurons were studied in each experiment. Rise-time, 1/2 width, and amplitude of each EPSP were measured and an analysis based on the Rall model was used to determine the location of the synaptic boutons on the soma and dendrites of the motoneurons. A total of 317 EPSPs was analyzed.

The mean amplitude of all EPSPs studied was 76.5μV. 162 EPSPs (51%) had shapes consistent with the predictions of the Rall model. For such EPSPs the electrotonic distance from the soma to the site of EPSP generation could be calculated. Putative somatic EPSPs had a mean amplitude of 84.5μV while EPSPs whose shape index suggested a site of generation >0.6 space constants from the soma had a mean amplitude of 106.8μV. The difference is highly significant. EPSPs which did not have shape indices consistent with the assumptions of the Rall model were of two types: "wide" EPSPs, whose 1/2 width was greater than would be predicted from the rise time, and "narrow" EPSPs, whose 1/2 width was too short. Many wide EPSPs were obviously composite, having abrupt changes or breaks in slope of either the rising or falling phases, or double peaks. Mean amplitude of wide EPSPs was 92.1μV, significantly larger than average. It is likely that such EPSPs are produced at a greater than average number of boutons and at more than one locus. Narrow EPSPs averaged 32.8μV in amplitude. Small EPSPs were elicited by impulses in fibers of any size; large EPSPs were evoked only by impulses in large fibers. Thus, both pre-synaptic and post-synaptic factors determine the shape and amplitude of EPSPs. (H.-R. L. was supported by a grant from the Swiss National Science Foundation. H.P.C., on leave from Virginia Commonwealth Univ., was supported by a grant from the A.D. Williams Fund; E.H. received support from the National Multiple Sclerosis Society and the National Institutes of Health.)

121.10 **PRIMATE MONOSYNAPTIC REFLEXES AND THEIR POST-TETANIC POTENTIATION. E. Vander Schaaf* and J. R. Wolpaw (SPON: R. A. Waniewski). Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, NY 12201; and Departments of Neurology and Anatomy, Albany Medical College, Albany, NY 12208.**

In preparation for studies investigating possible segmental substrates of long-term adaptive plasticity in primate spinal stretch reflexes and H reflexes (Wolpaw et al., this vol.), we are studying monosynaptic reflexes to dorsal root stimulation in anesthetized monkeys before and after spinal cord transection. The goal is to determine reflex amplitude, stability over time, bilateral symmetry, and inter-animal variability before and after post-tetanic potentiation and before and in the hours following spinal cord transection.

Monkeys (Macaca nemestrina) are anesthetized throughout with pentobarbital (and sacrificed by overdose at the conclusion of recording). A recording cuff is placed around each posterior tibial nerve at the knee. The cauda equina is exposed from L3 to S2. L5-S2 dorsal roots are identified and cut. Each ventral root from L5 to S2 is stimulated supramaximally and the posterior tibial nerve response measured. The sum of these ventral root responses gives the maximum motoneuron response against which the reflexes to proximal dorsal root stimulation are measured. The combined L5-S2 proximal dorsal roots are stimulated supramaximally at 0.5 Hz before and after potentiation (500 Hz for 20 sec). Data are collected hourly or more frequently on both right and left sides.

In the initial two animals pre-potentiation reflexes measured repeatedly on right and left sides over 4-6 hours averaged 16.0% (±6.2% SD) of maximum. Reflexes increased to 49.0% (±6.2% SD) at 15-20 msec after potentiation. They declined to pre-potentiation amplitude over the next 5 min. In one animal a second laminectomy was performed at T8 and the cord cooled and then transected. Pre- and post-potentiation reflexes did not change significantly over the subsequent 6 hours.

On the basis of these limited data, pre- and post-potentiation monosynaptic reflexes are stable over time and symmetrical in pentobarbital-anesthetized animals. If further data confirm these results, these reflexes should provide means of assessing the persistence and location of substrates underlying adaptive plasticity in stretch reflexes and H reflexes.

121.11 RECURRENT INHIBITION OF NECK MOTONEURONS IN THE CAT. E.E. Brink I. Suzuki*. The Rockefeller University, New York, N.Y. 10021.

Within the spinal cord, a powerful means of controlling motor outflow is provided by the recurrent actions of motor axons on homonymous and other motoneurons. The extent to which this mechanism operates within the neck segments of the spinal cord, for muscles involved in head movements, is controversial: reported as rare in one study (Rapoport, J. Physiol. 289: 311-327, 1979) but as frequent in unidentified dorsal neck motoneurons in another (Jankowska and Odutola, Brain Res. 194: 65-78, 1980). Indeed, it has been suggested that segmental mechanisms may be fairly unimportant for head movements; their role being supplanted by supraspinal centers (Rapoport, ibid). As important to this question of the role of segmental mechanisms in control of head movements, the occurrence of recurrent inhibition in the neck segments has been re-investigated.

Intracellular recordings were made in chloralose-anesthetized cats from motoneurons identified by their antidromic activation on stimulation of muscle nerves; dorsal roots were cut from C2-C5. The nerves stimulated were: C3,C4 nerves to Biventer cervicis; C3 Complexus; C3, C4 Splenius; C3, C4 Levator scapulae ventralis; Occipitoscapularis.

Recurrent inhibition was frequently found. Of 61 motoneurons, recurrent inhibitory postsynaptic potentials (ripsps) of 100 μV (criterion level) to 2.2 mV were seen in the majority: 22/25 Biv, 4/4 Compl, 6/9 Spl, 6/12 LSV, 9/11 Ocspl. Ripsps could be evoked in Biv, Compl, Spl, and Ocspl neurons from the motor axons to any of these muscles, but typically not from those to LSV. Frequency of occurrence and amplitude of the ripsps were greater when evoked from homonymous motor axons, synergist, or those of the same segmental level as the recorded neuron. Ripsps in LSV motoneurons were evoked from Spl motor axons. Central latencies of the ripsps ranged from 1.0 to 2.6 msec, the earliest compatible with disynaptic transmission. Additionally, interneurons (Renshaw cells) excited by stimulation of motor axons were frequently encountered: a number received convergent excitation from several nerves of the same segmental level. Earliest latencies indicated monosynaptic transmission. The interneurons typically responded with a burst of action potentials. Correspondingly, ripsps in motoneurons sometimes displayed distinct ripples, i.e. successive waves of inhibition. In all these features, the recurrent inhibition, and its organization, in the neck segments of the spinal cord resembles that described elsewhere. It is concluded that recurrent inhibition is a conspicuous feature of spinal cord organization within the neck segments, and, as such, may be an important mechanism for control of head movements. Supported in part by grants from NSF (BNS-8315908) and NIH (NS02619).

121.12 ESTIMATES OF BETA LOOP GAIN. J.L. Schotland*, G. Stuart*, and W.Z. Rymer. Neuroscience Program and Department of Physiology, Northwestern University Medical School, Chicago, IL 60611

Skeletofusimotor (beta) neurons are motoneurons that innervate both intrafusal and extrafusal muscle fibers. Since beta motoneurons receive excitatory feedback from the same muscle spindle afferents that they innervate, they constitute part of a positive feedback loop. The gain of this positive feedback loop has been estimated previously to be on the order of 0.4 by observing the reduction in spindle length sensitivity following interruption of the loop by transection of the dorsal roots (Grill and Rymer, Exp. Brain Res., 1985).

The point of the present series of experiments was to provide an independent measure of the gain of the beta loop. We estimated the loop gain in the decerebrate cat by recording the tonic vibration reflex (TVR) in a muscle and one of its close synergists before and after local anesthetic induced nerve block of the synergist muscle nerve. The local anesthetic blocks gamma efferent fibers to the muscle spindles. Since beta action on spindle afferents is severely attenuated when gamma fibers are not active (Grill and Rymer, Abstr. Soc. Neuro., 1983), the nerve block effectively opens the beta loop.

Medial gastrocnemius (MG) was vibrated longitudinally at 160 Hz with an amplitude of 75 microns, generating a substantial TVR in the MG and a smaller TVR in its close synergist, lateral gastrocnemius (LG). A nerve cuff on LG was then saturated with 0.02% lidocaine, thereby opening the beta loop, and the TVR repeated. A comparison of LG force production in open and closed loop configurations revealed differences of on the order of 10 - 30%, which imply a beta loop gain of approximately 0.3.

This measure of beta loop gain is potentially confounded by the effects of series compliance on primary afferent discharge rates. A large series compliance would tend to diminish the length changes seen by the intrafusal fibers, decreasing Ia discharge rates, and in this way decreasing the beta loop gain. Experiments are in progress to estimate the series compliance, as well as to directly measure the discharge rates of individual primary afferents of the synergist muscle, LG.

121.13 Membrane Potential and Input Resistance of Motoneurons in the Awake and Halothane-Anesthetized Cat. J.F. Whitney* & L.L. Glenn* (Spon: C.J. Smith), Department of Physiology, Ohio College of Podiatric Medicine, University Circle, Cleveland, Ohio 44106

General anesthetics are known to influence motoneuron function. Intracellular studies come almost exclusively from anesthetized or spinally-transected preparations due to the technical difficulty of recording from awake animals. It was therefore of interest to compare the properties of spinal neurons before and during the administration of general anesthetics in an intact animal.

We report preliminary results on 5 motoneurons tested during and immediately prior to deep halothane anesthesia. Frontal ECoG, M. cleidotrapezius EMG, and respiration were monitored to assess the depth of anesthesia. Tibial n., common peroneal n., and ventral root electrodes were used for the identification of motoneurons. Only cells with a membrane potential in excess of -50mV were studied. The input resistance of motoneurons was measured during voltage clamping, and taken from the amplitude of microelectrode current required to produce a 10 - 15 mV change using a single-electrode voltage clamp. Impalements with input resistances in excess of 4 MΩ were presumed to be dendritic and discarded. Measurements of membrane potential and input resistance were taken during wakefulness and during deep anesthesia as indicated by periods of silent EMG and cortical slow-waves. The table shows that little change occurred in membrane potential, however, anesthesia lowered input resistance by 21%

INPUT RESISTANCE (MΩ)		MEMBRANE POTENTIAL (mV)	
Awake	Anesthetized	Awake	Anesthetized
1.99 + 0.15	1.58 + 0.16	-53.24 + 0.80	-54.60 + 1.23

These data were surprising because we presumed that anesthesia would decrease spontaneous synaptic activity which would lead to an increase in input resistance. However, there is a potential source of synaptic input from dorsal horn cells that show little spontaneous activity until halothane is administered.[1]

121.14 BISTABLE MEMBRANE POTENTIAL IN SPINAL MOTONEURONS OF AWAKE CATS. L.L. Glenn, J.F. Whitney, J.S. Rewitzer, and J.A. Salamone (Spon: J.S. Baizer), Dept. of Physiology, Ohio College of Podiatric Medicine, University Circle, Cleveland, OH 44106

The membrane potential of some motoneurons in decerebrate and anesthetized cats have been shown to be bistable, in the sense that depolarizations over 10 mV from resting level longer than 30 ms can lock the membrane potential above the discharge threshold such that spontaneous firing occurs in the absence of synaptic drive or depolarizing current pulses (1,2). The present study was undertaken to estimate the proportion of spinal motoneurons that have a bistable membrane potential in awake, intact cats.

Spinal motoneurons of chronically-prepared cats were impaled and antidromically identified by stimulating ventral roots L7 and S1. A single-electrode multiplexing current clamp was used to pass 10-30 nA depolarizing pulses to determine if the membrane potential was bistable, as indicated by the triggering of sustained discharges or depolarizations that outlasted the microelectrode current pulse by a factor of 10 or more.

In a population of 34 motoneurons, 18 were bistable (53%). Depolarizing pulses, and not hyperpolarizing, were used to identify bistability, so the estimate should be regarded as a minimum. The spike mechanism deteriorated spontaneously in 11 motoneurons, showing a mean difference of 5.4 mV in the two stable membrane potential regions in these cells. We conclude that at least half of spinal motoneurons in unanesthetized, awake cats are bistable and thus motoneuron bistability is an important factor in the neural control of movement.

121.15 RELATIONS BETWEEN CROSS-CORRELOGRAMS AND POSTSYNAPTIC POTENTIALS IN MOTONEURONS: EFFECTS OF SYNAPTIC NOISE. E.E. Fetz, B. Bishop and A. Reyes, Dept of Physiology & Biophysics and Primate Ctr., Univ. of Washington, Seattle, WA 98195

In motoneurons excitatory postsynaptic potentials (EPSP's) produce a change in firing probability that is given by the cross-correlation histogram of motoneuron firing aligned with the source of the EPSP. The transform between the shape of an EPSP (e(t)) and the associated motoneuron firing rate in the cross-correlogram (f(t)) is relatively simple for large EPSP's in negligible synaptic noise. Threshold-crossing models (1,2) predict (3) and empirical tests confirm (3) that the motoneuron firing rate is given by the expression: $f(t) = fo + (fo/\dot{V})(de/dt)$
where fo = baseline firing rate and $\dot{V}$ is the rate of closure between membrane potential ramp and threshold. (This expression is valid so long as the EPSP does not decay more rapidly than $\dot{V}$.)

For small EPSP's in the presence of synaptic noise with comparable amplitude, the correlogram peaks are generally wider than the EPSP derivative (3-6). While the EPSP derivative may still account for much of the correlogram peak, subtracting a function proportional to the derivative (appropriately scaled and shifted in time) from the correlogram peak typically leaves a remainder term. Under certain conditions, this remainder term may be approximated by the EPSP itself (4,6), but often it is briefer than the EPSP (3,5).

To investigate how correlogram peaks are related to the EPSP shape and noise parameters, we used a computer model to simulate the threshold crossing process. EPSP's and noise are superimposed on a motoneuron membrane potential which approaches threshold with a rate $\dot{V}$. The model allows the shape of the EPSP to be arbitrarily defined or to assume the shape of empirically measured EPSP's. Similarly, the synaptic noise can be mathematically defined (Gaussian, Markov, random walk) or can follow the course of intracellularly recorded membrane fluctuations. Preliminary simulations with mathematical functions confirm that the correlogram remainder term increases with the size of the synaptic noise, and typically decays more rapidly than the EPSP. Simulations using experimentally recorded single-fiber Ia EPSP's have replicated the corresponding correlogram peaks obtained with cat motoneurons (5), suggesting that this model incorporates the essential features of the process.

121.16 STRUCTURAL DIFFERENCES BETWEEN DENDRITIC TREES OF CAT TRICEPS SURAE ALPHA-MOTONEURONS THAT INNERVATE FAST AND SLOW TWITCH MUSCLE UNITS. R.E. Burke, S. Cullheim*, J.W. Fleshman, and L.L.Glenn, Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

We have reported (Cullheim et al., Neurosci.Abstr. 9:430, 1983) on the spatial distribution of dendrites of 7 type-identified cat alpha-motoneurons. Further analysis of this material has disclosed systematic differences in dendritic branching structure and topology in cells that innervate fast twitch (F, including types FF and FR) versus slow twitch (S) muscle units. The average number of dendrites was similar for F and S motoneurons but the stem (zero order) dendrites tended to be thinner in S versus F cells (Burke et al., J.Comp.Neurol. 209:17, 1982). However, the difference between mean dendritic branch diameters in F and S cells disappeared beyond 300 μm from the soma, largely because the ratio of daughter to parent branch diameters at individual branch points was, on average, larger in S cell dendrites as compared to type F (mean $[\text{sum } d_{dau}^{3/2}] / d_{par}^{3/2}$ was 1.18 versus 1.10, respectively). For individual dendrites, the stem diameter (d_{stem}), membrane area (A_d), and number of terminations (T_d) were systematically interrelated but the correlations differed in F and S cells. The correlations between d_{stem} and A_d were best fit by a power function ($y=ax^b$), where b=1.74 for 44 F dendrites and b=1.05 for 35 S dendrites ($p<0.01$). The slopes of linear correlations between d_{stem} and T_d also were significantly different in F versus S dendrites (3.08 vs 1.38, respectively: $p<0.01$). Individual type S dendrites had fewer terminations than F dendrites (mean T_d was 10.6 versus 17.1, respectively) and branch order of terminating branches was, on average, lower in S cells (4.8 vs 6.2 in type F). Both observations show that type S dendrites were less profusely branched than type F. This difference in branching occurred between 200 and 1000 μm from the cell soma. Within this path distance range, the incidence of branching was relatively constant in S dendrites (about 10 branch points per 100 μm path distance from the soma), while it peaked at about 27 branch points per 100 μm shell (at 700 μm from the soma) in type F cells. A 'vertex analysis' of last order branching points (Berry and Flynn, Proc.Roy.Soc.B 221:321,1984) indicated that terminal branches tended to be more symmetrical in S cell dendrites than in F motoneurons. The branching topology of both F and S motoneuron dendrites was most compatible with a 'growth rule' indicating that branching occurs at growing terminals rather than along the shafts of existing dendrites (ibid., see also Van Pelt and Verwer, Bull.Math.Biol. 45:269, 1983). Thus, the anatomical differences between F and S dendrites probably arise as a consequence of intrinsic developmental differences.

121.17 DISTRIBUTION OF FLEXOR CARPI ULNARIS MOTOR NUCLEI IN THE MONKEY SPINAL CORD. E.M. Schmidt and J.S. McIntosh, Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205

We have recently shown (McIntosh et al., Anatom. Rec., 211: 403, 1985) that the flexor carpi ulnaris (FCU) is a bipinnate muscle in monkey composed of a predominately slow humeral head and a predominately fast ulnar head. This suggest that the two heads of FCU possibly subserve different functions and might be innervated from separate motor nuclei in the spinal cord.

To investigate this question, 3 Macaca fascicularis female monkeys (2.4 to 3.7 Kg) were injected with lectin-conjugated HRP. Using sodium pentobarbital anesthesia and sterile operating conditions the nerves leading to the humeral head of FCU in the left arm and the ulnar head of FCU in the right arm were exposed and injected with 3.5 to 6 ul of a 10% HRP solution. The incisions were closed, antibiotics administered and the animal allowed to survive for 96 hours. The animals were then deeply anesthetized and perfused with saline followed by 5% gluteraldehyde. Spinal segments C6 through T2 were sectioned horizontally at 50 or 75 um on a vibratome. The sections were processed with tetramethylbenzidine and counter stained with neutral red. The location and projected area of every labeled cell was determined with a computer coupled microscope.

The number of labeled cells in each animal after injection of the nerve to the humeral head of FCU was 346, 572, and 594 while injection of the nerve to the ulnar head labeled 376, 222, and 475 cells respectively. Estimates were made on the number of labeled alpha and gamma motoneurons by considering all cells with projected areas of less than 1300 um^2 as being gamma motoneurons. The ratio of gammas to alphas ranged from 0.21 to 0.37. There was no significant difference in the average size of alpha motoneurons in the two heads of FCU. The labeled cells were mainly located in spinal segments C8 and T1 with a few cells in T2. The peak density of labeled cells was in the C8 segment near the T1 border. There was no difference in the longitudinal location of labeled cells for the two heads of FCU. Likewise, there was no difference seen in the distribution of labeled cells in the grey matter for the two heads of FCU. The labeled cells of both heads of FCU exhibted some evidence of two subdivisions within the gray matter, similar to the findings of Iawamto, et al. (Neurosci. Letters, 20:25, 1980) for the cat. The majority of labeled cells were in a column located just dorsolateral to the center of the ventral horn. The second group was located dorsolateral to the major group at the border of gray and white matter.

From these preliminary findings no appreciable differences exist between the motoneurons innervating the two heads of FCU. If differences in function do exist in the two heads of FCU, as indicated by the different proportion of fiber types, they are produced by overlapping populations of motoneurons.

121.18 TOPOGRAPHY OF AFFERENTS ENTERING THE SPINAL CORD FROM CAT NEUROMUSCULAR COMPARTMENTS. O.I. Weeks* and A.W. English (Spon. Robert Holland) Emory University, Atlanta, GA 30322.

Studies of the compartmentalized cat lateral gastrocnemius muscle (LG) have indicated that its motor units and muscle afferents are partitioned peripherally (English and Weeks, Exp. Brain Res. 56:361-368, 1984) and that the synaptic organization of muscle spindle group Ia afferents onto motoneurons is similarly arranged centrally (Vanden Noven et al., Soc. Neurosci. Abstr. 10:329, 1984). Recent work from this laboratory has shown that the motoneurons innervating different LG neuromuscular compartments are topographically organized within the LG motor nucleus (Weeks and English, J. Comp. Neurol. 235, 1985). However, the result from a similar analysis of LG afferents (Weeks and English, Anat. Rec. 211:211A, 1985) demonstrate that dorsal root ganglion cells (DRG's) from any compartment are widely dispersed across the L_6-S_1 ganglia. The present study was undertaken to determine whether the entry point of afferents from different LG compartments to the spinal cord is topographically organized in a manner similar to that of the LG motoneurons.

In pentobarbitol anesthetized cats, spinal segments L_6-S_1 were isolated in continuity and used to record the compound potential elicited by suprathreshold stimulation of the lateral gastrocnemius-soleus (LG-S) muscle nerve. By noting the most rostral and caudal positions of active rootlets, the extent of the LG-S dorsal root entry zone was delineated. Individual fine dorsal root filaments were then dissected free and used to record the response to stimulation of the LG-S nerve and the nerve branches which supply different LG compartments. The muscle nerve branches were stimulated at different strengths to elicit afferent responses in different size classes. By carefully noting the entry point of each filament, the relative entry point of LG afferents belonging to different compartments was determined. Preliminary results are supportive of the hypothesis that the entry point of LG compartment afferents is topographically organized. Afferents of both large and small size classes from proximal compartments enter the spinal cord at the rostral end of the LG entry point with a higher probability than afferents from more distal compartments. Thus LG compartment afferents enter the spinal cord with greater frequency at positions where motoneurons innervating the same compartment would be encountered. It is concluded that at least some of the central partitioning of LG afferents onto motoneurons may be related to topographic considerations. Supported by NS 07137 from the USPHS.

121.19 PEPTIDERGIC INPUTS TO HUMAN AND MONKEY SPINAL MOTONEURON POOLS. S.E. Kapadia* and N.C. de Lanerolle, (Spon: E.E. Manuelidis) Sections of Anatomy and Neurosurgery, Yale Univ. Sch. Med., New Haven, CT. 06510.

The distribution of neuropeptides in motoneuron pools of the human and monkey spinal cord was examined by light and electron microscopic immunocytochemical techniques. In the human, motoneuron pools were abundantly supplied by thyrotropin releasing hormone-(TRH), Angiotensin II-(ANG), Substance P-(SP) and metenkephalin-(ENK) like immunoreactive fibers and terminals. TRH, ANG and SP processes were the most abundant, and were often seen closely apposed to motoneuron somata and outlined their dendrites. In earlier work we showed that the same motoneuron could be innervated by more than one peptidergic system (Neuroscience, 6:713-723, 1981). In the monkey ventral horn too TRH, ANG, SP, ENK and cholecystokinin (CCK) immunoreactive fibers and terminals were found among almost all motoneuron pools, the first four being the most abundant. Fibers and terminals immunoreactive for somatostatin (SOM), vasoactive intestinal polypeptide (VIP), neuropeptide Y (NPY) and prolactin (PRL) were also present in the ventral horn but in much smaller numbers. However, SOM, CCK, and ENK immunoreactive elements were found in greater density in some motoneuron groups such as the phrenic nucleus and Onuf's nucleus. Neurotensin-(NT) like immunoreactivity was found only in cervical motoneuron pools. The medial group of motoneurons in comparison to the lateral groups seem to have a greater innervation by the several neurochemical systems.

An electron microscopic examination of elements immunoreactive for TRH, ANG, SP and ENK in the thoracic ventral horn revealed that such immunoreactivity was mainly located in two types of synaptic terminals--those containing small, round agranular vesicles ('S'terminals) and those with an additional population of large dense-core vesicles ('G' terminals). These terminals formed asymmetrical synapses, most commonly with somata and large dendrites, and less commonly with small dendrites.

These studies point to several features of the neurochemical innervation of motoneurons. (i) Some peptidergic neuron systems (TRH, ANG, SP, ENK) innervate all motoneuron groups, but there may be differences in the degree of innervation of different motoneuron pools even by these peptidergic systems. (ii) Some peptidergic systems (SOM, CCK, NT) appear to selectively innervate only some groups of motoneurons. (iii) The same motoneuron may receive multiple neurochemical inputs. These features taken in conjunction with the facts that monoaminergic systems also strongly innervate motoneurons, and some neuropeptides may be co-exist with monoamines in nerve terminals point to a complex level of neurochemical modulation of motoneuronal activity.

(Supported by ALSSOA grant to N.C. de L)

121.20 EXCITATORY EFFECTS OF NOREPINEPHRINE ON LATERAL HORN CELLS OF NEONATAL RAT SPINAL CORD SLICES. Z. G. Jiang* R. C. Ma*and N. J. Dun. Dept. of Pharmacol., Loyola Univ. Med. Ctr., Maywood, IL 60153

Intracellular recordings were made from lateral horn cells including antidromically identified sympathetic preganglionic neurons (SPN's) situated in thin transverse sections of thoracolumbar spinal cord removed from 8-15 days old rats and the effects of norepinephrine (NE) on these neurons were investigated. Superfusion of NE (1-50 μM) caused dose-dependent depolarizations in 56 of the 71 lateral horn cells tested. Among the NE-sensitive neurons 23 were identified as SPN's by the appearance of antidromic spikes following stimulation of the ventral rootlets that remained attached to the slices by means of concentric bipolar electrode. Lateral horn cells that exhibited antidromic spikes had mean conduction velocity of 0.7 m/s (n=12) which is close to that of rat SPN axons. The membrane depolarization elicited by NE in presumed SPN's were similar to that evoked in unidentified lateral horn cells. The sensitivity of individual lateral horn cells to NE varied considerably as NE (10 μM) applied for 15 sec evoked a depolarization ranged from 2 to over 25 mV (mean = 8.7 $\pm$ 4.5 mV, n= 16) when recorded at the resting membrane potential between -50 and -60 mV. NE depolarizations were frequently associated with cell firings. In 8 of the 12 cells sampled NE depolarizations were not affected by low Ca (0.12 mM)/high Mg (12 mM) solution or tetrodotoxin (1 μM). In the remaining cells the depolarization was partially but never completely eliminated by low Ca or TTX. These findings suggest that in addition to depolarizing lateral horn cells directly, NE may liberate a depolarizing neurotransmitter(s) from spinal interneurons. NE depolarizations were accompanied by an increase in membrane resistance in the majority (12 of 16) of cells sampled. Membrane hyperpolarization reduced the amplitude of NE depolarization and the response was nullified between -80 and -90 mV at which the spike after-hyperpolarization was also eliminated. Further hyperpolarization did not result in a reversal of polarity. The depolarizing effect of NE on lateral horn cells were effectively and reversibly antagonized by pretreating the preparations with prazosin ($\leq$ 0.1 μM) and phentolamine (1-10 μM), whereas yohimbine (1-5 μM) and propranolol (1-10 μM) were without appreciable effect. It is concluded that NE is excitatory to lateral horn cells including those identified as SPN's and that the response is mediated by $alpha_1$ subtype of adrenergic receptors. This finding in conjunction with the evidence of the presence of noradrenergic fibers in the intermediolateral cell column suggest that NE may serve as an excitatory neurotransmitter to the SPN's. (Supported by NIH Grant NS18710).

122.1 THE MECHANISM FOR THIXOTROPIC EFFECTS AT RELAXED JOINTS. Allen W. Wiegner. Clinical Neurophysiology Lab., Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

Lakie et al. (J Physiol 353: 265, 1984) have described thixotropic effects at a number of human joints. That is, when the relaxed joint is subjected to a small sinusoidal torque, the amplitude of the steady-state response is increased up to several fold by a transient larger perturbation. The original, stiffer state is restored by several seconds of inactivity. We have previously found thixotropic behavior in the intact ankle joint of the rat as well as in the isolated ankle joint and isolated muscles acting at the ankle (Soc Neurosci Abstr 8: 329, 1982). In further experiments with a rat soleus muscle preparation (intact circulation, nerve cut) to explore the mechanism for thixotropy, we find the transition between stiff and loose states to be at the same magnitude of stretch (0.3% of muscle length) as the limit (range) of short range stiffness (SRS) of the relaxed muscle: when a ramp stretch or release is applied to a resting muscle, a stiff elastic response is first obtained, followed by a yield and a less stiff, often frictional response thereafter. SRS is calculated from $\Delta F/\Delta L$ in the initial stiff region. The range of SRS increases with velocity of stretch/release ($P<0.01$) and is symmetric with respect to direction (stretch or release). Elastic modulus of SRS is independent of direction and also independent of velocity over the range 0.0018-0.18 fiber lengths/sec. By stimulating the muscle and applying stretches from 0.3-7 sec thereafter, we find the time constant for redevelopment of SRS to be 2.5 sec at 34°C. Cooling the muscle from 34° to 9°C has no effect on range of SRS, but does produce a strongly viscoelastic response to stretch and, less markedly, to release. The latter asymmetry and lack of effect on range suggest that temperature effects are seen primarily in muscle structures other than those responsible for SRS. All of these properties of SRS are consistent with it being the mechanism underlying observations of thixotropy in isolated muscle preparations and contributing to thixotropy in intact joint preparations.

Both static and dynamic measurements of joint torque-angle relations in the intact and isolated joint suggest that the joint also contributes substantially (40-80%) to thixotropic effects in the rat ankle, possibly as a consequence of weeping lubrication of joints.

Thus, both the SRS of resting muscle and the lubrication properties of joints appear to contribute to thixotropic behavior seen at relaxed joints. Although these effects are small, they may be of physiological significance in that they reduce minute fluctuations in muscle length which might otherwise generate "afferent noise" from muscle spindles.

122.2 MISLEADING SPRING LIKE PROPERTIES OF MUSCLE Lloyd D. Partridge Univ. Tenn, Memphis TN 38163 and Thomas M. Hamm Dept Physiol. Univ. Arizona Health Sci Cntr., Tucson AZ 85724.

Muscle has often been considered to be spring like, with viscosity. Under restricted conditions this assumption seems to fit the data, but extension of the range of test invalidates the model. Failure is not a simple nonlinearity (Benton & Partridge '73-6 unpublished). Vibration at 200 Hz superimposed on slow movement (Hamm 1979 Dissertation) provides critical identification of changing viscous and elastic coefficients. These data, from soleus muscle of cat with the cut nerve subjected to constant stimulation, were studied in terms of power and mechanical impedance. The directly measured power output on shortening and input on stretch must balance internal elastic exchange, viscous loss, mechanical energy derived from chemical stores and mechanical potential energy loss by metabolic dissipation. For movements in physiological range, viscosity loss was small. Changes of elastic energy storage were in general smaller than the residue (net throughput from chemical process) as both varied in magnitude over the movement. As movement slowed at the low force end of the slow cycle, storage even increased while external energy was still being delivered by the muscle. Yet, at the opposite end the net stored elastic energy decreased while mechanical energy was entering the muscle. Under neural control the dominance of the power sink or source in chemical processes over the power of changes in elastic storage, makes the muscle look more like a servo-system than like a spring, though neither description is particularly good. This study shows that the modulation of chemical energy delivery and/or dissipation by mechanical factors, as well as modulation by neural activity must be included in understanding of motor control. 122.3 NONLINEARITIES IN ISOLATED FROG MUSCLE FIBER MECHANICAL DYNAMICS. Ian Hunter, Dept. of Physiology and Biomedical Engineering Unit, McGill University, Montreal, Canada H3G 1Y6.

When frog muscle fibers are subjected to step changes in length (input) the time course of the resulting tension (output) transient (step response) is dependent on the amplitude of the length-step perturbation. This finding has been taken as evidence that at least one of the muscle mechanical time constants (and hence the mechanical dynamics) is length-step amplitude dependent. In consequence recent models of muscle mechanical dynamics typically incorporate a length-step amplitude dependent time constant. However an alternative explanation is that the dynamics are invariant and followed by a static nonlinearity which transforms the dynamic response. Such a nonlinear system produces step responses whose "time constants" appear to be input-amplitude dependent.

In order to test whether muscle mechanics do indeed behave in this fashion single frog (Rana temporaria) tibialis anterior fibers were subjected to stochastic length perturbations of various peak-to-peak amplitudes (.05% to 3%) during tetanic stimulation at a mean sarcomere length of 2.2 μm. A nonlinear system identification technique appropriate for Wiener-type nonlinearities (i.e. a linear dynamic part followed by a static nonlinear part) was used. If muscle conforms to this type of nonlinearity then the dynamic portion of the model should be invariant and thus not require amplitude-dependent time constants. The step responses predicted by the dynamic part (before being transformed by the static nonlinearity) should therefore not be amplitude dependent. The figure shows that for the range of amplitudes tested this is indeed the case (mean and standard deviation of 35 amplitudes are shown). Thus under the conditions studied muscle mechanical dynamics is well modelled by a simple nonlinear model.

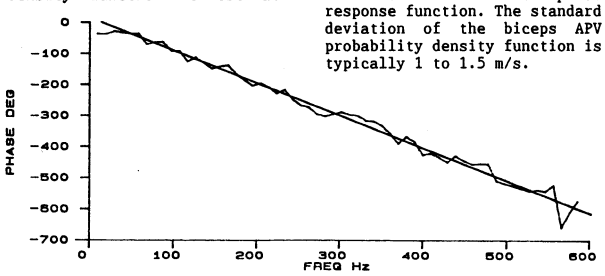
122.4 TWITCH PROPERTIES OF HUMAN MUSCLE DURING PASSIVE SHORTENING AND LENGTHENING. D. Gravel*, A.Y. Bélanger, C.L. Richards* and M. Filion. Laboratoire de Neurobiologie, Faculté de Médecine, Université Laval, Québec, Canada, G1K 7P4.

It has been shown, using tetanic contractions in animals (Joyce et al., J. Physiol., 204: 461, 1969) and maximum voluntary contractions in humans (Komi and Buskirk, Ergonomics, 15: 417, 1972), that the force generating capacity of a skeletal muscle is greater during lengthening (eccentric) than shortening (concentric) contractions. To our knowledge, there have been no studies of evoked contractions during passive muscle lengthening and shortening in human. The aim of the present study is to describe and compare the twitch properties of the plantarflexor muscle group examined at rest (isometric) and during lengthening and shortening movements of the ankle. Twitches were evoked by a supramaximal electrical shock delivered at the popliteal fossa in five healthy subjects. A KIN-COM dynamometer was used to passively move the ankle joint at a constant velocity of 30°/s. Each electrical stimulus was triggered at a predetermined angle for both lengthening and shortening movements. The peak twitch tension during muscle shortening was lower than either in lengthening or static conditions. No significant difference ($p< 0.05$) was noted between the lengthening twitch (peak tension) and the static twitch when the influence of the length was considered. There were no significant ($p< 0.05$) differences with regards to the twitch contraction time and half-relaxation time values between each testing condition. The lower peak tension of the twitch during shortening may in part be explained by a deactivation process in the contractile machinery (Edman, Acta Physiol Scand., 109: 15, 1980). Supported by l'Institut de Recherche en Santé et Sécurité du Travail du Québec (IRSST).

122.5 **COMPARISON OF BICEPS MUSCLE ACTION POTENTIAL CONDUCTION VELOCITY DETERMINED USING CROSS-CORRELATION, PHASE AND IMPULSE RESPONSE FUNCTION TECHNIQUES.** L.A. Jones, R.E. Kearney and I.W. Hunter. Dept. of Neurology and Neurosurgery, Biomedical Engineering Unit, Dept. of Physiology, McGill University, Montreal, Canada H3G 1Y6.

The usual technique for determining the action potential velocity (APV) of human muscle fibers from two surface EMG recordings involves cross-correlation. Typically the APV is calculated as the electrode spacing divided by the delay associated with the maximium absolute cross-correlation function value. However, for acceptable APV estimates the maximium of the cross-correlation function should not be used because of statistical variation in the correlation function estimates. It is preferable to use the maximum of a nonlinear function fitted to the correlation function by regression. The main problem in the cross-correlation function approach is in specifying and fitting the nonlinear function. An approach involving linear regression would clearly be preferable. We have developed a technique for estimating APV in which phase lags between the two EMG signals are determined. If there is a pure delay between the two EMGs then the phase part of the frequency response function determined between the two EMGs should be linearly decreasing with a slope equal to the delay. In practice it is found that the coherence of the frequency response function outside a 5 to 500Hz band is low. The phase slope and thus the delay is therefore conveniently estimated using coherence weighted linear regression. The figure below shows an example of the application of this technique in which the biceps APV was found to be 5.2 m/s. Neither the correlation nor the phase techniques yield estimates of the distribution of APVs. The impulse response function (inverse Fourier transform of the frequency response function) of a system consisting only of pure delays can be shown to be proportional to the delay probability density function. Using this principle we have developed another technique in which the APV probability density function is estimated from the inverse of the impulse response function. The standard deviation of the biceps APV probability density function is typically 1 to 1.5 m/s.

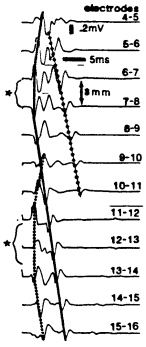


122.6 EMG MAPPING OF INDIVIDUAL MOTOR UNITS IN THE CAT TENUISSIMUS MUSCLE C.M. Chanaud, C.A. Pratt and G.E. Loeb. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205

The geometric relationships between muscle fiber architecture and whole muscle force and length indicate that long, parallel-fibered muscles [such as sartorius, biceps femoris, semitendinosus and tenuissimus(TEN)] should be well-suited for continuous force production during large muscle length changes. Although a variety of muscle fiber (and associated connective tissue) arrangements have been proposed for these muscles, few details are known about their actual architecture, which appears to incorporate anatomical features not previously considered (Rindos, et.al. Neurosci.Ab. #183.3, 1984). In this study, we used a novel electrophysiological technique to reveal details of the underlying architecture that are not easily obtained by the usual anatomical techniques.

The cat hindlimb was dissected to expose the TEN muscle, leaving the innervation and blood supply intact. A silastic rod (5X120mm) carrying 40 electrode contacts (interelectrode spacing=3mm) on the surface was inserted beneath the muscle, providing 39 possible serial pairs of bipolar EMG recording sites. The L7 and S1 ventral roots were accessed via laminectomy and proximally cut filaments were stripped down until a single TEN axon could be stimulated (1ms pulse width, 1pps). Single motor units (MU) were identified by changing the stimulus intensity near threshold and observing no change in the all-or-none potentials recorded by the EMG electrode array. The polyphasic signature was then recorded at each available site along the 120mm long array.

Sets of EMG tracings, as shown at right, demonstrated that every stimulated MU extended into both the proximal and distal portions of the muscle, which are innervated by separate nerve branches. Within a single MU, the polyphasic signature recorded at each site could be resolved into separate biphasic waveforms, defining fiber subgroups, each of which was presumably innervated by one of the numerous end-plate clusters along the muscle. End-plate regions were localized to specific regions (stars) by the polarity reversals of the shortest latency waveforms there. Each MU consisted of similar longitudinal (proximal to distal) distributions of subgroups. Subgroups belonging to a single unit were heavily interdigitated, not placed end-to-end. The subgroups ranged from 3.3-6.3 cm in length. Conduction velocity of the muscle action potentials (slopes of diagonal lines) ranged from 2.5-3.5 m/s.



122.7 STABILITY OF EMG SIGNAL PARAMETERS DURING SUBMAXIMAL PLANTARFLEXION CONTRACTIONS. A.V. Sirin* and A.E. Patla (SPON: G. Partlow) Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

This study was conducted to determine the stability of the two EMG signal parameters during isometric submaximal efforts, and analyse the behaviour of these two parameters during a 10s maximal isometric contraction. Eventual goal is to assess synergistic behaviour of the triceps surae during sustained fatiguing contractions.

A computationally fast method of estimating a fatigue index, modal frequency (MF), proposed by Bower et al (1984), was evaluated. Validation was carried out on EMG data from three muscles of the triceps surae of five subjects at 30% MVC, held for four minutes. Results showed a high average correlation (r=.901) between MF and mean power frequency which was calculated using a Fast Fourier transform algorithm.

Stability of the average EMG (AEMG) and MF was assessed by computing the coefficient of variation (CV) of five successive records of either 500ms, 1s, or 2s duration, sampled at 1024Hz. EMG signals from the three muscles of the triceps surae were analysed for six subjects while performing isometric plantarflexions at 25%, 50%, and 75% MVC. ANOVA results showed that the CV of MF was dependent on the record length at all three levels of MVC. Post-hoc tests revealed that the CV of 500ms record length was greater than that of 2s at 25% ($p<.08$), 50% ($p<.08$), and 75% ($p<.04$), and the CV of the 1s record length was greater than that of 2s at 25% MVC level ($p<.05$). The mean CV across muscles and contraction levels for record lengths of 500ms, 1s, and 2s were 12.6%, 10.5%, and 6.9% respectively. AEMG results revealed no significant differences between the CV of any of the record lengths at any contraction level, in any of the muscles. Based on these results a comparison of average Modal Frequency of 1s record length was made between five and ten consecutive record segments. T-tests revealed no significant difference between the means of five and ten record segments.

A 10s maximal isometric plantarflexion effort was evaluated. All three muscles of the triceps surae were monitored on six subjects. A moving average of 2s portions (5 segments, each 1s long) of the contractions were evaluated. ANOVA indicated that the MF of MG had a significantly ($p<.002$) greater rate of decline than either LG or SOL. The AEMG of all muscles however, did not alter significantly and neither did the plantarflexor torque.

122.8 EFFECTS OF MOTOR UNIT DISCHARGE RATE AND FIBER DIAMETER ON FORCE- EMG RELATIONSHIPS. M. J. Blaschak* and W. Z. Rymer. (SPON: W. T. Rainey). Dept. of Physiol., Northwestern Univ., Chicago, IL 60611.

Alterations in force-emg relationships have been demonstrated in human spastic paretic muscle following supraspinal lesions (e.g. Blaschak, M., et al., Neurosci. Abst., 9:904, 1984). These alterations could arise from disruptions in the normal pattern and rate of motor unit (MU) discharge, from muscle atrophy, or from a combination of the two. The purpose of this study was to investigate the effects of motor unit discharge rate and muscle atrophy on force-emg relationships in a computer generated surface emg simulation model.

This model, developed through a modification of an earlier study (Guha, S. and Anand, S., Comp. Biol. Med., 9:213, 1979), allowed changes in initial MU discharge rate, mean maximum MU discharge rate, and fiber diameter. The amplitude and duration of the individual MU action potentials were graded according to their order of recruitment and fiber diameter.

The initial discharge rate (2, 4, 6, 8, 10/sec), the final discharge rate (13 or 24/sec), and the fiber diameter (100%, 95%, 90%, or 80%) were set, and a series of simulated emg's were produced. Following the generation of each emg series, a variety of characteristics, including the mean rectified emg value (MREC), the frequency of mean power (MPF), and the associated force, were determined. EMG characteristics were then determined for all rate and diameter conditions across matched forces.

The results indicate that changes in initial and final discharge rates are reflected as alterations in the force-MREC (FE) relationship, while changes in fiber diameter are reflected as alterations in the FE relationship and in reductions in the MPF. For example, there was an increase in the MREC per unit force as demonstrated by a 20% increase in the slope of the FE relationship as the initial rate decreased from 8/sec to 2/sec and the maximum rate was decreased from 24/sec to 13/sec. There was a 4% decrease in the MPF over the same conditions. When the discharge characteristics were held constant, a 5%, 10%, and 20% reduction in fiber diameter gave a 12%, 20%, and 38% increase in the slope of the FE relationship, and a 10%, 22%, and 38% reduction in the MPF, respectively. These findings parallel a current animal study.

The results of this simulation support that while disruption in motor unit discharge rate leads to alterations in force-emg relationships, alterations in the force-emg relationship associated with a shift of the frequency content to lower frequencies are most probably due to a combination of reductions in both the mean motor unit discharge rates and in muscle fiber diameter. NIH 5 R01 NS19331

122.9 EMG POWER SPECTRUM AND MOTOR UNIT DISCHARGE IN AN ANIMAL MODEL OF SPASTIC PARETIC WEAKNESS. R.K. Powers, M.J. Blaschak*, and W.Z. Rymer. Dept. of Physiology, Northwestern University, Chicago, IL, 60611.

There is evidence that muscle weakness following stroke is partly the result of a disorganization of motor output to the muscle, so that more EMG is required to achieve a given force level (Tang, A. and Rymer, W. J. Neurol. Neurosurg. Psych., 44:690, 1981). A similar phenomenon has been reported in an acute animal model, and has been associated with abnormally low motor unit discharge rates (Rymer, W. et al., Exp. Brain Res, 37:93, 1979). In human paretic muscle, the frequency content of the EMG power spectrum is shifted toward lower frequencies (Blaschak et al., Neurosci. Abst., 10:904,1984), and such a shift could result from lower motor unit discharge rates. However, simulation studies indicate that the frequency content of the EMG power spectrum is much less sensitive to motor unit discharge rates than to changes in muscle fiber diameter. To evaluate the effects of changes in discharge rate alone, we have measured force, EMG spectra and discharge rates in an acute animal model of weakness where muscle fiber diameter remains constant.

Force, multiunit intramuscular EMG and the activity of single motor units were recorded in the medial gastrocnemius muscle of decerebrate cats before and after a dorsal hemisection of the cord at T12. Muscle length was held constant, and force was graded by manipulation of the contralateral hindlimb.

After the hemisection, the mean rectified EMG at matched force levels was 1.2 - 4.0 times greater than that recorded before the section. Based on our present sample of motor units, minimum steady discharge rates appear to be the same before and after spinal section. However, for matched levels of motor output (EMG), average discharge rates are lower after the section, indicating that maximum firing rates are probably lower. Similar discharge characteristics have been reported for single motor units in the tibialis anterior muscle of spastic paretic humans (Rosenfalck, A. and Andreassen, S. J. Neurol. Neurosurg. Psych., 43:907-916,1980). Even in animals showing large postsection changes in motor unit discharge rates and mean rectified EMG, there were only minor shifts in the frequency content of the EMG power spectrum, reflected as a 4% decrease in the mean power frequency.

122.10 CORRELATION OF SUPRASPINALLY GENERATED MOTOR UNIT (MU) RECRUITMENT ORDER WITH MOTOR AXON CONDUCTION VELOCITY (CV). T.E. Dick, F.-J. Kong, and A.J. Berger. Department of Physiology & Biophysics, University of Washington School of Medicine, Seattle, WA 98195.

Phrenic motoneurons (PM) are activated rhythmically with individual MUs recruited progressively during inspiration. This rhythmic behavior is generated primarily by descending bulbospinal inputs. Recruitment order of MUs may be a function of specific connections from supraspinal neurons (Hilaire and Monteau, J. Physiol. (Paris) 75: 765-781, 1979) and/or may be determined by intrinsic factors such as motoneuron size (Berger, J. Neurophysiol. 42: 76-90, 1979). Recently Bawa et al. (J. Neurophysiol. 52: 410-420, 1984) tested the size principle by determining recruitment order of hind limb MUs activated by segmental afferents. They compared pairs of simultaneously recorded MUs and reported that in 97% of cases, MUs with lower CVs were recruited first. Their data verified the size principle of Henneman for segmentally determined recruitment order.

In this study, we correlated recruitment order and axonal CV for simultaneously recorded pairs of phrenic MUs. We recorded single MU action potentials (MUAPs) with two tungsten microelectrodes placed in the sternal region of the diaphragm of anesthetized cats. Phrenic nerve activity was recorded simultaneously on hook electrodes at two sites along the nerve. Recruitment order was obtained by comparing the onsets of MUAPs during inspiration. Axonal conduction time was determined by using the MUAP to trigger averages of the two delayed whole-nerve recordings. Repeated measures showed that conduction times varied by 20 us or less over a distance of 100 mm. This corresponds to a variability of 0.5 m/s or less in estimates of CV in axons with CVs of 50 m/s.

For the population of MUs studied, recruitment times varied from 28 to 1028 ms after onset of phrenic nerve activity, and CV varied from 29.7 to 53.8 m/s. In 92% of cases (23 of 25 MU pairs so far tested in 5 cats), the pair-wise recruitment order was directly related to axonal CV.

We conclude that in normal supraspinally generated inspiration, the recruitment order of PMs is strongly correlated with axonal CV verifying the applicability of the size principle to at least a portion of this motoneuron pool. (This research was supported by NIH grant NS 14857, the Puritan-Bennett Foundation and the Shandong Medical College.)

122.11 FORCE-FREQUENCY RELATIONS OF CAT MOTOR UNITS DURING DIFFERENT PATTERNS OF STIMULATION. H.P. Clamann and S.A. Binder-Macleod*. Dept. of Physiology and Biophysics, Medical College of Virginia, Richmond, VA 23298

To match the force output of a muscle to a specific task the CNS selects the number of motor units needed (recruitment) and varies the rate of discharge of each active unit (rate coding). The relation between discharge rate and force of motor units is not well understood. A sigmoid relation between discharge rate and the force of single motor units is often described in animals, although a variety of other functions relate whole muscle force to discharge frequency of motor units in man. These may change qualitatively and quantitatively as the pattern of force output changes. To gain further insight into the force-frequency relationship in single motor units, several patterns of stimuli were applied to single motor units and the resulting force output measured.

Cats were deeply anesthetized with sodium pentobarbital. Axons of single medial gastrocnemius motor units were isolated in ventral root filaments and stimulated to determine twitch strength and contraction time, fusion frequency and maximum tetanic tension of the unit. Force output of the unit was measured at the Achilles tendon which had been detached from the calcaneus. Each unit was then stimulated with a train of stimuli varying linearly from 5 pulses per second (pps) to a maximum 20% above the unit's fusion frequency and linearly back to 5 pps. One period of such triangle-wave stimulation lasted 5 seconds. This pattern was repeated for 3 to 5 continuous periods of the triangle-wave pattern.

The force-frequency response was remarkably similar for all motor unit types and reproducible in each motor unit. It consisted of a hysteresis loop having a sigmoid ascending limb and a descending limb composed of a plateau of constant force which was maintained to a frequency of 15 to 25 pps below which force fell rapidly. With each successive trial the loop shifted to the left or lower frequencies. Force output at a given frequency was consistently greater when frequency was decreasing than when it was increasing; the difference was as great as 500%. When frequency was decreasing, force remained constant for most of the range, falling steeply below frequencies of 20 pps. When a unit was stimulated at any frequency above 30 pps which was then decreased linearly, force closely matched the descending limb of the hysteresis loop.

We conclude that motor unit force output is strongly dependent on immediate past stimulus history. The range of frequencies suitable for force modulation by rate coding is influenced by stimulus history and is poorly predicted by the unit's fusion frequency or twitch contraction time.

122.12 PATTERNS OF INNERVATION AND RECRUITMENT IN REINNERVATED HAND MUSCLES AFTER COMPLETE NERVE SEVERANCE. C. Thomas*, R. Stein T. Gordon, G. Elleker*, and R. Lee, Depts. of Physiology, Pharmacology, and Medicine, Univ.of Alberta, Edmonton, T6G 2H7 and Dept. of Clinical Neurosciences, Univ.of Calgary, T2N 4N1.

Orderly size relationships between nerve and muscle properties are redeveloped in cat triceps surae muscles, even when reinnervated by antagonistic nerves (Thomas et al., Neurosci. Abs. 10:144, 1984). Following reinnervation of a human muscle, an orderly pattern of recruitment was not observed (Milner-Brown et al., J. Neurol. Neurosurg. Psychiat. 37:670, 1974). In the human forearm, the ulnar and median nerves branch extensively to innervate muscles with different functions and separate spinal motor pools. We have studied the patterns of innervation and motor unit recruitment in reinnervated muscles of human patients who had accidentally severed and undergone fascicular resuture of the ulnar and/or median nerve in the past five years. EMG from single motor units was recorded with selective needle electrodes from ulnar reinnervated (first dorsal interosseus, abductor digiti minimi) and median reinnervated (abductor pollicus brevis, opponens pollicus) muscles. Normally innervated motor units were activated only by voluntary contraction of the muscle in which they were recorded. In patients, reinnervated motor units could also be activated by voluntary contraction of other muscles innervated by that same nerve. The original spinal motor pool of each motor unit was identified objectively as that muscle with the lowest force and EMG threshold for activation of the unit. This was confirmed by the patient as the muscle action which activated the motor unit most easily. Our data clearly show that reinnervation was non-specific as muscles were now innervated both appropriately by some of their original motor axons and inappropriately by motor axons that had previously innervated different muscles with different functions.

With spike triggered averaging, we determined the twitch tension and EMG activity associated with the slow steady firing of reinnervated motor units during isometric voluntary contractions. Following ulnar or high median nerve sections, there was no correlation between the size of the motor unit as measured by twitch tension and the voluntary force at which the motor unit fired reliably in the muscle being recorded from. This apparent absence of orderly recruitment in any one muscle may be due to recruitment of motor units from spinal pools with widely different functions. Following median nerve section at wrist level, where the reinnervated muscles have more synergistic actions, orderly recruitment appeared to be re-established. Thus, it would seem that the size principle of motor unit recruitment could be re-established after nerve section in humans, if motor axons innervate their original muscles or ones with closely synergistic functions.

122.13 THE INFLUENCE OF SPINAL CORD TRANSECTION ON POTENTIAL FOR INCREASING THE NUMBER OF SERIAL SARCOMERES IN SKELETAL MUSCLE FIBERS. P.V.Loubert* (SPON: P. Lacy). Dept. of Anatomy and Cell Biol., Univ. of Michigan, Ann Arbor, Michigan 48109.

Muscle fibers have been shown to have a remarkable capacity for increasing and decreasing their optimal length to accommodate changes in their functional environment. This occurs by addition and subtraction of serial sarcomeres within the muscle fibers (Goldspink, 1972; Williams, 1976). It has also been shown that length adaptations can occur to a normal degree in denervated muscles (Goldspink, 1974). McLachlan (1983) showed that denervation slows the rate of sarcomere adjustment, and Tabary (1971) theorized that these adjustments are inhibited in the presence of spastic cerebral palsy.

The present study utilizes a ratio of sarcomere numbers per soleus muscle fiber/unit length of tibia for assessing the relative changes in muscle fiber length. The use of this measurement tool is based upon a positive linear correlation between tibia length and the number of sarcomeres per soleus muscle fiber ($R=0.74$, $p<0.001$), and the consistent ratio of number of sarcomeres/mm tibia ($x=147.5\pm4.8$) over a wide range of sizes and ages in rats. The use of this tool normalizes for differences in sarcomere number due to size differences and changes due to normal growth during the course of the experiments.

The effects of spinal cord transection on the ability of soleus muscle fibers to increase the number of sarcomeres within the fibers was studied. Female rats received surgical transections of their spinal cords, followed by casting of their right ankles in complete dorsiflexion. Spinal transection was used to isolate the muscle from descending CNS influences, and casting was used to increase the functional length of the soleus muscles. Casting produced a significant increase in the number of sarcomeres in the soleus muscle fibers of the casted limbs ($p<0.001$). This indicates that muscle fibers retain the ability to increase the number of sarcomeres in series when upper motor neuron influence is removed.

This study was supported in part by the MPTA Institute for Education and Research, the Program in Physical Therapy at the Univ. of Michigan - Flint, and NIH grant NS-17017.

122.14 TEMPERATURE DEPENDENCE OF THE DYNAMIC BEHAVIOR OF MUSCLE SPINDLES M.N. Kruse* and R.E. Poppele Lab. of Neurophysiol., Univ. of Minnesota, Minneapolis, MN 55455

The dynamic behavior of mammalian muscle spindles, which is characterized by a rate or velocity dependence, can be observed in the frequency domain as an increasing response amplitude and phase lead to stretch frequencies greater than 1 Hz. At lower stretch frequencies, the response amplitude is nearly constant and there is a smaller phase lead. The transition or break between low and high frequency behavior occurs at a characteristic frequency corresponding to a single rate constant. The frequency at which the amplitude of spindle responses begins to increase is near the frequency at which the amplitude of changes in muscle tension begins to decrease when a tetanic tension is modulated sinusoidally. Thus, a rate constant associated with spindle dynamics acts to "compensate" for muscle dynamics in a simple stretch reflex.

We have determined the temperature dependence of the frequency characteristics of isolated cat muscle spindles taken from tenuissimus muscle using small amplitude sinusoidal stretches. Data from 2 primary endings and 1 secondary show the same change in break frequency with temperature on an Arrhenius plot which can be fitted well with either one or two lines; see Figure below. The equivalent activation energy (Ea) for the single line is about 9 Kcal/M and thus too low to be explained by a single active process such as channel gating. It is more consistent with a passive mechanism like one involving the mechanical properties of the intrafusal muscle.

The equivalent Ea's for the two line fit are 6 Kcal/M (25-44°C), and 23 Kcal/M (16-25°C). This interpretation of the data implies that there is more than a single process involved in determining the break frequency. The apparent increase of Ea associated with temperatures below 25°C could indicate the involvement of a membrane bound process, in which the increase accompanies a change of state in the membrane. However, the temperature data alone are insufficient to resolve the question about the origin of the spindle's "compensation" for muscle dynamics.

122.15 EFFECT OF Ca^{++} CHANNEL BLOCKERS AND Ni^{++} ON K^+ CONTRACTURES IN FROG TWITCH FIBERS. M. Huerta, R. Gamboa-Aldeco* and E. Stefani. Department of Physiology and Biophysics. CINVESTAV-IPN. Apdo. Post. 14-740. 07000 México, D.F.

Twitch fibers have an inward Ca^{++} current (I_{Ca}), which is located in T-System and a Ca^{++} influx during excitation. The role of I_{Ca} during K^+ contractures remains unclear. A reduction in external Ca^{++} causes a decrease on the amplitude and duration of K^+ contractures (Cota & Stefani, 1981. J.Physiol., 317:303). However, Ni^{++} substitutes Ca^{++} on the time course of K^+ contractures (Caputo. The Regulation of Muscle Contraction. Academic Press. 1981. pp 81-95). In order to obtain further information on the role of I_{Ca} on K^+ contractures, we studied K^+ contractures after decreasing or eliminating I_{Ca} with Ca^{++} channel blocker agents (Nifedipine and Diltiazem) or after replacing Ca^{++} by Ni^{++}.

Tension was isometrically recorded from isolated twitch muscle fibers of tibialis from Rana pipiens. The control saline was (mM): CH_3SO_3Na 117.5, CH_3SO_3K 2.5, $(CH_3SO_3)_2Ca$ 1.8 (pH 7.4) and contained 10^{-6} g/ml of TTX. The experiments were performed at room temperature (20-22 °C). The exposure of the fibers to control saline with Diltiazem (1 μM) added for 3 min. prior to the contracture (60-190 mM K^+) decreased the peak tension (66 ± 10%,n=9; $\bar{X}$ ± S.E.) and shortened the half amplitude duration (15 ± 7%,n=8). This effect was evident after the second contracture, probably due to the blocking mechanism of Diltiazem (Gonzalez-Serratos & Valle-Aguilera, 1983. Biophys. J., 41:395a). This action was reversible. Similar results were obtained when the fibers were preincubated for longer periods (22-30 min). Nifedipine (0.1-10 μM) produced similar effects (peak tension reduction: 57 ± 8%,n=16 and half amplitude duration decrease: 47 ± 4%,n=18). This blocking effect was evident from the first contracture. When external Ca^{++} was omitted from the contracture fluid (low Ca^{++} saline: 0 mM Ca^{++} + 3 mM Mg^{++}) a decrease on the amplitude and duration of K^+ contracture was found and when Ca^{++} was equimolarly substituted for Ni^{++} (1.8 mM Ni^{++} + 3 mM Mg^{++}) a further decrease of the tension was observed (peak tension decreased about 70%). This indicate that Ni^{++} was not able to restore the normal temporal course and amplitude of K^+ contracture. This effect was reversible. The present results can be explained by a modulation of I_{Ca} on K^+ contractures or by specific interactions between external Ca^{++} and Ca^{++} binding sites in the membrane.

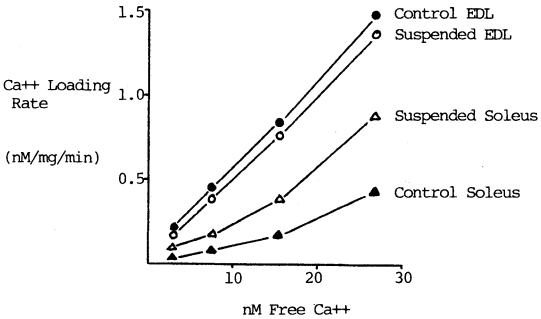
122.16 CALCIUM TRANSPORT IN SARCOPLASMIC RETICULUM FROM FAST AND SLOW RAT MUSCLES AFTER HYPOKINETIC SUSPENSION. G.T. Patterson, R.C. Gupta*, C. Petrone*, K.E. Misulis* and W-D. Dettbarn. Pharmacology Dept., Vanderbilt Univ. Med. Ctr., Nashville, TN 37232.

This laboratory and others have shown that hindlimb suspension causes acceleration of contractile speed in soleus muscle. We report here the effects of this non-neurogenic disuse on the sarcoplasmic reticulum (SR) calcium (Ca++) transport in the soleus and extensor digitorum longus (EDL) muscles from rats.

SR of functional integrity and high purity was isolated from EDL and soleus muscles of rats suspended 2 weeks and control rats by the procedure of Mrak and Fleischer (Muscle & Nerve 5:439, 1982). Ca++ loading rates were determined by a Millipore method. ATPase activity was determined by the measurement of inorganic phosphate production.

The Ca++ loading rates of SR from EDL and soleus of control and suspended rats are shown in the following figure:



Control EDL Ca++ loading rates are more than twice that of control soleus. The SR from EDL of suspended rats had a 10% reduction in Ca++ loading rates, while SR from suspended soleus had about a 45% increase. Preliminary results on Ca++-stimulated ATPase activity of SR from EDL and soleus of suspended rats indicated changes have occurred corresponding to the changes found for Ca++ loading rates.

These results on Ca++ loading rates in soleus correlate with the observed increased contractile speed and supplies more evidence that fiber type conversion in soleus occurs during suspension disuse. Whether a change in neural activity or the loss of weightbearing activity is responsible for these changes in the soleus are currently being studied. Supported by NASA Grant #NAG 2-301.

122.17 ACETYLCHOLINESTERASE FROM LAMPREY SKELETAL MUSCLE IS FOUND IN GLOBULAR AND ASYMMETRIC FORMS. Leo Pezzementi, Ellen Reinheimer*, and Maureen Pezzementi*. Oberlin College, Oberlin, OH 44074 and Birmingham-Southern College, Birmingham, AL 35254.

Last year, we reported preliminary work on the acetylcholinesterase activity of frozen lamprey skeletal muscle (Soc. Neurosci. Abstr. 10, 140.7). Here we present data from experiments performed on fresh muscle in the presence of protease inhibitors. Lamprey skeletal muscle acetylcholinesterase activity appears to be due to acetylcholinesterase, not pseudocholinesterase. Activity is inhibited by BW 284c51, but not by Iso-OMPA or ethopropazine. The enzyme has a high affinity for acetylthiocholine and is inhibited by high concentrations of substrate. A large fraction of the enzyme activity is a glycoprotein, since it is precipitated by concanavalin A-agarose. The precipitation is inhibited by glucose. Optimal extraction of acetylcholinesterase is obtained in a high-salt detergent-containing buffer. Fractional amounts of esterase are extracted in buffers lacking salt and/or detergent. The data suggest that globular and asymmetric forms of enzyme are present. Velocity sedimentation on sucrose gradients shows that the enzyme sediments predominantly as a broad peak of activity that could correspond to A_4 and/or G_4; additionally, there is usually a small peak of activity that could represent A_{12}. Sequential extraction of esterase in conjunction with velocity sedimentation reveals that the enzyme is found in G_2, G_4, A_4, A_8, and A_{12} forms. Some of these may be the products of proteolysis. This work was supported by a Cottrel College Science Grant from the Research Corporation and a grant from the Committee on Research and Development of Oberlin College.

122.18 ACETYLCHOLINESTERASE IN SERUM AND MUSCLES OF DIABETIC RATS. K.A. Skau. Coll. of Pharmacy, U. Cincinnati, Cincinnati, OH 45267.

Experimental diabetes in laboratory animals produces changes in the somatic nervous system such as reductions in conduction velocity and axonal transport. There have been few studies on changes in the end-organ (skeletal muscle) in response to these neuronal alterations. Acetylcholinesterase (AChE) is a sensitive indicator of muscle and nerve function as the molecular forms of this enzyme are regulated by such factors as axonally transported trophic factors, muscle contractile activity and neuronal acetylcholine release. In addition, AChE accumulates in the serum of patients with various neurological diseases. This study examined the potential usefulness of AChE in serum and muscle as indicators of neuronal or myopathic changes in diabetic rats.

Sprague-Dawley rats (180gm) were injected i.v. with streptozotocin (50mg/Kg) to produce a moderate diabetes (serum glucose of 37.6mM vs. 9.1mM for age-matched controls). Blood was withdrawn from a tail vein at 10 and 16 weeks, allowed to clot, centrifuged to sediment formed elements, and the serum was assayed for AChE activity using a radiometric assay. Assay tubes contained 45μM iso-OMPA to inhibit non-specific cholinesterases, and replicate samples were assayed in the presence of iso-OMPA and BW284C51 (10μM) to serve as blanks. At 16 weeks after diabetes induction, the animals were sacrificed and skeletal muscles were removed, homogenized in buffer (50mM Tris HCl, pH 7.4; 0.2mM EDTA) containing high salt (1.0M NaCl) and detergent (1% Triton X-100) to solubilize all forms of the enzyme. The molecular forms were separated on linear 5-20% sucrose density gradients.

Diabetic rats showed typical signs and symptoms of moderate hyperglycemia such as reduced growth rate, glycosuria, cataracts (after 4 mo.), gastric distention, diarrhea and bladder hypertrophy. At 10 wks and 16 wks after induction the diabetic animals exhibited 49% and 103% increases in serum AChE activity. Although the source of this increased activity is not clear, it should be noted that patients with amyotrophic lateral sclerosis, Alzheimer's dementia and progressive muscular atrophy have been shown by others to exhibit elevated serum AChE.

Hemidiaphragms (HD) and extensor digitorum longus (EDL) muscle have three major peaks of AChE activity corresponding to the G_1, G_4 and A_{12} forms. In diabetic rats the total AChE as well as the density of AChE (activity/gm of tissue) was reduced when compared to age-matched controls. In both HD and EDL the A_{12} form was relatively unaffected while the G_4 form was significantly reduced. The G_1 form was variable, being reduced in some muscles and unchanged in others. It is generally accepted that the A_{12} form is regulated by neurotrophic factor while the other forms may be regulated by muscle activity as well. Thus the disruption of AChE in diabetic muscle does not seem to be a simple denervation phenomenon.

PAIN: CENTRAL PATHWAYS II

123.1 SELECTIVE PRESYNAPTIC DEPOLARIZATION OF C FIBRE TERMINALS IN THE FELINE SPINAL CORD. O. Calvillo, M. Ghignone, L. Quintin. Department of Anesthesiology, Texas Tech University Health Sciences Center, Lubbock, TX 79430

Clonidine, an α_2 adrenoreceptor agonist is a powerful antinociceptive agent: behavioral observations rated it 60 times more potent than morphine. There are α_2 adrenoceptors in various regions of the the mammalian central nervous system including Laminae II-III of the spinal cord, which receives a large number of nocicepive afferent fibres. In this region C fibre input is amenable to presynaptic modulation.(1) We studied the effects of clonidine on the excitability of primary afferent terminals of cutaneous low and high threshold fibres. Changes in the excitability of these terminals can be an important determinant of synaptic efficacy. Experiments were done on cats, anesthetized with nembutal paralyzed with pancuronium bromide and ventilated mechanically. The spinal cord was exposed in the lumbosacral region and transected at T13-L1. The sural and posterior tibial nerves were dissected and mounted on electrodes for stimulation or recording. Primary afferent terminal excitability was tested by delivering constant current pulses (up to 375 A 0.5 ms duration) through metal microelectrodes. Antidromic action potentials were recorded from the sural nerve. Two responses were observed. The first had a short latency (2-3 ms) with a conduction velocity of 47-63 m/s identified as A fibre action potential. The second had a much longer latency (250-300 ms) and conduction velocity of 0.9-1.1m/s, its threshold was about 15 times greater than the short latency component belonging to C fibre action potential.(1) Excitability was calculated from the current ratio required to evoke a reponse that served as control to that current that would have been required to obtain the same response after drug administration. Clonidine in doses 1-5 μg Kg^{-1} did not effect the excitability of A fibre primary afferent excitability (n=5). Clonidine increased the excitability of the C fibre primary afferent terminals by about 85% (n=12). This effect was reversed by yohimbine (n=4) and phentolamine (n=8), thus suggesting mediation by α_2 addrenoceptors. Clonidine selectively increased the excitability of the C fibre primary afferent terminals signaling primary afferent depolarization (PAD). During PAD there is a depression of synaptic efficacy so that the responses of second order neurones can be selectively suppressed. Clondine did not affect the excitability of the A fibre terminals, suggesting that the noradrenergic sympathetic mechanism which mediates the antinociceptive action of clonidine is specific for nociceptive spinal pathways. In summary clonidine in spinalized cats selectively produces PAD of C fibre primary afferent terminals without affecting the A fibre terminals.

123.2 EXTRACELLULAR RECORDING OF DORSAL HORN SENSORY NEURON RESPONSES TO NOXIOUS THERMAL STIMULI: CRITICAL DEPENDENCE ON CHOICE OF ANESTHETIC. J.M.Peets* and B.H.Pomeranz. Dept. of Zoology, U. of Toronto, Toronto, Canada M5S 1A1.

In previous reports (Peets and Pomeranz, Pain, Suppl. 2;S370), we have studied the spinal pharmacology of high and low frequency transcutaneous electrical nerve stimulation (TENS) induced analgesia. Rats were intrathecally catheterized, given TENS treatment (either high (100 Hz) or low (4 Hz) frequency) and intrathecal injection of a variety of endorphinergic and serotonergic enhancers and blockers. These studies indicated that, on a spinal level, low frequency TENS analgesia , as determined by tail flick latency, appears to be mediated by opiate receptors. High frequency TENS analgesia does not appear to be endorphin mediated. Furthermore, we could not implicate spinal serotonin receptors in either high or low frequency TENS analgesia.

To further study this analgesia, we sought to record from dorsal horn sensory neurons in the anesthetized rat. Using extracellular multiunit recording techniques, we attempted to record responses to noxious thermal stimuli from these neurons. Rats were monitored for EKG and blood pressur in all experiments, and circulation in superficial cord vasculature was carefully observed. A variety of anesthetics was assayed, and in our experience, clear and reasonably consistent responses to noxious thermal stimuli to the skin were found only in pentobarbital-infused rats, but not in urethane, urethane-chloralose or halothane/nitrous oxide anesthetized rats at a variety of anesthetic depths.

Preliminary results indicate that the responses of dorsal horn sensory neurons to noxious thermal stimuli could be inhibited by low frequency TENS (4 Hz, 20 min.) administered bilaterally to the heels of the rat. We feel that the choice and depth of anesthetic are critical to the success of such recordings, and hence to the study of subtle modulating influences on thermal nociception in the rat.

123.3 SPINAL CORD LAMINAE I AND II NEURONS WHICH PROJECT TO THE CONTRALATERAL PONTINE RETICULAR FORMATION IN THE CAT.
A.R. Light, E.J. Casale*, and D. Menetrey*. Department of Physiology, UNC-Chapel Hill, Chapel Hill, N.C. 27514

Relatively few reports have been made on the physiological properties of lamina I neurons which project to rostral brain structures in the cat. In the present experiments we identified by antidromic activation 13 superficial lumbar dorsal horn neurons which projected to the contralateral parabrachial region of the pons.

Adult cats were anesthetized with sodium pentobarbital throughout the experiments. Monopolar tungsten microelectrodes were used for antidromic stimulation, and horseradish peroxidase (HRP)-filled micropipettes were used for recording both extra- and intracellularly from the somadendritic region of the neurons in the lumbosacral spinal cord.

All 13 rostrally-projecting neurons were nociceptive specific. Eight responded only to noxious mechanical stimulation and 5 responded both to noxious mechanical stimulation and to noxious thermal stimulation.

The conduction velocities of the axons projecting to the contralateral parabrachial region ranged from 0.8 to 10.0 meters/sec (mean 3.5 meters/sec). In addition, in two tested neurons, antidromic activation from the thalamus was also observed. In these two cases the axons' conduction velocity slowed down considerably between the parabrachial region and the thalamus.

Five of the neurons were labeled by iontophoresis of HRP from the recording micropipettes and subsequent diaminobenzidine-H_2O_2 histochemistry. Two of the neurons were small cells located in lamina I while 3 were small neurons located in outer lamina II.

These data suggest that some small, nociceptive specific neurons located in laminae I and II have slowly conducting axons that project contralaterally at least as far rostrally as the pontine parabrachial region. At least some of these also send axon collaterals to the contralateral thalamus.

Supported by NINCDS grants NS-16433 and NS-00534.

123.4 CONVERGENCE OF JOINT AND CUTANEOUS OR INTRAORAL AFFERENT INPUTS TO NOCICEPTIVE NEURONES IN TRIGEMINAL (V) SUBNUCLEUS CAUDALIS (MEDULLARY DORSAL HORN). J.G. Broton, J.W. Hu* and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Toronto M5G 1G6, Canada.

Recent studies in our laboratories have shown that there is extensive convergence of cutaneous, tooth pulp, visceral and muscle afferent inputs to single neurones in subnucleus caudalis of the V brainstem sensory nuclear complex. Most of the neurones showing this extensive convergence were functionally classified as cutaneous nociceptive neurones, and it was suggested that such convergent patterns may contribute to mechanisms of referred as well as deep pain. In the present study we wished to determine if neurones in caudalis also receive convergent afferent input from the temporomandibular joint (TMJ). The extracellular activity of single caudalis neurones was recorded in chloralose-anaesthetized cats. Each neurone encountered was tested to see if it could be activated by electrical stimulation of the TMJ and if it could be functionally classified on the basis of its responses to tactile and noxious orofacial stimuli as a low-tnreshold mechanoreceptive (LTM), wide dynamic range (WDR) or nociceptive-specific (NS) neurone. Electrical stimuli were also applied to facial skin and oral mucosa. For some neurones, the exposed and isolated TMJ capsule was also probed with a mechanical stimulus and algesic chemicals (7% NaCl, KCl, bradykinin, histamine; isotonic saline as control) were injected directly into the TMJ to determine if neurone activity could be evoked.

A total of 45 LTM, 7 WDR and 11 NS neurones in caudalis was tested with electrical stimulation of the TMJ; each of these neurones could be activated by electrical stimulation and tactile (LTM; WDR) or noxious (WDR; NS) stimulation of its facial or intraoral receptive field. Whereas only 8 of the 45 LTM neurones were activated by TMJ stimulation, 4 of the 7 WDR neurones and 8 of 11 NS neurones could be excited by electrical stimulation of the TMJ at latencies ranging between 4-12 msec. A comparable latency range was noted for their electrically evoked responses from cutaneous or mucosa afferent inputs. Most of the nociceptive neurones tested could also be excited by mechanical stimulation of the TMJ and by algesic chemicals injected into the TMJ.

These data indicate that many neurones in V subnucleus caudalis that receive nociceptive afferent inputs from superficial orofacial sites are also involved with transmission of joint afferent information that may also be of a nociceptive character. The findings are therefore consistent with our recent findings of convergence of other deep afferent inputs to caudalis and may explain the poor localization, spread and referral of TMJ pain. (Supported by NIH grant DE04786 to B.J.S. and DE05392 to J.G.B.).

123.5 AN ELECTROPHYSIOLOGICAL STUDY OF FELINE TRIGEMINAL SUBNUCLEUS CAUDALIS NEURONS EXCITED BY MIDDLE MENINGEAL (DURAL) ARTERY STIMULATION. Karen D. Davis* and Jonathan O. Dostrovsky. Department of Physiology, University of Toronto, Toronto, Canada M5S 1A8.

Vascular headaches, such as migraine, are thought to occur when intracranial and/or extracranial arteries dilate. The dural vasculature is known to be extremely pain sensitive and is one of the structures from which headaches are presumed to originate. Although in both anatomical and clinical studies the trigeminal nerve has been implicated in mediating these sensations no electrophysiological evidence has been presented to support this assumption. Thus a search was conducted for neurons in the trigeminal subnucleus caudalis (SNC) which could be excited by stimulation of the middle meningeal artery (MMA) which supplies the dura mater.

Experiments were performed on 7 chloralose anesthetized cats. A small unilateral craniotomy was performed to expose the major branches of the middle meningeal artery (MMA) and the ipsilateral caudal medulla was exposed by retraction of the neck muscles. Mean arterial blood pressure, expired CO_2 and rectal temperature were maintained within their physiological range throughout the experiment. Extracellular single unit recordings in SNC were made during bipolar stimulation (0.1-1.0ms single or double pulses, <15mA) of the MMA. Neurons were classified as either nociceptive specific (NS), wide dynamic range (WDR) or low threshold mechanoreceptive (LTM) according to their responses to nociceptive mechanical, thermal or nonnociceptive mechanical stimulation delivered to the facial skin and/or cornea.

Recordings were obtained for 33 SNC neurons excited by MMA stimulation of which 20 were examined in detail. Most of these cells (85%) were found to have cutaneous receptive fields in the ophthalmic skin and occasionally included the cornea. The few remaining cells (15%) had receptive fields located in the maxillary skin. With the exception of one LTM neuron, all neurons were classified as NS or WDR. The mean latency to neuronal activation from MMA stimulation was 13.3ms which suggests that small, slowly conducting myelinated fibers may be involved in mediating these responses. These results have provided evidence for the existence of neurons in SNC which can be excited by MMA stimulation and suggest that they are probably involved in vascular headache originating in the dural vasculature. These results may also provide an explanation for the phenomenon of vascular head pain which is referred to the periorbital region of the face.

123.6 ANTIDROMIC ACTIVATION OF NEURONS IN THE MEDULLARY DORSAL HORN FROM STIMULATION IN NUCLEUS SUBMEDIUS. J.O. Dostrovsky and J.G. Broton, (SPON: M. Charlton). Dept. of Physiology, Univ. of Toronto, Toronto, Canada M5S 1A8.

Craig and Burton, in a recent anatomical study (J. Neurophysiol., 45,443-466,1981), have described the existence of a specific projection from lamina I of the spinal and medullary dorsal horn (MDH) to nucleus submedius in the medial thalamus and have suggested that nucleus submedius may be a "pain center".

We have investigated this pathway using antidromic stimulation techniques in 5 chloralose anesthetized cats. A small-tipped tungsten microelectrode was stereotaxically placed in or near nucleus submedius and used to stimulate the axons of ascending neurons. A second microelectrode was placed in the MDH (trigeminal subnucleus caudalis) at or just caudal to the level of the obex to obtain extracellular recordings from single neurons. Antidromic invasion was based on constant latency, all or none responses at threshold, and ability of the action potentials to follow two stimuli at intervals of less than 3 ms. In most cases collision of antidromic and orthodromic spikes was also demonstrated.

Twenty-four neurons were recorded in the superficial region of the MDH in or close to lamina I which could be antidromically activated from the thalamic electrode by low stimulation currents (mean 37μA, range of 8 to 90μA). The mean antidromic latency was 5.1ms with a range of 2.0 to 14.5ms. All stimulation sites and some recording sites were verified histologically. For 17 of these neurons it was possible to determine the response characteristics to mechanical and thermal stimulation of the skin. Seven of them were excited by noxious pinch of the nose or whisker pad, and were similar to the lamina I nociceptive specific neurons described by others. Two neurons were excited by a vigorous tap or flick, and a third occasionally by extreme pressure to the nose and these responses although not typical were considered to be due to activation of nociceptors. One neuron was excited by both pinch and nonnoxious pressure and was classified as a wide dynamic range neuron. In addition to these nociceptive neurons, four neurons were excited by cooling and were classified as 'cold' cells, and for two neurons no orofacial mechanical or thermal receptive field could be found.

This study has confirmed using electrophysiological techniques the existence of a direct pathway from the superficial MDH to the region of nucleus submedius and has shown that most of the information transmitted in this pathway is related to noxious stimuli. However, it is not clear from the present study whether innocuous thermal information is transmitted to nucleus submedius or to a nearby region of medial thalamus. Supported by USNIDR grant 1R01 DE05404 and NIH postdoctoral fellowship to JGB.

123.7 TOOTH PULP DRIVEN NEURONS IN THE LATERAL BANK OF THE PRESYLVIAN SULCUS OF THE CAT. M.A. Biedenbach, Dept. of Physiology, Univ. of Texas Health Science Center, San Antonio, Texas 78284.

Electrical stimulation of tooth pulp is generally employed to activate neural mechanisms of nociception. In the cerebral cortex, tooth pulp driven neurons are known to occur in the primary somatosensory region and their functional properties are interpreted to indicate a role in sensory-discriminative aspects of nociception, e.g. stimulus localization, discrimination of stimulus intensity levels. Other cortical areas, although not yet identified, are thought to participate in additional aspects of nociception, e.g. affective-emotional, or pain modulating. The lateral bank of the presylvian sulcus is not part of the primary somatosensoy cortex but has a descending projection to the trigeminal nucleus.

In chloralose anesthetized cats unit potentials were recorded in the lateral bank of the presylvian sulcus while stimulating contralateral and ipsilateral canine tooth pulps. Only a small fraction of neurons in this cortex responded to the stimuli. The typical response to a tooth pulp stimulus consisted of one or a few spikes up to a short burst of spikes. On the basis of spike latency neurons divided into two main groups: an early group discharging between 12 and 30 msec. and coinciding with an early gross potential - and a later group discharging between 40-80 msec., coinciding with a second more variable gross potential. The late discharging group of neurons was the most numerous. In a given neuron, increasing the stimulus intensity from threshold to maximum resulted in a few additional spikes per response and a small decrease in latency. In some early discharging units in addition a second burst occurred during the late gross potential. However, these stimulus intensity produced response changes could be obtained alternatively by keeping stimulus intensity constant but going from a single shock to a pair of shocks. Some neurons responded only to ipsilateral, some only to contralateral and some to both tooth pulp stimuli.

Of course, more extensive studies are required to establish whether these tooth pulp driven neurons play a role in sensory-discriminative or affective aspects of nociception, or in a modulating system through the descending projection to the trigeminal nucleus. Supported by NIH grant NS 16934 and Biomed. Res. Support grant RR 07187.

123.8 RESPONSE CHARACTERISTICS OF NOCICEPTIVE NEURONS IN THE HAMSTER SUPERIOR COLLICULUS. M.A. Larson* and B.E. Stein. Dept. of Physiology and Biophysics, Medical College of Virginia, Richmond, VA 23298.

Most discussions regarding the superior colliculus (SC) center about its involvement with innocuous (usually visual) stimuli. However, investigators in the 1940's and 1950's believed it had a functional role in pain because electrical stimulation of the SC evoked pain in man and behavior indicative of pain in cats. It was not until recently that Stein and Dixon (1978) showed that some SC cells required frankly noxious stimuli for activation or for evoking the greatest number of discharges. These findings were confirmed by Rhoades, et al., (1983). The aim of the present study was to determine how these nociceptive SC cells code the intensity of graded mechanical and thermal stimuli.

Fifty-five nociceptive SC cells were studied in anesthetized hamsters. Two populations of cells were found: (a) wide dynamic range (WDR) cells (n=25) that responded to gentle mechanical, as well as, noxious mechanical stimuli (<100 mg/mm^2-noxious pinch); and, (b) nociceptive specific (NS) cells (n=30) that required higher intensity (1 g/mm^2 - 30 g/mm^2) mechanical and noxious thermal stimuli.

The stimulus-response profiles of WDR and NS neurons to graded skin temperatures closely approximated a linear function (r^2=.977) and the slopes for WDR and NS cells were not significantly different. Thermal thresholds for both groups were 42-46°C and responses increased monotonically from 44-50°C. Thermal responses of the WDR neurons were best described by a power function with an exponent of 2.3 ($f=T^{2.3}$, r^2=.988) and this is consistent with data from dorsal horn WDR neurons and the results from previous psychophysical studies using these same stimuli. NS responses were described by a power function with an exponent of 2.5 ($f=T^{2.5}$, r^2=.988) similar to, but, slightly steeper than the function describing NS neurons in the dorsal horn and with data from psychopysical studies.

These data show that the two populations of SC nociceptive neurons are not only capable of detecting and coding the graded intensities of noxious stimuli, but are remarkably similar to neurons in traditional pain related regions (e.g. dorsal horn, trigeminal n. caudalis, thalamus). It is reasonable to postulate that there is significant survival value in potentially harmful stimuli having ready access to a structure involved in alerting and orienting an animal to peripheral stimuli.

Supported by a grant from the Jeffress Foundation.

123.9 SOMESTHETIC THALAMIC UNIT RECORDINGS AFTER FORELIMB DEAFFERENTATION BY C5-T2 GANGLIONECTOMIES IN RATS. J. Ovelmen Levitt, T. Makachinas*, J. N. Young*, E. Rossitch, Jr.* and B. S. Nashold, Jr. Division of Neurosurgery, Duke University Medical Center. Durham, NC 27710

After unilateral forelimb deafferentation (C5-T2), rats exhibit a behavioral syndrome consisting of licking and biting to the point of amputation of the completely denervated portions of the limb, and, scratching in the adjacent ipsilateral partially denervated area. This phenomenon may be related to dysesthetic sensations referred to the denervated limb which in turn could be generated by abnormal central neuronal activity. Recently, Emmers (1981) has described 2-5 repetitive discharges for 500 msecs. from certain rhythm-emitting neurons in the posterolateral ventrobasal thalamus(SII) of rats after strong, noxious stimulation. This activity rhythm was found to be dependent on excitatory synaptic interconnections with neurons in the centrum medianum-parafascicular nuclear complex, and has been interpreted by Emmers as signalling a painful stimulus. We undertook to study under what conditions neuronal activity of this character was present in SI and SII thalamus after forelimb deafferentation.

Sixty-five thalamic units were recorded in 13 rats: 51 units in 10 control preparations and 14 cells in 3 animals that had 35 day C5-T2 unilateral ganglionectomies. Cells were identified in the face and forelimb area of SI and SII somesthetic thalamus. Responses to subcutaneous electrical stimulation were examined as was the character of spontaneous activity. After initial anesthesia of 90 mg/kg Ketamine, the recordings were done under light (10mg/kg/hr Ketamine) anesthesia and paralysis with Flaxedil.

In the forelimb area of the contralateral SI there was little or no spontaneous activity in either the control preparations or those that had 35 day chronic C5-T2 ganglionectomies. In SII forelimb area there was low level spontaneous activity (1-10 Hz irregular rhythm) of both controls and denervated animals.

Cells in SII were found to repond to wide and often bilateral fields. Rhythm emitting neurons were located in SII in control preparations which responded to strong contralateral face and/or forelimb stimulation. After denervation strong stimulation to the face produced a prolonged after-discharge which continued for seconds. Ipsilateral face and forelimb stimulation also produced an after-discharge.

Although we have not observed spontaneous repetitive discharges of rhythm-emitting neurons located in the forelimb area of SII, contralateral to 1 month C5-T2 ganglionectomies, there was an increased reponse in SII to strong stimulation of innervated receptive fields.

123.10 SPINOTHALAMIC TRACT CELLS IN THE DORSAL HORN OF THE CAT CERVICAL SPINAL CORD. D.G. Ferrington, L.S. Sorkin and W.D. Willis. Marine Biomedical Institute, Univ. Texas Medical Branch, Galveston, TX 77550.

Spinothalamic tract (STT) cells in the spinal cord of sub-human primates, carnivores and rodents respond to innocuous and noxious mechanical and thermal stimuli. In the cat there is little quantitative information about the coding of stimuli by STT cells in the dorsal horn. This is in contrast to the wealth of information available for STT cells in the monkey dorsal horn. In the cat, STT cells were found mostly in laminae I, V and IV of the cervical cord, while in the lumbar cord STT cells are predominantly in the ventral horn. We recorded extracellularly the activity of 56 STT cells in the cervical dorsal horn of chloralose anesthetized cats. Identification of STT cells by antidromic activation, mainly from the medial part of the posterior nucleus of the thalamus, was based on three criteria; constant latency of response; an ability to follow high frequency stimulation of the thalamus; and collision of anti- and orthodromic action potentials. Recovery of lesions or dye marks from histological sections indicated that most cells were located in the lateral two-thirds of laminae V and IV.

The cells were divided into 4 groups by their responses to innocuous and noxious levels of mechanical stimuli and manipulation of subcutaneous tissue. The groups were: low threshold (LT) - responded only to innocuous mechanical stimuli; high threshold (HT) - responded only to noxious mechanical stimuli; wide dynamic range (WDR) - responded to innocuous stimuli but with a greater response to noxious stimuli; and deep (D) - responded to manipulation of subcutaneous tissue. For 31 cells classified, the proportions in each class were 10% LT, 13% HT, 61% WDR and 16% D. Fourteen cells were tested for their response to 30 sec duration thermal stimuli in the range 43-55°C. Nine cells had thresholds $\leq$ 55°C (range 47-55; mean = 51 ± 8°C; SD) and showed a graded response to increasing stimulus intensity.

It is concluded that cat STT cells in the cervical dorsal horn respond to noxious thermal and mechanical stimuli and are capable of signalling to higher centers the intensity of a noxious thermal stimulus applied to the skin. In addition, the small receptive field sizes of these cells and their conduction velocities (range 9-76 m/s; mean = 38 ± 17 m/s; SD) suggest that the cells might play an important role in signalling the location of painful stimuli.

123.11 SOMATOSENSORY PSYCHOPHYSICAL RESPONSES OF PATIENTS WITH BURNING MOUTH SYNDROME (BMS). M. Grushka*, B.J. Sessle and T.P. Howley*. Fac. of Dentistry, University of Toronto, Toronto, Canada M5G 1G6.

BMS is a disorder primarily of post-menopausal women who experience a constant intra-oral burning sensation. Although little is known of the aetiology of this disorder, a strong neurological or psychogenic component is often inferred. We have initiated studies to determine whether there is any objective evidence of sensory dysfunction in the oral and perioral tissues of patients suffering from BMS. The study was carried out in 72 BMS patients (mean age ± S.D.: 57.5±10.6 years) in whom the most frequent site of pain was the tongue tip. We administered psychophysical tests of tactile and 2-point discrimination thresholds (by means of Semmes-Weinstein Pressure and Weinstein anaesthesiometers, respectively) on the tongue (4 sites), lower lip, anterior palate and right and left cheeks; oral stereognostic ability was also determined with the use of 20 geometric forms. In addition, a thermal stimulator (Thermal Devices Inc., Minnesota) was used to determine, in °C, thermal detection and pain thresholds, pain tolerance, and warm magnitude estimation at the tongue tip and lower lip. A group of 43 volunteers (mean age 56.2±9.6 years) served as age and sex-matched controls and the data were compared by t-tests or ANOVA.

No statistically significant ($p>0.05$) differences in mean values between BMS and control subjects were found, for any of the 8 sites tested, in tactile thresholds (range of $\log_{10}$ values, in mg: BMS, 1.04±.39 to 1.95±.46; controls, 1.03±.39 to 2.23±.49) or 2-point discrimination thresholds (range of values, in mm: BMS, 1.54±.75 to 14.00±5.62; controls, 1.45±.72 to 14.81±3.78). Mean oral stereognosis scores (BMS, 13.76±3.56; controls, 14.39±2.46), thermal detection thresholds (tongue tip: BMS, 0.73±.25; controls, 0.73±.23; lower lip: BMS, 0.76±.26; controls, 0.88±.27) and heat pain thresholds (tongue tip: BMS, 44.45±3.27; controls, 44.88±2.58; lower lip: BMS, 44.79±3.31; controls, 45.29±2.45), as well as warm magnitude estimation also were not significantly different. However, for heat pain tolerance (defined as the maximum temperature which subjects could withstand for 30 seconds) the mean value was significantly lower for BMS patients than for control subjects at the tongue tip (BMS, 46.43±2.32; controls, 48.12±1.12, $t=3.24$, $p<0.01$) but not at the lower lip (BMS, 47.32±2.44; controls, 48.27±1.60, $t=1.64$, $p>0.05$). In addition, no significant differences in heat pain tolerance were found between these two sites for each group.

These data suggest that changes do not appear to occur in tactile, stereognostic, and thermal detection and estimation capabilities of BMS patients. However, alterations may occur in peripheral or central pathways subserving some thermal pain functions, and this dysfunction may be localized to the tongue.

PEPTIDES: RECEPTORS II

124.1 MODULATION OF CENTRAL CHOLECYSTOKININ RECEPTORS BY GUANYL NUCLEOTIDES. L.P. Wennogle, H. Wysowskyj*, and B. Petrack. Neuroscience/Cardiovascular Research, CIBA-GEIGY Corp. Summit, New Jersey 07901.

The concept of endogenous modulators of neuronal activity has led to a tremendous interest in neuropeptides. A classic example of this principle is cholecystokinin (CCK) modulation over mesolimbic dopaminergic transmission in the mammalian CNS. In spite of intense interest, the mechanism by which CCK exerts an influence over neurotransmission is unknown; the connection between central CCK receptors and nucleotide regulatory proteins is poorly understood. We report here findings which clarify the link between central CCK receptors and guanyl nucleotides and indicate a possible mechanism of CCK action. Guanylyl-imidodiphosphate (GppNp) inhibited CCK binding to mouse cortical membranes in a complex fashion. CCK binding (Wennogle et al. Life Sciences 36, 1485, 1985), using a Bolton-Hunter iodinated CCK8 (^{125}I-CCK8), was reduced by micromolar GppNp, but binding plateaued at a value of 65%. Dissociation of radioiodinated ^{125}I-CCK8 was markedly increased when GppNp was included at the moment of initiation of ^{125}I-CCK8 dissociation by unlabeled CCK. Competitive interaction between GppNp and CCK could not account for the effect on dissociation and we concluded that GppNp is acting at a distinct site on the CCK-receptor complex. Scatchard analysis of ^{125}I-CCK binding in the presence and absence of GppNp revealed no change in receptor number at saturation, but a small decrease in affinity was caused by GppNp. The results are consistent with a conformational change in CCK receptors induced by guanyl nucleotides. A number of displacing ligands were tested on ^{125}I-CCK8 binding. The ratio of IC_{50} without/with GppNp was taken as a measure of the relative affinity of the displacer for the CCK receptor. By this analysis, some displacers had a GppNp ratio less than one, indicating that GppNp decreased their affinity for the receptor population. This group of compounds included CCK8, t-boc-CCK4, and caerulein; these agents are considered receptor agonists. Another group of agents, including benzotript and CBZ-CCK26-32, had GppNp ratios greater than one, indicating greater affinity in the presence of GppNp. These agents are considered receptor antagonists. The shift ratios ranged from 0.6 for agonists to 1.5 for antagonists. These observations suggest that central CCK receptors are regulated by guanyl nucleotides, perhaps indicating a dopamine modulatory mechanism.

124.2 NEUROTENSIN RECEPTORS IN THE FOREBRAIN AND MIDBRAIN OF THE PIGEON. S.E. Brauth, C.A. Kitt, A. Reiner and R. Quirion. Dept. of Psychology, Univ. of MD, College Park, MD, Dept. of Pathology, Neuropathology Lab., Johns Hopkins Univ., Balto., MD, Dept. of Anatomy & Cell Biology, Univ. of MI, Ann Arbor, MI and Douglas Hosp. Res. Centre, Verdun, Quebec, Canada.

Autoradiographic methods were used to assess the distribution of binding sites for 3-H Neurotensin (NT) in the forebrain and midbrain of the pigeon. Within the telencephalon the highest levels of NT-receptors were observed within the hyperstriatum ventrale (HV). Moderately high levels of NT-receptors were observed within the archistriatum, neostriatum intermedium and hyperstriatum accessorium. These telencephalic regions and HV are thought to be comparable to portions of mammalian neocortex. Low levels of binding sites were observed within the striatal complex including the laterally situated paleostriatum augmentatum and medially situated lobus parolfactorius. The lowest levels of NT-receptor sites in the telencephalon were observed within the paleostriatum primitivum (PP, believed comparable to mammalian globus pallidus), ectostriatum (comparable to layer IV of mammalian extrastriate visual cortex), Field "L" (comparable to layer IV of mammalian auditory cortex), hippocampus, septum and preoptic area.

Within the brainstem high levels of NT-receptors were observed in the lateral habenular nuclei, the ventral tegmental area of Tsai, nucleus tegmentipedunculopontinus, pars compacta (comparable to the mammalian substantia nigra, pars compacta), locus ceruleus and the nucleus subceruleus dorsalis. The latter four cell groups contain numerous catecholaminergic neurons. Corresponding catecholaminergic cell groups in mammalian forms also contain high levels of NT-receptors. Lower levels of NT-binding sites were observed within the following nuclei of the avian thalamus and midbrain: nucleus rotundus, nucleus triangularis, nucleus spiriformis lateralis, nucleus spiriformis medialis and nucleus ectomamillaris. Low levels of NT-receptors were also observed within the retinal terminal layers of the tectum (i.e. layers 1-7). This latter finding is consistent with immunohistochemical studies demonstrating the presence of a NT-related hexapeptide (i.e. LANT-6) within avian retinal efferents (W.D. Eldred and A. Reiner, unpub. obs.).

NT-receptors in the lateral spiriform nucleus may be a consequence of the input this cell group receives from PP. Immunohistochemical studies have shown that neurons of PP are rich in LANT-6. The tritiated NT used as ligand in the present study may have some affinity for the putative LANT-6 receptor of the avian brain. The basis for the high levels of NT-receptors in HV is uncertain. Although numerous telencephalic and thalamic cell groups which may project to HV contain abundant NT-positive neurons, the precise source of NT-containing inputs to HV is currently unknown. Supported by Grants No.BNS 8312571 (SEB) and NS 19620 (AR).

124.3 CHARACTERIZATION OF AVP EFFECTS ON B-50 PHOSPHORYLATION IN RAT HIPPOCAMPAL SYNAPTIC MEMBRANES. A. Hinko* and A.F. Pearlmutter* (SPON: T.H. Chiu). Department of Biochemistry, Medical College of Ohio, Toledo, OH 43699.

Our laboratory has reported previously the characteristics of specific AVP binding in the presence of Ni^{2+} to rat hippocampal synaptic plasma membranes (SPM) (Costantini, M.G. and Pearlmutter, A.F., J. Biol. Chem. 259: 11739, 1984). We have extended our investigation to determine if Ni^{2+}, AVP, and AVP analogs affect membrane protein phosphorylation in hippocampal SPM. Hippocampi were excised from anesthetized male Sprague-Dawley rats (100-150 g) and homogenized in 10 vol 0.32 M sucrose containing protease inhibitors. SPM preparation was done at 0-4°C. A crude mitochrondrial/synaptosomal pellet was prepared and resuspended in H_2O to cause synaptosomal lysis. The lysate was centrifuged and the supernatant layered onto a discontinuous gradient of 0.4 M and 1.0 M sucrose. After ultracentrifugation, the SPM material floating on the interface between the sucrose layers was collected and used for phosphorylation studies. Phosphorylation conditions were: 15-25 µg SPM, 10 mM Mg^{2+}, 0.1 mM Ca^{2+}, ± 5 mM Ni^{2+}, 20 mM tris, pH 7.4. After 5 min preincubation at 30°C, 5 µM ATP with 2 µCi [γ-^{32}P] ATP was added. Reactions were stopped 20 sec later with a solubilization solution. Peptides were added 30 sec prior to ATP. Proteins were separated by SDS-PAGE and analyzed by autoradiography or liquid scintillation counting of the bands. Ni^{2+} caused a reduction in overall SPM protein phosphorylation, but Ni^{2+} did not alter the changes in phosphorylation caused by the peptides. The peptides (10^{-4} - 10^{-3} M) reduced phosphorylation of a presynaptic phosphoprotein (B-50) in the following order of potency: AVP = oxytocin > desglycinamide AVP > deamino-8-D-arginine-AVP > $d(CH_2)_5$Tyr(Me)AVP = [pGlu^4,Cyt^6]AVP-(4-9). This generally corresponds to their relative efficacy in displacing [^{3}H]AVP from high affinity SPM binding sites. However, when 10^{-6} - 10^{-4} M AVP was added after maximum ^{32}P incorporation (30 sec after ATP addition), AVP markedly inhibited B-50 dephosphorylation over a 30 min period. In conclusion, AVP can affect both phophorylation and dephosphorylation of B-50 in hippocampal SPM; these effects depend upon incubation conditions. The physiological importance of these in vitro effects of AVP on SPM phosphorylation remains to be examined. This research was sponsored by NIH grant, NS 17848.

124.4 **CHARACTERIZATION OF BRADYKININ ANTAGONISTS IN A CULTURED NEURONAL CELL LINE.** **K. M. Braas[1], D. C. Manning[1], V. S. Wilson[*2], D. C. Perry[3], J. M. Stewart[3], R. J. Vavrek[*3], and S. H. Snyder[1]. [1]Dept. of Neuroscience, Johns Hopkins Univ. Medical School Baltimore, MD 21205, [2]Dept. of Pharmacology, George Washington Univ. Medical School Washington D.C. 20037, [3]Dept. of Biochemistry, Univ. of Colorado Medical School Denver CO 80262.**

The nonapeptide bradykinin (Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg) is present in a variety of tissues and appears to be involved in inflammation, pain and cardiovascular regulation. Bradykinin nonapeptide (Perry and Snyder, J. Neurochem. 43:1072, 1984) and immunohistochemically visualized bradykinin (Correa et al, Proc. Natl. Acad. Sci. 76:1489, 1979) occurs in neurons in brain. Until recently, specific sequence-related antagonists of bradykinin activities have not been available. Substitution of the proline in position 7 with D-phenylalanine (D-Phe) has been shown to convert bradykinin agonists to specific antagonists (Stewart and Vavrek, In: Kinins 1984, Greenbaum, L.M. ed., Plenum Press, NY, 1985). The antagonism is specific for bradykinin agonists in the rat uterus and guinea pig ileum smooth muscle assays and in the rat blood pressure kinin assay. Potency is enhanced when the phenylalanines at positions 5 and 8 are replaced with β-(2-thienyl)-L-alanine (Thi). To ascertain if these antagonists act at bradykinin receptors in neuronal cells, we have employed the cultured neuronal cell line NG108-15 which has many properties of normal differentiated neurons. NG108-15 cells plated at an initial density of 4000 cells/cm² were cultured with Dulbecco's modified Eagle medium supplemented with 10% newborn calf serum and HAT for 7 days. Binding of [³H]-bradykinin to NG108-15 cell membranes was assayed at 25°C in 25 mM Tes, pH 6.8, containing 1 mM 1,10-phenanthroline, 0.1 mM bacitracin, 1 mM dithiothreitol and 0.1% BSA for 90 min. Bound [³H]-bradykinin was separated from free by filtration over GF/B filters pretreated with 0.1% polyethyleneimine. Binding of [³H]-bradykinin was saturable, specific and of high affinity (Kd, ~50 pM), which is similar to that observed in previous studies for the N1E-115 cell line and guinea pig ileum. Competition experiments were performed using [³H]-bradykinin (50 pM) and unlabeled agonist or antagonist peptides. [³H]-bradykinin binding sites in NG108-15 cells displayed Ki values of 90 pM for bradykinin, 300 pM for [Thi⁵,⁸]-bradykinin and 10-15 nM for the antagonists [D-Phe⁷]-bradykinin and [Thi⁵,⁸,D-Phe⁷]-bradykinin. Substitution of hydroxyproline in position 3 or addition of Lys-Lys to the N-terminal does not decrease the potency of the [Thi⁵,⁸,D-Phe⁷] antagonist. Potencies of other antagonists with additional amino acid modifications and substitutions are currently being evaluated. The ability of these antagonists to inhibit bradykinin receptor-mediated cGMP formation and accumulation of [³H]-inositol phosphates in NG108-15 cells under investigation.

124.5 EVIDENCE FOR SPECIFIC NEUROPEPTIDE Y BINDING SITES IN RAT BRAIN MEMBRANES USING [^{3}H]NEUROPEPTIDE Y. J.C. Martel*, R. Quirion and S. St-Pierre* (SPON: E. Ramon-Moliner). Douglas Hospital Research Centre, Verdun, Quebec H4H 1R3 Canada and F,culté de Médecine, Université de Sherbrooke (Quebec) J1H 5N4 Canada.

Neuropeptide Y (NPY), a 36 amino acid member of the pancreatic polypeptide family, has been found to be widely distributed in mammalian brain with particularly high concentrations in hypothalamus and olfactory tubercle (P.C. Emson and M.E. DeQuidt, TINS, 7:31-34, 1984). Although NPY is thought to act as a neurotransmitter, little is known on the distribution of its receptors in brain. Earlier report on NPY binding in rat brain membranes (with radioiodinated NPY) have demonstrated the presence of specific binding sites for that peptide in the central nervous system (A. Saria et al., Eur. J. Pharm., 107:105-106, 1985). Here we report on the existence of NPY binding sites in rat brain using a tritiated ligand.

Rats were killed by a blow on the neck and decapitated. Brains were rapidly removed and put in ice cold Krebs-Ringer buffer. Brains (minus cerebellum) were homogenized using a Brinkmann polytron at setting 5 for 15 seconds and centrifuged for 15 minutes at 39,000 g. Pellets were rinsed with ice cold Krebs-Ringer, resuspended and centrifuged for another 15 minutes at 39,000 g. Final pellets were rinsed and resuspended in ice cold Krebs-Ringer (4.5 ml per brain). 100 µl of this membrane preparation were incubated for 60 minutes at room temperature in 400 µl of Krebs-Ringer buffer plus 0.1% BSA, 0.05% bacitracin and 2.0 nM [^{3}H]NPY (70 Ci/mmol, Amersham). Incubations were terminated by rapid filtration under reduced pressure through GF/C filters pretreated with 1.0% polyethyleneimine (PEI). Specific binding was defined as the radioactivity bound in presence or absence of 1.0 µM NPY. Under these conditions, specific binding ranged between 70-80%. This high specific binding is probably due to the pretreatment of filters with PEI and the extensive washing of filters with ice cold Krebs-Ringer. Non radioactive NPY displaced [^{3}H]NPY binding with a IC_{50} of 4.3 nM while human pancreatic polypeptide displaced [^{3}H]NPY with an IC_{50} of 900 nM. These data indicate that [^{3}H]NPY is a useful, newly available, ligand to study NPY receptor binding sites in the central nervous system.

124.6 VIP(10-28) IS AN ANTAGONIST OF VIP ADENYLATE CYCLASE STIMULATION* IN HT29 CELLS. J.T. Turner, C.J. Ray-Prenger and D.B. Bylund. Dept of Pharmacology, Univ. of Missouri Sch. of Med., Columbia, MO 65212.

One major limitation in studying many of the neuropeptides has been the lack of specific antagonists. In the HT29 human colonic adenocarcinoma cell line, the neurotransmitter vasoactive intestinal peptide (VIP) binds to specific receptors, increases adenylate cyclase activity and stimulates glycogenolysis (Rousset, et al., FEBS Letts 126:38, 1981). During our characterization of the HT29 VIP receptor-cyclase system, we observed that the 19 residue carboxy terminal fragment of VIP, VIP(10-28), inhibited ^{125}I-VIP binding in both intact cells and in membranes and also inhibited VIP-stimulated, but not basal or forskolin-stimulated, adenylate cyclase activity. In a representative experiment, the addition of 3 µM VIP(10-28) produced a 5 fold increase (2 nM-10 nM) of the ED_{50} for VIP stimulation of the enzyme without changing the efficacy of VIP, consistent with competitive antagonism. Two peptides structurally related to VIP, PHI-27 and PHM-27, also stimulated HT29 adenylate cyclase and the antagonism of the effects of these peptides by VIP(10-28) was also studied. A dissociation constant for VIP(10-28) from Schild plots with each agonist was determined. Although the potency of VIP(10-28) is low, the proteolytic cleavage of an endogenous agonist to yield a specific antagonist suggests an intriguing possible in vivo regulatory mechanism. This work was supported in part by a grant from the American Heart Association, Missouri Affiliate.

124.7 TACHYKININ RECEPTORS IN MAMMALS. J. E. Maggio[1], C. R. Mantyh and P. W. Mantyh[2], [1]Harvard Med. Sch. Dept. of Pharmacology, Boston, MA 02115 and [2]Center for Ulcer Res. and Educ., VA Wadsworth Center, Los Angeles, CA 90073.

Substance P (SP) is the best known member of the tachykinin family of bioactive peptides, which share the conserved carboxyl-terminal sequence -Phe-X-Gly-Leu-Met-NH_2. SP was once thought to be the only tachykinin in mammals, but in 1983 four groups independently reported that mammalian tissues also contain two additional tachykinins, substance K (SK) and neuromedin K (NMK), so named to reflect their homology with the amphibian tachykinin kassinin. The mammalian techykinins differ in their central and peripheral pharmacologies, suggesting that they may mediate different physiological functions through different receptors. Using ^{125}I-labelled Bolton-Hunter conjugates of tachykinins as radioligands, we have studied tachykinin receptors in the rodent CNS and periphery using homogenate binding and autoradiography.

The radioligands (BHSP, BHSK, BHNMK, etc.) were synthesized by conventional methods and purified to >2000 Ci/mmol by reverse-phase HPLC. The same ligands were used for both homogenate binding and autoradiography at 0.1 nM concentration in 0.05 M TrisHCl pH=7.5 containing 0.02% BSA, 40 mg/l bacitracin, 4 mg/l leupeptin, 5 mg/l chymostatin and 3 mM $MnCl_2$. Both binding and autoradiography experiments were worked up by extensive washings after 1-2 hr incubations with ligand. In test-tube binding experiments BHSP, BHSK, BHNMK were most effectively displaced ($IC_{50} < 10^{-8}$ M) by SP, SK, NMK, respectively, suggesting that each mammalian tachykinin has a distinct set of binding sites. Autoradiographic studies supported this conclusion and further revealed that each of the tachykinin binding sites has a distinct regional distribution. Striking geographical differences were noted in the cerebral cortex, amygdala, hippocampus, hypothalamus and olfactory bulb.

In addition, studies with Bolton-Hunter conjugates of the nonmammalian tachykinins kassinin (BHK) and eledoisin (BHE) suggested further subclassification of mammalian tachykinin receptors. Thus BHK appears to label a particular subset of SK receptors while BHE labels a particular subset of NMK receptors in rat brain. The mammalian tachykinin system is apparently more complex than previously supposed.

In summary, these studies demonstrate that each of the three known mammalian tachykinins has a distinct set of binding sites with a distinct regional distribution in the CNS and periphery. These presumptive receptors can be further subclassified on the basis of their ligand binding properties.

124.8 ELECTRON MICROSCOPIC VISUALIZATION OF NEUROTENSIN BINDING SITES IN RAT SUBSTANTIA NIGRA. E. Moyse*, M. Vial*, K. Leonard*, P. Kitabgi*, J.P. Vincent*, W. Rostène and A. Beaudet. (SPON: B.E. Jones). Montreal Neurol. Inst., 3801 University St., Montreal, Canada H3A 2B4; INSERM U-55, 84 rue du Fbg. St. Antoine, 75012 Paris, France; C.N.R.S., Fac. Sci., Parc Valrose, 06034 Nice, France.

Specific binding sites for neurotensin (NT) were localized in rat brain by high resolution radioautography using Tyr^3-monoiodinated NT (spec. act: 2000 Ci/mmole). The effects of histological processing on the binding and retention of ^{125}I-NT were first assessed on 20 µm-thick cryostat sections of the midbrain incubated for 1 h at 4°C. Binding of ^{125}I-NT to unfixed tissue sections was highly specific (> 90% of total) with a K_D of 7.7 nM and a B_{max} of 76 fmol/mg prot. These binding kinetics remained unchanged following pre-fixation of the brain with .75% paraformaldehyde, .1% glutaraldehyde and 1% tannic acid. The radioautographic distribution of ^{125}I-NT binding sites was similar in unfixed and pre-fixed sections, and conformed with that previously observed using ^{3}H-NT, with high labeling densities in the substantia nigra and ventral tegmental area. Post-fixation of the labeled sections with 4% glutaraldehyde followed or not by 2% OsO_4 ensured regionally proportional retention of more than 70% of the specifically bound ligand during subsequent dehydration, suggesting that the majority of bound ^{125}I-NT molecules had been cross-linked by glutaraldehyde onto or in the vicinity of their specific binding sites. For high resolution radioautographic visualization of these sites, 75 µm-thick pre-fixed vibratome slices from the ventral midbrain tegmentum were incubated with .3 nM ^{125}I-NT, rinsed in ice cold buffer, post-fixed as above, dehydrated in ethanols and flat embedded in epon. Semi-thin and thin sections were cut from each slice and respectively processed for light and electron microscopic radioautography according to standard dipping techniques. Light microscopic radioautographs exhibited an overall labeling pattern similar to that observed in cryostat sections. Within the substantia nigra, the label was diffusely distributed over the neuropil and selectively accumulated along the plasma membrane of the perikaryon and proximal dendrites of a sub-population of pars compacta neurons. There was also a conspicuous labeling of the capillary endothelium but this labeling, unlike the rest, was displaced neither by native NT nor by one of its natural metabolites (NT 1-8), even at concentrations of 100 µm. In electron microscopic radioautographs, bound ^{125}I-NT molecules were mostly detected as isolated silver grains overlying more than one cellular profile. A significant number of these grains appeared to be associated with neuronal, particularly axodendritic, membrane interfaces. Only a few, however, could be ascribed to synaptic junctions by resolution circle analysis. The present results demonstrate the applicability of ^{125}I-Tyr^3-NT to high resolution radioautographic detection of NT binding sites in rat brain and suggests that in the substantia nigra: (1) part of these binding sites is localized on the perikaryon and dendrites of a sub-population of pars compacta neurons and (2) only a small proportion is actually associated with synaptic junctions.

124.9 AUTORADIOGRAPHIC LOCALIZATION OF CALCITONIN GENE RELATED PEPTIDE BINDING SITES IN THE RAT BRAIN, GUINEA PIG PERIPHERY AND HUMAN SPINAL CORD. P.W. Mantyh, C.R. Mantyh*, N.C. Brecha, L. Kruger, and C. Sternini. Center for Ulcer Research and Education, Bldg. 115, Room 219, LA, CA, 90073 and Brain Research Institute, UCLA, LA, CA, 90024

Calcitonin Gene Related Peptide (CGRP) is widely distributed throughout the CNS and periphery and has been shown to possess potent in vivo actions when administered either centrally or peripherally.

Here we have used autoradiographic techniques to localize and quantify specific high affinity binding sites for human ^{125}I-CGRP (Amersham) in the rat brain, guinea pig periphery and human spinal cord. Rat and guinea pig tissue was removed immediately after death and the human tissue was obtained less than 10 hours postmortem. Serial tissue sections (30um) were obtained and preincubated in a solution of 50 mM Tris HCl (pH 7.4), 2% BSA, .05% bacitracin, and 5 mM $MgCl_2$ (10 min, 20°C). Sections were transferred to the same solution with 100pM ^{125}I-CGRP added (60 min, 20°C) and subsequently washed in 50mM Tris-HCl (4 times, 1 min each, 4°C). The slides were dried and exposed for 5 days against LKB Ultrofilm to generate autoradiograms. Autoradiograms were analyzed using densitometry. Specific binding was defined as that binding that was displaced by 1 uM human CGRP but not by unrelated peptides. Initial experiments determined that these incubation conditions resulted in the highest specific/non-specific binding ratios.

Autoradiograms revealed that in the rat CNS high concentrations of CGRP binding sites are present in the lateral septum, entorhinal cortex, lateral nucleus of the amygdala, solitary nucleus, dorsal motor nucleus of the vagus and the pars caudalis of the spinal trigeminal nucleus. In the guinea pig periphery high concentrations of CGRP binding sites are present in the epithelium of the lung, the collecting tubules of the kidney, the longitudinal smooth muscle of the duodenum, ileum, and colon and the smooth muscle of the vas deferens. In the human spinal cord high concentrations of CGRP binding sites are present in lamina 1,2,and 5-9. Our results indicate that CGRP binding sites in the rat, guinea pig and human can be labeled with high specific/non-specific binding ratios using human ^{125}I-CGRP as the radioligand and that if these specific binding sites do correspond to functional CGRP receptors it appears that CGRP modulates a diverse set of cells in both the CNS and the periphery. Supported by NS-5685, AM-17328, a Smith Kline and Beckman Award to to P.W.M., and Sloan Fellowships to P.W.M. and N.C.B.

124.10 CHARACTERIZATION OF INSULIN RECEPTORS IN THE CHOROID PLEXUS OF THE RAT BRAIN BY QUANTITATIVE AUTORADIOGRAPHY AND COMPUTER DENSITOMETRY D.A. Davidson*, E.S. Corp*, D. Figlewicz*, S.C. Woods, D. Porte Jr.*, D.M. Dorsa, D.G. Baskin, Depts. Medicine, Pharmacology, Psychology, and Biological Structure, Univ. of Washington, and VA Medical Center, Seattle, WA 98108.

We recently reported the presence of specific binding for insulin in the choroid plexus (CP) of the rat brain with in vitro autoradiography. We sought to determine if these binding sites exhibited pharmacological properties similar to those of peripheral insulin receptors. Therefore, we exposed lateral ventricle choroid plexus to [125-I]-human insulin (0.05 nM; SA = 300 µCi/µg for 18 hours at 4°C) using frozen sections of rat brain. Specific binding was defined as radioactivity displaced by 10 µM unlabeled porcine insulin. Techniques of in vitro receptor autoradiography and computerized densitometry on the resulting LKB film images were used to obtain measurements of insulin binding properties. Iodoinsulin binding was determined by a standard curve relating optical density to CPM/sq. mm. radioactivity in the tissue slice. Insulin binding to the choroid plexus showed time and temperature dependency, saturability and reversibility. Competition with [125-I] insulin for insulin specific binding sites was observed with the addition of increasing concentrations of unlabeled porcine insulin. No competition for insulin binding sites was observed with the addition of 1µM ribonuclease or glucagon. To establish specificity, competitions with insulin analogs were performed. The equimolar ratios of the IC-50 values for competition with human iodoinsulin to binding sites on the CP were: chicken insulin = 0.5; porcine insulin = 1; proinsulin = 3.75; tuna insulin = 11; desoctapeptide insulin = 95; IFG-1 = 667. The relative order of binding affinities of the various insulin analogs was similar to that of insulin receptors in peripheral tissues. Scatchard analysis revealed that the data could be fit using a two binding site model (N = 3 rats). The Kd (mean ± SD) of the high and low affinity binding sites were 2.0 nM ± 1.0 nM and 170.0 nM ± 60.0 nM, respectively. To determine the microanatomical localization of these receptors, intact choroid plexus was removed from the lateral and fourth ventricles and incubated with [125-I] insulin as described above. After embedding in methacrylate, sections of choroid plexus were prepared for autoradiography with NTB2 emulsion. Results showed most autoradiographic grains were on the CSF surface of the choroidal epithelial cells. There was a marked reduction of grains on both surfaces with the addition of 1 µM unlabeled porcine insulin. These findings support the conclusion that binding sites with characteristics of insulin receptors are present in the choroid plexus. This raises the new hypothesis that CP insulin receptors are involved in choroid plexus function and regulation of CSF composition.

124.11 CHARACTERIZATION OF ^{3}H-VASOPRESSIN BINDING SITES IN THE DEVELOPING RAT BRAIN BY QUANTITATIVE AUTORADIOGRAPHY. F. Petracca*, D. Baskin, J. Diaz, and D. Dorsa (SPON: D. Dorsa). GRECC, VA Medical Center, and Depts. of Pharmacology, Psychology, Biological Structure and Medicine, Univ. of Washington, Seattle, WA 98195

We have recently reported binding of ^{3}H-Arginine^{8}-vasopressin (AVP) in several regions of the developing rat brain (Soc. Neurosci. Abstr., Vol 10, Part 2, p. 1042, 1984), including the caudate nucleus, septum, dorsal hippocampus, cingulate gyrus, and amygdala. We observed that the pattern of distribution of the sites changes dramatically over the course of the early postnatal period, suggesting that vasopressin may play a role in brain development. In the present study, we examined the specificity and saturability of the ^{3}H-AVP binding sites which we have observed in the developing rat brain, to determine whether they are specific vasopressin receptors.

To determine saturability, Day 10 Long-Evans rat pups were sacrificed, and 20-micron, slide-mounted brain sections were incubated for 30 minutes in Tris buffer solution containing ^{3}H-AVP (concentrations ranging from .25 nM to 10 nM) in the presence or absence of 1 μM unlabeled AVP. For specificity studies, Day 6 brains were incubated in buffer solution containing 2.5 nM ^{3}H-AVP in the absence or presence of a 1 μM concentration of one of the following unlabeled peptides: AVP, oxytocin, or luteinizing hormone releasing hormone (LHRH). Slides were placed in contact with LKB Ultrofilm for 30-50 days. Concentrations of bound AVP were determined by computer densitometry, using a standard curve relating optical density to fmol ^{3}H-AVP/mm^{2} established using tissue containing known quantities of tritium.

In the cingulate gyrus, specific binding of ^{3}H-AVP increased to 45% of total at 2.5 nM and did not further increase over the range of ligand concentrations tested. In the septum, when exposed to 2.5 nM ^{3}H-AVP, we observed total binding (TB) of 0.15 fmol/mm^{2}, 53% of which (0.07 fmol/mm^{2}) was specific binding as defined using 1 μM unlabeled AVP. In the cingulate gyrus, TB was 0.18 fmol/mm^{2}, and specific binding was 0.10 fmol/mm^{2}, (55%). Specific binding of ^{3}H-AVP was also equally displaced in these areas when the tissues were incubated in the presence of 1 μM oxytocin but was not reduced by LHRH, a peptide of similar size but which is structurally unrelated to AVP. Results of the present study indicate that the ^{3}H-AVP binding which we have observed in the neonatal Long-Evans rat is saturable and demonstrates specificity for neurohypophyseal peptides. Whether this site is a specific receptor for AVP will require further specificity studies using similar methodologies.

This work was supported by NIH Grant NS 20311.

124.12 PHARMACOLOGIC CHARACTERIZATION OF VASOPRESSIN RECEPTORS IN THE BRAIN, LIVER AND KIDNEY OF THE BRATTLEBORO RAT. L. Shewey*, L.E. Cornett*, and D.M. Dorsa (SPON: C. Chavkin) GRECC, VA Medical Center and Depts. of Pharmacology and Medicine, Univ of Washington, Seattle, WA 98195 and UAMS, Little Rock, AR 72205

Recently, specific binding sites for ^{3}H-Arginine^{8}-vasopressin (AVP) have been localized and characterized in several tissues of the rat. In the homozygous Brattleboro rat (HO-BB), a recessive trait leads to a near complete inability to synthesize AVP in the brain, which results in diabetes insipidus (DI). HO-BB rats show several other behavioral and physiological deficiencies, which can be reversed by treatment with AVP suggesting that they do have functional receptors for this peptide. The present studies were performed to determine the effect of AVP absence on the pharmacological characteristics of the AVP receptors of the CNS and periphery in the Brattleboro rat.

For this study, age matched adult male heterozygous (HE-BB) and homozygous (HO-BB) rats were sacrificed, and liver, brain and kidney tissue removed and dissected. Membranes were prepared from pooled tissue, stored at -70°C and thawed for use. HE and HO-BB rat membranes were incubated in the same assay for 45 minutes at 22°C with ^{3}H-AVP (S.A. = 40 Ci/mmol) with or without 1 μM cold AVP.

The results of saturation experiments (using ^{3}H-AVP in concentrations from 0.25 nM-10 nM) yielded a single-site best fit as determined by a computerized Scatchard analysis, and are summarized in the following table: K_d (nM), B_{max} (fmol/mg protein).

		Liver	Renal Medulla	Hind-brain	Hippo-campus	Amygdala	Septum
		n=3	n=4	n=4	n=4	n=3	n=3
K_D	HE	4.8±.1	4.8±0.09	2.3±0.7	1.9±0.4	1.9±0.4	1.9±0.7
	HO	3.9±.32*	3.0±0.2*	3.3±0.7*	3.8±0.4**	2.8±0.2	3.2±0.7
B_{max}	HE	123±72	83±22	10±2.1	10±0.3	10.3±2.8	8.4±4
	HO	151±67*	145±48*	22±10*	16±3.0*	17.8±10.6	18.2±7*

Results shown are means ± standard deviation
* = p<.05 ** = p<.01

These data indicate that vasopressin receptors are present in greater numbers in the tissues studied of the HO-BB rat. This may be due to "up-regulation" in the absence of endogenous AVP. In addition, AVP receptor affinity may be altered in the Brattleboro rat. These changes in pharmacologic properties of AVP receptors could dramatically influence the physiologic and behavioral sensitivity of these animals to exogenously administered AVP.

124.13 SOMATOSTATIN BINDING SITES ARE DECREASED IN RAT FRONTAL CORTEX AFTER LESION OF THE ASCENDING CHOLINERGIC FIBERS FROM THE NUCLEUS BASALIS MAGNOCELLULARIS. J. Epelbaum, A. Enjalbert, M. Hamon, C. Kordon and Y. Lamour. INSERM U. 159, U. 161 and U. 114, Paris, France.

Evidence has accumulated that Alzheimer's disease, senile dementia of the Alzheimer's type and Parkinson's associated dementia are linked to relatively selective reductions in cholinergic and somatostatinergic parameters in the cerebral cortex and hippocampus. In this work we attempted to define more precisely the possible relationship between ascending cholinergic neurons from the basal forebrain and the intrinsic somatostatinergic neurons in cerebral cortex.

In a first set of experiments we compared the regional distributions of cholineacetyl transferase (ChAT) activity, somatostatin (SRIF) levels and 125I CGP23996 (a non reductible somatostatin analog) binding sites in 10 different cortical regions and hippocampus of the rat brain. There was a significant correlation (r = 0.72) between cortical ChAT activity and SRIF levels. However, no significant correlation was observed between SRIF levels or ChAT activity and 125I CGP23996 binding.

In a second set of experiments, the nucleus basalis magnocellularis (NBM) was lesioned by local ibotenic acid injections (10 ug in 0.8 ul). This resulted in a 40 % decrease in ChAT activity in the frontal and parietal cortices. SRIF levels were unchanged in the lesioned animals while 125I CGP23996 binding was also diminished in the frontal cortex (12.6 + 3.0 fmol/mg protein vs 89.4 + 33.2 fmol/mg protein in the control group means + sem n = 7). Examination of individual animals revealed a positive correlation (r = 0.76) between the decrement of ChAT activity and that of 125I CGP23996 binding in the frontal cortex.

These results suggest that 1) the regional distribution of cholinergic and somatostatinergic neurons (and/or terminals) are closely related in the rat cerebral cortex. 2) SRIF binding sites in the frontal cortex may be located on cholinergic terminals.

124.14 GUANINE NUCLEOTIDE INHIBITION OF BOMBESIN RECEPTOR BINDING. J.B. Fischer and A. Schonbrunn*. Laboratory of Toxicology, Harvard School of Public Health, Boston, MA 02115.

Amphibian bombesin (BBS) and its mammalian analog gastrin-releasing peptide (GRP) are part of a family of "brain-gut" peptides showing structural homology at their carboxy termini. Specific, saturable binding sites for this family of peptides have been defined in neural, exocrine and other tissues. Peripheral injection of BBS or GRP causes increased release of several hormones, including insulin, prolactin and growth hormone. This laboratory has characterized functional BBS receptors which mediate BBS stimulation of hormone secretion in two clonal cell lines, the HIT insulin-secreting pancreatic islet cell line (P.N.A.S. 81:1822, 1984), and the GH_4C_1 pituitary tumor cell strain, which secretes prolactin and growth hormone (ENDO. 110:352, 1982; J. BIOL. CHEM. 258:7527, 1983). To further study the biochemical mechanisms involved in the action of BBS we have studied the binding of [^{125}I-Tyr^{4}]BBS and [^{125}I]GRP_{14-27} in membranes prepared from these cells. The binding of both ligands was measured as described for [^{125}I-Tyr^{1}]somatostatin (ENDO. 114:1784, 1984). Membranes (10-30 μg of protein) were incubated at 37°C to equilibrium (60 min), then collected by centrifugation. BBS displaced both radiolabeled ligands with an IC_{50} of about 0.06 nM. Guanine nucleotides were found to inhibit the equilibrium binding of both ligands to membranes whereas App(NH)p had no effect. In GH_4C_1 membranes maximal inhibition was 70-90% whereas in HIT membranes maximal inhibition was only 30-50%. However the IC_{50} values for various GTP analogs were essentially the same in the two membranes types: $GTP\gamma S$, 0.1 μM; Gpp(NH)p, 0.2 μM; GDPβS, 3 μM; GTP, 0.1 μM; GDP, 2 μM; GMP, >100 μM. To learn more about the guanine nucleotide regulatory site which was coupled to the BBS receptor we prepared membranes from cells treated with maximal doses of cholera toxin or Bordatella pertussis toxin (islet-activating-protein). These toxins are known to ADP-ribosylate nucleotide regulatory proteins associated with adenylate cyclase-coupled receptors, and to affect guanine nucleotide regulation of agonist binding to such receptors. Toxin treatment did not affect the affinity or number of binding sites for [^{125}I]BBS or [^{125}I]GRP, or alter the Gpp(NH)p inhibiton of peptide binding. Furthermore, BBS had no effect on adenylate cyclase activity in these cells. Therefore the nucleotide regulatory site associated with the BBS receptor in both pituitary and pancreatic cells is different from those linked to adenylate cyclase-coupled receptors.

124.15 AGE-RELATED CHANGES OF VASOPRESSIN RECEPTORS IN THE RAT. M.A. Miller* and D.M. Dorsa (SPON: R. Steiner) GRECC, VA Medical Center and Depts. of Medicine and Pharmacology, Univ. of Washington, Seattle, WA 98195.

Recent reports have indicated that cellular responsiveness to exogenous arginine^8-vasopressin (AVP) declines with age in the rat. This decline has been attributed by some to a desensitization phenomenon induced by chronic AVP hypersecretion by the hypothalamo-neurohypophyseal system in aged animals. Others, however, have failed to confirm an elevation of basal AVP levels with aging in the rat and have suggested instead a diminished capacity to secrete AVP. We reasoned that changes of vasopressin responsiveness of tissues may result from age-related changes in vasopressin receptors themselves. We have, therefore, compared AVP receptor affinity and number in membranes prepared from the liver (V_1 type receptors) and kidney (V_2 type receptors) of young (3 mo) and old (24 mo) male rats and assessed plasma AVP levels in the two groups. Young (n=10) and old (n=7) Fischer 344 rats (supplied by the NIA Aging animal program) were killed by decapitation and trunk blood was collected for RIA. Liver and kidney tissue was pooled for each group and crude membrane fractions were prepared, frozen, and stored at -70°C. Saturation analysis was performed using ^{3}H-AVP (S.A. = 40 Ci/mm) over a concentration range of 0.25nM-10nM. Specific binding was defined by addition of a thousand-fold excess of unlabeled AVP. Binding site parameters were obtained by Scatchard-Rosenthal analysis.

Results of the RIA showed that the post-decapitation levels of AVP in old rats ($\bar{x}$ ± SE: 3.9±1.1 pg/ml, n=7) did not differ significantly from young animals (3.0±0.8 pg/ml, n=9). In addition, we found no significant difference in the K_d values measured for AVP receptors in either the liver (young: 0.74±0.08nM, n=3; old: 0.75±0.05 nM, n=4) or kidney (young: 1.92±0.19 nM, n=5; old: 1.99±0.23 nM, n=5) with aging. However, the number of AVP receptors in the liver of old rats (151±9.5 fm/mg protein, n=4) was significantly reduced ($p<0.01$) below that observed in young rats (271±22 fm/mg protein, n=3). While there was a tendency for AVP receptor numbers to be reduced in kidney tissue of old rats as well (old: 96±17.4 fm/mg protein, n=5; young: 138±36 fm/mg protein, n=4), this reduction was not significant. In summary, we found reduced numbers of vasopressin receptors in peripheral tissues of aged rats even though circulating vasopressin levels were similar to young animals. This suggests that diminished binding of vasopressin in aging may explain reduced vasopressin responsiveness. In additon, the lower receptor number may be due to factors other than receptor "down-regulation" in aged animals.

124.16 THYROTROPIN RELEASING HORMONE BINDING SITES IN ADULT HUMAN SPINAL CORD. M. Gudesblatt and K.H. Sonnenfeld (SPON: Gerald Cohen). Department of Neurology, Mt. Sinai Sch. of Med., New York, NY 10029.

Thyrotropin releasing hormone (TRH) has been found to be widely distributed, but discretely localized throughout the central nervous system (CNS). TRH has an excitatory action on spinal motor neurons and has multiple and sometimes conflicting electrophysiological actions on cortical neurons. Specific high affinity (K_d=2 nM) and low capacity binding sites have been demonstrated in the adult human brain (Parker, C.R., and A. Capdevila, Peptides 5:701-706, 1984). In addition, high affinity TRH binding sites have been localized by radioautography to Laminae II and IX of adult human spinal cord (Manaker, S., et al., Neurology 35:328-332, 1985). This study was undertaken to investigate the characteristics of TRH receptors in adult human spinal cord.

Post-mortem segments of adult human spinal cord were rapidly removed, frozen, and stored at -70°C. Tissue in ice cold sodium phosphate buffer (20 mM, pH 7.4) containing Bacitracin (50 µg/ml) was homogenized using a Brinkman Polytron PT 10 (one, 15 sec pulse). Following centrifugation (30,000g, 15 min) and washing, twice, the pellet was resuspended in fresh buffer (100 mg wet weight/400 ml buffer) using a Dounce tissue homogenizer. Binding was measured by incubating the homogenate at 0°C for 4 hours with ^{3}H-(3-Me-His^2)TRH. The ^{3}H-(3-Me-His^2)TRH bound to tissue was separated from free ligand by rapid filtration through Whatman GF/B filters followed by three washes with 3 ml of cold buffer. Nonspecific binding was determined by measuring in parallel incubations the amount of ^{3}H-(3-Me-His^2)TRH bound in the presence of 1 µM unlabeled ligand. Samples were counted on a Beckman liquid scintillation counter.

Measureable specific binding was present in adult human lumbar and sacral spinal cord. Binding obtained equilibrium within 4 hours. Specific binding to increasing amounts of tissue was linear over the range of tissue concentrations used in these experiments. ^{3}H-(3-Me-His^2)TRH binding was displaced by increasing concentrations of TRH. Unlabeled (3-Me-His^2)TRH was 10 times more effective in displacing tritiated ligand than was TRH. No significant displacement occured using the constituent amino acids of TRH, or agonist and antagonists for other receptors. Scatchard plot analysis of ^{3}H-(3-Me-His^2)TRH binding to adult human spinal cord indicates that the affinity constant (K_d) is approximately 4.5±2.0. These results are consistant with highly specific binding sites in adult human spinal cord with similar characteristics to the adult human brain TRH binding sites, previously reported. The specfic role that this receptor plays in spinal cord function requires further investigation.

124.17 DISTRIBUTION OF ^{3}H-SOMATOSTATIN BINDING SITES IN RAT AND HUMAN BRAIN.
CA Whitford[1*], DR Weightman[2*], CR Snell[3*], JM Candy[1*], CA Bloxham[4*], JA Edwardson[1*] (SPON: R.M. Gould) [1]MRC Neuroendocrinology Unit, and [4]Department of Pathology, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE; [2]Department of Medicine, University of Newcastle upon Tyne; [3]Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN.

Somatostatin binding sites in the brain have previously only been demonstrated using iodinated analogues of somatostatin. We report here the use of a tritiated ligand which is chemically and biologically identical to the natural ligand ([4-^{3}H (Phe^6)]-somatostatin-14) to demonstrate the distribution of high affinity binding sites which have pharmacological properties consistent with somatostatin receptors, in the rat and human brain.

In the rat brain, the density of ^{3}H-somatostatin binding sites on membrane fragments at 0.7nM ligand concentration was highest in the cerebral cortex and hippocampus (75-76 fmol/mg protein) and lowest in the medulla/pons and cerebellum (5 fmol/mg protein). Intermediate levels of binding were found in the striatum, midbrain and hypothalamus (14-23 fmol/mg protein). Preliminary studies using tritium film autoradiography show that areas with the highest density of binding sites include the deep layers of cerebral cortex, lateral septal nucleus, hippocampus, amygdala, claustrum, and habenula.

A more detailed study of the regional distribution of ^{3}H-somatostatin binding sites on membrane fragments in the human brain at 0.7nM ligand concentration showed that the cerebral cortex had a very high density of binding sites with the highest levels in the frontal and temporal cortex (62-70 fmol/mg protein), lower levels in the parietal and cingulate cortex (51-53 fmol/mg protein) and lowest in the occipital cortex (33 fmol/mg protein). The density of binding sites in the nucleus accumbens, caudate nucleus, hippocampus, hippocampal gyrus and claustrum was from 40-50 fmol/mg protein, while in the septum, putamen and amygdala, it was between 30-33 fmol/mg protein. Regions with a low level of binding included the globus pallidus (2 fmol/mg protein), hypothalamus (14 fmol/mg protein), substantia nigra (7 fmol/mg protein) and thalamus (4 fmol/mg protein). In contrast to the rat, the highest density of binding was in the cerebellar cortex (74 fmol/mg protein). Tritium film autoradiography revealed that the highest density of binding sites in the cerebellar cortex was present in the granule cell layer.

We conclude that the distribution of high affinity somatostatin binding sites is similar in rat and human brain, with the exception of the cerebellum.

124.18 QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF SOMATOSTATIN BINDING SITES IN DISCRETE AREAS OF RAT BRAIN. R. McCarty* L. Plunkett* K. Shigematsu*and J. M. Saavedra (SPON: I. Hanbauer). Section on Biochemical Pharmacology, NHLBI-NIH and Laboratory of Clinical Science, NIMH, Bethesda, MD. 20205

There is now excellent evidence from pharmacological and electrophysiological studies that somatostatin (SS) serves as a neurotransmitter or modulator of neural activity in many areas of the central nervous system. In the present study, we have studied the distribution of SS binding sites in discrete areas of rat brain by incubation of tissue sections with ^{125}I-SS, autoradiography, computerized densitometry and comparison with ^{125}I-standards. With this approach, we sought to examine the regulation of SS binding sites in various brain regions.

Adult male Sprague-Dawley rats were sacrificed and the brains were rapidly removed and frozen at -30°C. Sixteen micron coronal sections were cut in a cryostat at -14°C, thaw mounted onto subbed slides and kept overnight at 4°C. Sections were then incubated in 150 mM Tris (pH 7.4) which contained 5 mM $MgCl_2$, 0.1 mM bacitracin and 0.1% BSA and then incubated for 60 minutes in fresh buffer containing ^{125}I-SS, diluted 1:10 with unlabelled SS to yield concentrations of 0.13-2.0 nM. Non-displacable binding was studied in adjacent sections incubated in parallel with 10^{-5}M unlabelled SS. Sections were washed 3 times for 5 minutes each in Tris buffer at 4°C, dried under a stream of cool air and apposed to tritium-sensitive Ultrofilm. Displacable binding ranged from 50-85%.

Highest concentrations of SS binding sites in rat brain (fmol/mg protein ± SEM) were found in the claustrum (151 ± 29), central nucleus of the amygdala (90 ± 11), deep layers of the cerebral cortex (61 ± 9), lateral olfactory nucleus (58 ± 13), CA1 and CA2 regions of hippocampus (57 ± 11), medial and lateral septal nuclei (54 ± 9) and medial habenula (44 ± 5). Significant concentrations of SS binding sites were not found in the striatum or midbrain and brainstem areas. Scatchard analysis of 4 brain areas with high dendities of SS binding sites revealed an inverse relationship between maximum binding capacity (B_{max}) and binding affinity (K_a).

Our findings indicate that regulation of brain SS binding sites may be studied as one approach to examining the involvement of central SS pathways in various physiological and behavioral states.

124.19 WHOLEMOUNT LOCALIZATION OF FMRFAMIDE-IMMUNOREACTIVE NEURONS AND CHARACTERIZATION OF RECEPTORS TO FMRFAMIDE IN THE APLYSIA CNS. R. E. McCaman and J. K. Ono, Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA, 91010.

Previous studies have revealed a wealth of synaptic connections within the various ganglia of the Aplysia nervous system in which the chemical mediators are not conventional monoaminergic transmitters nor amino acids. Thus, we have begun to explore the possibility that some peptides may be involved in mediating conventional synaptic transmission, i.e., short latency, and relatively rapid conductance changes. The recent isolation of authentic FMRFamide (FMRFa) from the Aplysia CNS and the characterization of the nucleotide sequence encoding the amino acid sequence clearly establish the presence of this tetrapeptide in Aplysia. Furthermore, we have demonstrated selective and reproducible immunoreactive staining of an abundance of neurons in wholemounts of all the Aplysia ganglia using an antiserum obtained from Price & Greenburg. Previous reports indicate that FMRFa can induce excitatory and inhibitory responses in some Aplysia neurons (Stone et al., Neurosci. Absts. 7:636, 1982; Rubin et al., Neurosci. Abst. 10:1116, 1984). We have further characterized the various responses to FMRFa on different Aplysia neurons and find that these responses are due to two basic types of receptors, found either alone or in combination in various neurons. The depolarizing response appears to be due to an GNa^+ which reverses at approximately +10 mv and the hyperpolarizing response, as previously characterized by Rubin et al., is due to an GK^+. Both of these responses appear to have about the same threshold (10^{-7}M) to perfusion of FMRFa and their latencies, rise times and durations are demonstrably similar to those mediated by ACh, 5HT, and/or Hm applied under similar conditions and involving similar conductance mechanisms. We have tested various FMRFa analogues and find that some evoke a response to both the GNa^+ and the GK^+ (YFMRFa), others activate either the GNa^+ (d-amino acid substituted analogues, FMRdFa and FMdRFa) or the GK^+ (YGGFMRFa). Analogues lacking the C-terminal amide (FMRF) or other substitutions (LPLRFa) appear inactive.

The known presence of FMRFa in the Aplysia CNS along with our observations on the specificity of the receptors, the nature of the conductance changes mediated by FMRFa and the selective cellular localization of this peptide suggest that it may be a likely candidate for mediating chemical transmission within the ganglia. Discovery of monosynaptic connections between specific FMRFa-containing neurons and re-identifiable follower cells should provide an excellent opportunity for testing this possibility. (Supported by N.I.H. grant NS 18862)

124.20 **INTERACTIONS BETWEEN TYR-MIF-1 AND THE MU OPIATE RECEPTOR-SELECTIVE PEPTIDE MORPHICEPTIN (B-CASOMORPHIN 1-4 AMIDE) AT THEIR RESPECTIVE BINDING SITES.** J.E. Zadina and A.J. Kastin. Veterans Admin. Med. Cntr. and Tulane Univ. Sch. of Med. New Orleans, LA 70146.

The presence of a peptide very similar to TYR-MIF-1 (Tyr-Pro-Leu-Gly-NH_2) in rat brain has been supported by RIA (Kastin et al, Pharmac. Biochem. Behav. 13:901,1980; Br. Res. Bull., 7:697, 1981), HPLC (Kastin et al., unpub. observ.), and by the presence of specific, high affinity binding sites (Zadina et al., Pharmac. Biochem. Behav. 17:1193, 1982). Prominent among the actions demonstrated for Tyr-MIF-1 is antagonism of morphine-induced analgesia in the tail-flick test (Kastin et al., Pharmac. Biochem. Behav. 21:937, 1984).

Morphiceptin (Tyr-Pro-Phe-Pro-NH_2), is an amidated tetrapeptide fragment of the bovine milk protein, beta-casein. Its potent opiate agonist activity is indicated by the analgesia elicited after icv injection (Brantl et al., Life Sci. 28:1903,1981; Chang et al., Life Sci. 30,1547,1982) and it is selective for mu opiate receptors (Chang et al., PNAS 78:75, 1981).

Using in vitro assays, we have found that specific binding of ^{125}I-Tyr-MIF-1 to rat brain membranes is displaced with high potency by Morphiceptin and some of its analogs. In addition, Tyr-MIF-1 can displace ^{125}I-Morphiceptin from its binding sites.

Rat brain membranes were prepared as described (Zadina et al,1982), extensively washed, and preincubated at 37°C. The membranes were incubated for 18 (Tyr-MIF-1 assay) or 24 hr (Morphiceptin assay) at 4°C with 1nM iodinated peptide, an enzyme inhibitor (bestatin), and varying concentrations (1-1024 nM) of unlabeled peptide or analog. Nonpecific binding was determined as binding in the presence of a 10uM concentration of the corresponding unlabeled peptide. The biphasic displacement curves were analyzed by nonlinear curve-fitting programs (Allfit and Ligand). In the ^{125}I-Tyr-MIF-1 assay, morphiceptin as well as its active analog, NmePhe^3-D-Pro^4 morphiceptin (PL017), and the parent heptapeptide, beta casomorphin, all showed potent displacement activity. D-Pro^2 substitution however, which eliminates opiate activity, also eliminated its binding activity, and indicated a stereospecific reaction. Enkephalin analogs, dynorphin, kyotorphin, dermorphin, EKC, cyclazocine, DAGO and DHM were all inactive. Morphiceptin, PL017, and Tyr-MIF-1 all effectively displaced ^{125}I-Morphiceptin, but the D-Pro^2 morphiceptin analog was inactive. These results indicate a possible mechanism for the interaction of Tyr-MIF-1 and opiate substances.

REGENERATION: NEURONAL AND GLIAL RESPONSES

125.1 ACTINOMYCIN D DISINHIBITS POSTTRANSLATIONAL PROTEIN MODIFICATION BY AMINO ACID ADDITION IN REGENERATING RAT SCIATIC NERVES IN VITRO. R.V. Riccio, G. Chakraborty*, and N.A. Ingoglia. Department of Physiology, New Jersey Medical School, Newark, NJ 07103.

Posttranslational modification of proteins (PTPM) by amino acid addition has been shown previously in preparations of a 150k xg supernatant of rat sciatic nerves. The demonstration of this reaction is dependent on removing low molecular weight "regulatory" molecules by fractionating the supernatant by Sephacryl S-200 chromatography (excluding molecules < 125 kD), or by removing molecules <30 kD by ultrafiltration prior to the in vitro assay. We now report that addition of 2-20 μM Actinomycin D (Act D) to the 150 k xg supernatant of sciatic nerves 2 hrs post-crush allows for the expression of PTPM activity to levels similar to those obtained by either of the above molecular weight exclusion methods.

Rat sciatic nerves were crushed and 2 hrs later a 150k xg soluble supernatant was prepared from a homogenate of segments taken 1 cm proximal to the crush site (P1). The supernatant was divided and either fractionated by S-200 chromatography, filtered through a Centricon C-30 filter, or incubated with 2-20 μM Act D (20', 37°C). The void volume of the S-200 column, the C-30 retentate, and the samples containing Act D were then incubated with ^{3}H-lysine and a reaction mixture at 37°C for 30' and analyzed for incorporation of radiolabel into protein. Untreated supernatant, and supernatant incubated with Act D at 0°C or 4% mannitol (vehicle) at 37°C served as controls. Act D significantly increased ^{3}H-lysine incorporation above all controls and approached that seen after S-200 or C-30 treatment. Addition of Act D to the S-200 or C-30 fractions further increased ^{3}H-lysine incorporation above the untreated fractions.

These data indicate that the expression of the PTPM reaction can be released by the addition of Act D to the 150k xg supernatant in addition to removing putative inhibitory agents by molecular weight exclusion. (Supported by NINCDS grant NS19148 from NIH).

125.2 INCREASES IN POSTRANSLATIONAL PROTEIN MODIFICATION AND PROTEIN SYNTHESIS IN RAT SCIATIC BUT NOT OPTIC NERVES FOLLOWING INJURY. S.S. Athwal, R.V. Riccio and N.A. Ingoglia, Dept. of Physiology, New Jersey Medical School, Newark, NJ 07103

Posttranslational protein modification by amino acid addition (PTPM) occurs in both rat optic and sciatic nerves, but 18 hrs. after a crush injury there is a 2-fold increase in activity in the sciatic nerve and a 25% decrease in optic nerve activity (Athwal, S.S. et al. Soc. Neurosci. Abstract, V.10; 1031, 1984). The present experiments investigate these reactions at earlier time points after a nerve crush, and compare them with glial and Schwann cell protein synthetic activity over the same time period.

The right optic or sciatic nerve was crushed, and 10 minutes to 3 days later nerve segments just proximal to the crush were removed and assayed for PTPM or protein synthesis. In protein synthesis experiments, rats were injected intravenously with a mixture of ^{3}H-amino acids one hour prior to sacrifice. PTPM activity was determined by incubation of a fraction of the 150K xg supernatant with ^{3}H-Lys as described elsewhere (Zanakis, M.F. et al., J. Neurochem., 43:1286, 1984). Incorporation of ^{3}H-amino acids into proteins for both PTPM and protein synthesis was determined by extraction in hot and cold TCA. In each experiment, contralateral sham operated nerves were used as internal controls. PTPM in sciatic nerves increased 1.5 times control levels 10 minutes after crush and continued to increase to a maximum of 9.5 times control by 2 hrs. post-crush. In optic nerves, activity was decreased by approximately 50% of controls throughout the time course studied. Protein synthesis was also depressed by approximately 50% in crushed optic nerves, but in sciatic nerves an initial depression (up to 1 hr. post crush) was followed by a doubling of protein synthetic activity at 2 hrs. In sciatic nerves, protein synthesis remained elevated up to 3 days later.

These results indicate that in a nerve which is capable of regeneration (sciatic), PTPM increases immediately (10 minutes post crush) following injury, but a nerve incapable of regeneration (optic) is incapable of activating the modification reaction. The finding that protein synthesis is not activated in injured optic nerves suggests that nerve crush stimulates gene activation in Schwann cells of the sciatic nerve but not in glia of the optic nerve. These findings may be significant for understanding the reasons for the lack of a regenerative response in central mammalian nerves. (Supported by NINCDS grant NS19148 from NIH).

125.3 IMMUNOHISTOCHEMICAL LOCALIZATION OF A NEURONAL GROWTH-ASSOCIATED PROTEIN (GAP 43) IN NEONATAL RAT BRAIN. C. B. McGuire*, J. J. Norden, S. S. Bock, and J. A. Freeman. Dept. of Anatomy, Vanderbilt University Medical School, Nashville, TN 37232.

It is likely that axon growth, terminal formation, and synaptogenesis involve the synthesis and transport of specific growth-associated proteins (GAPs) to the developing axonal endings. A search for candidate proteins involved in rat neurogenesis has yielded a 43 kDa membrane protein (GAP 43) which is synthesized and axonally transported by rat retinal ganglion cells during periods of axon growth and synaptogenesis in the developing visual system. In order to further study the role of GAP 43 in neuronal development, we have produced a specific rabbit antiserum against the 43 kDa protein purified by preparative two-dimensional polyacrylamide gel electrophoresis (2D-PAGE). We have used this antiserum to immunohistochemically localize GAP 43 in frozen sections of neonatal rat brains.

Brains from rats 0-30 days old were sectioned and processed for immunohistochemistry, using a standard peroxidase anti-peroxidase procedure. In order to control for the specificity of anti-GAP 43 immunostaining, we partially purified GAP 43 from a membrane fraction (1000,000 x g) of 7 day old rat brains by DEAE ion-exchange chromatography followed by one-dimensional preparative PAGE and used it to pre-absorb GAP 43 immunoreactivity on adjacent brain sections. We found that GAP 43 is localized to very fine, irregular profiles in the retinal recipient layers of the developing superior colliculus throughout the time-course of retinal ingrowth and synaptogenesis. This result indicates that GAP 43 is localized to axon terminals during e periods of axon growth and maturation. Several other brain areas showed similar immunoreactivity, including the molecular layer of the dentate gyrus, where staining is most pronounced during the period of rapid synaptogenesis, postnatal days 7-21. We propose that GAP 43 is involved in the formation and maintenance of presynaptic membrane specializations. Two biochemical studies are consistent with this hypothesis. First, a role for GAP 43 in neurogenesis is supported by our finding that GAP 43 is enriched in growth cones isolated from fetal rat brains. Second, we have observed small but significant quantities of GAP 43 in adult rat brains indicating a role for GAP 43 in normal nerve function. We are presently trying to elucidate, by immunoelectron microscopy, the subcellular localization of GAP 43 and the precise developmental stages at which GAP 43 is being incorporated into individual axon endings in an effort to discover the function of this neuronal growth-associated protein. (Supported by NIH Grant NS18103 and NEI Grant EY01117 to J.A.F.).

125.4 LOCALIZATION OF A SPECIFIC 37kDa PROTEIN-LIKE IMMUNOREACTIVITY IN THE MAMMALIAN PNS AND CNS DURING WALLERIAN DEGENERATION. G.Stoll* and H.W.Müller (SPON:K.H.Mauritz). Dept. of Neurology, Univ. of Düsseldorf, F.R.Germany.

As a specific response to denervation the synthesis of a 37kDa protein was significantly stimulated in the nerve sheaths of mature PNS and CNS of rat. The synthesis of the 37kDa protein was inhibited in the peripheral nerves when proper reinnervation was established whereas 37kDa synthesis continued at maximal rate in non-regenerating CNS for at least 3 months. However, the cellular localization and function of the 37kDa protein in Wallerian degeneration in unknown.

Specific antibodies raised in rabbits to purified 37kDa protein isolated from regenerating sciatic nerve were used to identify the cell types expressing this protein in PNS and CNS. Paraffin and plastic thin sections were prepared from sciatic nerve and optic nerve and stained by avidine-biotinylated peroxidase-complex technique. In sham-operated control sciatic nerve the antigen was recognized at the outer surface of the myelin sheaths and the Schwann cell bodies suggesting a distribution similar to basal lamina. Two weeks after crushing the sciatic nerve the amount of antigen was significantly increased in the distal nerve segment. At this time the antigen was localized predominantly within a cell type that morphologically resembled macrophage. A small fraction of the antigen remained associated with the myelin and Schwann cell surface similar to control nerves.

In sham-operated control optic nerve the antibody to peripheral 37kDa protein recognized only granular structures distributed within the cell body and processes of astrocytes. In contrast to sciatic nerve the total amount of detectable 37kDa-like immunoreactivity did not increase in the optic nerve within 2 weeks after a crush lesion. However, the immunoreactivity disappeared from most of the astrocyte cell bodies and reappeared in vesicular or granular structures distributed evenly throughout the cross-section of the nerve. Recognition of epitope(s) in CNS by an antibody raised to 37kDa protein from peripheral nerve suggests homology of the central and peripheral 37kDa proteins. Since myelin resorption is one of the important functions of macrophages in Wallerian degeneration the role of the 37kDa protein in PNS and CNS will be discussed in this regard.

125.5 POST-TRANSLATIONAL MODIFICATION OF THE 48 kD GROWTH-ASSOCIATED PROTEIN IN THE REGENERATING GOLDFISH RETINA. N.I. Perrone-Bizzozero and L.I. Benowitz. Dept. of Psychiatry and Program in Neuroscience, Harvard Med. Sch.; Mailman Res. Ctr., McLean Hosp., Belmont, MA 02178.

Regeneration of the optic nerve in goldfish involves a shift in the retinal ganglion cells' program of protein synthesis and axonal transport (Grafstein & Murray, Exp. Neurol. 25:494, 1969; Benowitz et al, J. Neurosci. 1:300, 1981; Heacock & Agranoff, Neurochem. Res. 7:771, 1982). Among the membrane-bound proteins that are conveyed to the developing nerve terminals by rapid axonal transport, presumably to participate in phenomena such as axon elongation, growth cone motility, and target recognition, the most striking change associated with regeneration is a 50-100 fold increase in a group of proteins, the principal component of which has a molecular weight of 48,000 daltons (48 kD) and a pI of 4.7 (Benowitz & Lewis, J. Neurosci. 3:2153, 1983). Proteins presumed to be similar to this are found in a number of other developing and regenerating systems, both in lower vertebrates and in mammals, and it has been proposed that the expression of these and several other growth-associated proteins (GAPs) may be a basic feature of axonal outgrowth (Skene, Cell 37:697, 1985). In the present studies we examined certain aspects of the biosynthesis of the 48 kD protein in order to understand better the cellular level at which changes in its expression come about during growth, and to gain further insight into its biochemical properties. Intact or regenerating goldfish retinas were pulse-labeled in vitro with ^{35}S-methionine or ^{3}H-proline for 20-30 minutes, and then either frozen or incubated for another 30-60 minutes with an excess of non-radioactive amino acids. Results of these pulse-chase experiments show that the 48 kD protein is post-translationally modified over a period of about 30 minutes, and is synthesized only when the retina is undergoing axonal regeneration. Tunicamycin, an inhibitor of N-glycosylation through the dolichol phosphate pathway, prevents the 48 kD and several other proteins from appearing when regenerating retinas are pre-incubated with the inhibitor for 1 hour. Tunicamycin prevents outgrowth of axons from the goldfish retina in culture (Heacock, Brain Res. 241:307, 1982). The observation that the 48 kD protein is one of only 2-3 regeneration-specific proteins whose synthesis is blocked by this inhibitor therefore supports the idea that this protein may be essential for axonal outgrowth. Research in progress is attempting to identify the unglycosylated precursor of the 48 kD protein to ascertain whether it is a growth-specific m-RNA translation product. Supported by NIH EY05690 and American Paralysis Association Contract 84-04.

125.6 QUANTIFICATION OF THE SYNAPTIC VESICLE PROTEINS, SYNAPSIN I AND p38, AND THE ASTROCYTE-SPECIFIC PROTEIN, GLIAL FIBRILLARY ACIDIC PROTEIN, FOLLOWING TRIMETHYLTIN-INDUCED INJURY TO THE RAT CENTRAL NERVOUS SYSTEM. M.E. Viana*, T.O. Brock and J.P. O'Callaghan. Neurotoxicology Division, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711 and Northrop Services, Inc., Research Triangle Park, NC 27709.

Lesion- or chemical-induced injury to the central nervous system (CNS) is associated with complex biochemical and morphological responses. In order to characterize and quantify these responses, we are examining changes in nervous-system proteins (NSP) and brain morphology produced by exposure to known neurotoxicants (O'Callaghan and Miller, TIPS 4: 388, 1983). In the present investigation, we characterized the effects of trimethyltin (TMT), a neurotoxic organometal that produces cytopathological changes in rat CNS that are largely restricted to the limbic system. NSP measurements consisted of radioimmunoassays of synapsin I and p38 (formerly p36; see Jahn, et al. PNAS 81: 1684, 1984), two synaptic vesicle-associated proteins, and glial fibrillary acidic protein (GFAP), an astrocyte-specific protein. Computer-assisted densitometry also was employed to quantify NSP resolved by two-dimensional gel electrophoresis (2D-PAGE). Morphological indices consisted of 1) morphometry of hippocampal pyramidal cells and 2) immunocytochemistry of GFAP.

Acute administration of TMT (0.0-9.0 mg/kg, i.v.) to adult LE rats caused both dose- and time-dependent decreases in synapsin I and p38 in the hippocampus. Large reductions in synapsin I (73%) and p38 (60%) were observed following 9.0 mg/kg. Both of these proteins were decreased maximally at 5 weeks after TMT administration but approached control values 12 weeks after administration. Resolution of hippocampal proteins by 2D-PAGE revealed a TMT-induced loss of a protein tentatively identified as neurofilament 68K; this same protein also was reduced in samples of frontal cortex from TMT-treated rats whereas synapsin I and p38 values were not affected. TMT (0.0-9.0 mg/kg) caused large dose- and time-dependent increases in GFAP in both hippocampus and frontal cortex. Maximal effects were observed 5 weeks after TMT administration and were of similar magnitude (500-600% of control) in both regions; by 12 weeks GFAP values had decreased to near control values. Microdissection of slices of dorsal hippocampus demonstrated regional differences in the extent to which TMT affected GFAP with area CA3 showing the greatest increase (6000% of control).

Morphological examination of the hippocampal formation revealed a loss of pyramidal cells and predominant GFAP immunoreactivity in astrocytes throughout Ammon's horn and fascia dentata. Collectively, these data suggest that NSP may be used to characterize cell-type-specific responses to CNS injury.

125.7 METABOLIC ACTIVITY IN GOLDFISH OPTIC TECTUM: EFFECTS OF OPTIC NERVE CRUSH AND REGENERATION. M. Murray and N. Berman. Dept. of Anatomy, Medical College of Pennsylvania, Philadelphia, PA 19129.

The staining method for cytochrome oxidase is sensitive to long term changes in neuronal activity resulting from denervation. The goldfish optic system provides a favorable system to examine the effects of denervation and reinnervation on metabolic activity of tectal neurons and the surrounding neuropil using this method. Synaptic number in the stratum fibrosum et griseum superficialis (SFGS), the main recipient lamina for optic axons, fails by 40% after optic nerve crush. Regenerating optic axons enter the SFGS by 3 weeks postoperatively but the normal number of contacts does not return until after 3 months postoperatively.

We crushed the right optic nerve in large goldfish and then sacrificed them at intervals from 2 days to 2 years postoperatively. Fish were perfused with paraformaldehyde: glutaraldehyde, the brains were cut and the sections were incubated with cytochrome and diaminobenzidine, mounted and coverslipped. Sections were examined in the light microscope and the density of the brown reaction product was quantitated using a Quantimat 920 image analyzer. Differences in the intensity of staining between the control (right) and experimental (left) SFGS were determined. The density of staining in the stratum marginale, the most superficial lamina which receives no optic input, was equivalent between left and right sides in all animals. Little difference in staining of the SFGS between two sides was apparent at 2 days postoperatively. By 4 days, the density of staining of SFGS was substantially reduced on the experimental side. Recovery of control levels of staining occurred by 3 months postoperatively. We conclude that the metabolic activity of the SFGS parallels the synaptic density and may act as a sensitive indicator of reinnervation.

125.8 **EARLY APPEARANCE OF A25 (A MODIFIED RAPIDLY TRANSPORTED POLYPEPTIDE) IN FROG SCIATIC NERVE FOLLOWING DAMAGE, AND THE EFFECTS OF A CONDITIONING LESION.** G.W. Perry, Bruce Tedeschi* and David L. Wilson. Department of Physiology and Biophysics, Univ. of Miami School of Medicine, MIAMI, FL 33101.

Previously, a protein designated A25 was seen only at regenerating nerve tips, and only several days after nerve damage. A25 (apparent size of 70,000 daltons) appears to be the product of post-translational modification of a rapidly transported protein, and is retrogradely transported along intact axons (Tedeschi and Wilson, 1983 J. Neuroscience 3,1728). Using a new solubilization procedure we now detect A25 much earlier after nerve damage, but still only at or distal to a site of damage. We have also detected another protein, designated A30, with a greater molecular weight (about 100,000) in normal sciatic nerve that was previously obscurred by background labelling of fluorographs in the less acidic regions of our 2D-gels. Intriguingly, A30 disappears, or is absent, in damaged nerve segments whenever A25 appears. Both polypeptides exhibit microheterogeneity, and we are exploring the possibility that A30 is the precursor of A25. As the nerve elongates distally from the site of damage, A25 is detectable, but not A30, along the entire length of the regenerated portion of nerve.

The appearance of A25 was enhanced in damaged nerves that had received a prior "conditioning lesion". However, when rapidly transported proteins were collected prior to arrival at regenerating nerve regions, a prior conditioning lesion appeared to have relatively little effect on the majority of transported proteins, including A30, beyond those changes seen previously following a single lesion (Perry and Wilson, 1981 J.Neurochemistry 35,1203). In addition, with our new solubilization procedure, we have detected changes following nerve damage in a few other rapidly transported proteins, including A30.

We conclude that A25 appears at damaged nerve sites much earlier than was previously seen, and that another rapidly transported protein, A30, may be its progenitor. It is also tempting to speculate that among the roles possible for A25 may be a role in signalling the cell body about axon damage.

125.9 CHANGES IN THE LEVELS OF IN VITRO SYNTHESIZED INTERMEDIATE FILAMENT PROTEINS ACCOMPANYING GOLDFISH OPTIC NERVE REGENERATION. P. Tesser* and N. Schechter. Departments of Psychiatry and Behavioral Science, and Biochemistry SUNY at Stony Brook, New York 11794

Changes in protein and mRNA synthesis accompanying goldfish optic nerve regeneration have been investigated by in vitro translation of RNA derived from retinas at various time points after nerve crush. The resulting translation products were examined by 2-dimensional gel electrophoresis and immunoprecipitation.

We have concluded that the level of total protein synthesis remains virtually constant during regeneration as judged by the level of in vitro protein synthesis which is directed by equivalent amounts of total RNA at each time point. Furthermore, the amount of total RNA which can be isolated from retina also remains relatively constant during regeneration. However, the synthesis levels of certain structural proteins show large increases.

Previously, the proteins designated as ON_{1-4} had been identified as intermediate filament proteins of the goldfish visual pathway (Quitschke and Schechter, J. Neurochem., 42:569, 1984). ON_1 and ON_2 are of neuronal origin and their levels of synthesis are linked to nerve regeneration. Conversely, ON_3 and ON_4 are non-neuronal and change very little in abundance during regeneration. We have used polyclonal antibodies specific for either ON_1 and ON_2 or ON_3 and ON_4 and a general monoclonal anti-intermediate filament antibody for further characterization. Antibodies raised against the optic nerve ON_1 and ON_2 proteins react specifically with the in vitro synthesized ON_1 and ON_2 proteins thus confirming their retinal origin. Increased synthesis of ON_1 and ON_2 is observed ten days after crush and reaches a maximum at about twenty days; by 85 days they are translated at levels equal to those before crush. Antibodies to ON_3 and ON_4 do not react with any proteins translated from retinal RNA. The monoclonal antibody reacts with both ON_1 and ON_2 as well as with several putative intermediate filament proteins. We also observe on 2-D gels a previously unidentified protein which is not detectable before crush and is synthesized at high levels twenty days after crush.

Because ON_1 and ON_2 are synthesized as two distinct proteins in vitro and because no post-translational modifications occur during the in vitro reaction, it appears that ON_1 and ON_2 differ slightly in amino acid composition and are encoded by two distinct mRNAs.

It is possible to conclude that regeneration of the goldfish optic nerve involves very specific changes in gene expression rather than a general increase in mRNA and protein synthesis. (This research was supported by grant EY 05212 from the NIH.)

125.10 CONSEQUENCES OF PARTIAL AXOTOMY FOR PRODUCTION OF NEUROTRANSMITTER VESICLES AND ROUTING OF MATERIAL MOVING BY FAST TRANSPORT IN THE AXONAL TREE. D.J. Goldberg and R.T. Ambron. Depts. of Pharmacol. and Anat. and Cell Biol., Columbia U. CPS, NY, NY 10032.

It is known that axotomy reduces the export from the cell body of materials associated with synaptic transmission. We previously showed, using a giant invertebrate neuron with a simple axonal tree, that the reduction in export of transmitter storage vesicles seems to be an expression of a feedback regulation that closely couples vesicle export to the extent of the synaptic field (Science, 213: 913, 1982; J. Neurosci., 4:1800, 1984). We have now sought to determine whether export is regulated by decreasing the rate of synthesis of transmitter vesicles or by slowing their exit from the cell body after synthesis. Two lines of evidence indicate that synthesis decreases. First, we counted serotonergic vesicles in electron micrographs of several areas of the cell body of the Aplysia neuron GCN 3 days after proximal transection of one branch of the bifurcate axon. Export of vesicles is stably decreased by half at this time, and were this due to an increase in the time required for formed vesicles to exit the cell body, we would expect to see them accumulate in the cell body. We observed no such increase in their numbers. Second, we measured the extent of incorporation of ^{3}H-fucose into a 75kD putative vesicle glycoprotein. Reduced incorporation was evident 1 day after transection of one branch, and was dramatic when both branches were transected. Fucosylation of other glycoproteins was relatively unaffected.

We also found previously that distal axotomy of one branch of the axon causes, within hours, transmitter vesicles to be preferentially routed into the intact branch, despite the fact that the transected branch remains capable of carrying its full normal complement of vesicles. We wondered whether this routing was selective for vesicles, especially since considerable sprouting occurs at the proximal stump of the transected branch. We thus analyzed, using SDS PAGE, the partitioning between the two axonal branches of 6 fucosyl glycoproteins 2 weeks after distal transection of one branch. Included among these glycoproteins was at least one whose transport moderately increases after transection, as well as the 75kD putative vesicle protein. We found that there was considerable variability in the partitioning ratios of the glycoproteins within an individual axon during our relatively brief assay period. No difference was consistent from one axon to the next, however. We conclude that there is stochastic variation in the composition of material received by axon endings but, at least insofar as the glycoproteins we have studied in detail are concerned, there is no selectivity in the partitioning of material.

125.11 REGENERATION ASSOCIATED CHANGES IN AXONAL MICROTUBULE PROTEIN TRANSPORT IN DORSAL ROOT GANGLION CELLS OF RAT. M.M. Oblinger. Dept. of Biological Chemistry & Structure, The Chicago Medical School, North Chicago, IL 60064.

Axotomy of peripheral sensory axons induces a series of metabolic changes in dorsal root ganglion (DRG) neurons that involve the axonal cytoskeleton. For example, a decrease in the synthesis and subsequent axonal transport of neurofilament proteins in slow component a (SCa) occurs during regeneration of peripheral DRG axons (Oblinger & Lasek, 1983, Soc. Neurosci. Abstr., 9:148; 1985, in press). The faster moving slow component of transport, SCb, had not been previously studied during regeneration of DRG axons. SCb moves at a rate similar to observed axonal outgrowth rates in the DRG cell and conveys a significant portion of the axonal cytoskeleton, including some of the tubulin and most of the actin. Recent evidence indicates that the tubulin conveyed in SCb differs in its subunit composition and solubility properties from that conveyed with neurofilaments in SCa (Tashiro et al., 1984, J. Neurochem., 43:1220). The present study examined the effects of axotomy on the SCb associated microtubule proteins in mature peripheral sensory axons of albino rats.

Two peripheral axotomy conditions were examined: axotomy induced by either a forceps crush of the sciatic nerve or by removal of a 2mm segment of nerve. The peripheral axotomy site was 48-52 mm from the L5 DRG. For comparison, nerves from normal or sham-operated animals and animals that sustained a central crush lesion of the L5 dorsal root were used. Injections of ^{35}S-methionine into the L5 DRG were made 1-2 weeks after axonal injury and animals were sacrificed 3,5 and 7 days after labeling. Aliquots of successive 2 mm segments of the sciatic nerve, proximal and distal to the injury, were subjected to gel electrophoresis and fluorography. The tubulins, actin and several additional SCb proteins were excised from gels and the radioactivity measured.

In response to axotomy induced by either a cut or crush of the sciatic, the amount of SCb tubulin was significantly increased in peripheral DRG axons compared to the amount in control conditions. Additionally, a marked increase in the rate of transport of SCb tubulin was apparent in regenerating systems compared to control axons. This rate increase was evident by analysis of the movement of the labeled tubulin peak or front with time. Less dramatic changes in the transport profiles of other SCb proteins were found. The alterations in SCb tubulin transport may contribute to the mechanism of the priming lesion effect documented in the DRG system (Oblinger and Lasek, 1984, J. Neurosci., 4:1737). That is, the increased elongation rates that result when peripheral axons are lesioned 1-2 weeks after a first lesion may be related to the availability of increased amounts and rates of microtubule protein needed to support faster and more extensive neurite elongation.

125.12 CHANGES IN CELL PROLIFERATION IN THE GOLDFISH RETINA FOLLOWING OPTIC NERVE CRUSH. D.B. Henken and M.G. Yoon. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, B3H 4J1

In goldfish new cells are continuously added to the retina throughout life. In this study we examined how optic nerve crush (ONC) affects the rate of cell birth in the retina. Unilateral ONC's were performed on 25 fish. Either 3, 6, 9, 12, 15, 20, 25, 30, or 40 days later both eyes were injected with tritiated thymidine (^{3}H-TdR, 6.7 Ci/mmole, ICN). The fish were sacrificed one day after ^{3}H-TdR administration and embedded in paraffin for standard light microscopic autoradiographic examination of labelled cells.

Differential changes in the labelling pattern of the experimental eye, relative to the control eye, were seen at various post-operative periods. ^{3}H-TdR incorporation in the deep layers of the retina (ganglion cell and optic fiber layers) was enhanced as early as three days following ONC. The increased rate of labelling in the experimental retina (as compared to the control) reached a peak at around 12 days and returned to control levels by day 30.

Differential labelling was also found in the photoreceptor layer. Enhanced labelling was seen in the experimental retina 10-12 days following ONC. At 15 days and onward, however, labelling in the experimental retina fell below that of the control.

The differential labelling described here in response to ONC occurred through all topographic regions of the retina, although labelling was always clearly highest in the peripheral germinal zones. These results suggest that axotomy and regeneration of ganglion cell axons affect the rates of cell birth in the photoreceptor layer as well as in the deep layers of the retina in adult goldfish.

125.13 MORPHOLOGY OF REGENERATED RETINAL AXONAL TERMINAL ARBORS IN THE GOLDFISH TECTUM. C.A.O.Stuermer, M.Beckmann* and E.Kalko*. Max-Planck-Institut für Entwicklungsbiologie, D-7400 Tübingen, FRG.

Regenerated goldfish retinal axons and terminal arbors (TAs) were labeled by applying crystals of HRP either to the stumps of the resectioned optic nerve (early regenerates) or to cut axon bundles in retina at defined retinal positions (late regenerates). Two to four days later the tectal lobes were removed, reacted with DAB, fixed, dehydrated, cleared, whole mounted under Permount and coverslipped for light microscopic examination.

Most regenerated axons and TAs resemble the normal in that the axon enlarges to form the stem segment of the arbor which first bifurcates into two major branches and then into branchlets. The TA's stem and major branches were either oriented in the same direction as their parent axons - or particularly in peripheral tectum - the stem and/or one or both major branches were perpendicular to their axon. Axons and TAs extend horizontally and contribute to superficial and deep layers of the synaptic layer SFGS (Stuermer, J.Comp.Neurol. 229:214, 1984).

At early regeneration stages (15 days) the front of axons and TAs were confined to the rostrocentral and dorsal and ventral peripheral tectum. Along their length, the axons had regularly spaced elongated thickenings which were about 20 times longer than the spindle-like enlargement of the normal. TAs ranged between 50x90µm up to 180x350µm. These TAs showed several peculiarities: the stem and the major branches appeared broader and longer than normal. They were lobular and contained irregularly shaped bulges and protrusions. The major branches divided into numerous processes some of which exhibited growth cone-like globular or pear-shaped swellings with tender twigs. Occasionally, a third branch arose from the proximal part of the stem. Close to the entrance of the optic tract we noted axons ending in growth cone-like enlargements which possessed filopodia-like extensions.

Axons and TAs at 2,4,6 and 12 months had normal morphologies and sizes (Stuermer, 1984). Most TAs were located at retinotopic sites (Neurosci. Abstr.10, 1984).

Thus we conclude that regenerating TAs in goldfish are basically of the same extent and shape as normal TAs. They do not exceed excessively the normal dimensions.

125.14 SEROTONIN-LIKE IMMUNOREACTIVITY IN NORMAL AND REGENERATING CEREBRAL GANGLIA OF THE SNAIL MELAMPUS. R.L. Ridgway and S.B. Moffett, Dept. of Zoology, Washington State University, Pullman, WA 99164-4220.

In the pulmonate snail Melampus the capacity to regenerate central nervous system tissues following injury extends into adulthood and may include the replacement of lost neurons. For example, after unilateral cerebral ganglionectomy the cerebral connectives, commissure, and distal nerves regrow, converge, and often form a new ganglion bud. Ultrastructural studies have established the presence of morphologically differentiated neurons in long term (>6 months) regenerating ganglia (Moffett and Austin, J. Comp. Neurol. 207:177-182, 1982). Serotonergic cells are among the strong candidates for replacement in the event of loss because of their importance to such behaviors as feeding and locomotion. We have used immunohistochemistry to identify serotonergic cells in normal and regenerating cerebral ganglia.

Normal cerebral ganglia of adult Melampus contained 30-35 cells having serotonin-like immunoreactivity, most of which were found in 4 spatially distinct clusters. The size, number, and axonal distributions of neurons were characteristic for each cluster. Two large (35-50 µm diam.), single neurons were also among the immunoreactive cells of each ganglion. One of these, C1, appears homologous to the "metacerebral giant cells" of other gastropod species. It sends axons to the ipsilateral buccal ganglion and median lip nerve, and to the contralateral cerebral ganglion.

All of the regenerating snails had undergone left cerebral ganglionectomy 1-5 years prior to sacrifice. The degree of ganglion bud development varied from a simple swelling to an enlargement one-half the size of control ganglia. This variability cannot be directly correlated to post-operative time since poorly developed buds were found among the longest term regenerates. Serotonin-like immunoreactivity within poorly developed buds consisted of profusely distributed neurites arising from cells of neighboring (non-excised) ganglia. Buds of intermediate development were characterized by neuropil regions and distinct axon tracts, and sometimes by the presence of small, scattered immunoreactive cells. Some of these cells were located in adjacent nerve trunks. We are still in the process of examining ganglion buds of more advanced development.

Our findings to date confirm the reestablishment of axonal pathways following injury in Melampus and show that the regenerative capacity of this nervous system is sufficient to generate new serotonergic cells.

125.15 RELEASE OF A DIFFUSABLE SIGNAL FROM INJURED PERIPHERAL NERVE STIMULATES MACROPHAGE INFILTRATION DURING WALLERIAN DEGENERATION.
P.Minweger* and H.W.Müller (SPON: H.J.Freund). Dept. of Neurology, Univ. of Düsseldorf, F.R.Germany.

Sciatic nerves of young adult rats were injured by cryo-lesions at upper thigh level. One group of animals received repetitive i.p. injections of silica quartz dust. This substance is cytotoxic for cells of the monocyte-macrophage series. Removal of myelin in the distal nerve stump undergoing Wallerian degeneration was significantly retarded in animals receiving silica as compared to the control group.

When segments of autologous sciatic nerve were transplanted into Millipore diffusion chambers of 0.22 um pore size which were then implanted in the peritoneal cavity the myelin sheaths persisted for at least 3 weeks. This method eliminated the access of non-resident cells to the transplant but allowed excellent survival of denervated sheath cells within the nerve segment (Beuche and Friede, J.Neurocytol.,13:767,1984). In contrast, in diffusion chambers of 5.0 um pore size which allowed penetration of non-resident cells myelin was removed at a time course similar to Wallerian degeneration in situ. The cells migrating through the latter membrane could be identified as macrophages. To exclude the possibility that (a) macrophages infiltrate the nerve tissue by random migration, and (b) other hematogenous cells (pre-) infiltrating the nerve release the signal which attracts macrophages we carried out experiments using a novel diffusion chamber cell trap. To a diffusion chamber of 0.22 um pore size which contained the nerve an additional chamber (trap) was attached consisting of an outer membrane of 5.0 um pore size and a common 0.22 um membrane shared by the two chambers. Under these conditiones removal of the myelin sheaths in the nerve was inhibited as described for the 0.22 um chamber. However, a large population of macrophages accumulated in the trap chamber within one week after transplantation. Our data suggest the release of a diffusable signal from injured peripheral nerve which specifically attracts non-resident macrophages to infiltrate the nerve tissue during an early period of Wallerian degeneration.

125.16 THE EFFECT OF IMMUNOSUPPRESSIVE DRUGS ON REMYELINATION.
R.M. Herndon and L.C. Triarhou, Ctr. for Brain Research, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642, and Dept. of Pathology, Div. of Neuropathology, Indiana Univ. Sch. of Med., Indianapolis, IN 46223

Anti-inflammatory and immunosuppressive drugs are being used in the treatment of multiple sclerosis (MS) with increasing frequency. Since many of these drugs are antimitotic and there is evidence that division of oligodendrocytes is essential to remyelination, we investigated the effect of dexamethasone, azathioprine, cyclophosphamide, and silica quartz dust (which suppresses macrophage activity) on remyelination following lysolecithin-induced demyelination. Four week old rats were anesthetized and subjected to midthoracic laminectomy. Two µl of 1% lysolecithin were then injected into the ventrolateral white matter using a glass micropipette attached to a Hamilton syringe held in a micromanipulator. Animals were anesthetized and killed by perfusion at 8, 12, 28 and 60 days post surgery. Dexamethasone was given by continuous infusion using Alzet minipumps in a dose of 0.56 mg/rat/day for 14 days beginning on the day of surgery. Azathioprine and cyclophosphamide were given by intraperitoneal injection in a dose of 15 mg/kg/day beginning either 5 days before surgery, the day of surgery, or beginning 5 days after surgery. The silica quartz dust was injected intraperitoneally in a dose of 200 mg the day before surgery. Dexamethasone appeared to decrease the extent of the demyelination but produced a clear and substantial delay in remyelination which was most evident 4 weeks after the lesion. Both azathioprine and cyclophosphamide unexpectedly enhanced remyelination (by 50% at 28 days) when given over a 5 day period before surgery. When given beginning immediately after or 5 days after lysolecithin injection, the effect was still significant, although less pronounced. Silica quartz dust decreased the macrophage response and delayed the clearance of myelin debris but had little apparent effect on remyelination. These findings raise the possibility that some of the improvement seen following immunosuppressive therapy in MS patients could be due to enhanced myelin regeneration.

125.17 EVIDENCE FOR REMYELINATIVE POTENTIAL OF ADULT OLIGODENDROCYTES: COMPUTER RECONSTRUCTIVE ANALYSIS OF TISSUE CULTURE EXPERIMENTS.
M.K. Wolf, M. Brandenberg*, and S. Billings-Gagliardi. Department of Anatomy, University of Massachusetts Medical School, Worcester, MA 01605; and the Image Graphics Laboratory, Department of Neuroscience, Children's Hospital Medical Center and Department of Neuropathology, Harvard Medical School, Boston, MA 02115.

Previous work has established that when a fragment of mouse optic nerve is added to an organotypic culture of mouse cerebellum, the optic nerve oligodendrocytes are capable of migrating into the cerebellar tissue and forming myelin around cerebellar axons. This system was developed to study mutant mice with CNS hypomyelination, and previous work has utilized immature (0 to 14 postnatal day) optic nerve. We now find that adult optic nerve oligodendrocytes have similar capabilities. In six consecutive trials, adding fragments of 50 to 93 postnatal day mouse optic nerve to cultures of newborn mouse cerebellum which lacked resident myelinating oligodendrocytes, either because of a genetic mutation or previous drug treatment, produced myelin in some cultures each time. A few cultures produced abundant myelin, as previously obtained with immature optic nerve. Small size of the fragments, and dissection in Ca- and Mg-free saline seemed critical for success. This is direct experimental evidence that adult mammalian oligodendrocytes can potentially regenerate myelin following CNS injury. The experimental system can now be used to look for factors which promote regenerative behavior and to characterize this behavior in quantitative terms. For computer analysis, serial sections of a culture are mapped directly onto computer datafiles, via a digitally controlled microscope, a vector display system, and a digitizing tablet. Each such section map consists of contours delineating the position of the optic nerve and myelin. Contours are "tagged" so as to identify the corresponding structure in the section. The maps are then registered, stacked, and displayed as 3-dimensional reconstructions, which can be rotated and pseudocolored with perceived enhancement or suppression of any feature. Displays are recorded either by an X-Y pen plotter or by photography of the display screen. Additional software permits extraction of numerical data, such as interstructure distances, from the same section database. Numerical analysis completed to date shows that oligodendrocytes are capable of migrating at least 1.6 mm. Graphic analysis suggests that the true migration trajectories may be much longer.

125.18 INCREASED NUMBERS OF MICROGLIAL CELLS IN THE HYPOGLOSSAL NUCLEUS AND DORSAL MOTOR NUCLEUS OF THE VAGUS NERVE IN THE CAT FOLLOWING PERIPHERAL NERVE TRANSECTION: J.L. Cova* and H. Aldskogius. Depts. of Anat. and Neurosci., Med.Coll. Ohio, OH. 43699 and Dept. of Anatomy, Karolinska Institutet, Stockholm, Sweden.

Numerous previous studies have described an extensive proliferation of glial cells, particularly microglial cells, in the vicinity of axotomized motorneurons of rodents and lagomorphs. In a study on the adult and adolescent cat using paraffin sections (4 µm thick) no significant changes were observed in total number and density of perineuronal glial cells in the spinal cord ventral horn after brachial plexotomy (Cova, J.L., Aldskogius, H., Anat.Embryol. 169:303, 1984). However, microglial cells normally constitute only a small fraction of the entire glial cell population. Therefore, a significant increase of this type of cell could occur without altering the total number of glial cells significantly. In a recent study using plastic-embedded, 0.5 µm thick sections to permit differential counts of various glial cell types, no changes in their number or density were observed following crush injury of the hypoglossal nerve in the cat (Cova, J.L., Aldskogius, H., J.Comp.Neurol., 233:421, 1985). The present study extends these previous studies by examining the effect on the glial cell population in the hypoglossal nucleus and dorsal motor nucleus of the vagus nerve after nerve section. The data have been related to the longterm effects of nerve section on neuronal numbers in these two brainstem nuclei.

The left hypoglossal and right vagus nerves were transected in adult cats under barbiturate anesthesia. Ten, 20, 35 and 80 days later the animals were reanesthetized and perfused with aldehyde solutions. Blocks containing the hypoglossal nucleus and dorsal motor nucleus of the vagus nerve from both sides of animals surviving 10-35 days were embedded in Vestopal W, sectioned at 0.5 µm, stained with toluidin blue and analyzed quantitatively with regard to the number of various glial cell types as described before (Cova, J.L., Aldskogius, H., J. Comp.Neurol., 233:421, 1985). The brain stem from the 80-days survivals were embedded in paraffin, serially sectioned at 10 µm and stained with cresyl violet. Neuronal numbers were estimated from nucleolar counts in every tenth section. Intact animals were used as controls.

There was about a two-fold increase in the number of microglial cells in both examined nuclei ipsilateral to nerve transection. No changes were observed with regard to oligodendrocytes and astroglial cells. Neuronal counts indicated a slight cell loss in the hypoglossal nucleus and a somewhat more marked cell loss in the dorsal motor nucleus of the vagus nerve. These findings show that a perineuronal glial cell reaction occurs in the cat following peripheral nerve section. However, it appears to be considerably less prominent than in rodents and lagomorphs and may be related to a moderate degree of axotomy-induced neuronal degeneration.

125.19 NERVE INJURY STIMULATES APOLIPOPROTEIN SECRETION BY NON-NEURONAL CELLS. G. Jack Snipes*, and John A. Freeman. (SPON: D. Buxbaum). Dept. of Anatomy, VAnderbilt Univ, Nashville TN 37232.

Nerve trauma initiates significant changes in the overall composition of proteins secreted by non-neuronal cells in the rat. The expression of one such protein, as 37 kDa protein, correlates with the time-course of nerve growth both during neurogenesis and during nerve regeneration. In addition, the secretion of a 26 kDa protein by non-neuronal cells is associated specifically with central nervous system development and its response to injury. We now report that we have identified the 37 kDa protein as apolipoprotein E (apo E), and we present evidence that the 26 kDa protein is apolipoprotein Al (apoAl).

We have produced a highly specific rabbit antibody against the 37 kDa protein isolated from regenerating sciatic nerves. This antiserum recognizes a 36 Kda protein in rat serum which we have purified and identified as apolipoprotein E on the basis of its molecular weight, isoelectric point, and amino acid composition. In addition, the anti 37K antiserum recognizes apo E on western blots of authentic samples of high density lipoproteins (HDLs) and very low density lipoproteins (VLDLs) isolated from rat serum. The nerve 37 kDa protein essentially comigrates with apo E by two-dimensional electrophoresis, and shares a similar amino acid composition with apo E. The purified apo E specifically blocks the immunoprecipitation of [35-S] methionine labeled 37 kDa protein synthesized by non-neuronal cells. Thus, on the basis of its molecular weight, isoelectric point, amino acid composition, and immunological properties, we conclude that the 37 kDa protein associated with nerve development and regeneration is apo E.

Apolipoproteins and lipids together form lipoprotein complexes. In order to identify additional apolipoproteins synthesized in the nervous system, we labeled non-neuronal cell proteins with [35-S] methionine and immunoprecipitated apo E containing lipoprotein complexes with the anti-apo E antibody. The immunoprecipitated [35-S] labeled apolipoproteins, synthesized by non-neuronal cells, were identified by 1D- and 2D-PAGE. We found that optic, but not sciatic nerves secrete a 26 kDa apolipoprotein which we have identified as apo Al on the basis of its association with apo E, its molecular weight, and its isoelectric point.

We propose that these apolipoproteins are synthesized by phagocytic cells during development and following nerve injury for the purpose of mobilizing lipids produced as a consequence of axon and myelin degeneration. Additionally, it is interesting to consider the possibility that these lipoproteins are utilized by developing and regenerating neurons to deliver lipids necessary for axon growth.

125.20 METHOTREXATE DID NOT INHIBIT REACTIVE GLIOSIS AFTER FIMBRIA TRANSECTION IN ADULT RAT BRAIN. K.A. Ayyad* and J.S. Wendt* (SPON: Robert S. Sloviter). Dept. of Neurology, VA Medical Center and Univ of Tex Health Science Center, Dallas, TX 75216.

Reactive gliosis may be an impediment to CNS regeneration in mammals. Pre-treatment of adult rats with methotrexate (MTX) (2.5mg/kg I.P.) for 5 days followed by cortical lesions has been reported to inhibit glial proliferation (Immunopharmacol 5:91,1982). Also, intraventricular injection of MTX (10ul of a 200nM solution) just prior to perforant pathway transection has been reported to inhibit glial proliferation in denervated dentate gyrus in the rat (Brain Res 265:160,1983). The present pilot study was conducted to determine whether administration of MTX according to either of these protocols would inhibit reactive gliosis after fimbria transection in the rat.

In the first experiment 9 adult Sprague-Dawley rats received MTX 2.5mg/kg x 5 days; 7 control animals received corresponding saline injections. On day 5 hippocampal fimbria transections were performed stereotaxically with a fine surgical blade. By post-operative day 5, 8 of 9 MTX animals had died of intracerebral and/or gastrointestinal hemorrhage. One control died. The last MTX animal and 2 controls were sacrificed on post-op day 11, and frozen horizontal brain sections were stained for astrocytes by Cajal's gold chloride method. Extensive reactive gliosis was noted in all animals, and the MTX animal also had an intracranial hematoma.

In the second experiment fimbria transection was accompanied by intralesional injection of 10ul phosphate buffer with MTX (200nM, 20mM, 2mM or 0.2M) into the lesion site. In one animal the 0.2M dose was repeated 48 hr post-surgery. Two control animals received fimbria transection surgery and phosphate buffer injections. After sacrifice at 13 days post-op and tissue processing as above, all animals showed extensive gliosis around the lesion site.

These results suggest that MTX does not substantially inhibit reactive gliosis around a traumatic brain lesion.

PSYCHOTHERAPEUTIC DRUGS: ANXIOLYTICS

126.1 MIDAZOLAM DISCRIMINATION IN RATS: GENERALIZATION TESTS AND PRETREATMENT STUDIES. I.P. Stolerman, H.S. Garcha* and I.C. Rose*. Departments of Pharmacology and Psychiatry, Institute of Psychiatry, De Crespigny Park, London SE5 8AF, England.

The discriminative stimulus effects of drugs can provide highly specific methods for quantifying their central effects and for studying their mode of action. For studies on benzodiazepines, there may be advantages associated with training on a short-acting, water-soluble compound which appears not to have active metabolites. Rats were, therefore, trained to discriminate midazolam from saline with a two-bar operant conditioning procedure and food reinforcement (tandem VI-1 FR-10 schedule). Midazolam (0.4 mg/kg s.c.) or saline was injected 5 minutes before 10-minute training sessions. After 35-40 training sessions, 5-min extinction tests took place twice weekly, with training continuing on intervening days. Results were calculated with both quantitative and quantal indices of response, which yielded similar findings.

Midazolam (0.025 - 0.4 mg/kg) yielded a clear dose-response relationship: drug-appropriate responding, expressed as a percentage of the overall numbers of responses, averaged 3% after saline as compared with 97% after midazolam (0.4 mg/kg). Dose-related generalization occurred with several other benzodiazepines (flunitrazepam, 0.025 - 0.4 mg/kg s.c.: clonazepam, 0.1 - 0.8 mg/kg i.p.: diazepam, 0.5 - 8 mg/kg i.p.: chlordiazepoxide, 0.5 - 8 mg/kg i.p.: all 30 min before tests). Generalization to pentobarbitone (1.25 - 10 mg/kg s.c.) took place only at doses which severely suppressed overall rates of responding. Several drugs without anxiolytic or sedative-hypnotic effects were not generalized, even in doses which reduced response rates markedly (amphetamine, morphine, nicotine, oxotremorine, quipazine, and picrotoxin). The midazolam stimulus was detected as early as 2.5 min after injection, it was maximal from 5 - 15 min. and it disappeared after 30 - 90 min.

The benzodiazepine antagonist Ro 15-1788 (1 - 32 mg/kg i.p. 20 min before tests) completely blocked the discriminative effect of midazolam in a dose-related manner, and was not itself generalized. The GABA antagonist picrotoxin (0.2 - 1.6 mg/kg s.c. 20 min before tests) blocked generalization to pentobarbitone (7.5 mg/kg). However, picrotoxin did not block midazolam and Ro 15-1788 did not block generalization to pentobarbitone. Under the conditions used, the midazolam discriminative stimulus seemed to provide a highly specific behavioural assay for benzodiazepine-like central effects. The discriminative effects of midazolam and pentobarbitone in rats may be mediated through different, independent receptor sites.

126.2 INTERACTION OF PLATELET ACTIVATING FACTOR (PAF) WITH NEUROACTIVE DRUGS AND WITH NEURAL CELLS. E. Kornecki, R. Lenox, and Y. Ehrlich. Neuroscience Research Unit, Dept. of Psychiatry, Univ. of Vermont, Burlington, VT 05405.

Platelet activating factor (PAF) is a naturally occurring phospholipid (1-O-alkyl, 2-acetyl, glyceryl-3 phosphorylcholine) with potent biological effects. PAF has antihypertensive activity, induces bronchoconstriction and contraction of smooth muscle, and is one of the most powerful activators of platelets. We have reported previously that the triazolobenzodiazepine drugs, alprazolam and triazolam, act as specific and potent inhibitors of PAF-induced activation of human platelets (Science: 226, 1454, 1984). These findings suggest that the effectiveness of triazolobenzodiazepines in the treatment of certain neuropsychiatric disorders (e.g. agoraphobia and panic attacks) may involve interactions of the drugs with processes mediated by PAF or PAF-like phospholipids in the central nervous system. In the present study we have extended our investigation on the interaction of various neurotropic drugs with PAF-induced platelet functions, and examined the effects of PAF on neural cells grown in culture. Human platelets obtained from drug-free, 10 hr fasted, normal volunteers were collected and washed by passing platelet-rich-plasma through a Sepharose 2B column equilibrated in Tyrode solution (pH 7.4) containing 0.5mM $CaCl_2$. Platelet aggregation, secretion and shape change were measured with a Chronolog Lumi-aggregometer. The most potent inhibitor of PAF-induced platelet aggregation was the triazolobenzodiazepine triazolam (IC_{50}= 300 nanomolar). Inhibition by alprazolam gave an IC_{50} value of 500 nanomolar. Diazepam, a benzodiazepine without a triazole ring, had an IC_{50} value of 130 micromolar. Other benzodiazepines (chlordiazepoxide, RO5-4864, RO11-3624, oxazepam) had low potencies (IC_{50} values in the range of 45 to 90uM). Similarly, when using psychotropic drugs of other classes (imipramine, trazodone, pargyline, phenylzine) we found that higher drug concentrations (IC_{50} values from 20 to 500um) were required to inhibit PAF-induced platelet aggregation.

In parallel studies, cells of neuronal origin (clone NG108-15) were grown in a chemically defined (serum-free) medium supplemented with insulin, transferrin and linoleic acid, in the presence or absence of PAF for 1-6 days. Low PAF concentrations (0.1-1uM) enhanced the morphological differentiation of these cells and increased the proportion of cells bearing long neurites. In contrast, 5uM PAF induced loss of neurites and subsequently cell death.

These results suggest that low concentrations of PAF may play a regulatory role in neuronal function, whereas higher concentrations of PAF may contribute to neuronal damage induced by trauma. The triazolobenzodiazepine drugs, alprazolam and triazolam, may exert some of their therapeutic effects by inhibiting PAF-mediated cellular responses in the nervous system.

126.3 FURTHER INVESTIGATION OF THE ANTI-ANXIETY ACTIVITY OF SR 41378. A. Perio* R. Calassi*, J.P. Terranova*, R. Roncucci*, K. Biziere (SPON: L. Tapia-Arancibia). Sanofi Recherche, CRCM, Rue du Pr. J. Blayac, F-34082 Montpellier, France.

SR 41378 is the 3-(4'-hydroxy-piperidinyl)-6-(2,4 dichlorophenyl)-pyridazine. It is a potent hypnotic drug in animals (Biziere K. et al, Brit. J. Pharmacol., 84 : 168 P, 1985). As most of the sleep-inducing agents, it exhibits sedative myorelaxant and anticonvulsant activities in mice. In rats, it proved to relieve behavioral suppression induced by electric shocks in an approach-avoidance conflict test. This effect is not directly mediated by benzodiazepine receptors. Moreover, the compound genreralizes to the clonazepam cue in a drug discrimination paradigm (Biziere K. et al ., Brit. J. Pharmacol., 84 : 116P, 1985). The present experiment further investigates the anxiolytic properties of SR 41378.

Methods : i) Antagonism of the pentetrazole cue : male rats were trained to discriminate pentetrazole (20 mg/kg ip) from saline in a two lever operant chamber (method from Colpaert F.C. et al., Arch. Int. Pharmacodyn. Ther., 218 : 268, 1975). SR 41378 was injected ip 10 min prior to pentetrazole (i.e. 25 min before testing). ii) Male Sprague Dawley rats were trained in the conflict paradigm (procedure by Davidson A.B. and Cook L., Psychopharmacologia, 15 : 159, 1969). On test days animals were placed in Skinner boxes (Campden) 1h, 2h and 4h after dosing with SR 41378 (10 and 20 mg/kg ip), each session lasted 30 min. iii) Antagonism by CGS 8216 : the antagonist was injected ip 5 min before 10 and 20 mg/kg of SR 41378, the conflict test was carried out 30 min later.

Results : SR 41378 counteracted the pentetrazole cue. At 10 mg/kg it alleviated the behavioral suppression induced by electric shocks at the 1h session, and at 20 mg/kg it released punished responding for at least 2h. CGS 8216 completely reversed the desinhibitory action induced by 10 mg/kg of SR 41378 but not the reduction of responding elicited by 20 mg/kg.

Conclusions : The antagonism of the pentetrazole cue further confirms the anxiolytic property of SR 41378. In the conflict test, SR 41378 at low dose level is active for 1 hour. CGS 8216 reverses the desinhibition induced by SR 41378 but not the sedation. In a previous experiment RO 15-1788 did not antagonize SR 41378 in the same procedure. However it must be remembered that CGS 8216 unlike RO 15-1788 antagonizes also the desinhibitory activity of barbiturates and carbamates (Petrack B. et al., 14th CINP congress, FLorence, june 1985). Therefore the mechanism of action of SR 41378 could be similar to that of barbiturates or carbamates.

126.4 SR 41378, A HYPNOTIC AMINOPYRIDAZINE : ELECTROENCEPHALOGRAPHIC ASSESSMENT IN THE RAT. V. Santucci*, M. Fournier*, J.P. Chambon and K. Bizière. Dept. of Neurobiology, Sanofi Recherche, Rue du Pr. J. Blayac, 34082 Montpellier Cedex, France.

SR 41378, 3-(hydroxy-piperidinyl)-6-(2,4 dichlorophenyl)-pyridazine, is a chemically original psychotropic compound with both anticonvulsant and hypnotic properties (Santucci et al., Neurosci. Lett., supp. 18:204, 1984 ; Bizière et al., Brit. J. Pharmacol., 84:198, 1985). The purpose of the present study was to evaluate the electroencephalographic (EEG) as well as hypnotic effects of SR 41378 in comparison to those of diazepam (DZP), pentobarbitone (PB) and secobarbital (SB). The compounds were studied per se, against the insomnia induced by the i.p. injection of caffeine (10 mg/kg) and in interaction with the benzodiazepine antagonist CGS 8216 (10 mg/kg). Male Sprague-Dawley rats (200-400 g) were chronically implanted with cortical electrodes in order to record cable-transmitted EEG. The duration of slow-wave sleep (SWS) was measured by visual inspection. The EEG was continuously recorded for 6 h, in sessions separated by 7-day intervals. The sessions were distributed according to a modified latin square matrix paradigm. When administered alone, SR 41378 (10, 30, 100 mg/kg p.o.) induced the appearance of fast-frequency activities in the EEG which were also present under PB (10, 30, 60 mg/kg p.o.), SB (30, 60 mg/kg p.o.) and, to a lesser extent, DZP (1, 3, 10 mg/kg p.o.). Moreover, like PB and SB, SR 41378 induced spindle-like activities, mainly visible during wakefulness. SR 41378 increased SWS duration in a dose-dependent manner, which was also the case for DZP, PB and SB. SR 41378 was equipotent to PB and exhibited a similar time course of activity. SR 41378 (30, 100 mg/kg p.o.), as well as PB (30, 60 mg/kg p.o.) antagonized the wakefulness-inducing effects of caffeine. It was found that CGS 8216 induced a diphasic profile of activity, with facilitation of wakefulness followed by increase of SWS, as opposed to symmetrical profile for DZP. CGS 8216 reduced the hypnogenic activity of SR 41378 (10 mg/kg p.o.), PB (30 mg/kg p.o.) and DZP (10 mg/kg p.o.). As SR 41378, like the barbiturates, does not bind to the benzodiazepine receptor, the mechanism of their interaction with CGS 8216, at the EEG level, remains to be elucidated. It is concluded that SR 41378 has a potent hypnogenic activity in the rat, which resembles more that of barbiturates, than that of DZP.

126.5 SEX DIFFERENCES IN BEHAVIORAL RESPONSES TO THE PUTATIVE ANXIOLYTIC TVX Q 7821. J. E. Johnston,* J. P. Ryan, and R. L. Isaacson. Department of Psychology and Center for Neurobehavioral Sciences, SUNY-Binghamton, Binghamton, New York 13901.

The putative anxiolytic, TVX Q 7821, has been compared to diazepam in regard to its effects on aggressive and fear-related behaviors, sensorimotor skills, and pentylene-tetrazol-induced convulsions. This drug has been shown to bind with high affinity and regiospecificity to 5-HT_1, rather than benzodiazepine, receptors in calf and rat hippocampus (Glaser et al., Neurosci. Abst. 10: 259, 1984; Traber et al., Brain Res. Bull. 12: 741, 1984). The present study compared TVX Q 7821 to the behavioral effects of the serotonergic agents methysergide and quipazine in the open field in both male and female rats. The animals were pretreated with either saline, quipazine, or methysergide and subsequently received either saline or TVX Q 7821 (all drugs 10 mg/kg). The locomotor activity of males was reduced by quipazine. However, females responded heterogeneously to quipazine, i.e., the activity levels of some females were decreased while others were unaffected. Variance changes were evaluated by Levene's test for homogeneity of variance. Methysergide did not affect the locomotor activity of either sex. Although TVX Q 7821 administration did not affect saline-pretreated males, females again responded heterogeneously to the drug. This drug potentiated the effect of quipazine in males and the activity levels of females that received both drugs were uniformly decreased. Finally, TVX Q 7821 in combination with methysergide did not affect the locomotor activity of males, but this combination of drugs consistently decreased such activity in females. The discovery of sex differences in response to TVX Q 7821 was unexpected as was the fact that it frequently acted to potentiate the effects of other serotonergic drugs when not producing an effect of its own. Our results indicate that: (1) TVX Q 7821 may act as a partial or regionally specific serotonergic agonist and (2) its effects may interact with the hormonal constitutions of the animals.

126.6 LACK OF WITHDRAWAL EFFECTS IN MICE AFTER CHRONIC ADMINISTRATION OF THE NON-SEDATING ANXIOLYTIC CGS 9896. C. A. Boast, S. C. Gerhardt*, Z. L. Gajary* and W. N. Brown* (SPON: J. J. Welch). Neurosci. Res., Pharma Div., CIBA-GEIGY Corp., Summit, NJ 07901.

CGS 9896 is a pyrazoloquinoline with a nonsedating potential anxiolytic profile (Drug Dev Res, 4:75 , 1984). The drug is a mixed agonist/antagonist at benzodiazepine binding sites (JPET, 231:572, 1984) and might be expected to show reduced withdrawal effects, compared to diazepam, after chronic administration.

Male CF-1 mice were treated once daily with vehicle, diazepam (30 mg/kg p.o.) or CGS 9896 (30 mg/kg p.o.) for four weeks. Animals were tested behaviorally 1,3,8 or 15 days after this drug treatment. At each time period, groups of mice were treated with vehicle (spontaneous withdrawal), or the benzodiazepine inverse agonist CGS 8216 (30 mg/kg p.o.) (precipitated withdrawal). Thirty min following this treatment, movement time and distance travelled were recorded for 15 min in motor activity chambers (Omnitech Digiscan). At one hour, pentylenetetrazol (PTZ) (2.5 mg/ml i.v.) was infused in increments until each mouse showed seizure activity. The total dose (mg/kg) of PTZ required to produce the seizure was recorded.

Movement time was not altered in any treatment condition. Distance travelled was reduced in the 1-day and 3-day diazepam-treated, precipitated withdrawal groups only. PTZ threshold was reduced by CGS 8216. The diazepam-treated spontaneous withdrawal groups showed further threshold reductions at 1, 8, and 15 days of withdrawal. After 15 days of withdrawal, the diazepam-treated spontaneous withdrawal group also showed a lowered threshold compared to vehicle-treated mice. Animals treated chronically with CGS 9896, showed no differences in seizure threshold compared to controls at any time.

The present techniques appear to be useful for measuring withdrawal effects after drug-induced benzodiazepine binding site modulation, and indicate that chronic treatment with CGS 9896 does not induce any of these signs. This lack of withdrawal in mice following chronic CGS 9896 is in agreement with a previous study in baboons (Drug & Alcohol Dependence, 14:11, 1984) and suggests a major clinical advantage of this new nonsedating anxiolytic.

126.7 A NON-SEDATING ANXIOLYTIC, CGS 9896, IS DIFFERENTIATED FROM DIAZEPAM IN BEHAVIORAL TESTS OF TOLERANCE IN MICE. S. C. Gerhardt*, Z. L. Gajary*, W. N. Brown* and C. A. Boast. Neurosci Res., Pharma Div., CIBA-GEIGY Corp., Summit, N.J. 07901.

CGS 9896 is a recently described (Drug Dev Res, 4:75, 1984) pyrazoloquinoline with a nonsedating potential anxiolytic profile. The drug binds to benzodiazepine sites and consequently might be expected to show tolerance after chronic administration (e.g. Psychopharmacol., 62:61, 1979). To test this possibility, CF-1 male mice were injected once daily with vehicle, diazepam (3.0, 10 or 30 mg/kg p.o.) or CGS 9896 (3.0, 10 or 30 mg/kg p.o.) for periods of 1, 2, 3 or 4 weeks. Additional groups received drug acutely on the day of behavioral assessment. Thirty min after the last dose, movement time and distance travelled were recorded for 15 min. in motor activity monitors (Omnitech Digiscan). One hour after dosing, traction reflex was assessed, and pentylenetetrazol (PTZ)(10 mg/ml i.v.) was then infused in increments. The total dose of PTZ (mg/kg) required to produce a seizure was recorded.

Movement time was reduced by the acute 10 and 30 mg/kg doses of diazepam. After chronic diazepam, this reduction was no longer apparent. This parameter was not altered by CGS 9896 at any dose or time. Distance travelled was increased by 3 mg/kg diazepam, regardless of treatment duration. The 10 and 30 mg/kg doses of diazepam slightly reduced the distance measure when given acutely but increased it after chronic administration. CGS 9896 increased distance travelled after acute administration, but this effect was no longer apparent after 4 weeks of treatment. Traction was impaired after acute administration of diazepam. After chronic dosing, however, this impairment was considerably reduced. CGS 9896 did not impair traction at any dose or time. PTZ seizure threshold was increased after acute treatment with either drug. Chronic diazepam treatment reduced threshold relative to the acute values. After chronic CGS 9896, threshold was not different from acute values.

These data indicate that tolerance for the anticonvulsant and muscle relaxant properties of diazepam occurs after one week of daily dosing in the mouse. In contrast, CGS 9896 did not induce muscle relaxation and did not show tolerance for its anticonvulsant action. These differential effects may reflect subtle modulation of benzodiazepine receptors.

126.8 THE DIFFERENTIAL SEDATIVE/MUSCLE RELAXANT PROFILES OF SEVERAL CLASSICAL AND NOVEL ANXIOMODULATORS IN FOUR BEHAVIORAL PARADIGMS. C.L. Corradi, D.A. Bennett, J. Diverio* and D.E. Wilson*. Neurosci. Res., Res. Dept., Pharm. Div., CIBA-GEIGY Corp., Summit, N.J. 07901.

While classical benzodiazepine anxiolytic drugs are effective in alleviating anxiety, they also produce sedation and muscle relaxation which often interfere with normal functioning. Various novel anxiolytic compounds have been identified which induce fewer side effects. Preclinical profiling of the sedative/muscle relaxant properties of these compounds is very often a prerequisite for clinical evaluation.

In the present investigation, various anxiomodulators (benzodiazepine agonists, partial agonists and antagonists) were evaluated in four tests designed to predict sedative/muscle relaxant effects in rats: Rotorod performance, motor activity measures of distance travelled and movement time, potentiation of hexobarbital-induced sleep time or potentiation of alcohol-induced rotorod deficit. A profiling of these compounds and a comparison of the sensitivity of the various behavioral measures were obtained.

The results separate these anxiomodulators into four distinctive groups. Diazepam, chlordiazepoxide, alprazolam, CL 218,872 and pentobarbital showed sedative/muscle relaxant effects at low doses in each of the four test systems. A different profile emerged with halazepam, premazepam and quazepam. These compounds did not induce rotorod deficit and produced motor activity reductions only at high doses (100-300 mg/kg p.o.), if at all. Some deficit was noted in the drug potentiation studies with an increase of sleep time produced by quazepam (300 mg/kg p.o.), halazepam (100 mg/kg p.o.) and premazepam (10 mg/kg p.o.). Each of these drugs interacted with alcohol at relatively low doses (1-10 mg/kg p.o.). A third profile was exhibited by CGS 9896 and fenobam. These compounds were without effect in each of the test systems with the exception of alcohol interaction. Even here, the interaction of these compounds was only noted at doses of 30-100 mg/kg p.o. CGS 8216 and CGS 9895 formed a fourth profile as these compounds, producing benzodiazepine antagonist activity, did not induce sedation or muscle relaxation in any of the four behavioral paradigms. CGS 8216 actually increased some of the parameters in the motor activity study.

Of the behavioral assays used, the drug combination paradigms (hexobarbital and alcohol) appeared to be the most sensitive, although some of the interaction effects were only noted at relatively high doses. Rotorod and motor activity paradigms easily characterized sedative/muscle relaxant effects of the classical drugs and identified most of the novel compounds as free from side effects. For the most efficient evaluation of novel compounds, it appears that test systems measuring the effects of the drug alone in addition to test systems that investigate the potential potentiation of another drug effect should be conducted.

126.9 EVIDENCE THAT CGS 9896 AND DIAZEPAM DIFFER IN THEIR ACTIONS ON GABA TRANSMISSION. S.L. Fallon* and C.M. Sinton. Research Dept., Pharmaceuticals Division, Ciba-Geigy Corp., Summit NJ 07901.

CGS 9896 is a nonbenzodiazepine anxiolytic with potency approximately equal to that of diazepam in neurochemical and behavioral tests. Although it binds with high affinity to benzodiazepine receptors in vitro and in vivo, ^{3}H-Flunitrazepam binding and photo-labelling studies indicate that CGS 9896 may act via a mechanism distinct from that of benzodiazepine agonists like diazepam. To characterize further the differences in the central actions of the two compounds, we examined the effects of CGS 9896 and diazepam on the firing rate of single units recorded in the Substantia Nigra Zona Reticulata (ZR). This region is innervated by the GABA-ergic striatonigral tract and it possesses the highest density of GABA terminals in the brain. Neuronal activity in the ZR has been shown to be sensitive to GABA modulation, and any differentiation in response at this level is likely to reflect differences in action on GABA transmission. Rats were anesthetized with chloral hydrate (400 mg/kg i.p.) and a glass microelectrode was lowered stereotaxically to the ZR. Units were identified on-line by their characteristic firing pattern and rate, and by their position just ventral to nigral dopamine cells. The two anxiolytics were also tested against the benzodiazepine antagonist CGS 8216. All drugs were administered i.v. through a tail vein - in control experiments, the vehicle was administered alone. Confirming previous studies, diazepam (1 mg/kg) produced prolonged reductions in ZR firing rates of up to 70 %. This effect was reversed by treatment with CGS 8216 (1 mg/kg). In contrast, CGS 9896 (1 mg/kg) produced only small ZR firing rate reductions which lasted for approximately 5 min. When diazepam was administered following CGS 9896, the inhibitory action of the former compound was blocked. Conversely, when CGS 9896 was administered following diazepam, CGS 9896 was without effect on the inhibition induced by diazepam. CGS 8216 alone increased the firing rate of ZR neurons. In conjunction with data from binding studies, these results indicate that CGS 9896 and diazepam may produce their anxiolytic effects by competitive action at overlapping recognition sites on the benzodiazepine receptor; both compounds can also be antagonized by CGS 8216. Despite these similarities, however, CGS 9896 and diazepam appear to differ in their action on the benzodiazepine-GABA receptor complex. Diazepam is known to act by increasing the opening frequency of the chloride ionophore in response to GABA, whereas the results reported here imply that CGS 9896 may have only a minimal effect on GABA transmission. These findings could have important implications for the dependence liability and adaptation effects that occur after prolonged administration of anxiolytics.

126.10 ANTICONFLICT ACTION OF MUSCIMOL IN THE LATERAL SEPTUM OF THE RAT. Jacqueline N. Crawley, Robert C.Drugan, Phil Skolnick, and Steven M. Paul. Clinical Neuroscience Branch, NIMH, and Laboratory of Bioorganic Chemistry, NIADDK, National Institutes of Health, Bethesda, MD 20205.

Several brain areas within the limbic system have been proposed to be critical in the modulation of anxiety and the facilitatory effects of the benzodiazepines on anticonflict behavior. GABA-mimetics as well as benzodiazepines have been shown to increase punished responding in a "thirsty-rat" conflict test when microinjected into the lateroposterior and basolateral nuclei of the amygdala (Scheel-Krüger, J. and Petersen, E., Eur. J. Pharmacol., 82:115-116, 1982). Intracerebroventricular (icv.) muscimol has also been demonstrated to have an anticonflict action (Cananzi, A., Costa, E., and Guidotti, A., Brain Res., 196: 447-453, 1980).

In the present study, we investigated the efficacy of musimol microinjected into the lateral septum on conflict behavior in the "thirsty-rat" conflict test. Rats were implanted with a stainless steel 24 gauge hypodermic cannula (A-P + 0.2, lat. - 0.7, vert 4.5 mm) into the lateral septum. One week later, rats were water deprived for 24 hours. Muscimol (0.1, 2, 5, 10, or 1000 ng) or vehicle (artificial CSF) was infused in a volume of 0.4 µl over a one minute period through a 31 gauge injection tube 5 minutes prior to the conflict test session. A dose-dependent increase in punished responding was observed, which reached significance at 5 ng of musicimol. However, at higher doses sedation and ataxia were observed, markedly reducing the number of approaches to the water spout.

The present data support the hypothesis of Gray (Gray, J. and McNaughton, N., Neurosci. Biobehav. Rev., 7:119-188, 1983) suggesting that the lateral septum may be a critical structure in anxiety-related behaviors. Moreover, the effective dose (5 ng) of muscimol used in the present study is much lower than those used in previous studies, e.g. 25 ng and 150 ng injected into the amygdala or ventricles, suggesting greater sensitivity of the lateral septum to the anticonflict actions of muscimol.

126.11 **ANXIOLYTIC TESTING OF BUSPIRONE IN RODENTS.** J. H. Porter, D. N. Johnson, and J. Y. Jackson* (SPON: G. H. DeVries). Department of Psychology, Virginia Commonwealth University and A. H. Robins Co., Richmond, VA 23261.

Buspirone, a dopamine antagonist, has been reported to have anxiolytic activity in humans. The drug was developed in the 1970s as a neuroleptic, but it produced only transient antipsychotic effects. Its anxiolytic potential was first realized during these early clinical trials; however, some have reported that it does not appear to possess the typical anxiolytic effects in animals. We have studied buspirone in a variety of anxiolytic testing procedures in rodents and compared it with both typical and atypical anxiolytics.

While both diazepam (ED_{50} = 1.0 mg/kg) and cartazolate (ED_{50} = 10.6 mg/kg) blocked seizures induced by electroconvulsive shock in mice (N = 5-8/group, buspirone was inactive in doses up to 100 mg/kg (IP). Similarly, buspirone (3.16, 10, and 31.6 mg/kg) failed to block seizures induced by picrotoxin; whereas, cartazolate (ED_{50} = 38.6 mg/kg) did block this chemically induced seizure. Other effects characteristic of most anxiolytics, such as muscle relaxation and sedation, were not seen with buspirone. In a disinhibition procedure (Poschel, Psychopharmacologia, 19:193, 1971) adult female rats (N = 5/group) were given access to a novel food (diluted, sweetened, condensed milk) for 4 hr. Chlordiazepoxide (20 mg/kg, PO; mean intake = 10.2 mL), but not buspirone (50 mg/kg, PO; mean intake = 5.2 mL), significantly increased the amount of milk consumed compared with control animals (vehicle; mean intake = 2.6 mL).

Finally, buspirone (IP) was assessed in a modified conflict procedure (Geller & Seifter, Psychopharmacologia, 1:482, 1960). Adult male rats (N = 34) were maintained at 80% body weight and tested in daily 30-min sessions on a multiple, fixed-interval 1-min (food reward only), fixed-ratio 1 (food plus scrambled foot shock) schedule. As shown in the table below, buspirone produced a significant increase in punished responding at the 3 lowest doses, but the magnitude of its antipunishment effect was much less than that for diazepam.

These findings are in agreement with recent reports (e.g., Riblet et al, Psychopathology, 17:69, 1984) that buspirone, unlike the benzodiazepines, lacks anticonvulsant, sedative, and muscle-relaxant properties. However, buspirone is active in the Geller-Seifter conflict procedure that is predictive of antianxiety activity.

Mean Punished Responding in the Conflict Test (% of Control Day)

	Vehicle	1.25	2.5	5.0	10	20 mg/kg
Buspirone	120.8	217.4*	317.2*	243.8*	111.1	46.9
Diazepam	127.1	2 mg/kg = 1451.1*		4 mg/kg = 2179.3*		

*Significantly different from vehicle ($p<0.05$).

126.12 BUSPIRONE AND MJ-13805 SELECTIVELY ATTENUATE FEAR AS MEASURED WITH THE POTENTIATED STARTLE PARADIGM. M. Davis, J.H. Kehne, and J.V. Cassella. Dept. Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508.

Benzodiazepines have been widely used in the treatment of anxiety in humans. Recently, buspirone, a compound structurally unrelated to benzodiazepines, has been reported to be anxiolytic with minimal muscle relaxant or sedative side effects. A useful model system for studying fear or anxiety in animals is the potentiated startle paradigm whereby the amplitude of acoustic startle is enhanced by eliciting the response in the presence of a light previously paired with a shock. Potentiated startle is reduced by anxiolytic drugs including benzodiazepines (i.e., diazepam). Given buspirone's reported clinical efficacy, the major aim of the present study was to investigate the effects of buspirone on the potentiated startle response.

Initially, rats were fear conditioned with multiple presentations of a light paired with a foot shock. Subsequently, rats were tested for potentiated startle by presenting the startle stimulus in the presence of the light that had previously been paired with shock. Subcutaneous injections of buspirone immediately before testing resulted in a dose-dependent blockade of potentiated startle. The ED-50 was approximately 0.7 mg/kg, in close agreement with clinically effective doses. Buspirone selectively blocked potentiated startle without reducing baseline startle amplitude. MJ-13805, a buspirone analog with a different neurochemical profile, has also been reported to have anxiolytic actions. In the present study, subcutaneous injection of MJ-13805 dose-dependently blocked potentiated startle without altering baseline. The ED-50 for MJ-13805 was approximately 2.0 mg/kg. In a control study, buspirone was compared with the antipanic/-antidepressant drug, imipramine. While imipramine is beneficial in treating panic disorder, it does not have anxiolytic properties. Neither acute (10 mg/kg ip injected 15 minutes before testing) nor chronic administration (10 mg/kg/day for 21 days) of imipramine reduced potentiated startle despite adequate plasma levels of the drug.

In summary buspirone and MJ-13805 showed potent and selective anxiolytic activity using the potentiated startle paradigm. Current studies are investigating the mechanism of buspirone's action on this model system.

126.13 BUSPIRONE DIFFERENTIALLY AFFECTS HYPER-RESPONSIVENESS TO APOMORPHINE AFTER BILATERAL OR UNILATERAL 6 OHDA LESIONS IN RATS. A. Baduel*, L. Stinus* and M. Le Moal (SPON :S. Laroche). INSERM U-259 Psychobiologie des Comportements Adaptatifs, rue Camille Saint-Saëns, 33077 Bordeaux, France.

The mechanism of action of buspirone (Bus) a potent non-benzodiazepine anxiolytic drug is unknown. However binding studies and studies which reveal neuroleptic-like properties suggest an interaction with DA neurons. Since Bus exerts only subtle effects on spontaneous or drug-induced behaviors in control rats, we studied its effects on hyper-responsiveness to apomorphine (Apo) after 6 OHDA lesions of DA neurons.

In experiment 1, rats received bilateral 6 OHDA lesions of either n. accumbens or striatum. After DA mesolimbic denervation, Apo (50µg/kg sc) induced locomotor hyperactivity. After DA nigrostriatal denervation, Apo (500µg/kg sc) induced intense stereotyped behavior. In both cases, the delay between lesion and test was critical for the effect of Bus : at 4 weeks post lesion, Bus (1mg/kg sc) reduced Apo-induced behaviors and at 8 weeks post lesion, Bus totally blocked both behaviors. In experiment 2 we studied Apo-induced (50µg/kg sc) contralateral turning after unilateral 6 OHDA lesions of lateral hypothalamus. Bus reduced turning (25%) at 2 weeks post-lesion while it enhanced turning (60%) at 7 weeks post-lesion.

The opposing results obtained after bilateral and unilateral lesions are difficult to reconcile but may be explained by complex differences in neuronal state occurring after the two types of lesion. Our results indicate that in addition to its acute anxiolytic effect, Bus must have other pharmacological properties which are revealed only on a pathological substrate. The delay needed to obtain a robust effect of Bus suggests that this drug is acting on long term disturbances and thus could be of therapeutic use in psychopathological disorders. Experiment 1 indicates a neuroleptic-like action of Bus, however it does not act as a DA receptor antagonist as indicated by experiment 2. It may be that Bus acts on neurons post-synaptic to DA receptors. The present results may provide a pharmacological model for understanding the mechanisms of action of Bus.

126.14 BUSPIRONE EFFECTS IN A PRIMATE MODEL OF EXTRAPYRAMIDAL MOTOR DYSFUNCTION. D.A. Downs, S.E. Harrigan*, and T.G. Heffner. Department of Pharmacology, Warner-Lambert/Parke-Davis, Ann Arbor, MI 48105

Buspirone is a novel anxiolytic which lacks affinity for benzodiazepine receptors but appears to have both dopamine agonist and antagonist actions. Because drugs which alter central dopaminergic function can cause or attenuate extrapyramidal side-effects in man, we tested buspirone in a primate model of extrapyramidal dysfunction (EPD). Cebus monkeys were sensitized to the acute dyskinetic effects of haloperidol by repeated doses over several weekly intervals. In these sensitized monkeys, acute haloperidol and other neuroleptics but not clozapine reliably induced EPD characterized by tonic extension of the limbs, twisting of the neck or upper torso, protrusion of the tongue, chewing, biting, or sucking movements, circling or thrashing about the cage, and other dyskinesias or dystonias. When given approximately four hours after haloperidol, low doses of buspirone (0.3 mg/kg i.m.) reversed haloperidol-induced acute EPD. Apomorphine, atropine, and clozapine produced similar reversals of haloperidol-induced EPD. However, the same or higher doses of buspirone (10-32 mg/kg p.o., 1.0 mg/kg s.c., and 0.3 mg/kg i.m.) when given alone caused dose-related EPD in the haloperidol-sensitized monkeys. Although the quality and diversity of signs elicited by buspirone resembled those caused by haloperidol, they were generally of shorter duration. In addition, tremors, salivation, and marked depression were seen with buspirone but not with comparably active doses of haloperidol. Like haloperidol and other neuroleptics, buspirone caused EPD at approximately the same doses which blocked conditioned avoidance responding in non-sensitized cebus monkeys, and these buspirone-induced EPD were reversed by apomorphine and atropine. These effects of buspirone are consistent with mixed agonist and antagonist actions on dopaminergic neurotransmission, and indicate, to the extent that the primate model is predictive, that high doses of buspirone may cause haloperidol-like extrapyramidal side-effects (EPS) in man.

127.1 **THE MECHANISM OF ACTION OF MPTP AND MPP ON DOPAMINE RELEASE FROM THE RAT CORPUS STRIATUM AND SUBSTANTIA NIGRA SUPERFUSED IN VITRO.** G.D.Chang* and V.D.Ramirez (SPON:G.Davis). Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

The action of N-methyl-4-pheynl-1,2,3,6-tetrahydropyridine (MPTP) and N-methylphenylpyridine (MPP) on dopamine (DA) metabolism was examined in the rat corpus striatum (CS) and substantia nigra (SN) using an in vitro superfusion system. Adult male rats were killed by decapitation between 10:00 and 10:40. The corpus striatum from both sides of the brain of one animal was dissected out and superfused with Krebs-Ringer Phosphate medium, pH 7.4 containing 0.18% glucose (KRP). For the study with SN, tissue from three animals was used for each superfusion chamber. Following a 30-min stabilization period, perfusate samples were collected on ice for seventeen 15-min intervals. For the experimental groups, 10^{-6}M and 10^{-5}M of MPP or 10^{-5} and 10^{-4} of MPTP was administered for 45 min starting from interval four. All groups received a 15 min infusion of 30 mM K^+ in KRP at interval 13. Twenty µl of untreated perfusate samples were then subjected to HPLC-EC analysis of DA and 3,4-dihydroxyphenylacetic acid (DOPAC).

The rate of DA release from control CS decreased significantly during the first two hours of superfusion and then reached a stable release rate of about 3.0 pg/mg/min while DOPAC release rate retained a constant value of 9.5 pg/mg/min one hour after superfusion. MPTP, at 10^{-5}M and 10^{-4}M, suppressed DOPAC release rate to 50 and 25% that of control, respectively. In addition, at 10^{-4}M, MPTP caused an increased in DA release from rat CS (7.04±1.31 pg/mg/min vs 2.93±0.86 pg/mg/min at interval 10). On the other hand, at 10^{-6}M and 10^{-5}M, MPP exerted very potent and rapid inhibition of DOPAC output and stimulated DA release in a dose-dependent manner. The peak DA release was noted 45 min following 10^{-5}M MPP (44.99±17.74 pg/mg/min vs 7.21±3.23 pg/mg/min) and 75 min following 10^{-6}M MPP (12.89±4.72 pg/mg/min vs 2.93±0.86 pg/mg/min). Furthermore, pretreatment of MPP markedly potentiated K^+-stimulated DA release from CS.

The release rates of endogenous DA and DOPAC from SN were much lower than those from CS. Unfortunately, 60 min after superfusion, output of DA from SN became barely detectable in control group. However, with 10^{-5}M MPP infused for 45 min, a significant increase in DA release was evoked (2.60±0.58 ph/mg/min at interval seven vs 0.64 pg/mg/min the lowest detectable value). Interestingly, DOPAC release from SN was not affected by 10^{-5}M MPP and the DOPAC release profiles from control and MPP groups were superimposable. The possible mechanism of action of these two drugs on DA metabolism in nigrostriatal neurons will be discussed.

127.2 EFFECTS OF 1-METHYL-4-PHENYL-PYRIDINIUM ON MONOAMINE OXIDASE AND ON NIGROSTRIATAL DOPAMINE NEURONS. M. L. Leavitt*, M. L. Gittings*, S. K. Hemrick-Luecke*, D. W. Robertson* and R. W. Fuller (SPON: W. E. Hoffman). Biomed. Sci. Dept., Southwest Missouri State Univ., Springfield, MO 65804 and Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

1-Methyl-4-phenyl-pyridinium (MPP+) is a metabolite of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) that has been implicated in the neurotoxic effects of MPTP on nigrostriatal dopamine neurons (Chiba et al, Biochem. Biophys. Res. Commun. 120:574, 1984). MPP+ iodide was synthesized, and some of its in vitro and in vivo effects were compared to those of MPTP.

MPP+, like MPTP, inhibited rat brain mitochondrial monoamine oxidase (MAO) in vitro. Like MPTP, MPP+ was a competitive inhibitor of MAO-A and a noncompetitive inhibitor of MAO-B. MPP+ (Ki = 2 µM) was more potent than MPTP (Ki = 9 µM) as an inhibitor of MAO-A, but was less potent than MPTP as an inhibitor of MAO-B (Ki values were 370 and 106 µM, respectively).

In mice, MPTP HCl injected systemically (20 mg/kg s.c. daily for 4 days) resulted in marked depletion of striatal dopamine, DOPAC (3,4-dihydroxyphenylacetic acid) and HVA (homovanillic acid) one week after the last dose. MPP+ iodide injected in the same way was lethal to 5 of 8 mice. In the 3 surviving mice and in mice treated in the same way with 10 mg/kg of MPP+, a nonlethal dose, there was no depletion of striatal dopamine at one week. The ineffectiveness of MPP+ probably indicates the inability of the quaternary nitrogen compound to cross the blood-brain barrier.

MPP+ was administered intranigrally to male Sprague-Dawley rats. Stainless steel guide cannula were chronically implanted with the tip extending 1 mm dorsal to the substantia nigra pars compacta. Following recovery, rats were infused daily for 3 days with either 10 µg MPP+ iodide or saline (5 µl) via an injector cannula that projected 1 mm beyond the guide. On the fifth day after intranigral microinjection, rats were observed subsequent to treatment with the indirect dopamine agonist, d-amphetamine (5 mg/kg). Two days later, striata from both sides of the brain were removed for analysis. Behavioral effects including contralateral circling were observed acutely after MPP+ administration. Amphetamine induced ipsilateral rotation. Marked reductions in the striatal concentrations of dopamine (55%), DOPAC (50%) and HVA (40%) were found in ipsilateral vs. contralateral striata.

The data suggest that MPP+ can be neurotoxic to nigrostriatal dopamine neurons and that MPTP administration may be a means of introducing MPP+ into the region of these neurons. MPP+ may release dopamine and inhibit its oxidation by MAO-A, but there is no direct evidence that these actions are essential to the neurotoxic effect of MPP+.

127.3 MPTP ALTERS BOTH MESO-LIMBIC AND NIGROSTRIATAL DOPAMINERGIC SYSTEMS IN MICE. M.Gupta, S.Y.Felten and D.L.Felten. Dept. of Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

N-Methyl-4-Phenyl-1,2,3,6-tetrahydropyridine(MPTP) alters nigrostriatal dopamine neurons in humans, monkeys, and mice. Some reports suggest that MPTP also affects other monoaminergic systems, perhaps paralleling well established neurochemical changes reported in humans with Parkinson's disease. The present study was undertaken to investigate the extent to which MPTP alters other monoaminergic systems in addition to the nigrostriatal dopamine system. Male Swiss-Webster mice were injected intraperitoneally with MPTP at doses of 3, 30 or 60mg/kg body weight for three consecutive days. Control animals received vehicle injections. All mice were sacrificed by decapitation 21 days following the last injection. The brains were removed and microdissected to permit neurochemical and neuroanatomical examination of individual nuclei containing cell bodies and terminal projections from nigrostriatal and meso-limbic dopaminergic systems, from noradrenergic systems, and from serotonergic systems. Dopamine, norepinephrine, epinephrine, and serotonin levels from these microdissected regions were analysed using high-performance liquid chromatography with electrochemical detection (LCEC). MPTP treatment depleted the nigrostriatal system of its dopamine content in a dose dependent manner. In addition, high dose treatment with MPTP also depleted dopamine content in nucleus accumbens and olfactory tubercle, the major terminal fields for the meso-limbic dopamine projection from the ventral tegmental area. However, dopamine levels in mediobasal hypothalamus were unaltered with MPTP treatment at all doses. Additional alterations in serotonin levels were found in specific nuclei. These findings suggest that both the nigrostriatal and meso-limbic dopamine systems are susceptible to toxic damage from MPTP administration. Since both of these dopaminergic systems show degenerative changes in humans with Parkinson's disease, we suggest that MPTP treatment in mice may provide a good animal model for investigating neurodegenerative phenomenon and potential therapeutic approaches that may apply to Parkinson's disease.

127.4 CHRONIC TREATMENT OF MICE WITH 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP) RESULTS IN A DECREASE OF RETINAL DOPAMINE AND THE APPEARANCE OF LIPOFUSCHIN-LIKE MATERIAL.
N.H. Neff, A. Mariani and M. Hadjiconstantinou. Lab. of Preclinical Pharmacology, NIMH, St. Elizabeth's Hosp., Washington, DC 20032 and Lab. of Neurophysiology, NINCDS, Bethesda, MD 20205.

Retina catecholamines were studied in mice treated with MPTP by histofluorescence and HPLC. After treatment with MPTP, 10 mg/kg IP, two doses 16 hr apart and killing 4 hr after the second dose, there was a significant rise of dopamine content and a fall of its metabolite 3,4-dihydroxyphenylacetic acid (DOPAC). Consistent with the biochemical findings, catecholamine fluorescence was considerably brighter in the cell bodies and neuronal processes indicating an increase of the amacrine cell content of dopamine.

After chronic treatment with MPTP, 30 mg/kg IP for 7 days and killing on the 8th day, there was a significant decrease of dopamine and DOPAC content of the retina. Histochemically there was a dramatic reduction in the number of fluorescent amacrine cells and neuronal processes. Although the number of catecholamine amacrine cells were reduced, those present were brightly fluorescent and well defined. Interestingly, there was a profusion of bright yellowish-orange lipofuschin-like granules of various size not found with acute MPTP treatment. These granules were located in a plane much deeper in the retina than the catecholaminergic amacrine cells, presumably in the pigment epithelium. The pronounced increase of the autofluorescent lipofuschin-like pigment in the retina with chronic MPTP treatment might be indicative of premature aging of the retina. Indeed, chronic MPTP treatment might be useful model for studying the biochemistry of neuronal aging.

127.5 STRUCTURE-ACTIVITY STUDY ON THE MECHANISM OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP)-INDUCED NEUROTOXICITY. S.K. Youngster*, W.J. Nicklas and R.E. Heikkila, Dept. of Neurology, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854

MPTP selectively destroys nigrostriatal dopaminergic neurons in monkeys and in mice. The 1-methyl-4-phenyl-pyridinium ion (MPP^+) is the predominant metabolite of MPTP in both of these species. Inhibitors of monoamine oxidase-B (MAO-B) including deprenil prevent MPP^+ formation from MPTP, and MPTP-induced neurotoxicity (Markey, S.P., et al. Nature, 311:464, 1984; Heikkila, R.E., et al. Nature, 311:467, 1984). MPP^+ has a high affinity for the dopamine uptake system while MPTP has a much lower affinity. Furthermore, the dopamine uptake inhibitor mazindol blocks both the neostriatal uptake of MPP^+ (Javitch, J.A., et al. Proc. Natl. Acad. Sci. USA, 82:2173, 1985) and MPTP-induced neurotoxicity in mice. In addition, the stereotaxic injection of MPP^+ into the nigrostriatal pathway of rats causes destruction of dopamine neurons and MPP^+, but not MPTP, inhibits NADH-linked respiration in mitochondria. These findings, taken together, are consistent with the following mechanism for MPTP-induced neurotoxicity: MPTP is taken up by MAO-B containing cells (perhaps glial cells) and oxidized to MPP^+, which is then released. MPP^+ is subsequently accumulated by dopamine neurons, and reaches concentrations sufficient to inhibit mitochondrial respiration, which results in the death of dopaminergic neurons. To test this possible mechanism, we have synthesized analogs of MPTP and MPP^+ and studied their effects on dopamine uptake, their capacity to be oxidized by MAO, their capacity to inhibit mitochondrial oxidation, as well as their ability to damage striatal dopamine neurons. For example, we find that 1-methyl-4-cyclohexyl-1,2,3,6-tetrahydropyridine (MCTP) is a comparable substrate to MPTP for MAO. 1-Methyl-4-cyclohexyl pyridinium (MCP^+), the MAO oxidation product of MCTP, is, like MPP^+, a good substrate for the dopamine transport system and capable of inhibiting NADH-linked respiration in mitochondria. MCTP injected i.p. into mice produced reductions in dopamine and dopamine metabolite levels in the neostriatum as did MPTP. In contrast, although 1-methyl-4-benzyl-1,2,3,6-tetrahydropyridine (MBzTP) is a good substrate for MAO and its oxidation product 1-methyl-4-benzyl-pyridinium ($MBzP^+$) is capable of inhibiting mitochondrial respiration, $MBzP^+$ is not a good substrate for the dopamine carrier and MBzTP is not toxic to dopamine neurons in vivo. Only compounds capable of being oxidized by MAO to a pyridinium ion which is a substrate for the dopamine carrier and is capable of inhibiting mitochondrial respiration were found to be toxic in vivo. In conclusion, it appears as if all three of these above parameters are required for a compound to exhibit MPTP-like neurotoxicity.

127.6 PROTECTION AGAINST 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP) NEUROTOXICITY WITH DOPAMINE UPTAKE INHIBITORS. R.A. Mayer* and R.E. Heikkila, Dept. of Neurology, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854

There is considerable evidence that the neurotoxicity of MPTP depends upon its metabolism by monoamine oxidase B to 1-methyl-4-phenylpyridine (MPP^+). MPP^+ is actively taken up by dopaminergic neurons, while MPTP is only weakly transported (Javitch, J.A., et al. Proc. Natl. Acad. Sci. USA, 82:2173, 1985). Moreover, MPP^+, but not MPTP, inhibits NADH-linked respiration in mitochondria. Based on these observations, it is possible that MPTP is accumulated by monoamine oxidase B-containing cells outside of the dopaminergic neuron and oxidized by MAO-B to MPP^+. After its release, MPP^+ is actively accumulated into dopaminergic neurons by the dopamine transport system and, once inside the cell, exerts its neurotoxic effect, perhaps through its action on mitochondria. The purpose of the present study was to examine the role of the dopamine transport system in MPTP-induced neurotoxicity. Specifically, we: 1) evaluated the in vitro release of ^3H-dopamine induced by MPP^+, 2) determined the degree to which a series of dopamine uptake inhibitors could prevent the MPP^+-induced release of ^3H-dopamine and 3) determined if compounds effective in blocking MPP^+-induced release might be able to prevent MPTP-induced neurotoxicity.

In tissue slices prepared from the neostriata of male Swiss-Webster (CF-W) or C57-black mice, MPP^+ caused a dose-dependent release of previously accumulated ^3H-dopamine. For example in CF-W mice, 2.5 μM MPP^+ caused a 31% release of ^3H-dopamine, and 10 μM MPP^+ a 57% release. We evaluated the capacity of several agents to prevent the ^3H-dopamine release induced by 10 μM MPP^+. The compounds tested included GBR-13069, amfonelic acid, mazindol, WIN-35,428, WIN-35,065-2, nomifensine, cocaine and desmethylimipramine. All of the drugs except desmethylimipramine, at 2.5 μM, significantly attenuated MPP^+-induced release. For example, MPP^+-induced release in the presence of mazindol was only 5%, compared to the 57% release induced by MPP^+ alone. Mazindol by itself, did not release ^3H-dopamine. In a representative in vivo experiment, MPTP, injected into C57 black mice at a dose of 30 mg/kg/day for 5 days, caused a 79% decrement in the neostriatal content of dopamine (2.5 μg/g compared to a control value of 11.8 μg/g). In contrast, mice treated with 10 mg/kg of mazindol 30 min prior to MPTP had a neostriatal dopamine content of 8.6 μg/g. Mazindol and other dopamine uptake inhibitors also protected against MPTP-induced toxicity in CF-W mice. These results, and other data on the effects of the uptake inhibitors on ^3H-MPP^+ accumulation, support the premise that the selective toxicity of MPTP is dependent upon the uptake of MPP^+ into dopaminergic neurons by the dopamine transport system.

127.7 MPP^+: BINDING AUTORADIOGRAPHY, REGIONAL UPTAKE, DOPAMINE NEUROTOXICITY, AND BEHAVIORAL PHARMACOLOGY FOLLOWING D2 PROLIFERATION. M. R. Marien, †R. E. Heikkila and C. A. Altar. Neurosci. Res., CIBA-GEIGY Corp., Summit, NJ 07901 and †Dept. Neurology, UMDNJ-Rutgers Medical School, Piscataway, NJ, 08854.

The dopaminergic neurotoxicity of MPTP (N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) has been associated with its oxidation to MPP+ (N-methyl-4-phenylpyridine) (Markey et al, Nature 311:464, 1985). The autoradiography of [3H]MPP+ and the dopaminergic uptake, neurochemistry and behavioral effects of intracerebral MPP+ injection in the rat are presented here.

Quantitative autoradiography revealed a regional distribution of specific (MPP+-displaced) and saturable (Bmax = 138-965 fmol/mg protein) binding sites of high-affinity (Kd = 13-61 nM) for [3H]MPP+. Regions with the highest Bmax included nucleus accumbens (NA), interpeduncular nucleus, claustrum, subiculum/CA1 and lateral septum. Binding also occurred in the caudate-putamen (CP), VTA and SN. Binding was not displaced by benztropine (10 uM) nor was it reduced by dopamine neuron destruction with 6-hydroxydopamine. The Bmax values of [3H]MPP+ sites correlated ($r = +0.73$, $n = 11$, $p < 0.02$) with those of specific [3H]tryptamine binding sites (see L. L. Martin et al, This Volume).

Using the method of Javitch and Snyder (Eur. J. Pharmacol. 106:455,1985), we found that [3H]MPP+ was accumulated to about the same extent by homogenates of CP, NA and olfactory tubercle (OT) by a high-capacity (Vmax = 12.8-17.8 pmol/mg protein/8 min), benztropine-sensitive (75-77% blocked) mechanism. Injections of 10-25 ug MPP+ along the left medial forebrain bundle produced dose-dependent losses of DA (up to 95-98%) in the ipsilateral CP and NA. In these rats, no contralateral rotation to apomorphine (0.25 mg/kg) or carbidopa (20 mg/kg) was observed, but d-amphetamine (1.5 mg/kg) produced ipsiversive rotation. Quantitative autoradiography with [3H]spiroperidol showed that at 4 wk these lesions increased the Bmax of D2 sites in the CP by 42% without a Kd change and without affecting D2 sites in the NA. Whether disruption of descending pathways by MPP+ explains the inability of DA agonists to induce rotation and for the denervated NA to not proliferate D2 sites is under investigation.

We conclude that binding sites for MPP+ exist in rat brain. Consistent with MPP+ uptake into the CP, NA and OT and its ability to proliferate D2 sites in the CP, MPP+ is toxic to rat A9 and A10 neurons.

127.8 ^3H-MPTP BINDS TO NEUROGLIA IN THE RAT BRAIN. Arthur Hess, A. Bretschneider*, T. Sullivan* and P. J. Adamo*. Department of Anatomy, Rutgers Medical School, University of Medicine and Dentistry, Piscataway, NJ 08854.

MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) administration causes symptoms of Parkinson's disease in humans and degeneration of the dopaminergic nigrostriatal pathways in monkeys and mice.

Unilateral severe lesions of the medial forebrain bundle in rats produced by injections of MPP+ (1-methyl-4-phenylpyridinium iodide), a toxin produced after oxidation of MPTP by MAO B (monoamine oxidase B) (Markey, S. P. et al, Nature (Lond.), 311:464, 1984), resulted in drastic, virtually complete neuronal cell loss and massive gliosis in the zona compacta of the substantia nigra on the operated side. Histofluorescent studies revealed a severe loss of dopamine and radioautographic studies after in vitro incubation in ^3H-spiperone showed an increase in dopamine D2 receptors in the caudate nucleus on the operated side. Radioautographs after in vitro incubation in ^3H-MPTP revealed a substantial increase in binding of ^3H-MPTP in the zona compacta of the substantia nigra of the operated side, with minimal binding in the substantia nigra on the normal side. The large increase in ^3H-MPTP binding in areas with absence of neurons and intense proliferation of glia indicates that ^3H-MPTP binds largely, if not exclusively, to neuroglia.

It is suggested that MPTP is metabolized by glial cells and that the initial genesis of the toxic metabolites of MPTP occurs in neuroglia. The localization of MAO B in glial cells (Levitt, P. et al, Proc. natl. Acad. Sci. USA, 79:6385, 1982) allows MAO B to metabolize MPTP readily. Inhibition of MAO B in glia readily blocks metabolism of MPTP, also located in the same neuroglia, and probably accounts for the ability of MAO B inhibitors to block the toxic effects of MPTP on the catecholaminergic systems of the brain (Heikkila, R. E. et al, Life Sci., 36:231, 1985). The role of neuroglia should be considered further in attempts to understand the mechanism of MPTP-induced dopaminergic neurotoxicity.

The brain stem lesioned rats were provided by Dr. R. E. Heikkila and L. Manzino, Department of Neurology.

127.9 POSITRON EMISSION TOMOGRAPHY VISUALIZED BRAIN DAMAGE IN MPTP-INDUCED PARKINSONIAN MONKEYS BY USING FLUORINE-18 LABELED 6-F-DOPA. C. C. Chiueh, G. Firnau*, R. S. Burns*, C. Nahmias*, R. Chirakal*, I. J. Kopin, and E. S. Garnett*, NIMH/NINCDS, Bethesda, Maryland, 20205, U. S. A. and Department of Nuclear Medicine, McMaster Univ. Medical Centre, Hamilton, Ontario L8N 3Z5, Canada.

The degree of brain damage in patients suffering from Parkinson's disease depends upon clinical assessments and confirmation by postmortem examination. The object of the present study is to employ a newly developed positron emission tomographic (PET) procedure (Garnett et al., Nature, 305: 137, 1983) using a presynaptic ligand of 6-F-DOPA (Firnau et al., J. Nuclear Med., 25: 1228, 1984; Chiueh et al., Neurosci. Abs., 10: 883, 1984) to visualize and determine in vivo the degree of striatal damage in rhesus monkeys with MPTP-induced parkinsonism (Burns et al., Proc. Nat. Acad. Sci.,80: 4546, 1983). Such a PET procedure could prove useful for identifying patients with subclinical Parkinson's disease or other syndromes involving brain dopaminergic systems.

Following an intravenous injection of 1.5 to 2 mCi purified 6-^{18}F-DOPA (sp. act. 75 mCi/mmole), pentobarbital anesthetized monkeys were examined in the McMaster PET scanner (Nahmias, Nuclear Instru. Methods, 221:113, 1984). The total radioactivity attributed to 6-F-DOPA and its metabolites in a 17 mm horizontal brain slice along the orbitomeatal plane was measured for 2 to 3 hours. At various intervals, blood samples were drawn and assayed for 3-methylated 6-F-DOPA which was found to disappear within about 40 min. Each animal was sacrificed at the end of the experiment. Disc shape punches of tissue from the caudate nucleus and the putamen were assayed for dopamine and its biosynthetic enzymes.

By carefully titrating the MPTP dose (0.5 to 2.5 mg/kg i.v.), we were able to obtain monkeys suffering from different degrees of parkinsonism: subclinical, mildly affected and severely affected (Burns et al., Adv. Neurol., in press, 1985). L-DOPA therapy was required in animals which suffered more than 80% damage to the nigrostriatal system. Dopamine and its synthetic enzymes were absent from the striatum of the severely affected monkeys. In controls, the striatal ^{18}F-PET activity was maximum at 15 min and declined with a half-life of 5 hours. The turnover rate of ^{18}F activity was diminished 3 days after MPTP administration. Two to three weeks later, the accumulation of 6-^{18}F-DOPA and its major metabolite, 6-^{18}F-dopamine, was diminished in the striatum of the mildly affected monkey and absent in the severely affected animal. The striatal ^{18}F-dopamine activity calculated by PET in vivo correlated with the content of endogenous dopamine measured postmortem in each animal.

The present results suggest that the PET brain ^{18}F-dopamine imaging may be useful in providing an index of dopamine depletion in patients with Parkinson's disease and allied disorders.

ELECTROENCEPHALOGRAPHY AND EVOKED POTENTIALS

128.1 REFERENCE FREE CHARACTERIZATION OF EEG WAVEFORM SOURCES BY LAPLACIAN COMPUTED TOPOGRAPHIC MAPS. R. Coppola. Laboratory of Psychology and Psychopathology, NIMH, Bethesda, MD 20205

Computer color display capability has added to increased interest in the topographic mapping of scalp recorded EEG data. This interest comes in part from the desire to localize brain electrical activity with the accompanying hope that this activity can be correlated with neural function. Mapping requires that EEG be recorded from multiple electrode sites all referenced to the same point. Linked ears, a non-cephalic reference, or common average electrode have been among those used. The particular choice greatly affects the resulting map complicating the interpretation with respect to localization of acitivity. The source derivation method of Hjorth (Electroenceph. Clin. Neurophysiol., 50:282, 1980) has been suggested as a reference-free method. The source derivation was meant to be an approximation to the Laplacian of the potential field thus representing the current source density distribution. Most methods used to implement the derivation either require having electrodes placed in a special arrangement or are only a poor approximation using distance weighted values.

In order to achieve a better estimate to the Laplacian we have first developed a surface fit method to provide an accurate interpolation for potential values between electrodes. Each pixel in the display of the potential map is then treated as if it were an electrode and the Laplacian then computed on those values. This results in a very spatially sharpened source density map.

Maps of resting alpha rhythm activity computed in this manner reveal two distinct source locations in a normal population (N=30), one over parietal cortex and one over occipital cortex. Maps of abnormal EEG from epilepsy and tumor patients show source locations in very good agreement with clinical or surgical data relating to the underlying brain pathology.

128.2 Transluminal Intracranial Electroencephalography in Primates: An Endovascular Procedure for Localizing Temporal Lobe Epileptic Foci. J.M. Pile-Spellman*, B.B. Sandrew*, K. Baker*, G. Pransky*, S. Schachter*, N.T. Zervas and J.M. Taveras. Departments of Neuroradiology and Neurosurgery, Massachusetts General Hospital and Harvard Med. Sch., Boston, MA 02114.

The benefits of surgery for medically intractable epilepsy are denied most of the 175,000 Americans thus afflicted because of the difficulty in patient selection. While CT, MRI, and angiography may identify structural abnormalities related to the seizure activity, the electrophysiological assessment of patients with medically intractable complex partial epilepsy remains the critical data indicating surgery. A majority of patients considered for surgery require surgically implanted chronic depth electrodes. The inherent problems of such recording procedures prompted the development of a less invasive technique for localizing and evaluating epileptic foci.

In 4 primates, via a transcutaneous femoral approach, selective cerebral angiograms were performed. Using a 3.5 Fr. coaxial system, a specially designed 450um electrode was then passed into the intracranial vessels and electrically induced paroxysmal activity in the temporal lobe was successfully recorded. In each case, the transluminal intracranial electrode (TIE) recordings were of high fidelity, with little artifact in wither the ictal or interictal states. Of particular significance, TIE could be repeated several times in each animal without complication, consistently producing records superior to the dural electrodes and comparable to the depth electrodes in the same animal.

128.3 NEUROTRANSMITTER INFLUENCES ON HUMAN EVOKED POTENTIALS. E.J. Hammond*, B.J. WILDER, Neurology Service, Veterans Administration Medical Center, Gainesville, Florida 32602.

Although much work has been done on the localization of various components of human evoked potentials, almost nothing is known about their biochemical basis. We studied the effects of manipulation of CNS acetylcholine, a widespread excitatory neurotransmitter, and gamma aminobutyric acid (GABA), an ubiquitous inhibitory neurotransmitter, on click-evoked human auditory brainstem and pattern reversal visual cortical evoked potentials (check size: 50 min). We administered scopolamine, a centrally acting acetylcholine antagoinst, to 4 subjects in a physiologically active dose (0.4 mg i.m.) and made serial evoked recordings for 6 hrs. There was no change in either latency or amplitude for auditory wave I, II, III, IV, V or visual N70, P100 or N145 components. In contrast, a marked influence on the auditory cognitive P3 potential has been reported (Hammond et al, in press).

To study GABAergic effects, gamma vinyl GABA, a new anticonvulsant drug, which is a specific inhibitor of the GABA catabolizing enzyme GABA-T, was administered to 15 patients in a centrally acting dose (4 gm/day). Evoked responses were measured at monthly and bimonthly intervals for 1 yr, but no change in auditory brainstem or cortical visual evoked potentials could be detected.

These studies indicate a lack of effect of cholinergic and GABAergic manipulation on auditory brainstem and pattern reversal visual cortical evoked potentials.

128.4 FOCAL LESIONS OF VISUAL CORTEX: EFFECTS ON FLASH EVOKED POTENTIALS (FEPS),PAIRED FEP RECOVERY FUNCTIONS, AND PATTERN REVERSAL EVOKED POTENTIALS (PREPS) IN RATS. R.S. Dyer, K.F. Jensen and W.K. Boyes Neurophysiol. Branch, NTD, HERL, USEPA Research Triangle Park, NC 27711

FEPs, FEP recovery functions, and PREPs are used as indicators of visual system neurotoxicity, yet little is known about factors which alter specific peaks or the rate of recovery of these peaks in a paired stimulation paradigm. In this study we investigated the role of heat-induced focal destruction of cortical tissue in the vicinity of the electrode.

Adult male Long-Evans hooded rats (N=40) were implanted with chronic 00-90 screw electrodes at the following locations: ground - 2 mm anterior to bregma, 2 mm left of midline; reference - 2 mm anterior to bregma, 2 mm right of midline; visual cortex - 6 mm posterior to bregma, 4 mm on either side of the midline. All electrodes were connected by nichrome wires to a headplug. Visual cortex electrodes on the left side of the brain had, at the time of surgery, a hot soldering iron applied to them for about 0.5 sec, while those on the right side had no such treatment. One week later the rats were tested unanesthetized. For FEPs, averaged responses to 64 flashes were obtained simultaneously at the two visual cortex electrode sites for each animal. Similarly, averaged responses to 64 paired flashes were obtained at the two sites for interflash intervals of 200, 400, 600 and 800 msec, and the recovery function was constructed from ratios of second flash amplitude to first flash amplitude. For PREPs, averaged responses to 200 reversals of a square wave grating were obtained.

The FEP results indicated that all but the last negative peak (N3) were affected by the lesion. P1 was virtually eliminated by the lesion, and N2 amplitude was greatly reduced. N1 was enhanced by the lesion. The group average waveforms of the recovery function portion of the experiment indicated that recovery of P1N1 was greatly enhanced by the lesion, suggesting partial elimination of a normal recurrent inhibitory process. In the PREP recordings the group average waveforms indicated that N1 amplitude was enhanced by the lesion, but that N3 amplitude was depressed. Preliminary histological examination indicated that surface focal damage occurred in about a 1-1.5 mm radius and extended to a cortical depth as great as 1.4mm at the center. These findings demonstrate that while visual evoked potentials recorded from skull screw electrodes reflect activity from surrounding cortex as well as the cortex immediately beneath the electrode, damage to the immediately underlying cortex significantly alters waveform morphologies.

128.5 MIDLATENCY AUDITORY EVOKED RESPONSES: DIFFERENTIAL RECOVERY CYCLE CHARACTERISTICS. R. Erwin and J. Buchwald, Brain Res. Inst., Ment. Ret. Res. Ctr., Dept. Physiol., UCLA Med. Ctr., Los Angeles, CA 90024.

Recent studies have indicated that two middle latency response (MLR) components of the human auditory evoked potential, Pa (20-40 ms latency) and P1 (50-80 ms), may be analogous to the cat Wave 7 (12-15 ms) and Wave A (20-25 ms) respectively. Depth mapping and lesion procedures indicate that the cat Wave 7 reflects a generator in auditory cortex while the cat Wave A reflects a generator system extending through the mesencephalic reticular formation upward into the intralaminar thalamus (Hinman and Buchwald, Brain Res. 264: 573, 1983). Both the cat Wave A (Chen et. al., Neurosci. Abst. 10: 1141, 1984) and the human P1 (Erwin et. al., Neurosci. Abst. 10:1140, 1984) diminish and disappear during slow wave sleep, as compared to wakefulness, and reappear during active, rapid eye movement sleep. In contrast, the earlier auditory brainstem reponses (ABRs), cat Wave 7 and human Pa, do not vary in amplitude across states of sleep and wakefulness.

The present study attempted to extend these parallels by using a different experimental manipulation. In the cat the amplitudes of the ABRs and of Wave 7 do not change as rates of stimulation increase from 1 to 10/sec. In contrast, wave A disappears across this range of increasing rates (Buchwald et. al., Brain Res. 205: 91, 1981). Since the human Pa and P1 components have not been examined simultaneously for possible differential effects of stimulus rate, a parametric study of stimulus rate on waveform amplitudes was undertaken.

MLRs were recorded from a group of 7 normal adults in response to clicks (0.1 ms, 50 db HL) presented at 5 rates: 1/2 sec, 1/sec, 5/sec, 8/sec and 10/sec. Evoked potentials were recorded from the vertex (Cz) and bipolar eye electrodes were used to monitor eye movements. For each block of 500 stimuli at one rate, an evoked response average was generated.

Analyses of the MLR amplitudes indicated that the Pa amplitude did not vary systematically across rates, while the P1 amplitude decreased significantly at faster stimulation rate ($F(4,24)=10.21$, $p< .001$). These findings indicate that P1 is generated by a system which is physiologically different than the Pa generator system, i.e., the P1 system shows significantly longer recovery cycles. The similar recovery cycles characteristics responses of human Pa and cat Wave 7, and of the human P1 and cat Wave A across different stimulation rates provides additional evidence to support the hypothesis that these pairs of human-cat components reflect common generator substrates. (Supported by USPHS HD-05958 and HD-04612)

128.6 EFFECT OF A UNILATERAL PONTINE LESION ON HUMAN BRAINSTEM AUDITORY EVOKED POTENTIAL. D.H. York and C. Watts, Dept. of Physiology and Neurology, and Division of Neurosurgery School of Medicine, University of Missouri, Columbia, Mo. 65212.

The extensive crossing of auditory fibers at various levels through the brainstem and midbrain is frequently cited as the reason for the lack of detection of a unilateral brain lesion, especially in audiometric testing. This study describes a predominantly ipsilateral deficit observed in the brainstem auditory evoked potential (BAER) of an individual with brainstem infarct confined to one side of the dorsolateral pontine-midbrain region. The patient was a 21 year old male involved in a motor vehicle accident who was found unconscious at the scene and required ventilatory assistance. Pupils were equal and responsive to light upon admission. A BAER evaluation was done at 90 dB with 60 dB masking of opposite ear at gain of 10^4, bandpass 150-3000 Hz. The vertex (Cz) response to 2000 click stimuli at 17/sec showed only the presence of waves I, II and III on left ear testing. The latencies were 1.5, 2.7 and 3.7 respectively. The opposite ear showed the presence of waves I, II, III, IV, V with wave I at 1.6 msec, wave II at 2.8 msec, wave III at 3.7 msec, wave IV at 4.8 msec and wave V at 6.2 msec. The patient remained comatose for 39 days, whereupon he expired due to cardio-pulmonary failure. Brain pathology showed a localized infarct in the left dorsal mid-pons extending into the midbrain up to the substantia nigra. The lesion obliterated the lateral lemniscus on the left side. The presence of wave I-V at normal latencies on right ear testing suggests that crossing fibers in the trapezoid body may not play a major role in conducting click evoked responses. A decrease in amplitude of wave V on right ear test suggests only minimal involvement. The complete abolition of waves IV-V on left ear testing, ipsilateral to the lesion suggests that ipsilateral fibers of the lateral lemniscus are important in conducting auditory information evoked by click stimuli and may offer evidence of localizing value in lesions of the brainstem.

128.7 THE BRAINSTEM AUDITORY PATHWAY IN CAT AND MAN. J. K. Moore. Dept. of Anat. Sci., SUNY at Stony Brook, Stony Brook, NY 11794.

Interpretation of early auditory evoked potentials has been based on a combination of human clinical cases and experimental studies in mammals such as the cat. For this reason, cat and human brainstems have been subjected to identical histological processing, and stained sections have been used to produce graphic and computer-assisted reconstructions of the brainstem auditory pathway. The two- and three-dimensional images produced by these reconstructions provide quantitative information on the nuclei and tracts which are the neural generators of the early evoked potentials.

The human cochlear nuclei are more elongated than those of the cat, extending up to 8mm dorsally and 10mm medially in the lateral recess from the point of entry of the auditory nerve into the nuclei. Commissural axons from the nuclei converge to form a compact trapezoid body at the posterior edge of the pons. Other efferent axons from the nuclei run rostromedially in the acoustic striae and trapezoid body toward the ipsilateral superior olivary complex. In the human olivary complex, only one of the three principal nuclei identified in other mammals is well developed. This nucleus, the medial olivary nucleus, is a sheeo of bipolar neurons which extends 4mm rostrocaudally. A small lateral olivary nucleus is identifiable, and the complex is ringed by periolivary cell groups. The elongated rostral pole of the complex contains globular neurons which resemble cells of the nucleus of the trapezoid body in other species. Overall length of the human olivary complex is 13mm, compared to 4mm in the cat. Rostral to the olivary complex, the lateral lemniscus contains a ventral nucleus consisting of islands of small fusiform cells. This nucleus, 5mm in length, is longer than that of the cat, but cell density is less. A dorsal lemniscal nucleus, very similar in size to that of the cat, gives rise to apparent commissural axons.

In terms of overall length of the brainstem auditory pathway, an axon(or series of axons) passing from the cochlear nuclei to the centra of the opposite inferior colliculus travels a distance of 24mm in the cat, but courses approximately 42mm in man. Given the size of neuronal populations in human auditory nuclei, the largest component of the ascending pathwya in man should be direct axons from multipolar and fusiform cells of the cochlear nuclei to the contralateral inferior colliculus. A smaller, but still sizeable, component of the system should be cochlear nucleus spherical cells projecting through the medial olivary nuclei to the colliculus bilaterally. (Supported by the Deafness Research Foundation).

128.8 SOURCES OF THE FREQUENCY FOLLOWING RESPONSE IN MAN: AN ANALYSIS USING PHASE. R. Batra and S. Kuwada. Department of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

Electrical potentials which follow the periodicity of low frequency tones can be recorded from the scalp of both animals and humans. Previous studies indicate that the source of this frequency following response (FFR) is from multiple generator sites. We demonstrate here that the FFR has at least two sources in man. Signals from these sources sum in different proportions depending on electrode configuration.

Continuous tones were used instead of the more traditional tone bursts as data can be collected more efficiently using the former. Moreover, continuous tones avoid transient responses produced by tone bursts which complicate the response pattern. Stimuli were delivered monaurally at 95 dB SPL via an electrically and magnetically shielded headphone. Potentials were differentially recorded between vertex and either ipsilateral or contralateral earlobe. They were amplified, averaged and assessed using Fourier analysis. Presence of a response was determined using a statistical criterion derived from background noise.

Responses recorded between vertex and ipsilateral earlobe exhibit the presence of at least two generators. Both amplitude and phase measurements show a sequence of peaks and valleys as a function of frequency. Responses above 600 Hz are nearly sinusoidal while those at lower frequencies have substantial harmonic content indicating a neural origin. In contrast, amplitudes of responses measured between vertex and the contralateral earlobe increase up to about 200 Hz and then decline. Responses are rarely seen above 600 Hz. The phase of responses below 300 Hz changes linearly as a function of frequency, implying a source with a latency of 8.2 ± 0.1 ms (mean ± standard deviation, 4 subjects). Phase analysis indicates that the FFR is generated by interference between at least two sources summing in different proportions when different electrode configurations are used. One has a latency of 0.25 to 2 ms and dominates at high frequencies while the other has a latency of about 8 ms and produces most of the response at lower frequencies. The former is consistent with a cochlear origin while the latter probably lies in the midbrain.

These results clearly demonstrate that the FFR recorded in man has at least two sources, the signals from which either sum or cancel one another depending on frequency. An implication for those using the FFR is the necessity of measuring the response at several closely spaced frequencies in order to identify these extremes. The frequencies at which such extremes occur and the invariant latency of the neural generator seen while recording between vertex and the contralateral earlobe may be useful for clinical diagnosis.

128.9 SCALP-RECORDED POTENTIALS TO AMPLITUDE MODULATED TONES: A METHOD FOR ASSESSING HEARING. S. Kuwada, R. Batra and V.L. Maher*. Department of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

The early detection of hearing abnormalities is desirable so that remedial procedures may be implemented. The goal of electrical audiometry is to assess hearing in those unable or unwilling to participate in standard behavioral audiometric testing, such as infants and the mentally retarded. Most techniques involve the analysis of scalp-recorded potentials evoked by clicks or tone bursts. To date, the most fruitful approaches have been the analysis of short latency brainstem evoked responses, the frequency following response, and the middle latency response. However, none of these methods alone or in combination can assess frequency-specific hearing thresholds across the full audiometric range (250-8000 Hz). We report here that sinusoidally amplitude modulated (sine AM) tones evoke scalp-recorded responses which can be used to assess the sensitivities of hearing-impaired subjects on a frequency by frequency basis, across the whole audiometric range.

We tested adults with normal hearing as well as those with low, high and mid-frequency hearing losses. Sine AM tones were presented through an electrically and magnetically shielded headphone. The scalp-potentials were differentially amplified between vertex and the contralateral earlobe, averaged, and digitally filtered. A fast Fourier transform was used to measure the amplitude and phase of the response.

The largest responses were seen to modulation frequencies in the 30-50 Hz range, although potentials were detected as high as 400 Hz. The phase of the response from normal subjects indicates that the generator for this following potential has a latency of about 30 ms at modulation frequencies below about 70 Hz. At higher frequencies the latency is about 7 ms. In general, responses to 50 Hz amplitude modulation increased as a function of intensity and declined as a function of carrier frequency. In hearing impaired subjects, responses were recorded to a 50 Hz modulation at carrier frequencies between 250 and 8000 Hz, usually at intensities between 50 and 60 dB HL. In such subjects, there was a close correspondence between the amplitude of the 50 Hz potential and the subject's behavioral audiogram. At higher intensities this correspondence was not as close, presumably due to the spread of excitation along the basilar membrane. As the threshold for this following response is close to that of hearing, we were also able to determine absolute levels of hearing loss at each of the frequencies tested. Thus, it seems that scalp potentials to sine AM tones can be used to accurately evaluate hearing sensitivities on a frequency by frequency basis across the audiometric range.

This work was supported by a NIH grant (NS18027, S. Kuwada) and the University of Connecticut Research Foundation (G. Leonard).

128.10 Inversion of the Scalp-Recorded P300 in a Tumor Patient R. Johnson, Jr. and P. Fedio. National Institutes of Health, NINCDS/MNB, Building 10, Room 4N246, Bethesda, MD 20205.

In recent years, much effort has been expended in attempts to localize the neural generator of the P300 component of the event-related potential (ERP). Whereas the initial results placed the P300 generator in the amygdala, pes, uncus and anterior hippocampal areas, more recent work has demonstrated that these sources do not appear to contribute to the activity of the scalp-recorded P300. Despite the fact that a given scalp distribution cannot uniquely determine the sources of a particular ERP component, it does provide important information which must be accounted for by any proposed source. Therefore, if the scalp distribution of P300 is altered in either surgical or tumor cases, such data can provide constraints on the number of backward solutions for testing hypotheses about source localization.

The subject (S.M.) was a 34 year old right-handed white male with 15 years of education and an above average IQ. He had a papillary tumor located in the right lateral ventricle. The standard "Oddball" task, with 20/80 stimuli, was used to elicit the P300. The stimuli were presented in three modalities (auditory, visual, and somatosensory) either bilaterally or unilaterally in different series. The subject's task was to press one of two buttons depending upon which stimulus was presented. The EEG was recorded from FPz, Fz, Cz, Pz, Oz, F3, F4, C3, C4, P3, P4, O1, O2, T3, and T4, all referred to linked mastoid electrodes.

The averaged waveforms revealed that normal looking ERP components were elicited in all three modalities except for the P300 component. Although larger potentials were elicited by rare events than by the frequent events, the overall scalp distribution of P300 in S.M. was different from that usually observed. Thus, while P300 was distributed normally over the central and posterior areas of the scalp, P300 amplitude was notably smaller than usual at the F_z electrode. Most surprising was the activity at the FPz electrode site where the P300 component was completely inverted (i.e., negative going) relative to more posterior electrode sites. This phase reversal of the P300 at FP_z was in clear contrast to the normal polarities for all of the earlier components at the same electrode. These results were obtained in all three modalities, for both bilaterally and unilaterally presented stimuli. There were no hemispheric asymmetries in any of the ERPs which were associated with the presence of the tumor.

The data from this subject represent the first reported scalp-recorded polarity reversal of the P300 component. Although these data alone are not sufficient to specify completely the generator of P300, they do provide constraints which must be accounted for by any hypothesized generators.

128.11 THE EFFECT OF ALTERATION OF VASCULAR FACTORS ON RECOVERY OF SPINAL CORD CONDUCTION AFTER TRAUMA IN RATS. H. F. Martin III, J. G. Blackburn, and S. Katz. Dept. of Physiology, Medical University of S. C., Charleston, S. C. 29425.

Rats were anesthetized with pentobarbital and ketamine for surgical preparation then maintained by supplemental ketamine alone. Somatosensory evoked potentials (SEPs) were recorded bilaterally from stimulation of sciatic nerves, before and after calibrated spinal cord trauma. SEPs were monitored at regular intervals during 4-6 hours of acute recovery. At 4-8 g-cm trauma, SEPs fully recovered following initial loss. With 10-16 g-cm trauma, slow recovery occurred over a 2-4 hour period, frequently terminated by a secondary loss at 3½-5 hours. With 20-24 g-cm trauma, most animals had no recovery of SEPs. Since 24 g-cm is just above the level of variable recovery in untreated animals, this was used in subsequent trials. A set of untreated animals had recovered only 16% of pre-trauma SEP at 3½ hours post-trauma.

In order to reduce the contribution of the formed elements of the blood to vascular reactions after trauma, animals were transfused with perfluorocarbon emulsion (Oxyferol, Alpha Therapeutics) to Hct.<10%. This resulted in 54% SEP recovery at 3½ hours ($p<.002$). To block participation of prostaglandins in vascular response, animals were pretreated with the cyclooxygenase inhibitor Ibuprophen (Upjohn, 15 mg/kg). This resulted in 32% SEP recovery at 3½ hours followed by secondary loss. To block the vasoconstrictor and clotting effects of thromboxane A_2, animals were pretreated with the thromboxane synthetase inhibitor Dazoxiben (Pfizer, 30 mg/kg). This resulted in 60% SEP recovery at 3½ hours ($p<.005$). In order to increase blood volume and decrease viscosity, animals were transfused with 4cc of 10% Dextran-40. This hypervolemic hemodilution resulted in 90% SEP recovery at 3½ hours ($p<.001$). Identical hypervolemic hemodilution with normal saline produced no recovery.

These results suggest that alterations in hemodynamic factors play a role in recovery of spinal cord conduction after trauma. Also prostaglandins, especially thromboxane, may mediate part of the post-traumatic response. Current studies are under way to assess the role of other agents and correlate changes in spinal cord blood flow.

DISEASES OF THE NERVOUS SYSTEM: ISCHEMIA, TRAUMA

129.1 PRETREATMENT WITH SCOPOLAMINE ACCELERATES RECOVERY OF LOCOMOTOR FUNCTIONING FOLLOWING CEREBRAL CONCUSSION IN THE RAT. C. E. Dixon, B. G. Lyeth, M. L. Giebel,* T. Yamamoto,* H. H. Stonnington,* D. P. Becker and R. L. Hayes. Division of Neurosurgery, Department of Psychology and Department of Rehabilitation Medicine, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0001.

Recent data suggest that increased functional activity of cholinergic systems located in the brain stem contributes to components of behavioral suppression following concussion (Hayes et al., Science, 233:301-303, 1984). Additionally, pretreatment with scopolamine has been shown to attenuate some acute (<60 min) neurological deficits following cerebral concussion produced by fluid percussive techniques (Lyeth et al., Neurosci. Abst., 1985). The present investigation examined the effects of pretreatment of scopolamine, a muscarinic, cholinergic antagonist, on the rate of recovery of locomotor functioning following concussion.

Prior to injury, 40 rats were trained on a beam-walking task similar to that employed by Feeney et al. (Science, 217:855-857, 1982) in which rats traversed a narrow beam to escape white noise and bright light. Baseline intervals to traverse the walking beam were obtained. Additionally, the rats' ability to traverse the beam was assessed by a rating scale (e.g. number of foot slips) made by independent observers. The interval to maintain balance on a separate balance beam task was also assessed prior to injury. Following injury rats were retested daily for 10 days. Rats were surgically prepared 24 hours prior to injury by chronically placing a hollow injury screw epidurally over a hole trephined along the sagittal suture, midway between lambda and bregma. Scopolamine (0.1, 1.0, or 10.0 mg/kg) or saline was injected i.p. 15 minutes prior to injury. Under methoxyflurane anesthesia, animals were concussed at 2.86 atm (an injury level associated with transient areflexia and more enduring motor dysfunctions) using a fluid percussion method modified for rats in our laboratories (Dixon et al., Neurosci. Abst., 1984). Results indicated that scopolamine (1.0 mg/kg) facilitated the rate of recovery of locomotor functioning as indicated by a significantly more rapid return to baseline of walking-beam traversal times ($p<0.5$), rating scale scores ($p<0.5$), and balance beam times ($p<0.5$) when compared to saline treatment. These findings indicate that the observed, seemingly beneficial effects of pretreatment with scopolamine associated with acute neurological recovery may also be associated with an accelerated rate of recovery of more enduring motor deficits. These findings lend further support to the hypothesis that the components of behavioral suppression associated with concussion are not necessarily related to nonspecific disorganization of brain functions or histopathology but to an active cholinergic inhibitory system. Supported by NIH Grant #NS 12587.

129.2 NEUROLOGICAL DEFICITS FOLLOWING EXPERIMENTAL CEREBRAL CONCUSSION IN THE RAT ATTENUATED BY SCOPOLAMINE PRETREATMENT. B. G. Lyeth, C. E. Dixon, R. J. Hamm, T. Yamamoto,* M. L. Giebel,* H. H. Stonnington,* D. P. Becker and R. L. Hayes. Department of Psychology, Division of Neurosurgery, and Department of Rehabilitation Medicine, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0001.

Recent data from our laboratory suggest that some consequences of cerebral concussion may be mediated by increased activity within an endogenous cholinergic system located in the brain stem and capable of suppressing responses organized both supraspinally and at the level of the spinal cord (Hayes et al., Science, 233: 301-303, 1984). The present investigation examined the effects of systemic preinjections of a cholinergic antagonist on acute features (<60 min) of behavioral suppression following concussion.

Sixty rats were surgically prepared under sodium pentobarbital anesthesia 24 hours prior to injury by chronically placing a hollow injury screw epidurally over a hole trephined along the sagittal suture, midway between lambda and bregma. Rats were assigned to one of four groups: scopolamine 0.1 mg/kg, 1.0 mg/kg, 10.0 mg/kg, or saline (equal volume). Drugs were injected i.p. 15 minutes prior to injury. Experimenters were uninformed of drug and dosage. Animals were anesthetized five minutes prior to injury with methoxyflurane. Animals were concussed at 2.86 atm (saline pressure pulse, 18 ms duration) with a fluid percussion injury device (Dixon et al., Neurosci. Abst., 10:998, 1984). Animals were assessed neurologically for 60 minutes immediately following injury. The durations of suppression of righting, pinna, corneal, and auditory startle reflexes were scored. Spontaneous locomotion, ability to support the head, tail and hind paw flexion, proximal tail pinch, and organized escape from tail pinch were also assessed. Scopolamine (1.0 mg/kg dose) produced significantly shorter ($p<.05$) durations of suppression of certain spinally mediated behavioral responses: paw flexion, escape, and proximal tail pinch. Scopolamine had no effect on other response measures. Mortality for the 1.0 mg/kg scopolamine group (23%) was significantly lower ($p<.05$) than for the saline group (72%). Scopolamine administered prior to injury appears to improve behavioral recovery after cerebral concussion and decrease mortality. Our findings lend further support to the hypothesis that the components of neurological disruption associated with concussion are not necessarily related to nonspecific disorganization of brain functions or histopathology but to an active cholinergic inhibitory system. Supported by NIH Grant #NS 12587.

129.3 **ATTENUATION OF PROGRESSIVE BRAIN ISCHEMIA FOLLOWING EXPERIMENTAL SUBARACHNOID HEMORRHAGE BY LARGE I.V. DOSES OF METHYLPREDNISOLONE.** M.A.Travis and E.D.Hall, CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

The purpose of this study was to examine the ability of a large i.v. dose of methylprednisolone sodium succinate (MPSS) to affect acute post-subarachnoid hemorrhage (SAH) cerebral vasospasm and the associated fall in local regional blood flow. MPSS was chosen for study due to its previously disclosed action to enhance chronic neurological recovery after SAH in dogs (Chyatte and Sundt, J. Neurosurg. 59:925, 1983).

Experimental SAH was produced in alpha-chloralose-anesthetized cats by slow injection through a butterfly cannula of 0.5 ml/kg of autologous arterial blood into the cisterna magna. Blood flow (CBF) was measured by H_2 clearance in the caudate nucleus before, at 5 min post-SAH, and every 30 min thereafter until 3 hrs. MPSS (Solu-Medrol® Sterile Powder) or its buffered aqueous vehicle was administered by i.v. bolus at 2 min prior to the 30 min post-SAH blood flow.

In all experimental groups, the SAH produced a transient hypertension and increase (40-50 mmHg) in intracranial pressure (ICP). In the vehicle-treated group, a two-phase decrease in CBF was observed with an initial rapid (20.9%) drop by 5 min followed by an additional, but slower, 37.0% decrease over the ensuing 3 hrs (see Table 1). Although the mean arterial pressure (MAP) remained stable at a normal level, the ICP increased slowly from about 5 up to 15-20 mmHg, leading to a decrease in the cerebral perfusion pressure (CPP; MAP-ICP). Associated with the fall in CBF was a slow elevation in the cerebral vascular resistance (CVR; CPP/CBF). In contrast, in animals treated with 30 mg/kg MPSS following SAH, CBF and CVR were stabilized. In fact, a partial restoration of both parameters toward the pre-SAH levels was observed even though the progressive increase in ICP and decrease in CPP were unaffected. In the 15 mg/kg MPSS-treated group, only a slight attenuation of the decrease in CBF and increase in CVR following SAH was seen.

TABLE 1. Effect of vehicle or MPSS on CBF, CVR, ICP and CPP at 3 hrs after SAH (values = mean ± S.E.) *$p<0.05$ by t-test versus vehicle.

Group	N	% Decrease in CBF	ICP (mmHg)	CPP (mmHg)	CVR (CPP/CBF)
V	5	57.9±4.4	17.5±2.5	93.3± 6.2	5.7±1.2
15 mg/kg	4	47.7±9.7	18.7±8.5	100.4± 9.3	4.3±1.3
30 mg/kg	4	23.0±1.4*	17.0±5.0	88.0±10.0	2.8±0.5*

These results demonstrate that MPSS in high doses can antagonize the development of acute post-hemorrhagic ischemia. Although the specific mechanism(s) by which acutely administered MPSS is able to stabilize blood flow following SAH has yet to be elucidated, a decrease in hemorrhage-induced microvascular lipid peroxidation is a possible contributing effect. A similar conclusion has been reached in previous studies concerning the prevention of post-traumatic spinal cord ischemia by MPSS (Hall et al., J. Neurosurg. 61:124, 1984).

129.4 PAROXYSMAL FIRING IN HIPPOCAMPAL SLICES DURING THE EARLY PHASE OF HYPOXIA. M. Balestrino* and P.G. Aitken
Dept. of Physiology, Duke Univ. Medical Center, Durham, NC 27710

Paroxysmal firing is the repeated, synchronous discharge of large numbers of neurons not time-locked to stimulus pulses. Such firing can be caused in CA1 of hippocampal slices by delivery of stimulus trains to afferent pathways (Aitken, P.G., Neurosci. Abstr., 10:547, 1984). We report here that paroxysmal firing can also be triggered in CA1 by a hypoxic insult.

Transverse hippocampal slices 400μ thick were maintained at 35-36°C in an interface chamber superfused with artificial cerebrospinal fluid (pH=7.35; K^+=3.5mM; Ca^{++}=1.2mM; Mg^{++}=1.2mM). The gas phase above the slices was warmed, humidified 95% oxygen - 5% carbon dioxide. Hypoxia consisted of replacing the gas phase with warmed, humidified 95% nitrogen - 5% carbon dioxide, flowing at the same rate. Extracellular electrical activity was monitored in stratum pyramidale of CA1 with a micropipette electrode inserted to the depth for maximum amplitude responses to Schaffer collateral stimulation. DC-coupled low gain and AC-coupled high gain records were made on tape recorder.

All slices responded to hypoxia with negative shifts of the extracellular sustained potential (SP). This SP shift occurred in two phases: an initial, slow shift of 2-8mV beginning 135-210 sec after the start of hypoxia, followed by a larger, rapid shift of 15-30mV occurring 140-263 sec after the start of hypoxia. Unsynchronized single unit firing often occurred shortly before or during the slow SP shift.

Paroxysmal firing was seen in approximately 30% of hypoxic episodes. This firing consisted of a 1.2 - 4.1 sec burst of compound action potentials (population spikes), with each population spike having 1-6mV amplitude and 3.0 - 6.5msec duration. Paroxysmal firing could occur either shortly before or during the slow SP shift. We cannot rule out the possibility that this paroxysmal firing was a direct consequence of hypoxic metabolic changes. It is suggestive, however, to think that it was a consequence of the hypoxia-induced cellular depolarization. This latter possibility is consistent with earlier suggestions from this laboratory that en masse depolarization of CA1 pyramidal cells, from whatever cause, results in an increase in electrotonic and/or ephaptic communication between neurons; this in turn could result in synchronization of normally unsynchronized neural activity.

(Supported by NIH grants 18670 and 17771.)

129.5 EFFECTS OF VINPOCETINE IN A RAT MODEL OF CEREBRAL ISCHEMIA. G. A. King, D. Narcavage, L. Romanski, D. Hannig, and A. Shieh. Ayerst Laboratories Research Inc., CN 8000, Princeton, NJ, 08540.

Vinpocetine is an eburnamenine derivative which has been reported to have beneficial effects in acute focal cerebrovascular disease (P. Kalvach, et al., Cs. Neurol. Neurochir. 45:380, 1982). We have examined the effects of vinpocetine and other drugs in a rat model of cerebral ischemia. Male, Fisher (F-344) rats were anesthetized with halothane, and the carotid arteries were doubly ligated and cut bilaterally. Following recovery from anesthesia the animals were observed for 12 hr. In drug-free animals, seizures began as early as one hour post-surgery, and by 4 hr post-surgery approximately 80% of rats experienced one or more seizures. These animals died at a rate that was linear with respect to time post-surgery, and less than 10% of the animals remained alive after 12 hr. Drugs were administered i.p. either acutely, BID, once immediately post-surgery and again 6 hr later, or subchronically once a day for five days, the last injection being given immediately post-surgery. On BID administration, vinpocetine (50 and 100 mg/kg) and a structurally related drug vincamine (50 and 100 mg/kg) significantly delayed the latency to seizure onset, while the anticonvulsant drug, phenytoin (12.5 and 25 mg/kg), had no effect. On subchronic administration, neither vincamine nor phenytoin altered the latency to seizure onset nor the latency to death, as compared to control rats. Subchronic administration of vinpocetine (25 and 50 mg/kg) significantly delayed seizure onset, and at 25 mg/kg the drug significantly delayed time to death. Therefore, vinpocetine exhibited protective effects in this model of cerebral ischemia, and its potency and efficacy were increased by subchronic administration. While vincamine had effects similar to those of vinpocetine when given acutely, its activity was not maintained after repeated administration. Vinpocetine's effects in this model were probably not due to an anticonvulsant action, since phenytoin at anticonvulsant doses was inactive in this test.

129.6 INFLUENCE OF TISSUE-TYPE PLASMINOGEN ACTIVATOR ON BLOOD FLOW DURING EVOLUTION OF THROMBOTIC STROKE. B.D. Watson*, W.D. Dietrich, R. Busto*, M.D. Ginsberg and C.F. Hoyng* (SPON: J. N. Barrett). Cerebral Vascular Disease Research Center, Univ. Miami School of Medicine, Miami, FL 33101 and Genentech Inc., San Francisco, CA 94080

The recent synthesis by recombinant techniques of human tissue-type plasminogen activator (rt-PA) has facilitated thrombolysis of isolated coronary arterial occlusions in animals and in man, without inducing systemic fibrinogenolysis. Cerebral thrombolysis with rt-PA has not been reported, however. Recently we have developed in the rat a reproducible model of photochemically induced thrombotic stroke. In this model we have observed primary endothelial injury which likely arises from singlet oxygen-induced lipid peroxidation reactions initiated by the photochemical reaction. Platelet adhesion is stimulated, followed by degranulation and formation of occlusive aggregates in small vessels throughout the depth of the cortex. The purpose of this study was to determine whether rt-PA infusion following the initiation of infarct formation would alter the progressive decline in cerebral blood flow (CBF) previously demonstrated in this stroke model.

Alterations in CBF were assessed autoradiographically at 30 minutes and 4 hours following photochemically induced cortical infarction. The infarction was produced by irradiating the brain through the intact skull for 20 minutes with green light following the systemic injection of the photosensitizing dye rose bengal. At 10 minutes following the irradiation period, saline or rt-PA (15 ug/kg/min) in saline was infused for 20 minutes into the external carotid artery. CBF was determined either immediately following the infusion period or following a 4-hour survival period. Thirty minutes following irradiation, autoradiograms demonstrated a focus of reduced CBF (less than 0.02 ml/g/min) in saline-infused rats. In contrast, rats infused with rt-PA and studied 30 minutes following irradiation demonstrated no such focal hemodynamic defect. Both saline and rt-PA-infused rats at 4 hours demonstrated a zone of severely reduced CBF extending to the level of the subcortical white matter. These results indicate that the early infusion of rt-PA appears to inhibit vascular occlusion by fibrin-stabilized platelet aggregates within the irradiated cortex. Once rt-PA infusion is discontinued, however, aggregation appears to proceed and by 4 hours this results in a focus of severely depressed flow. Studies in progress will determine the duration of rt-PA infusion needed irreversibly to inhibit platelet aggregation.

Supported by NIH Grant NS 05820.

129.7 CEREBRAL EMBOLISM THERAPY WITH TISSUE PLASMINOGEN ACTIVATOR. J.Zivin, M.Fisher*, U.DeGirolami, J.Stashak*, C. Hemenway*. Neurology Dept., Univ. Of Massachusetts Med. Center, Worcester, MA 01605

Embolic stroke is potentially treatable by thrombolytic therapy, but use of streptokinase or urokinase has been complicated by frequent hemorrhages. Tissue plasminogen activator (tPA) can lyse existing thrombus without producing widespread hematological abnormalities and has been effective in treatment of coronary artery thrombosis. We used a newly developed embolic stroke model which does not depend on prediction of lesion size and location to demonstrate efficacy of tPA in reducing cerebral ischemic damage.

New Zealand white rabbits were anesthetized. In each animal one external carotid artery was ligated, a cannula was placed in the common carotid artery, and the incision was closed so that the cannula was accessible externally. The rabbits were allowed to recover from anesthesia. Blood was drawn from a donor animal and allowed to clot at 37°C for 2 hr. The clot was fragmented with a Polytron and the fragments were suspended in Dulbecco's PBS buffer. The fragments were then sized between screens of 104 μm^2 and 240 μm^2. The rabbits were restrained and predetermined amounts of clot particles were injected into the carotid artery cannula. Intravenous infusion of tPA* was begun 1 min after clot injection. The total dose of tPA was 1 mg/kg; 20% was given immediately and the remainder infused over 30 min. Controls were similarly treated but saline replaced tPA.

When 42 to 72 mg of clot fragments were injected into control animals, 7 of 12 were grossly encephalopathic (signs included lethargy, weakness, ataxia, and nystagmus) or dead at 24 hrs. Of 11 tPA treated animals given identical amounts of clots, 1 died and the remainder were normal. This difference is significant by Fisher's Exact Test (p=0.027). External examination of the brains of tPA treated animals did not reveal evidence of hemorrhage.

This in vivo study demonstrated that tPA was able to prevent major neurological deficits when the drug was given after emboli entered the cerebral circulation. The tPA appears to be safe at doses used in this model.

(*a gift from Genentech, Inc., So. San Francisco, CA)

129.8 CEREBRAL METABOLISM DURING KAOLIN-INDUCED HYDROCEPHALUS IN THE RAT: A 2-DEOXYGLUCOSE STUDY. E.H. Elowitz*, D.L. Dow-Edwards, and T.H. Milhorat. Lab. of Cerebral Metabolism, Dept. of Neurosurgery, SUNY, Downstate Medical Center, Brooklyn, NY 11203.

The model of kaolin-induced hydrocephalus has been shown to produce alterations in cerebrospinal fluid (CSF) physiology and brain morphology. Following cisternal injection of kaolin, the outlets of the fourth ventricle become obstructed leading to a temporary rise in intracranial pressure and a permanent dilatation of the ventricular system. While chronic low-pressure hydrocephalus is clinically associated with dementia and ataxia, little is known about the metabolic derangements caused by hydrocephalus. To better understand the functional and metabolic changes during kaolin-induced hydrocephalus in the rat (Hochwald, G.M. et al., Z.Kinderchir., 34:403-410, 1981), the quantitative autoradiographic 2-deoxyglucose (2DG) method (Sokoloff, L. et al., J. Neurochem., 28:897-916, 1977) was employed.

Male Sprague-Dawley rats (350-400g) were anesthetized with IP pentobarbital and fixed in a stereotaxic frame. Under sterile conditions, a 23G needle was percutaneously inserted into the cisterna magna and 0.1 ml of CSF was withdrawn. Either 0.1 ml of sterile normal saline or sterile kaolin (250mg/ml saline) was then injected over one minute. The animals were allowed to recover for a period of four weeks. During the first two weeks all kaolin animals lost about 30% of their body weight and almost half died. The remaining animals regained their original body weight by the fourth week when the 2DG method was performed. Catheters were inserted into the femoral artery and vein of each rat under halothane-N_2O anesthesia and the animals were allowed to recover. ^{14}C-labeled 2DG was injected into the venous catheter. Timed arterial blood samples were collected. At 45 minutes, the animals were killed with pentobarbital. Local cerebral glucose utilization was determined from autoradiographic analysis and the integrated arterial curve for 2DG and glucose.

The kaolin produced a variable degree of hydrocephalus with some animals having massive ventricular dilatation. Kaolin was seen in the basal cisterns, around the cerebellum and into the fourth ventricle. Preliminary analysis of data indicate little alteration in cerebral metabolism. Only parietal cortex appears to have decreased glucose utilization during experimental hydrocephalus.

129.9 NODAL AND PARANODAL STRUCTURAL CHANGES IN EARLY WALLERIAN DEGENERATION. J. Ishise* and J. Rosenbluth (SPON: V. DeCrescito). Depts. Physiology and Rehab. Medicine, New York University School of Medicine, New York, NY 10016.

Ultrastructural changes in the nodal and paranodal regions of myelinated nerve fibers during early stages of Wallerian degeneration were studied in freeze-fracture replicas and thin sections. Frogs (Rana pipiens) were anesthetized with ethyl carbamate; the optic nerve was exposed on the right side through the palate and then transected under microscopic observation, sparing the opthalmic artery. The eye was not removed. Animals were fixed by vascular perfusion of aldehydes from one to eight days after the date of the surgery (day 1), and the degenerating optic nerve and contralateral normal nerve were removed from each animal. There was no sign of regeneration across the gap between proximal and distal segments in any case. The observations below apply to the segment ~ 1-2 mm from the eye. However, degenerative changes developed at widely different rates among different fibers in this segment, and it was therefore impossible to time the sequence of events precisely. The earliest changes appeared on day 3. Thin sections showed disorientation of axonal microtubules and some detachment of paranodal loops of myelin immediately adjacent to the node. In freeze-fracture replicas irregularities appeared in the paranodal axolemma, and detachment of myelin loops adjacent to the node was also apparent in some cases, but there was no change in the distribution of nodal particles. On day 5 some axons showed accumulations of mitochondria and dense lamellar inclusions in the nodal region. Widening of nodes became more apparent as a result of detachment of myelin loops from the paranodal axolemma. In some axons the "undercoating" along the nodal surface appeared patchy in thin sections, and in replicas a corresponding mixture of particle clusters and particle-free areas appeared in both P- and E-faces of the axolemma at some nodes. Demyelinated paranodal regions showed few node-like particles at this stage. In addition, many new "lakes" appeared between shrunken paranodal loops, but unlike those in the normal paranodal axolemma they contained few E-face particles. On day 8 the concentration of E-face particles was lower than normal at some nodes (~ 600/μ2 vs. 1350/μ2) and higher than normal in the adjacent demyelinated region of the paranodal axolemma (~ 250/μ2 vs. 25/μ2). Since the distal axon was no longer connected to the cell body, it is not likely that the increase in paranodal particles resulted from insertion of new particles. It is concluded from these results that Wallerian degeneration in the optic nerve is associated with detachment of lateral loops of myelin lamellae from the axolemma beginning adjacent to the node and that nodal E-face particles subsequently redistribute into these formerly junctional paranodal regions. Supported by grants from the NIH (NS 07495) and National Multiple Sclerosis Society.

129.10 Recovery of the Hippocampal Slice Preparation Following Hypoxia is Profoundly Influenced by the Physiological Buffer. John Grigg and E.G. Anderson Dept. of Pharmacology, Coll. of Medicine, Univ. of Illinois at Chicago, IL 60612.

Studies were initiated on the ability of synaptic activity in the hippocampal slice to recover after significant periods of anoxia. Slices (400 μm) were prepared from 150 gm rats, and immersed in 1 ml of physiological buffer infused at a rate of 2 ml/min. Bath temperature was held at 37°C. Recordings were made with a glass microelectrode placed near the cell bodies in the CA_1 region. Synaptic activity was assessed by the size of the population spike evoked by stimulating the Schaffer and commissural afferents. Pyramidal Cell viability was tested by antidromic stimulation of their axons in the alveus. Hypoxia was induced by switching to infusion media which had been bubbled with 95% N_2 and 5% CO_2. Oxygen electrode measurements showed a 90-95% reduction in O_2 content.

These experiments were initfated using an artifical cerebral spinal fluid (ACSF) containing: Na^+, 152.24; K^+, 2.5; Ca^{2+},2.4; Mg^{2+}, 1.3; Cl^-,133.3; HCO_3^-,25; HPO_4^-, 1.24; SO_4^{2-}, 1.3; glucose 11 (in mM). Under these conditions, all detectable synaptic acitvity disappeared within 2-3 mins of initiating hypoxia. The fiber spike and antidromic spike remained throughout the anoxic period. Following exposure to 20 to 90 minutes of hypoxia, reperfussion with oxygenated buffer resulted in rapid reappearance of the population spike. After 20 minutes of hypoxia reoxygenation resulted in reappearance of the population spike within 2.5 to 5 minutes and recovery reached 95-125% of the control spike within 7.5 minutes.

Kass and Lipton (J. Physiol (Lond) 332:459-472, 1982) using a comparable protocol have reported irreversible damage to hippocampal slices after 10 mins. of anoxia. The ACSF used in their experiments had a higher K^+ (5.4 mM) and lower glucose (4 mM). Using this buffer we found that a hypoxic medium induced failure of the population spike within 2 to 3 mins. From 4 to 6 mins during hypoxia a brief period of erratic recovery occurred followed by total failure. The antidromic and fiber spike then proceeded to fail. After 20 minutes of hypoxia, irreversible damage had occurred since return to oxygneated buffer failed to restore any observable activity. Initial experiments using ACSF with 6.1 mM K^+ and 10 mM glucose (Dunwiddie, Dev. Neurosci 4:165-175, 1981) showed recovery after 20 mins of hypoxia. Experiments are in progress exploring the role of low glucose in facilitating irreversible damage by hypoxia.

129.11 CARDIOVASCULAR SYSTEM TOXICITY ASSOCIATED WITH LOCAL ANESTHETIC INJECTIONS IN THE CENTRAL NERVOUS SYSTEM. R.D. Thomas, M.M. Behbehani, D.E. Coyle, D.D. Denson (sponsor: N. Sperelakis), Departments of Physiology and Biophysics and Anesthesiology, University of Cincinnati, College of Medicine, Cincinnati, Ohio 45267-0576.

Numerous in vivo and in vitro studies of bupivacaine (BUP) cardiotoxicity have recently appeared. However, none of the studies to date have addressed the issue of concomitant cardiovascular system (CVS) and central nervous system (CNS) toxicity. This study was designed a) to evaluate the potential contribution of the CNS to CVS toxicity associated with amide local anesthetics, and b) to clarify the relative influence of the C1 area of the medulla versus the tractus solitarius (NTS) on the maintenance of resting mean arterial pressure (MAP).

Rats were anesthetized with chloral hydrate (400 mg/kg). In all experiments, the MAP and electrocardiogram (ECG) were continuously monitored. Next, 1 ul 2% or 4% BUP or 1.6 ul 2% lidocaine (LID), equimalor with 4% BUP, were infused into C1, NTS, or the cervical spinal cord (thus, only affecting the C1 fibers). Also, single unit recordings of C1 neurons and the effect of BUP on the firing rate of these cells were examined. Control injections of 0.9% saline was completed on each animal.

The results of these experiments showed that saline injections caused no change in heart rate (HR) or MAP. When injected into C1, 4% BUP and 2% LID caused a drop in MAP (-42.6 ± 18.2 vs -17.5 ± 3.5 mm Hg) and slight bradycardia, but neither drug produced a change in any of the ECG intervals. Recordings of C1 cells showed that 4% BUP produced an increase in the cell firing rate of 18.0 ± 5.2 Hz (a 58% increase), but iontophoretic application of BUP at currents varying from 80 nA to 200 nA produced no changes in the firing rate. Also, 4% BUP infused at the cervical spinal cord produced a drop in MAP of -51.2 ± 30.6 mm Hg. Infusion of 2% or 4% BUP or 2% LID on NTS produced bradycardia (-15.3 + 4.2 vs -61.7 + 48.2 vs -25.4 + 9.2 bpm) and hypotension (-13.3 ± 2.3 vs -31.7 + 15.9 vs -13.0 + 4.4 mm Hg). When 4% BUP was infused on NTS, the PR interval lengthened, the T wave either disappeared or became inverted, and arrythmias usually resulted.

Results obtained in these experiments indicated that 1) LID and BUP act on axons and not on nerve cell bodies; 2) the C1 region has a tonic excitatory influence on resting MAP and NTS influences both resting MAP and the electrogenic conduction in the heart; 3) direct placement of local anesthetics within the CNS can result in arrythmias and hypotension similar to those reported following a massive intravenous injection. These data, therefore, suggest that the CNS plays a role in mediation of CVS toxicity with local anesthetics.

129.12 HIGH-FIELD PROTON NMR OF HUMAN CEREBROSPINAL FLUID. RK Yu, OAC Petroff*, T Ogino*.
Departments of Neurology and Molecular Biophysics and Biochemistry, Yale University, New Haven, CT 06510.

Human CSF samples were obtained from the clinical chemistry laboratory of Yale-New Haven Hospital. The medical records of the patients involved were reviewed for clinical information including the reasons the CSF samples were obtained and the results of the clinical laboratory's analysis. Samples were analyzed near or after concentration by lyophilization. The latter samples were resuspended in 100 mM neutral phosphate in deuterium oxide buffer with a known amount 3-trimethylsilylproprionate (TSP) added as an internal standard. Spectra were obtained at 500 or 360 MHz at 25°C using a 30° pulse and a 5 or 10 second repetition rate. Low power pre-saturation of the water resonance was used as needed.

Preliminary assignments were made on the basis of pure compound spectra and literature values. These compounds include beta hydroxy butyrate (1.21 & 2.36 ppm), lactate (1.33 & 4.12 ppm), acetate (1.92 ppm), glutamine (@ 2.1 & 2.4 ppm) and creatine (3.06 ppm). The region between 3.2 and 4.0 ppm contained multiple resonances from choline containing compounds, glucose, fructose, and polyols. The alpha and beta conformers of glucose showed resonances at 4.65 and 5.24 ppm, respectively. Quantitation of these glucose resonances using the TSP standard showed good agreement with the measurements made by the clinical laboratory on the same samples. Values calculated for lactate, creatinine, and glutamine were within the range listed in the literature.

129.13 LACK OF DYNORPHIN, BUT NOT ENKEPHALIN OR SUBSTANCE P, IMMUNOREACTIVITY IN THE DORSAL GLOBUS PALLIDUS IN GILLES de la TOURETTE'S SYNDROME. S.N. Haber, N.W. Kowell, J.P. Vonsattel, E.D. Bird and E.P. Richardson. Department of Anatomy, University of Rochester School of Medicine, Rochester, NY 14642, and Departments of Neurology and Pathology, Harvard Medical School, Boston, MA 02114.

The normal distribution of enkephalin (ELI)-, dynorphin (DLI)- and substance P (SPLI)-like immunoreactivity have been described in detail in the human forebrain.[1] We report here the peptide distribution patterns in the forebrain of a patient diagnosed as having Gilles de la Tourette's syndrome (TS), a disease which has, to date no known associated pathology.

The brain was removed less than 4 hours post-mortem. Tissue to be processed for pathological analysis was immediately placed in buffered formalin and blocks were divided for routine stains used for pathological analysis and for immunohistochemical studies. Peptide distribution patterns from this brain were compared to five brains from neurologically normal patients and from three patients diagnosed as having Huntington's Chorea.

ELI, DLI and SPLI normally appear in a unique pattern in the globus pallidus (and substantia nigra), now termed woolly fibers. All three peptides appear densest in this form and levels in the globus pallidus and nigra are the highest in the brain.

The routine pathological examination of the TS brain did not reveal a specific anatomical locus of pathology to account for the patient's illness. Both enkephalin and substance P-positive woolly fibers were very densely stained and their distribution appeared normal in the TS brain. DLI, however, appear to stain lighter than normal throughout the brain. The most striking observation was the complete lacking of dynorphin-positive woolly fibers in the dorsal globus pallidus. Very faint staining was noted in the ventral pallidum. These results, indicating a decrease of dynorphin in striatal fibers projecting to the pallidum, are intriguing, and represent the first suggestion of a possible pathology in TS.

Supported by NIH 5R23-NS20467, The Scottish Rite Schizophrenia Program and NIH MH-NS31862.

129.14 CHOLINERGIC PROTEINS IN ALZHEIMER'S DISEASE S.G. Younkin, J. Katz*, D. Nafziger*, L.H. Younkin, Depts. of Pathology and Pharmacology, Case Western Reserve University, Cleveland, Ohio 44106

Candy et al. (J. Neurol. Sci. 54: 59: 277, 1983) have reported that in Alzheimer's disease (AD) the decreases in choline acetyltransferase (over 90%) and acetylcholinesterase (79%) in the nucleus basalis of Meynert (nbM) are more extensive than the loss of cholinergic perikarya (35%). Their observations suggest that altered metabolism of cholinergic proteins in nbM neurons may contribute to the loss of cholinergic proteins observed in Alzheimer's disease (AD). To evaluate this possibility, we assayed choline acetyltransferase (ChAT) and the several molecular forms of acetylcholinesterase (AChE) and counted cholinergic neurons in alternating 24 um cryostat sections through the nbM in 17 AD and 8 age-matched control brains. ChAT and AChE forms were also assayed in cerebral cortex (Brodmann area 21). Only a small fraction of the nbM blocks and cryostat sections prepared from each brain were required to make these measurements. Thus we have accumulated a "library" of frozen nbM blocks and cryostat sections that are well characterized and available for additional biochemical and histological analysis. In cases similar to those described by Candy et al. in which there was a subtle decrease in the number of cholinergic nbM neurons, the ChAT/ cholinergic neuron decreased significantly as previously described. The seven cases in this category showed a decline in nbM cholinergic neurons to 68% of normal (282-461 neurons/section vs 357-836 neurons/section in control brains), a decrease in nbM ChAT to 51% of normal, and a decline in cortical ChAT to 51% of normal. In those cases in which there was a large decrease in the number of cholinergic nbM neurons, we observed a significant five-fold increase in mean ChAT/cholinergic neuron. The nine cases in this category showed a marked decline in nbM cholinergic neurons to 22% of normal (26-201 neurons/section vs 357-836 neurons/section in control brains) no change in nbM ChAT, and a marked decline in cortical ChAT to 22% of normal. The cases with a low ChAT/cholinergic neuron and relative preservation of cholinergic neurons and cortical ChAT could be explained by postulating reduced ChAT synthesis with relative preservation of ChAT transport. The cases with a high ChAT/cholinergic neuron are most easily explained by postulating severe disruption of ChAT transport. It is currently unclear if the differences observed represent different stages in the evolution of a single disease process or are due to fundamentally different disease processes.

129.15 THREE-DIMENSIONAL DISPLAY OF REGIONAL CEREBRAL BLOOD FLOW USING EMMISION COMPUTED TOMOGRAPHY. D.S. Schlusselberg, W.K. Smith, T.R. Simon*, D.J. Woodward. University of Texas Health Science Center at Dallas, and Dallas VA Medical Center, Dallas, TX.

Emission tomography provides quantitative information within a 3D volume, but current display techniques are limited to serial cross-sectional slices or rotating projection images. We have developed new algorithms which provide computer-generated 3D images of radiopharmaceutical activity from analysis of tomographic data. Regional cerebral blood flow data is provided by intravenous injection of radioactive iodoamphetamine. A rotating gamma camera provides projection images which are used to compute serial transverse sections by backplane projection algorithms.

Combinations of manual perimeter tracing and computed edge-detection are used to create 3D regions of interest from the serial slices. The 3D regions of interest can either be selectively displayed with overlying activity removed, or enhanced within a transparent volume. Other imaging strategies include: surface models, color-coded circumferential histograms, and transparent slices. Multiple imaging strategies can be combined in a single image to enhance anatomic localization of abnormal areas. The images can be displayed on most raster-based display devices currently used to examine serial tomographic sections.

These techniques provide a new tool for assessment of regional cerebral blood flow abnormalities in normal aging humans and patients with neurological disorders.

Supported by NIAAA AA3901 and the Biological Humanics Foundation.

129.16 STRUCTURAL AND FUNCTIONAL CORRELATES OF PEDOPHILIA. B. Graber, S.E. Hendricks, C.J. Golden* and K. Hartmann* Dept. of Psychiatry, Univ. Nebr. Med. Ctr., Omaha, NE 68106

Diagnosed pedophiles detained as mentally disordered sex offenders were compared to a control group and established norms utilizing several neurodiagnostic techniques. Measures obtained included regional cerebral blood flow (rCBF), computerized tomographic (CT) brain scan, and neuropsychological assessment. We estimated rCBF using a Xenon-133 inhalation technique. Eight detector probes were distributed over each hemisphere. Blood flow was estimated for both white and gray matter. CT scans were examined to select three slices reflecting cortical frontal lobe activity. The mean density of each hemisphere was determined. Neuropsychological assessments we obtained using the Standardized Luria-Nebraska Test Battery. Pedophiles were found to differ from controls and/or normative data with respect to all of these measures. Findings are consistent with an interpretation of pedophilia being associated with atypical CNS structure function.

129.17 IMPAIRMENT IN RECOGNITION OF FACES, MIMIC AND GESTURES IN PATIENTS SUFFERING FROM SCHIZOPHRENIA OR UNILATERAL BRAIN LESIONS. O.J. Grüsser, K.Berndl*, M. von Cranach* and R.Kiefer*.Dept.Physiology, Freie Universität Berlin and Landeskrankenhaus Kaufbeuren (Germany-West).

A test film consisting of 12 different silent movie scenes, each of 10 sec duration, was used to test elementary abilities in perception and recognition of mimic and gestural expressions. 10 verbal and non-verbal multiple choice tests were applied to each scene (fig. 2), all tests being very easy for normals (fig. 1).

(a) In patients suffering from a unilateral left- or right - hemisphere lesion a reduction in all tests was found with an expected additional increase in errors when verbal tests were applied in aphasic patients. Patients suffering from lesions in the temporo-occipital region tended to have the highest error scores.

(b) A surprisingly severe impairment of mimic and gesture recognition was found in a second group of 81 schizophrenics (fig. 1). For more than 90 percent of the schizophrenic patients the test results were outside of the range found in a group of age-matched normals. Error score was slightly correlated with schizophrenic defect.

(c) In a third group of adolescent schizophrenics the same impairment was found, indicating that long-term hospitalization, drug treatment etc. are not essentially responsible for this cognitive defect. Since many schizophrenic patients suffer from severe behavioural impairment in the social field, our data might indicate the underlying cause of this disturbance.

129.18 AN ISCHEMIC STROKE MODEL IN THE RAT WITH CONSISTENT LARGE CORTICAL INFARCTION. S. T. Chen*, C. Y. Hsu, E. L. Hogan and J. D. Balentine*. Departments of Neurology and Pathology, Medical University of South Carolina, Charleston, SC 29425.

We have developed a reproducible model of ischemic stroke in the rat by graded interruption of the collateral circulation to the occluded middle cerebral artery (MCA). Three groups of animals were investigated in the process: Group 1, ligation of the right MCA; Group 2, ligation of the right MCA and ipsilateral common carotid artery (CCA); Group 3, ligation of the right MCA and CCA plus clip compression of the left CCA for 1 hour. Sham operated animals received isolation of bilateral CCAs, and passage of needle underneath the right MCA without ligation. The relative surface blood flow of the cortex supplied by the right MCA was determined by laser Doppler flowmetry (Periflux, Perimed, Sweden). MCA ligation produced a fall of blood flow to 62 $\pm$ 11% of the baseline (mean $\pm$ SEM, n=5). Additional occlusion of ipsilateral CCA and bilateral CCAs reduced the flow to 48 $\pm$ 10% and 18 $\pm$ 4% respectively. The reduction in the relative surface blood flow after each successive ligation was significant by paired-t test ($p<0.005$). Morphological studies conducted 3 days post surgery showed grossly visible infarcts in cerebral cortex supplied by the right MCA in all group 3 animals (n=10), but only 3 in Group 2 (n=10) and none in Group 1 (n=10). The maximum cross-sectional area of infarction was 10.4 $\pm$ 3.5 mm^2 (mean $\pm$ SEM, n=10), 4.8 $\pm$ 1.9 mm^2 (n=10) and 1.7 $\pm$ 0.8 mm^2 (n=10) in Group 3, 2, and 1 respectively. In Group 3, the surface area of infarction measured on a Videoplan interactive image analysis system (Carl Zeiss, West Germany) was 100 $\pm$ 6 mm^2 (mean $\pm$ SEM, n=10). In sham operated animals pathological changes were restricted to a surface lesion of the surgical site (1-4 mm diameter). Using the Group 3 rat as a stroke model we have followed the post-ischemic changes up to 14 days and noted the progressive accumulation of calcium and degredation of neurofilament proteins corresponding to evolving histopathological findings. This model thus offers the advantages of a consistent large cortical infarct, satisfactory long term survival and a relatively low mortality rate of 7% (n=70).

129.PO TRIMETHYLTIN (TMT) INDUCED NEUROPATHOLOGICAL CHANGES IN THE NEONATAL RAT. L.W. Chang. Dept. of Pathology, Univ. of Ark. for Medical Sciences, Little Rock, AR 72205.

Trimethyltin (TMT) as a potent neurotoxicant, especially on the limbic system, is well recognized. Our previous study indicated that the developing nervous system was even more sensitive to TMT than that of adult animals. A single injection of TMT between postnatal day (PND) 11-15 produced total destruction of the Ammon's horn within 3-4 days. Our present study is to provide a more detailed time-course evolution of this rapid pathological action of TMT. Neonatal rats (Sprague-Dawley) were injected (i.p.) with a solution of trimethyltin chloride at a dose of 6.0 mg/kg b.w. on postnatal day 13 (PND 13). Control animals were similarly injected with equal volumes of saline solution. Animals, in groups of 5, were sacrificed at 8 hour intervals following TMT administration. At sacrifice, animals were perfused intracardially with saline solution followed by 2.5% buffered glutaraldehyde. Brains were carefully removed. Left hemispheres of the brains were further fixed in 10% buffered formalin and prepared for light microscopy examination. The hippocampus from right hemisphere of the brains were dissected out and processed for electron microscopy. No remarkable light microscopic histopathology was observed at 8 and 16 hours after intoxication. By 24 hours post-injection, significant neuronal changes, including neuronal swelling and necrosis, were found in the olfactory (OC), pyriform (PC), and entorhinal (EC) cortices. The large pyramidal neurons of the Ammon's horn, particularly those in field CA_3, also showed progressive neuronal necrosis. Involvement of the $CA_{1,2}$ neurons of the Ammon's horn was also evident but was considerably less than those in field CA_3. Despite the rapid destruction of the OC, PC, and EC neurons as well as the Ammon's horn, involvement of the granule cells in the fascia dentata was only moderate and subsided rapidly. Such degenerative pattern resulted in total destruction of the Ammon's horn with a relatively intact fascia dentata by 72 hours post-injection. Electron microscopy revealed extensive accumulation of lysosomes in the pyramidal neurons as early as 16 hours after intoxication with increasing and progressive neuronal degeneration and necrosis with time. The present study demonstrated that the neonatal rat limbic system is extremely sensitive to TMT toxicity, particularly during the third week of postnatal life. The overall sensitivity among the limbic neurons to TMT may be rated as: OC $\geq$ PC/EC $\geq$ CA_3 > $CA_{1,2}$ > granule cells of fascia dentata. It is of interest to note that the septotemporal gradients for TMT-induced lesion, as those observed in adult animals, also existed. The overall sensitivity for Ammon's horn pyramidal neurons, particularly those in field CA_3, was septal > temporal and for the fascia dentata granule cells was temporal > septal. Neurons in the dorsal hippocampal formation are by far more sensitive than those in the ventral hippocampus.

STAINING AND TRACING TECHNIQUES

130.1 A SURVEY OF CARBONIC ANHYDRASE HISTOCHEMICAL ACTIVITY IN THE NERVOUS SYSTEM. V. Wong, C.P. Barrett, E.J. Donati, and L. Guth (SPON: T.H. Oh). Dept. of Anatomy, Univ. of Maryland Sch. Med., Baltimore, MD 21201.

While it is generally believed that neurons do not contain carbonic anhydrase, a recent histochemical study has demonstrated that a subpopulation of dorsal root ganglion (DRG) neurons contain the enzyme (J. Histochem. Cytochem. 31:292-300). Such observation raises questions on the role of carbonic anhydrase in neurons. In the present study, we describe a global histochemical survey of carbonic anhydrase activity in the nervous system, including structures derived from the neural crest and non-neural crest ectoderm. We found that carbonic anhydrase histochemical activity is present in many neurons of neural crest origin, including dorsal root, trigeminal, nodose and celiac ganglia, myenteric plexus, and glial cells throughout the CNS. Quantitative study revealed that, in first order sensory neurons, the enzyme is found only in neurons of large (50 um or above) and medium (20-50 um) size. Small neurons (< 20 um) did not show reactivity. In the DRG, the reactive neurons constitute about 35-40% of the total neurons; the distribution between heavily and moderately stained cells are 23% and 16%, respectively. The action of the enzyme is hydration of carbon dioxide; however, since carbon dioxide can be the by-product of many metabolic pathways in the nervous system, the specific function of carbonic anhydrase in each of these cell types may be different. We speculate that carbonic anhydrase in neurons of the dorsal root and trigeminal ganglia is responsible for maintaining a carbon dioxide tension necessary for optimal monosynaptic reflex function. While further experimentation is necessary to confirm this, we believe that the histochemically demonstrable amount of neuronal carbonic anhyrase is related to physiological functions of these neurons.

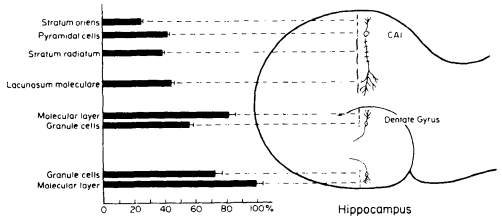
130.2 REGIONAL HETEROGENEITY OF NEUROFILAMENTS REVEALED BY MONOCLONAL ANTIBODIES. M. Vitadello, C. Triban*, M. Fabris*, R. Zanoni*, A. Gorio and S. Schiaffino*[1]. Fidia Research Laboratories, 35031 Abano Terme, (PD), Italy and [1]Institute of General Pathology, University of Padua, Padua, Italy.

A library of monoclonal antibodies directed against neurofilament protein was obtained immunizing Balb/c mice with a crude neurofilamnet preparation (Wood J.N. and Anderton B.H., Bioscience Reports, 1:263-268, 1980). These antibodies were characterized by indirect immunofluorescence technique on adult rat cerebellum cryosections and by immunoblotting procedures on whole protein homogenates from rat PNS and CNS. The distribution of neurofilament protein recognized by the different antibodies was checked on cryosections from different regions of rat nervous system and results showed that immunoreactivity was present exclusively in neuronal structures. The distribution of neurofilament antigens was in general identical with the different antibodies. However, certain neurofilament populations, such as those in dendrites and cell bodies of motor neurons were not labeled by some antineurofilament antibodies. These results suggested that in some locations, like motor neuron cell bodies and dendrites, neurofilament have a reduced or even absent complement of the different subunits. An alternative possibility is that different isoforms of the neurofilament subunits exist in different regions of the nervous system.

130.3 A VOLTAGE MAP OF THE HIPPOCAMPUS USING CYANINE VOLTAGE-SENSITIVE DYE AS A HISTOLOGICAL MARKER. R. M. Dasheiff. Epilepsy Center, VA Hospital; and Dept. of Neurology, Univ. Wis., Madison, WI 53705

It is desirable to know the electrical properties of large neuronal populations when studying epilepsy and seizure activity. Current electrophysiologic techniques lack the ability to sample large anatomical areas. Although histologic techniques allow the entire brain to be examined, existing methods could not produce a direct record of membrane potential. Voltage-sensitive dyes (VSD) have been successfully used to monitor membrane potential in living tissue. However, all previous work with VSD has required direct optical access to the tissue, and the recordings performed in real-time. We now show how cyanine VSD can be used as a histologic marker of membrane potential.

DiO-C_2-(5) was injected into the common carotid artery of awake rats. The dye (10^{-4}M) was mixed with a 30% concentration of mannitol, 5% EtOH, to open the blood brain barrier. Two ml were injected at 6.8 cc/min. Electrodes implanted into each hippocampus showed minimal or no changes during the 20-sec injection. Awake animals were induced to have a seizure by either bicuculline (0.25 mg/kg in dimethylsulfoxide injected into the jugular vein) or kainic acid (12 mg/kg, i.p.). The injection of dye during a seizure did not abort the seizure but sometimes caused a reduction in the voltage of the waveforms on the EEG. Animals were decapitated immediately after dye injection, their brains frozen in 2-methylbutane, 10-μ thick sections cut on a cryostat and cover-slipped with permount. I have discussed the concept and validity of using the rate of dye uptake into tissue as a measure of membrane potential (J Neurosci Methods 13:199-212, 1985). A computerized fluorescent microscope scanned the septal hippocampus and quantitatively assessed dye content. Absolute voltage could not be calculated. Instead, data from each slide were normalized to the molecular layer of the inferior blade of the dentate gyrus. The normalized voltage map obtained from 130 sections from 4 control rats is shown below. Error bars are S.E.M. ANOVA yields $P < .001$. Voltage maps from seizing animals differed from control and will be displayed.



130.4 HISTOFLUORESCENT METHOD FOR HIPPOCAMPAL ZINC. M.L. Blockus*, J.D. McCourt*, E.J. Kasarskis, and C.J. Frederickson. Lab. for Neurobiology, University of Texas at Dallas, Richardson, TX 75080 and Department of Neurology, University of Kentucky, Lexington KY, 40536.

Quinoline derivatives form fluorescent chelates with zinc and have been used successfully for fluorometric assays and visualization of zinc in somatic tissues and fluids (Smith et al., J. Histochem. Cytochem., 1969,17:749). In search of a micro histochemical technique for studying zinc in brain tissue which would be (1) quantitative, (2) of high-resolution, and (3) reasonably efficient, we have examined the usefulness of quinoline fluorescent methods for studies of zinc in the hippocampal mossy fiber neuropil in the mouse.

Both intravital and post-mortem procedures have proved acceptable for fluorescent labeling of the mossy fiber zinc with 2-methyl-8-hydroxy quinoline. With the intravital method, strong fluorescence is obtained when animals are sacrificed 5 - 20 minutes after systemic injection of acidic aqueous quinoline solution, and brains are either cryotomed fresh or after a brief perfusion with buffered aldehydes. For post-mortem staining, unfixed cryostat sections, as well as aldehyde-fixed sections and JB4-embedded sections, have all been found to yield a fluorescent reaction in the mossy fiber neuropil. Besides the mossy fiber tissue, other zinc-rich tissues including the amygdala, pancreas, and adult male mouse submandibular gland also fluoresce after the quinoline staining procedures.

When excited with 360 nm ultraviolet light, the fluorophore emits the characteristic yellow-green zinc-quinoline fluorescence spectrum which is approximately symmetrical with an emission peak at 520 nm. With the intravital method, the intensity of emisions found in the tissue increases monotonically with low doses of quinoline, but plateaus at about 500 mg/kg, suggesting that fluorescence intensity at the higher doses is quantitatively determined by the concentration of endogenous tissue zinc. The results indicate that quinoline fluorescence may be a useful tool for histoanalytic studies of zinc in the brain.

130.5 LONG-TERM PRODUCTS OF NEURAL DEGENERATION IN PRIMATE VISUAL SYSTEM. Alfredo A. Sadun and Betty M. Johnson, Dept. of Ophth., USC School of Med., L.A., CA. 90033.

There is a long held dictum that axonal products of degeneration in the CNS are transitory. Conventional wisdom suggests that metabolic degradation and phagocytic processes in the mammalian brain remove degenerated axonal elements. Successful silver impregnation of degenerating axons produced by a lesion usually require a survival period of 3-7 days from the beginning of Wallerian degeneration. Despite this limitation, which precluded many investigators from attempting to trace degeneration in the human brain, Mesulam (1979) and Grafe (1980) have recently demonstrated the persistence of argyrophilic degenerating elements in the human CNS with survival periods in excess of one year.

Most neuroanatomic tracing techniques are not suitable for studies in man. We recently addressed this problem and developed the PPD staining method. This method reliably stains degenerated axons and axon preterminals in postmortem human brains even with very long (years) survival periods. Application of this method on 22 human necropsy brains has permitted us to histologically confirm retinofugal pathways to LGN and pretectum, and significantly, to demonstrate retinal projections to the superior colliculus, pulvinar, and 3 hypothalamic nuclei in man (Sadun, 1982-1985).

PPD-method studies suggest that products of degeneration persist for years in some pathways in the human brain. Ultrastructural confirmation of long-term products of degeneration is difficult in the human brain because of the poor quality of fixation. We therefore examined twelve brains from monkeys who had uniocular enucleation one month to one year prior to sacrifice by perfusion. Tissue from the optic nerves, optic tracts, and LGN was examined by the PPD technique and by EM. We compared the results of these two methods and demonstrated, by ultrastructural criteria, products of degeneration in the primate visual system one year following injury to the retinal efferents.

Differences in degeneration rates have been shown to exist in different fiber systems and in different species. We feel the present evidence for long-term degeneration in the primate visual system provides a basis for the direct study of human visual neuroanatomy by techniques such as the PPD method.

130.6 NOVEL STAINING PROPERTIES OF EPIDERMAL MERKEL CELLS AND THEIR MECHANOSENSORY INNERVATION. C.A. Nurse. Dept. of Biology, McMaster University, 1280 Main St. W., Hamilton, Ontario L8S 4K1.

In mammalian hairy and glabrous skin, the epidermal Merkel cells (MCs) aggregate in well defined patterns at locations concerned with tactile sensation. These MCs contain large dense cored granules and are frequently innervated by large myelinated sensory fibers. Vital staining with the fluorescent dye quinacrine (QC) has been used to study the distribution of MCs in the vertebrate integument (Nurse et al., 1983, Cell Tiss. Res. 228: 511-524) and the role of sensory nerves in their postnatal development in rat hairy skin (Nurse et al., 1984, Neurosci. 11: 521-533). I now report that MCs can also be stained with low concentrations (0.01 mg/ml) of another vital dye Neutral red (NR), following ½ hr incubations of epidermal tissues in buffered physiologic salt solutions. This NR-staining reveals similar cell patterns to that seen with QC-fluorescence in various rat tissues including the vibrissal follicle and the split epidermis of the whisker pad, the (glabrous) footpad and the touch dome. Further, in monolayers of dispersed vibrissal (outer root sheath) cells, NR stains a select cell population that was previously QC-positive; the latter cells were previously shown to be MCs by ultrastructural criteria (Nurse et al., 1983). Preliminary studies on developing skin tissues suggest however that quantitatively more cells are labelled by QC than by NR; this may simply reflect differences in the sensitivity of the two methods, especially with respect to immature MCs. This NR-staining of MCs appears general since it also occurs in the split epidermis of adult salamander (hind limb) skin where the MCs are irregularly distributed; in this tissue the NR-stained cells were also QC-positive and occurred typically with a density of 180-300 cells/mm^2 and a size of 14-18 μm. It is of interest that though several monoamine containing cells possessing large dense cored granules can also be vitally stained with NR (Stuart et al. 1974, Cell Tiss. Res. 153: 55-61), the MCs so far appear unable to synthesize or accumulate the common biogenic monoamines. The innervation of the MCs in rat skin is also being studied using a zinc iodide-osmium procedure; in 10-20 μm frozen sections, sensory nerve fibers and their terminations are readily stained including those in the MC-rich regions of the upper vibrissal follicle and of the overlying epidermis. More recently, I have successfully used the fluorescent dye 3,3'-diethyloxadicarbocyanine iodide (see Yoshikami and Okun, 1984, Nature 310, 53-56) for vital staining of sensory nerves in rat skin. Since this dye fluoresces in the red wavelength and can be used in combination with quinacrine (which fluoresces in the green), the double labelling procedure appears potentially useful for studying the innervation of MCs by a vital staining technique. (Supported by NSERC Canada; studies were initiated under PHS grant NS 15592-02 to J. Diamond.)

130.7 THE USE OF SUPER GLUE IN ISOLATING TRACER PLACEMENT IN PERIPHERAL TARGETS. T. C. Bour* and A.O. Humbertson, Jr. Department of Anatomy, The Ohio State University, Columbus, Ohio 43210.

Retrograde tracers have been used to identify neurons of the central nervous system that contribute to the innervation of peripheral structures. A major difficulty in using retrograde tracers for this purpose is that inaccurate labelling may be caused by the diffusion of peripherally applied tracers into surrounding tissue. Tracer diffusion can be especially compromising when examining visceral innervation due to the close proximity of visceral structures. Accordingly, it is of importance to develop techniques that can be used to apply retrograde tracers without tracer diffusion. This abstract will report one such technique.

Six adult white rats received a visceral application of the fluorescent tracers True Blue and Diamidino Yellow. The tracers were separately and exclusively applied to pairs of visceral organs, such that if True Blue was used for one organ of the pair (eg., stomach), Diamidino Yellow was used for the other (eg., pancreas). Following blunt dissection of the epithelium, crystals of the tracer were applied directly to the exposed wall of a given organ. The opening and the crystals were then covered with Super Glue. After an appropriate survival time, the animals were sacrificed and all tissues surrounding the tracer application sites, as well as the brainstem and spinal cord, were removed, sectioned, and examined for tracer diffusion and labelling. Examination of visceral tissue revealed no tracer diffusion; the glue contained the tracer at the application site. Furthermore, cells of the dorsal motor nucleus of the vagus nerve and of the nucleus ambiguus were labelled by the tracers in a pattern similar to that obtained by other investigators, indicating that the glue did not interfere with retrograde transport. The results of this study suggest that Super Glue may be effectively used to isolate the placement of retrograde tracers in peripheral targets.

T. Bour was supported by the Samuel J. Roessler Fund of the Ohio State University College of Medicine.

130.8 ORIGIN AND IDENTIFICATION OF FIBERS IN THE CRANIAL NERVE IX-X COMPLEX OF *XENOPUS LAEVIS*: LUCIFER YELLOW BACKFILLS *IN VITRO*. H. Blair Simpson*, M. Tobias and D. B. Kelley. Dept. of Biol. Sciences, Columbia Univ., New York, N. Y. 10027

Neurons of cranial nerve nucleus (n.) IX-X in *Xenopus laevis* are sexually dimorphic in cell size, number and dendritic extent. Golgi-Cox impregnations which reveal dendritic morphology do not permit precise identification of motor neuron muscle targets. We have therefore developed a Lucifer Yellow backfill method for use in identifying motor nuclei and sensory projections of cranial nerves in an isolated brain preparation. Male and female frogs were anesthetized, chilled and the brain anterior to the first spinal nerves gently removed and placed into a Hepes-buffered Ringer's solution. A Histoacryl-vaseline cup was built around the nerve root of interest and a drop of 4%LY-Ch applied for 1-2 hours. The brain was then fixed in 4% buffered paraformaldehyde, cryostat sectioned at 60μ, dehydrated and viewed with a fluorescent microscope. Lucifer Yellow filled laryngeal motor neurons were recognized by retrograde labelling with horseradish peroxidase (HRP). For double label experiments, 1-2μl of HRP was injected into the larynx. Following a two day survival, frogs were saline-perfused, LY-backfilled as above and fixed in 0-1% buffered paraformaldehyde/0.1% glutaraldehyde.

Neurons of cranial nerve nucleus (n.) IX-X send axons to the periphery through the most posterior root (4) of the IX-X nerve complex. In some preparations, a small population of anterior n. IX-X cells exit the medulla with root 3. Root 4 also contains axons of autonomic preganglionic neurons whose cell bodies are located medial to n. IX-X. Double label (LY-HRP) studies indicate that the majority of n. IX-X cells project to the bipennate muscles of the larynx via root 4. Comparison of male and female root 4 fills reveal cells of three morphological classes (triangular, ovoid and elongate) in both sexes. Males have more large n. IX-X neurons than females; females more small n. IX-X neurons than males. Primary and secondary dendrites of n. IX-X neurons are well filled in both sexes. Root 3 contains afferent fibers projecting to five anatomically distinct sensory projection zones; these include cutaneous afferents from the shoulders and trunk and presumed somatosensory fibers projecting to the dorsal column nuclei. Root 2 has sensory fibers terminating in the nucleus tractus solitarius and axons of lateral line efferents. The most anterior root (1) contains lateral line afferents terminating in the lateral line lobe.

With this LY-backfill method, spinal or cranial nerve roots can be filled and the location of sensory terminal fields and efferent cell bodies rapidly mapped with good resolution. In combination with HRP tracing, the origins or targets of LY-filled central projections can be determined. We anticipate that this method may, with modifications, be useful for combined anatomical and electrophysiological studies of laryngeal motor neuron activity underlying the generation of vocal behavior in male and female *X. laevis*.

130.9 DIFFERENTIAL LABELLING OF IDENTIFIED NEURONS AND SEROTONERGIC FIBERS IN THE STOMATOGASTRIC GANGLION OF DECAPOD CRUSTACEA. P.S. Katz and R.M. Harris-Warrick. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853

We have developed a double label protocol using the established peroxidase visualization techniques of o-dianisidine (DIA, Sigma) and diaminobenzidine (DAB, Sigma II) to differentiate intracellularly injected horseradish peroxidase (HRP, Sigma VI) from peroxidase tagged antibodies at the light microscope level. Using this technique, we are able to map the distribution of dendritic processes of single cells in the stomatogastric ganglion, which appear light brown due to the DIA chromagen, and serotonergic (5-HT) afferents which are dark brown or black due to the DAB reaction product.

Physiologically identified neurons in the pyloric CPG of the lobster, Homarus americanus, and the crab, Cancer irroratus were pressure-injected with HRP (5% in filtered 0.2M KCl) Fast Green FCF (2mg/ml) was added to allow visual confirmation of cell fills. After allowing one hour for the HRP to diffuse, the ganglia were fixed in 0.2% glutaraldehyde, 0.5M NaCl for one hour followed by paraformaldehyde-lysine-periodate fixative (McLean and Nakane, J. Histochem. Cytochem., 22:1974) for 16 hours. The ganglia were soaked in 0.1M $NaBH_4$ to remove excess aldehydes. The HRP was then developed using a modified DIA procedure (Colman et al., Brain Res., 102:1976) to produce a light brown reaction product. The tissue was soaked in 0.3mg/ml DIA in 0.1M phosphate buffered saline (PBS) containing 1% nitroprusside (NP). After 30 minutes, 33μl of 1.2% acidified H_2O_2 was introduced for each ml of solution. The reaction was stopped after 5 minutes with 2 changes of 3% NP followed by PBS. The ganglia were soaked in 20% sucrose for at least 24 hours prior to cryostat sectioning. For immunocytochemistry, sectioned material on slides was rinsed in PBS + 0.3% Triton-X100 + bovine serum albumin (1mg/ml). 150μl of 1:200 anti-5-HT antibody (New England Nuclear) was placed on the sections for 90 minutes in humidity chambers. The sections were rinsed in PBS-Triton + 10% normal goat serum. The 5-HT antibody was then labelled with peroxidase using either Avidin-Biotin (Vecta Stain) or peroxidase-anti-peroxidase (Polysciences) with a goat-anti-rabbit bridge (Sternberger-Meyer). The peroxidase-labelled antibody was developed using a standard DAB reaction to produce a dark brown product. (Freshly made 0.5mg DAB/ml PBS to which 0.1ml 3% H_2O_2 was added for each 100ml of solution.) The slides were rinsed, counterstained and coverslipped.

This technique provides a convenient method for examining the anatomical connections of physiologically well-studied invertebrate systems. Supported by HATCH Grant NYC191410 and NIH NS17323.

130.10 A FRAGMENT OF "FAST BLUE" BUT NOT "FAST BLUE" ITSELF IS TRANSPORTED BY AXONS. G.F.Alheid. Dept. of Behavioral Medicine and Psychiatry, Univ. Virginia Sch. of Med., Charlottesville, Va 22908.

The retrograde fluorescent tracers have been a powerful tool for identifying long axonal pathways in the brain, and when used in the correct combination may allow tracing of collaterals to two different targets in the brain. Furthermore, identification of the potential transmitter used by neurons projecting to a particular area may be accomplished by using retrograde fluorescent tracers combined with immunofluorescence for an antigen specific to a particular transmitter system.

Of the available fluorescent tracers, "FAST BLUE" [trans-1-(5-amidino-2-benzofuranyl)-2-(6-amidino-2-indoyl) ethylene dihydrochloroid; Bentivoglio et al. Neurosci. Lett. 18:25, 1980] is one of the more interesting since in our experience it appears to be transported retrogradely better than most of the other available tracers, fluorescent or otherwise, and it apparently also is transported anterogradely.

After receiving a new sample of "FAST BLUE" we found that, using the same concentration and volume of the compound, transport was minimal. The new sample differed superficially from the old sample in color; the new sample was a yellow powder (YFB), while the old sample was a brown powder (BrFB). Using mass spectroscopy we verified that the new sample was indeed "FAST BLUE" while the old sample contained a major contaminent which differed from the peak for YFB by 17 daltons. Presuming the contaminent is a by-product of the synthesis of YFB, the difference may be accounted for by a missing amine group. Since there are two amine groups on YFB, the contaminent could be one of two compounds either of which would have a reactive cyano-group on one end.

This result suggests that the reason that BrFB is transported so avidly is that a reactive (non-aminated) end of BrFB could readily bind with amine groups in vivo, thus attaching itself to pre- and post-synaptic cell membranes. This same logic may apply to other related fluorescent tracers, so that more avidly transported compounds might be designed in a variety of colors.

This work was supported by NIH grant R NS1774303. Harvey Laboratories Inc., Charlottesville, Va. generously performed the mass spectroscopy.

130.11 SULFORHODAMINE 101 AS A FLUORESCENT PROBE FOR INTRACELLULAR DYE-FILLS, DIFFUSION BACKFILLS, AND DOUBLE LABELING WITH LUCIFER YELLOW. J.W. Pendleton* and H. Keshishian (SPON: E.R. Roederer). Biology Department, Yale University, New Haven, CT 06511.

Lucifer Yellow (LY) has proved invaluable as an intracellular dye for revealing the anatomy of individual neurons. A second fluorescent probe with qualities similar to LY but fluorescing red would be very useful for double labeling purposes. Here we describe the use in both vertebrate and invertebrate preparations of sulforhodamine 101 acid chloride (aka Texas Red, TR) as well as its similarities to and differences from LY. TR absorbs maximally at approximately 584nm and at that wavelength its fluorescent emission maximum is at approximately 600 nm. Neurons filled with TR fluoresce brilliantly red when excited with conventional rhodamine filter sets. The cells are essentially invisible when viewed using FITC optics. Because of these spectral characteristics, TR is suitable for double labelling experiments, for example in indirect FITC immunocytochemistry.

Giant axons in the larval lamprey spinal cord may be filled with Texas Red (5% in saline or distilled water) by diffusion from a spinal transection. Stained axons remain clearly visible in preparations 10 days after injection of TR into a spinal transection, demonstrating that TR is a vital and long-lasting fluorescent stain. The dye may also be intracellularly iontophoresed into neurons using hyperpolarizing current. The microelectrodes had tips filled with 5% TR in distilled water, with 3M KCl in the shafts. TR proved to be an excellent intracellular dye in cells ranging from small (5 micron) interneurons and efferents in Drosophila to giant bulbar cells in the lamprey. TR is retained within the cells during the impalement, and does not leak across the cell membrane. It diffuses rapidly, revealing fine neuritic processes, as well as filopodia on growth cones. TR appears to be a vital dye when not excited; filled neurons exhibited action potentials and retained stable resting potentials. The dye is fixed using the same protocols as for LY, i.e. 4% paraformaldehyde. In an effort to test whether the extent of the intracellular TR dye-fills equalled that observed using LY, we examined the anatomy of a set of motoneurons (the AM cells) of the terminal ganglion of grasshoppers using both intracellular dyes. As these neurons comprise an identified cluster of cells with essentially indistinguishable CNS arborizations, the two dyes could be easily compared in a single ganglion. We did not notice any significant difference in the extent or detail of the arbors revealed by both dyes. Given the small molecular weight of TR (MW = 625), we tested whether it can cross junctions is a manner similar to LY, using systems that previously have been showed to be dye-coupled. Intracellular fills of the columnar ectodermal epithelium of the grasshopper limb-bud revealed a rapid transfer of the dye between cells. Similar dye-coupling was demonstrated between afferent neurons (the Ti1 pioneers) in the embryonic grasshopper leg.

130.12 EFFECTS OF RETROGRADELY TRANSPORTED RICIN ON VAGAL NEURONS: TIME COURSE OF RICIN TRANSPORT, INHIBITION OF NEURONAL PROTEIN SYNTHESIS AND MORPHOLOGIC CHANGES. R.G. Wiley. Neurology Dept., Vanderbilt U. Medical School and VAMC Nashville, TN 37203.(SPON: S. Wall)

Ricin, the toxic lectin from castor beans, injected into peripheral nerves is taken up by axons in that nerve and retrogradely transported to their parent cell bodies resulting in destruction of those neurons. This 'suicide transport' strategy has been used to ascertain the cellular localization of substance P receptors in brainstem and spinal cord and to investigate reorganiza- of somatosensory cortex responses to mechanoreceptor stimulation after sciatic nerve ablation with ricin. However, sophisticated application of the suicide transport technique requires detailed knowledge of the effects of retrogradely transported ricin on motor and sensory neurons. In the present study, 300 ng of ricin-horseradish peroxidase conjugate (RCA-HRP; E-Y Labs, San Mateo,CA) dissolved in 300 nl of PBS was pressure microinjected into the cervical vagus nerves of adult male rats. RCA-HRP was demonstrable by TMB histochemistry for peroxidase within ipsilateral nodose ganglion sensory neurons in less than 9 hours after injection and within ipsilateral dorsal motor nucleus of the vagus neurons within 11 hrs. Transganglionic labelling of vagal sensory neuron terminals in the nucleus tractus solitarius was never seen. Application of vincristine to the vagus nerve proximal to the injection site for ricin prevented labelling of vagal neurons for 24 hrs but not 48 hrs. Appearance of cytotoxic cell changes was also delayed for a similar period. Light microscopic cytotoxicity (loss of Nissl substance) was normally evident by 15 hrs post vagal ricin injection. Electron microscopy localized RCA-HRP to cytoplasmic membranes and revealed that the loss of Nissl substance was due to disaggregation of polyribosomes with dissolution of the rough endoplasmic reticulum into numerous small vacuoles. Autoradiography using ^{3}H-leucine (2 mCi injected i.p. 4-6 hrs before sacrifice) revealed profound inhibition of protein synthesis limited to vagal sensory and motor neurons within 18-24 hrs after vagal ricin injection. Lastly, coinjection of ricin and wheat germ agglutinin-horseradish peroxidase conjugate (WGA-HRP) gave abundant retrograde labelling of vagal neurons, but the prominent transganglionic (anterograde) labelling usually seen with WGA-HRP was decreased. These results indicate: 1 - ricin reaches cell bodies via fast axonal transport; 2 - ricin produces the same morphologic and biochemical changes in neurons as it does in other cell types; 3 - the initial metabolic and morphologic effects occur within a few hours after ricin arrives in the cell body; 4 - within the time interval studied, these effects of ricin are limited to neurons sending axons through the cervical vagus nerve injection site; and 5 - fast axonal transport fails rapidly after arrival of ricin in the cell body. (Supported by VA Merit Review Award.)

130.13 CONCENTRATION GRADIENTS AT AN INTRACEREBRAL INJECTION SITE. M.F.Dubach*, Y.Nievergelt* and D.M.Simmons* (SPON: P. Prinz). Regional Primate Research Center, University of Washington, Seattle, WA 98195; Department of Mathematics, St. Olaf College, Northfield, MN 55057; Salk Institute for Biological Research, La Jolla, CA 92037.

The concentration gradients of an intracerebrally injected substance can be estimated in three dimensions by applying a mathematical model to punch-scintillation data. The model, in the form of a series of computer programs in BASIC, will be presented along with results of its application to dopamine injection sites in Macaca fascicularis.

Tritiated dopamine was injected at six striatal sites in the monkey, at time intervals before perfusion of 120, 60, 30, 20, 10, and 2 minutes. Sites were selected to avoid the ventricles and white matter, to satisfy the basic assumptions of the model. The brain was perfused with 4% paraformaldehyde and the portion bearing the injection sites was frozen on a copper plate packed with dry ice. Thick sections (760 um) were cut while frozen, and punch samples were taken by pressing a 5 x 5 grid of sharpened pieces of 22-ga stainless steel needle stock through the region of each injection site, as it appeared in each of several sections. Each sample was treated and counted separately in a scintillation vial.

The model is based on the assumption of an isoplethic distribution of the substance, such that for a given injection site its concentration at any given point is a function of the three-dimensional location of that point relative to the center of the site. This assumption implies that for a given concentration between maximum and background, the locus of points characterized by that concentration will take the form of an ellipsoidal shell, and that the relative proportions of the three principal axes will be the same for all such shells. The model first considers the average shell, finding the center of the site in each section and determining the axes for this shell that best fit the punch-sample counts. The computer then uses the ratios of principal axes and the center of the injection site determined by this best-fit analysis, to project the location of each sample onto a single axis, so that counts can be considered as a function of location along this axis. The points of the gradient, so derived, fit an exponential equation that describes the gradient quantitatively. Best-fitting coefficients for three such equations describe the distribution of the label at the injection site.

Comparison of the time-staged injection sites suggested that the injectate reached approximately 70% of its ultimate extent during the injection itself, driven by pressure from the needle, and that diffusion over the next two hours carried amounts of label above background only slightly further. Comparison of distribution along the three axes suggested that the bevel and orientation of the injection needle influenced the shape and orientation of the injection distribution.

The interpretation of anatomical and behavioral studies based on intracerebral injection requires an understanding of the physical and temporal dimensions of the affected region. The method presented here provides a highly quantitative approach to this problem.

130.14 Somata of Rat Facial Nucleus: Comparison of Techniques for retrograde labeling. Kyoi Horikawa* and Ervin W. Powell, Department of Neurosurgery, University of the Rukyus, Okinawa, and Dept. of Anatomy, University of AR for Medical Sciences, Little Rock, AR 72205.

Comparisons of procedures are usually stimulated by uncertainties regarding specific features of their overall descriptions. This study of retrograde tracers was undertaken to select the procedures resulting in the greatest number of clearly labeled neurons. Horseradish peroxidase (HRP, 10%), wheat germ agglutinin (WGA, 1%), WGA-HRP conjugate (1%), and cholera toxin subunit B (CHB, 1%) are compared. The vibrissal area of the snout of 15 anesthetized adult rats was injected with 50µl of one of the four tracers listed. The animals were killed 48 hrs later. Perfusion of the fixative (800 ml) was preceded by a quick saline wash (300 ml) and followed by 800 ml of cold sucrose (20%) in phosphate buffer (PB). The brain was removed from the skull and stored overnight in 20% sucrose in PB. Thirty micron thick sections were cut through the facial nucleus. The avidin-biotin-peroxidase (ABC) immunocytochemical method was used along with the proper antibodies for localization of the transported substances. Both diaminobenzidine (DAB) and amino-ethylcarbazole (AEC) were used as chromogens. Cobalt chloride was used for intensification of the transported HRP. Labeled neuronal somata of the facial nucleus were counted and the counts were compared relative to changes in the procedures. The WGA-HRP Congugate (Vector Labs) and CHB (using anti-CHB; List Bio. Labs) labeled twice the number of neurons as did 10% HRP (Sigma VI). The greatest number of neurons was labeled when WGA (using anti-WGA) was used as a tracer. Glutaraldehyde in any concentration greater than 0.5% reduced the number of neurons labeled for all tracers, with number and intensity of the HRP-labeled neurons being least affected by this fixative. The most satisfactory fixative was 3.8% paraformaldehyde (pH 7.4), which provided the best fixation without detrimental effects to the visualization of the label. The ABC immunocytochemical technique was equally effective for CHB or WGA (same number of facial neurons labeled) with either the DAB or AEC procedures.

130.15 A NOVEL PROCEDURE FOR THE SIMULTANEOUS IMMUNOPEROXIDASE DEMONSTRATION OF TWO TISSUE ANTIGENS. A.I.Levey[1], D.B.Rye[1], J.P.Bolam[*2], and B.H.Wainer[1]. [1]Univ. Chicago, Dept. Pharm. and Phys. Sciences, Chicago IL, 60637; and [*2]Oxford Univ., Dept. of Pharm., Oxford.

Procedures for the simultaneous visualization of two tissue antigens have focused on employing immunoperoxidase and enzymatic visualization with diaminobenzidine (DAB), followed by immunolabeling of a second antigen with i)other enzyme/chromogen combinations; or ii)colloidal gold conjugated reagents. While these methods have proven useful, their light level analysis is limited by submaximal differentiation of the two chromogens, or by a difficulty in resolution of the second marker. In the present study, tissue incubated with a polyclonal rabbit-anti-tyrosine hydroxylae (TH) antisera, a goat-antirabbit bridging antisera, and rabbit PAP was employed to establish optimal conditions for the visualization of peroxidase with benzidine-dihydrochloride (BDHC). A 6-8min. incubation in .01M sodium phosphate buffer (pH=6.6) containing 0.01% BDHC, 0.002% hydrogen peroxide, and 0.02% sodium nitroprusside resulted in the labeling of TH-positive cells and processes with a coarse blue granular reaction product that was also visible with darkfield illumination. In the rat brainstem, choline acetyltransferase (ChAT) and TH were demonstrated in the same tissue employing visualization of ChAT with a monoclonal rat-antiChAT, goat-antimouse bridging antisera, rat PAP and DAB histochemistry, followed by the immunoperoxidase visualization of TH as described above. The resultant diffuse brown (DAB/ChAT) and granular blue (BDHC/TH) reaction products contrasted sharply, and allowed for a clear demonstration of topographic relationships between cholinergic and catecholaminergic cells and processes in the brainstem. Appropriate controls for residual peroxidase and antibody cross-reactivities were negative. In summary, we report here the utility of BDHC as a new, sensitive, blue chromogen in immunoperoxidase staining, alone, and for the simultaneous visualization of two tissue antigens.
Supported by the McKnight foundation and USPHS 5T32-GM07281, HD-0453, and NS-17661.

130.16 LOWICRYL METHODS FOR POSTEMBEDDING IMMUNOELECTRONMICROSCOPY. D.A. Crumrine* and K.L. Valentino (SPON: K.Buckley). Dept. Physiology, UCSF, San Francisco, CA 94143.

We have recently reported methods for rapidly embedding CNS tissue into Lowicryl K4M and using postembedding immunogold techniques (Valentino et al., J. Histochem. Cytochem., in press). We have since made several variations in these methods, in order to increase sensitivity and improve fixation.

For glutaraldehyde sensitive antigens, and especially for peptide antigens, the addition of 15% picric acid (final concentration) to 4% paraformaldehyde in (0.1 M Na cacodylate buffer), gives good ultrastructural preservation with or without the addition of glutaraldehyde. Following overnight fixation, the fixative is carefully washed out prior to en bloc uranyl acetate staining (2% aqueous uranyl acetate for 1 hour). Dehydration and embedding in Lowicryl proceed as previously described.

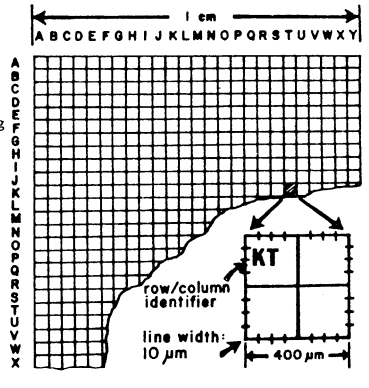
While immunogold detection of antibodies on ultrathin Lowicryl sections proves to be a useful method for many antigens, it does suffer from a lack of sensitivity. Sensitivity can be increased by variety of methods, including using an unlabeled bridging antibody, followed by colloidal gold conjugated IgG, and also by using immunoperoxidase methods. For immunoperoxidase detection, the grids are incubated in first antibody, followed by incubation in biotinylated second antibody (Vector, 1:500, 15 minutes), and incubation in streptavidin-horseradish peroxidase complex (Enzo, 1:100, 10 minutes). The reaction was developed in a solution of diaminobenzidine and H_2O_2 for 2 minutes, and grids were stained with 2% aqueous osmium tetroxide for 10 minutes and 2% aqueous uranyl acetate for 5 minutes. The HRP reaction product can be visualized easily at low magnification, and is specific.

These methods have been used to localize a large number of antigens in a wide variety of tissues, including cultured cells, and are easily adapted to double labeling studies.

Supported by Runyon-Winchell Fellowship DRG-611 and NIH grants NS16033 and NS07067.

130.17 CELL RELOCATION SLIDES FOR TISSUE CULTURE AND CLINICAL MICROSCOPY. J.B. Kirkpatrick, J.H. Lucas*, W. Wen*, L.E. Czisny* and G. Gross. Baylor College of Medicine, Houston, TX 77030; Texas Woman's University, Denton, TX 76201; Polytronix, Inc., Richardson, TX 75083.

Many investigations in neurobiology and in hospitals require specific identification of individual cells by light microscopy. Graduated stages, expensive machine-scored slides, or ink spots have served this purpose until now. These methods are cumbersome and inexact. We have produced a new type of glass cell relocation slide, using techniques from the computer industry. A coat of indium tin oxide (ITO) 300 A thick is deposited on a glass plate. This is heavier and darker than ITO used for liquid crystal displays. A pattern mask of 1 sq cm ruled into squares 200 x 200 um is projected on the ITO plate, then the extra ITO is etched away. The small squares are lettered alphabetically for specific identification. For tissue culture, one 1 cm square pattern is placed in the center of a 2 x 2 in glass plate. For clinical microscopy, the 1 cm square is repeated 2 x 4 times to fill the useful portion of a 1 x 3 in glass slide. The resulting grid survives washing and manipulations in tissue culture. It can be fixed and stained by the usual methods except for harsh basic solutions used in some silver stains. Tissue slices can be mounted over the grid. The grid is transparent, yet can be easily seen through the tissue. The ITO does not interfere with polarized light. The grid lines do not alter the spreading of cells in tissue culture, hematology or cytology, but cells adhere preferentially to the ITO unless the slide is coated with polylysine or collagen. We have found the slides useful for sequential observations in tissue culture, and for teaching and quantitative studies in the clinical setting.



130.18 Circumvention of Dehydration-Induced Morphological Artifacts in Intracellularly Stained Neurons by a Rapid DMSO Clearing Process. A. A. Grace & R. Llinas, Dept. of Physiology & Biophysics, New York Univ. Med. Ctr., New York, NY 10016. †Present Address: Depts. Psychology & Psychiatry, Univ. Pittsburgh, Pittsburgh, PA 15260.

In order to observe the morphology of intracellularly stained neurons in slices at the light microscope level, the tissue must be cleared of opaque matter. This clearing process involves first dehydrating the slice, typically by passing it through a series of increasing concentration alcohol solutions. The lipid components are then cleared by organic solvents such as xylene. Although this dehydration step is necessary to allow the xylene to have access to the lipids, it results in a large amount of slice shrinkage. Indeed, we found that the dehydration process reduces the size of guinea pig frontal cortical brain slices to 46% ± 6% of the control slice in area (mean ± SD). Furthermore, the shrinkage is not uniform over different brain regions.

We then investigated how this shrinkage affects the morphology of stained neurons contained in the slice. This was done by observing how the morphology of well-stained neurons in uncleared slices was altered at each stage of the clearing process. The dehydration process was found to induce artifacts in cellular morphology which were dependent on the type of staining technique used. Thus, cells stained with Lucifer yellow were found to decrease in size as the slice shrank, resulting in neurons less than 2/3 of their original dimensions. In contrast, cells filled with the HRP-polymerized diaminobenzidine (DAB) were apparently incapable of shrinking as the slice decreased in size. Thus, the cell soma remained its original size, but the dendrites were compressed due to slice shrinkage. This resulted in an alteration of dendritic morphology in which the previously long, straight dendritic processes assumed a bent, helical appearance. Consequently, neurons stained with HRP appeared to encompass a much larger proportion of the dehydrated slice, in addition to demonstrating an abnormally curled dendritic morphology.

In order to find a slice clearing technique which circumvented these artifacts, we investigated solvents which were capable of clearing the membrane lipids in an aqueous environment and thus obviating the need for slice dehydration. This was accomplished by using the dipolar aprotic solvent DMSO. Fixed slices placed in 100% DMSO for 15 minutes were rapidly and completely cleared of opaque matter without undergoing shrinkage. As a result, no observable morphological artifacts were noted in the stained neurons contained within the slice regardless of whether HRP or Lucifer yellow filled neurons were studied. Thus, DMSO effectively cleared the tissue slices to allow detailed morphological observations of intracellularly stained neurons without the morphological artifacts induced by the dehydration process.

131.1 GABA-TRANSAMINASE-DEHYDROGENASE ACTIVITY IN THE RAT MYENTERIC PLEXUS. A. Krantis and R.K. Harding, Dept. of Physiology, Univ. of Ottawa, Ottawa, Ont., K1H 8M5.

A number of the important criteria (Orrego, F., Neuroscience, 4: 1037, 1979) for γ-aminobutyric acid (GABA) to be classified as a neurotransmitter of the mammalian enteric nervous system (ENS) have now been satisfied, including the presence of GABA and its enzyme of synthesis (glutamic acid decarboxylase, GAD) as well as high affinity uptake sites for ^{3}H GABA, in the myenteric plexus (Jessen et al., Nature, 281: 71, 1979; Kerr, D.I.B. and Ong, J., Br. J. Pharmac., 83: 169, 1984; Krantis, A. and Kerr, D.I.B., Neuroscience Let., 23: 263, 1981.; Taniyama et al., 29: 53, 1982).

Recently, the primary enzyme for GABA degradation, GABA-transaminase (GABA-T) has been found in the myenteric plexus of humans and other mammals including the rat (Miki, et al., J. Neurochem., 40(3): 861, 1983) however the disposition of the sites of GABA degradation in the myenteric plexus have not been determined.

In this study, the presence and distribution of the degradative enzymes for GABA, GABA-T (4-aminobutyrate: 2-oxoglutarate aminotransferase)-SSADH (succinic semialdehyde dehydrogenase), in the rat myenteric plexus was investigated histochemically (using the tetrozolium salt, Nitro-BT) in laminar stretch preparations of the small intestine. Individual segments (laminar preparations) of the proximal ileum, and jejunum were incubated for 30-60 min in light proof containers with the reaction mixture: GABA (5 mg/ml), α-ketogluturate (5 mg/ml), NAD^+ (2 mg/ml), malonate (0.05 mg/ml), phenozine methosulphate (PMS, 0.2 mg/ml), Nitro-BT (1 mg/ml), in AMP_2 buffer (pH 7.6, 37°C), final volume 1 ml. In some experiments, aminooxyacetic acid (AOAA) .01 mg/ml or gabaculine 0.2 mg/ml, inhibitors of GABA-T, were present in solution throughout the equilibration and incubation period.

Strong blue-diformazan staining resulting from reduction of Nitro-BT by the transaminase step in the GABA-T-SSADH degradation of GABA was present to a scattered population of ileal and jejunal myenteric ganglion cells. By contrast, such staining was prevented in laminar preparations treated with GABA-T inhibitors. Tissues incubated in GABA free or NAD^+ free reaction mixture also remained unstained. Where ganglion cells were strongly stained, emergent processes were on occasion seen, coursing only within the ganglia. The stained cells generally comprised two types: those with a relatively round, smooth soma and eccentrically placed nucleus (usually with only one stout process and, on occasion, displaying a few smaller emergent processes); or cells with a more elongate soma and a single stout process.

These results indicate that GABA is enzymically degraded at specific sites in the rat enteric nervous system.

131.2 **SIMULTANEOUS DETERMINATION OF HOMOVANILLIC ACID (HVA), VANILMANDELIC ACID (VMA) AND 3-METHOXY-4-HYDROXY PHENYLGLYCOL (MHPG) IN HUMAN PLASMA BY HPLC WITH ELECTROCHEMICAL DETECTION.** C.J. Drebing*, G.A. Gerhardt and R. Freedman* (SPON: M. Reite). Dept. of Pharmacol., University of Colorado Health Sciences Center and Medical Research, Denver VA Medical Center, Denver, CO 80262.

Methoxylated metabolites of the catecholamine neurotransmitters in human plasma have received considerable attention in recent studies of schizophrenia and affective disorders. In addition to the measurement of the dopamine metabolite HVA, it would be advantageous to measure both MHPG and VMA, to help evaluate central and peripheral noradrenergic activity simultaneously. However, no method currently exists for the simultaneous determination of metabolites of both dopamine and norepinephrine. We now report a sensitive and reliable method for the simultaneous determination of HVA, MHPG AND VMA in human plasma by HPLC with electrochemical detection. After a simple plasma extraction, the three compounds are separated by a solvent gradient reverse phase HPLC system with subsequent dual-electrode coulometric electrochemical detection.

A portion of the proteins are removed from the human plasma samples by dilute acid precipitation and centrifugation. The supernatant is extracted with several aliquots of ethyl acetate over NaCl. These fractions are combined, evaporated to dryness and the residue is resuspended in a small volume of pH 5.0 buffer. A 20 uL portion of the sample is then directly injected into the HPLC system.

All separations are performed using an Altex 15 cm Ultrasphere-ODS 5u reverse phase column. The HPLC sytem consists of a Beckman 332 gradient liquid chromatography system, with a 420 control module, 504 autoinjector and an ESA 5100A dual-electrode coulometric eletrochemical detector. The firt electrode of the dual-electrode system is set at +.15V and is used for detection of more easily oxidizable species and initial cleanup of the eluting compounds. The second detector is set at +.36V and detects HVA, VMA and MHPG. Eluent A (pH 3.9 citrate-acetate buffer + octyl sodium sulfate) is used to first separate and detect VMA and MHPG. The gradient system is then used to change over to eluent B (eluent A with 10% methanol) for separation and detection of HVA. The gradient process has been optimized for complete sample throughput and re-equilibration of the system in 45 minutes.

The sensitivity of this method is currently better than 2 pmol/ml of plasma for all three of the species of interest. This is a considerable improvement in sensitivity as compared to many of the previously reported methods. (Supported by MH-38321).

131.3 A616U - A SELECTIVE INHIBITOR OF MAO-A WITH NEGLIGIBLE TYRAMINE-POTENTIATING ACTIVITY AND POTENTIAL ANTIDEPRESSANT ACTIVITY. H.L. White, M. Harfenist*†, O. Beek*, F. Soroko*, B.R. Cooper and R.A. Maxwell*, Depts. of Pharmacology and Organic Chemistry†, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

A616U is a novel, reversible, and selective inhibitor of monoamine oxidase-A (MAO-A) with a competitive mechanism of inhibition vs the substrates serotonin and tyramine (Ki = 0.016 μM using serotonin as substrate for MAO-A of human or rat brain). Following oral administration of A616U to rats, MAO-A inhibition in brains and livers was maximal between 3 and 7 hours after dosing and was negligible by 24 hours. Inhibition of MAO-A was completely reversible by dialysis, and no significant inhibition of MAO-B was observed. The selectivity and reversibility of the MAO-A inhibition were maintained after 10 days of chronic oral dosing.

In order to test whether the unique inhibitory mechanism of A616U might eliminate the danger of hypertensive crises in response to dietary tyramine, an animal model of this syndrome was developed in which blood pressure response to orally-administered tyramine was measured in conscious, unrestrained rats. To compare effects at equipotent and relevant antidepressant doses, A616U and other MAO inhibitors were given at oral doses which produced approximately 80% inhibition of brain MAO-A and at least 90% inhibition of liver MAO-A at the time of tyramine administration. Under these conditions A616U caused negligible potentiation of mean arterial blood pressure elevations induced by tyramine (15-90 mg/kg p.o.), while phenelzine increased the responsiveness to tyramine 3- to 10-fold.

A616U (12.5-100 mg/kg p.o.) showed dose-dependent activity in the tetrabenazine (sedation) and Porsolt models of depression in rodents, while no overt symptoms occurred after single oral doses of 1000 mg/kg. Thus A616U is a potential MAO-A inhibiting antidepressant not likely to produce a limiting side-effect observed with conventional MAO inhibitors.

131.4 **DOPAMINERGIC NEUROTRANSMISSION IN MALE RAT NUCLEUS ACCUMBENS (NA) AND CAUDATE (CN): EFFECT OF PROLACTIN.** J.C.Chen* and V.D.Ramirez (SPON:J.Kemnitz). Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

We published that prolactin (PRL) increases either in vitro dopamine release or in vivo DOPAC output from corpus striatal dopaminergic terminals. Here we report: (1) the spontaneous in vivo activity of mesolimbic dopaminergic terminals of the NA in freely moving rats, and (2) the mechanism by which PRL modifies the activity of dopaminergic neurons innervating either the CN or the NA. To examine the in vivo activity of the NA, adult male rats were implanted with push-pull cannulas (PPC) and perfused within 30d post-implantation. DOPAC, HVA and 5-HIAA were determined with HPLC-EC every 20 min. The basal output of DA was non-detectable through the perfusion session (1120-2100h) while DOPAC output showed a 2-3 time increase from low afternoon values (60 pg/min) to high evening values (160 pg/min). The output of HVA oscillated between 80 to 120 pg/min while 5-HIAA remained unchanged with a mean value of 40 pg/min. This pattern was observed only in animals bearing PPC in the central region of the NA. To examine whether PRL will affect the synthesis rate of DA, an inhibitor of Dopa decarboxylase, NSD 1015 was employed. Animals were injected with ovine PRL (0.25 or 2.5 μg/kg, s.c. in the neck 30 min before NSD 1015 (100 mg/kg, i.p.) in each group and all animals were decapitated 30 min after drug injection. NSD 1015 specifically blocked decarboxylase activity in the CN and NA. Non-detectable values of Dopa in the saline groups rose to 15.4 and 19.6 ng/mg protein in the CN and NA of rats injected with the drug; whereas DOPAC levels decreased 92% and 91%, and HVA decreased 75% and 77%, respectively. Dopa concentration in rats treated with the 2.5 μg PRL were significantly lower than the control group (11.9±1.0 vs 15.4±1.2ng/mg protein) while DOPAC levels from either PRL groups (0.25 or 2.5 μg/kg) were higher (1.9±0.3 and 2.3±0.2 vs 1.0±0.2 in controls). Similar results were also found in the NA. To investigate whether PRL-evoked DOPAC increase is due to enhanced tyrosine hydroxylase (TH) activity, NSD 1015 was administered 30 min before 2.5 μg PRL and animals were then decapitated 30, 60 or 90 min afterwards. No significant differences were detected among all the groups in either CN or NA. These results indicated that PRL-evoked DOPAC stimulation was not due to an increase in CN or NA TH activity.

The spontaneous in vivo rise in DOPAC output from mesolimbic dopaminergic terminals in the NA suggests an increase in DA neurotransmission during the evening hours similar to those demonstrated earlier in the CN. It is possible that PRL may play a role in the activity of these two dopaminergic systems through changes in the release phase of DA from nerve terminals.

131.5 EFFECT OF AGE ON BILATERAL DOPAMINE METABOLISM. C.A. Taylor and T.P. Jerussi, Dept. of Pharmacology and Toxicology, Rutgers Univ., P.O. Box 789, Piscataway, NJ 08854 and Anaquest/BOC Health Care Group, 100 Mountain Ave., Murray Hill, NJ 07974.

Bilateral dopamine (DA) metabolism was investigated in two groups of female Sprague-Dawley rats approximately 10 and 16 weeks of age. Rats were tested twice for one hour, a week apart, for amphetamine (1.omg/kg, ip)-induced rotation. One week later, animals which had at least 10 full rotations/hour were decapitated at 0, 5, 10 or 20 minutes following pargyline (50mg/kg, ip) administration. DA, homovanillic acid (HVA) and 3,4 dihydroxyphenylacetic acid (DOPAC) concentrations were determined by HPLC-EC in the left and right corpora striata, olfactory tubercles (TO) and frontal cortices (FC).

There were no significant steady state left-right differences in the striata of both groups. However, each group had significantly greater DOPAC turnover in the left striata. In addition, in the 16 week old rat DOPAC turnover and steady state levels were significantly greater in the striatum ipsilateral to the direction of rotation.

Steady state DA, DOPAC and HVA were significantly greater in the TO of the 16 week old animals. Moreover, steady state DA and DOPAC levels and DOPAC turnover were significantly greater in the right than the left TO of the 16 week old animals, but no left-right differences were not evident in the younger rat. In contrast, ipsilateral-contralateral differences were not apparent in the TO of the 16 week old animals, yet DOPAC turnover in the younger rats was significantly greater in the ipsilateral TO.

Steady state DA and HVA levels were significantly greater in the FC of the 16 week old rat. Significantly greater DOPAC turnover was evident only in the left FC of the older rats, and there were no ipsilateral-contralateral differences in the FC of both groups.

It is evident from these data that the brains of older (16 weeks) rats are more lateralized with respect to dopamine metabolism, and the asymmetrical development of dopaminergic systems appears to develop at different rates.

131.6 IMIPRAMINE METABOLISM IN RATS IS INFLUENCED BY AGE AND GENDER. M.A. Wilson and E.J. Roy. Neural & Behavioral Biology Program and Dept. of Psychology, University of Illinois, Champaign, IL 61820.

Previous studies have suggested that both age and gender can influence the metabolism of the antidepressant imipramine. Studies from our laboratory examining changes in hypothalamic imipramine binding sites following chronic imipramine treatment in rats strongly suggested that age altered the neural retention of imipramine metabolites following such treatment (Wilson and Roy, 1984).

In the present study we examined the effects of age and gender on the levels of imipramine metabolites in the hypothalamus-preoptic area (HPA) and serum of rats 24 hours after the cessation of chronic (14 day) imipramine treatment. To examine whether the effects of age and/or gender were the result of differences in the initial metabolism of imipramine, age and sex were also analyzed for their influences on levels of imipramine (IMI) and its metabolite desmethylimipramine (DMI) in the HPA and serum one hour after a single imipramine injection. IMI and DMI were measured using high pressure liquid chromatography.

Age significantly increased the levels of DMI remaining in the HPA and serum following chronic imipramine treatment (CIT). Hypothalamic levels in middle-aged females were increased 220% compared to juvenile females (1.5 months old). HPA and serum also showed sex differences in the level of DMI remaining after CIT, with females having higher levels.

Repeated sampling of serum from individual juvenile and middle-aged animals showed contrasting profiles of serum imipramine metabolites after a single imipramine injection. Juvenile animals showed a sharp rise in DMI and a rapid decline in total metabolite levels; middle-aged females showed a prolonged elevation of serum DMI levels. This pattern was confirmed by the HPA tissue concentrations of IMI and DMI one hour after a single imipramine injection. Juvenile animals furthermore exhibited a sex difference in the metabolite profile, indicating more rapid metabolism of imipramine in males at this age.

The results indicate that in rats, female animals and older animals both show a reduction in the initial metabolism of imipramine which leads to an enhanced accumulation of DMI in the brain and serum during chronic imipramine administration. These changes in imipramine metabolism may be important to the neurochemical changes observed after chronic imipramine treatment in animals and, perhaps, the clinical efficacy of such antidepressant treatments in humans.

131.7 EXPOSURE TO 60-HZ ELECTRIC AND MAGNETIC FIELDS ALTERS BIOGENIC AMINE METABOLITE CONCENTRATIONS IN NON-HUMAN PRIMATE CEREBROSPINAL FLUID. R. F. Seegal. Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, NY 12201.

A major concern of exposure to extremely low frequency (ELF, 1-300 Hz) electric (E) and magnetic (B) fields has been the delineation of possible adverse effects on the central nervous system (CNS). Our results suggest that exposure to 60-Hz sinusoidal E and B fields significantly decreases cerebrospinal fluid (CSF) concentrations of biogenic amine metabolites in the non-human primate, Macaca nemestrina (pig-tailed macaque).

We have exposed six M. nemestrina to uniform 60-Hz E and B fields of up to 30kV/m and .9 gauss (g) for 63d. The monkeys are exposed to either sham or actual E and B fields for 18 h/day. The first 21d period consists of sham exposure to determine baseline neurochemical values. Animals are then exposed to 3, 21d intervals of E and B fields of 3kV/m and .1g, 10kV/m and .33g and 30kV/m and .9g. The final 21d interval consists of a post-exposure sham period to determine if possible alterations in CNS function induced by exposure to E and B fields persist. At the end of each 21d interval homovanillic acid (HVA), a metabolite of dopamine and 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, were determined in lumbar CSF of M. nemestrina following pretreatment with intravenous probenecid (100 mg/kg). Concentrations of HVA and 5-HIAA were determined by high-performance liquid chromatography with electrochemical detection (HPLC-ECD).

Results are expressed as a percentage of the concentration of the biogenic amine metabolites determined during the initial pre-exposure period. No animal demonstrated an increase or lack of change during exposure. E and B field exposure resulted in a 20-30% decrease in CSF-HVA with the greatest change observed at the 30kV/m and .9g exposure level. CSF-5-HIAA concentrations decreased by approximately 10-15% with no discernible dose-response relationship.

These findings are important because: (1) this study is among the few that have reported significant, repeatable neurochemical changes following exposure to E and B fields; (2) the study was undertaken in a species that is neurochemically similar to man and (3) they suggest significant decreases in the activity of either central biogenic amine neurons or the degradatory enzymes that inactivate the neurotransmitters dopamine and serotonin.

Supported by the Power Authority of State of New York.

131.8 CARBACHOL STIMULATION OF POLY-PHOSPHOINOSITIDE TURNOVER IN [^{3}H]-INOSITOL-LABELED RAT BRAIN SYNAPTOSOMES. H-M. Huang* and G.Y. Sun. Biochem. Dept. and Sinclair Comparative Med. Res. Farm, Univ. of Missouri, Columbia, MO 65203.

Although muscarinic cholinergic stimulation of polyphosphoinositide breakdown by the phosphodiesterase has been well-demonstrated in brain and other tissues, most studies have been carried out with intact tissue slices preincubated in a medium containing the labeled precursor. Studies of synaptosomal phosphoinositides metabolism have been confronted with difficulties, mainly because synaptosomes lack the essential ingredients for active de novo biosynthesis of membrane phospholipids. Our present study describes a procedure for labeling the phosphoinositides (PI, PI-P and PI-P_2) with ^{3}H-inositol through the CMP and Mn^{2+}-dependent PI:myo-inositol exchange route as described by Berry et al. (Biochem. Biophys. Res. Commun. 112:817-821, 1983). Incubation of synaptosomes under this condition resulted in large incorporation of [^{3}H]-inositol into PI, but PI-P and PI-P_2 were only slightly labeled. After the prelabeled synaptosomes were washed, they were resuspended in Krebs-Ringer bicarbonate (KRB) buffer supplemented with glucose and ATP. Incubation of the prelabeled synaptosomes in this medium alone elicited a time-dependent decrease in labeled PI but the radioactivity was not recovered in any of the water soluble inositol phosphates (i.e., IP, IP_2 and IP_3). The decrease in label may be attributed to the Ca^{2+}-dependent phospholipase A_2 which utilizes PI and PC as substrate. When prelabeled synaptosomes were incubated in the KRB medium containing LiCl (10 mM), addition of carbachol elicited an obvious increase in labeled IP which accumulated with time of incubation. There was a small increase in IP_2, but practically no label was recovered in the IP_3 fraction under stimulated or non-stimulated conditions. Very little change in labeled PI-P and PI-P_2 was observed after carbachol stimulation, but there was a decrease in labeled PI concomitant with the increase in labeled IP. Results indicate that carbachol stimulated the turnover of the entire phosphoinositide cycle. The inositol-labeled synaptosomes provide a feasible system for studying the receptor-mediated poly-PI turnover mechanism and subsequently drugs which may affect this metabolism. (Supported in part by AA06661 from NIAAA.)

131.9 PHOSPHORYLATION OF HUMAN CHOLINE ACETYLTRANSFERASE
Gordon Bruce* and Louis B. Hersh, Department of Biochemistry, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

Choline acetyltransferase (ChAT, EC 2.3.1.6), the terminal biosynthetic enzyme for the neurotransmitter acetylcholine, is located in the cytosol of the pre-synaptic cholinergic neurons. In recent years the study of cholinergic function has taken on a new interest in relation to Alzheimer's disease with ChAT being implicated in both the etiology (Perry, et al. [1982] Neurosci. Lett. 33, 311-315) and the possible therapy (Hefti, et al. [1984] Brain. Res. 293, 305-311) of this disorder. However the control of cholinergic function is poorly understood although mounting evidence shows an important part of neuronal control to be achieved through protein phosphorylation. Thus both neurotransmitter synthesizing enzymes (tyrosine hydroxylase) and neurotransmitter receptors (acetylcholine receptor) are now known to be controlled by phosphorylation. We report here, for the first time, that human ChAT can be phosphorylated in vitro.

Human ChAT was purified from placenta using immuno-affinity purification. This placental enzyme has been shown to be identical to the human brain enzyme (Bruce, et al. [1985] Fed. Proc. 44, 1634). The purified human ChAT was phosphorylated in vitro by kinase/s present in a cell free extract of rat brain. This phosphorylation was shown to be both time and concentration dependent, with maximum phosphorylation achieved after a 5 min incubation. A study of the subcellular location of the rat brain kinase/s involved in this phosphorylation showed both a membrane and cytosolic location. Phosphorylation was not stimulated in the presence of either cAMP or cGMP (final conc = 1 μM) but was completely inhibited in the presence of EGTA (final conc = 1 mM). Amino acid analysis of the phosphorylated ChAT showed serine to be the exclusive phospho-amino acid. The role of this phosphorylation in relation to the function of ChAT will be discussed.

131.10 ASSEMBLY OF MONOMERIC AChE INTO TETRAMERIC AND ASYMMETRIC FORMS
S.K. Brockman*, M.F. Usiak*, and S.G. Younkin, Dept. of Pharmacology, Case Western Reserve University, Cleveland, Ohio 44106

A pulse-chase experiment was performed in embryonic rat myotube cultures to examine possible precursor-product relationships between the various forms of AChE. Cultures were first treated with 5 mM methanesulfonyl fluoride (MSF) to irreversibly inactivate almost all (98%) of the active AChE present in the cells. The MSF was washed from the cultures and medium containing 0.1 μM paraoxon was applied to the cultures for a period of 55 minutes. The paraoxon inactivated AChE synthesized by the myotubes during this labelling period by diethylphosphorylating the enzyme at its active site. Diethylphosphorylated AChE can be reactivated by treating it with 1-methyl-2-hydroxyimino-methylpyridinium (2-PAM). Labelled AChE then is defined as AChE that regains enzyme activity following treatment with 2-PAM. At the completion of the labelling period the paraoxon was washed off the cultures. MSF (20 mM) was again applied to the cultures immediately before they were harvested to inactivate any unlabelled AChE present that could interfere with the measurement of labelled AChE. Cells were harvested at 0 and 2 hours after the labelling period. AChE was sequentially extracted to separate globular forms from asymmetric forms. Samples were assayed before and after treatment with 2-PAM in order to determine the amount of labelled AChE present in the samples. Samples were also applied to sucrose gradients in order to separate the various forms of the enzyme. The results of four such pulse-chase experiments show that the amount of labelled G_1 AChE activity (expressed as picomoles of acetylcholine hydrolyzed per minute per culture dish) decreased from 336 to 150 ($p<.01$) during the chase period, while labelled G_4 AChE increased from 14 to 19 ($p<.05$) and labelled asymmetric forms increased from 14 to 19 ($p<.025$). These results indicate that complex forms of AChE are assembled from globular precursors. Additional experimentation indicates that the A_{12} form, in particular, is assembled from precursor forms. Since a pulse-chase experiment is required to demonstrate hypothesized precursor-product relationships, this data constitutes the first definitive proof that more complex forms of AChE are assembled from simpler precursor forms.

DISEASES OF THE NERVOUS SYSTEM: GENETIC DISEASES, MODELS

132.1 **Tremor Measurement in an Inherited Feline Tremor.**
G.A.Hegreberg, K.P.Hines*, J.M.Frame*, D.E.Norby*, and M.H.Ratslaff*. College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Inherited feline tremor (IFT) is a progressive neurodegenerative disorder transmitted as an autosomal recessive trait. Tremors, the earliest clinical manifestation, are observed in kittens as early as 2 weeks of age. The tremors are apparent in all affected kittens by the age of 4-5 weeks. Initially, the tremors are fine and of low amplitude involving the head, tail, and limbs. The tremors progress in severity with age and at the clinical apogee (8 to 16 weeks of age) are throbbing, rhythmical, and of high amplitude. Classified on the basis of appearance, the tremors are both action and postural. The tremors are absent when the kittens are completely at rest or asleep. Other neurologic and behavioral changes occur as the disease progresses, including posterior paresis, generalized seizures, limb rigidity, visual impairment, unprovoked agitated behavior, affective response, inadequate grooming practices, repetitious activity, and catatonia.

The tremor frequency was measured in 9 affected kittens ranging in age at the time of measurement from 21 to 44 days. The tremors were measured using a tremor plate devise consisting of a box resting on piezoelectric crystal sensors. Signals were recorded on a TEAC data cassette recorder. Hard copies of the data were obtained from a Honeywell oscillographic recorder. The tremors in all kittens were similar and the frequencies ranged from 5.8 to 6.9 Hz. The mean and 1 standard deviation of the tremor frequencies were 6.3+0.4 Hz. The types of tremor (action and postural) and the frequency of the tremor (approximately 6 Hz) in this feline disorder are similar to essential tremor and Parkinsonism of people.

This study was supported in part by NIH grant RR 00515, the WSUCVM locomotion laboratory, and Washington State University.

132.2 PREDICTIVE TESTING FOR HUNTINGTON'S DISEASE AND GENETIC COUNSELING: SCIENTIFIC AND ETHICAL CONCERNS.
S.J. Bird. Center for Policy Alternatives and Science, Technology, and Society Program, Massachusetts Institute of Technology, Cambridge, MA 02139.

Huntington's disease (HD) is a serious and debilitating hereditary disease. It is an autosomal dominant disease with a late onset. Offspring of those with HD have a 50-50 chance of inheriting it, or, if they carry the gene, of passing it on. Until disease onset at approx. 40 yrs., those who carry the gene cannot be detected. Several surveys indicate that, in spite of the absence of preventive treatments, a safe, accurate and reliable test for HD is sought by many at risk because of the information it would provide for personal decisions regarding career, family planning, etc.

Recent research using recombinant DNA technology has identified a marker genetically linked to HD (Gusella et al., 1983, Nature 306:234). There are limitations to a predictive test based on this work, as well as a number of ethical and policy concerns associated with genetic screening in general. Yet it is likely that a testing program for HD based upon a genetic marker can and will be developed in the near future.

A marker-based test has some limitations. Because it requires samples of DNA from relatives of those at risk, and is dependent upon the form of the marker carried by those relatives, it would not be universally available or informative. In addition, because of the possibility of genetic crossover, the test can only provide a more accurate prediction of the probability of inheriting the disease, not a definite answer regarding gene-carrier status. Unlike other predictive tests for HD, the marker-based test could be done prenatally.

Given the substantial emotional impact and the significance of test results, what are the essential components of a predictive testing program? What are the appropriate roles of scientific and health care professionals, lay organizations, and effected individuals and their families in the development and implementation of such a program? Prenatal testing coupled with abortion raises issues associated with the abortion of a fetus that has the potential for several decades of normal life before the onset of disease. What are the attitudes and assumptions of health care professionals and others that may affect the decisions individuals feel able or compelled to make? These ethical and policy issues will be explored and discussed.

132.3 LATE ONSET MOTONEURON DEGENERATION IN A NEW MUTANT MOUSE. Anne Messer, Norman L Strominger, Mary Zotta* and Lorraine Flaherty. Wadsworth Center for Labs and Research, N.Y. State Dept. of Health, Albany, N.Y. 12201; Dept. of Anatomy, Albany Medical College, Albany, N.Y. 12208.

A late-onset, hereditary neurodegenerative disease has recently been identified in a C57Bl/6 substrain, in the mouse colony of the immunogenetics laboratory of Dr. L. Flaherty. Affected animals have a progressive deterioration of motor function (stiff-legged gait, abnormal limb placements and grasping, and finally paralysis), with a variable age of onset (beginning at 5 - 11 months of age), and moving from rear to forelimbs. Few survive beyond 12 months. Preliminary neuropathology shows dramatic degeneration of spinal cord motoneurons, more severe in the lumbar-saccral than in the cervical and thoracic regions, as well as some pathogenesis in hypoglossal and dorsal vagus nerves, red nucleus, restricted areas of the cerebral cortex and dorsal root ganglia. The mutation affects both sexes, and all affected animals seem to be fertile, although the motor dysfunction restricts breeding after 7-8 months of age. The late age of onset, symptoms and pathology all suggest that this mutant is a good model of amyotropic lateral sclerosis (ALS).

The pathology is consistent with severity of the symptoms, irrespective of the age of onset. Severely affected animals showed loss of many motoneurons, paticularly in the lower spinal cord, with substantial pathology obvious in most of the remaining large neurons. Mice with only slight ataxia showed some clearly pathologic cells, but many more healthy motoneurons than the cases above. Finally, 2 totally asymptomatic 3-month-old mice of the same substrain showed clear evidence of isolated pathological neurons in the lower spinal cord, with one case more prominent than the other. Controls were normal in all cases. Overall, there seems to be an ascending progression of the pathology, from anterior horn cells of the lower spinal cord to highest brainstem motor nuclei. Electron microscopy to further examine the nature of the pathology is in progress.

The mutation is on a C57Bl/6 background which carries a recombinant 17th chromosome. It appears that this mutation arose at the same time or shortly after the recombinational event, which affects the major histocompatibility region. Thus, the recombination site and the mutation may be closely linked, although the presence of an independent mutation cannot be ruled out. Since either symptoms or pathology have been evident in every mouse of this strain examined to date, it appears that the gene is homozygous. We cannot distinguish between recessive and semi-dominant inheritance, however, until the obligate heterozygotes are older.

132.4 PRIMARY AND MODIFIER GENE ASSIGNMENTS IN JOSEPH DISEASE. A.I. Grossman,* L.A. Warmoth,* P.M. MacLeod* and R.N. Rosenberg (SPON:R.M. Stewart) Dept. Neurology, UTHSC, Dallas, TX 75235; Dept. Pediatrics, Queen's University, Kingston, Canada K713N6.

Joseph disease (JD) is a distinct autosomal dominant neurological disorder presenting either symptoms of spasticity, rigidity, and dystonia in the first to third decades of life or dysarthria, cerebellar ataxia, and amyotrophy in the fifth to seventh decades of life. Both symptoms and neurological findings of neuronal death and glial proliferation, most notably in the cerebellar cortex, irreversibly progress to death after 10-20 years of illness. Analysis of a large number of JD families revealed that there are two genes which determine the number of affected descendents in a family. They are the JD gene which actually causes the disease and the modifier (Mo) gene which reduces severity of JD or totally represses the expression of the JD gene. The JD gene has been preliminarily assigned on the short arm of chromosome 1 using protein and blood type polymorphisms (C.J. Forster-Gibson et al., Abstract. Amer. Soc. Hum. Genet., 1984, N.E. Simpson et al., Abstract. Human Gene Map, 1985). Using cDNA probe for Amy gene (chromosome 1, 1p21) we found a cosegregation of particular haplotypes with JD patients in two families. The existence of a number of pedigrees with a "skipped generation" supported a hypothesis of the presence of the Mo gene in some families. This gene was tentatively assigned to short arm of chromosome 2 near EAP-1 locus (2p23). The DNA hybridization of POMC probe (chromosome 2, 2p23) with genomic DNA's of one family indicated that the Mo gene might be situated closer to EAP gene than to POMC gene. Activity of mitochondrial and supernatant glutamate dehydrogenase (GDH) (localization is unknown) and malate dehydrogenase (MDH) (chromosome 2, 2p23) from cerebellar cortex of JD patients and dominantly inherited OPCA have been compared with corresponding fractions of enzymes from clinically normal patients. A significant increase of GDH activity was found in the supernatant fraction of JD and OPCA patients compared with controls and in OPCA patients compared with JD. A significant decrease of MDH activity was found in both mitochondrial and supernatant fractions of OPCA patients compared with control and JD patients. The differences in GDH and MDH activities among JD, OPCA and control patients did not appear to result from altered K_m's, but rather was consistent with the amount of available total enzyme activities.

132.5 PRENATAL DYSMYELINOGENESIS IN CAPRINE β-MANNOSIDOSIS. K.L. Lovell, M.Z. Jones, N.K. Ames*, and C. Blaze*. Depts. of Pathology and Large Animal Clinical Science, Michigan State University, E. Lansing, MI 48824

Caprine β-mannosidosis, an autosomal recessive deficiency of glycoprotein catabolism, is associated with a deficiency of β-mannosidase activity, tissue accumulation of oligosaccharides, and cytoplasmic vacuolation in many cell types in the nervous system and viscera. Severe neurological deficits present at birth include an intention tremor, ataxia and inability to stand. Morphological changes previously reported in neonatal animals, in which myelination is nearly complete, include severe myelin paucity in the brain, with consistent regional variation. In the present study, fetuses at 124/150 days gestation were obtained to investigate prenatal development of morphological changes in β-mannosidosis.

An obligate carrier doe was artificially inseminated with semen from an obligate carrier male. The presence of triplets was determined by radiography. At 124 days gestation, Cesarian section was performed under halothane anesthesia. After each fetus was removed from the uterus, heart blood was obtained for measurement of β-mannosidase activity and perfusion was initiated via the heart with glutaraldehyde/paraformaldehyde solution. Sections from the brain were taken for embedding in paraffin and Epon-Araldite. Measurement of plasma and kidney β-mannosidase activities demonstrated that one of the three fetuses was affected and thin layer chromatography of kidney extracts showed the accumulation of oligosaccharides only in the affected animal. Gross examination of brain sections indicated ventricular enlargement and a deficiency in white matter in the affected animal, sufficient to serve as a diagnostic indicator in these fetuses.

Light microscopic examination of white matter in selected brain regions of the two unaffected fetuses revealed varying degrees of myelination, consistent with that expected for 124 day goat fetuses. Substantially less myelin was present in the affected fetus than in the control fetuses. In addition, glial cell morphology was abnormal in the affected fetus, even in regions where myelination had not yet begun. These results indicate that the pathogenetic process leading to cellular abnormalities and myelin deficits in β-mannosidosis has been initiated prior to 124 days gestation. Further analysis of the prenatal CNS lesions will contribute to a better understanding of the pathogenesis of dysmyelinogenesis in this genetic disorder.

133.1 THE EARLY DEVELOPMENT OF THE OLFACTORY PLACODE IN XENOPUS LAEVIS EMBRYOS. H.Kim*, P.P.C. Graziadei and G.A. Monti Graziadei. Department of Biological Science, Florida State University, Tallahassee FL 32306-3050

The olfactory organ originates from the so-called olfactory placode. However, the early stages of the development of this structure are not well known. We have used the amphibian Xenopus laevis to study in some detail the structural and ultra= structural development of the organ and the beginning of its ana= tomical connections with the brain. We have been primarily conce= rned with the morphological differentiation of the sensory neurons their initial growth and maturation patterns, the growth of their axons and the contacts of that these axons establish with the primitive prosencephalic vesicle before and after the development of the glomerular structures.

Xenopus laevis embryos, stages 23 to 37/38 were fixed by immersion in 1% glutaraldheyde and 0.4% paraformaldheyde in buffer and post-fixed in OsO_4. Following Araldite 506 embedding, the preparations were sectioned at 1 micron thickness and inter= mediate thin sections were also obtained for ultrastructural obser= vation.

We have been able to confirm that neurons originate exclusive= ly from the nervous layer of the ectoderm while the supporting cells originate from the non nervous layer of the ectoderm. The two populations of cells commingle by stage 28, the first axons originate from the placode by stage 29/30 and the first axons penetrate the C.N.S. by stage 32. The modalities of axonal growth and the first contacts with the neuronal populations of the forebrain will be illustrated at both LM and TEM.

133.2 NEUROGENESIS IN THE RAT PRIMARY OLFACTORY CORTEX. Shirley A. Bayer, Indiana-Purdue Univ., Indianapolis, IN 46223.

Neurogenesis in the rat primary olfactory cortex was examined with ^{3}H-thymidine autoradiography. The experimental animals were the offspring of pregnant females given an injection of ^{3}H-thymidine on two consecutive gestation days. Nine groups of embryos were exposed to ^{3}H-thymidine on E13-E14, E14-E15,....E21-E22, respectively. On P60, the percentage of labeled cells and the proportion of cells originating during 24 hour periods were quantified at selected anatomical levels of the dorsal peduncular cortex (DPC), anterior piriform cortex (APC), and posterior piriform cortex (PPC). Neurons in the DPC originate between E14-E20 in an older caudal to younger rostral gradient of neurogenesis. Caudal parts of the DPC also have an older lateral to younger medial neurogenetic gradient. The most lateral part of the DPC does not have the typical older deep to younger superficial gradient seen throughout the rest of the DPC. Neurons in the APC, lying lateral to the caudal anterior olfactory nucleus and olfactory tubercle, are generated mainly between E14-E18 in an older caudal to younger rostral neurogenetic gradient. Neurons in the PPC, lying lateral to the caudal olfactory tubercle and the entire amygdala, are generated mainly between E14-E17 simultaneously along the rostrocaudal plane. Throughout the entire piriform cortex, deep cells are generated earlier than superficial cells. Superficial cells in the piriform cortex have some additional neurogenetic gradients: In the APC, ventromedial cells originate earlier than those located dorsally and laterally. In the PPC, younger neurons are located at middle dorsoventral levels while older neurons lie above and below. The neurogenetic gradients in the primary olfactory cortex, along with patterns of neurogenesis throughout the olfactory peduncle can be related to the termination patterns of afferents from the main olfactory bulb.

133.3 Tactile stimulation during postnatal olfactory experience facilitates the subsequent neural and behavioral response of rats to that odor. R.M. Sullivan* and M. Leon. Dept. of Psychobiology, University of California, Irvine Ca 92717.

Rat pups develop a behavioral attraction to an odor previously associated with tactile stimulation which mimics maternal licking. Those experiencing the odor without such stimulation do not develop an attraction to the familiar odor (Sullivan, Hofer & Brake, submitted). Rat pups also have an enhanced neural response in specific olfactory bulb glomeruli to odors that were experienced during such stimulation (Coopersmith & Leon, 1984). The present study determined whether this enhanced neural response is dependent simply on odor familiarity, or if the odor must be accompanied by stimulation.

Olfactory experience consisted of 10 min per day from postnatal day 1 to 18 of either: 1) peppermint odor and vigorous stroking of the back with a brush to mimic maternal licking, 2) peppermint odor only, 3) stroking only, and 4) neither stimulus. On day 19, all pups were injected with 14C-2-deoxyglucose (200uCi/kg) and given a 45-min test exposure to peppermint in an apparatus which recorded pup respiration patterns. The developed autoradiographs were then analyzed with the aid of a computer-based image processing system which permits quantitative analysis and comparison of specific olfactory bulb area.

Pups that experienced peppermint simultaneously with tactile stimulation demonstrated both a behavioral attraction and enhanced 2-DG uptake in specific olfactory glomeruli (1.5-2.1mm from rostal pole of the olfactory bulb) upon subsequent presentation of peppermint. Pups in the remaining three groups demonstrated neither the behavioral attraction nor an enhanced 2-DG uptake to peppermint.

These results indicate that odor familiarity alone is not sufficient to induce an enhanced neural response. Rather, it requires association of odor experience with stimulation of the type normally experienced in the nest.

133.4 THE ENHANCED NEURAL RESPONSE INDUCED BY POSTNATAL OLFACTORY EXPERIENCE IS ODOR-SPECIFIC AND LONG-LIVED. R. M. Coopersmith* and M. Leon. (SPON: E. DEMET) Dept. of Psychobiology, University of California, Irvine CA 92717.

Norway rat pups develop a preference for familiar odors which is accompanied by an enhanced response in their olfactory systems. After 18 daily exposures to peppermint odor, the olfactory bulbs of the odor-familiar pups show an increased uptake of 14C-2-deoxyglucose (2-DG), in three groups of glomeruli on the lateral aspect of the bulb, 1.5-2.1 mm from its rostral pole. The enhanced response is not due to increased respiration. We now report that the enhanced response is long-lived, and can be induced by familiarity with other odors.

To measure the duration of the enhanced response, pups were exposed to either peppermint odor or clean air on postnatal days 1 to 18. Pups were weaned on day 25 and were not disturbed until day 85, when we implanted catheters into their jugular veins. On day 90, animals were injected with 2-DG (150 uCi/kg, i.v.) and given a 45-min test exposure to peppermint. Just as in 19-day old animals, three complexes of laterally located glomeruli showed significantly higher uptake in the peppermint-familiar animals than in the peppermint-unfamiliar animals. Thus, the enhanced neural response induced by neonatal olfactory experience persists for least 90 days.

On postnatal days 1 to 18, rat pups were exposed to either cyclohexanone odor (cyclohexanone-familiar) or clean air (cyclohexanone-unfamiliar). On day 19, all pups were injected with 2-DG (200 uCi/kg) and given a 45-min test exposure to cyclohexanone in an apparatus that allowed us to analyze respiration rate and sniff frequency. Autoradiographs prepared from olfactory bulb sections were analyzed with a computer-based digital image processor which allowed us to make quantitative comparisons between uptake sites.

Both groups of animals showed reliable uptake in a medial group of glomerular complexes 2.5-2.9 mm from the rostral pole of the bulb. In the cyclohexanone-familiar pups, uptake in these areas was significantly higher than in the cyclohexanone-unfamiliar pups. Respiration frequency pattern did not differ between the groups. The enhanced response therefore is odor-specific.

133.5 MORPHOLOGICAL AND METABOLIC CHANGES IN THE OLFACTORY BULB ACCOMPANY THE ENHANCED NEURAL RESPONSE TO FAMILIAR ODORS IN RAT PUPS. C. C. Woo*, R. M. Coopersmith*, and M. Leon. (SPON: D. Aswad) Dept of Pyschobiology, University of California, Irvine, CA 92717.

A familiar odor induces both a behavioral attraction and an increased 14-C-2-deoxyglucose (2-DG) uptake in olfactory bulb glomeruli specific to that odor in Norway rat pups. In this experiment we characterized the glomerular response with other metabolic and morphological techniques. Our strategy was to use the 2-DG technique to localize the glomerular areas of enhanced activity. The areas of enhanced 2-DG uptake were then matched with stained sections. Alternate sections were histochemically processed for cytochrome oxidase (CO), succinic dehydrogenase (SDH), or glycogen phosphorylase (GP). Other pups had alternate sections stained with a silver impregnation technique.

Rat pups received experience with either peppermint odor (peppermint-familiar) or clean air (peppermint-unfamiliar) on postnatal days 1-18. On day 19, all pups were injected with 2-DG (200 uCi/kg) and given a 45-min test exposure to peppermint in an apparatus that recorded their respiration rate and sniff frequency. Autoradiographs and stained sections were analyzed using a computer-based digital image processor and a light microscope.

In the peppermint-familiar pups, the areas of enhanced glomerular response identified in the autoradiographs corresponded to very large glomeruli which protruded into the external plexiform layer. This modification was not seen in the peppermint-responsive areas of the peppermint-unfamiliar pups. Heavy GP staining was also seen in the internal plexiform layer opposite these large glomeruli. In addition, glomeruli within the areas of enhanced 2-DG uptake had heavier CO and SDH staining at their perimeters and lighter staining centers, a pattern not seen in other glomeruli in either group. Early odor experience therefore induces morphological and metabolic changes in the olfactory bulbs of young rats which may underlie the increased neurobehavioral response to familiar odors.

133.6 NEUROPHYSIOLOGICAL CORRELATES OF ENHANCED 2-DG UPTAKE TO FAMILIAR ODORS IN THE OLFACTORY BULB OF NEONATAL RATS. D.A. Wilson, R.M. Sullivan* and M. Leon, Dept. of Psychobiology, Univ. of California, Irvine, CA.

Rat pups have an enhanced olfactory bulb response to familiar odors, as reflected by an increased 14C 2-DG uptake in specific glomeruli (Coopersmith & Leon, Science, 1984, 225:849-851). The present study examined the neurophysiological correlates of this response by recording single units in the mitral cell layer near the areas of enhanced glomerular 2-DG uptake.

Pups were exposed for 10 min/day to either peppermint-scented air or to clean air for the first 18 days of life. All animals received perineal stimulation during the sessions to facilitate odor preference acquisition. On day 19, animals were exposed to peppermint and tested for 1) their 2-DG glomerular uptake, 2) their behavioral attraction, or 3) their mitral cell response.

Single units were recorded in the mitral cell layer in the ventral-lateral area of the olfactory bulb (1.5 - 2.1 mm from rostral pole), corresponding to the area of enhanced 2-DG uptake. Single mitral cells were isolated and identified by depth and/or antidromic activation. Following isolation of a cell, peppermint or orange odor were randomly presented to the external nares for 4 sec, 3 times, with at least 60 sec between presentations. Responses were classified as excitatory when there was an increase in peak frequency above baseline variability, or inhibitory when peak frequencies were less than mean baseline frequency.

Odor-familiar pups preferred the odor and had an enhanced uptake of 2-DG. The mitral cells of such pups demonstrated significantly fewer excitatory and more inhibitory responses to peppermint than controls ($p < 0.001$). There were no differences in excitatory and inhibitory responses to orange odor between groups ($p > 0.10$).

Neonatal exposure to odors selectively alters subsequent mitral cell responsiveness to that odor. Since the enhanced 2-DG uptake to familiar odors appears not to be due to increased mitral cell activity, it may be due to increased activity in either external tufted cells (Macrides, 1984) or inhibitory interneurons.

133.7 GRANULE CELL PLASTICITY IN THE OLFACTORY BULB OF THE MUTANT MOUSE PURKINJE CELL DEGENERATION. Charles A. Greer. Sec. of Neurosurgery and Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

The mutant mouse Purkinje Cell Degeneration (PCD) loses all of its olfactory bulb (OB) mitral cells (MCs) between 12 and 20 weeks postnatal (Greer & Shepherd, 1982). Due to MC loss a subpopulation of the interneurons, granule cells (GCs), are deprived of the reciprocal dendrodendritic synapses normally present and contributing to the network of OB local circuits. Ultrastructural studies have demonstrated that some of the dennervated GCs establish new reciprocal dendrodendritic synapses with another class of OB primary neuron, tufted cells (TCs), which are apparently not affected by the pcd gene (Greer, Halasz & Shepherd, 1983). To further examine the apparent plasticity of GCs and their capacity for reorganizing following dennervation, quantitative Golgi analyses were conducted on dendritic and spine morphology following MC loss.

Affected PCD mice and normal littermate controls were processed for Golgi-Kopsch staining at 16 - 18 weeks postnatal. Granule cells were reconstructed with camera-lucida at 1,000X oil immersion. The distribution and morphological characteristics of dendrites and spine like appendages were quantitatively established.

In littermate control mice the distribution of GCs, their dendritic processes and their spines were comparable to that previously reported for rats. At least 3 catagories were broadly defined: 1) deeply placed somas whose dendrites innervated the deep EPL; 2) superficially placed somas whose dendrites innervated the superficial EPL; and 3) variably placed somas whose dendrites innervated the entire width of the EPL. Mean spine density for these groups was 0.21/1um of dendrite.

In affected PCD mutants the morphology and distribution of GC dendrites was dramatically altered. Dendrites typically extended across the entire width of the EPL in coronal section and did not exhibit the sublaminar distribution found in control mice. Although the mean number of spines/GC decreased by 20%, an accompanying decrease in the length of dendrites resulted in spine density remaining at 0.21/1um. In control mice dendrites were generally oriented radially and somewhat obliquely through the EPL, however, many dendritic branches in the PCD mice assumed a horizontal orientation within the EPL.

The data thus far indicate an extensive reorientation of GC processes in PCD mice following MC loss. Prior EM analyses demonstrated heterologous synaptogenesis following MC loss. The current data reveal a marked reduction in numbers of spines which suggests that not all spines establish new synapses. This may indicate that the availability of synaptic sites on TCs influences, in part, the survival of spines and the extent to which synaptic reorganization of GCs within local circuits may occur.

Supported by NINCDS NS19430 and MOD Basil O'Connor 5-420.

133.8 EFFECTS OF EARLY OLFACTORY DEPRIVATION ON THE INTERNAL GRANULAR CELLS OF THE OLFACTORY BULB. E. MEISAMI AND E. NOUSHIN-FAR*. Dept. Physiol.-Anat., Univ. Calif., Berkeley, Calif. 94720, & Inst. Biochem. Biophys., Univ. Tehran, Tehran, Iran.

We have previously shown that early olfactory deprivation by nare closure results in significant reductions in growth and development of the olfactory bulb (OB) as measured by several biochemical and structural parameters. In this study we report on the number, morphometry and spine number in the granule cells(GC)of the internal granular layer (IGL) and mitral cell layer (MCL). Albino rat pups were subjected to olfactory deprivation on one side by unilateral nare occlusion begining in the neonatal period. At day 25 postnatal, both control and anosmic OBs were stained with the Rapid Golgi method and the granule cells were studied quantitatively. It was found that compared to the control OB, the anosmic OB showed significant reductions in several parameters as follows: Number of GC, 19% in IGL, 12% in MCL; total length of GC, 19% in IGL (24% length of main apical branch, 24% soma, 24% diameter of deep branches, 14% diameter of superficial branches). Number of spines per GC in IGL, 25%, in MCL, 19%; number of spines per main apical branch 29%, per deep branches 26%, per superficial branches, 14%. In MCL, number of spines per GC 20%, per main apical branch 31%, density of spines 29%. The stained GC in IGL appeard often as clusters. The number of these clusters in the anosmic OB was reduced by 30% and the number of GC per cluster was reduced by 22%. The entire length of the cluster was reduced by 10% and its width by 3% which were not significant. In the control OB, total spine number per GC of IGL was $111^{\pm}$ 10 of which 42% were on the main apical branch and 26% on the deep branches and 23% on the superficial branches, and 4% on the soma. In the GC of MCL, total spine number per cell was about 81 of which 34% were on the main apical branch, 7% on soma, 28% on deep branches and 29% on superficial branches.

These results indicate early olfactory deprivation reduces the rate of proliferation, growth and spinogenesis of the GC of the OB. Since the GC are not directly connected to the primary olfactory neurons, it follows that the observed effects must be transmitted to the GC either via functional or trophic interactions involving the mitral and tufted cells which make connections with the GC in OB. However, the nature of these interactions remains to be elucidated. In general, these data provide further proof that the development of central neural structures are in part influenced by peripheral factors. (Supported by grants from Univ. of Tehran & Ministry of Science of Iran.)

134.1 ONSET AND DEVELOPMENT OF NEURON-SPECIFIC ENOLASE IMMUNOREACTIVITY IN THE PERIPHERAL VESTIBULAR SYSTEM OF THE MOUSE. C.J. Dechesne*, A. Sans* and A. Keller* (SPON: European Neuroscience Association). Lab. Neurophys. Sens. U.254 USTL Pl. E. Bataillon 34060 MONTPELLIER cedex France.

Immunohistological experiments have suggested that the initial appearance and gradual increase of neuron-specific enolase (NSE) in central nervous system might be correlated with differentiation and/or synaptic activity of cells (Schmechel, D.E. et al, Brain Research, 190 : 195, 1980). Maturation and synaptogenesis in the vestibular system are well documented and display precise sequences of spatio- temporal differentiation. Thus, it was of interest to study the onset and development of NSE immunoreactivity in these structures and compare the observations with the features of morphological maturation.

Antisera against purified mouse NSE were prepared in rabbits and tested as previously described (Keller, A. et al., J. Neurochem., 36 : 1389, 1981). They did not crossreact with non-neuronal enolase. CBA/C57 mice ranging from 14 gestation day (gd) to 15 postnatal day (pd) were fixed with McLean and Nakane's fixative (J. Histochem. Cytochem., 22 : 1077, 1974). Serial cryostat sections of the vestibular receptors and ganglion were processed for immunohistochemical staining using the peroxidase-antiperoxidase method (Sternberger, L.A., Wiley and Sons, NY, 1979). Anti-NSE serum was diluted 1/1000 to 1/5000.

The earliest faint staining of some vestibular ganglion cells was detected at 15 gd. At 17 gd all ganglion cells were stained and the adult intensity of staining was reached between 2 and 4 pd. In the vestibular receptors some NSE-positive sensory cells were detected at 17 gd. Supporting cells were not reactive. NSE immunoreactivity developped in the cristae with two main gradients : (1) a general apex/base gradient and, (2) a center-periphery gradient in each hemi-cristae. At 8 pd all sensory cells displayed an adult intensity of staining.

Staining development, in the vestibular structures studied, paralleled their maturational progression, thus the ganglion cells were positive before the sensory cells. Onset of NSE reactivity in the ganglion cells is concomittant with the formation of contacts without presynaptic differentiations between the afferent fibers and sensory cells, and is observed in hair cells during the period in which the first synaptic structures form. The fact that NSE reactivity develops in the cristae with an apex/base gradient is in accordance with previous findings concerning crista maturation. However this technique revealed the existence of a sequential gradient of maturation along the length of the cristae which had not been observed by other methods. The maturation gradients in the cristae are observed during 5-6 days after the onset of NSE-reactivity and demonstrate that sensory cell development is not simultaneous in the vestibular receptors.

134.2 IN VITRO EFFECTS OF EXCITATORY AMINOACID ANALOGUES ON EMBRYONIC AND NEWBORN MOUSE INNER EAR SENSORY STRUCTURES. J. Raymond* and G. Desmadryl* (SPON : European Neuroscience Association). INSERM U-254, Lab. Neurophysiol. Sensorielle, USTL, 34060 MONTPELLIER Cedex, France.

Excitants related structurally to the transmitter candidates L-Glutamate and L-Asparte are neurotoxic when injected intracerebrally. The most studied of these compounds is kainate (KA) which acts as a potent and selective neurotoxin on various neuron populations in brain or sense organs (for review see Coyle, J.T., J. Neurochem., 41 : 1, 1983). The neurotoxic effects of these excitants were proposed to be associated with overdepolarization following excessive receptor activation and seem to be in relation with the presence of high affinity recognition sites for L-Glutamate (Fagg, G.E. and Foster, A.C., Neuroscience, 9 : 701, 1983). As it has been suggested that glutamate may be involved at the hair cell-afferent fiber synapse in the vestibular and cochlear sensory epithelia (Dechesne, C. et al., Ann. Otol. Rhinol. Laryngol., 93 : 163, 1984 ; Eybalin, M. and Pujol, R., Neuroscience, 9 : 863, 1983), we examined the effects of three of the most selective compounds for the neuronal receptors of this amino-acid on the inner ear structures.

Using an in vitro system for maintaining isolated embryonic and newborn mouse otic vesicles (Desmadryl, G. et al., C.R.Acad. Sci. Paris, 8 : 223, 1984) we exposed the inner ear structures to N-methyl D aspartate (NMDA) quisqualate (QA) and kainate (KA) at different stages of development. Following 1 hour preincubation with fresh medium the isolated organ was exposed to one of these compounds (0,05 to 0,2 mM final concentration) for 5 to 30 minutes in vitro. After processing for ultrastructural observations, the pattern of the acute effects of each amino-acid analog was investigated by light and electron microscopy.

The neurotoxic effects affected the vestibular and cochlear ganglion cells and the NMDA was the less potent of the 3 compounds. In the younger stages, damage was first apparent in the vestibular structures and resulted in a severe swelling of afferent dendrites below the hair cells where are the postsynaptic components of the synapses. The hair cells had a normal ultrastructural appearence. The primary vestibular neurons presented a massive degenerative aspect with vacuolization : the mitochondria and the endoplasmic reticulum were disrupted. In the cochlea, the number of damaged spiral neurons increased with age. The increase in the sensitivity to the neurotoxic effects as a function of age suggests that functional high affinity binding sites to excitatory aminoacid analogues developped in the vestibular and auditory primary neurons in parallel with their synaptic maturation. These neurotoxic effects are consistent with a glutamatergic hypothesis for the neurotransmission in these sensory structures.

134.3 QUANTITATIVE HISTOCHEMICAL MEASUREMENTS OF MALATE DEHYDROGENASE IN NORMAL AND DEAFFERENTED CHICK BRAIN STEM AUDITORY NEURONS. D. Durham, E.W Rubel, and F.M. Matschinsky. Depts. of Otolaryngology and Physiology, U. Virginia Medical Center, Charlottesville, VA 22908 and Dept. Biochemistry, U. of Pennsylvania, Philadelphia, PA 19104.

Cochlea removal in young chickens results in rapid changes in the metabolism of second-order brain stem auditory neurons in n. magnocellularis (NM). Within 8 hours of cochlea removal, histochemical staining for the oxidative enzyme succinate dehydrogenase (SDH) increases in ipsilateral NM neurons, followed after several days by a decrease in reaction product (Durham, D. and Rubel, E.W, J. Comp. Neurol., 231:446, 1985). The surprising initial increase in SDH staining following deafferentation led us to examine the activity of a related metabolic enzyme, malate dehydrogenase (MDH), using a direct fluorometric assay.

The right cochlea was removed in 10 day-old anesthetized chickens. Four hours, 12 hours, or 9 days later birds were anesthetized and their brains quickly removed, blocked and frozen. Cryostat sections were cut, collected, and freeze dried. Tissue samples from NM were dissected from individual dried sections and assayed for MDH activity (oxalacetate formation, Hintz, et al., Am. J. Physiol., 239:C58, 1980).

Mean values (6-14 samples) from individual birds are given below in moles/kg dry wt/min s.e.m. Samples from the left NM contralateral to the cochlea removal and from unoperated animals serve as controls. Asterisks indicate that the mean differs significantly from that in unoperated birds ($p < .01$).

	control	4 hours	12 hours	9 days
right	0.59±.06	0.65±.06 0.64±.07	0.70±.04 0.77±.05*	0.37±.03*
left	0.66±.03 0.63±.03	0.58±.07 0.64±.08	0.51±.02* 0.64±.04	0.57±.04
ratio R/L	0.90	1.12 1.00	1.36 1.21	0.65

The data obtained with this direct assay for MDH are similar to our results with SDH staining. As with SDH, the ratio of MDH activity in ipsilateral NM to activity in contralateral NM was unchanged 4 hours, increased 12 hours and decreased 9 days following cochlea removal. Further study of the short-term increase in metabolism is in progress. (Supported by NIH grants NS 15395 and NS 07466 and the Virginia Lions Club).

134.4 EFFECTS OF EARLY EXPOSURE TO A LOW-NaCl DIET ON RAT CHORDA TYMPANI TASTE RESPONSES. David L. Hill, Dept. of Psychology, Univ. of Toledo, Toledo, OH 43606.

Environmental influences on rat neurophysiological taste responses occur when experimental procedures are imposed during early development. Exposure to a NaCl-free diet from 3 days gestation to 28-45 days postnatal led to flattened NaCl response-concentration functions compared to those in controls.

To learn whether similar alterations occur when rats are fed a low-NaCl diet, multifiber chorda tympani responses were recorded after exposure to a 0.03% NaCl diet for the same period as the earlier study. Additional recordings were made to learn of concomitant changes in receptor membrane components and to determine if exposure to a NaCl-replete diet after deprivation would result in responses similar to controls. As found in rats fed the NaCl-free diet, NaCl response-concentration functions (0.01M-0.5M) in rats fed the 0.03% NaCl diet were flattened compared to controls; NH_4Cl and KCl response-concentration functions were unaffected. Responses to a concentration series of NaCl after lingual application of amiloride (500 μM), suppressed NaCl responses in both deprived and control rats but the magnitude of suppression was disproportionate between groups. The response-concentration functions, expressed relative to the respective 0.1M NaCl response, for both deprived and control rats after amiloride application were similar to those in deprived rats before amiloride. Finally, response-concentration functions for NaCl in rats fed the 0.03% NaCl diet to 28 days postnatal and then fed a sodium replete diet for 10 days or less were similar to rats always fed the 0.03% NaCl diet. Response-concentration functions to NaCl in rats fed the NaCl-replete diet for 15 days, however, were intermediate to those in deprived and control rats.

These results demonstrate that specific neurophysiological taste response alterations occur to NaCl when rats are fed a 0.03% NaCl diet during early development. Response changes were similar to those in rats fed a 0% NaCl diet. A possible mechanism for the changes may relate to increased numbers of functional amiloride-sensitive membrane components. Moreover, the gustatory system is somewhat "plastic" in that responses change with changing environment conditions.

134.5 CENTRAL REPRESENTATION OF DENTAL STRUCTURES IN THE KITTEN USING TRANSGANGLIONIC HRP TRANSPORT. M.A. Henry*, L.R. Johnson* and L.E. Westrum (SPON: J.D. Loeser). Depts. of Neurological Surgery and Biological Structure, Univ. of Wash., Seattle, WA 98195.

The transganglionic transport of horseradish peroxidase (HRP) following pulpal injections in permanent teeth has been used to demonstrate the central representation of dental structures in the adult cat, but similar detailed studies in kittens with primary teeth are lacking. The present study describes the light microscopic pattern of central labelling following HRP injections in the primary maxillary cuspids of 8-9 week old kittens and compares the results to those of similar studies in adult cats. The periapical area of the injected tooth is also examined to investigate the possible spread of HRP to supporting structures. Kittens had 5 µl of 30% HRP injected into the primary maxillary cuspid on 2 successive days. One day later the animal was transcardially perfused and the brain stem and ganglia processed by the tetramethyl benzidine method of Mesulam. The injected tooth and its supporting tissues were removed as a block and following decalcification were reacted as above. Clusters of HRP cells were located in the ipsilateral ganglion and examination of the trigeminal brain stem nuclear complex (TBSNC) identified an extremely dense projection to each ipsilateral nucleus of the complex. Labelled fibers were found in layers I, II and V of the upper cervical spinal cord. In caudal medullary dorsal horn, the pattern is to the same layers as spinal cord but becomes increasingly more dense (especially in layer V) and broader including a limited projection to layers III and IV near obex. The distribution is in a dorsomedial position in caudal pars interpolaris (PI) with a gradual shift to a ventromedial location in rostral PI. Within pars oralis (PO) there is a gradual shift from a ventromedial to a dorsomedial position as rostral levels are approached. The labelling to main sensory nucleus remains dense especially in the dorsomedial subdivision. Large labelled fibers are seen in the V root entry zone and are seen ascending in the mesencephalic (MES) tract of V, where MES cells are also labelled. Examination of the periapical area of the injected tooth identified HRP within the periodontal ligament of the primary and developing permanent cuspid but not within the permanent tooth itself. This study identifies a more extensive and denser projection to all nuclei of the ipsilateral TBSNC and MES nucleus in kittens as compared to adult cats. This could reflect either 1) a greater central representation of primary teeth and associated structures than permanent ones, that may be modified with exfoliation of primary teeth and eruption of permanent teeth, or 2) a greater ability of the less mature system to transport HRP transganglionically.

134.6 TOPOGRAPHIC REPRESENTATION OF THE FACE WITHIN THE TRIGEMINAL (V) GANGLION OF THE NEONATAL RAT. B.G. Klein, A.M. Szczepanik* and R.W. Rhoades, Dept. of Anatomy, UMDNJ-School of Osteopathic Medicine and Rutgers Medical School, Piscataway, NJ 08854.

There is considerable anatomical and physiological evidence for inter- and intra-divisional somatotopy of the V ganglion neurons innervating different parts of the face and head in the adult rat. We have used fluorescent retrograde tracers to examine the representation of the face within the V ganglion of newborn rats. Within 12 hr. of birth, true blue (TB) and diamidino yellow (DY) were injected, in various combinations, into ophthalmic, maxillary and mandibular skin. In addition, tracers were injected into either the A-row and E-row vibrissa follicle regions or into the C1 and C5 regions to examine the intra-divisional representation of the whiskerpad. Animals were perfused transcardially 24-48 hr. later.

In rats which received maxillary (TB) vs. mandibular (DY) injections (N=4) there was no overlap between the TB and DY labelled neurons. TB labelled cells were located medially, throughout the region morphologically analogous to the adult ophthalmic-maxillary division, while the DY labelled neurons were found posterolaterally in the presumptive mandibular division. Similar results were observed for the ophthalmic (TB) vs. mandibular (DY) injections (N=4). In the ophthalmic (DY) vs. maxillary (TB) cases (N=4) all labelled cells were located in the ophthalmic-maxillary zone and there was considerable overlap in the distributions of the cells labelled by the different tracers. However, in 3 of 4 cases, DY labelled cells were concentrated dorsomedial to the TB labelled neurons.

A-row (DY) vs. E-row (TB) whiskerpad injections (N=6) labelled neurons throughout the ophthalmic-maxillary region. DY labelled cells were located medial to TB labelled neurons with little or no overlap. C1 (DY) vs. C5 (TB) (N=5) injections also labelled neurons within the ophthalmic-maxillary division, but provided no clear evidence of an ordered ganglionic representation of the rostrocaudal axis of the whiskerpad.

These results demonstrate inter- and intra-divisional somatotopy of the V ganglion in the neonatal rat. This organization is quite similar to that observed in adult animals.

134.7 RECOVERY FROM EXPERIMENTAL MYOPIA DEPENDS ON THE TYPE OF VISUAL RESTRICTION. Lisa Wentzek*, Michael D. Gottlieb and Josh Wallman. Dept. of Biology, City College, CUNY, New York, NY 10031

Severe myopia can be produced in experimental animals by several different visual restrictions. In monkeys, tree shrews and chicks, total form-deprivation either by neonatal lid-suture or by occluders placed over the eyes results in consistent axial myopia. There are no reports that these experimental myopias are reversible. In chicks, restriction of vision to the frontal visual field also produces severe axial myopia, which can be reversed if the restriction is removed. To explore whether this difference in reversibility is a function of the species used or of the type of visual restriction employed, we now compare the effects of partial and total visual restriction on the course of recovery from experimental myopia in chickens.

Chicks were raised with the visual field of one eye either entirely occluded or restricted to the frontal visual field by means of translucent plastic occluders. The occluders were removed at either 2 or 4 weeks of age, the eyes measured, and remeasured 2 and 4 weeks later to assess ocular refractions, corneal curvatures, and axial dimensions (by A-scan ultrasound).

Development of myopia--As in our previous studies, all treated eyes became myopic after 2 and 4 weeks of treatment. Totally occluded (T) eyes became much more myopic than did eyes restricted to the frontal visual field (F)(median at 2 weeks, T:-32.1 D vs. F:-14.3 D; at 4 weeks, T:-29.9 D vs. F:-12.9 D). These myopias were associated with greatly elongated vitreal chambers. In addition, particularly in the totally occluded eyes, the anterior chambers became deeper and the corneal curvatures steeper.

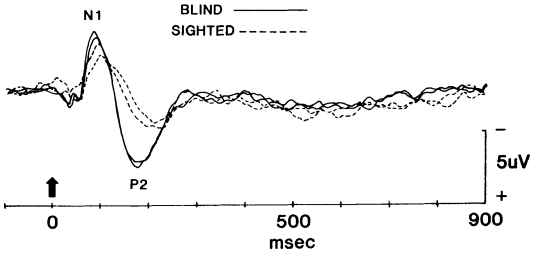
Recovery from myopia--Removal of the occluders caused a dramatic recovery from the myopia in all the eyes restricted to the frontal visual field and in the eyes totally restricted for only 2 weeks. This recovery was associated with a cessation of growth of the vitreal chamber, while the rest of the eye continued normal growth. We interpret this finding as suggesting a functional regulation of axial growth apart from the growth of the eye in general. In contrast to these results, the eyes totally occluded for 4 weeks did not become emmetropic (median at 8 weeks, T:-15.4 D), and the vitreal chambers continued to elongate at approximately the normal rate.

These differences in recovery suggest that only under particular conditions can the growing eye regulate its growth to achieve emmetropia. Perhaps once the eye is beyond a certain degree of refractive error or of vitreal elongation, it loses the normal ability to regulate its growth in the service of its ocular needs. Clarifying the conditions under which this normal growth regulation operates would be of clear importance in our understanding of the etiology of myopia. (Supported by NIH EY-02727.)

134.8 EARLY BLINDNESS REORGANIZES AUDITORY PROCESSING IN HUMANS David L. Woods, C. C. Clayworth* and P. Bach-y-Rita[2] Clinical Neurophysiology Laboratory, Dept. of Neurology, UC Davis, VA Medical Center, Martinez, CA 94553 and [2]Dept. of Rehabilitation Medicine, University of Wisconsin, Madison, WI 53705

We compared auditory evoked potentials (AEPs) in normal subjects and age and sex-matched subjects who had been blind since early infancy. Blind and sighted subjects had comparable brainstem auditory evoked potentials (BAEPs) but blind subjects showed shortened latencies and, in some cases, enhanced amplitudes of middle and long-latency AEPs.

Intergroup differences were first observed at latencies of 50-70 msec in middle latency recordings. The blind also showed amplitude enhancements in tone-evoked N1 and P2 components (below), and shortened latencies of P3s and reaction times in a target detection task. The results suggest that the reorganization of the auditory system following early blindness is primarily the result of changes in auditory structures in the forebrain.



134.9 POSTNATAL DEVELOPMENT OF EVOKED RESPONSE COMPONENTS OF THE COCHLEA AND BRAINSTEM IN RAT. J. Coleman, B. Blatchley*, and W. A. Cooper*. Depts. of Psychology, Physiology and Communicative Disorders, University of South Carolina, Columbia, South Carolina 29208.

Development of auditory function was studied in Sprague-Dawley rats using auditory brainstem recordings. Rat pups were anesthetized with ketamine and acepromazine and pure tone pips presented monaurally. The stimuli consisted of 0.5 msec rise-fall times and 1 or 2 msec at maximum amplitude presented up to 106 dB PeSPL. Repeated vertex-chin recordings were made on postnatal days 9, 10, 12, 14, 15, 16 and 20 from 24 animals. Recordings on postnatal days 9 and 10 showed no response to 3, 8, and 40 kHz stimuli. On postnatal day 12 stimulus dependent responses were reliably recorded. However, response generation was dependent upon the frequency of the stimulus presented. At 3 and 8 kHz stimulation 60% of the animals showed a major deflection at 95 dB. In the same animals 40% showed a response at 40 kHz at 95 dB; four of these animals showed no response at this frequency at 106 dB.

The source of the first response was examined by varying stimulus duration and repetition rate. Doubling stimulus duration correspondingly increased the response envelope by a factor of two. These responses were recorded to random phase presentation suggesting that they were summating potentials which are generated by cochlea. Increasing the repetition rate from 20/sec to 80/sec yielded a response with the same morphology and latency characteristics. The absence of a latency shift implies that this component is not of neural origin.

At 14 days two waves appear to stimulation at 3 and 8 kHz at 95 dB in all animals tested. These waves show neural elements. A third wave now appears in most animals at 3 and 8 kHz and a fourth wave also emerges in some animals. Less than 50% of animals at 14 days show a response to 40 kHz stimulation and later waves are infrequently observed. At 16 days of age four waves appear in all animals at 3 and 8 kHz, although only two routinely appear at 40 kHz. A fifth wave is observed at 20 days to low frequencies, but not to 40 kHz. These results show that for cochlear as well as neural structures the responses to lower frequency stimuli precede those to higher frequencies in the rat. 134.10 DEVELOPMENT OF COCHLEAR AND BRAINSTEM AUDITORY EVOKED POTENTIALS IN THE MONGOLIAN GERBIL. N. K. WOOLF AND A. F. RYAN*, Otolaryngology Research Laboratory, University of California Medical School and Veterans Administration Medical Center, San Diego, CA 92103.

Cochlear N1 compound action potentials (AP) and auditory brainstem evoked responses (ABR) of mongolian gerbils (Meriones unguiculatus) were examined at 10, 12, 14, 16, 18 and 30 days after birth (DAB). This range of ages includes the onset of neonatal hearing through the achievement of mature auditory system characteristics. Neonatal responses were compared to those for adults.

AP was measured utilizing standard round window recording techniques. Click evoked AP was first observable at 12 DAB. AP thresholds at 12 DAB exceeded 120 dB SPL (peak). At that time AP showed significant immaturities with respect to threshold, asymptotic latency and maximum response amplitude. Furthermore, at 12 DAB AP magnitude showed more rapid adaptation with increasing repetition rate than was the case at later ages. Between 12 and 30 DAB AP thresholds decreased approximately 100 dB. Mature asymptotic latency and repetition rate responses for AP were achieved by 16 DAB, while other parameters, including threshold and maximum response amplitude did not reach adult levels until after 18 DAB.

ABRs were first observed at 12 DAB. Only peaks I, II and IV were present in the youngest subjects. The ABR waveforms at 12 DAB had broad peak widths, high thresholds and were very sensitive to repetition rate. The ratio of peak I/peak IV at 12 DAB was greater than one, whereas at later ages it was always less than one. Five positive peaks were apparent for subjects 14 DAB, or older. For all subjects ABR peaks I and II correlated well with the N1 and N2 negative peaks of the AP. With increasing chronological age through 30 DAB, ABR thresholds and latencies decreased, the width of each of the five peaks became more narrow and the relative amplitude of the later peaks increased.

These results indicate that the generators of the peaks in the ABR waveforms mature in a hierarchical fashion, with the more peripheral regions of the auditory system reaching maturity before those for more central regions. For each peak the parameters of latency and rate adaptation reached maturity prior to that of absolute magnitude.

DEVELOPMENT AND PLASTICITY: SENSORY SYSTEM II

135.1 EFFECTS OF ALTERED VISUAL INPUT UPON VISUAL AND SOMATOSENSORY REPRESENTATIONS IN THE HAMSTER'S SUPERIOR COLLICULUS. R.D. Mooney, B.G. Klein and R.W. Rhoades. Dept. of Anatomy, UMDNJ-School of Osteopathic Medicine and Rutgers Medical School, Piscataway, NJ 08854.

It is well known that neonatal removal of one eye and ablation of the ipsilateral superior colliculus (SC) in hamster results in an abnormally extensive ipsilateral retino-SC pathway (eg. So, K-F. and Schneider, G.E., Brain Res., 147:277, 1978) and an abnormal visual map in the superficial laminae of the remaining colliculus (Finlay, B.L. et al., J. Comp. Neur., 183:721, 1979). We used this preparation to determine whether the altered visual map in the superficial SC laminae was associated with a change in the somatosensory representation in the deep layers of this structure.

Hamster pups were subjected to enucleation of the right eye and ablation of the superficial layers of the right SC within 12 hr. of birth and then used in recording experiments no less than 3 mon. later. These experiments showed that the expanded retino-SC projection was roughly mirror symmetic with that observed normally. There were, however, numerous irregularities and discontinuities. The somatosensory representation in the remaining SC was also markedly altered. The changes here included the presence of numerous cells with bilateral or even strictly ipsilateral low threshold receptive fields, cells with split receptive fields and large changes in the magnification factor for different parts of the body. The overall polarity of the somatosensory representation was, however, normal.

Additional anatomical experiments demonstrated only one abnormal somatosensory input to the deep laminae of the left SC: A weak projection from the contralateral somatosensory cortex which innervated the medial portion of the colliculus on this side. Removal of the source of this projection at the time of the recording experiment did not reduce the incidence of abnormalities in the somatosensory representation of the neonatally brain damaged hamsters.

Our results thus show that an altered visual SC map is associated with changes in the somatosensory representation in this structure. The somatosensory changes do not, however, bring this map into alignment with the visual representation.

135.2 THE EFFECT OF NEONATAL EYE ROTATION ON THE REPRESENTATION OF AUDITORY SPACE IN THE FERRET SUPERIOR COLLICULUS A.J. King*, M.E. Hutchings*, D.R. Moore and C. Blakemore, University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, England.

The deep layers of the ferret superior colliculus (SC) contain a two dimensional map of auditory space which is in register with the visual map in the overlying superficial layers (Hutchings, M.E. & King, A.J., 1985, J. Physiol. 358, 31P). In order to determine whether registration between these maps requires sensory experience during postnatal development, we have examined the effect of neonatal eye rotation on the relationship between the representation of visual and auditory space in the SC of the adult ferret.

A 180° intorsion of the left eye was performed in 6 ferrets anaesthetized with halothane and N_2O at or soon after normal eye opening, at 31-36 days of age. The right eye was removed. Animals were between 5 and 7 months old at the time of recording. They were anaesthetized with alphadolone/alphaxalone, surgically prepared for extracellular recording, paralysed with gallamine triethiodide and artificially ventilated. Paralysis was maintained by infusion of gallamine triethiodide and sodium pentobarbitone. White-noise bursts (500Hz-40kHz) were presented under anechoic conditions from a loudspeaker, which was moved in both azimuth and elevation using a hoop system. The visual receptive fields of cells in the superficial and deep layers were mapped with a discrete flashing light source.

The map of the visual world in the contralateral SC was shifted according to the degree of eye rotation. Thus, in animals in which there was no de-rotation, anterior visual space was represented in caudal SC and superior visual space was represented in lateral SC. The responses of 91 auditory units in the deep layers were analysed. The majority of these units responded best to an area of space restricted in both azimuth and elevation. The best areas of most units varied systematically in azimuth from the anterior to the posterior field along the rostro-caudal axis of the SC, and from superior to inferior along the medio-lateral axis. The representation of auditory space in these animals therefore appeared normal and was out of register with that of visual space.

We conclude that the auditory map in the deep layers of the ferret SC does not adapt to alteration of the visual representation, suggesting that the topography of the auditory representation is not regulated during normal postnatal development by the map of the visual world.

135.3 POST-EMBRYONIC HAIR CELL PRODUCTION IN THE SACCULE OF A TELEOST FISH. A. N. Popper and B. Hoxter*. Dept. of Anatomy, Georgetown Univ. Schools of Med. and Dent., Washington, DC 20007.

In contrast to amniotes, a number of anamniote species continue to add sensory hair cells to the inner ear for at least several years after birth. Post-embryonic proliferation of sensory hair cells is particularly extensive in the teleost Astronotus oscellatus (the oscar). A 2-cm long animal has approximately 5,500 hair cells on the sensory epithelium in one saccule, whereas a 19-cm long animal has over 250,000 sensory hair cells (Popper, A. N. and B. Hoxter, Hearing Res. 15:133, 1984).

Studies of proliferation of sensory hair cells in elasmobranchs and amphibians indicate that the post-embryonically produced sensory hair cells in these animals are added at the edges of the sensory epithelium in these species (Corwin, J. T., Abst. Assn. Res. Otolaryngol. 7:56, 1984).

In order to determine sites of hair cell proliferation in the saccule, specimens of Astronotus were injected with tritiated thymidine for one or more days and sacrificed at various times after injection. Tissue was prepared using standard autoradiographic techniques to locate cells in the saccule that had divided after injection.

Labeled cells of various types were found throughout the saccular sensory epithelium. In animals sacrificed soon after thymidine injection the majority of labeled cells were located just above the basement membrane, at the level of the supporting cells. Animals sacrificed several days or more after injection had labeled cells just above the basement membrane, labeled sensory hair cells, and labeled cells that were located somewhat above the basement membrane but below the level of the hair cells. While some of the labeled cells were located close to the edges of the sensory epithelium, the majority of the labeled cells, including most of the labeled sensory hair cells, were located closer to the center of the epithelium than to the edges.

We found mitosis towards the center of the saccular epithelium. In addition, most labeled cells were found in pairs. These findings lead to the suggestion that there is active production of new cells within the sensory epithelium, rather than such cells migrating into the epithelium from the edges. Thus, our findings demonstrate that post-embryonic hair cell production in Astronotus occurs throughout the saccular epithelium and not just at the edges, unlike the addition of post-embryonic hair cells in other anamniotes or embryonic addition of hair cells in mammals.

Our results also lead to the hypothesis that the newly added sensory hair cells arise from stem cells located just above the basement membrane throughout the saccular epithelium. These stem cells divide and produce cells which grow towards the apical surface of the epithelium and ultimately develop into mature sensory hair cells. (Supported by NIH and NSF.)

135.4 EFFECTS OF UNILATERAL COCHLEA REMOVAL ON THE CYTOARCHITECTURE OF THE THIRD-ORDER AUDITORY NUCLEUS IN A SONGBIRD. J.M. Greenspon*, J. Humpal* and D.H. Reynolds* (SPON: D. Olton) Psychology Dept., Hobart and Wm. Smith Colleges, Geneva, NY 14456; Dept. of Psychol. Johns Hopkins Univ., Baltimore, MD 21218.

The brainstem auditory system (BAS) in avians is considered a model system for investigating the effects of deafferentation on neuronal morphology (Parks, T.N., and Rubel, E.W., J. Comp. Neurol. 164:435-448, 1975). The organization of the chicken BAS is relatively simple. We have examined the neuronal architecture of the third-order auditory nucleus (N. laminaris, NL) in the canary songbird, and the effects of unilateral cochlea removal (UCR) on its neurons. Our investigations reveal that the organization and composition of NL is more complex in a songbird than in the chicken. Concomitantly, the canary's NL exhibits a very different response to UCR than does the chicken's.

In contrast to the chicken's NL, which contains a uniform monolayer of medium-sized, bipolar projection neurons, the canary's NL is composed of three neuronal layers containing several neuronal types: a bipolar projection type; and four types of local circuit neurons. Each neuronal type can be distinguished on the basis of its morphology and position within NL.

Compared to the chicken, the canary's NL exhibits a different response to UCR. In the developing chicken, unilateral damage to the auditory nerve results in severe atrophy of the dendrites of NL neurons which receive bilateral afferents from the second-order nucleus magnocellularis (NM). In contrast, adult chicken NL appears to be unaffected by this damage. In the adult canary, however, NL neurons exhibit a subtle reorganization in response to UCR. There is a decrease in the number and length of higher-order, distal NL dendrite segments in damaged subjects, relative to those contained in intact brains. At the same time, the proximal dendrite segments show a dramatic increase in length. These changes in dendritic morphology observed in birds sustaining UCR were related to patterns of connectivity between NM and NL.

Our studies of the adult canary BAS reveal an order of complexity not observed in the chicken BAS. The complexity in the canary BAS may be related to the songbird's reliance on auditory information for vocal learning, a talent not exhibited by chickens. Our results suggest that the avian BAS is a model for the comparative analysis of structure-function relationships as well as for the study of afferent influences on neuronal morphology.

This research was supported by Hobart and Wm. Smith Colleges and a faculty development grant from the Andrew W. Mellon Foundation through Hobart and Wm. Smith Colleges to J.M.G.

135.5 EARLY DIFFERENTIATION OF THE AFFERENT NERVOUS SYSTEM IN THE OPOSSUM (MONODELPHIS DOMESTICA). Terrell E. Jones* and Bryce L. Munger* (SPON: D.F. Peeler). Department of Anatomy, The Milton S. Hershey Medical Center of The Pennsylvania State University, Hershey, PA 17033

Early differentiation of afferent fibers innervating the snout skin of Monodelphis domestica was studied by electron microscopy and light microscopic, silver staining techniques. This study was undertaken to investigate the relationship between dermal and epidermal innervation at or following birth. Skin from young opossums was studied at birth (zero day) and postnatal days one, three and five.

Opossum pups were processed by immersion fixation using 10% neutral buffered formalin for paraffin embedding and Karnovsky's fixative for Durcupan ACM plastic embedding. Standard fixation times and procedures were used. Serially sectioned, paraffin embedded tissue was cut at 6-8 microns and processed for silver techniques. Plastic embedded tissue was sectioned at 700-900 Angstroms and processed for normal electron microscopy.

Portions of the afferent nervous system were present in the newborn opossum pup. Neurite bundles were seen within the dermis, epidermis, and penetrating the dermal-epidermal junction. Merkel cells were consistently present in large numbers. Mature Merkel cells had granules polarized toward the associated neurite and were located in the base of the rete pegs. Immature Merkel cells were characterized by a lack of granules and lacked an apposed neurite. Continguous Merkel cells had junctional complexes in zero and one day animals. Schwann cells, identified by their contact with neurite bundles, were present in large numbers, especially in superficial dermal layers. Melanocytes could be identified in the epidermis only in five day pups. No melanocytes were seen in the dermis. Developing rete pegs could be recognized in zero day animals and became prominent in five day pups.

These observations suggest that afferent fibers are present at a much earlier age than previously indicated and that these fibers are anatomically mature. Merkel cells are present early and can maintain themselves without neurite association. Rete pegs form after the time at which nerve fibers can be detected in the epidermis. These findings support the concept of a dependence during differentiation of the dermis, epidermis, and afferent nerve fibers. (Supported in part by USPHS Research Grant NS19462.)

135.6 DEVELOPMENT OF THE MEDIAL LEMNISCUS IN THE POUCH YOUNG OPOSSUM. J.C. Hazlett,[1] T.A. Collins[1], G.F. Martin[2] and T. Cabana[2]. Depts. of Anatomy, Wayne State Univ.[1] and Ohio State Univ.[2]

The development of the medial lemniscus was studied in the neonatal opossum using the axonal transport of WGA-HRP and orthograde degeneration. All animals were anesthetized for the experimental procedures. Specimens from postnatal days 3 and 5 were subjected to WGA-HRP injections of the diencephalon. In the younger group it was difficult to identify individually labeled dorsal medullary neurons. However, a fine dust-like reaction product was observed over cellular nuclei on the dorsal aspect of the contralateral medulla. In the postnatal day 5 animals similar placements resulted in unequivocal neuronal labeling in the contralateral dorsal medulla. The location of these cells was in accord with the positions of the gracile, cuneate and lateral cuneate nuclei in the adult. In an effort to determine the development of the infrathalamic lemniscal connections, lesions of the dorsal column nuclei were performed in litters of 14, 18, 21 and 26 day postnatal animals. Specimens from the 14 and 18 day old litters yielded equivocal results with regard to the course and termination of the medial lemniscus. The axonal debris was quite sparse and difficult to trace. While scattered argyrophilic granules were present in the contralateral inferior olivary nucleus, dorsal aspect of the pontine nuclei, red nucleus and zona incerta, only a few degenerating fibers were observed in the medial lemniscus. Furthermore, there was little evidence for degeneration in the ventrobasal complex. In contrast, material from the 21 and 26 day old litters clearly defined the course of the medial lemniscus. Axonal debris representing the degenerating lemniscus was present in the ventromedial brainstem from inferior olive to mid-pointine levels. From this point the degenerating fillet coursed into the midbrain where it was located ventral and lateal to the red nucleus. At the mesodiencephalic junction degenerating fibers entered the caudal zona incerta and terminated in the overlying ventrobasal complex. All brainstem structures normally innervated by the medial lemniscus in the adult contained axonal debris in both the 21 and 26 day old litters. In summary, on the basis of the HRP studies, we suggest that lemniscal projections to the diencephalon are present as early as the third postnatal day. Lemniscal projections to medullary, pontine and midbrain targets were revealed by degeneration procedures in postnatal day 14/15 animals. We are proceeding with attempts to demonstrate these latter connections at progressively earlier ages. As described here, the early development of lemniscal connections revealed by the HRP technique provides a basis for reevaluating previous studies suggesting a somewhat later appearance for this pathway. (Supported by BNS-8118455 to JCH and BNS-8309245 and NS-10165 to GFM.)

135.7 EVIDENCE FOR A DEVELOPMENTAL SEQUENCE IN THE ORIGIN OF SUPRASPINAL PROJECTIONS TO THE DIENCEPHALON OF THE NORTH AMERICAN OPOSSUM. G.F. Martin, R.H. Ho and T. Cabana, Department of Anatomy, The Ohio State University, Columbus, Ohio 43210.

The origin of supraspinal projections to the diencephalon has been studied in a series of pouch young opossums using the axonal transport of wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP). The opossum was chosen because it is born 12 days after conception and is available for experimental manipulation at very early stages of development. All animals were anesthetized for the operative and injection procedures. In the youngest pups subjected to WGA-HRP injections of the diencephalon (postnatal day 3), labeled neurons were difficult to identify. They were never-the-less found in the reticular formation and the dorsal column nuclei. They were probably present in other areas, including the dorsal raphe and superior central nuclei, although masked by spread of the marker and orthograde labeling. Indeed, immunohistochemical processing of brains from animals of the same age revealed evidence for serotonergic axons within the diencephalon and serotonergic neurons within the dorsal raphe and superior central nuclei. The latter nuclei provide most of the serotonergic projections to the diencephalon in the adult opossum. By postnatal day 5, injections in the diencephalon labeled immature neurons in most of the brainstem areas similarly labeled in the adult animal: the dorsal raphe and superior central nuclei, the presumptive coeruleus complex, the reticular formation, the vestibular nuclei as well as the sensory trigeminal and dorsal column nuclei. Where it could be assessed, the pattern and laterality of labeling was comparable to those in the adult. Labeled neurons were also seen in the cerebellar primordium. They were numerous in the nuclear and cortical transitory zones on the side ipsilateral to the injections, but a few were also present contralaterally. Examination of the neurons labeled ipsilaterally in progressively older pups suggested that most of them become incorporated into the parabrachial nuclei. Labeling within the contralateral nuclear transitory zone (presumptive deep nuclei) was well developed by postnatal day 12. At the same age neither orthograde nor retrograde labeling was found in the diencephalon after multiple injections of WGA-HRP into the neocortex. Such labeling was present, however, by postnatal day 18.

Our results suggest that neurons within the brainstem core, including the sensory trigeminal and dorsal column nuclei, innervate the diencephalon very early in development. Crossed cerebellar axons reach the diencephalon somewhat later, followed by those from the cerebral cortex. Such a developmental sequence is best explained by temporal factors such as the birthdates and maturation rates of the neurons in question.

135.8 ULTRASTRUCTURAL RECONSTRUCTION OF EVENTS RELATED TO THE DEVELOPMENTAL GRADIENTS OF THE COCHLEA. C.D. Fermin and G.M. Cohen. Department of Otorhinolaryngology and Communicative Sciences. Baylor College of Medicine. Houston, Texas 77030, and Department of Biological Sciences. Florida Institute of Technology. Melbourne, Florida 32901.

For this study, chick embryos (Gallus domesticus) ranging between 5 days of incubation and hatching (21 days) were fixed by immersion in 3% cold (4°C) glutaraldehyde in cacodylate buffer, embedded in Araldite 502 and processed for light (LM) and transmission electron microscopy (TEM). Serial sections were cut along the entire cochlear length at 2 and 5 um and examined under the LM. Thin sections (70 to 90 nm) were collected at every 100 um interval and photographed under the TEM.

Reconstructions of the developing chick cochlea (lagena) allowed us to identify ultrastructural events that were finely tuned with time around which the onset of hearing is known to occur (Rebillard and Rubel, Brain Res.,229,15,1981). Our observations were based primarily on synaptogenesis of afferents onto hair cells, cytodifferentiation of hair cells (development of the cuticular plate, stereocilia and of synaptic specializations), modifications of temporary synapses and of the afferent growth cones, and the appearance of the efferent terminals on the bases of the hair cells. We identified a longitudinal and lateral gradient on the chick cochlea (Fermin and Cohen, Acta Otolaryngol.,97:39, 1984) and found a parallel trend on the development of the statoacoustic (VIIIth cochlear) ganglion (Fermin and Cohen, Acta Otolaryngol.,98:42,1984), and the formation of the tectorial membrane (Cohen and Fermin, Hear. Res., In Press, 1985). It seems that these coordinated events taking place in the cochlea around the time of the onset of hearing, are responsible for the gradual improved responses that have been recorded in the past from young and older embryos and from newly hatched chicks. Thus, the contribution of the mentioned events must all be taken into account for explaining the progressive improved hearing of the embryos, and special attributes to individual components of the auditory system should be avoided.

The correspondence between the finely tuned morphological events with electrophysiological data obtained by others in this species (Rubel et al., Ann. Otol. Rhinol. & Laryngol.,93:609,1984) corroborate the usefulness of the chick embryo for this type of study. The importance of these findings will be discussed.

135.9 THE EFFECT OF NEONATAL INFRAORBITAL NERVE SECTION ON THE PATTERN OF THALAMOCORTICAL PROJECTIONS TO THE SOMATOSENSORY CORTEX OF THE ADULT RAT. K.F. Jensen and H.P. Killackey*. Div. Neurotoxicology, HERL, U.S.E.P.A., Research Triangle Park, N.C. 27711 and Dept. Psychobiology, Univ. of California, Irvine, CA 92717

Each level of the rat trigeminal system between the brainstem and cortex is characterized by a discrete pattern of afferent terminations which is related to the distribution of whiskers on the face of the rat. Previous studies have reported that infraorbital nerve cut at birth abolishes this pattern in the principal sensory nucleus and ventral posterior nucleus. In the present study we have investigated the effect of this same manipulation on the pattern of thalamocortical projections.

The infraorbital nerve of Sprague-Dawley rat pups was sectioned on the day of birth. When the rats reached adulthood, one group was injected with 0.25-0.75 microliters of 10% WGA-HRP into the ventral posterior nucleus. After a survival time of 12 to 24 hours, the rats were perfused, their cerebral cortices removed, flattened, sectioned tangentially, and reacted with TMB. In additional rats, tangential sections of flattened cortex were processed for SDH histochemistry.

Infraorbital nerve section on the day of birth resulted in a marked alteration in the pattern of thalamocortical projections. These projections were distributed in amorphous clusters which were irregularly spaced and of varibale size rather than organized into the rows of discrete clusters characteristic of the normal animal. In addition, the amorphous clusters tended to form bands which extended in a posteromedial to anterolateral orientation and were separated by zones which are relatively free of label. In certain regions, the outside border of this aberrant pattern was as distinct as in normal animals. For example, there was a relatively label free area between the aberrant pattern and the area of the forelimb representation as in the normal animal. The distinctive border of the aberrant pattern suggests the areal extent of the pattern may be the same as in the normal animals. We interpret these results as evidence that thalamocortical projections are maintained and exhibit a limited degree of organization after neonatal nerve cut. This limited organization may reflect the topographic relationship among thalamocortical projections present at birth. Conversely, the aberrant aspects of the pattern may reflect the absence of the normal postnatal peripheral influences which play a role in shaping the terminal arbors of axons.

135.10 AGE-DEPENDENT REORGANIZATION OF SI CORTEX IN CATS FOLLOWING SPINAL TRANSECTION. P.A. McKinley, W. Jenkins, M.M. Merzenich, S Hamer and J.L. Smith. Dept. Kinesiology, UCLA, Los Angeles, CA 90024 and Coleman Lab, UCSF San Francisco CA 94143

The somatosensory cortex (SI) in mammals has been shown to respond dynamically to limited peripheral changes, such as the amputation of one finger, by reorganization of its somatotopic map (Kaas,J. etal Ann Rev Neurosci., 6:325, 1983). However, the capacity for reorganization after large sensory deficits (such as loss of an entire limb), has not been examined. Also, the extent to which organization is age-dependent has been little explored. In this study we examined the reorganizational responses of SI in chronic spinal cats deprived of sensory input from the hindlimbs due to cord transection at T_{12} at 3 ages: adults, and juveniles of 2 and 6 weeks of age.

Receptive field (RF) characteristics of most of the mediolateral strip of SI were mapped electrophysiologically from multiunit responses to light tactile stimulation in ketamine anesthetized cats. The differences between the cortical maps of the transected animals and the normal cat (Felleman, D. etal.J Neurosci.,3:1648, 1983; McKenna, T. etal. J Neurophysiol., 45:667, 1981) are dramatic and the difference between the age at which transection occurred was striking. Briefly, SI cortex in cats spinalized as adults or at 6 weeks of age was characterized by expansions of the trunk and forelimb representations medialward into the region normally occupied by the hindlimb afferent input. Additionally, the entire trunk representation, including the medially placed part attributed to the lesion, was narrowed along the rostrocaudal axis as compared to normal representation. In contrast, SI cortex in cats spinalized at two weeks of age was characterized by double representation of the the trunk and forelimb, and was organized topologically along the mediolateral axis in two halves that were mirror reflections of each other and occupation of SI cortex along the rostrocaudal axis appeared to be normal for both representations. However, all age groups exhibited some characteristics in common: areas within normally occupied SI cortical zones that were active but unresponsive to light cutaneous stimuli; increased trunk representation, appearance of large receptive fields.

In summary, it is interesting to note that the distances over which reorganization has been observed were greater than those reported in SI cortex of monkeys for more restricted peripheral lesions. Additionally, although the rostrocaudal extent of SI in transected adults was a fraction of that found in normals, it was difficult to distinguish any differences cytoarchitecturally between normal and lesioned animals. Supported by NS 19864

135.11 BEHAVIORAL CONSEQUENCES OF CHRONIC VIBRISSA ACTIVATION OF RAT VIBRISSA-CORTICAL BARREL SYSTEM. K.M. Gallo*, W.J. Carr*, R.L. Craik, P. Hand (SPON: J. Walsh) Beaver College, Glenside, PA 19038 and Dept. of Anim. Bio., Sch. of Vet. Med., Univ. of Penna., Phila, PA 19104

Previous (^{14}C)-deoxyglucose (2DG) studies revealed an enlarged and diffuse pattern of labeling of C3 representation in contralateral SI 90 days after neonatal follicle ablations sparing #3 vibrissa of row C (C3) (Sheu and Hand, Neurosci. Abst., 1982). In a subsequent study, continued stimulation ("enrichment") of one C3 vibrissa on bilaterally follicle ablated rats resulted in an increased local cerebral metabolic rate of glucose (LCMRG) in contralateral SI compared to matched C3 controls (Craik et al, Neurosci. Abst., 1983). These data indicated that (1) a remaining intact receptor organ increased its central representation in SI cortex in response to deafferentation of the surrounding "vibrissal" region of SI and (2) that chronic stimulation of the spared intact receptor organ (C3) produced an increase in LCMRG. The purpose of this study was to determine if there was a correlation between increased metabolic activity and somatosensory related behavior. The present research examined the effect of C3 enrichment on the manner in which rats explore a novel environment, known to evoke wall-hugging (Gallo and Carr, Proc. and Abst., East. Psych. Assoc. 1985). On postnatal days 1-4 (PND 1-4), 20 rats (Sprague-Dawley) had follicles bilaterally ablated, sparing both C3s. Left C3 was mechanically stroked for 10 min per day in 10 animals; the other ten rats had right C3 stroked. "Enrichment" continued from PND 5 to PND 90.

The rats were tested individually in a darkened cylindrical pen (125 cm in diameter) for 2 min per day for 5 consecutive days. It was predicted that prior stroking of the left C3 would tend to evoke clockwise wall-hugging and that prior stroking of the right C3 would evoke counter-clockwise wall-hugging. The findings confirm the hypothesis; i.e., during the ten-minute test, the rats spent significantly more time ($p < 0.05$) and traversed a greater distance ($p < 0.05$) wall-hugging in the predicted direction than in the opposite direction. The experiment reported here suggests that continued mechanical stimulation of spared C3 affects somatosensory related locomotor behavior in rats. The chronic mechanical stimulation of a spared peripheral receptor organ resulted in use of this "enriched" vibrissa to negotiate a novel environment. Such behavioral results appear to correlate with LCMRG in the SI representation of the "enriched" spared C3 vibrissa reported on previously. (Supported in part by BSRG, RR05464, 55-21851)

135.12 MORPHOGENESIS OF DORSAL ROOT GANGLION CELLS WITH PROCESSES IN THEIR SYNAPTIC TARGET ZONE OF EMBRYONIC SPINAL CORD. R.P. Barber* and J.E. Vaughn. Beckman Research Institute of the City of Hope, Duarte, CA 91010.

This study focused upon the morphogenesis of dorsal root ganglion (DRG) cells whose central processes had reached their synaptic target zone in the embryonic mouse (C57BL/6J) spinal cord. On embryonic days 12-15 (E12-15), horseradish peroxidase (HRP; 1-14nl) was pressure injected into the spinal association region through micropipettes. The embryos were then cultured at 35°C for 2-5 hours in an oxygenated medium consisting of heat-inactivated 50% rat serum and 50% Waymouth's solution. Embryos were fixed, cryoprotected, and sectioned on a cryostat. Slide mounted sections were incubated in $CoCl_2$ followed by DAB/H_2O_2, and were then counterstained and coverglassed. Retrogradely labeled DRG cells were measured and classified into four categories representing successive developmental stages: 1) primitive bipolar cells, that were spindle-shaped, symmetrical cells with one process extending from each pole; 2) early transitional bipolar neurons that were asymmetric cells with their two processes approaching one another at an angle exceeding 90°; 3) late transitional bipolar cells that exhibited central and peripheral processes closing toward each other at an angle of 90° or less; and 4) pseudounipolar neurons with a morphology typical of mature DRG cells.

On E12, the mean major and minor somal diameters of labeled DRG cells were 17.06±0.31μm and 8.36± 0.18μm, respectively. Nine percent of the E12 labeled cells were of the primitive bipolar type, whereas 91% were early transitional cells. On E13, the mean major and minor somal diameters were 17.69±0.33μm and 11.04±0.22μm, respectively. Early transitional cells accounted for 77% of the labeled population, while late transitional cells made up 11%. Primitive bipolar cells (10%) and pseudounipolar neurons (2%) accounted for the remainder of the cells labeled at E13. On E14, the mean major and minor somal diameters were 15.39±0.34μm and 12.17±0.28μm, respectively. Early transitional neurons accounted for 60% of the labeled cells, pseudounipolar neurons for 17%, primitive bipolar cells for 13%, and late transitional cells comprised 10% of the labeled population. Finally on E15, the mean major and minor labeled somal diameters were 19.77±0.40μm and 14.60±0.32μm, respectively. Pseudounipolar neurons accounted for 43% of the labeled cells, and late transitional cells made up 36% of the total. Early transitional cells (19%) and primitive bipolar (2%) cells accounted for the remainder. A salient finding of this study was that even the less differentiated forms of DRG neurons had axons within their central synaptic target field during early stages of spinal cord development. Supported by NSF grant BNS-8219831.

135.13 EFFECTS OF DORSAL ROOT GANGLION REVERSALS ON SKIN SENSORY INNERVATION PATTERNS IN CHICK HINDLIMB. S.A. Scott, Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

During embryonic development dermatomes and axonal projections of lumbosacral dorsal root ganglia (DRGs) are established in a precise, orderly fashion in the chick, suggesting that sensory neurons may be specified for their axonal pathways or target skin. Alternatively, motor neurons may guide the outgrowth of sensory axons (Landmesser & Honig, Neurosci. Abst. 1982). To investigate these possibilities the rostrocaudal order of DRGs T7-LS3 was reversed to cause sensory axons to enter the limb from a novel location; at St.15-16 either the entire neural tube opposite somites 26-29 was excised, rotated and reimplanted or the dorsal neural tube alone was rotated, leaving the ventral neural tube (including the motor neuron precursors) intact. In some embryos quail neural tissue was transplanted into chicks to aid in later identification of rotated tissue. The resulting dermatomes and axonal projections were studied at St.29-40.

Rotation of the neural tube led to a partial reversal of skin sensory innervation patterns (see also Honig, Neurosci. Abst. 1979), as if some but not all axons from rotated DRGs established "embryologically correct" innervation. For example, in control embryos most skin sensory axons of DRGs T7 and LS1 project in the CFL nerve to serve dermatomes mainly on the thigh; DRG LS2 divides its axons roughly equally between the CFL and CFM nerves, and between the thigh and shank; DRG LS3 projects mostly in the CFM nerve to serve a dermatome mainly on the shank. When neural tube was rotated, the DRGs that developed at T7 and LS1 had a significantly larger percentage of their axons in the CFM and a significantly larger percentage of their dermatomes on the shank, approaching but seldom achieving the innervation patterns of DRGs LS2 and LS3 from which they were derived. In contrast, when only the dorsal neural tube was rotated, leaving motor neuron precursors largely intact, innervation patterns were nearly identical to controls, as if DRG axons established innervation in accord with their position in the embryo. Thus, skin sensory innervation patterns closely follow the motor projection patterns, which are reversed following neural tube rotations (Lance-Jones & Landmesser, J. Physiol. 1980) but are nearly normal following dorsal neural tube rotations. These results suggest that if skin sensory neurons are specified with respect to their peripheral connectivity, the specification is relatively weak, with the innervation patterns being greatly influenced by the corresponding motor neurons. Attempts are now being made to investigate skin sensory innervation patterns in the absence of motor neurons. (Supported by NIH grant NS16067 and an Alfred P. Sloan Foundation Fellowship).

135.14 SELF-MUTILATION AFTER DORSAL RHIZOTOMY: ROLE OF EXTENT AND LOCATION OF LESION. E. Schneider and D. Berman (SPON: A.J. Berman). Psychology Dept., Queens College, CUNY, Flushing NY.

Deafferentation in animals is frequently, but not always, followed by self-mutilation (autotomy) of the affected limb. Rabin et al. (Pain, 21: 117-128, 1985) suggest that, after nerve section in the rat, it is the extent of lesion which is critical, with total denervation of the limb resulting in a markedly different pattern of autotomy than follows partial denervation. The present study is an attempt to elucidate the role of extent and location of dorsal rhizotomy on autotomy in the rat.

Male Long-Evans rats were subjected to section of dorsal roots innervating the left forelimb.

n	Dorsal roots sectioned	
	Location	Number
4	C7-C8	2
5	C6-C8	3
5	C7-T1	3
4	C6-T1	4
5	C5-T2	5

All rats, save two in the C7-C8 group and one in the C6-C8 group, self-mutilated to some degree. There was no significant relationship, however, between the number of roots cut and severity of autotomy. Severity did not differ between rats with lesions of two roots (C7-C8) and those with one of the three-root lesions (C6-C8), nor between rats with the other three-root lesion (C7-T1) and those with four roots cut (C6-T1). Furthermore, rats with section of C7-T1 had as high a level of autotomy as did rats with section of six roots (C5-T2). The particular roots cut, on the other hand, appeared to be critical in determining the course of autotomy. Section of C6 did not affect the phenomenon; autotomy did not differ between rats with lesions of C7-C8 vs C6-C8. Section of T1, however, did affect autotomy; rats with lesions of C7-T1 showed a significantly greater degree of self-mutilation than did rats with section of C7-C8 alone. In fact, all rats with lesions including T1 showed more severe autotomy than did animals with lesions of C7-C8. In addition, rats with lesions including T1 showed deficits in limb placement during ambulation that were not present in rats with lesions excluding T1.

These results are not supportive of the hypothesis that post-dorsal rhizotomy autotomy reflects a pain state (Lombard et al., Pain, 6: 163-174, 1979), unless it is assumed that the addition of T1 to a C7-C8 lesion leads to a greater increment of pain than does the addition of C6. These results do support the view that there is a relationship between functional use of a deafferented limb and relative protection from self-mutilation (Berman et al., Pain, Suppl.1, S105, 1981).

136 SPECIAL LECTURE. MPTP-INDUCED PARKINSONISM: MECHANISMS OF TOXICITY AND SELECTIVE VULNERABILITY. I.J. KOPIN, NINCDS, NIH, Bethesda, MD 20205.

Accidental exposure to 1-methyl-4-phenyl 1,2,3,6-tetrahydropyridine (MPTP), either as an impurity in an illicit narcotic or during its synthesis as a pharmaceutical intermediate, produces a parkinsonian syndrome in humans.

In experimental animals the acute pharmacological effects of MPTP differ markedly from the chronic toxic effects. In all species tested the acute effects of MPTP are consistent with evoked amine release, producing in rats a characteristic "serotonin-syndrome" and an autonomic reaction. There is a striking disparity, however, in the susceptibility of various species to the toxic effects. When administered to non-human primates, after dissipation of acute effects, there develops over a period of several days a movement disorder resembling human parkinsonism. There is selective destruction of dopaminergic neurones in the nigrostriatal pathway and biochemical changes in brain and cerebrospinal fluid consistent with loss of these neurones. Dogs are also very sensitive to the toxin, whereas mice require high doses of MPTP to produce limited and largely reversible damage to the brain catecholaminergic neurones. Rats, rabbits and guinea pigs are almost totally resistant to the toxin.

Oxidation of MPTP to its pyridium derivitive, MPP^+, appears to be mediated by monoamine oxidase (MAO). Since drugs such as deprenyl or pargyline which inhibit monoamine oxidase B (MAO-B) and block formation of MPP^+ protect animals from MPTP toxicity, MPP^+ formation is necessary for the toxic effect.

The selectivity of dopaminergic neurones as targets for MPTP appears related to formation of MPP^+ by MAO-B in astrocytes and subsequent uptake of the metabolite into dopaminergic neurones. This does not, however, explain why rodents are relatively insensitive to the toxin. The vulnerability of primates and dogs to MPTP toxicity may be related to the higher concentrations of neuromelanin in the substantia nigra of these species in contrast to its absence in rodent brain and to differences in MPTP metabolism. Neuromelanin exists as a redox polymer which can be a source of free radical generation. The resemblance of MPP^+ to paraquat, a toxin which appears to be mediated by free-radical redox cycling, and the possible role of free radicals in mediating the effects of other toxins such as 6-hydroxy-dopamine, suggest that free radical formation may be involved in MPP^+ toxicity mechanisms. Thus metabolic conversion to MPP^+, accumulation of MPP^+ in specific neurones by the dopamine uptake mechanisms, and involvement of granular neuromelanin in redox cycling of MPP^+-$MPP^{\cdot}$ to yield toxic free radicals may explain the tissue and species specificity of MPTP neurotoxicity.

In addition to providing a useful animal model of Parkinson's Disease, the selective vulnerability of the nigrostriatal neurones of primates and dogs to the toxic effects of MPTP may provide useful insights into the mechanisms involved in the degenerative processes which cause Parkinson's Disease and serve to test therapeutic agents which may retard the degenerative process or replace the missing neurotransmitter systems.

137 SYMPOSIUM. PHYSIOLOGICAL AND BIOCHEMICAL BASIS OF FATIGUE IN THE MOTOR UNITS OF MAMMALS. E. Henneman, Harvard Medical School (Chair); M.J. Kushmerick*, Brigham and Womens Hospital; H.P. Clamann, Medical College of Virginia; D. Kernell*, University of Amsterdam; C.J. DeLuca, Boston University; B. Bigland-Ritchie, J.B. Pierce Foundation.

Fatigue is defined as the inability to produce or sustain an expected level of force. Changes in electrical, mechanical or chemical events precede and accompany fatigue. Any of these could be a cause. The site(s) of fatigue are not the same for all muscles but depend on the structure and function of the muscle and on the pattern of contraction it is called on to produce. M. Kushmerick will discuss intracellular chemical changes in muscle which may cause fatigue. During active force development chemical activity in a muscle produces changes in high-energy phosphate levels and intracellular pH which may be large and quantitatively different for different fiber types. ^{31}P-NMR is a powerful tool which may be used to explore these changes while muscle force is monitored simultaneously. In this way effects of chemical changes on force output may be determined. P. Clamann will examine EMG and force changes of single motor units in response to various stimulus patterns. With all stimulus patterns tested, force of fast fatiguing motor units declines more quickly than EMG. Fatigue resistant motor units fatigue only during high frequency stimulation, and failure seems to be electrical. Rest periods of < 1 s allow recovery from electrical fatigue. When frequency is changed during a stimulus train, force output depends on stimulus history so that there is no unique relation between frequency and force. D. Kernell will discuss central and peripheral aspects of motor unit function during fatigue. Motoneuron discharge rate declines even with constant excitation, resulting in a central fatigue which is most prominent in fast fatiguing motor units. In the periphery, EMG changes precede and accompany mechanical fatigue. The mechanisms have been investigated in vitro. The susceptibility of motor units to EMG and force fatigue is profoundly influenced by chronic stimulation, showing an adaptation to long-term activity. C. DeLuca will interpret changes in the EMG signal recorded during fatigue. The power spectrum of the EMG shifts preceding and during fatigue. This change may be used to predict force loss in a muscle, and may serve as a tool to study the metabolic and electrical events which cause it. B. Bigland-Ritchie will discuss differences in the mechanisms underlying fatigue in human limb and respiratory muscles. In limb muscles, the force of a maximum voluntary contraction (MVC) cannot be increased by stimulating the muscle, showing that fatigue is peripheral. By contrast, the force produced by stimulating the diaphragm declines more slowly than the force of MVC, showing that this fatigue has a central component.

138 SYMPOSIUM. MOLECULAR BASES OF THE IMMUNE RESPONSE TO NEURAL ANTIGENS. L.A. Lampson, Univ. of Pennsylvania Sch. of Med. (Chair); S.I. Rapoport, National Inst. on Aging, NIH; R.T. Johnson, Johns Hopkins Univ. Sch. of Med.; A.A. Zalewski, NINCDS, NIH; R.P. Lisak, Univ. of Pennsylvania Sch. of Med.

The nervous system has long been considered immunologically privileged. Recent work demands a re-evaluation of the extent and nature of this privilege. We will examine factors that permit, or prevent, an immune response to neural antigens. Our goal is to provide a conceptual framework for understanding recent studies of the immune response to infected, damaged, transformed, or transplanted neural tissue, and how that response can be manipulated clinically.

Immune privilege can be understood, first, in terms of a physical barrier. Rapoport will define the physical blood-brain barrier. He will discuss the extent to which it sequesters neural tissue from antigens, and from immunocompetent cells and antibodies. He will illustrate pathological conditions under which the barrier is breached, and discuss how the barrier may be circumvented for therapeutic reasons.

Immune privilege also has a molecular component. Immunocompetent cells must recognize antigen in association with products of the major histocompatibility complex (MHC). Lampson will describe the normal paucity of MHC products in neural tissue. She will discuss circumstances under which greater expression occurs, or can be induced. Illustrations will focus on the immune response to neural tumors.

Viral infections display unusual features in the nervous system. Johnson will discuss the extent to which the latency or progression of viral infections, and the observed pathology, can be understood in terms of the immune response, or its failure.

Transplantation of functional neural tissue holds great clinical promise. In part, its full potential will depend on the extent to which transplants can be made between different individuals or species. Zalewski will discuss factors that influence the survival of neural allografts and xenografts.

Lisak will draw attention to the heterogeneity of immune effector mechanisms. He will review the requirements for stimulating cell-mediated and antibody-mediated responses, and discuss the consequences of the two types of attack against antigens in neural tissue. Examples will emphasize the role of the immune response in demyelinating diseases.

139.1 PET QUANTIFICATION OF DOPAMINE RECEPTORS WITH COMPETITIVE NEUROLEPTIC DRUGS IN THE LIVING HUMAN BRAIN. D.F. Wong*, H.N. Wagner, Jr.*, A. Gjedde*, J. Coyle, R.F. Dannals*, S. Snyder, J. Links*, M.J. Kuhar (SPON: W. Jankel). Dept. Rad. (Nucl. Med.), Neuroscience, Johns Hopkins U., PANUM Inst., Copenhagen, DK., Addiction Res. Ctr., Balto., MD 21205

We have previously shown that C-11 3-N-methylspiperone (NMSP) binds specifically to the human D2 dopamine and, to a lesser extent, to S2 serotonin receptors (Science 222:1264, 1983). After the injection of C-11 NMSP, the caudate/cerebellar ratio (CA/CB), an estimate of D2 receptors, increases linearly with time in both normal and patient subjects (Science 226:1393, 1984). A 3-compartment model was proposed where the binding rate to the receptor, k3, was related to the slope of the CA/CB vs. time.

Two important applications of this PET imaging is comparing potencies of neuroleptics in vivo and in absolute quantification of receptors. We have measured the in vivo competition of neuroleptics with NMSP and compared the relative blockade of dopamine receptors in vivo by the neuroleptics haloperidol (Hal) and molindone (Mol) in normal volunteers, using this approach. Hal (0.05 mg/kg) resulted in a 68% drop in the slope of the CA/CB vs. time. When Mol was given in the clinically equivalent doses that were 4 times that of Hal, in the same people (N=3), a similar degree of blockade was measured, despite the fact that Mol has a 30 times lower in vitro binding affinity at the D2 receptor. A graded response was demonstrated for both Hal (range 0.05-0.082 mg/kg) and Mol (0.16-0.44 mg/kg) (N=3).

We used the blocking studies with Hal to quantify the density of dopamine receptors in normal human volunteers. The most recent model employed the estimate of k1, k2 and k3 from the curve fit of the caudate and cerebellar distribution volumes (tissue/plasma activity conc.) vs. effective time (integral of the plasma activity conc./plasma activity conc., designated PI/P). A correction for metabolites was employed using the cerebellar distribution volume vs. PI/P which agreed well with HPLC metabolite measurements.

We obtained different values of k3, that is, the rate of binding of the ligand to the receptor, with different blocking doses of Hal, and we estimated values for receptor density times koff and the inhibition constant K_i for Hal. Assumption of values of koff and of partition coefficients for Hal allowed an estimate of receptor density B_{max} (5-10 pm/gm) and Ki (1-2 nM) (N=4) which agreed well with values obtained in in vitro binding assays in human brains obtained at autopsy. Hence, it is now possible to compare directly the in vivo blockade of receptors by neuroleptic drugs and to use the blockade to quantify absolute receptor values. (Supported by NS 15080)

139.2 HUMAN BRAIN D-1 DOPAMINE RECEPTORS LABELLED WITH ^{3}H-SCH 23390. J.L.Waddington and K.M.O'Boyle*. Dept. Clin. Pharmacol., Royal College of Surgeons in Ireland, Dublin 2.

SCH 23390 is a potent and selective dopamine D-1 receptor antagonist. Recently, the binding of ^{3}H-SCH 23390 to rat striatal membranes has been described and may be superior to ^{3}H-piflutixol as a selective D-1 receptor ligand. We have investigated ^{3}H-SCH 23390 binding in human putamen.

A crude membrane preparation was prepared from human post-mortem putamen tissue. Radioligand binding assays were carried out essentially as described previously for ^{3}H-piflutixol. Specific binding was defined as that displaced by 100 nM piflutixol. The results of saturation studies were consistent with binding to a single population of sites with a B_{max} of 14.2 pmol/g wet weight and a K_d of 1.3 nM (mean of 3 estimations on the same tissue pool). The number of D-2 receptors was measured twice on this same tissue pool using ^{3}H-spiperone and amounted to 8.1 pmol/gm wet weight. Relative potencies of dopamine and reference dopaminergic antagonists to displace the binding of 0.8 nM ^{3}H-SCH 23390 are shown in the Table. Non-dopaminergic antagonists such as prazosin (α_1) and ketanserin (5-HT_2) had IC_{50} values >25μM.

Displacing Agent	IC_{50} (nM)
SCH 23390	2.1
R-SK&F 83566	4.2
S-SK&F 83566	>1,000
Fluphenazine	106
Domperidone	4,910
Sulpiride	>100,000
Dopamine	2,216

means of 2-5 estimations

In this study, ^{3}H-SCH 23390 showed a typical D-1 receptor profile, being displaced potently by SCH 23390 and stereospecifically by the R- but not the S- enantiomer of the selective antagonist SK&F 83566. The non-selective agents fluphenazine and dopamine itself were also active. Among the selective D-2 antagonists domperidone was 2000-fold less active than SCH 23390 and sulpiride was inactive. The ratio of D-1:D-2 sites was approximately 2:1. The binding dissociation constant and drug displacement potencies are similar to those reported in rat striatum, consistent with selective labelling of D-1 receptors in human brain.

We thank Schering for ^{3}H-SCH 23390, Smith Kline & French for enantiomers of SK&F 83566, and Dr. J.Dinn for human brain tissue. This work was supported by the Medical Research Council of Ireland and the Royal College of Surgeons in Ireland.

139.3 QUANTITATIVE AUTORADIOGRAPHIC EVALUATION OF [^{3}H]-SCH 23390 AS A DOPAMINE D-1 RECEPTOR ANTAGONIST IN RAT AND HUMAN BRAIN. T.M. Dawson, D.R. Gehlert*, S.S. Stensaas, H.I. Yamamura, A. Barnett and J.K. Wamsley. Depts. Psych., Pharm. and Path., Univ. Utah Sch. Med., SLC, UT 84132, Dept. Pharm., Univ. Arizona, Tucson, AZ 85724, Schering, Bloomfield, NJ 07003

Agonist-stimulated adenylate cyclase indicates the existence of dopamine (DA) D-1 receptors in the prefrontal cortex of rats. Localization of D-1 receptors by binding techniques would be the next logical step in further characterization of DA receptors in the central nervous system.

Classic saturation and competition experiments were combined with quantitative autoradiography to determine the suitability of [^{3}H]-SCH 23390 as a D-1 receptor antagonist in several discrete microscopic regions of brain. Ten micron, slide-mounted, serial tissue sections from rat brain or human postmortem cortex were incubated with 1 nM [^{3}H]-SCH 23390 with varying concentrations of cold SCH 23390, fluphenazine, SKF 38393, cis-(Z)-piflutixol, trans-(E)-piflutixol, sulpiride, methysergide and ketanserin. Saturation isotherms were generated by incubating the slide-mounted tissue sections in varying concentrations of [^{3}H]-SCH 23390. Autoradiograms were produced by apposition of the labeled tissue sections along with tritium standards to LKB Ultrofilm. Data was analyzed using computerized microdensitometry.

Binding of [^{3}H]-SCH 23390 to several discrete microscopic regions of rat brain (substantia nigra reticulata, accumbens nucleus, caudate-putamen, olfactory tubercle, prefrontal cortex) and human brain (striatum, superior frontal gyrus, hippocampus, substantia nigra) was saturabe, of high affinity and stereospecific. Displacement data indicate that [^{3}H]-SCH 23390 binding to human and rat brain structures, under the conditions employed for autoradiography, is selective for the D-1 receptor.

The anatomic distribution and density of D-1 receptors was then determined. The highest concentrations of D-1 receptors were noted in the substantia nigra and striatum of both human and rat brain. D-1 receptors were hetereogenously distributed in the amygdaloid and hippocampal structures. Low to very low concentrations of D-1 receptors were identified in the cortices of both human and rat brain with the deeper laminae containing approximately a two-fold greater concentration than the superficial laminae.

The localization of D-1 receptors in the frontal cortex provides strong evidence for a role of these receptors in the mediation of behavior and thought. This suggests the possibility of new therapeutic modalities, free from the adverse side-effects associated with most neuroleptics, in the treatment of schizophrenia.

139.4 COMPARISON OF THE DISTRIBUTION OF D-1 AND D-2 DOPAMINE RECEPTOR SUBTYPES IN THE RAT CNS BY QUANTITATIVE AUTORADIOGRAPHY. J.K. Wamsley, T.M. Dawson and D.R. Gehlert*. Depts. Psychiatry and Pharmacology, Univ. Utah Sch. of Med., Salt Lake City, UT 84132.

Two subtypes of dopamine receptors have been reported to exist in the CNS. The stimulation of adenylate cyclase is believed to be mediated by agonist interaction with the D-1 receptor subtype while the D-2 receptor appears to be negatively linked or not coupled to this enzyme. These subtypes can be identified in ligand binding studies on the basis of distinct pharmalogical properties. Recently, a radiolabeled form of the highly selective D-1 antagonist SCH 23390 has been reported to bind with high affinity and specificity to slide-mounted sections of rat brain (Dawson et al., Eur. J. Pharmacol., 108:323, 1985; this meeting). In order to compare the distribution of D-1 and D-2 receptors in the rat brain, we have labeled serial sections with either [^{3}H]-SCH 23390 or the selective D-2 antagonist [^{3}H]-sulpiride for the detection of receptors by quantitative autoradiography. We have also localized the high and low affinity conformations of these receptor subtypes and investigated their guanine nucleotide sensitivity.

The D-1 receptor was labeled with [^{3}H]-SCH 23390 (1 nM) while the D-2 receptor was labeled with [^{3}H]-sulpiride (20 nM) (Gehlert et al., Eur. J. Pharmacol., 98:311, 1984; Neurochem. Int., in press). Additional sets of sections were incubated with various concentrations of SKF 38393 (D-1) or ADTN (D-2) in the absence or presence of 10 micromolar Gpp(NH)p. Autoradiograms were produced by apposition to tritium-sensitive film in x-ray cassettes for appropriate exposure periods. Autoradiograms were quantitated using computerized densitometry with radioactive standards.

A highly discrete distribution was observed for each receptor subtype. Structures such as the caudate-putamen, nucleus accumbens and olfactory tubercle contained a high density of both D-1 and D-2 receptors. Relatively high D-1, but low D-2 receptor binding was detected in the substantia nigra, cerebral cortex, endopiriform nucleus, claustrum and the suprachiasmatic nucleus. ^{3}H-SCH 23390 binding was very low in the pituitary and olfactory bulb areas which exhibited a high density of ^{3}H-sulpiride binding sites. Sparse, but differential labeling was noted for both ligands in areas of the hypothalamus, thalamus, brainstem and cerebellum. A distinct regional distribution for the guanine nucleotide-sensitive high affinity agonist conformation of each receptor subtype was also noted. These results not only provide additional evidence for the existence of D-1 and D-2 receptor subtypes; but indicate distinct brain regions, for further study of the functional role that these subtypes may play in neurotransmission.

139.5 CHRONIC BLOCKADE OF D1 DOPAMINE RECEPTORS INCREASES ^{3}H-SCH 23390 BINDING SITES IN THE RAT STRIATUM. M.L. Porceddu*, E. Ongini and G. Biggio, Institute of Biology, Chair of Pharmacology, University of Cagliari, Italy.

Chronic administration of SCH 23390 (0.03 mg/kg s.c., three times daily), a selective D1 receptor blocker, increased markedly the ^{3}H-SCH 23390 binding in the rat striatum. As revealed by the Scatchard plot analysis of saturation data from striatal homogenates, SCH 23390 increased the total number of binding sites by 40% when compared to tissue from solvent-treated rats, but failed to change the apparent affinity of ^{3}H-SCH 23390 for its binding sites. Moreover, chronic treatment with haloperidol (0.5 mg/kg s.c., three times daily), a dopamine receptor antagonist with mixed selectivity for D1 and D2 receptor sites, produced a slight but significant increase of D1 dopamine receptor subtypes. In fact, this treatment increased the Bmax of ^{3}H-SCH 23390 binding sites by 15% and failed to change the apparent affinity of ^{3}H-SCH 23390 for D1 receptor sites. In contrast with the effect of these drugs, chronic administration of (-)sulpiride, a selective blocker of D2 receptor site, failed to change ^{3}H-SCH 23390 binding. The Scatchard plot analysis of saturation data carried out on (-)sulpiride treated and solvent-treated rats, revealed that this treatment failed to change the number as well as the apparent affinity of ^{3}H-SCH 23390 binding sites in striatal membrane preparation. The results indicate that a) chronic blockade of D1 receptor sites by a selective antagonist (SCH 23390) can lead to an increase in their total number; b) ^{3}H-SCH 23390 is a selective ligand for D1 dopamine receptor subtype.

139.6 DIFFERENTIAL RECOVERY RATES OF D-1 AND D-2 DOPAMINE RECEPTORS IN RAT STRIATUM AS A FUNCTION OF AGING AND CHRONIC DRUG TREATMENTS. Andrew B. Norman*, George Battaglia and Ian Creese. Dept. of Neuroscience, M-008, U.C.S.D. School of Medicine, La Jolla, CA 92093.

Changes in the Bmax of a number of neurotransmitter receptors have been reported following chronic pharmacologic blockade or as a function of aging. Since receptors are not stable components of cell membranes but rather are subject to constant degradation and synthesis, we investigated whether the processes regulating striatal dopamine receptor numbers might be altered in response to aging and chronic reserpine treatment. We found a reduction in the Bmax of both striatal D-1 and D-2 receptors of 21% and 26% respectively in senescent (28 months) compared to mature (4 months) Fischer 344 rats. We investigated the time-dependent recovery of D-1 and D-2 receptors by following increases in the Bmax of [^{3}H]flupentixol (in the presence of 30nM spiperone) and [^{3}H]spiperone (in the presence of 40nM ketanserin) binding after irreversible blockade of these receptors by N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (10mg/kg i.p.) In senescent rats the rate of recovery was markedly slower than in mature rats for D-1 (3.8 vs 6.7pmol/g tissue/day) and D-2 (1.4 vs 2.5pmol/g tissue/day) receptors. However, whilst the Bmax of both D-1 and D-2 receptors returned to control values 16 days following EEDQ treatment in senescent rats, the maximal recovery (up to 32 days) of both D-1 and D-2 receptors in mature rats achieved only 80% of control values. Interestingly, the Bmax in mature rats at 16 and 32 days was similar to the control Bmax observed in senescent rats. These data indicate that the turnover of the majority of D-1 and D-2 receptors may be markedly slower in senescent compared to mature rats and furthermore, that a subpopulation of D-1 and D-2 dopamine receptors may be lost as a function of aging.

21 day reserpine treatment (0.5mg/kg/day) produced a 31% increase in the Bmax of D-2 receptors in mature rats but no significant change in senescent rats. Similarly, chronic reserpine treatment produced a small (10%) but significant increase in the number of D-1 receptors in mature rats but no change in senescent rats. Although the rate of recovery of D-2 receptors was faster in reserpinized mature rats (4pmol/g tissue/day), there was no significant effect of reserpine on the rate of recovery of D-2 receptors in senescent rats. However, no significant increase in the apparent rate of recovery of D-1 receptors was observed following chronic reserpine treatment in either mature or senescent rats. These data demonstrate that recovery rates of distinct receptors can be differentially regulated by chronic drug treatments and that this regulation may differ as a function of aging.

139.7 SPIPERONE AND SCH-23390 DISCRIMINATE (^{3}H)FLUPHENAZINE LABELED D-1 AND D-2 DOPAMINE RECEPTORS IN MOUSE STRIATUM. D.G. Morgan and C.E. Finch. Andrus Gerontology Center, and Dept. of Biol. Sciences, Univ. Southern Cal., Los Angeles, 90089-0191.

D-1 and D-2 dopamine receptors in mouse striatal membranes were labeled in vitro with (^{3}H)fluphenazine. Assays were conducted in a physiological ions buffer for 30 minutes at 25°C, and filtered with a cell harvester. Nonspecific binding was reduced considerably by prewetting the GF/C filters with 0.1% polyethyleneimine, and including 0.15 M NaCl in the wash buffer. Apomorphine (100 µM) was used to estimate specific binding, and, typically, displaced less (^{3}H)fluphenazine than the more hydrophobic dopamine antagonists. Some of these dopamine antagonists also displaced (^{3}H)fluphenazine from heat-denatured membranes; apomorphine did not.

The D-1 and D-2 specific binding of (^{3}H)fluphenazine was discriminated by the selective dopamine antagonists SCH-23390 (D-1 selective) and spiperone (D-2 selective). Saturation analyses of these two sites indicated that the density of D-1 sites in mouse striatum was 1400 fmol/mg protein, and the D-2 density was 700 fmol/mg protein, irrespective of the competitor used to discriminate the D-1 and D-2 components. The affinity of (^{3}H)fluphenazine for the D-2 site was slightly greater than for the D-1 site (equilibrium dissociation constant, K_d = 0.7 and 3.2 nM, respectively).

Dopamine had a greater affinity than other neurotransmitters for both sites labeled by (^{3}H)fluphenazine. Moreover, displacement curves from a series of dopaminergic and nondopaminergic antagonists indicated that the pharmacological specificity of (^{3}H)fluphenazine binding in the striatum was dopaminergic. Only small amounts of dopamine specific (apomorphine sensitive) (^{3}H)fluphenazine binding were found in other brain regions. However, chlorpromazine displaced (^{3}H)fluphenazine binding from all brain regions, particularly in cerebellum, suggesting the existence of a nonmonoaminergic (^{3}H)fluphenazine binding site with, perhaps, a phenothiazine specificity.

Replacement of the physiological ions buffer with one containing 4 mM EDTA, increased specific (^{3}H)fluphenazine binding at a concentration of 1.5 nM, and truncated the plateau region of the spiperone (but not SCH-23390) displacement curves. Preliminary experiments suggest this increase is due to a greater affinity of dopamine antagonists for D-1 binding sites in the EDTA buffer.

139.8 DOPAMINE RECEPTORS IN HIPPOCAMPUS: IN VIVO AND IN VITRO CHARACTERIZATION, AND THEIR PHARMACOLOGICAL RELEVANCE. S. Bischoff*, A. Bruinink* and A. Vassout* (SPON: A. Matus). Res. Dept., Pharma Div., Ciba-Geigy, Basel, Switzerland.

A large body of evidence supports our hypothesis of the existence of a dopaminergic system in the hippocampus (Bischoff,S., in Isaacson and Pribram (Eds), The Hippocampus, Plenum Press, 1985). In particular, dopamine (DA) receptors have been identified using the in vivo (^{3}H)spiperone radioreceptor assay. The present study was aimed to further characterize these receptors.

In rat hippocampus, under in vivo conditions, spiperone bound specifically (80%) and stereoselectively to DA receptors. No significant binding was found either to spirodecanone acceptor sites or to serotonin or alpha-adrenergic receptors. The effects of neuroleptics in the hippocampus correlated (r: .963) well with those on spiperone binding in striatum. However, the atypical neuroleptics (eg. clozapine and benzamides) inhibited spiperone binding at lower doses in hippocampus than in striatum. They also exerted an almost complete inhibition in hippocampus whereas in striatum some of them displayed only partial effect.

Previously, DA receptors have not been identified in the hippocampus in vitro. Now, we found that in vitro, in hippocampal homogenates, (^{3}H)spiperone (25pM) bound to several high affinity sites. One of them appeared to be DA D_2 receptors as defined by the displacement of (^{3}H)spiperone binding by 1 uM l(-)sulpiride (IC_{50}: 18 nM). The density of the sites was about 70times lower than in striatum. As concluded from pH dependency, the other sites may predominently be spirodecanone sites.

To check the pharmacological relevance of these DA receptors in hippocampus, we compared the potency of neuroleptics to inhibit in vivo (^{3}H)spiperone binding in hippocampus and to antagonize apomorphine-induced climbing in mice. A close correlation was found between both parameters even with atypical neuroleptics suggesting that the hippocampal DA receptors are of the same type than those responsible for the apomorphine-induced climbing, and therefore, that their inhibition may reflect the antipsychotic efficacy of a drug.

139.9 ELECTROPHYSIOLOGICAL CHARACTERIZATION OF PUTATIVE A13 DOPAMINE NEURONS. M.K. Sanghera, Depts. of Psychiat. and Physiol., Univ. of Texas Halth Science Center, Dallas, TX. 75235.

The rat hypothalamus contains four distinct groups of dopamine (DA)-containing nuclei designated A11-A14 by Dahlstrom & Fuxe, (Acta physiol. scand., 62:1-52, 1964). Of these, perhaps the tuberoinfundibular system (A12), located in the arcuate nucleus, has been most thoroughly studied and shown to be intimately involved in the regulation of prolactin from the adenohypphysis. The A11 group, located in the caudal hypothalamus, has been demonstrated to project caudally to the spinal cord region. On the other hand, comparatively little is known about the A13 and A14 DA neurons.

The purpose of the present study was to determine whether the A13 neurons have similar electrophysiological properties as the midbrain DA neurons. Anatomically, DA neurons were labelled with antibodies raised to tyrosine-hydroxylase (TH) using the immunoperoxidase staining method. These neurons are located medial to the zona incerta at the infundibular level of the hypothalamus. Electrophysiologically, extracellular single cell recordings were made from cells in the A13 in the chloral hydrate anesthetized male rat. The center barrel of a 5-barrel micropipette was used for recording neuronal activity and to mark the recording site at the end of the experiment with Fast Green dye. One barrel was filled with 3M NaCl and was used as the current balance and the other barrels were filled with DA hydrochloride (0.1M), sodium glutamate (GLU, 0.05M), and GABA (0.01M). The cells in the A13 were found to have action potentials greater than 2 msec in duration, similar to midbrain DA neurons. Firing rates ranged from silent to 2 impulses/sec. The silent cells could be made to fire by the iontophoretic application of GLU. Application of DA onto these cells inhibited the GLU-induced activation of these cells. This inhibition was selectively attenuated by the intravenous administration of haloperidol (0.1 mg/kg) while GABA continued to inhibit the firing rates of the cells. Histological verification of the recording sites indicated that these putative DA-containing cells were located within the A13-TH rich region of the hypothalamus. These data indicate that A13 DA neurons have action potential and autoreceptor characteristics similar to midbrain DA neurons. However, these A13 neurons are normally silent in the chloral hydrate anesthetized preparation. Research supported by grants MH-30546 and MH-39699.

139.10 BEHAVIORAL EVIDENCE FOR A D_2-LIKE DOPAMINE RECEPTOR IN THE CNS OF RHESUS MONKEYS. W.L. WOOLVERTON AND J.B. KAMIEN.* DRUG ABUSE RESEARCH CENTER, UNIVERSITY OF CHICAGO, CHICAGO, IL 60637.

Rhesus monkeys (N=4) were trained in a two-lever, food-reinforced drug discrimination paradigm to discriminate apomorphine (APO; 0.12 or 0.25 umol/kg, IV, 5 minutes presession) from saline. When the discrimination was acquired, various doses of APO, as well as other dopamine (DA) agonists, were injected before test sessions. In addition, DA antagonists were tested in combination with several doses of APO. APO (0.06-1.0 umol/kg, IV, 5 minutes presession) produced a dose-related increase in the percent of responses that occurred on the drug lever during test sessions. In substitution tests, the selective D_2 agonist piribedil (0.12-4.0 umol/kg, IV, 5 minutes presession) produced a dose-related increase in drug lever responding that was comparable to that seen with APO, while the selective D_1 agonist SKF38393 (0.12-64 umol/kg, IV, 5 minutes presession) resulted in principally saline lever responding, even at doses which substantially reduced response rate. Administration of DA (1.0-2.0 umol/kg, IV, 5 minutes presession), which does not readily cross the blood-brain barrier, also resulted in principally saline lever responding. Pimozide, (0.007-0.125 umol/kg, IV, 120 minutes presession), a selective D_2 antagonist, blocked the ability of APO to occasion drug-appropriate responding and this blockade could be overcome with a higher dose of APO. Domperidone (0.07 umol/kg, IV, 120 minutes presession), a potent D_2 antagonist, but one that does not cross the blood-brain barrier, did not block the APO discriminative stimulus. SCH23390 (0.007-0.25 umol/kg, IV, 30 minutes presession), a D_1 antagonist, reduced drug lever responding following APO in one monkey but not in another. This blockade could also be overcome with a higher dose of APO. The results from substitition tests with DA agonists and the blockade of the APO cue with pimozide suggest that the discriminative stimulus properties of APO are based on its action at a receptor that is similar to the D_2 receptor. The failure of DA to substitute for APO as well as the failure of domperidone to block the APO discriminative stimulus indicate that this receptor is located in the central nervous system (CNS). The results with SCH23390 raise the possibility that D_1 and D_2 receptors are not independent in the CNS. This experiment provides in vivo evidence for the existence of a functional D_2 receptor in the CNS of rhesus monkeys. (Research supported by N.I.D.A. Grant DA-00250).

139.11 SOLUBILIZATION AND ISOLATION OF ^{3}H-SPD BINDING SITES FROM THE CAT BRAIN CORPUS STRIATUM. L. L. Hsu, K. Moroi* and J. R. Yu*. Dept. of Psychiatry and Behav. Sci., Univ. of Texas Med.Branch, Galveston, TX 77550.

We have previously characterized one population of ^{3}H-spiperone (SPD) binding sites in the crude mitochondrial membranes of the cat brain corpus striatum. The apparent K_d value for this popualtion of SPD binding sites was 1.00 nM and the appatent B_{max} value was 395 fmol/mg protein. We have solubilized these SPD binding sites and further purified them to apparent homogeneity by gel filtration and DA-affinity chromatography as previously described (Moroi & Hsu, J. Neurosci. Res. 12:113, 1984). Twenty-five adult cats were used for this study. Cats were anesthetized with Nembutal, decapitated & brains were rapidly removed. Corpus striata were carefully dissected over ice, frozen on dry-ice and stored at -60 °C until used. 25 pairs of striata were thawed, homogenized in 9 vol. of 0.32 M sucrose in 10 mM Tris-HCl, pH 7.4, containing 2 mM EDTA, 0.1 mM phenylmethylsulfonylfluoride (PMSF), and 0.2% NaN_3. The homogenate was subjected to differential centrifugation to yield P_{2M} membranes according to the method of de Robertis et al (J.B.C. 242:3487,1967). The SPD binding sites were solubilized from P_{2M} by 1% digitonin in 0.05 mM Tris-HCl,pH 7.4,containing 1 mM EDTA, 0.1 mM PMSF, and 1 mM DTT. The solubilized SPD binding sites in the digitonin extract were further purified by gel filtration, DA-affinity chromatography and disc gel electrophoresis. Results indicated that the ^{3}H-SPD binding to the digitonin extract was also saturable with an apparent K_d value of 3.43 nmol and an apparent B_{max} value of 310 fmol/mg protein. Bio-Gel A-5m gel filtration resulted in several protein peaks with fractions 30-50 having the highest ^{3}H-SPD binding. Subsequent DA-affinity chromatography of these fractions resulted in a single protein band on the native polyacrylamide gel after electrophoresis. This apparently pure SPD-binding protein from cat striatum showed specific ^{3}H-SPD binding of 15,986 fmol/mg protein, indicating a 127 fold purification over the homogenate. Furthermore, this purified SPD-binding protein also exhibited a single type of subunit as from the rat brain cortex, with an apparent molecular weight of 72 K on the SDS gel. The identity of this purified SPD-binding site as a subtype of DA receptors remains to be determined.

(This work was supported in part by a Robert A. Welch grant H-827.)

139.12 SYNTHESIS AND PHARMACOLOGICAL CHARACTERIZATION OF PIMOZIDE DERIVATIVES: A NEW CLASS OF POTENTIAL PHOTOAFFINITY LABELS FOR DOPAMINE RECEPTORS. Randall B. Murphy, Miroslav Trampota* Frank R. Arnold and David I. Schuster. Department of Chemistry, New York University, New York, NY 10003.

Pimozide (structure I, R = R' = H) is a highly active neuroleptic drug with a high affinity toward dopamine (DA) receptor sites as measured by binding in competition with radiolabeled spiperone, haloperidol and apomorphine (Seeman, P. Pharmacol. Rev. (1980) 32, 229). As part of a program to characterize dopamine receptors using the technique of photoaffinity labeling, we have synthesized some derivatives of pimozide which might serve as effective photolabels for such sites. The affinity of these compounds for D_2 sites in rat striatal homogenates has been determined in each case by a standard binding assay vs. [^{3}H]-spiperone. The phenethyl derivative of clopimozide (R = $PhCH_2CH_2$, R' = Cl) was prepared by reaction of the parent compound with phenethyl bromide and sodium hydride in dry THF for three weeks; the IC_{50} for this compound was 6.3 nM. The p-nitrobenzyl derivative of pimozide (R = p-NO_2-Ph-CH_2, R' = H) was readily prepared by treatment of pimozide with the corresponding bromide, KH and [18]-crown-6 in dry THF under nitrogen. This compound was reduced to the corresponding p-aminophenyl derivative which was converted to the p-azidophenyl analogue. The IC_{50}'s for these compounds in the binding assay were 25, 28 and 25 nM. Products of ring iodination of the amino- and azidophenyl systems are currently being purified and characterized. The relatively high dopaminergic activity of this series of compounds has prompted us to explore their utility as specific agents for photoaffinity labeling of DA receptor sites.

140.1 RATES OF FORGETTING IN H.M.: SIX-MONTH RECOGNITION.
David M. Freed* and Suzanne Corkin (SPON: Richard Held).
Dept. Psychology, MIT, Cambridge, MA 02139

Using a picture-recognition paradigm that provided amnesic subjects with additional study time in order to make their initial yes/no recognition comparable to that of control subjects, Huppert and Piercy (1979) examined rate of forgetting in two etiologies of amnesia. These authors concluded that H.M., with bilateral medial temporal-lobe pathology, demonstrated abnormally rapid forgetting over the course of a week, whereas patients with diencephalic pathology due to Korsakoff's Syndrome did not. Freed, et al. (1984) reported that H.M. did not display rapid forgetting over the course of a week in either yes/no or forced-choice recognition when the mean of 4 experiments was examined. This study emphasized the variability of H.M.'s performance and how this factor could account for Huppert and Piercy's results. It was noted that there were differences in memory performance as assessed by yes/no and forced-choice recognition techniques at the 24-hour retention interval. In the present study H.M.'s recognition memory was tested 6 months after initial recognition testing that employed a week delay. H.M.'s 6-month recognition was evaluated on each of 3 different forms of the rate of forgetting test over the course of a year. He performed at chance levels when tested using a yes/no recognition technique, but his delayed-match-to-sample (DMS) and delayed-non-match-to-sample (DNMS) performance were comparable to that of control subjects 6 months after initial testing. In addition, H.M.'s recall of photographs is impoverished at a time when his forced-choice recognition memory is comparable to that of control subjects. These results indicate that there are important differences in the memory performance of amnesic subjects as assessed by different recognition techniques. Despite being severely amnesic, with appropriate techniques H.M. can demonstrate intact recognition memory over extended periods of time.
Supported by grants MH 24433, MH 32724, 2 T 32 GMO 7478, and RR 00088.

140.2 RECOGNITION OF SPATIAL LOCATION IN THE AMNESIC PATIENT H.M.
E.V. Sullivan, J.D.E. Gabrieli*, H.J. Sagar*, and S. Corkin.
Department of Psychology, MIT, Cambridge, MA 02139.

Spatial location, recency, and frequency are often encoded equally well under incidental and intentional conditions; in contrast, memory for specific items can be improved by instruction to remember (e.g., Mandler, Seegmiller, & Day, 1977; Hasher & Zacks, 1979). Despite the encoding commonality among temporospatial contextual attributes, the ability to recall the location of an item and the item itself appear to be subserved by medial temporal-lobe structures (Smith & Milner, 1981), whereas memory for when and how often an event occurred is subserved by frontal-lobe structures (Corsi, 1972; Milner, 1977; Smith & Milner, 1983). Smith and Milner, studying recall of location in an incidental learning situation, found that the globally amnesic patient H.M. was severely impaired in the immediate and delayed recall of spatial location, although immediately after presentation (but not 24 hours later) he did show appreciation of the random spatial array of items. The present experiment used an intentional learning paradigm and a forced-choice recognition procedure in order to measure the course and nature of forgetting of spatial location in H.M. and in age-matched control subjects. Each of 352 words was presented in 1 of 20 locations for 2 seconds on a computer screen. At various times throughout the test, subjects had to decide which of 2 words had been seen or in which of 20 locations a word had appeared. Content and location questions occurred 1, 3, 6, 10, 15, 25, 50, 100, and 150 items following the initial presentation of the stimulus; thus, the rate of forgetting for content and for location could be computed separately and compared directly. Distances between inaccurate location responses and the correct locations were also calculated. H.M.'s recognition of content fell to chance by the stimulus-test interval of 15; his recognition of exact location was at chance by the interval of 6. When scoring for location reflected the distance of errors from target locations, his performance was better than chance at intervals where his recognition of items was at chance. H.M. apparently maintained an estimate of target locations over most of the intervals tested. In contrast to Smith and Milner's finding of grossly impaired incidental recall of spatial location in H.M., our study, which used intentional recognition testing, found relative preservation of information about spatial location. The forced-choice recognition format may provide contextual cues that can be taken advantage of by amnesic patients, and that are not available in free recall. We conclude that recognition of spatial location, like that of recency and frequency, is relatively spared in global amnesia resulting from temporal-lobe pathology.

140.3 CONSTRAINTS UPON THE ACQUISITION OF COGNITIVE SKILLS IN AMNESIA: STUDIES WITH PATIENT H.M. AND PATIENTS WITH ALZHEIMER'S DISEASE.
John D.E. Gabrieli,* Ira Haimowitz,* and Suzanne Corkin.
Department of Psychology, MIT, Cambridge, MA 02139.

The progression of experiments searching for preserved learning in amnesia has revealed, successively, the lasting acquisition of motor, perceptual, and cognitive (or problem-solving) skills in the face of impaired fact learning. In one such study, patients with global amnesia showed improvement in the application of a mathematical rule 24 hours and 17 weeks after initial exposure to problems (variants of the Fibonacci series) that had to be solved by the discovery and use of that rule (Wood et al., 1982). The present studies investigated the range and limits of the acquisition of cognitive skills in the patient H.M., whose severe and pervasive amnesia is the consequence of a bilateral resection of medial temporal-lobe structures, and in patients with memory disorders due to Alzheimer's disease. H.M. had previously learned the solution to another cognitive task, the Tower-of-Hanoi puzzle (Cohen & Corkin, 1981); there are no reports of such cognitive skill learning in the latter group.

H.M. demonstrated considerable improvement in the application of the Fibonacci rule 24 hours, though not 1 hour, after initial exposure to 15 problem-sets. However, H.M. showed similar improvement 24 hours after testing when asked to supply the three correct numbers that completed an arbitrary five-number string presented 15 times. This result indicates that his 24-hour improvement on the Fibonacci problems was due to a combination of minimal declarative learning and task constraints, and does not reflect normal procedural learning of any rule. In a second experiment, H.M. and two patients with Alzheimer's disease took part in a problem-solving task derived from Barry and Broadbent (1984). Control subjects (N = 40) showed considerable improvement on this task despite poor conscious awareness of the nature of the solution as indicated by questionnaire responses. The two patients with Alzheimer's disease also demonstrated acquisition of the cognitive skill and retained the skill for at least 24 hours. In contrast, H.M. failed to show any learning within sessions or across days. These results suggest that only certain cognitive skills, perhaps under certain testing conditions, may be acquired and retained normally in the face of amnesia, and that different kinds of cognitive skills may be mastered by patients whose amnesias differ both in etiology and in severity.

140.4 THE SUBICULAR CORTICES IN ALZHEIMER'S DISEASE: NEUROANATOMICAL RELATIONSHIPS AND THE MEMORY IMPAIRMENT, B.T. Hyman, G.W. Van Hoesen, L.J. Kromer and A.R. Damasio. Departments of Neurology and Anatomy, University of Iowa, Iowa City, IA 52242.

The subicular cortices constitute a grey matter passageway interposed between the hippocampus and the temporal cortex. Anatomical studies in the primate have shown that the subicular cortices give rise to the final common pathway for hippocampal efferents to the cerebral cortex. The subicular cortices also have powerful connections with the thalamus, basal forebrain and amygdala. The subiculum proper is one of the principal areas of pathological involvement in Alzheimer's disease, but the full extent of subicular pathology and the degree of involvement of the parasubiculum and presubiculum has not been addressed. For these reasons we examined the entire antero-posterior extent of all subicular cortices in 10 cases of Alzheimer's disease and in 8 age-compatible controls using Nissl, Congo red, thioflavin S and silver staining methods. We observed that the pathologic changes of Alzheimer's disease occur specifically in only certain subdivisions of the subicular cortices, leaving adjacent divisions spared. The Alzheimer brains showed neurofibrillary tangles in the subicular-CA1 zone, including the transitional area of the prosubiculum, while the dentate gyrus, and CA2, CA3 and CA4 hippocampal subfields were largely spared. In all cases the subicular-CA1 zone was more heavily involved than the more medial aspect of the subiculum proper, or the adjacent presubiculum. In contrast, the parasubiculum contained many neurofibrillary tangles. At the level of the uncal and genual parts of the hippocampal formation, many cells contained prominent tangle involvement. Caudally, at the level of the lateral geniculate nucleus, the entire subiculum proper was heavily involved, and remained so throughout the posterior extent of the structure. Neuritic plaques appeared throughout the subiculum. They formed a prominent line in the deepest part of the molecular layer of the subiculum, a zone that in lower mammals, receives serotinergic projections from the raphe complex. Five age-matched control brains, and cases of multi-infarct dementia, pseudodementia, and Huntington's chorea, did not show subicular changes. From a neural systems viewpoint, the subicular pathology in Alzheimer's disease deprives the hippocampal formation of its major output, including the critical link to the cortex. Such changes are likely to contribute to aspects of the memory impairment in much the same way that anoxic damage to Sommer's sector or bilateral hippocampal destruction do. (Supported by NIH grants NS14944, IF32EY05720, and PO NS 19632).

140.5 ALZHEIMER'S DISEASE SPARES MOTOR LEARNING. P.J. Eslinger and A.R. Damasio. Dept. of Neurology, Univ. of Iowa, Coll. of Med., Iowa City, IA 52242.

A progressive impairment of recent memory is an early and characteristic sign of senile dementia of the Alzheimer type (SDAT). Patients with surgical ablation of the medial temporal lobes, herpes simplex encephalitis, and alcoholic Korsakoff's syndrome also have pervasive memory impairments, but their ability to learn motor and perceptual skills are not affected. Our study ascertained if SDAT patients would exhibit a similar dissociation between motor learning and learning of specific sensory-based information.

Eight patients diagnosed with probable SDAT ($\bar{X}$ age = 71) and eight healthy older persons ($\bar{X}$ = 71) were examined in 3 experiments of learning and memory, each comprising 5 consecutive learning trials and one 20-min delayed trial, assessing retention. In the first experiment, total time on target was recorded in a rotary pursuit task. In the second experiment, subjects learned a 10-item grocery list, and in the third experiment, subjects learned to recognize 8 unfamiliar faces. Analysis of time on target revealed a significant motor learning effect ($p<.001$), but no group difference. The SDAT group showed an improvement of 161%, with every patient improving. On the delay trial, neither group exhibited significant decline in performance level. In contrast, controls exhibited significant verbal learning and facial learning while the SDAT group did not. On the delayed memory trial, SDAT performance fell to almost zero for the verbal recall task (73% decline vs 11% decline for controls) and to chance level for the facial recognition task (29% decline vs 2% decline for controls).

The striking dissociation between the acquisition and retention of specific sensory-based information (i.e., declarative knowledge such as words and faces) and a motor skill (i.e., rotary pursuit performance), in SDAT patients suggests there is a selective impairment of declarative memory systems, causing an overt amnesic syndrome. But the memory systems responsible for learning and retaining a new motor skill remained untouched. Declarative memory mechanisms have been associated with the limbic system, especially the hippocampal region, while perceptual-motor learning is likely to be mediated by primary sensory cortices and motor system structures of the frontal lobe, basal ganglia, thalamus, cerebellum and related pathways, all of which operate apart from limbic system control and are relatively resistant to degenerative changes of Alzheimer's disease. These behavioral findings may be correlates of the recently reported specific hippocampal system damage in SDAT (Hyman et al. 1984). Supported by NIH Grant PO1S19632-02.

140.6 COVERT RECOGNITION OF FAMILIAR FACES BY PROSOPAGNOSICS: EVIDENCE FOR INTRAMODAL REPRESENTATION OF LEARNED STIMULI. D. Tranel and A.R. Damasio (SPON: K. Johnson). Department of Neurology (Division of Behavioral Neurology), University of Iowa College of Medicine, Iowa City, IA 52242.

Prosopagnosia is a defect of visually triggered contextual memories related to a specific face. The ability of two prosopagnosic subjects to recognize familiar faces was tested with a newly developed technique, using the electrodermal skin conductance response (SCR). It has been shown previously that the SCR is sensitive to stimuli that have special significance, or "signal value," for the perceiver. Furthermore, we have established that, in normal subjects, highly familiar faces have "signal value," and tend to elicit more frequent and larger amplitude SCRs than unfamiliar faces. Against this background, we hypothesized that prosopagnosics, despite their complete inability to recognize familiar faces, might nonetheless produce discriminatory covert responses to these faces via an autonomic route which might be indexed with the SCR.

We studied two prosopagnosic subjects with stable bilateral lesions to the occipito-temporal region. They were shown several series of faces while skin conductance responses to these faces were recorded and measured. Each series comprised several familiar faces (of family members and other persons well-known to the patient) randomly embedded amongst unfamiliar faces (belonging to persons definitely not known to the patient). We found that both patients generated more consistent and significantly larger amplitude SCRs to the familiar faces than to the unfamiliar ones.

The accurate electrodermal discrimination of familiar faces shown by our subjects indicates that an early step of the physiological process of recognition is still taking place, in spite of the inability to allow the process to unfold to a conscious level. The results of this early step are not made available to awareness, yet can be indexed via the electrodermal skin conductance response.

We believe this covert recognition depends on the availability of intramodal memories for specific faces, organized in the form of a dynamic representation system which is unconsciously accessed and "matched" by incoming percepts of previously learned stimuli.

140.7 STRENGTH AND DURATION OF PRIMING EFFECTS IN AMNESIC PATIENTS AND NORMAL SUBJECTS. A. P. Shimamura*, L. R. Squire and P. Graf*. Dept. of Psychiatry,, Univ. of CA, La Jolla, CA 92093, Vet. Admin. Med. Ctr., San Diego, CA 92161, and Dept. of Psychology, Univ. of Toronto, Canada.

In a series of experiments, we assessed priming and recognition performance in amnesic patients, alcoholic subjects, and healthy normal subjects. Priming was assessed by showing word fragments of previously presented words (e.g. DEF for DEFEND) and asking subjects to complete each fragment with the first word that came to mind (word completion test). Tests of word completion and recognition memory were given after an immediate, 2-hour, and 4-day delay. In Experiment 1, word completion was assessed with cues that could be completed to form several common words (e.g., MOT for MOTHER, MOTEL, MOTOR) one of which had been presented previously. Priming effects were equivalent in amnesic patients and control subjects and disappeared within 2 hours. Recognition memory was impaired in amnesic patients at all test delays. In Experiments 2 and 3, the duration of word completion was tested with cues that uniquely specified the study words (e.g., JUI for JUICE; or A__A__IN for ASSASSIN). In these cases, amnesic patients exhibited a smaller word completion effect than control subjects at immediate testing, and their word completion effect disappeared within 2 hours. By contrast, control subjects exhibited completion effects that lasted at least 4 days. One exception to this pattern was that other amnesic patients, patients prescribed bilateral electroconvulsive therapy (ECT), exhibited word completion effects that persisted for at least 1 day (Experiment 3). In Experiments 2 and 3 we also varied the degree of semantic encoding during study (semantic vs nonsemantic orienting conditions). We found that the semantic condition increased the level of word completion performance of control subjects but had a negligible effect on the performance of amnesic patients. Moreover, in the nonsemantic condition control subjects and amnesic patients performed similarly. We suggest that the weaker and more transient word completion effects found in amnesic patients and in control subjects under nonsemantic conditions involve processes (i.e., priming) which do not depend on the integrity of the brain structures damaged in amnesia. The longer-lasting word completion effects by control subjects in the semantic conditions appear to reflect declarative processes that are impaired in amnesic patients.

140.8 HUMAN AMNESIA AND THE MEDIAL TEMPORAL REGION: MEMORY IMPAIRMENT FOLLOWING A BILATERAL LESION LIMITED TO THE CA1 FIELD OF THE HIPPOCAMPUS. S. Zola-Morgan, L.R. Squire and D.G. Amaral. V.A. Medical Center, San Diego, CA 92161, Dept. Psychiatry, UCSD, San Diego, CA 92093 and Salk Institute, San Diego, CA 92138.

Bilateral medial temporal lobe damage has been known for a quarter of a century to cause profound amnesia in humans. Much of the relevant information comes from surgical cases in which portions of the temporal lobes have been removed in an effort to relieve severe epilepsy. These cases have suggested that medial temporal amnesia depends at least in part on damage to the hippocampal formation.

Despite this evidence converging on the hippocampus, the status of memory functions in these cases often is based on anecdotal reports or on incomplete histological information, and there are few if any well-studied cases of amnesia where the damage is limited to the hippocampus. Recently, we have obtained extensive clinico-pathological information from a deceased 57 year old male, who developed memory impairment as a result of a hypoxic-ischemic episode that followed cardiac bypass surgery. This patient survived for five years following the episode, during which time he participated in our long-term studies of the neuropsychology of amnesia. We present here a well-documented amnesia with neuropathological evidence of bilateral damage limited to the hippocampus.

Neuropsychological Data: Following surgery patient R.B. showed no signs of dementia or significant cognitive impairment other than memory (WAIS = 111; WMS=91). Compared to control patients he was markedly impaired on tests of anterograde memory (e.g. Paired Associates: 2.2 vs 9.4 for Control Group; Delayed Story Recall: 1.0 vs 5.0 for Control Group; Delayed Diagram Recall: 5.3 vs 24.3 for Control Group. His retrograde amnesia was mild, extending back for approximately 1-2 years prior to the onset of his amnesia. Despite his memory impairment, he exhibited an intact capacity for priming.

Neuropathological Findings: Histological analysis of Nissl and fiber stained serial sections throughout the brain revealed a bilateral lesion limited to the CA1 field of the hippocampus and involving its entire anterior-posterior extent. In addition, there were two small focal unilateral lesions, one in the left somatosensory cortex and one in the right striatum. All other brain regions, in particular the mammillary bodies, the dorsomedial nucleus of the thalamus and the amygdala appeared normal.

This case shows that a circumscribed lesion limited to a subfield of the hippocampus can produce a clinically meaningful memory impairment. The possible reasons for the apparent selective vulnerability of CA1 pyramidal cells will be discussed.

140.9 RETROGRADE AMNESIA FOLLOWING COMBINED HIPPOCAMPUS-AMYGDALA LESIONS IN MONKEYS. D.P. Salmon*, S. Zola-Morgan, and L.R. Squire (Spon: D. Amaral). Dept. of Psychiatry, Univ. of California Med. Sch. (San Diego) and San Diego VA Med. Ctr.

It is well established in both humans and non-human primates that bilateral combined lesions of the hippocampus and amygdala (H-A) result in a deficit in recognition memory (i.e. declarative knowledge) while the ability to learn and retain motor skills (i.e. procedural knowledge) is preserved. Here, we present a first attempt to examine the status of premorbid memory (i.e. retrograde amnesia) following H-A lesions in monkeys by assessing the retention of information acquired at various time periods prior to surgery.

Eight cynomolgus monkeys were trained on five sets of 20 two-choice object discrimination problems. A different set was administered beginning 32, 16, 8, 4, and 2 weeks prior to surgery. Retention of each set of discrimination problems was assessed 24 hrs after acquisition by presenting a single trial with each of the 20 stimulus pairs. Additionally, six weeks prior to surgery, all monkeys were trained on a motor skill task. Monkeys learned to retrieve a candy lifesaver that was threaded onto a metal wire by moving the lifesaver around a right angle bend to the end of the wire.

Surgery took place after acquisition of the fifth and final discrimination set. The monkeys were divided into an operated group (bilateral hippocampus-amygdala lesion, N 4) and a control group (N 4) such that the average 24-hr retention test scores were approximately equal for the two groups on each of the five problem sets, and their rate of acquisition of the motor skill task was comparable.

Three weeks after surgery remote memory for the object discriminations was assessed by presenting a single trial with each of the 100 stimulus pairs. The control group evidenced little forgetting for discriminations in any of the five preoperative time periods. The H-A group, in contrast, demonstrated a profound loss of memory for the discriminations from all time periods. Retention of the motor skill task was relatively well preserved in both groups.

To examine fully the status of retrograde amnesia in experimental animals, additional studies will be needed. Some of the methodological issues that need to be addressed in such studies will be discussed.

140.10 ENHANCEMENT OF TRISYNAPTIC PATHWAY IN THE HIPPOCAMPUS DURING PERFORMANCE OF SPATIAL WORKING MEMORY TASKS: A 2-DG BEHAVIORAL STUDY IN RHESUS MONKEYS. H.R. Friedman and P.S. Goldman-Rakic, Sec. Neuroanat., Yale Sch. Med., New Haven, CT. 06510.

Knowledge of the role of the hippocampal formation (HPC) in learning and memory is largely based on examination of behavioral deficits that follow surgical ablation. We used Sokoloff's ^{14}C-2DG technique to directly examine HPC metabolism in intact monkeys while they performed tasks with different mnemonic demands. We report that functional activity in subsectors of the HPC is augmented during performance of spatial working memory tasks relative to performance on a reference memory task or a task with no memory requirement.

Male rhesus monkeys were trained to criterion on 1 of 4 behavioral paradigms. Two of the tasks, spatial delayed response and spatial delayed alternation, were working memory tests which require that memory of reward placement be updated on every trial. The two control tasks were (1) a visual discrimination (VD) test which presents the same problem on every trial and therefore taps only reference memory processes, and (2) a sensorimotor task with no memory component. Monkeys were given a single intravenous dose (100uCi/kg) of ^{14}C-2DG and tested for 45 minutes. Local cerebral glucose utilization (LCGU) values for discrete brain regions on X-ray autoradiographs were obtained using a digital image processing system. Quantitative densitometry of separate laminae in the dentate gyrus (DG) and Ammons horn (CA fields) was accomplished by superimposing the X-ray autoradiograph on nissl-stained tissue sections. The LCGU values obtained were subjected to statistical analysis.

LCGU in the DG, CA1 and CA3 fields was augmented in monkeys performing working memory tasks relative to monkeys performing the VD and sensorimotor control tasks. This elevation of functional metabolism was most pronounced in the granule and molecular layers of DG and the molecular and pyramidal layers of CA1. To a lesser extent metabolism in the molecular and pyramidal cell layers of CA3 also was increased. In contrast, LCGU in the oriens layer of CA1 and CA3 was similar for all groups. It is significant that the zones of raised metabolic activity represent synaptic links in the perforant pathway - a major source of cortical afferents to the HPC. These results are the first in vivo visualization of functional activation of this trisynaptic pathway during performance of spatial mnemonic tasks in the monkey and provide evidence of a special role for this pathway in spatial working memory.

Supported by USPHS grants.

140.11 EFFECTS OF MAMMILLARY BODY VS. DORSOMEDIAL THALAMIC LESIONS ON SPATIAL MEMORY IN MONKEYS. E.J. Holmes and C.E. Tenke*. Depts. of Psychiatry and Neuroscience, Kennedy Center, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Neuropathological reports of the consistent and prominent degeneration of the dorsomedial nuclei of the thalamus (DMT) and the mammillary bodies (MB) of the hypothalamus in alcoholic Korsakoff patients has led to the belief that these nuclei may be of critical significance in the mediation of short-term memory. Earlier findings have shown that lesions of the mammillary nuclei in monkeys do indeed affect the short-term retention of spatial location in a 30-sec. delayed alternation task (Holmes et al., Neurosci. Abstr., 8:23, 1982). As an extension of these findings, monkeys with MB lesions were directly compared to monkeys with DMT lesions on another task of short-term memory, i.e., delayed response.

The subjects were 17 M. fascicularis monkeys. Four monkeys received bilateral MB lesions, 4 monkeys received bilateral DMT lesions, 6 monkeys served as operated controls for the MB and DMT groups, and 3 monkeys remained unoperated. Training and testing was conducted in a Wisconsin General Test Apparatus. During pre-operative training, the subjects were allowed to watch the experimenter bait one of two foodwells in a test tray and subsequently cover both foodwells with identical Plexiglas plaques. Initially, the subjects were allowed to displace one of the plaques and retrieve the reward immediately after the foodwells were covered until they performed at a criterion of 27 correct responses in 30 consecutive trials. After attaining criterion with the 0 sec. delay, progressive response delays of 1 sec., 2 secs., etc., up to 5 secs. were inserted while obscuring the subject's view from the test tray. The subjects were required to attain the criterion of 27/30 correct at a particular delay before proceeding to the next delay. After surgery, the animals were retrained on the 5 sec. delay problem until they reattained the pre-operative criterion. Following retraining, successive delays of 10, 20, and 30 secs. were systematically inserted to determine the effect of timed intervals on retention.

The results show that all of the control animals were at 90% performance at all delays during testing. The results also show that although the monkeys in the MB and DMT groups were at 90% performance in the retention of the 5 sec. delay task, the subjects in both groups were impaired in varying degrees on the 10, 20, and 30 sec. intervals with some of the animals performing consistently at or near chance even before the 30 sec. delay. The severity of the impairment for both the MB and DMT groups seemed to coincide well with the extent of the neuronal damage. Thus, it appears that both the mammillary and dorsomedial nuclei share responsibility for the retention and retrieval of spatial information. It remains to be determined, however, if the quality or character of the information to be retained is the same since the efferents and afferents of these two nuclei are quite different.

140.12 THE EFFECT OF SELECTIVE LESIONS TO THE PERIARCUATE CORTEX ON THE PERFORMANCE OF TWO NONSPATIAL CONDITIONAL TASKS. M. Petrides. Dept. of Psychology and the Montreal Neurological Institute, McGill Univ., Montreal, Quebec, Canada, H3A 1B1

It has been demonstrated that damage to the periarcuate region (areas 8 and 6) of the dorsolateral frontal cortex in the monkey is critically involved in the performance of conditional associative tasks. In these tasks, the animal has to learn and perform according to the conditional rule: if stimulus A is presented, select response X, and if stimulus B is presented, select response Y (see Petrides, Behav. Brain Res., 5: 407, 1982).

It must, however, be emphasized that although the periarcuate cortex can be distinguished from other frontal cortical regions on the basis of certain anatomical characteristics, such as direct input from first-order, modality-specific "association" cortical areas, there are also differences in the connections of various parts of this region. These anatomical results suggest that different parts of the periarcuate cortex may be predominantly involved in the control of different kinds of conditional tasks.

In the present experiments, performance on two nonspatial conditional tasks after lesions restricted to the anterior (area 8) or posterior (area 6) arcuate cortex was investigated. The two tasks differed only in the responses that were required, the type of stimuli used and their mode of presentation being the same. In one experiment, the monkey was faced with two white perspex boxes placed close to each other. On any given trial one of the boxes, chosen according to a random but balanced sequence, was lit and the other remained unlit. The monkey was trained to select the lit box when object A was shown and the unlit box in the presence of object B. After mastery of this task, monkeys (Macaca nemestrina) received bilateral lesions of the anterior or the posterior arcuate cortex. Monkeys with damage to the anterior arcuate cortex were severely impaired in comparison with normal controls, but those with damage to area 6 were not. In contrast to this, the animals with posterior arcuate lesions (but not those with anterior lesions) were impaired in acquiring a go, no-go task with symmetrical reinforcement. In this conditional task, the subject was rewarded for responding when one stimulus was presented, and for withholding responding for a given period of time when the other stimulus was shown.

The results are consistent with the known anatomical connections of these parts of the periarcuate cortex. The anterior arcuate cortex, damage of which impaired performance on a conditional task requiring visual responses, is preferentially connected with the visual system; in contrast, the posterior arcuate cortex, damage of which impaired performance on a task involving two kinaesthetically distinct responses (go or no-go), is preferentially linked to the motor cortex and the somatosensory system.

140.13 RHINAL CORTEX: A THIRD TEMPORAL-LOBE COMPONENT OF THE LIMBIC MEMORY SYSTEM. E.A. Murray, J. Bachevalier, and M. Mishkin. Laboratory of Neuropsychology, N.I.M.H., Bethesda, MD 20205

Monkeys trained on a visual recognition task, delayed nonmatching-to-sample (DNMS) with trial-unique objects, were given a six-week long performance test in which they were required to remember, first, single objects for increasingly longer periods of time (30, 60, or 120s) and, then, increasingly longer lists of objects (3, 5, or 10). Previous experiments indicated that whereas normal monkeys learn the basic task in 100 trials and score over 95% correct responses on the performance test, monkeys with combined ablation of the amygdaloid complex and hippocampal formation, including a large portion of the ventromedially adjacent rhinal (i.e. ento-, pro-, and peri-rhinal) cortex, relearn in about 1000 trials and obtain an average performance score of about 60%. An equally severe deficit followed combined ablation of the amygdaloid complex plus rhinal cortex (relearning, 2000 trials; performance, 60%), but only a mild deficit followed ablation of the hippocampal formation plus rhinal cortex (relearning, 340 trials; performance, 84%). These findings in monkeys with one limbic structure spared appeared to support the view that the medial temporal lobe contained just two structures critical for memory, the amygdaloid complex and the hippocampal formation, and that ablating or disconnecting both was necessary and sufficient to insure a severe memory loss. According to this view, the rhinal cortex ablation was effective when combined with amygdalectomy simply because it deafferented the hippocampus from its neocortical inputs.

This view was brought into question, however, by results from monkeys in which the pathways connecting the two limbic structures with the basal forebrain/diencephalon were transected while the rhinal cortex itself was largely spared. For example, monkeys with combined transection of the amygdalofugal pathways and fornix and those with combined amygdaloid ablation plus fornical transection relearned DNMS in an average of 280 to 350 trials and obtained average performance test scores of 69 to 74%.

To test whether the rhinal cortex participates in memory processes independently of serving as a sensory gateway to the hippocampus, we prepared monkeys with combined ablations of the amygdaloid complex and hippocampal formation that spared the rhinal cortex. These animals relearned DNMS in an average of 350 trials, and preliminary results on the performance test indicate scores well above those found earlier for monkeys with combined ablation of the amygdaloid complex and hippocampal formation that included most of the rhinal cortex. The results suggest that the rhinal cortex, perhaps via its diencephalic projections, can sustain a substantial level of visual recognition memory in the absence of both the amygdaloid complex and hippocampal formation.

140.14 INFEROTEMPORAL OUTFLOW TO AMYGDALA AND FRONTAL LOBE IN DISCRIMINATION AND REINFORCEMENT IN THE MONKEY. D. Gaffan* and S. Harrison* (SPON: B. H. Turner). Dept. of Experimental Psychology, University of Oxford, Oxford OX1 3UD, England.

Bilateral amygdalectomy is known to impair monkeys' spontaneous emotional reactions to exteroceptive stimuli. Our first question was whether it impairs also their response to exteroceptive stimuli with an acquired reinforcing significance under experimental control. Monkeys learned visual simultaneous discriminations with purely auditory reinforcement during acquisition, as follows. In each daily session 30 new discrimination problems were presented serially. A correct visual choice produced white noise and an incorrect choice produced clicks. A food reward was delivered only if there were 4 correct choices in succession. If there were 4 wrong choices in succession there was 10 sec of darkness. After either of these events the current problem was terminated and the next began. Thus non-auditory reinforcement was delivered only after solution of a problem had succeeded or failed.

Bilateral amygdalectomy reduced the rate of successful solution from 92 percent to 66 percent. Solution rate was unimpaired by crossed unilateral lesions of visual association cortex and amygdala. In a similar but simpler task, learning was profoundly impaired by crossed unilateral lesions of visual association cortex and of the area of termination of the uncinate fascicle in the inferior convexity of the frontal lobe. These results show that the direct input to amygdala from sensory association cortex is not essential for the modality of the retrieval cue in learning and memory, and imply that the importance of the amygdala is rather in securing the effectiveness of reinforcers. Further they suggest that the direct input to frontal lobe from temporal association cortex in the modality of the retrieval cue is crucial for the effectiveness of the cue. The uncinate fascicle may have been unduly neglected in hypotheses of the neuropathology of amnesia.

DEVELOPMENT AND PLASTICITY: VISUAL PATHWAYS I

141.1 ADAPTATION EFFECTS FROM CONDITIONING AREA 17 CORTICAL UNITS IN KITTENS DURING PHYSIOLOGICAL RECORDING. A.B. Saul* and J.D. Daniels (SPON: J.A. Anderson). Center for Neural Science and Division of Engineering, Brown University, Providence RI 02912.

The most typical demonstration of plastic changes in visual cortex involves abnormal rearing of kittens in a restricted visual environment, after which most cells respond poorly to deprived stimuli but respond well to experienced stimuli. We have been studying the changes which occur in the activity of a single neuron by recording immediately before and after conditioning, as well as monitoring the responses during the conditioning session.

These experiments were performed on eight fully anaesthetized and paralyzed kittens, aged 4-8 weeks. We first derived detailed receptive field (RF) plots under computer control. One eye was then occluded during one hour of conditioning with drifting spots, bars, gratings, or complex stimuli. Conditioning was unidirectional and repetitive, although stimulus sweeps were alternated with blank trials of approximately equal duration. At the end of each hour of conditioning the RFs were replotted. Often, this sequence was repeated while units were held for up to 14 hours.

We observed changes, albeit less dramatic than those seen in awake kittens. While some cells gain or enhance a preference for the experienced stimulus, the most striking result is that most changes involve loss of responsiveness to certain patterns which share features of the conditioning stimulus. The effects include shrinkage of RFs, weakened response to the conditioned direction, movement of the orientation tuning curve away from the conditioned orientation, and in general adaptation to the conditioning stimulus. Response properties were selectively altered, as opposed to a general weakening of response as in fatigue. RFs remained in their adapted state for at least 4 hours in some cases.

Ocular dominance and orientation selectivity do not change consistently. Direction selectivity changes most dramatically, typically decreasing in cells conditioned in their preferred direction. Directional preference reverses in some cells.

Responses consistently fall during the hour of conditioning. The level of evoked activity at the beginning of the session is rarely matched at any later point. Responsiveness oscillates as it decays, with both sides of its envelope falling.

Although these results are obtained in anaesthetized kittens, the behavior of single cells appears similar to psychophysical data. Presumably, adaptation is an integral part of the plastic phenomena addressed by longer-term experiments, despite the fact that the induced changes are in the opposite sense.

141.2 ORIGINS OF CORTICAL PLASTICITY IN VISUAL CORTEX AND CLAIRE-BISHOP AREA IN THE CAT. D.N. Spinelli. Center for System Neuroscience, Univ. of Masschusetts at Amherst, MA 01003.

We have demonstrated that unique visual experiences during development result in unique functional properties of single cells in visual cortex and in the Claire-Bishop area of cats (Spinelli&Jensen,Science, 203, 75-78, 1979.) A unique visual experience, for animals with frontally located eyes, is one that requires associating vertical bars viewed by one eye, with horizontal bars viewed by the other. Signature cells, that is cells which are binocular, but respond best to vertical bars for one eye and horizontal bars for the other, can then be found in visual cortex, Claire-Bishop and other cortical areas. We refer to these cells as signature cells because they have incorporated the signature of the experience. Cells with these properties are not found in cats that did not have these experiences. To define the parameters that lead to this adaptation and to study the anatomical circuitry that is involved we have exposed three groups of normally reared kittens to simple alternations of vertical bars for one eye and horizontal bars for the other. The stimuli were switched every 300 msecs. in one group and every 400 and 500 msecs. respectively in the other two groups. No behavior was required and no reinforcement delivered. These stimulus sequences were presented for about 8 minutes a day over a period of three months.

Visual receptive fields of single cell in visual cortex, area 17, and Claire-Bishop were mapped. At the end of the recording session Horseradish Peroxidase (50% solution, 1 microliter) was injected in the area of the microelectrode penetration to trace connectivity. The results show that significant numbers of signature cells are present both in area 17 and Claire-Bishop indicating that simple stimulus alternation is sufficient to produce unusual functional properties in visual neurons even in normally reared kittens. The optimum duration for each stimulus proved to be 400 msecs. The anatomical study shows that even in Claire-Bishop the principal inputs are from the lateral geniculate nucleus and that there is very little intracortical connectivity. Local connectivity and time relationships between the stimuli seem to account for the observed results.

141.3 EFFECTS OF UNEQUAL ALTERNATING MONOCULAR OCCLUSION AND DIFFUSION ON CAT VISUAL SYSTEM. W.G. CHRISTEN*and G.D. MOWER, Dept. of Neurology, Children's Hospital, Boston, Mass. 02115.

Strabismic animals that alternately fixate do not develop visual deficits while animals that preferentially fixate do. In preferential fixation the lesser used eye is placed at a disadvantage not only because it receives less normal visual input than the more used eye, but also because it receives more abnormal stimulation.

We have explored, separately, the effects of these imbalances on cortical and LGN physiology using various ratios of unequal alternating monocular occlusion and diffusion. Four ratios of eye usage were used (4/4,7/1,50/1 and 100/0) and each eye received visual exposure daily. A contact lens was used to restrict vision to one eye during visual exposure sessions and rearing was continued until the time of physiological investigation (5 months of age or older). Some cats were reared with opaque contact lens occluders (OCCLUSION) to investigate the effects of different amounts of normal visual input between the two eyes. These occluders eliminated the VEP to both form and light stimulation so that a particular eye experienced either normal visual stimulation or no stimulation at all. Other cats were reared with translucent diffusers (DIFFUSION) which abolished the VEP to form but permitted diffuse light stimulation. These animals were used to investigate the effects of an imbalance in normal and abnormal input between the eyes.

In visual cortex no differences between OCCLUSION and DIFFUSION cats were observed. Binocularity was reduced in all cats but for both groups a ratio of 50/1 was needed before takeover by the more experienced eye was seen (65-75% of cells dominated by the more experienced eye). Takeover was greater in the 100/0 cats (90-96% domination).

In the LGN only DIFFUSION animals developed an X-cell acuity deficit in the less experienced eye. This deficit occurred in 50/1 and 100/0 cats but not in 4/4 and 7/1 cats. All OCCLUSION cats developed normal X-cell acuities in both eyes in spite of the reduced usage of one eye. This result shows that the X-cell acuity deficit occurs only with abnormal stimulation and that a relatively small amount of normal input is sufficient to negate this deleterious effect.

In summary, these results indicate that occlusion and diffusion have different effects on the developing visual system and that surprisingly little normal vision is needed to prevent the development of eye specific deficits.

141.4 OCULAR DOMINANCE, SELECTIVITY, AND RESPONSIVENESS IN KITTEN AREA 17 NEURONS, AFTER DARK REARING PLUS BRIEF MONOCULAR EXPERIENCE. J. D. Daniels & A. B. Saul*. Center for Neural Sciences and Division of Engineering, Brown University, Providence, Rhode Island, 02912.

If a young kitten lives in total darkness for a few weeks, the responses of its visual cortical neurons become sluggish and lose (or fail to develop) selectivity. Binocularity, however, is retained. If such a kitten is then allowed monocular experience (ME), after several days visual cortical neurons will become *responsive, monocular, and selective* for direction and orientation. How does ocular dominance (OD) plasticity correlate with the improvement in responsiveness and selectivity?

We have given dark-reared 4-9 week old kittens 0-24 hours of ME, then have recorded from area 17 neurons, documenting OD, selectivity, and responsiveness.

In order to assess correlations quantitatively, we record averaged orientation tuning curves for each eye's receptive field. We use a selectivity rating $SEL = 1 - \frac{mean}{max}$ $(0 \leq SEL \leq 1)$ for the responses to stimulus sweeps within $\pm 90°$ of the optimal direction. Picking the best response for each eye's field, we compute an ocular dominance rating $OD = \frac{open}{open + closed}$ $(0 \leq OD \leq 1)$. To quantify responsiveness, we rely on *variability* of the unit over several sweeps.

From our data, the following seems probable:

(1) Within hours of the beginning of ME, some cells improve their *responsiveness*, producing more spikes per stimulus presentation and showing *less variability* over a series of stimulus sweeps than do sluggish dark-reared neurons.

(2) Along with the improvement in responsiveness, some neurons begin to shift ocular dominance (average OD = .71). This shift occurs without substantial improvement in selectivity (average SEL = .46).

(3) Other cells shift OD more slowly, and a number of these cells show a differential (open vs closed) change in selectivity before the shift is complete.

Over the time we have studied, 0-24 hours of ME, the improvement in responsiveness is the most apparent feature, with ocular dominance and selectivity changing at slower rates.

141.5 OCULAR DOMINANCE AND VISUAL ACUITY CHANGES FOLLOWING TERMINATION OF REVERSE OCCLUSION IN THE KITTEN. K.M. Murphy* and D.E. Mitchell, (SPON: D.P. Phillips). Dept. of Psychology, Dalhousie University, Halifax NS. Canada.

Early visual experience exerts a strong influence upon the functional development of the visual system. Monocular deprivation early in the critical period shifts cortical ocular dominance and visual acuity in favor of the nondeprived eye. These effects may be reversed if vision is restored to the deprived eye sufficiently early in the critical period and at the same time the other eye is occluded (reverse occlusion).

Previous work has shown that following 5 or 6 weeks of monocular deprivation only 18 days of reverse occlusion will promote the maximum shift in cortical ocular dominance. We have examined the effect on visual acuity and ocular dominance in area 17, of a period of binocular visual experience provided subsequent to reverse occlusion. Control kittens recorded from immediately upon termination of 18 days of reverse occlusion, after either 5 or 6 weeks of monocular deprivation, were virtually identical to those reported by Movshon (1976). Following a subsequent period of binocular vision (4-8 weeks) the percentage of exclusively monocular cells (groups 1 & 7, < 20%) and binocular cells (groups 2-6, > 80%) was similar for both conditions. However, the distribution of binocular cells differed in the two conditions, with a tendency for the initially nondeprived eye to dominate when monocular deprivation was extended until 6 weeks of age. Measurement of visual acuity made using the jumping stand technique demonstrated extremely poor acuity for both eyes following either deprivation regimen. Visual acuity recovered to only 1-3 cycles/deg following 5 weeks of initially monocular deprivation and was marginally better (2-4 cycles/deg) after 6 weeks initial monocular deprivation. Although binocularity was restored in area 17 following these deprivation regimens, visual acuity was very poor and never recovered.

Movshon, J. A. (1976) J. Physiology (London), 261, 125-174.

141.6 SPLIT CHIASM AND MONOCULAR DEPRIVATION DURING DEVELOPMENT: A MODEL OF NONCOMPETITIVE MECHANISM IN VISUAL CORTEX NEURONS. U. Yinon*, A. Hammer* and Z.D. Weiser*. (SPON: M.S. Myslobodsky). Physiol. Lab., M & G Goldschleger Eye Res. Inst., Tel Aviv Univ., Sackler Faculty of Med., C. Sheba Med. Ctr., Tel Hashomer 52621, Israel.

The effects of the absence of the conventional binocular convergence on cortical cells following optic chiasm split and of monocular deprivation were studied during development.

In five kittens absence of binocularity was induced at six weeks of age by a sagittal section of the optic chiasm and monocular deprivation was induced by lid suturing (OCX-MD). In this way binocular competition between the "experienced" and "deprived" visual inputs on cortical cells may either be cancelled or take place via the indirect callosal pathway. Unit recording (438 cells) was made in these cats during adulthood from area 17-18 boundary, the callosal projection zone of the visual cortex. For comparison, recordings were similarly made from thirteen normal adult cats(544 cells) six adult cats monocularly deprived as kittens (MD; 283 cells) and twelve cats with chiasm split made during adulthood(OCX;729 cells).

The majority of the responsive cells in each hemisphere of the OCX-MD cats reacted monocularly to the ipsilateral eye,as in the OCX cats. A minor proportion of contralaterally driven cells were found reacting to the experienced (3.6%) and to the deprived(0.4%) eye. Only very few cells with binocular input were found in the OCX-MD cats as in the MD cats, in contrast to the result in our normal cats. While 67.2% of the cells in the hemisphere ipsilaterally to the experienced eye were responsive and 32.4% of the cells were unresponsive, the opposite result, namely 31.4% responsive cells and 64.9% unresponsive cells, were found in the hemisphere ipsilaterally to the deprived eye.

We conclude that except for a small interference due to an active callosal transfer, a neuronal effect of a noncompetitive process has been found, as reflected by the fact that each hemisphere is almost independently dominated by its own eye.

141.7 EFFECTS OF CORTICAL ACTIVITY BLOCKADE ON OCULAR DOMINANCE PLASTICITY IN KITTEN VISUAL CORTEX. H.O. Reiter, D.M. Waitzman and M.P. Stryker. Div. of Neuroscience and Dept. of Physiology, School of Medicine, UCSF, San Francisco, CA 94143.

Monocular visual deprivation during early life has long been known to reduce the response of visual cortex neurons to stimulation through the deprived eye. Many lines of evidence suggest that this effect occurs principally in the cortex and is due to a modification of the electrical activity of cortical neurons. Our experiments tested the hypothesis that a blockade of electrical activity in the visual cortex during the period of monocular deprivation would prevent the shift in ocular dominance.

A 33 ga. cannula attached to an osmotic minipump (Alza 2002) was implanted into area 17 of 4-5 week-old kittens. The pump was filled with a mixture of 10^{-5}M tetrodotoxin (TTX) and ^{3}H-proline (1μCi/ml) for experimental animals or saline alone for control animals. Two days after implantation of the pump and cannula, the lid of the contralateral eye was sutured closed. Five days later, acute extracellular single-unit recordings were made to assess the extent of cortical activity blockade anterior to the cannula. Both spontaneous and evoked discharges of cortical neurons were absent or severely suppressed over a distance of at least 6-8mm anterior to the cannula and to a depth of several millimeters. After disconnecting the minipump and closing the ipsilateral eyelid as well, we found that the blockade wore off over the following 20-36 hours. At this point a series of single-unit recordings from cortical neurons was made in the previously blocked area anterior to the cannula. Receptive field characteristics, including ocular dominance, were determined for each cell.

The principal result was that cortical activity blockade largely prevented the ocular dominance shift found in control animals. This provides further evidence for the idea that a binocular imbalance in cortical activity is necessary for monocular deprivation to exert its effect during the critical period.

141.8 EVIDENCE FOR AN ENHANCED ROLE OF GABA INHIBITION IN AMBLYOPIC CATS. G.D. Mower, W.G. Christen*, F.H. Duffy. Laboratory of Developmental Neurophysiology, The Children's Hospital, Boston, MA.

Application of the GABA antagonist bicuculline reveals binocular responses in visual cortical neurons of monocularly deprived (MD) and strabismic cats. A similar effect occurs in monocular cells of normal cats. The question arises, therefore, as to whether abnormal visual rearing results in an enhanced role of GABA inhibition. The present study addressed this question by comparing the effects of iontophoretic bicuculline on the ocular dominance of cortical cells in normal, MD, and strabismic cats. To date, 117 cells have been studied in the three preparations.

In all preparations, GABA disinhibition produced changes in ocular dominance in a higher proportion of originally monocular (51%) than originally binocular cells (15%). Thus, GABA inhibition affects a higher proportion of the total population of cells in MD (44%) and strabismic (51%) cats than in normal cats (20%). This result suggests that the role of inhibition is physiologically enhanced as a result of abnormal visual experience during early life.

Comparison of the pre-drug and during-drug ocular dominance distributions provides insights into the role of inhibition in producing amblyopic deficits in visual cortex. The pattern of ocular dominance that is"revealed" by disinhibition appears to reflect underlying changes in afferent connectivity. During disinhibition, a high proportion of cells are binocularly driven in MD (48%) and strabismic cats (67%). The shape of the during-drug distribution, however, is not normal in either preparation. In MD cats, most cells remain more responsive to the non-deprived eye. In strabismic cats, most cells remain dominated by the originally effective eye. These patterns are consistent with the changes in afferent connectivity from the two eyes in MD (loss of input from one eye) and strabismic cats (exaggerated segregation of the two eyes).

We conclude that the role of inhibition on cortical ocular dominance is enhanced as a result of abnormal visual rearing. GABA inhibition appears to sharpen underlying biases in afferent input to determine overall cortical ocular dominance in amblyopic preparations.

141.9 DARK-REARED KITTENS: EFFECTS OF A GABA ANTAGONIST ON RESPONSIVITY OF VISUAL CORTICAL CELLS. T. Tsumoto and R. D. Freeman. Group in Neurobiology, School of Optometry, University of California, Berkeley, CA, 94720 and Dept. of Neurophysiol., Osaka University Medical School, Kitaku, Osaka, 530 JAPAN

In dark-reared kittens neurons in the visual cortex are unresponsive or only weakly responsive to visual stimulation. By ionophoretic application of an excitatory amino acid (DL-homocysteate) these cells can be activated visually (Ramoa et al., Soc. Neurosci. Abstr. 10, 1077, 1984). One possible explanation of this finding is that intracortical inhibition, mediated mainly by γ-aminobutyric acid (GABA) (Sillito, J. Physiol. 250, 305, 1975), masks excitatory inputs to cortical neurons in dark-reared kittens. To test this possibility we studied the effects of ionophoretic application of bicuculline methiodide (BIC), a GABA antagonist, on visual responsivity of neurons in 14-19 week-old dark-reared kittens. Standard physiological techniques were used along with a four-barreled glass microelectrode with a sharpened tungsten wire projecting from one of the barrels to enable simultaneous recording of single units and ionophoresis of BIC.

Of 110 cells recorded from 4 cats, 59 were unresponsive or very weakly responsive to visual stimuli. Of the 51 visually responsive cells, only 24 were selective for stimulus orientation. These results are in accord with findings of previous studies. About 80 % of the originally unresponsive or weakly responsive cells became clearly responsive during BIC application, although the cells remained largely unselective to stimulus orientation. In addition, for cells which had been responsive initially BIC generally increased levels of responsivity. However, for most of these cells, BIC did not alter selectivity. Thus, the effect of BIC in dark-reared kittens is somewhat different from that found for normal adult cats. In the latter case, selectivity for stimulus orientation is often lost during BIC application but tuning characteristics do not usually seem to be affected in dark-reared animals. This suggests that there may be two types of cortical inhibition. The first kind is responsible for orientation tuning and the second is a type of tonic inhibition which exerts an influence over general levels of cortical responsivity (Tsumoto et al., Exp. Brain Res. 34. 351, 1979). The present results suggest that inhibitory synapses related to selectivity are either not well developed in the visual cortex of dark-reared kittens or become dysfunctional during lack of visual stimulation, and those related to general or tonic inhibition are fully functional.

141.10 ACETYLCHOLINE, NOREPINEPHRINE AND THE EXTRATHALAMIC CONTROL OF VISUAL CORTICAL PLASTICITY. Mark F. Bear and Wolf Singer.* Max Planck Institute for Brain Research, 6000 Frankfurt 71, F.R.G.

It is now quite clear that cortical NE depletion, by itself, is not a sufficient condition to prevent ocular dominance (OD) plasticity in kitten striate cortex. We therefore turned our attention to a possible cholinergic contribution to experience-dependent cortical development. This possibility was examined by destroying the cortically-projecting cholinergic neurons of the basal telencephalon and then testing for a deficit in the ocular dominance shift that normally results from brief periods of monocular deprivation (MD).

Unilateral NMDA lesions of the diagonal bands of Broca and the substantia innominata were made in 4- to 5-week-old kittens. The effectiveness of the lesions was confirmed in all cases by using AChE histochemistry. Despite a drastic reduction in the density of AChE+ axons in striate cortex, 7-10 days of MD caused an apparently normal OD shift to the open eye. However, when cortical ACh and NE were both unilaterally depleted, the OD shift was significantly retarded on that side. The combined depletion was accomplished either by making chemical lesions of both the basal forebrain and the dorsal noradrenergic bundle, or by surgical lesions of the cingulum bundle. In either case, HPLC analysis confirmed that cortical NE was reduced by more than 50% in the hemispheres with the lesions.

These results indicate that while removal of either system alone is ineffective, the combined depletion of ACh and NE is sufficient to block plasticity. This suggests that these two extrathalamic projections are able to functionally compensate for one another, and raises the possibility that they exert their effects on synaptic plasticity via a common molecular mechanism.

141.11 6-HYDROXYDOPAMINE INTERFERES WITH CHOLINERGIC TRANSMISSION IN STRIATE CORTEX. Wolf Singer* and Mark Bear (SPON: L.N Cooper). Max Planck Institute for Brain Research, 6000 Frankfurt 71, F.R.G.

Continuous intracortical infusion of the catecholamine neurotoxin 6-hydroxydopamine (6-OHDA) will disrupt the normal plastic response to monocular deprivation (MD) in kitten striate cortex. However, this effect probably is not attributable solely to the depletion of cortical norepinephrine (NE) since other methods of NE depletion leave cortical plasticity intact. Because the concurrent removal of both cholinergic and noradrenergic projections does appear to disrupt the normal ocular dominance shift after MD (Bear and Singer, this session), we examined the possibility that 6-OHDA also inferferes with cholinergic transmission in striate cortex. This was accomplished by testing the effects of iontophoretic ACh (2.0 M, +15- +60 nA) on cortical neurons before, during and after 6-OHDA iontophoresis (0.2 M, +40- +80 nA) from a piggyback microelectrode assembly. While the 6-OHDA had variable effects on neuronal discharge by itself, it consistently attenuated the cellular response to ACh. The ACh-dependent enhancement of visual responsiveness was usually reduced by about 50%, but in some instances the application of 6-OHDA completely abolished the ACh effect. These results suggest that intracortical 6-OHDA may disrupt plasticity in striate cortex by a combined action on noradrenergic and cholinergic neurotransmission.

141.12 TWO METHODS OF CATECHOLAMINE DEPLETION THAT YIELD DIFFERENT EFFECTS ON PLASTICITY BOTH DEPRESS NE*STIMULATION OF ADENYLATE CYCLASE (ACase) ACTIVITY. C. Aoki & P. Siekevitz, Rockefeller Univ., NY,NY 10021 & J.D.Daniels, Brown Univ., Providence, R.I. 02912.

Upon release, NE can bind to postsynaptic beta-adrenergic receptors and stimulate ACase, an enzyme that converts intracellular ATP to cAMP. Kasamatsu et.al. (J.Comp.Neurol.185:163) have hypothesized that this cascade of events is involved in maintaining ocular dominance plasticity. One evidence supporting this hypothesis is that when visual cortical catecholamines are depleted by intracortical perfusion with a neurotoxin, 6-OHDA, at 6-wk of age (acute lesion), the procedure prevents the loss of binocular cells following monocular deprivation. Bear et.al. (Nature 302:245), however, found that a cortical depletion achieved by IP injection at birth of 6-OHDA (chronic lesion) does not alter plasticity. Could the difference in the state of plasticity be explained by the difference in the stimulation of ACase by the residual NE? To answer this idea, the basal, the maximal catalytic and the NE-stimulated activities of ACase were compared between the tissues lesioned by the two methods versus control tissues. The assay was done blind, without the knowledge of whether the tissues were controls or experimentals.

Three cats were acutely lesioned. From each brain, one block within the 5 mm radius of the site of 6-OHDA injection (lesioned site), another within the 5 mm radius of the site of the vehicle injection in the contralateral hemisphere (control site), and another 10 mm anterior to the 6-OHDA injection site (anterior site) were collected. The blocks were then homogenized and stored frozen at -70°C until the time of the assay. Basal and maximal catalytic activities were the same in all three cases at every site. In contrast, in two animals, sites of lesion exhibited significant depressions in NE-stimulation when compared to the control sites (-35%, -38%) consistently over the range of NE concentrations of 5 up to 250 uM. In another animal, there was no consistent decrease of NE stimulation at the lesioned site.

Five cats wer e prepared for the chronic lesion study, two of which were injected with 6-OHDA and three that were injected with the vehicle solution IP at birth. Tissues were prepared for the assay exactly as described above. Basal and maximal catalytic activities were similar, but the NE-stimulations were significantly depressed, compared to controls (-67%, -33%).

Thus, NE-stimulation of ACase decreased following both methods of lesion. The results corroborate Kasamatsu's earlier finding that after acute lesions, an exogenous source of NE reinstates plasticity, since as is shown here, ACase remains stimulatable by NE. However, since both methods of lesion depress NE-stimulation of ACase activity, the reason for the difference in the state of plasticity appears to reside elsewhere. *NE=norepinephrine

141.13 RECOVERY OF NEURONAL PLASTICITY IN THE KITTEN VISUAL CORTEX PERFUSED WITH A β ADRENORECEPTOR ANTAGONIST. T. Shirokawa and T. Kasamatsu. Smith-Kettlewell Institute of Visual Sciences, 2232 Webster St., San Francisco, CA 94115.

In the visual cortex of developing kittens, the number of β adrenoreceptor binding sites rapidly increases with age, showing a prominent peak larger than the adult value between the 5th and 11th week after birth (Jonsson and Kasamatsu, Exp. Brain Res. 50: 449, 1983). Recently, we showed that direct perfusion of β adrenoreceptor antagonists into kitten visual cortex suppressed, in a dose-dependent manner, the shift in ocular dominance following brief monocular lid suture. When the kitten visual cortex was directly perfused with 10^{-2} M propranolol (in an osmotic pump) for a week, in conjunction with monocular lid suture, the expected shift in ocular dominance was maximally blocked. The resulting binocularity of 67% was compared to that of ~15% in control (Shirokawa and Kasamatsu, ARVO abst., 25. 1984). Taken together, these findings strongly suggest that normally functioning β adrenoreceptors may be critically involved in the regulation of neuronal plasticity in the immature visual cortex (Kasamatsu and Shirokawa Exp. Brain Res., 1985, in press). In the present study, we further examined whether visuocortical plasticity which had been lost to a blockade of β adrenoreceptors by propranolol could be restored some time after the end of its cortical perfusion.

First, the visual cortex of kittens (5-6 weeks old) was directly perfused with 10^{-2} M propranolol for a week. About 60% of visually responsive cells remained binocular, when tested immediately after the end of monocular deprivation which had begun upon the end of propranolol perfusion. Reemergence of the usual extent of the shift in ocular dominance was clearly observed, however, when the lid suture was started one week after the end of the blocker perfusion (binocularity, 20-30%). These results were interpreted as suggesting that β adrenoreceptors blocked by propranolol became functional again, at least partly, within two weeks after the end of the blocker perfusion, causing the obvious shift in ocular dominance following brief monocular lid suture.

Next, noradrenaline (NA, 5×10^{-5} M) was perfused directly into the visual cortex, immediately after the end of the propranolol treatment, over a period of one week concurrently with monocular deprivation. Exogenous NA apparently accelerated the recovery of visuocortical plasticity; about 60% of cells in the NA-treated cortex exclusively responded to stimulation of the nondeprived eye, reducing binocularity to ~20%. This level of binocularity was significantly lower than that (~60%) obtained in the comparable condition but without exogenous NA.

Thus, we concluded that reactivation of β adrenoreceptors by endogenous NA gave rise to reemergence of the visuocortical plasticity and that exogenous NA seemed to further accelerate the recovery.

142.1 DEMONSTRATING THE NONLINEAR INTERACTION BETWEEN EXCITATION AND INHIBITION IN DENDRITIC TREES USING COMPUTER-GENERATED COLOR GRAPHICS: A FILM. P. O'Donnell*, C. Koch, and T. Poggio. Artificial Intelligence Laboratory and Center for Biological Information Processing, M.I.T., Cambridge, MA 02139.

Computer simulations of the action of synaptic conductance changes on the somatic potential in anatomical reconstructed cat retinal ganglion cells have shown that the specific interaction between synaptic excitation and inhibition with a reversal potential close to the resting potential of the cell (silent inhibition) implements a synaptic veto-operation, inhibition shunting excitation only if it is on the direct path between excitation and inhibition (Koch, Poggio, and Torre, 1982). We have examined the effect of two different types of inhibition, silent inhibition (as for instance activated through the $GABA_A$ receptor) and inhibition with a reversal potential negative to the resting potential (hyperpolarizing inhibition; $GABA_B$ receptor), onto the somatic potential evoked by excitatory synaptic input. If the inhibitory conductance change is above a minimal value, the major difference between these two inhibitions is their specificity: while silent inhibition needs to be localized exactly on-the-path between excitation and the soma in order to effectively reduce the EPSP, hyperpolarizing inhibition is far less demanding, usually reducing the potential in the dendritic tree within a given neighborhood of the synapse. Moreover, we have examined the action of a passive membrane, of the branching geometry, and of the density of active channels on the ability of the inhibition to veto the spike. Our major tool is a set of high-level computer programs enabling us to automatically construct the appropriate circuits describing active and passive electrical properties in complex neuronal structures from the measured morphological data. A graphic front-end processor allows us to directly inject current or place synaptic input onto the graphic version of the reconstructed cell and its dendritic tree. The computations are performed using an electrical circuit simulation program, SPICE. Subsequently, the voltage throughout the whole dendritic tree is displayed on a color monitor as a function of time, different colors coding for different voltages. We will present a color film demonstrating the above effects.

142.2 K^+ CONDUCTANCE ACTIVATED BY GANGLIONIC α_2 RECEPTORS MAY BE Ca^{2+} INSENSITIVE. P.E. Rafuse, J.A. Zidichouski* & P.A. Smith. Department of Pharmacology, University of Alberta, Edmonton, Canada, T6G 2H7.

The adrenaline induced hyperpolarization (Ad_H) in bullfrog sympathetic ganglia was investigated using the sucrose gap technique. Experiments were performed in the presence of 0.5 μM desipramine. Previous work suggested that the Ad_H was generated via an α_2 adrenoceptor and subsequent activation of potassium conductance (g_K, Smith, J. Physiol, 347, 377, 1984). In agreement with this, we found that the Ad_H was blocked by the K^+ channel blocker, Ba^{2+} (2 mM) yet was not altered when isethionate was substituted for extracellular Cl^-. The response was antagonized by phentolamine (IC_{50}=0.53 μM), idazoxan (IC_{50}=0.59 μM) and yohimbine (IC_{50}=6.2 nM) but not by β blockers or by prazosin (1 μM). Since mobilization of intracellular Ca^{2+} has been associated with α_1 receptor activation (Boulton, Physiol. Rev. 59, 606, 1979, Exton, pp 117 in Adrenoceptors and Catecholamine Action I ed. Kunos G. Wiley, NY, 1981), we investigated whether this mechanism could also be involved in the generation of an α_2 adrenergic response such as the Ad_H. If this were so, the Ad_H might result from activation of Ca^{2+} sensitive g_K following mobilization of intracellular Ca^{2+}. To test this, we compared the effects of various K^+ channel blockers on the Ad_H with their effects on spontaneous, rhythmic, caffeine induced hyperpolarizations. (R. $Caff_H$, Kuba, J. Phyiosl., 298, 251, 1980). These responses, which are attributed to activation of Ca^{2+} sensitive g_K were recorded intracellularly during continuous superfusion of 5 mM caffeine. R. $Caff_H$ responses were antagonized by 10 mM tetraethylammonium (TEA) or by 50 μM quinidine but not by 1 mM 4 aminopyridine (4-AP). On the other hand, the Ad_H was antagonized by both 1 mM 4-AP and 50 μM quinidine but not by 10 mM TEA or 0.5 μM apamin. The differential sensitivity of the two responses to K^+ channel blockers suggest that different K^+ channels may be involved in each case. Furthermore, the Ad_H was not affected by dantrolene (60 μM), a substance thought to interfere with intracellular Ca^{2+} movements. These results imply that a Ca^{2+} sensitive g_K may not be activated during the Ad_H and that the effects of α_2 receptor stimulation may be independent of the mobilization of intracellular Ca^{2+}.

142.3 **CHARACTERIZATION OF SYNAPTIC TRANSMISSION IN THE INFERIOR MESENTERIC GANGLION OF THE RABBIT.** M. A. Schumann* and D. L. Kreulen (SPON: S. Hameroff). Department of Pharmacology, University of Arizona, College of Med., Tucson, AZ 85724.

The properties of the inferior mesenteric ganglion of the rabbit were studied with intracellular microelectrodes. Isolated ganglia with attached nerve fibers were pinned in a recording chamber and nerve fibers were stimulated with bipolar electrodes. The resting membrane potential averaged -54 mV (± S.E. 1.2 mV) and the cell input resistance averaged 24 MΩ (± S.E. 8 M). Eight per cent of the cells studied (23 of 280) had continuous excitatory postsynaptic potentials (EPSPs) which were blocked by hexamethonium (10^{-4}M). Most cells received convergent nicotinic cholinergic synaptic input from all of the nerve fibers attached to the ganglion. Following repetitive stimulation (30 Hz) of any of the nerve fibers, slow changes in the membrane potential were observed in 84% of cells tested. In 71% of the cells a slow hyperpolarization was followed by a slow depolarization; in 13% of the cells repetitive stimulation produced a slow depolarization only. Both potentials were abolished in low Ca^{+2} high Mg^{+2}. The slow hyperpolarization was associated with a decrease in input resistance, its amplitude ranged from 2 to 15 mV (mean: 7 mV, ±S.E.4 mV) and its duration ranged from 2 to 20 sec (mean: 8 sec, ±S.E. 5 sec). Atropine depressed the slow hyperpolarization by 60% and hexamethonium (10^{-4}M) abolished it. Adenosine (10^{-6}M) and dipyridamole ($3x10^{-6}$M) either together or separately increased both the amplitude and the duration of the hyperpolarization. The slow depolarization that followed the hyperpolarization was associated with a 20% increase in input resistance, its amplitude ranged from 2 to 16 mV (mean: 7 mV, ±S.E. 4 mV) and its duration ranged from 1 to 4 min. The depolarization was not depressed by either atropine or hexamethonium. Adenosine and/or dipyridamole decreased both the amplitude and duration of the depolarization. These studies demonstrate some unique characteristics of the rabbit inferior mesenteric ganglion compared to this ganglion in other species: continuous activity and both hyperpolarizing and depolarizing noncholinergic synaptic potentials. 142.4 VOLTAGE DEPENDENT SYNAPTIC AND NON-SYNAPTIC CONDUCTANCES IN THE MAUTHNER CELL. D.S. Faber and H. Korn, Div. Neurobiol., Dept. Physiol., SUNY, Buffalo NY 14214, and Lab. de Neurobiologie Cellulaire, INSERM U261, Institut Pasteur, Paris, France.

Current clamp analyses of the Mauthner (M-) cell have indicated that its soma-dendritic membranes are electrically passive. We have used single and double electrode voltage clamp techniques, and report that the M-cell's leakage conductance and a synaptically activated inhibitory conductance are both decreased during hyperpolarization. The M-cell was penetrated with one or two KCl microelectrodes, injected with sufficient Cl^- ions to permit detection of IPSPs evoked by stimulation of either the recurrent inhibitory network or individual presynaptic interneurons, and voltage clamped at resting potential (-70 to -85 mV). Leakage conductance was measured during command pulses of 15 to 30 msec duration and -50 to +30 mV magnitude; at the pulse onset the M-cell membrane was quite linear, and its input conductance averaged 3.85 μS (s.d.=1.91 μS, n=21). However, during hyperpolarizations of 10 mV or more, the leakage current often decayed up to 50% by pulse offset. This current sag presumably reflects voltage dependent properties of the M-cell rather than the charging characteristics of its distributed soma-dendritic membranes since: 1) the responses to hyper- and depolarizing command pulses were asymmetrical, and ii) there was no overshoot at the termination of the hyperpolarizing command pulses. Since there was Cl^- loading, these results suggest the M-cell has a voltage dependent potassium conductance which is normally maximal near resting potential.

Inward IPSCs were also recorded at resting potential and during the hyper- and depolarizing command pulses. In some cases, the IPSC current-voltage relation was non-linear, with the synaptic conductance appearing to decrease during hyperpolarizations of 15 to 20 mV or more. Although this voltage dependence was somewhat labile, its occurrence was correlated with neither the level of Cl^--loading nor the magnitude of the synaptic current. In addition, it was not due to a shift in the Cl^- equilibrium potential during the clamp pulses as it was apparent within a few msec after the onset of hyperpolarization. Two possible mechanisms could explain these observations: i) inadequate voltage control of the synaptic membrane, with an increased non-synaptic resistance in that region underlying the decreased synaptic current, and ii) a voltage dependent shift in the kinetics of the activated synaptic channels. The latter is more likely since hyperpolarization consistently decreased the decay time of the synaptic currents in a voltage dependent manner. Thus, hyperpolarization may decrease the mean lifetime of transmitter activated Cl^- channels. Supported in part by NIH Grant #NS-15335.

142.5 INHIBITORY SYNAPTIC CONDUCTANCES AND DRIVING FORCE IN THE MAUTHNER CELL: COMPARISON OF VOLTAGE AND CURRENT CLAMP DATA. H. Korn and D.S. Faber, Lab. de Neurobiologie Cellulaire, INSERM U261, Institut Pasteur, Paris, and Div. Neurobiology, Dept. Physiology, SUNY at Buffalo, Buffalo, NY 14214.

In order to directly measure the driving force (ΔV) and the peak conductances of its Cl^--dependent IPSPs, the Mauthner (M-) cell was penetrated with one or two KCl microelectrodes for single (SEVC) or double (TEVC) electrode voltage clamping, iontophoretically loaded with Cl^- ions, and clamped at resting potential. Unitary inhibitory postsynaptic currents (IPSCs; measured with SEVC) were evoked by intracellular stimulation of single presynaptic neurons, while activation of the M-cell's recurrent inhibitory network produced the full-sized collateral IPSC (measured with SEVC or TEVC). SEVC chopping frequency was 18-33 kHz (Axoclamp, Axon Instr.). IPSCs were measured at the holding potential and during brief (~20 msec) depolarizing and hyperpolarizing command potentials. The driving force was determined either by extrapolation from plots of IPSC amplitude vs. membrane potential, when linear, or directly with depolarizations to the reversal potential. Analysis of the results obtained with these two techniques indicated that: i) g_{coll}, the peak conductance during the collateral IPSC, averaged 5.93 μS (n=10, s.d.=4.75 μS), which is comparable with the previous estimate of 6.08 μS obtained with current clamp techniques (Faber, D.S. and Korn, H. J. Neurophysiol. 48:654, 1982), and ii) the average unitary inhibitory conductance, g_{ipsc}, was 144 nS (n=5, range: 80-179 nS).

Previous indirect estimates of the unitary conductances (mean=172 nS) involved normalizing unitary IPSP amplitudes (V_{ipsp}) relative to the magnitude of the collateral IPSP (V_{coll}), since the latter was found to be a constant fraction (k=0.5) of the driving force. That is, although ΔV varied from one experiment to the next, it could be taken as $2xV_{coll}$ in the formula $g_{ipsp} = [V_{ipsp}/(\Delta V - V_{ipsp})]g_M$, where g_M is the M-cell's input conductance. We have now confirmed that conclusion during voltage clamping: in 16 experiments where V_{coll} ranged from 6 to 22 mV, ΔV was between 10 and 48 mV, and k averaged 0.54 (s.d=0.09). In addition, even when strychnine, which acts postsynaptically to reduce or block IPSPs in the M-cell, decreased g_{coll} by greater than 50%, there were no significant changes in ΔV. In summary, these experiments strengthen our earlier conclusions and derivations of both the size of the binomial quantal conductance and the relative synaptic strengths of individual presynaptic neurons (Korn, H., Mallet, A., Triller, A. and Faber, D.S. J. Neurophysiol. 48:679, 1982). Supported in part by NIH Grant #NS-15335.

142.6 A SEROTONIN-INDUCED INCREASE OF CALCIUM CURRENT IN IDENTIFIED MOLLUSCAN NEURONS MIMICKED BY cGMP BUT NOT BY cAMP. D. Paupardin-Tritsch*, C. Hammond*, and H.M. Gerschenfeld* (SPON: Y. Ben Ari), Laboratoire de Neurobiologie, Ecole Normale Supérieure, 75230 Paris 05, France.

In cardiac muscle cells, beta-adrenergic agonists evoke an increase of the duration of the Ca-action potential by inducing a cAMP-dependent increase of the Ca-current (see Reuter, Nature 1983,301,569; Tsien, Ann.Rev.Physiol. 1983,45,381). In contrast, neurotransmitters like serotonin (5HT) and dopamine have been reported to induce an increase of the duration of the Ca-spike of molluscan neurons by decreasing the S-current (Klein et al., PNAS 1982,77,543), a cAMP-dependent K-current (Klein & Kandel, PNAS 1978,75,3512; PNAS 1980,77,3512; Paupardin-Tritsch et al., Brain Res. 1981,217,201; J.Neurosci. , in press; Deterre et al., PNAS 1982,79,7934; Siegelbaum et al., Nature 1982,299,413).

We have now observed that in two identified neurons located on the ventral face of the left parietal ganglion of the snail Helix aspersa 5HT increases the duration of the Ca-spike and that this effect is not mimicked by cAMP. Voltage-clamp studies revealed that in these neurons 5HT did not affect the outward current recorded in a Ca-free extracellular medium containing 30 mM TEA and did not evoke any current when the potential was held at +10 mV. In contrast, 5HT markedly increased the inward current recorded in a TTX-TEA-BA medium. The I-V curves showed that 5HT increased the Ca-current.

This effect of 5HT on the Ca-current was mimicked neither by intracellular injections of cAMP nor by forskolin, whereas the intracellular injection of cGMP did increase the Ca-current. When 5HT evoked a maximal increase of the Ca-current, the intracellular injection of cGMP became ineffective and conversely, when cGMP evoked a maximal increase of the Ca-current, 5HT application became ineffective. IBMX and RO 20-1724 had no effect on the Ca-current. Another phosphodiesterase inhibitor, zaprinast (M&B 22-948) 100 uM also evoked an increase of the Ca-current but did not potentiate the effects of 5HT. Phorbol-ester TPA, which also evoked an increase in Ca-current, did not interfere with 5HT effects. Intracellular injection of EGTA did not affect the 5HT-induced increase of Ca-current.

These results show that 5HT can also increase the duration of the Ca-spike of molluscan neurones by a second mechanism involving an increase in Ca-current. The possible involvement of cGMP as a second messenger will be discussed.

142.7 PHORBOL ESTERS INDUCE THE TRANSLOCATION OF SOLUBLE Ca^{2+}/PHOSPHOLIPID-DEPENDENT PROTEIN KINASE IN ADRENAL CHROMAFFIN CELLS. B. C. Wise and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

We have shown (Wise and Costa, J. Neurochem., in press) that the bovine adrenal medulla and its constituent chromaffin cells contain significant quantities of the Ca^{2+}/phospholipid-dependent protein kinase (protein kinase C) and endogenous substrate proteins for the enzyme in both cytosol and membrane fractions. With the finding that tumor-promoting phorbol esters activate this enzyme (Castagna et al., J. Biol. Chem. 257: 7847, 1982) by mimicking the action of diacylglycerol, an important tool became available to study the in vivo activation and function of the enzyme. In the present studies, we have investigated the effects of phorbol esters on the subcellular distribution of protein kinase C activity and on catecholamine secretion in bovine adrenal chromaffin cells maintained in primary culture. Pretreatment of chromaffin cells with 12-O-tetradecanoylphorbol 13-acetate (TPA) causes a dose-dependent (EC_{50}= 20 ng/ml) decrease in Ca^{2+}-dependent enzyme activity in the soluble fraction with a maximal effect (90% decrease) seen at between 0.1-1 μg/ml TPA. There is a concomittant increase in the levels of enzyme activity in the membrane fraction by TPA pretreatment with an EC_{50} value of 10 ng/ml and a maximal effect (93% increase) seen at 100 ng/ml. With doses of TPA up to 100 ng/ml, there is no change in the total cell level of enzyme activity and, therefore, the results indicate an apparent translocation of enzyme activity induced by TPA from a soluble fraction (containing about 50% of total enzyme activity under resting conditions) to a membrane fraction. The translocation is rapid with near maximal effects seen after 5 min of TPA treatment. Other phorbol esters (such as 4β-phorbol 12,13-dibenzoate, 4β-phorbol 12,13-dibutyrate, and 4β-phorbol 12,13-didecanoate) which stimulate protein kinase C in vitro are also effective in causing the enzyme translocation. Inactive phorbol esters (i.e. ineffective enzyme activators in vitro) are ineffective in situ in chromaffin cells. We also find that TPA treatment of cells results in a dose-dependent release of both norepinephrine (NE) and epinephrine (E) with an EC_{50} value of about 10 ng/ml and a maximal effect (10-13% stimulated release) seen at 100 ng/ml for both NE and E release. The TPA-induced release of catecholamines is lower than the nicotine-induced release which suggests that other components may be involved in the normal physiological release of catecholamines. The results suggest that the translocation of protein kinase C from a soluble to a membrane-bound form may be an important step in the activation and functioning of the enzyme in such processes as exocytosis.

142.8 NOVEL EFFECT OF PHORBOL ESTERS ON REPETITIVE FIRING IN RAT HIPPOCAMPAL CA1 PYRAMIDAL NEURONS. J. M. Baraban, S. H. Snyder and B. E. Alger, Dept. of Neurosci,. Johns Hopkins Univ. Sch. Med., Batimore, MD 21205 and Dept of Physiol., Univ. of MD. Sch. Med., 21201, Baltimore, MD.

Phorbol esters stimulate protein kinase C, a calcium- and phospholipid-dependent phosphorylating enzyme present in high concentrations in mammalian brain. In order to examine the role of protein kinase C in neuronal function, we studied the electrophysiological effects of phorbol esters on hippocampal CA1 pyramidal neurons in the slice preparation with intracellular recording techniques. We found that phorbol esters block the afterhyperpolarization (AHP) initiated by a brief train of action potentials (Proc. Natl. Acad. Sci. USA., 82:2538, 1985). The calcium-dependent potassium conductance responsible for this AHP also contributes to the marked slowing of firing ("accomodation") that is observed during prolonged depolarizing current pulses in many cell types. Accordingly, during administration of 1 uM phorbol 12, 13 diacetate, an active phorbol ester, blockade of accomodation develops in parallel with inhibition of the AHP. However, blockade of accomodation is transient. After approximately twenty minutes, the number of spikes elicited during a two-second depolarizing pulse decreases dramatically, even though the AHP following a 100 msec pulse remains blocked. We refer to this phase as "paradoxical accomodation".

To investigate the mechanism of this effect, we have studied repetitive firing elicited in CA1 pyramidal cells by both carbachol and 2 sec depolarizing current pulses. In addition to decreasing the number of spikes produced by depolarizing current pulses, phorbol 12,13 diacetate, 1 uM, also markedly reduces the repetitive firing elicited by application of carbachol, 1-20 uM. Nevertheless, individual spikes induced either synaptically or by current injection are unaffected, indicating that the suppression of repetitive firing is not due to a local anesthetic effect of phorbol esters. In the presence of 100-200 uM $CdCl_2$, which blocks synaptic transmission and Ca entry into the cell, phorbol esters still initially increase the number of action potentials evoked by a 2 sec depolarizing pulse and then produce a paradoxical accomodation pattern. Small, discrete, voltage-dependent depolarizing potentials appear to trigger individual action potentials during prolonged membrane depolarizations. Phorbol esters block these small depolarizations, a phenomenon which may account in part for paradoxical accomodation.

These findings support the conclusion that phorbol esters inhibit repetitive firing via a postsynaptic mechanism distinct from a Ca-dependent K conductance.

142.9 VOLTAGE CLAMP ANALYSIS OF SLOW CHOLINERGIC SYNAPTIC TRANSMISSION IN THE HIPPOCAMPUS. D.V. Madison, B. Lancaster†, R.A. Nicoll and P.R. Adams†. Depts. of Pharmacology and Physiology, University of California, San Francisco, CA. 94143; and †Dept. of Neurobiology, State University of New York, Stony Brook, NY. 11794.

A slow muscarinic excitatory postsynaptic potential (slow EPSP), accompanied by an increase in membrane input resistance and by a blockade of calcium-activated potassium afterhyperpolarizations (AHPs), can be elicited in CA1 pyramidal neurons in vitro. This is achieved by electrical stimulation of cholinergic afferents within the hippocampal slice (Cole and Nicoll, J. Physiol. 352, 173; 1984). In the present study we have used a single-electrode voltage clamp to examine the membrane current underlying the slow EPSP. Of particular interest was the possible role of two muscarine-sensitive K^+ currents, I_{AHP}, which produces the afterhyperpolarization, and a voltage-sensitive current, I_M (Halliwell and Adams, Brain Res. 250, 79; 1982). I_M was seen as a time-dependent inward relaxation in membrane current during hyperpolarizing voltage commands (1 sec.; 10-20mV) from holding potentials of -30 to -40 mV. I_{AHP} was elicited by depolarizing commands (1 sec.; 20-40mV) from holding potentials of approximately -60mV.

Under voltage clamp the slow EPSP is a slow inward current (slow EPSC) which decreases in amplitude as the membrane potential approaches E_{K^+}. During the slow EPSC, membrane conductance was decreased and I_{AHP} was reduced dramatically, while I_M was unaffected (n=20). Only in two cells, which were bathed in eserine and stimulated with several times the strength needed to produce a slow EPSC, was I_M reduced noticibly. This finding differs from that described in cultured CA3 neurons reinnervated by cholinergic fibers (Gahwiler and Brown, Nature 313, 577, 1985).

To assess the relative sensitivity of I_M and I_{AHP} to cholinergic agonists, bath applications of carbachol were made. Carbachol concentrations which produced an inward current comparible to the slow EPSC (ie. 1uM), decreased membrane conductance and I_{AHP} with little effect on I_M. Only with higher carbachol concentrations (eg. 10uM) was I_M clearly decreased. All actions of carbachol were sensitive to 0.1uM atropine.

We conclude that in CA1 pyramidal cells I_{AHP} is more sensitive than I_M to muscarinic receptor activation, and that selective reductions in I_{AHP} are observed during most slow EPSCs. Although I_M can be reduced by high agonist concentrations or very strong synaptic activation, blockade of I_M is not a prerequisite for the generation of the slow EPSC. We are currently investigating whether the block of I_{AHP} can account in full or in part for the production of the slow EPSC.

Supported by MH 38256 and MH 00437 to R.A.N.; the Wellcome Trust to B.L.; NIH 15987 to P.R.A.; and the Klingenstein Fund to P.R.A. and to R.A.N.

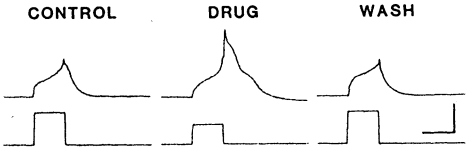
142.10 EPILEPTIFORM ACTIVITY INDUCED BY INHIBITORS OF THE Na/K PUMP IN RAT HIPPOCAMPAL SLICES: FACILITATION OF Ca^{++} SPIKES. M. McCarren and B.E. Alger. Dept. Physiol., Univ. MD, Sch. Med., Balto., MD 21201.

Block of the Na/K ATPase (Na/K pump) can lead to epileptiform activity in mammalian brain, but the mechanism is unknown. Using intracellular recordings from the stratum pyramidale region of CA1 of the rat hippocampal slice preparation, we have investigated the effects of Na/K pump inhibition by cardiac glycosides (CGs) on pyramidal cell membrane properties and synaptic potentials.

We have assessed Na/K pump antagonism by measuring $[K^+]_o$ with K^+-sensitive electrodes and glial cell membrane potentials. As anticipated, perfusion with CGs (strophanthidin or dihydroouabain) increased resting $[K^+]_o$ from a baseline of 5.4 mM and decreased the rate of K^+ clearance following its elevation by stimulus trains.

Field potential recordings indicated that CGs caused repetitive firing (bursts) in response to single stimuli. Intracellular recordings showed that neuronal resting potentials became depolarized by 2-8 mV. Ipsps were reduced, although not as markedly as reported previously for ouabain, a more potent CG. Furthermore, even with ipsps blocked by picrotoxin, CGs facilitated bursting and depolarizing afterpotentials, but interpretation of these data is complicated by possible effects on synaptic transmission and Na^+ gradients. To test whether CGs might directly enhance neuronal burst generating properties, we studied Ca^{++} action potentials (in 1 uM TTX and 5 mM TEA) in the presence and absence of CGs. In the cell illustrated below, a Ca^{++} spike was elicited by less current in 10 uM strophanthidin than was necessary in either control or wash solutions. (Calibration: 40 mV, 0.5 nA and 100 ms). The facilitation of Ca^{++} spikes by CGs was not due simply to depolarization, since it persisted when the membrane was repolarized to the control membrane potential and was not mimicked by perfusion with 6-9 mM K^+_o. Input resistance either did not change or increased slightly (20%) in CG, yet the facilitation was not blocked by simultaneous perfusion with a variety of K^+-conductance antagonists (Ba^{++}, 4-AP, TEA, carbachol), suggesting an action of the CGs distinct from blockade of a K^+ current.

It appears that interference with the Na/K pump can lead to burst firing due not only to a depression of ipsps but also to an increase in the intrinsic excitability of the pyramidal cells.



142.11 THE TEMPERATURE DEPENDENCE OF HIPPOCAMPAL CA1 POSTSYNAPTIC FIELD POTENTIALS - EVIDENCE FOR ENHANCEMENT SUBSEQUENT TO COOLING. R.M. Lebovitz. Dept. Physiology, University of Texas Health Science Center, Dallas, Texas 75235.

Hippocampal slices (400 micron) taken from 150-250 g Sprague-Dawley rats were equilibrated at 35.5°C for 3 hours in an interface-type chamber. Temperature was monitored by a thermistor located just below the slice and, in separate calibration experiments, by a bead thermistor embedded in the slice from above. Stable temperature shifts were imposed by a Peltier device placed below the chamber. Orthodromic evoked potentials were elicited by a bipolar electrode placed on the Schaffer collaterals in stratum radiatum of CA2-3. The CA1 population spike and excitatory postsynaptic potential (EPSP) fields were recorded via glass microelectrodes located in stratum pyramidale and stratum radiatum, respectively. Field data were obtained as a function of stimulus intensity (I/O curves) at the base temperature, at several stable temperatures as the slice was cooled to 24-26°C, then again after rewarming. The slice was stimulated at a constant rate (0.1 Hz) at 50% of maximal intensity (population spike amplitude) continuously throughout each experiment.

The CA1 population spike showed evident saturation at high stimulus intensities so that stimulus-dependent and stimulus-independent (plateau) segments of the I/O relation could be defined. Both the slope of the intensity-dependent and the magnitude of the plateau segments were reduced by cooling, with little or no change in intercept response threshold. The immediate effect of cooling on population spike discharge was not, therefore, well characterized as a "shift" in the I/O curve but rather as a flattening. The EPSP field potential slope was proportional to stimulus intensity over a broad range (5-80 V); saturation generally was not observed. EPSP slope was reduced by cooling with little or no change in intercept threshold, so that the slope of the I/O curve for this response component declined with cooling. Upon rewarming to the base temperature in a substantial number of instances (70%) the population spike I/O curves were observed to be shifted to the left, relative to baseline. In these instances, the I/O curves recovered to baseline form 60-120 minutes after the return to the base temperature. Comparable enhancement and shift of the I/O curves could be seen after moderate warming of the slice, but not after repeated I/O determinations at a fixed baseline temperature. The data suggest the appearance of a reversible potentiation of the response to low-rate stimuli that is made evident by temperature cycling of the preparation.

143.1 NALTREXONE INDUCES DOSE-DEPENDENT DECREASES IN SELF-INJURIOUS BEHAVIOR. B.H. Herman, M.K. Hammock*, J. Egan*, C. Feinstein*, I. Chatoor*, R. Boeckx*, N. Zelnick*, R. Jack*, and J. Rosenquist*. Brain Res. Cen. and Depts. of Psychiat., Neurosurg., Lab. Med. and Child Health & Develop. of Children's Hospital Nat. Med. Cen. and George Washington Univ. Sch. of Med., Washington, D.C. 20010.

Opioid systems in the brain have been implicated in the regulation of antinociception in animals and humans. Over-activity in some brain opioid pathway may underlie the self-injurious behavior (SIB) exhibited by some severely mentally retarded individuals. This is the first report demonstrating that the potent orally administered opiate antagonist - Naltrexone HCl (NALTRX) - is effective in reducing the frequency of SIB.

The subject (S) was a 17 year old male with severe SIB since the age of 7, phenylketonuria, and severe mental retardation. S was in good health: heart rate, blood pressure, body weight, EEG, CAT scan, and clinical chemistry tests (e.g., aspartate transaminase, serum alanine aminotransferase) were within normal range. No side effects of NALTRX were observed.

The frequency of the following SIB types were recorded: hand-to-ear hits, chin-to-shoulder hits, and self-biting. Each test session was 10 min long with five one min test trials surrounded by one min rest intervals. S was tested 1h and 4h after oral administration of NALTRX (DuPont Pharmaceuticals). Behavior was rated by three individuals (two blind to drug and one not blind to drug) (inter-rater reliabilities $\geq +0.96$, p's $< .001$). Sessions were videotaped for blind behavioral analyses. S was tested on drug or placebo for two days followed by two no drug days.

Table. Effect of Naltrexone on Total SIB Frequency

Condition	Day	SIB Frequency
Placebo (Before)	1	45.7 ± 1.7*
Placebo (Before)	2	39.7 ± 0.7
0.5 mg/kg NALTRX	1	35.7 ± 0.9
0.5 mg/kg NALTRX	2	32.0 ± 1.8
1.0 mg/kg NALTRX	1	13.0 ± 0.6
1.0 mg/kg NALTRX	2	6.7 ± 0.3
1.5 mg/kg NALTRX	1	9.3 ± 0.7
1.5 mg/kg NALTRX	2	0.0 ± 0.0

*Mean ± S.E.M. of three raters.

The table shows the effects of NALTRX, 1h after drug, on total SIB frequency as rated by three individuals. There is a dramatic dose-dependent decrease in SIB frequency with increasing doses of NALTRX. Indeed, the second day of 1.5 mg/kg NALTRX reduced SIB frequency to zero. The long half-life of NALTRX may explain the enhanced Day 2 drug effects.

143.2 FURTHER CHARACTERIZATION OF AN ENDOGENOUS OPIOID ANTICONVULSANT: MEASUREMENT OF OPIOID PEPTIDE IMMUNOREACTIVITY IN RAT CEREBROSPINAL FLUID FOLLOWING A GENERALIZED SEIZURE. J.B. Long, C.J. Molineaux[1] and F.C. Tortella. Neuropharm. Br., Dept. of Med. Neurosci., Div. of NP, Walter Reed Army Inst. of Res., Washington, D.C. 20307 and [1]Dept. of Pharmacol., Unif. Ser. Univ. Hlth. Sci., Bethesda, MD 20814.

Seizure-activated endogenous opioid systems appear to inhibit subsequent seizure activity. Repeated maximal electroshock (MES) in rats produces a progressive decrease in seizure severity which is abolished by both naloxone and morphine tolerance (Tortella, et al., Brain Res. 332:174, 1984). Similarly, MES produces a naloxone-reversible increase in the threshold to a subsequent flurothyl-induced seizure (Tortella and Cowan, Life Sci. 31:2225, 1982). We recently observed that cerebrospinal fluid (CSF) collected from rats following an MES-induced seizure causes an increase in flurothyl seizure threshold when administered intracerebroventricularly (icv) to naive rats (Tortella and Long, Science, In Press). This anticonvulsant action was blocked by opioid antagonists and enhanced by peptidase inhibitors. Additional results from these and other experiments (Tortella and Long, INRC, 1985) indicate that the endogenous anticonvulsant substance in CSF is a peptide with a MW less than 10,000 daltons, and that the anticonvulsant effects of this substance involve an interaction with δ opioid receptors. Therefore, in the present experiments we sought to identify convulsion-induced alterations in CSF concentrations of known opioid peptides in order to distinguish which, if any, of these opioids serves as an endogenous anticonvulsant.

Ten min following a single MES seizure or sham treatment, CSF was collected from the cisternal space of donor rats into tubes on ice containing aprotinin and bacitracin (756 kallikrein units and 1mg per ml of CSF, respectively). CSF was acidified with acetic acid and heated at 90°C for 10 min prior to radioimmunoassay for β-endorphin, dynorphin, met-enkephalin, and leu-enkephalin -like immunoreactivity. MES caused a generalized tonic-clonic convulsion which was associated with a selective 3.5 fold increase in β-endorphin immunoreactivity relative to sham treated rats (265 ± 15 vs 62 ± 10 pg/ml). In contrast, CSF levels of dynorphin, met-enkephalin, and leu-enkephalin (101 ± 6, 196 ± 11, and 147 ± 13, pg/ml, respectively) were unaltered following MES.

From these results it appears that if the seizure-activated anticonvulsant activity in rat CSF is attributable to a known endogenous opioid, it is most likely associated with a molecule immunologically recognized as β-endorphin.

143.3 β-FUNALTREXAMINE (β-FNA) AND THE RESPONSE OF NEUROBLASTOMA IN MICE. I.S. Zagon, P.J. McLaughlin, A.E. Takemori* and P.S. Portoghese*. Department of Anatomy, The M.S. Hershey Medical Center of The Pennsylvania State University, Hershey, PA 17033 and Departments of Pharmacology and Medicinal Chemistry, University of Minnesota, Minneapolis, MN 55455.

Previous studies with a variety of opioid agonists and antagonists have shown that endogenous opioids and opioid receptors control neuro-oncogenic events (Zagon, I.S. and McLaughlin, P.J., Life Sci., 28:1095, 1981; Science, 221:671, 1983; Life Sci., 35:2057, 1984). Unfortunately, all of the compounds utilized to date have a cross-reactivity with various opioid receptor types, limiting our knowledge as to which specific receptor(s) is (are) involved in neural cancer. Recently developed selective antagonists provide a unique opportunity to elucidate the importance of each receptor. In the present experiments, the effects of β-FNA, a highly selective and irreversible μ opioid receptor antagonist, on tumor response in mice inoculated with neuroblastoma was determined.

S20Y neuroblastoma, cloned from the A/Jax mouse C1300 neuroblastoma, were injected subcutaneously (10^6 cells/animal) into A/Jax mice. Tumors were measured in 2 dimensions with vernier calipers every 3rd day beginning on the first day a measurable (5 mm or larger) tumor was observed. Incidence of tumor appearance, total survival time, as well as time between tumor cell inoculation and tumor appearance, were analyzed. Beginning 2 days after tumor cell inoculation, mice were injected with either 2 mg/kg or 10 mg/kg β-FNA, or sterile water. Injections were given every 48 hr and continued until all tumor-bearing mice were dead.

Inoculation of neuroblastoma cells in control subjects resulted in 100% tumor incidence within 16 days. Mean and median survival times of 36 and 35 days, respectively, following tumor inoculation were recorded in control animals. Tumor incidence and survival times were comparable to controls for mice given chronic injections of 2 mg/kg and 10 mg/kg β-FNA. Tumor size on the day of death did not differ between control mice and those given 2 mg/kg β-FNA, but tumor size of mice in the 10 mg/kg β-FNA group was 21% smaller than control levels. Both dosages of β-FNA were found to block morphine-induced analgesia for 48 hr. These results suggest that, in and by themselves, μ receptors selectively antagonized by β-FNA do not play an important role in neuro-oncogenic events.

143.4 CSF FROM MORPHINE DEPENDENT RATS PRECIPITATES OPIATE ABSTINENCE SYNDROME. D.H. Malin, L. Dussack*, P. Jenkins*, J. Zografos, P.D. Bruce*, L. Harter* and R. Monfort*. Univ. of Houston-Clear Lake, Houston, Texas, 77058.

There have been several reports that injection of CSF or brain extract from morphine dependent rats could induce tolerance to morphine analgesia. In addition, there were earlier reports that brain extract from dependent rats interferes with morphine effects on the vas deferens assay. These findings raise the possibility of an endogenous opiate antagonist in opiate dependent organisms. It was therefore of interest to determine whether CSF from dependent rats could, like the artificial antagonist naloxone, precipitate withdrawal in morphine treated rats. The third ventricle was chosen as a target for CSF injection, based on preliminary studies showing that i.c.v. naloxone at that site precipitated the most rapid onset of abstinence signs.

Twelve recipient rats were cannulated in the third ventricle and implanted subcutaneously with 2 Alzet 2001 osmotic minipumps, infusing them with 0.35 mg/kg/hr morphine sulfate, or with saline alone. Twelve donor rats were implanted with one larger Alzet 2ML1 minipump, infusing them with 3.5 mg/kg/hr morphine sulfate, or with saline alone. After 7 days of infusion, the donors' pumps were removed and 6 hours was allowed for clearance of morphine from their CSF. CSF (75 μl) was then withdrawn, under ether anestesia, from the cisterna magna of each donor and was gradually injected by motorized syringe (10 μl/min) into the third ventricle of a conscious recipient rat. Recipients were observed for a standard checklist of abstinence signs for 30 min following the onset of CSF injection.

In the 4 cases where the donor and the recipient had both been morphine infused, 37.75 ± 9.66 abstinence signs (M ± SEM) were observed, beginning shortly after the onset of CSF injection. The predominant signs were abdominal writhes, wet-dog shakes and ptosis, with teeth chattering, scratching, head shakes and seminal ejaculation also observed.

In the 4 control cases where the donor had been saline infused and the recipient had been morphine infused, there were 3.25 ± 2.85 abstinence signs. In the 4 control cases where the donor had been morphine infused and the recipient had been saline infused, there were 3.25 ± 2.32 abstinence signs. According to Dunnett's multiple comparison test, there were significantly more abstinence signs, $p < .01$, in the group where both donors and recipients had been morphine infused than in either of the control conditions. The results are thus consistent with the hypothesis that prolonged opiate exposure induces in the CSF a substance with certain opiate antagonist properties. (University of Houston-Clear Lake Organized Research Grant).

143.5 STEREOSPECIFIC MODULATION OF NEURO-ONCOGENESIS BY OPIOID ANTAGONISTS. P.J. McLaughlin and I.S. Zagon. Department of Anatomy, The M.S. Hershey Medical Center of The Pennsylvania State University, Hershey, PA 17033

Growth of murine neuroblastoma has been shown to be modulated by opioid agonists and antagonists (Zagon, I.S. and McLaughlin, P.J., Life Sci. 28:1095, 1981; Science 221:671, 1983; Life Sci. 35:2057, 1984). The mechanism underlying this regulation of oncogenesis is suggested to involve endogenous opioid systems. If tumor response is regulated at the level of the opioid receptor, this interaction should be stereospecific. To address this question, the response of neuroblastoma in mice following administration of (-) and (+) isomers of naloxone was studied.

S20Y neuroblastoma, cloned from the A/Jax mouse C1300 neuroblastoma, were injected subcutaneously (10^6 cells/animal) into A/Jax mice. Tumors were measured in 2 dimensions with vernier calipers every 3rd day beginning on the first day that a measurable (5 mm or larger) tumor was observed. Incidence of tumor appearance, total survival time, as well as time between tumor cell inoculation and tumor appearance, were analyzed. Beginning 2 days after tumor cell inoculation, mice were injected with either 15 mg/kg (-) naloxone, 15 mg/kg (+) naloxone, or sterile water. Injections were continued daily until all tumor-bearing mice were dead.

By 13 days after tumor cell inoculation, 100% of the mice in the control and (+) naloxone groups had measurable tumors but only 47% of the mice in the (-) naloxone group had tumors. Five of the 17 mice ($p<0.01$; chi-square test) in the (-) naloxone group did not develop a tumor by day 56 when the experiment was terminated. The control and (+) naloxone mice did not differ from each other in regard to mean and median total survival time, survival time after tumor appearance, or time between tumor cell inoculation and tumor appearance. However, the (-) naloxone mice had median and mean survival times that were 43% and 28%, respectively, longer than control mice. Latency time between tumor cell inoculation and appearance of a measurable tumor was significantly ($p<0.01$) delayed by 33% for mice in the (-) naloxone group in comparison to control and (+) naloxone mice. No difference in the pattern of tumor growth was observed between naloxone-treated and control animals. In opioid agonist challenge experiments, (-) naloxone blocked morphine-induced analgesia for 4-6 hr; analgesic responses of (+) naloxone and control animals to morphine were similar.

These results demonstrate that opioid antagonists can modulate the course of neural neoplasia, and that these effects are stereospecific. Data from this investigation provide further evidence that endogenous opioid systems play a role as regulators of neural cancer.

143.6 BEHAVIORAL AND BIOCHEMICAL PROFILES OF AGONISTS AND ANTAGONISTS AT THE SIGMA (SKF 10,047) RECEPTOR. G.F. Steinfels, S.W. Tam, and L. Cook, E.I. DuPont de Nemours & Co., Biomedical Products Dept., Wilmington, DE 19898, U.S.A.

Over the past several years there has been a growth in the use of drug discrimination (DD) procedures as a tool for investigating the interoceptive cues produced by opiates. Much interest has been focused on the sigma receptor because it is believed to be responsible for the production of opiate-produced psychotomimetic behaviors in humans. Although there have been studies in rats indicating that (±)-N-allynormetazocine (NANM/SKF 10,047) can be used as a discriminative stimulus (DS), there are recent studies now indicating that the two stereoisomers of NANM have different pharmacologic profiles. For example, using guinea pig brains we can demonstrate that the (-)-but not (+)-isomer of NANM has high affinity binding to the kappa receptor. An isolated guinea pig ileum preparation indicates that the kappa receptor binding is agonistic. However, despite the high affinity kappa receptor agonist binding, analgesic studies in rats demonstrate that (-)-NANM does not possess the same degree of intrinsic analgesic activity as do other kappa agonist analgesics (e.g. U50488H). Rats were trained to discriminate between 3.0 mg/kg (+)-NANM and saline in a two-choice discrete trial avoidance task. To correlate DD behavior with receptor affinity (IC50), the drugs were tested in a brain sigma receptor binding assay using (+)-[^{3}H]NANM. At the highest dose tested (18 mg/kg), (-)-NANM (IC50=496nM) only partially generalized (65%) to (+)-NANM (IC50=68nM) and (-)-NANM caused sedation and ataxia. However, pretreatment with naloxone (1 mg/kg), which presumably blocks the mu, kappa, and delta receptor effects of (-)-NANM, results in complete generalization of (-)-NANM with (+)-NANM. (-)-NANM was 1/3 as potent as (+)-NANM. Cyclazocine (IC50=79nM), completely generalized to and was 1.1 times as potent as (+)-NANM. In contrast, PCP (IC50=777nM), despite its relatively low affinity for the sigma receptor, completely generalized to and was 1.7 times more potent than (+)-NANM. Thus although there is previous biochemical data suggesting that PCP and (+)-NANM occupy different receptor sites, these drugs share similar DS properties. Although it has been inferred that the pharmacologic properties of sigma agonists may be mediated through the dopamine receptor, the dopamine receptor agonist apomorphine did not generalize to (+)-NANM. Haloperidol, which has high affinity binding to the dopamine and sigma receptor, antagonized the DS properties of (+)-NANM. Since (+)-NANM apparently lacks apomorphine generated cues, the antagonism of (+)-NANM produced by haloperidol was probably mediated at the sigma receptor site. The alpha-2 antagonist yohimbine, has no measurable affinity for the sigma receptor, yet it could antagonize the DS properties of (+)-NANM. These data may indicate a link between the sigma receptor and noradrenergic system, the latter of which may have an important role in psychotomimetic behavior.

143.7 EFFECTS OF A SUSTAINED DECREASE IN OPIOID TONE ON LH SECRETION IN INTACT AND LONG-TERM CASTRATED RATS. Nicole Fournet*, L.G. Allen*, P.S. Kalra* and S.P. Kalra (SPON. W. Luttge) Dept. OB-Gyn, Univ. Fla. Col. Med., Gainesville, FL 32610

Considerable evidence suggests that endogenous opioid peptides (EOP) may be involved in the regulation of LH release in male rats. The observations that a bolus injection of an opiate receptor antagonist, naloxone (NAL), stimulated LH release in intact but not in long-term castrated rats, led to the hypothesis that EOP may exert a tonic inhibitory influence on LH release only in intact rats. We tested this hypothesis by continuous NAL infusion to achieve a sustained decrease in opioid tone in intact and long-term castrated rats. Two side-by-side cannulae were placed intracardially in intact and castrated rats (18-20 days post-castration). NAL (2 mg/h/1.2 ml) or saline alone was infused continuously through one cannula, and 100 µl blood samples were withdrawn through the other with the aid of a peristaltic pump at 5 min intervals for 2-1/2 - 3 h for estimation of plasma LH by radioimmunoassay. In intact rats, saline infusion did not change basal LH secretion. However, NAL infusion evoked a significant 2-fold increase in LH release ($p < 0.05$) after 20 min and elevated levels were sustained for an additional 10 min. LH secretion gradually returned to pre-NAL levels and the basal LH secretion pattern was seen as in control saline-treated rats for the remainder of the NAL infusion period. In long-term castrated rats, saline infusion did not influence episodic LH secretion in any fashion through the 3 h infusion period. Quite unexpectedly, NAL infusion produced a bimodal LH response - increase followed by sustained decrease. Within 15 min after NAL infusion, LH rose significantly ($p < 0.05$), elevated levels were observed for another 15 min. LH secretion gradually returned to pre-NAL infusion levels and thereafter, despite continuous NAL infusion, it slowly decreased and stayed below the control castrate levels ($p < 0.02$) during the remaining 105 min infusion period. These studies show that (1) a sustained curtailment of opioid influence induced an immediate excitation of LH release, the magnitude of LH response was quite similar in intact and long-term castrated rats, (2) in addition, in castrated rats continuous NAL infusion decreased LH release. Since our previous studies showed a marked decrease in the hypothalamic LHRH content of castrated rats, it is likely that the attenuation of NAL-induced LH release observed in these rats may be due to exhaustion of releasable stores of LHRH after initial hypersecretion, and (3) contrary to previous evidence based on bolus NAL injection, these studies show that a tonic EOP inhibitory influence may exist in intact as well as castrated rats. (Supported by NIH HD 11362).

143.8 MORPHINE EFFECTS ON [^{3}H] THYMIDINE INCORPORATION INTO NEONATAL RAT BRAIN DNA. H.I. Kornblum*, S. Loughlin and F.M. Leslie. Department of Pharmacology, California College of Medicine, Irvine, CA 92717.

The early appearance of opioid peptides and receptors in the developing brain has led to the hypothesis that these systems may play a role in neuronal development. One possible function is control of brain growth. Chronic administration of the opioid antagonist, naltrexone to neonatal rats causes an increase in brain size (Zagon,I. and McLaughlin,P.; Science, Vol 221, 1983, 1179-80.) Furthermore, opioid peptide immunoreactivity has been detected in the germinal zone of the lateral ventricle of rats 1 to 5 days of age (Loughlin,S., Massimiri,T., Kornblum,H. and Leslie,F., Neuropeptides, Vol 5, 1985, 469-472), and in the proliferative zone of the cerebellum of 10 day old rats (Zagon,I., Rhodes,R. and McLaughlin,P., Science, Vol. 227, 1985, 1049-1051.) In order to test the hypothesis that opioids control cellular proliferation within the brain, we have examined the effects of morphine on [^{3}H] thymidine incorporation into brain DNA of one day old rats. Pups were injected with morphine (5mg/kg) followed 30 minutes to four hours later by [^{3}H] thymidine (1µCi/gm). Animals were sacrificed 30 minutes following the last injection. Brains and spleens were removed and homogenized in 1 M NaOH. DNA was extracted by acid precipitation and hydrolysis in 10% $HClO_4$ (PCA). A sample of homogenate was taken prior to DNA extraction in order to determine [^{3}H] thymidine availability to the target tissue. Morphine administration depressed [^{3}H] thymidine incorporation in brain by approximately 40 %. This effect was observed at the shortest (30 min) and longest (4 hr) time periods of treatment examined and was not due to decreased availability of [^{3}H] thymidine. Inhibition of brain DNA synthesis by morphine was antagonized by pretreatment with 5 mg/kg naloxone. Naloxone alone had no effect on DNA synthesis. Morphine did not depress incorporation into spleen DNA, although it did decrease the availability of [^{3}H] thymidine to spleen. In order to test the hypothesis that morphine inhibits DNA synthesis by direct action on proliferative cells within the germinal zone we have also examined the effects of morphine on [^{3}H] thymidine incorporation into brain slices. Brains were removed, sectioned coronally into .5mm coronal slices and incubated in an oxygenated Kreb's solution containing glucose. Incubations were performed in the presence or absence of morphine for varying periods of time followed by [^{3}H] thymidine (5 µCi/ml) for thirty minutes. Following incubations, the slices were collected and DNA was extracted. Morphine, in doses of .1 to 10 µM, had no effect on *in vitro* [^{3}H] thymidine incorporation into brain DNA over the time periods examined (.5 to 4 hr.) These results indicate that morphine administration *in vivo* inhibits DNA synthesis in neonatal rat brain. However, this effect may not be directly on proliferative cells in the germinal zone. (This work was supported by NIH grant NS 19319.)

143.9 TAIL-FLICK LATENCIES IN RATS ARE MODULATED BY NONNOCICEPTIVE PSYCHOLOGICAL FACTORS. R. Dantzer*, A. Tazi* and M. Le Moal (SPON: D. Beaubaton). INSERM U-259 Psychobiologie des Comportements Adaptatifs, rue Camille Saint-Saëns, 33077 Bordeaux, France.

Variations in tail-flick latencies following exposure to a wide variety of stressors have been interpreted as reflecting activation of endogenous pain suppression mechanisms by stress. The present experiments were undertaken to investigate the possibility that this phenomenon reflects not only the physical properties of stressors, but also their psychological aspects, by varying the ability to control and predict reinforcement contingencies in food deprived rats.

Experimental and yoked animals differed in their possibility of controlling the delivery of food by lever pressing (controllability), predicting its occurence thanks to a prefood signal (predictability) or developing adjunctive activities (schedule-induced polydipsia, SIP).

In the controllability experiment, six experimental rats were submitted to a continous reinforcement schedule and six yoked animals received concomitantly the same amount of food. Over 6 successive daily training sessions, post-session tail-flick latencies were higher in yoked than in experimental animals (5.25 versus 4.68 sec, $p<0.01$, mean pre-session tail-flick latency : 4.06 sec). Presentation of massed food or withdrawal of reinforcement (extinction) induced a significant increase in post-session tail-flick latencies of experimental animals.

In the predictability experiment, 12 rats were exposed to a variable-time 60 sec schedule of food reinforcement with a 10 sec light signal predicting the delivery of food or unrelated to delivery of food. Over 9 training sessions, animals submitted to unsignaled food developed higher post-session tail-flick latencies than animals exposed to signaled food (4.53 versus 4.01 sec, $p<0.01$; mean pre-session tail-flick latency : 3.85 sec).

In the SIP experiment, 27 rats were submitted to a fixed time 1 min schedule of food reinforcement with (n=18) or without (n=9) water bottle. Nine out of 18 rats developed consistent drinking (about 10 ml in 30 min session) within 9 sessions. They had lower pre-session tail-flick latencies than rats which did not develop drinking (3.68 vs 4.33 sec, $p<0.01$). Development of SIP was accompanied by a significant reduction of the difference between post- and pre-session latencies so that SIP rats had lower post-session tail-flick latencies than animals without access to water (3.88 vs 4.11 sec, $p<0.01$). Removal of the water bottle induced a significant increase in tail-flick latencies of polydipsic animals.

These results demonstrate for the first time that tail-flick latencies are very sensitive to psychological aspects of nonnociceptive stressors.

143.10 VASOCONSTRICTOR ACTION OF METHIONINE AND LEUCINE ENKEPHALIN GIVEN INTRAVENOUSLY TO UNRESTRAINED RATS. J.A. Thornhill and W.S. Saunders*. Department of Physiology, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0.

Recent studies have shown that endogenous opioids (methionine enkephalin, ME and leucine enkephalin, LE) are co-released from the adrenal medulla along with catecholamines upon splanchnic innervation of the tissue. This finding has prompted investigators to seek out the possible physiological action of the adrenal enkephalins, including their possible modulatory role in affecting blood pressure regulation. The current study was undertaken to first determine the blood pressure (BP) responses of unanesthetized, unrestrained rats to intravenous (iv) administration of ME and LE and the possible mechanism(s) of action responsible for the resultant BP response. Under sodium pentobarbital anesthesia, male Sprague-Dawley rats had their femoral artery and veins cannulated for subsequent BP monitoring and drug administration, respectively 24-48h later. Random iv injections of ME or LE acetate (1.6, 16 or 48 nmoles) to unrestrained rats caused a rapid but brief dose-related pressor response (greater with LE) while heart rate (HR) was not changed from pre-injection control values. These responses were similar qualitatively to iv administration of norepinephrine (NE) HCl (.48, 2.4 and 4.8 nmoles) although NE caused a greater reflex bradycardia. Combination iv injections of NE (2.4 nmoles) with ME or LE (16 nmoles) did not significantly change the BP and HR responses from that when NE (2.4 nmoles) was given alone. Pretreatment antagonist studies were then conducted using atropine sulphate, propranolol HCl, phentolamine HCl, naloxone HCl and diprenorphine HCl in order to determine the possible receptor mechanism(s) involved in the mediation of the pressor response to LE and ME. IV injection of the antagonists (10 µg -> 1 mg/ml) 10 min before iv LE, ME (16 nmoles) or NE (2.4 nmoles) revealed that the pressor response of rats to LE and NE could be attenuated by phentolamine (α-receptor antagonist). Both naloxone and diprenorphine (mu and delta opiate receptor antagonists) caused a slight blockade of the pressor effect of LE. Antagonism of the pressor response to ME was not achieved with the doses used of any of the receptor blockers tested. The results suggest that LE and ME given intravenously causes an increase in BP in unrestrained, unanesthetized rats with no associated rise in heart rate. The pressor response elicited by LE is probably caused by vasoconstriction of the peripheral vasculature.

143.11 μ AND k OPIATE RECEPTORS MEDIATE SPECIFIC BEHAVIOURAL SYNDROMES FROM THE SUBSTANTIA NIGRA.
M. Morelli and G. Di Chiara. Institute of Exp. Pharmacology and Toxicology, University of Cagliari, Cagliari, Italy.

Recent studies have indicated the presence of μ and k opiate receptors in the basal ganglia: μ receptors are primarily activated by morphine, while k receptors are activated by dynorphins. Moreover these subtypes of opiate receptors display different sensitivity towards naloxone antagonism, μ receptors being 10 to 20 times more sensitive than k receptors to its antagonism. No experimental evidence is available as far as regards the physiological role of these receptor subtypes in the basal ganglia; therefore we studied the effect of local injections, into the rat substantia nigra, of different compounds acting specifically on μ and k receptors. Agonists of μ receptors like morphine and different types of β-Casomorphins, when injected bilaterally into the substantia nigra produced stereotyped behaviour characterized by hypermotility, sniffing and gnawing depending on the doses used. Low doses of naloxone (0.5 mg/kg s.c.) effectively antagonize the gnawing but only high doses (10 mg/kg s.c.) were able to antagonize the hypermotility and sniffing, suggesting an involvement of μ receptors in the mediation of gnawing but not in the mediation of hypermotility and sniffing. On the contrary the bilateral intranigral injections of different types of dynorphins or k-agonists like bremazocine and U 50-488, which are known to be more specific than dynorphin at the k receptor, produced dose-dependent hypermotility and sniffing, but were unable to produce gnawing even at doses 10 times higher than those able to induce hypermotility and sniffing. High (10 mg/kg s. c.) but not low (0.5 mg/kg s. c.) doses of naloxone were able to antagonize this behaviour. These results suggest that gnawing is elicited by stimulation of μ opiate receptors in the substantia nigra while hypermotility and sniffing are due to stimulation of k receptors. Moreover, the administration of 0.05 mg/kg of haloperidol s.c. which blocks the dopaminergic receptors, antagonize the hypermotility and sniffing produced by the intranigral injection of k and μ agonists but is unable to antagonize the gnawing behaviour produced by stimulation of μ receptors indicating that the hypermotility and sniffing is mediated by dopamine while gnawing is independent from it.

143.12 OPPOSITE EFFECTS OF μ AND k OPIATE AGONISTS ON DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS AND IN THE CAUDATE OF FREELY MOVING RATS.
A. Imperato* and G. Di Chiara. Institute of Exp. Pharmacology and Toxicology, University of Cagliari, Cagliari, Italy.

The opiate analgesics are known to produce a variety of pharmacological and behavioural syndromes such as analgesia, physical and psychological dependence, euphoria and sedation. μ-Receptors agonists, like morphine, show addicting properties in animals, while pure k-agonists are apparently devoid of this property. Moreover, k-agonists, elicit sedation, while μ-agonists in low doses produce behavioural excitation. Brain dopamine has been related both to the reinforcing and the motor stimulating properties of opiates, but the evidence supporting this, is essentially indirect. Recently we have developed the technique of trans-cerebral dialysis for estimating the release and metabolism of DA in awake, freely-moving rats. Using this procedure we have studied the effect of morphine, μ-agonist, and bremazocine and U 50,488, k-agonists, on the in vivo release and metabolism of DA and we have correlated it, to the spontaneous behaviour of the animals. Systemic administration of a low dose of morphine (1.0 mg/kg s.c.) significantly stimulated DA-release in the n.accumbens but not in the caudate. DA-release in the accumbens was maximally stimulated (30% basal values) already 20 minutes and up to 80 min after administration. This dose of morphine elicited behavioural stimulation characterized by grooming, hypermotility and rearing. Administration of a low dose of naloxone (0.1 mg/kg s.c. 15 min before morphine) completely prevented the stimulation of DA-release as well as the stimulation of behaviour. Higher doses of morphine (5 mg/kg s.c.) produced frozen postures and immobility for about one hour, followed by behavioural stimulation for the next 2hr 20 min. DA-release increased maximally by about 80% in the accumbens and by about 50% in the caudate. After this dose of morphine, DA-release stimulation was initially associated with behavioural inhibition but out lasted it, and continued for the whole duration of the behavioural stimulation. In contrast to morphine, a dose of 5.0 mg/kg s.c. of the highly selective k-agonist U 50,488, produced a rapid and pronounced reduction of DA release in the accumbens and in the caudate. This dose of U 50,488, in agreement with the literature, reduced motility. Both the behavioural and the biochemical effects of U 50,488 were unaffected by low doses of naloxone (0.5 mg/kg s.c.) while rather large doses of naltrexone (5 mg/kg s.c.), a pure opiate antagonist were able to reverse the inhibitory effects of U 50,488 on behaviour and on DA-release in the accumbens and in the caudate. The present results provide evidence for the idea that the differential effects of μ and k opiate agonists on behaviour are dependent upon a differential effect on mesolimbic and mesostriatal DA-system. In particular our results suggest that the lack of behavioural stimulant properties and the low abuse liability of k-opiate agonists is related to the lack of stimulation of the mesolimbic DA system.

144.1 PURSUIT AND SACCADE ASYMMETRIES IN LATENT NYSTAGMUS. T.C. Hain*, S.E. Kelman*, and D.S. Zee. Dept. of Neurology, Johns Hopkins Hospital, Baltimore, Maryland 21205

We recorded eye movements (search coil) during monocular viewing in 3 patients with latent nystagmus (LN), congenital esotropia, and amblyopia. All patients had a conjugate nystagmus with the slow phase of the viewing eye directed toward the nose. The nystagmus changed direction when the patient moved a cover from one eye to the other, even in complete darkness. Slow phase velocities ranged from 2 to 6 deg/sec.

For pursuit tracking (triangular-wave, 30 deg/sec), viewing with the eye with better acuity evoked gains (peak eye vel/target vel) when the target was moving in the direction of LN drift that were 1.2-1.4x higher than gains for tracking against the drift. When tracking with the more amblyopic eye, gains were 2-4x higher for tracking in the direction of the drift than against the drift. For tracking step-ramp stimuli, similar directional asymmetries in gain and initial pursuit acceleration were seen. The direction of the initial acceleration of the eye and of the ramp were the same except when the step was in the direction of the drift and the ramp was against the drift. Then the eye initially accelerated in the direction of the step (e.g. 20-50 deg/sec^2 for a step of 3 deg and ramp of 10 deg/sec), followed about 40 msec later by an acceleration in the direction of the ramp.

Saccades in the direction of the drift were composed of a series of saccades with brief (20-100 msec) intersaccadic intervals during which the eye drifted onward with high velocity (e.g. 25-50 deg/sec). Saccades directed opposite the drift were larger, usually single and had a backward post-saccadic drift resembling dynamic overshoot. For example, in one patient, for 40 deg target steps with L eye viewing (drift to R) the average primary saccade to the R was 24.0 deg, to the L, 37.6 deg. With R eye viewing the average primary saccade to the R was 35.2 deg, to the L, 20.0 deg. Peak saccadic velocities were normal and appropriate to saccade size regardless of direction.

In conclusion, in LN there are large directional asymmetries in pursuit gain, initial pursuit acceleration, saccadic accuracy and post-saccadic drift. These asymmetries change direction according to which eye is viewing and consequently according to which direction the eyes are drifting. Also, during step-ramp tracking, when the step is in the direction of the drift (onto temporal retina) there is an initial smooth acceleration directed toward the position of the step even when the ramp is directed oppositely. Whether these directional asymmetries in saccade and pursuit tracking reflect differences in processing of visual information from nasal versus temporal retina or are determined by the underlying direction of drift of LN remains to be discovered.

144.2 EYE-HEAD COORDINATION: HOW ANIMALS HOLD THEIR NECKS. A. Berthoz, W. Graf, and P.P. Vidal. Lab. Physiologie Neurosensorielle, C.N.R.S., Paris, France; The Rockefeller University, New York; NYU Medical Center, New York (SPON: J.I. Simpson).

The orientation of the cervical vertebral column in the sagittal plane was determined quantitatively by X-ray photography of the head-neck region of nine unrestrained and awake species of vertebrates (man,monkey,cat,rabbit,guinea pig,rat,chicken,frog,lizard). In addition, the orientation of the horizontal semicircular canals was measured in three species from landmarks at the skull whose spatial relationship to the canals is known. In all vertebrates studied, with the exception of frog and lizard, the general orientation of the curved cervical vertebral column was vertical when animals were at rest, and not horizontal or oblique as suggested by the macroscopic appearance of the neck. The posture of the animal, whether lying, sitting or standing had little effect on this general vertical orientation, although some variability was noticed depending on the species. This variability prompts the definition of a resting zone, rather than of a resting position. The cervical column can take any orientation within ± 11° of a mean position. The objective vertical direction (gravity vector) was always within this resting zone. The vertical orientation of the cervical column causes the odontoid process of the axis (C2) to be oriented vertically, which thus provides the axis of rotation for yaw movements of the head. This axis is identical to that of the horizontal semicircular canals. However, at rest, animals did not hold their heads with the horizontal canals oriented earth horizontally all the time, but maintained them pitched up by 5 - 15°, as also reported for man. At other times, presumably when the vigilance level increased, the horizontal canals were brought into the earth horizontal plane. - The cervical vertebral column composes part of the S-shaped structure of the entire vertebral column, with one inflection around the cervico-thoracic (C7/Th1) junction. This particular configuration is interpreted to provide mechanical advantages by functioning as a shock absorber through its curvature, and by introducing a stable, energy saving balance of the head. Furthermore, when the head is lowered or raised, the atlanto-occipital and cervico-thoracic junctions are predominately involved, while the entire cervical column largely preserves its intrinsic configuration. - The vertical organization of the cervical vertebral column in birds and mammals, whether the animal is quadrupedal or bipedal points to a common organizational principle of head movement and oculomotor systems, including common neuronal elements for gaze control and related reflexes (vestibular, optokinetic, cervical), with collinearity of the rotational axes of the head around the odontoid process, the horizontal semicircular canals, and the horizontal extraocular muscles.

144.3 SELECTIVE LABELLING OF BRAINSTEM AFFERENT NEURONES TO THE CAT ABDUCENS NUCLEUS BY RETROGRADE TRANSPORT OF [^{3}H]-GLYCINE. R.F. Spencer and R. Baker. Dept. Anat., Med. Coll. of Virginia, Richmond, VA 23298, and Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Neurones that utilize a specific neurotransmitter possess high affinity uptake and transport mechanisms that provide the basis for transmitter-specific retrograde labelling (Streit, 1980). In the present study, the localization and distribution of brainstem afferent neurones to the cat abducens nucleus labelled by retrograde transport of [^{3}H]-glycine has been compared to that of neurones retrogradely labelled by horseradish peroxidase (HRP).

Microiontophoretic injections of HRP into the abducens nucleus label neurones located in the ipsi- and contralateral medial vestibular nucleus (MVN), prepositus hypoglossi nucleus (PHN), oculomotor nucleus and overlying supraoculomotor region, and pontomedullary reticular formation (RF). Similar injections of [^{3}H]-glycine, however, selectively label by autoradiography only neurones located in the ipsilateral, and occasionally contralateral, MVN, and contralateral PHN and dorsomedial RF. In the ipsilateral MVN, small-diameter neurones are concentrated in the dorsomedial region lateral to the internal genu of the VIIth nerve, while medium-diameter neurones are located in the ventrolateral part of the nucleus. Small-diameter neurones in the contralateral PHN are located ventral in the nucleus, extending into the underlying RF. Near the caudal portion of the abducens nucleus, a third population of small- and medium-diameter neurones is observed in the contralateral dorsomedial RF, corresponding to the location of inhibitory burst neurones. The selectivity of uptake and retrograde transport of [^{3}H]-glycine is indicated by the absence of labelling of this third population of neurones ipsilateral and in close proximity to the injection site, where local uptake by diffusion could have occurred. The specificity of uptake and transport is demonstrated by the absence of retrograde labelling following injections of [^{3}H]-GABA or [^{3}H]-leucine into the abducens nucleus.

The findings suggest that glycine may be the putative inhibitory neurotransmitter of neurones that are related to the horizontal vestibulo-ocular and saccadic eye movement systems. By contrast, GABA may be the neurotransmitter of second-order inhibitory vestibular neurones that are related to the vertical semicircular canals and that establish synaptic connections with oculomotor and trochlear motoneurones.

144.4 A COMPARISON OF CONNECTIONS OF THE PRIMARY OCULOMOTOR CORTEX (FRONTAL EYE FIELD) AND PRIMARY HAND/ARM MOTOR CORTEX (DORSOLATERAL PRECENTRAL GYRUS) IN THE MONKEY. G. R. Leichnetz. Department of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.

Bruce and Goldberg (1985) have shown that the frontal eye field (FEF) cortex of the rostral bank of the arcuate sulcus contains neurons which fire prior to saccadic eye movements, and further that large amplitude saccades are elicited from microstimulation of dorsal area 8 and smaller saccades from more ventral area 8. Eye movements were produced with currents as low as 8 μa and latencies as short as 25 msec. Schlag and Schlag-Rey (1985) have shown that a region in the dorsomedial prefrontal cortex (a possible supplementary FEF) has similar oculomotor characteristics. This pre-oculomotor physiology led us to ask whether area 8 should be regarded as the primary oculomotor cortex, and whether its connections, previously studied, resemble those of the hand/arm area of the dorsolateral precentral gyrus, area 4. We, therefore, made horseradish peroxidase (HRP) gel implants in area 4 and used the TMB protocol of Mesulam (1978) to define its afferents and efferents.

While area 8 receives its principal cortico-cortical inputs from inferior parietal (PG), superior temporal sulcal, cingulate, prestriate (MT), and medial parietal (PGm) cortices, area 4 receives its inputs from supplementary motor cortex, postcentral, superior parietal, inferior parietal (PF) and cingulate cortices. The ipsilateral SMA and area 5 connections were heavily reciprocal and columnar (retrogradely labelled lamina III cells were heaviest, but lamina V cells were also observed). Area 8 received a moderate input from the middle claustrum and basal amygdaloid nucleus, but area 4 received only a small input from the dorsal claustrum and no projections from the amygdala. Area 8 had heavier thalamic connections with paralaminar mediodorsal, ventral anterior and medial pulvinar nuclei, whereas area 4 had heavy connections with a vertical serrated configuration of VL and VPLo, and centromedian intralaminar nucleus. Both regions received considerable input from the central lateral intralaminar nucleus. The two regions also shared common inputs from the nucleus basalis of Meynert, lateral hypothalamus, locus ceruleus, superior central and dorsal raphe nuclei. The FEF projected to the nuclei of Darkschewitsch and Bechterew, whereas area 4 had a very heavy projection to ND but not NB. Area 4 showed a prominent projection field in the ventral parvicellular red nucleus. Area 8 projected to the ipsilateral dorsomedial basilar pons and bilaterally to pontine tegmentum, while area 4 had a more extensive circumferential corticopontine projection. Area 4 projections contributed to the medullary pyramidal tract and to the cervical spinal cord, whereas area 8 did not.

144.5 CONNECTIONS OF THE PHYSIOLOGICALLY-DEFINED FRONTAL EYE FIELD IN SQUIRREL MONKEYS. M. F. Huerta, L. Krubitzer, and J. H. Kaas, Department of Psychology, Vanderbilt University, Nashville, TN 37240.

Combined physiological and anatomical methods were used to study the connections of the frontal eye field (FEF) in squirrel monkeys. Contralaterally-directed saccadic eye movements were elicited by intracortical microstimulation (40 msec train of biphasic 25-300 μA, 0.5 msec pulses at 300 Hz) within the oval-shaped FEF (1 x 1.5 mm) near the inferior arcuate dimple. Adjacent to the FEF, stimulation of up to 300 μA did not produce eye movements, but resulted in other movements, typically of the vibrissae. Borders of the FEF were marked with small electrolytic lesions, and injections of horseradish peroxidase conjugated to wheat germ agglutinin were placed in this field. After perfusion, cerebral cortex was separated from the brainstem, unfolded, flattened, and sectioned parallel to the flattened suface; the brainstem was cut coronally. Sections were stained for Nissl substance, myelin, cytochrome oxidase or reacted with TMB. Injection sites were confined to the physiologically-defined FEF.

The FEF is reciprocally connected with three zones in the ipsilateral frontal lobe. One of these is located 2 mm rostral, another 2 mm medial, and another 1 mm caudal to the FEF. Reciprocal ipsilateral connections are also present with a region in the medial parietal lobe on the ventral bank of the caudal cingulate sulcus, a region in the inferior parietal lobule on the ventral bank of the lateral fissure and a region in the temporal lobe on the rostral bank of the medial superior temporal sulcus. Callosal connections are with the FEF and surrounding cortex. Finally, the FEF is connected with numerous subcortical structures which have been implicated in eye movement functions including the paracentral, medial dorsal, ventral anterior and pontine nuclei, layer IV of the superior colliculus, and the paramedian pontine reticular formation. The location of the physiologically-defined FEF varied with respect to sulcal patterns. Thus, connectional studies are optimized by combining physiological and anatomical methods.

144.6 FUNCTIONAL PROPERTIES OF TECTAL PROJECTION NEURONS IN THE MONKEY FRONTAL EYE FIELD. M. A. Segraves and M. E. Goldberg. Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, Maryland 20205.

The monkey's arcuate frontal eye field (FEF) is the primary cortical area responsible for the control and initiation of purposive saccades. Bruce and Goldberg have recently shown that 54% of the neurons examined in the FEF discharged before eye movements. Forty percent of the presaccadic neurons examined in detail responded exclusively to visual stimuli, 20% discharged before purposive saccades regardless of the presence or absence of a visual stimulus, and 40% exhibited a combination of visual and movement responses. In the present study we have examined the activity of FEF neurons antidromically activated from the superior colliculus (SC) to determine the relative contributions of the various FEF neuron types to the output of the FEF.

In 2 awake behaving monkeys, 46 FEF neurons were antidromically activated by a monopolar microelectrode positioned within the ipsilateral SC using single negative-first biphasic pulses, 0.4 msec in duration. Current thresholds for antidromic activation varied from 6 μA to 1 mA, and the latency from 1.2 to 6.0 msec. Antidromic activation was verified using collision criteria.

Compared to the entire population of FEF neurons sampled by Bruce and Goldberg, the activity of a disproportionately large number of neurons that project to the SC was movement related (24 neurons, 52%). Eighteen of these neurons exhibited exclusively movement related responses, the remaining 6 also had a visual component in their activity. In addition, there was an unusually large number of neurons (13 neurons, 28%) with foveal receptive fields and/or anticipatory activity presumably important for the triggering process important for saccade initiation. The remaining 9 neurons did not fit the above categories. Their responses included visual, postmovement, tracking, and reward related activity. Only one unit was undrivable.

Testing at 250μ intervals with the stimulating electrode localized the site of lowest threshold for antidromic activation to the intermediate layers of the SC for the majority of neurons. The lowest threshold was obtained in the superficial layers for a single visual neuron, and was below the intermediate layers for a few additional neurons. Antidromically activated neurons were usually clustered within a narrow range in depth in a single penetration. Microlesions have localized these neurons to layer V. Eye movements were electrically evoked at low threshold from these FEF recording sites.

We conclude that the robust projection from FEF to SC does not provide substantial visual information; instead its primary purpose is to provide eye movement targeting and triggering information for the guidance of purposive saccades.

144.7 IMPAIRED TRACKING AND LOSS OF PREDICTIVE EYE MOVEMENTS AFTER REMOVAL OF THE FRONTAL EYE FIELDS. E.G. Keating, S.G. Gooley*, and D.V. Kenney*. Department of Anatomy and Cell Biology, SUNY-Upstate Medical Center, Syracuse, N.Y. 13210

Pathology of the frontal eye fields (FEF) slows visual search, makes it difficult to orient the eyes away from visual targets or foveate remembered target positions. The notion drawn from these findings is that the FEF supplies to eye movements a command derived from internal cognitive decisions. Foveal pursuit of moving targets often involves such an internal component, a prediction about the target's trajectory that is drawn from experience.

Two normal monkeys (M. mulatta) learned to pursue a target moving horizontally across a screen. The targets were sinusoidal (amplitude = 9.0°; freq. = 0.4 - 1.4 HZ.) or had a constant velocity (20-90°/sec). Repeated presentations of the same target trajectory produced predictive eye movements. The monkeys' pursuit sometimes preceded the target's motion. At occasional probe points the target was made to disappear for an interval or to move in unexpected ways. At 38% of these probe points the eyes moved away from the actual target and in the direction of the expected target trajectory. Both smooth and saccadic predictive movements were observed. The velocity of these smooth epochs and the amplitude of the saccades indicated that the monkeys were predicting both the direction and velocity of the target.

Ablation of FEF, first in one hemisphere and later bilaterally, degraded foveal pursuit. Tracking of targets that moved toward the lesioned side became increasingly saccadic. The gain of the remaining pursuit epochs (saccades removed) was reduced even for the low velocity sine and ramp targets. Some recovery occurred by 3 weeks after surgery, but reduced gain of the higher velocity targets persisted for the maximum 2.5 months of observation. The table shows for one subject the average gain of pursuit of two sine targets before and one week after removal of the left, then right FEF.

Targ. Freq.	Preop	l. FEF	r.FEF
0.4 Hz	.97	.87	.56
1.4 Hz	.79	.47	.20

Predictive eye movements were also reduced to a rarity for 1-2 wks following surgery. They returned thereafter but occurred uncommonly and were of small amplitude and short duration. The loss of predictive movements was not simply a reflection of the general lowering of pursuit gain. Predictive saccadic movements were also curtailed even though saccadic amplitude was not otherwise impaired by FEF ablation (USPHS EY04005).

144.8 FAILURE IN RECOVERY OF VISUALLY-GUIDED SACCADES IN HEMIDECORTICATED MONKEYS. R.J. Tusa, Johns Hopkins University, Baltimore, MD 21205.

Visually-guided saccades have been reported to recover in monkeys and human beings with lesions in striate cortex (blind sight). Although this recovery is believed to be mediated by the superior colliculus, little is known about the role of extrastriate cortex in this recovery process.

In this study visually-guided saccades were examined in 3 trained juvenile rhesus monkeys following hemidecortication. A 0.25 deg target light at an intensity of 3.0 ft L with a background intensity of 0.1 ft L was used (recovery of visually-guided saccades has previously been reported in monkeys with bilateral occipital lobectomies using this target light in our lab: Zee et al., 1982). In addition, a very bright target light was used in one of the monkeys (2,000 ft L, background 1 ft L).

Three different saccade paradigms were used: 1) Target Steps of 5-40 degs; 2) Step-Ramp target trajectories where the target was first stepped and then ramped 5-60 deg/sec; 3) Express Saccade paradigm where a 200 msec time gap occurred between the fixation light offset and the onset of the target light.

All 3 monkeys have been examined at least 6 months post-op. Accurate saccades were always made to targets stepped into the normal visual hemifield and latencies were at pre-op values for paradigms 1 and 2 and less than 100 msec for paradigm 3.

For targets stepped into the blind hemifield during all three paradigms, saccades were always made in the appropriate direction, but saccadic amplitudes were unrelated to target step size and mean saccadic latencies were 231 msec longer than pre-op. These saccades are likely to be searching saccades triggered by the disappearance of the fixation light as they are no different from saccades made when the fixation light was turned off without the onset of a target light (blank trials). Although saccadic amplitudes did not depend upon target step size, they did depend upon orbital positions of the eye prior to the saccade with the largest saccades evoked from orbital positions ipsilateral to the lesions.

In conclusion, subcortical regions are not sufficient for recovery of visually-guided saccades to stationary or moving targets in hemidecorticated monkeys. Zee, D.S., et al. Soc. Neurosci. Abstr. 8:291, 1982.

144.9 A QUANTITATIVE STUDY OF VISUAL PURSUIT DEFICITS FOLLOWING LESIONS OF THE FRONTAL EYE FIELDS IN RHESUS MONKEYS. J.C. Lynch and J.C. Allison*. Department of Anatomy, University of Mississippi Medical Center, Jackson, MS 39216.

The frontal eye fields (FEF) have been implicated in the control of saccadic eye movements by electrical stimulation and single-neuron recording studies. However, experimental destruction of the FEF has consistently produced only mild deficits in the performance of saccadic eye movements. Furthermore, only a small percentage of neurons in the FEF are active during saccades, many have sensory receptive fields, and some are active during pursuit eye movements or head movements. Few quantitative studies of eye movement performance following FEF lesions have been performed. In order to investigate the effect of frontal eye field lesions on a broad range of eye movement tasks, two rhesus monkeys were trained on a group of visual fixation tasks, visually-evoked saccade tasks, and visual pursuit tasks. The monkeys were trained to fixate and follow a 0.1° target projected onto a 52° square screen. Oculomotor performance was measured during horizontal and vertical saccades ranging from 8° to 24° in amplitude; during visual pursuit of targets moving in the horizontal and vertical planes at velocities of 20°/sec to 40°/sec; and during the steady fixation of stationary targets at various locations on the screen. Eye position was monitored using chronic EOG electrodes. After performance on the tasks became reliable, bilateral surgical removal of the anterior bank of the arcuate sulcus and the banks of the posterior third of the principal sulcus was performed under sterile conditions using pentobarbital sodium anesthesia. The major finding of this study is that bilateral lesions of the FEF produced a severe deficit of visual pursuit performance in both the horizontal and vertical planes, whereas saccade performance was only mildly affected. For several weeks following the lesion, monkey R-5 was unable to match eye velocity to target velocity and could follow the target only by means of a series of small saccades when the target moved 20°, 30°, or 40°/sec. Eight days after the lesion, pursuit gain was 0.18 at 20°/sec and 0.12 at 40°/sec. Thirty-six days after the lesion, pursuit gain had increased to 0.51 at 20°/sec and 0.60 at 40°/sec. Horizontal pursuit performance of monkey R-6 was similar. Vertical tracking was tested in monkey R-6 and showed defects comparable to those seen in horizontal pursuit. Horizontal saccade velocity for 20° or 24° saccades decreased by about 10% following the lesions, while saccade latency increased by about 30%. These changes are similar to those produced by bilateral parieto-occipital cortex lesions. Vertical saccade performance was less severely impaired. These results suggest that the frontal eye fields are involved in the control of visual pursuit movements to a greater extent than has heretofore been recognized. [Supported by grants from NIH (EY-04159) and the Vaughan Stroke Research Trust]

144.10 UNEQUAL SACCADES DURING CONVERGENT EYE MOVEMENTS IN THE MONKEY. P.D.R. Gamlin and L.E. Mays, Dept. of Physiological Optics and the Neurosciences Program, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

Studies in humans have demonstrated that saccades occurring during convergent eye movements can be markedly unequal in amplitude. For example, if a rightward saccade occurs during a convergent movement, the saccade in the left eye may be twice as large as the saccade in the right eye. This saccadic inequality is too large to be explained by the linear addition of the saccadic and convergent movements. We have observed a similar phenomenon in monkeys. These unequal saccades might result from saccadic size being programmed independently for each eye, or they might arise from non-linear interactions at the level of the oculomotor nucleus or plant. We have used two approaches to examine these possibilities in the monkey.

First, we trained monkeys to make symmetrical convergent movements in response to step changes in disparity. We were also able to produce predominately horizontal saccades by electrical stimulation of the superior colliculus. Neither the timing nor the occurrence of this stimulation could be predicted by the animal. Stimulation just before or after a convergent movement produced saccades of equal amplitudes. In contrast, when the colliculus was stimulated during a symmetrical convergent movement, saccades of different amplitudes were elicited in the two eyes.

In a second experiment, we recorded from vergence cells in the midbrain during both symmetrical convergent movements and those in which unequal saccades occurred. For symmetrical vergence, these cells exhibit a firing rate that is closely coupled to vergence angle (Mays, L.E., J. Neurophysiol., 51:1091, 1984). If the saccadic system were mediating changes in vergence by programming unequal saccades, then these cells might be expected to show a smaller change in firing rate for convergent movements in which unequal saccades occurred. However, we found that the behavior of these cells was similar regardless of the dynamics of the vergence movement.

These results suggest that the large inequalties observed in saccades during vergence eye movements are not the result of central programming. Rather, they appear to result from non-linear interactions at the level of the motoneurons and, or alternatively, as suggested by Kenyon et al. (Am. J. Optom. Physiol. Opt. 57:586, 1980), at the level of the oculomotor plant. (Supported by NIH grants EY03463 & EY03039)

144.11 QUANTITATIVE FEATURES OF PERCEIVED TARGET MOTION DURING SMOOTH PURSUIT EYE MOVEMENTS. J. Pola and H.J. Wyatt. Institute for Vision Research, SUNY State College of Optometry, NY, NY 10010.

During smooth pursuit tracking of a moving target in an otherwise dark environment, one perceives motion of the target. Since no target-background relative motion occurs (because of the dark), and there is little target motion at the retina, it is assumed that this perception comes from some sort of extraretinal signal, contingent on eye movement. Recently, it has also been suggested that such perception, perhaps arising from a corollary discharge, may be involved in the control of pursuit movements via positive feedback (Yasui & Young 1975; Wyatt & Pola 1979).

In spite of the role that this perception may play in normal pursuit, little is known about its quantitative features. We have performed the following experiment: To investigate the influence of an extraretinal signal on perception and avoid contaminating effects of retinal target motion, we used a complex stimulus. This consisted of a vertical bar within a square (4 x 4 deg), the bar jumping from side to side of the square at a given frequency. The bar-plus-square was retinally stabilized and centered at the fovea, so that the bar jumped from side to side of the fovea. Subjects, in an otherwise dark room, attempted to look at the jumping bar. The result of this was oscillatory smooth pursuit (to the foveal offset of the bar) at the same frequency as the jumping bar, occasional saccades, and concomitant movement (due to stabilization) of the bar-plus-square in space. The subjects task was to assess the peak-to-peak amplitude of motion in space of the square (which did not move at the retina and was perceptually distinct from the bar), and to compare it to the amplitude of a similar stimulus observed subsequently in the light.

We were able to vary the frequency of smooth pursuit and concomitant stimulus motion by varying frequency of bar motion (0.5 - 1.5 Hz). We found that at the frequencies studied, the perception of amplitude of motion of the square was less than the amplitude of smooth pursuit. Furthermore, as frequency increased, the ratio of perceived motion to eye movement decreased. For all subjects this decrease in perception was characterized well by a second-order transfer function; that is, the extraretinal signal responsible appears to pass through a second order lag prior to registration in perception.

Perception of target motion was also determined as subjects tracked sinusoidal motion of a small round target (3 deg pk-pk, motion retinally stabilized at fovea). Since in this case the assessment of motion included retinal target motion, the ratio of perceived motion to eye movement differed from the first experiment, increasing notably at high frequencies. These results, together with the results of the first experiment (above) can be accounted for if it is assumed that the perceived motion involves a time advance of 150 msec in addition to a second order lag.

144.12 Smooth-Pursuit Eye Movement Related Visual and Visuo-motor Responses in Dorsolateral Pontine Nucleus of Alert Monkey. D.A. Suzuki, E.L. Keller and R.D. Yee*. Jules Stein Eye Inst., UCLA Sch. Med., Los Angeles, CA 90024 and Smith-Kettlewell Inst. Visual Sci., San Francisco, CA 94115.

Physiological recordings and behavioral studies of monkeys with pharmacological lesions in the dorsolateral pontine nucleus (DLPN) implicate this structure as an important source of sensori-oculomotor information for the smooth-pursuit eye movement system. The determination of visual receptive field structure and interactive, visuo-oculomotor mechanisms was sought to further clarify the role of the DLPN in the regulation of smooth pursuit.

Extracellular activity was recorded in alert monkeys during the performance of a battery of visuo-oculomotor tasks. Visual responses were elicited by presenting discrete and large field visual stimuli while the monkeys were required to fixate a stationary fixation spot. Retinal image motion- and eye movement-related DLPN activities were studied during the initiation and maintenance of smooth-pursuit eye movements and also during pursuit of a moving target that was superimposed upon a random dot background pattern.

Results to date indicate that visual responses in DLPN are characterized by five receptive field (RF) types: (1) small, foveally centered and (2) large RFs that encode retinal image velocity, (3) large, retinal image acceleration RFs, (4) large, direction-only (non-velocity related) RFs, and (5) small, eccentric RFs that respond to discrete, stationary stimuli. All visual responses to moving stimuli were direction selective.

The responses of DLPN cells with RF types 1 and 4 could best account for the specific changes in eye acceleration that were observed during pursuit initiation. Eye accelerations were largest when retinal images were close to the fovea and RF type 1 would be activated. In contrast, eye acceleration was smaller and less correlated with target velocity for the eccentric retinal image motion that would stimulate activity in RF type 4.

Some DLPN cells exhibited both retinal image and eye movement-related responses. In some of these units, the eye movement-related modulations in discharge rate were facilitated when the monkeys tracked the target in the presence of a random-dot background pattern.

The results lend single-unit support for the behavior based conclusion that foveal inputs are more effective than eccentric visual stimuli for pursuit initiation (Lisberger, NSAbst 8). The facilitated pursuit response during conditions of visuo-oculomotor interactions suggests a role for the DLPN in optimizing pursuit in the face of anti-phase, relative background motion.

145.1 IN VIVO REGENERATION OF RHODOPSIN AND PORPHYROPSIN IN THE NEURO-RETINA. J.M. Flores* and A.T.C. Tsin. Division of Life Sciences, The Univ. of Texas at San Antonio, San Antonio, TX 78285.

The neuroretina of goldfish (Carassius auratus) contains a pair of scotopic (rod) visual pigments - rhodopsin and porphyropsin. The composition of these visual pigments changes in response to light and temperature and the mechanism of this visual pigment change is not known. In several in-vitro experiments, Suzuki, Makino-Tasaka and Miyata (Vision Res., 25: 149-154, 1985) found that rhodopsin regenerated faster than porphysopsin and therefore suggested that the rate of visual pigment regeneration provided a possible mechanism of visual pigment changes. In the present study, we have examined the regenerations of goldfish porphyropsin and rhodopsin in-vivo. Goldfish with porphyropsin-rich retinas were obtained from Grassyfork Fisheries, IN. Goldfish with rhodopsin-rich retinas were obtained by subjecting fish to a specific light and temperature regimen (16L/8D, delivered by a 7.5W light bulb, water temperature: 30°C; Tsin and Beatty, Exp. Eye Res., 29: 15-26, 1979) for one month. Before the experiment began, goldfish were placed in a dark room overnight and then illuminated by bright light (two 300W, two 100W and one 150W bulbs, in a 30 gal. aquarium) for one hour to bleach all visual pigments. They were then returned to the dark room and sampled at these time intervals (0, 30, 60, 90, 120, 180, 240, 300, 600 minutes of dark adaptation, n=3 to 6). The neuroretina was dissected out under dim red light and placed immediately in 1:1 mixture of phosphate buffer (0.1M, pH=7) containing hydroxylamine (0.1M). The visual pigments were extracted by 2% digitonin in 0.1M hydroxylamine (pH=7) and then analysed by a spectrophotometer. The initial bright illumination bleached 80-90% of these scotopic pigments. The porphyropsin-rich retina (92% porphyropsin) required 10 hours to completely regenerate all its visual pigments (maximum rate of regeneration: 14nmol/kg/hr at 20°C) and this time course is in agreement with Baumann's in-vivo study of the regeneration of porphyropsin in the crucian carp (Carassius carassius) performed at a similar temperature (15°C) (Nature, Lond., 233: 484-485, 1971). However, we found that the rhodopsin-rich retina (62% rhodopsin) required only 5 hours to regenerate all rod pigments (i.e. 29nml/kg/hr, at 30°C), thus the regeneration of rhodopsin seemed faster than that of porphyropsin. (Supported by NIH Grant No. RR-08195-05 and NSF Grant No. BNS-82-03064.)

145.2 CIRCADIAN ALTERATION OF DARK ADAPTATION IN LIMULUS LATERAL EYE. L. Kass, Eastern Virginia Med. Sch., Norfolk, VA 23501

Photoreceptors in the lateral eye of Limulus polyphemus have been shown to exhibit circadian rhythms in sensitivity, gain (response/photon), and spontaneous (dark) "bump" rates.[1] These circadian rhythms are mediated by about a dozen efferent optic nerve fibers that synapse in the retina.[2] I report changes that occur from day to night on parameters associated with a quantitative description for the time course of dark adaptation.

Electroretinographic recordings (ERGs) were elicited from the lateral eye in situ using the methods of Barlow.[3] The animal was restrained and partially submerged in a sea water aquarium within a light-proof cage. Light was projected onto a diffusing screen directly in front of the lateral eye. The adapting light and the ERG test flash had durations of 3 sec and 50 msec, respectively. The ERG was conducted to a differential amplifier via a corneal electrode and was recorded on a computer diskette. The ERG amplitudes were compared with the intensity response function measured in the dark adapted state. In this way, retinal sensitivity as a function of time after the adapting light was obtained. This defines the time course for dark adaptation.

A computer program was utilized to curve-fit the data. A "best-fit" analysis revealed that the sensitivity vs. time functions measured both during the daytime and nighttime states could be well described by the following equation:

$$S = A_1 e^{-t/\tau_1} + A_2 e^{-t/\tau_2}$$

where S is the sensitivity (in log units of light intensity) at time t after the adapting flash. A_1 and A_2 are the coefficients for the two exponentials, whereas τ_1 and τ_2 are the time constants. At 4-5 log units of intensity above threshold for the ERG, τ_1 and τ_2 are about 40 and 500 sec, respectively. During the day, A_1 and A_2 are about 0.8 and 1.1, respectively. At night, A_1 decreases in size by about 30%, A_2 increases in size by about 40%, and changes in τ_2 were not apparent. Thus, dark adaptation takes longer to fully recover after an equivalent number of photons are delivered to the eye at night, even though at earlier times ($t < \tau_1$) dark adaptation begins to recover more quickly. These circadian alterations in the time course for dark adaptation appear to come about primarily through changes in A_1 or A_2, rather than through alterations in the photoreceptor processes underlying the time (or rate; $k=1/\tau$) constants.

145.3 THE B-WAVE OF THE ELECTRORETINOGRAM AS A MEASURE OF CIRCADIAN ROD OUTER SEGMENT DISC SHEDDING IN ALBINO RABBITS. P. A. HOCK*, M. P. White, and M. F. Marmor*. Dept. of Ophthalmology, Stanford University and Veterans Administration Medical Center, Palo Alto, CA 94304.

The shedding of outer segment discs in rod photoreceptors is cyclic in nature. This has been demonstrated histologically as a daily increase in pigment epithelial phagosomal content soon after light onset in the morning (La Vail, M. M., Science, 194: 1071, 1976). With autoradiography it has been shown that mammalian rod outer segment turnover requires 9-11 days, thus 10% of the rod outer segment length must be shed daily (Young, R. W., Invest. Ophthalmol. Vis. Sci., 15:700, 1976). It cannot be determined from anatomical evidence how much of the daily complement of disc shedding is accounted for by the morning shedding event nor can the time course of disc shedding be determined. We have used the b-wave of the electroretinogram (ERG) to provide a new means to measure the shedding event.

Rabbits were maintained on a 12 hr light:12 hr dark schedule for at least 3 weeks. AC ERGs were recorded in the dark from anesthetized rabbits using a corneal contact lens electrode. The b-wave amplitude elicited by constant intensity, 50 ms, 500 nm, and 630 nm test lights, presented at 1 min intervals, was measured for a period of 1-2 hrs. The constant intensity stimuli were chosen at the beginning of each session to elicit a criterion response of 40 uV. Recording began either shortly before the usual time of light onset or in the middle of the usual light period of the entrained light-dark cycle.

30 min after the time of light onset we find a decrease in the amplitude of the b-wave obtained with a 500 nm test light. The calculated decrease in sensitivity required to produce this change in amplitude is approximately .1 log unit, which is the expected change if 10% of the discs are shed. We find no change in amplitude when ERGs are recorded in the middle of the light period. With histological examination of the pigment epithelium, we find the expected increase in large phagosome content shortly after light onset, and low phagosome numbers at midday (Bunt, A. H., Invest. Ophthalmol. Vis. Sci., 17:90, 1978).

We have also used the ERG to measure shedding in freerunning conditions, recording from animals housed in continuous darkness or with unilateral eyepatches. In these animals, the change in ERG amplitude shifts temporally with the changes in the lighting conditions. This is the first time that the ERG has been used to measure a shedding event in the living eye and has been correlated with the histology in the same species.

145.4 CYCLIC GMP CHANGES THE SOLUBILITY OF A PHOSPHORYLATED PEPTIDE, COMPONENT II, IN ROD OUTER SEGMENTS. H. Hamm. Dept. of Physiol. and Biophys., Univ. of Ill. Coll. of Med., Chicago, IL 60612.

Components I and II are rod outer segment (ROS) phosphopeptides of molecular weights 13 and 12 Kdaltons which are normally phosphorylated in the dark and are reported to dephosphorylate in the light. Cyclic GMP as well as cAMP can stimulate their phosphorylation in broken ROS.

This study addresses the subcellular localization of CI&II in ROS. In Percoll-purified, broken rods, incubated with γ-^{32}P-ATP, the phosphorylated peptides can be found entirely in the supernatant after brief centrifugation. Reincubation of the resultant membranes with γ-^{32}P-ATP again yields similar amounts of soluble phosphorylated CI&II, suggesting that the phosphorylated form of CI&II is soluble, while an unphosphorylated pool remains bound. This cycle of removal of soluble CI&II and rephosphorylation of membranes can be repeated at least four times with no apparent decrease of the non-phosphorylated membrane-bound pool. The released, phosphorylated form cannot be regulated by cGMP, cGMP-dependent protein kinase, or a monoclonal antibody to Gα called 4A, while the membrane-bound form is highly regulated by these agents. This suggests that CI&II are subject to regulation only when bound to the membrane, and phosphorylation causes release into the cytoplasm.

Cyclic GMP alters the solubility of one of these peptides, Component II, causing some phosphorylated CII to be membrane bound. This redistribution effect is half-maximal in the presence of 50 μM 8-bromo cGMP, or 250 μM cGMP. Cyclic AMP and 8-br cAMP can also support this redistribution, but 5'GMP, 5'AMP, GDP and ADP do not. It appears that cGMP has altered the ability of phosphorylated CII to bind to the membrane.

In an effort to determine whether similar redistributions occur in intact cells, rods were incubated with $^{32}P_i$ and allowed to synthesize γ-^{32}P-ATP. Dark-adapted rods contain some membrane-bound CII, and incubation with dibutyryl cGMP increases this phosphorylation. Bright light (1% or more rho bleached) causes the dephosphorylation of this membrane-bound CII. Conceivably it is this membrane-bound form that might participate in cGMP- and protein phosphorylation-mediated events in ROS.

145.5 **MONOCLONAL ANTIBODIES THAT DEMONSTRATE LIGHT DEPENDENT LABELING OF ROD OUTER SEGMENTS.** Grant W. Balkema, John N. Wood* and Ursula C. Drager, Dept. Neurobiology, Harvard Med. Sch., Boston, and Sandoz Inst., Univ. College, London*.

In retina sections treated with antibodies against the 200K neurofilament subunit we had observed variable labeling of photoreceptor outer segments. As outer segments are not known to contain neurofilaments, the labeling pointed to crossreactivity of the antibodies with unrelated compounds. Here we asked whether the variability represents different functional states in these compounds, by testing for light dependence of the labeling. We found two neurofilament antibodies--RT97 and R3--out of ten tested that labeled rod outer segments, only when the retina had been illuminated. The affinity for RT97 increased up to a saturated level over the duration of a bright illumination, whereas affinity for R3 appeared at the onset of the light stimulus, grew to a maximum and decreased with steady bright illumination. A third unrelated antibody, #16, recognized selectively dark-adapted rod outer segments. In addition to the illumination dependent labeling of rod outer segments all three antibodies recognized other components of the retina independent of the illumination history: RT97 and R3 labeled cell types known to be rich in neurofilaments and #16 labeled profiles associated with synaptic terminals.

To determine the molecular weights of the illumination dependent antigens, we removed retinas from light and dark adapted mice and prepared Western blots. So far we found a clear light/dark difference on blots only for RT97: in light adapted, but not dark adapted retinas, RT97 strongly recognized bands at 32-42K molecular weight, which lined up with bands labeled by RET-P1, a monoclonal antibody against rhodopsin (a gift from Colin Barnstable); when light adapted retinas were prepared under conditions that allow aggregation of rhodopsin, both RT97 and RET-1 labeled additional bands at 72-80K, presumably rhodopsin aggregates.

The 200K neurofilament subunit is known to be very heavily phosphorylated, and a major covalent modification of rhodopsin with light adaptation is phosphorylation. To test whether the modifications recognized by the two neurofilament antibodies are due to phosphorylation, we treated whole retinas, neurofilament preparations and isolated outer segment preparations with alkaline phosphatase, and tested antibody binding by solid phase RIA. In all preparations binding declined with such treatment, indicating that RT97 and R3 either recognize a phosphorylated site directly, or a conformational change brought about by nearby phosphorylation, which is in agreement with observations of others on 200K neurofilament antibodies. Antibodies selective for particular states of sites that undergo reversible covalent modifications may allow the study of physiological events with morphological means. Supported by EY 01938, EY 05716, and the Am. Fed. for Aging Research

145.6 A MONOCLONAL ANTIBODY THAT BINDS TO THE OUTER SEGMENTS OF CONES. V. Lemmon. Dept. of Anatomy and Cell Biology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

Preliminary immunohistochemical experiments indicated that antibody 50-1B11 bound to the outer segments of a subset of photoreceptors in chickens. Subsequent tests showed that 50-1B11 also bound to a subset of photoreceptors in bull frogs, rats, rhesus monkeys and humans. Based on the distance between 50-1B11 positive photoreceptors, and a comparison with information available in the literature, it appeared that 50-1B11 might be binding to cones in monkeys.

Therefore, we performed a series of double label experiments based on those of de Monasterio et al. (Science, 213:1278, 1981). We observed that the procion yellow stained a subset of photoreceptors. The dye was present in highest concentrations in the outer segments but there was also label in the inner segments, soma and dendrites of some photoreceptors. When these same cells were examined for staining with 50-1B11, they were also found to be labeled but the staining was restricted to the outer segments. Examination of numerous sections from four different injected eyes indicated that there was excellent correspondence between the procion label and the 50-1B11 staining. Since de Monasterio has shown that procion yellow is selectively taken up by cones, our experiment gives strong evidence that 50-1B11 binds to the outer segments of cones in monkeys.

In other experiments, flat mounts of monkey retina were examined and 50-1B11 positive outer segments were observed to correspond perfectly to the pattern of cone ellipsoids. Tissue culture experiments indicate that the antigen is intracellular and associated with the membrane.

Since this antibody binds to such a wide variety of species, it should be a very powerful tool for studying cone differentiation in vivo and in vitro as well as in retinal transplants and in retinoblastomas. More importantly, it should allow, for the first time, relatively easy studies of human retinal degeneration where it should be possible to distinguish degenerating cones from rods.

Supported by NIH grant #EY05284.

145.7 **TRANSMITTER-GATED MEMBRANE CURRENTS RECORDED FROM SYNAPTICALLY CONNECTED AND FROM ISOLATED BIPOLAR CELLS OF THE SALAMANDER RETINA.** **M. Wilson, D. Attwell*, P. Mobbs*, M. Tessier-Lavigne*. Dept. of Zoology, University of California, Davis, CA 95616, and Dept. of Physiology, University College London, UK.**

Isolated bipolar cells obtained from the salamander (Ambystoma) retina by enzymatic dissociation have been examined using whole-cell patch-clamping. Two morphologically indistinguishable classes of bipolar cell may be discriminated by their response to applied L-glutamate, the probable photoreceptor transmitter (Slaughter and Miller, J. Neurosci. 5:224, 1985). One class, provisionally identified as hyperpolarizing bipolar cells, showed a conductance and current noise increase to transmitter, while the other, provisionally identified as depolarizing bipolar cells, showed a conductance and current noise decrease. Glutamate-induced currents in both types of cell reversed at approximately 0 mV with the extracellular and patch pipette solutions described previously (Attwell, Bevan, Mobbs, Tessier-Lavigne and Wilson, J. Physiol. 360:19P, 1985).

A comparison of membrane currents measured from isolated bipolar cells with those from synaptically connected cells has been made by whole-cell patch-clamp recording of bipolar cells in retinal slices (Werblin, J. Physiol. 280:449, 1978) prepared in dim red light and viewed under infra-red illumination. Unequivocal identification of these cells as bipolar cells was facilitated by the addition of Lucifer Yellow to the patch pipette solution. Bipolar cells in retinal slices and those isolated from the retina showed similar time-dependent, voltage-gated currents evoked by depolarizing steps, however the input resistance of cells in slices was much lower than for isolated cells.

In response to illumination with a small spot, depolarizing bipolar cells in slices showed an inward current that increased with hyperpolarization and nulled at 0 mV.

145.8 COLOR-CODED HORIZONTAL CELLS IN THE TURTLE RETINA. R. Siminoff and T. Ohtsuka (SPON: C. Clemente) Dept. of Inform. Sci., Fac. of Eng., Tohoku Univ., Sendai and Dept. of Inform. Physiol., Natl. Inst. Physiol. Sci., Okazaki, Japan.

Three spectral response types have been found in horizontal cells (HCs) of many vertebrate retinas. These distinct responses, i.e., luminosity (L) type, and biphasic (B) and triphasic (T) chromaticity types, have been thought to be developed through a cascading pathway between three chromatic types of cone photoreceptors and three spectral types of HCs. Recently, however, morphological evidences against this cascading circuitry have been found in the turtle retina. 1) Spectral sensitivities of six morphological types of cones in the turtle retina were re-examined with 4 red, 1 green, and 1 blue cones (Ohtsuka, J. Comp. Neurol., '85). 2) Ribbon synaptic contacts between these 6 cones and 3 spectral types of horizontal cell were studied using intracellular injections of HRP and electron microscopy; both cell body and axon terminal of LHC receiving direct synaptic inputs from 30 to 60 cones of the three chromatic types, BHC receiving inputs from about 20 green cones, and THC receiving inputs from about 20 cones in the ratio 2 red and 1 blue cones (T. Ohtsuka & N. Kouyama, in preparation). 3) Furthermore, chemical synapses from the luminosity to the chromaticity type HC have also been shown (Kolb and Jones, J. Neurocytol., '84). Thus, based on these morphological pathways, a model of the cone-HC circuitry has been developed, and impulse responses simulated for various monochromatic stimuli at different mean illuminance levels. The linear model of the cone-HC circuit was developed, based on the retinal elements acting as low-pass filters (Siminoff, Biol. Cybern. '85). Intracellular responses were recorded from eyecup preparations of the freshwater turtles (Pseudemys scripta elegans and Geoclemys reevesii) using 20 msec monochromatic flashes covering the entire retina. The model gives simulated responses of the horizontal cells that are in excellent accord with the experimental data and (a) a simple wiring diagram consisting of direct hyperpolarizing inputs from the appropriate cones and a depolarizing input from the LHC acting as a voltage divider gives the basic responses patterns of the BHC and THC, and (b) a negative feedback circuit from LHC to cones and having the negative feedback gain directly proportional to the mean illuminance level are necessary features to account for deviations of the response patterns from the simple form. Thus, both BHC and THC are basically the same differing only as to the direct cone input.

145.9 RETINAL HORIZONTAL CELLS IN TURTLE:SPATIAL TRANSFER FUNCTION DEPENDENCE ON CONTRAST AND TEMPERATURE;ORIENTATION AND DIRECTIONALLY SELECTIVE CELLS. A.R.Adolph (SPON:E.Newman). Eye Research Institute and Harvard Medical School, Boston, MA 02114.

Luminosity horizontal cells(L-HC) of turtle retina are sensitive to stimulus spatial frequency. They exhibit two major classes of spatial transfer function(STF)in response to drifting sinusoidal gratings,low-pass and band-pass. High frequency asymptotes of both classes are similar,with upper corner frequency between ca. 0.3c/mm and 0.8c/mm. Slope of h.f. asymptote ranges from ca. -3dB/oct to -16dB/oct. The band-pass types are peaked in the frequency range of ca. 0.2c/mm to 0.5c/mm, and have l.f. aymptotes more gradual than their h.f.aymptotes, ca. 1dB/oct to 6dB/oct. The shape of STF is independent of contrast over a 20% to 60% range. High freq. asymptote,upper corner freq.,and band-pass peak freq. are relatively temperature insensitive. The major effect of temperature on STF is to increase l.f. asymptote slope as temperature decreases. STF may be modelled by the sum of two lowpass Gaussians, one positive wide band and one negative narrow band. STF exhibits lowpass or bandpass characteristics depending on relative widths and amplitudes of the two Gaussians. Line spread function(LSF) is the Fourier transform of STF and is a centrally peaked Gaussian with varying degrees of negative surround depending on the lowpass or bandpass character of STF. A retinal circuit which exhibits observed STF behavior includes surround inhibition of a central HC by lateral HC via a negative feedback pathway:surround HC-surround receptor-central receptor(via electrotonic coupling)-central HC. Since observed l.f. asymptotes have relatively small slopes, the surround effect is inferred to be small. As temperature decreases, synaptic responses are slowed and attenuated. There is a decrease in forward transmission, noticeable mainly in the central receptor-HC pathway, which results in increased l.f. asymptote slope. STF with 0.3c/mm corner freq.(1/2 power point) corresponds to LSF with 1/2 width of 0.6mm; STF with 0.8c/mm corner freq. corresponds to LSF with 0.5mm 1/2 width.

L-HC exhibit other spatially dependent properties, in some measure. Some are orientation sensitive with symmetrical, elongated response field patterns showing equal responses to sweeps in opposite directions. Others are directionally selective with unequal responses to sweeps 180° apart. (Supported by EY-03383).

145.10 **Rod suppression of cones and achromatic cone pathways in amphibian retina.** **Thor Eysteinsson* and T. E. Frumkes, Dept. of Psychology, Queens College of CUNY, Flushing, New York 11367.**

Intracellular recordings were obtained from all types of neurons in the superfused retina of mudpuppy and Xenopus. In general, a small test stimulus was used which was derived from a red light emitting diode which was was concentric with the recording electrode. Clearest data were obtained with sinusoidal flicker presented in the presence of diffuse background fields of different wavelength and irradiance. In dark adapted cones, achromatic horizontal and bipolar cells and in some third order neurons, backgrounds can enhance flicker responses by as much as 500%. This effect has an action spectrum which adheres quite closely to the pigment sensitivity of the green-absorbing (red-appearing) rods, and is maximal with flicker frequencies >5 hz and test stimuli 240-630 uM in diameter. This effect is much smaller or absent with much larger stimuli and/or with flicker frequencies <2 hz, and is unobserved in rods or in rod-driven responses from other neurons. The forgoing suggests that this effect at least partially reflects rod-modulation of horizontal cell feedback: by changing the ambient membrane potential of horizontal cells, rods control the horizontal cell influence upon cones. However, other types of evidence suggest the operation of a different and/or an additional mechanism: 1) although under mesopic conditions action spectra suggest that both rods and cones can mediate this background effect, the cone contribution is much smaller and the effect is totally absent in the light adapted retina; 2) in some individual hyperpolarizing bipolar cells and in cones, this effect can be observed both with background fields that depolarize and that hyperpolarize cones. Moreover in horizontal cells themselves, this effect is uninfluenced by large amounts of depolarizing and hyperpolarizing current injection; 3) This effect is not influenced by high concentrations of picrotoxin, although this substance is known to at least partially block horizontal cell feedback in Xenopus; 4) this effect cannot be observed in any second order neuron displaying a c-type s potential, even though these neurons receive input from the same cone-type as achromatic neurons showing the effect.

145.11 DOPAMINERGIC EFFECTS ON NEURAL MECHANISMS IN HUMAN VISION. S. Mitra,[1] I. Bodis-Wollner,[2] T. Hutton,*[3] and T. KRILE*[1]. Department of Electrical Engineering/Computer Science[1], Texas Tech University, Lubbock, Texas, 79409, Department of Neurology[2] and Ophthalmology, The Mount Sinai School of Medicine, New York, NY 10029 and Department of Neurology[3], Texas Tech University Health Sciences Center, Lubbock, Texas 79430.

The effect of dopamine deficiency on the spatiotemporal contrast response suggests altered neural mechanisms in the retina. We studied the effect of dopamine on human vision (Bodis-Wollner and Mitra, 1984). Patients with Parkinson's disease have a dopamine deficiency in the basal ganglia. They also demonstrate dopamine-dependent visual abnormalities However, the site of this abnormality is unknown.

An approach to understanding the mechanisms of the spatiotemporal response function has been proposed by Kelly (1969). The essential feature of his model is a cross-connecting filter controlling the contrast gain in the retinal network. According to this model, we calculated the gain function from the flicker sensitivities to uniform fields and counterphase gratings of 2 c/d in normal and Parkinsonians. The cross-connecting filters of the Parkinsonians demonstrated marked deviations from a normal filter in the cut-off temporal frequencies. Moreover, the cross-connecting filters showed a gain over a wider temporal frequency domain under a condition of severe dopamine deficiency. These results suggest a specific role of dopaminergic neurons in contrast gain mechanisms in human vision.

145.12 ERG HYPER-RESPONSES AND DELAYS IN 6 HYDROXYDOPAMINE INDUCED DOPAMINE DEPLETION IN THE RABBIT RETINA. P. Olivier*, F. Jolicoeur, J.R. Brunette*, G. Lafond*, and A. Drumheller*. Deptartments of Ophthalmology and Psychiatry, Faculty of Medicine University of Sherbrooke, Sherbrooke, Quebec Canada J1H 5N4.

Adult pigmented rabbits weighing approximately 2.5 kg were used to study the effect on the ERG of a selective degeneration of dopaminergic neurons in the retina. 6 hydroxydopamine (6OHDA) 300 µg in 0.3 cc of a 0.9% NaCl solution which also contained 600 µg ascorbic acid was injected intravitreally into one eye; the fellow eye, used as a control, was injected with the same amount of the physiologic solution containing 600 µg ascorbic acid alone. After 7 days ERGs were performed. Subsequently animals were sacrificed and retinas isolated for biochemical analysis. Retinal dopamine (DA), norepinephrine (NE) and serotonin (5HT) concentrations were determined by HPLC with electrochemical detection.

DA content in the treated retinas was reduced by almost 68% (6OHDA treated 0.06 ± 0.05 ng/mg wet weight, control 0.187± 0.11 ng/mg) P <0.01, while 5HT and NE levels remained unchanged (5HT 6OHDA treated 0.008 ±0.002 ng/mg, control 0.018± 0.17 ng/mg)(NE 6OHDA treated 0.075 ±0.033 ng/mg, control 0.088± 0.038 ng/mg).

ERG recordings showed marked increases in amplitude of both a and b waves (a wave 6OHDA treated 45.7 ±15.5 µV, control 22.1± 5.9 µV, P <0.01) (b wave 6OHDA treated 217.1± 63.1 µv, control 65 ±11.2 µv P <0.01). This increase in amplitude was accompanied by a significant increase in the implicit response time of both wave forms (b wave implicit time 6OHDA treated 137.8± 5.6 ms, control 105.3± 4.8 ms, P <0.01)(a wave implicit time 6OHDA treated 24.85 ±3.9 ms, control 21.5 ±1.9 ms, P <0.05).

Our results demonstrate that 300 µg 6OHDA produces a selective reduction in DA retinal levels in rabbits and that this decrease is accompanied by concomitant increases of a and b wave amplitudes and implicit response time.

146.1 NEURAL OSCILLATORS: PATTERN GENERATORS AND PATTERN INTERPRETERS. S.F. Gizster* (SPON: K.J. Thompson). Crump Inst. for Med. Eng., U.C.L.A., Los Angeles, CA 90024.

Behaviors have often been shown to be generated by multiple (and often apparently redundant or degenerate) oscillators, or single oscillators with several oscillatory mechanisms. The functional role of such multiplication of oscillators is sometimes unclear. In locusts a set of abdominal oscillators are found involved in abdominal ventilation. They are all phaselocked to a single master driving oscillator. The local oscillators sometimes misfire at random and hence seem to interfere with the execution of the simple motor program, in principle achievable by the metathoracic ganglion driver oscillator alone. What function do they perform which justifies these misfiring effects?

Arguing from engineering ideas, several possible functional uses of oscillators may be emphasized. Many of these uses are optimum when the oscillator is utilized as a phaselocked loop mechanism: (1) Oscillators are the best means for phase and frequency synthesis. (2) Real systems are affected by stochastic variations and circuitry involved in oscillatory behavior must cope with this problem. (3) Oscillators are an optimal way to detect and interpret periodic signals carrying AM, FM, or PM information. (4) Oscillators are the best way for timing integration of information from several sources.

Apparent redundancy of neural oscillators may often reflect these uses. Indeed these are possible functions of any neural oscillator, even if it acts alone. Neural oscillators may act as transponders i.e., systems to amplify and relay periodic information, either from central or peripheral signal sources. Oscillators may be used as demodulators for interpreting timing and phasing aspects of sensory or central signal sources. They may be used as synchronizers to time the collection and integration of signals from several sources. Finally, they may act as phase and frequency synthesizers (drivers of behavior), as in the classical central pattern generator view. A functional explanation of some multiple oscillator arrangements is possible in this framework, and suggests the possibility that some conventionally defined 'central pattern generators' may be peripheral pattern interpreters. In the freely behaving animal such oscillators might be under the complete control of afferent information.

The organization and functioning of the locust ventilatory system illustrates the transponder relay and integration notions of local oscillator function in a CPG. The local oscillators and their connections form components of a delay line multiplier circuit similar to those used in digital tape recorders. The ensemble optimally detects the metathoracic driver's ventilatory control signals, which have stochastic frequency flutter. The accuracy of this detection by the network outweighs the cost of occasional local failures of entrainment.

146.2 INTEGRATION OF EXCITATORY AND INHIBITORY SYNAPTIC DRIVE IN MOTOR NEURONS DURING PRODUCTION OF THE FICTIVE SCRATCH IN THE TURTLE. Gail A. Robertson and Paul S.G. Stein.
Biology Dept., Washington University, St.Louis, MO 63130.

Mechanisms involved in the production of the motor patterns for the three forms of fictive scratch in the turtle (J. Neurophysiol. 53:1533,1985) include both (1) synaptic excitation and inhibition of motor neurons and (2) intrinsic membrane properties that modulate motor neuron firing frequency. Intracellular injections of chloride ions (Cl) reveal that synaptic inhibition of each motor neuron is mediated by an increased conductance to Cl during the quiescent phases of its rhythmic motor output. In addition, synaptic excitatory and inhibitory conductances overlap in time during certain phases of the cycle such that the membrane voltage may be held depolarized relative to E(Cl) but below threshold, or depolarized relative to threshold but at a controlled, low frequency of firing. The control of membrane voltage at each point in the cycle in motor neurons of each pool is critical to the production of the appropriate motor pattern. Isolation of excitatory from inhibitory synaptic components, e.g. by local iontophoresis of strychnine, will reveal important aspects of the organization of premotor synaptic output during the production of fictive scratch motor patterns.

We observed membrane voltage trajectories during the fictive scratch in the absence of Na spikes by injecting QX222, a quaternary derivative of lidocaine that blocks voltage-sensitive Na channels (Strichartz, J.Gen.Physiol. 62:37, 1973), into hip protractor motor neurons (VP-HP). We found no evidence that QX222 affected synaptic conductances. For many scratch responses the depolarizing membrane voltage varied directly in time with the amplitude modulations of the integrated VP-HP motor pool burst. Stimulation of certain sites, however, elicited a dramatic depolarization that was poorly correlated in time with the more gradual amplitude modulations during the latter part of the integrated VP-HP burst. The motor output of the VP-HP pool does not reflect this putative synaptic drive, suggesting that intrinsic mechanisms may be important for limiting the firing frequency of the motor neuron and thus in shaping the output of the motor pool.

Some of the mechanisms by which motor neurons integrate synaptic drive to produce diverse motor patterns will follow from two lines of inquiry: (1) resolving synaptic drive into inhibitory and excitatory components in the absence of action potentials; and (2) altering intrinsic conductances, such as the Ca-dependent g(K), which serves to modulate firing frequency. These experiments may also lead to predictions regarding the organization of the interneuronal output underlying the different scratch motor patterns in the turtle, as well as changes in interneuronal activity that precipitate the transition from one motor pattern to another. Supported by NIH grant NS-15049.

146.3 AROUSAL BREATHING IN LAMPREYS: MODULATION OF THE RESPIRATORY PATTERN GENERATOR. D.F. Russell, C.M. Rovainen, and K.J. Thompson. Washington University School of Medicine, Dept. of Cell Biology and Physiology, St. Louis, Missouri 63110.

The breathing rhythm of lampreys is spontaneously active and drives brief synchronous bursts in the motorneurons of cranial nuclei VII, IX and X. These bursts can be modulated in amplitude, duration, and cycle period, either spontaneously or in response to a variety of sensory or central stimuli. Adult Lampetra fluviatilis, Ichthyomyzon unicuspis, Petromyzon marinus, and Lampetra lamottenii were used.

"Arousal breathing" is defined as an episode of enhanced frequency, amplitude, and duration of bursts in the respiratory motorneurons, continuing approx. 5 sec to minutes. It was studied in semi-intact preparations of the head, or the isolated brain or medulla. Arousal breathing was correlated with discharge in the medial reticular formation, in reticulospinal neurons, and in trigeminal motorneurons to the sucker. Episodes could occur spontaneously or in response to the following stimuli: (1) repetitive electrical stimulation of the floor of the isthmus; (2) stimulation of the optic nerve, or photic stimulation in head preparations; (3) repetitive stimulation of sensory branches of nerve V; (4) mechanical stimulation of the labyrinths or electrical stimulation of nerve VIII; (5) stimulation of the dorsal tracts of the spinal cord or intracellular stimulation of sensory dorsal cells in the rostral spinal cord. Arousal breathing is part of a general increase in brainstem activity, affecting a variety of motor systems.

Other types of modulation were also observed. (1) In head preparations from L.f., EMG bursts were sometimes absent in the caudal gill sacs (innervated by X motorneurons), or could wax and wane in amplitude over a time scale of minutes. In contrast, rostral gill sacs (innervated by VII and IX motorneurons) showed more consistent burst amplitudes. (2) Intracellular stimulation of 6/11 medullary dorsal cells suppressed or slowed fictive breathing in L.f.. (3) Stimulation of the IX-X roots, which contain afferents from the gill sacs, produced bilateral bursts of long duration ("coughs") and tended to suppress respiration, without producing prolonged discharages in the reticular and trigeminal systems.

Supported by the CNRS-France (DFR), USPHS NS09367 (CMR,KJT), and USPHS NS07541 (KJT).

146.4 SWIMMING IN APLYSIA BRASILIANA: BEHAVIORAL AND CELLULAR EFFECTS OF SEROTONIN. D.W. Parsons* and H.M. Pinsker. Marine Biomedical Institute, Depts. of Physiology and Psychiatry, UTMB, Galveston, Texas 77550

Aplysia brasiliana swim by flapping their bilaterally symmetrical parapodia. Continuous swimming can be elicited by suspending an animal above the substrate, but swimming is abolished by a bilateral lesion of the cerebro-pedal connectives (CPC). CPC-lesioned animals will, however, swim during tonic electrical stimulation of a cut CPC or after injection of serotonin (5-HT; approximate circulating concentration 10^{-5}M). Putative primary motoneurons for parapodial opening and closing are located in the pedal ganglia. We now describe the effects of 5-HT on the swimming motor program (SMP) in intact animals and reduced preparations; and on the modulation of the activity of parapodial opener and closer neurons in isolated brains.

When monitored from parapodial nerves in intact animals, 5-HT injections elicited the SMP; bath-applied 5-HT also elicited the SMP in semi-intact preparations. In isolated brains, bath-applied 5-HT induced smooth bursting in identified parapodial opener neurons monitored intracellularly.

To determine whether 5-HT might be acting directly on these putative motoneurons, we examined the effect of localized iontophoretic application of 5-HT to opener cell bodies. Iontophoretic 5-HT induced smooth bursting in opener neurons, but had no effect on closer neurons. These effects of iontophoretic 5-HT were qualitatively similar to those of tonic stimulation of the CPC: typically a brief period of tonic firing in the opener neuron preceded the development of smooth bursting. In contrast, intracellular depolarization of an opener neuron produced only tonic firing.

The period of the bursting elicited by iontophoretic 5-HT application was temperature dependent. Iontophoretic 5-HT gave smooth bursting even when synaptic input was blocked in high Mg^{++}. In addition, a surgically-isolated opener neuron soma also produced smooth bursting. These findings indicate that 5-HT induced bursting in these normally-silent parapodial opener neurons is the result of an endogenous pacemaker mechanism that is released by 5-HT, and is not attributable to phasic synaptic modulation. Thus, parapodial opener neurons can be classed as "conditional endogenous bursters".

To further evaluate the role of 5-HT in normal swimming, we examined the effect of methysergide (a 5-HT antagonist) and 5,7-DHT (a "cytotoxic" analog of 5-HT) in intact animals. Acute administration of methysergide, and chronic administration of 5,7-DHT produced a selective decrease in the amplitude of parapodial flapping. The frequency of flapping did not change.

146.5 DESCENDING AND PERIPHERAL MODULATION OF A LOCOMOTORY PATTERN GENERATOR. R.A. Satterlie. Dept. of Zoology. Arizona State Univ. Tempe, AZ. 85287

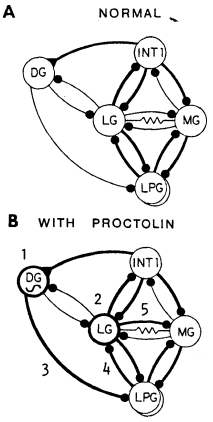
The primary circuit representing the pattern generator for swimming in the pteropod mollusc Clione limacina includes only four interneurons located in the paired pedal ganglia. The interneuronal circuit alternately excites and inhibits two antagonistic populations of wing motorneurons via monosynaptic connections. The central pattern generator will "free run" in the absence of cerebral and peripheral input, with a regular cycle frequency of 1-2 Hz. With intact cerebral ganglia, the swimming system will exhibit a variable cycle frequency ranging from 1 to 10 Hz. Increases above the basal frequency are associated with tonic depolarization of the pattern generator interneurons, and this input can be eliminated by severing the cerebro-pedal connectives.

Peripheral sensory input to the swimming system includes primarily inhibitory pathways activated during wing retraction (and associated swim inhibition). Inhibitory pathways include direct inhibitory inputs at both the interneuronal and motorneuronal levels and can be eliminated by severing the main wing nerve. Putative sensory structures include ciliary tufts and cones located on the leading edge, trailing edge and dorsal and ventral surfaces of the wings.

146.6 PROCTOLIN MODULATION OF THE GASTRIC OSCILLATOR IN THE LOBSTER STOMATOGASTRIC GANGLION. H.-G. Heinzel* and A.I. Selverston Dept. of Biol., Univ. of Calif. San Diego, La Jolla, CA 92093

The gastric oscillator of the lobster has previously been thought to operate as a network oscillator containing no endogenous bursters. It has been shown, however, that at least one neuron of the circuit (the dorsal gastric motoneuron DG) is capable of acting as a conditional endogenous burster. It shows, in rare cases, spontaneous slow regenerative depolarizations, which can also be induced by nerve stimulation (Hartline, D.K. and D.F. Russell, J. Neurobiol. 15:345,1984) or bath application of octopamine (Wadepuhl, M. and A.I. Selverston, in prep.). In all these cases, however, all other members of the gastric circuit are silent or show tonic firing, demonstrating that the weak output connections of DG are not strong enough to drive the network.

We show that bath application of proctolin to the stomatogastric ganglion, in a combined preparation, is able to influence DG so strongly that the whole gastric output pattern is changed. Nerve recordings and up to eight simultaneous intracellular recordings show that proctolin in concentrations as low as 10^{-12}M can change the normal gastric oscillator as follows: (1) DG which normally is mainly driven by the strong excitatory input from Interneuron 1, as confirmed by photoinactivation of INT 1, becomes an endogenous burster. (2) LG shows plateauing and (3) the DG to LPG inhibition becomes stronger leading to (4) disinhibition of LG from LPG. (5) The plateauing LG inhibits its synergistic motoneuron MG stronger than before causing a delay of its burst.



In addition, the action of proctolin on DG gives rise to output patterns where the medial tooth subsystem (DG and GM motoneurons) runs with different frequencies in relation to the lateral teeth subsystem (LG, MG, LPG) in vitro. Such patterns also occur in intact lobsters, as shown by endoscopic movie analysis of the teeth movement. The strong action of proctolin is also demonstrated by the finding that the gastric oscillator shows vigorous rhythmic activity, even with the stomatogastric nerve cut or blocked, a procedure which normally stops gastric cycling.

146.7 NEURONAL TARGETS OF THE MODULATORY ACTION OF PROCTOLIN ON THE PYLORIC SYSTEM OF THE STOMATOGASTRIC GANGLION OF PANULIRUS INTERRUPTUS. S.L. Hooper and E. Marder. Biol., Brandeis University, Waltham, MA 02254.

The neuropeptide, proctolin, is present in input fibers to the stomatogastric ganglion (STG), and bath-application of proctolin modifies the pyloric and gastric mill motor patterns generated by the isolated STG (Marder, Hooper & Siwicki, submitted). Proctolin (10^{-9} to 10^{-6}M) increases both the frequency of the pyloric rhythm and the amplitude of the membrane potential excursions in the anterior burster (AB), pyloric dilator (PD), and lateral pyloric (LP) neurons. In a few cases the amplitude of the membrane potential excursions in the ventricular dilator (VD) and the pyloric (PY) neurons was also increased. Additionally, in about 60% of the experiments, periodic interruptions of the pyloric rhythm which are associated with activation of the gastric system were seen. These interruptions change the firing rate and/or membrane potential excursions of all the pyloric network neurons. This suggests that proctolin is a neurally released modulator of the STG. In order to characterize in greater detail the physiological actions of proctolin, we have attempted to determine which of the neurons in the pyloric network of the STG are responsive to proctolin. We have used two general strategies: a) individual neurons were deleted from the STG using the Lucifer yellow photoinactivation technique (Miller & Selverston, Science, 1979) to determine whether the proctolin effects required the presence of that neuron in the circuit b) individual neurons were isolated from electrical and chemical synaptic inputs (by photoinactivation and pharmacological agents) to determine which isolated neurons are sensitive to proctolin.

Deletion of no single neuron removes all of proctolin's effects on the pyloric motor pattern. The excitatory action of proctolin persisted after deletion of the AB, VD, LP, or two PD neurons. Thus the effects of proctolin on the intact circuit are due to actions on at least two different cell types. Isolated AB neurons responded strongly to proctolin. The amplitude of AB membrane potential excursions and burst frequency were increased. Isolated LP neurons were weakly excited by proctolin. Isolated PD and PY neurons were relatively unaffected by proctolin. The interruption of the pyloric rhythm associated with gastric rhythm activation remained after deletion of any single neuron of the pyloric network.

We conclude that in the intact ganglion the increased frequency of pyloric cycling and amplitude of membrane potential excursions in the electrically coupled AB and PD neurons is due to proctolin's excitatory effects on the AB neuron. The dramatic excitation of the LP neuron in the intact ganglion can be explained by proctolin's dual excitation of both the AB and the LP neurons. Research supported by NS-17813 to E.M.

146.8 SYNAPTIC TRANSMISSION IN THE 7TH ABDOMINAL GANGLION OF THE SCORPION, HETEROMETRUS FULVIPES. P. Murali Mohan*, K. Yellamma* and K. S. Babu* (Spon: R. L. Klein). Dept. of Pharmacol. Toxicol, Univ. Miss. Med. Ctr., Jackson, MS 39216, and Dept. of Zoology, S.V. Univ., Tirupati 517502, India.

In H. fulvipes the 5th (last) metasomatic segment, bearing the telson, is capable of only upward and downward movements, while the other metasomatic segments are capable of sideward movements also. The 4th (4n) and 5th (5n) metasomatic segmental nerves and the telsonic nerve (Te), arising from the 7th (last) abdominal ganglion, innervate the musculatures of the 4th and 5th metasomatic segments and the telson respectively. The mobility of segments could arise in part from the functional organization of the neurones in the CNS, corresponding to the heterogeneity of innervation between the 4th and 5th metasomatic segments. This aspect was examined in the present study.

For this purpose, the general features of synaptic organization in the 7th abdominal ganglion were studied by electrophysiological and anatomical methods. Electrophysiological recordings from 5n, Te and 4n were made by using extracellular platinum hook electrodes, while stimulating the ipsilateral and contralateral connectives anterior to the ganglion. The anatomical organization of neurones in the ganglion was traced by the extracellular cobalt chloride back-filling technique of Pitman et al. (1973).

Stimulation of the ipsilateral connective elicited a burst of activity with both large and small action potentials in 5n, Te and 4n (Thresholds 2.2-4.0 V; conduction velocities 1-7 m/s; synaptic delays 0.5-1.2 msec). In contrast, contralateral stimulation induced very little activity in 5n and Te, with one or two small and labile action potentials (Threshold 3-5 V; conduction velocities 1-1.5 m/s; synaptic delays 4-4.4 msec). However, contralateral stimulation induced large bursts of activity in 4n (Thresholds 2.4-3.0 V; conduction velocities 1.5-6.5 m/s; synaptic delays 1.2-1.4 msec). The anatomical organization of the 7th ganglion indicated the possibility of synaptic contacts for 5n and Te only ipsilaterally. In contrast, the dendritic arborizations of motor neurones of 4n extended also to the contralateral side of the ganglion. This explains the higher activity in this nerve for both ipsi- and contralateral stimulations. The existence of ipsi- and contralateral connections seems to bear significance in the multidirectional movement of the 4th segment. In contrast, 5n and Te innervating the 5th segment and telson respectively seem to restrict their synaptic contacts predominantly to the ipsilateral side of the ganglion.

146.9 IDENTIFICATION OF CANDIDATE PEPTIDERGIC FEEDING REGULATORY NEURONS IN HELISOMA. A.D. Murphy, W,K. Stell, and K. Lukowiak*. Depts. of Medical Physiology and Anatomy, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Feeding in the snail, Helisoma, largely results from cyclical alternating contractions of protractor and retractor muscles. The motoneurons for both sets of muscles, as well as the central pattern generator which drives the motoneurons, are located in the buccal ganglia. The basic feeding behavior is relatively stereotyped. Intuitively, however, one would expect regulation of feeding to be complex, reflecting a variety of external and internal environmental signals. Previously, it has been shown that serotonin and dopamine could initiate or increase feeding patterned motor activity (PMA) in Helisoma. Recently, we found that micromolar concentrations of small cardioactive peptide B (SCP_B) similarly initiated or increased PMA of the buccal ganglia. In addition, micromolar concentrations of FMRFamide reduced spontaneous PMA to approximately one-third the control rate and 10^{-9}M FMRFamide completely suppressed PMA. We began the search for peptidergic regulatory neurons by immunofluorescence staining utilizing antisera to FMRFamide (from T.L. O'Donohue) and a monoclonal antibody to SCP_B (from S. Kempf, B. Masinofsky and A.O.D. Willows). A number of candidate regulatory neurons, which display FMRFamide-like or SCP_B-like immunoreactivity, have been localized with either their somata in the buccal ganglia or with axons projecting to the buccal ganglia. On the ventral surface of each of the paired buccal ganglia, there is a single neuron with FMRFamide-like immunoreactivity which stains very brightly, and often two to four other somata that are less immunoreactive. A cluster of about 30 small FMRFamide-like neurons are located on the dorsal surface of the buccal ganglia. Usually seven or eight pairs of SCP_B-like immunoreactive somata were found on the dorsal surfaces and an additional 4 or 5 pairs on the ventral surfaces of the buccal gnaglia. In addition, there are both FMRFamide-like and SCP_B-like immunoreactive axons in the cerebro-buccal connectives and there are peripheral neurons on the gut which show immunoreactivity to one or both of these peptides and project axons to the buccal ganglia. Characterization of these candidate regulatory neurons is in progress. Several of the SCP_B-like neurons in the buccal ganglia are primary effector neurons and have no effects on PMA. These include protractor motoneurons B18 and B19 and the salivary effector neuron B4. Preliminary experiments suggest that an SCP_B-like immunoreactive neuron (designated C2) with its soma in the cerebral ganglia and an axon projecting to the buccal ganglia increases PMA. A definite demonstration awaits double staining of the physiologically active neuron with Lucifer Yellow followed by the antibody to SCP_B and a rhodamine conjugated second antibody. Supported by AHFMR and MRC.

146.10 POSSIBLE MODULATORY ROLES OF ARGININE VASOTOCIN ON FEEDING MOTOR OUTPUT IN HELISOMA. J.E. Richmond, A.G.M. Bulloch, A.D. Murphy and K. Lukowiak. Department of Medical Physiology, University of Calgary, Calgary, Alta., Canada T2N 4N1.

The importance of modulation of motor activity by neuroactive peptides is becoming increasingly evident. Our laboratories have examined the roles of peptides in the context of two well-defined molluscan behaviors: (1) the gill withdrawal response of Aplysia and (2) feeding, primarily in Helisoma. It was found that food satiated Aplysia had a suppressed gill withdrawal reflex. Superfusion of arginine vasotocin, (AVT) over the abdominal ganglion of Aplysia produced a suppression of the gill-withdrawal reflex which paralleled the effects of satiation. This suggested the possibility that AVT might be a molluscan "satiety factor" with effects on the expression of feeding behavior. Feeding in Helisoma occurs readily in dissected preparations and is known to be modulated by both peptides (SCP_B and FMRFamide) and monoamines (5-HT and dopamine). Therefore we began to examine the role(s), if any, of AVT on feeding in Helisoma.

In the present study immunohistochemical evidence suggested two possible pathways by which an AVT-like substance might influence feeding patterned motor activity (PMA). The central pattern generator underlying feeding motor output is known to be in the buccal ganglia. These ganglia receive descending inputs from the central ring of ganglia via the cerebro-buccal connectives (CBC) and receive peripheral feedback via the buccal ganglionic nerve roots. Indirect immunofluorescent staining with an AVT antibody (provided by K. Lederis) showed a single pair of brightly stained somata on the ventral surfaces of the pedal ganglia. These neurons have a dendritic arborization in the pedal ganglia and axons that circumnavigate the central ring. They also have extensive arborizations in the cerebral ganglion neuropil but no AVT-like processes were seen in the CBCs. Thus any effects of these cells on feeding PMA must be indirect. There are also AVT-like processes projecting to the buccal ganglia from the gut via the gastric nerves which could directly modulate PMA.

Preliminary pharmacological studies suggest that AVT may produce a long-latency stimulation of feeding PMA in Helisoma as indicated by intracellular recording from identified buccal neurons. These effects, however, were not mediated by activation of the identified modulatory serotonergic neurons C1. Further studies are in progress. Supported by AHFMR and MRC (Canada).

146.11 BURST-ORGANIZING MECHANISMS DIFFER IN TWO CLASSES OF NEURONS IN THE LOBSTER CARDIAC GANGLION. A. Berlind. Biology Dept., Wesleyan University, Middletown, CT 06457.

Cardiac ganglia isolated from the hearts of lobsters (Homarus americanus) generate repetitive bursts of nerve impulses by a mechanism which involves both network interactions and endogenous burst-organizing potentials ("driver potentials", DPs). Tazaki and Cooke have presented evidence that a DP mechanism exists in each of the constituent neurons of the system (4 small "pacemaker" cells and 5 larger motorneurons) and that the DP in motorneurons is a slow depolarizing potential, localized to a region near the soma, with most of the inward current carried by calcium ions. The data presented here provide indirect evidence, from experiments in altered ionic media, that the DP mechanism in lobster pacemaker neurons is qualitatively or quantitatively different from that previously described in crab and lobster motorneurons. When a lobster cardiac ganglion is superfused with saline containing 18 mM manganese, which completely suppresses DPs in the motorneurons, the ganglion continues to generate spontaneous bursts, which are reduced in amplitude and frequency as compared to the activity in normal Mn^{++}-free saline. When the level of calcium in the perfusion fluid was reduced from the normal level (26 mM) to 1.3 or 2.6 mM (5 or 10% of normal), motorneuron DPs were eliminated but very long duration bursts, characterized by high-frequency interburst action potential discharge, were generated. Clear bursting behavior persisted in the intact ganglion even when all Ca^{++} was eliminated from the perfusion fluid. Three experimental modifications of the isolated ganglion preparation suggest that the prolonged bursts observed in low Ca^{++} salines reflect the persistence of the burst-generating capabilities of the small pacemaker neurons under conditions which suppress the large cell DPs. 1) In ganglia in which the 3 anterior motorneurons are functionally separated from the small cells by a tight silk ligature around the ganglionic trunk, low Ca^{++} saline eliminated bursting anterior to the ligature; burst duration in the 2 posterior motorneurons, which retained connections to the pacemakers, was prolonged. 2) When the two ends of the ganglion were placed in two independent perfusion pools, bursting was prolonged when only the small cells were exposed to low Ca^{++} saline, but not when only the large cells were so treated. 3) If the discharge of the motorneurons was silenced by perfusion with tetrodotoxin in such a two-pool preparation, the resultant small cell bursts were prolonged and intensified in low-Ca^{++} saline. Thse results suggest that the inward current responsible for DP generation in the small cells, unlike that in the motorneurons, includes a substantial contribution from an ion other than calcium.

146.12 SLOW OSCILLATIONS IN MEMBRANE POTENTIAL OF INTERNEURONS THAT CONTROL HEARTBEAT OF THE MEDICINAL LEECH. Edmund A. Arbas and Ronald L. Calabrese Biological Laboratories, Harvard University, 16 Divinity Ave. Cambridge, MA. 02138.

The heartbeat rhythm of the leech arises from the activity of a network of interneurons, the HN cells, of which there is a pair in each of the first 7 segmental ganglia. HN neurons of the 3rd and 4th ganglia, HN cells (3) and (4), are elements of the timing oscillator that generates the beat rhythm, and also control the firing of motorneurons that deliver the rhythm to the muscular hearts. The HN(3) and (4) cell pairs oscillate through their endogenous properties and strong reciprocal inhibitory connections. The premotor HN(7) neurons follow the beat rhythm that is delivered to them synaptically but do not contribute to its generation. All of these HN cells have an activity rhythm in which "slow" depolarizations of membrane potential capped by firing of fast action potentials alternate with hyperpolarized silent periods dominated by synaptic inhibition from other HN cells of the network. The slow oscillation spans about 10 mV and is centered around a mean between -45 and -50 mV.

The ionic basis of the activites of these HN cells was studied by intracellular recording and stimulation in isolated ganglia bathed by salines of various compositions. Replacement of Na^+ by Tris in the saline eliminated the production of fast action potentials, led to hyperpolarization of membrane potential to values near -60 mV and revealed the ability to form a plateau potential with a threshold near -55 mV and a peak near -30 mV. The plateau potential is prominently activated upon release from hyperpolarizing injected currents. Plateau formation was found to be accompanied by an increase in membrane conductance. Plateaus were enhanced by elevation of Ca^{++} concentration in the saline or by replacement of Ca^{++} by Ba^{++}. They could also be formed when Sr^{++} replaced Ca^{++}, but were blocked by addition of Mg^{++} or Co^{++} to the saline with the latter ion being effective at lower concentrations. We conclude that a voltage sensitive inward current carried by Ca^{++} generates the plateau.

Both the HN(7) neurons and the timing oscillator interneurons exhibited plateau potentials. In elevated Ca^{++}, HN interneurons of the timing oscillator additionally exhibited stable oscillations of membrane potential that were independent of Na^+-mediated fast action potentials. They depended on the production of plateaus, graded reciprocal inhibitory transmission, and escape from inhibition by the hyperpolarized neuron. Transitions in the state of the two neurons in each cycle were effected by the activation of a plateau potential in the previously inhibited neuron that terminated the plateau and caused hyperpolarization in the previously depolarized neuron. 146.13 **COMPUTER SIMULATION OF THE LEECH HEART MOTOR NEURON (HE-CELL).** E. De Schutter* (SPON: European Neuroscience Association) and R. L. Calabrese. Dept of Neurology, Univ. Hosp. of Antwerp, B2520 Edegem, Belgium and Biological Laboratories, Harvard Univ., Cambridge MA 02138.

A computer model of the motor neuron (HE-cell) that drives the heart tubes of the leech *(Hirudo medicinalis)* has been developed with the Nodus simulation software (*Neurosc. Lett., S. 18:* 154, 1984). The model contained 51 compartments, with 15 dendrites and one active site in the exon at a distance of about 300 µm from the soma. Nerve crush experiments showed that in contrast with other leech motor neurons, the HE-cell action potential is generated inside the ganglion. The passive membrane parameters were based on experiments by Peterson (*Biophys. J. 43:* 53, 1983), the specific membrane resistivity was 35 kΩ cm^2 and the capacitance was 2.0 µF/ cm^2, cytoplasmic resistivity was 300 Ω/cm. The voltage dependent conductances at the active site were described by Hodgkin-Huxley like equations. The equations for an inward Na^+-current and for two outward K^+-currents (an A-current and the delayed rectifier) were based on measurements by Connor and Stevens (*J. Physiol. 213:* 31,1971). The model made an accurate simulation of an isolated HE-cell possible.

The electrotonic coupling of bilateral HE-cells has been examined. Five dendrites of the HE-cells were connected through identically shaped compartments with a diameter of 0.75 µm. The frequency coupling of this model and its response to DC current was similar to the values obtained by Peterson (1983). The coupling had only a small influence on cells that were firing in phase (a small decrease in firing frequency). When the cells were not in phase, the coupling drove them in phase by decreasing the difference (at a rate of up to 10% of the phase difference per cycle). This tendency to couple the firing of the two cells was not observed in *in vitro* experiments (using a low Cl^- bathing solution to block the interneuron generated IPSPs). It is possible that the coupling was masked by the jitter of the cells or by their difference in firing frequency. The effect of a difference in firing frequency on the coupling will be simulated. The A-current could be important in the coupling of action potentials observed in the simulation, changes in ion currents will be examined.

Recent experiments have shown that a small Ca^{++}-conductance exists in HN-cells (interneurons of the circuit that generates the heart rhythm) and in HE-cells (Arbas, abstract in this volume), but it is not clear if Ca^{++}-currents play a role in the bursting behaviour of HE-cells in a quiet leech. Simulations of the bursting of HE-cells, caused by barrages of IPSPs, will be done to examine the importance of different ion currents during bursting.

TRANSMITTERS IN INVERTEBRATES II

147.1 ACETYLCHOLINE CAUSES SQUID IRIDOPHORE CELLS TO BECOME IRIDESCENT IN VITRO. R.T. Hanlon* and K.M. Cooper* (SPON: J.E. Bottenstein). Marine Biomed. Inst., Univ. Texas Med. Br., Galveston, TX 77550.

Color change in cephalopods is produced by neurally controlled dermal chromatophore organs that are underlain with iridophore cells. Based upon the first evidence that some squid iridophores may be physiologically active in vivo (Hanlon, R.T., Malacologia 23(1):89, 1982), we now show that acetylcholine (ACh) applied in vitro changes the optical properties of the iridosomal platelets to produce iridescence. Excised layers of iridophores were prepared from the dorsal mantle of the bay squid Lolliguncula brevis. Application of $2.75x10^{-7}$M ACh in artificial sea water (500mM NaCl, 10mM KCl, 12mM $MgCl_2$, 10mM $CaCl_2$, either unbuffered or buffered with 4mM Hepes pH 7.4) changed iridophore cells from colorless or non-iridescent blue to bright iridescent red and gold when viewed with incident light. TEM examination of the cells revealed that there are ultrastructural differences within the platelets that can explain these different optical properties. The effect of ACh-induced iridescence was reversed by washing with artificial sea water. Equimolar atropine blocked the ACh response, while tubocurarine did not, suggesting the involvement of muscarinic receptors.

The excised iridophore preparations also contained a muscle layer as well as some nerve fibers embedded in the connective tissue. Squid iridophores have never been shown to have muscle or nerve connections, but it is possible that ACh acts upon one of these other tissue components, with a secondary effect on the iridophores. However, KCl applied in a concentration (80mM) that caused chromatophore muscle contraction had no effect on the ACh response, nor did 10^{-7}M tetrodotoxin. We suggest that the iridophores themselves may be the target cells. Calcium appears to affect ACh-induced iridescence. Treatment of iridophores with ACh in Ca-free medium resulted in a brief appearance of red iridescence which quickly faded. Verapamil ($2x10^{-4}$M), a calcium channel blocker, inhibited to a great degree the effect of ACh on these cells.

ACh is present naturally in the dorsal mantle iridophore layers at levels of approximately 1mM ACh/mg protein. Our evidence suggests the possibility of cholinergic, non-synaptic control of the iridophores similar to that found in sea urchin tube feet (Florey, E.F. and Cahill, M.A., J. Exp. Biol. 88:281, 1980). Such a system would be a novel mechanism of color change and would complement the neurally controlled chromatophores in producing complex body patterns in cephalopods.

147.2 INGESTIVE BEHAVIOR DECREASES THE SEROTONIN IN THE LEECH C.N.S. C.M. Lent. BioMed, Brown Univ., Providence RI 02912.

In the medicinal leech, the impulse activity of identified serotonin (5-HT) neurons is sufficient for pharyngeal peristalsis, biting and salivation: physiological components of ingestion. Neural 5-HT is necessary for these components and the expression of feeding behavior. Serotonergic effector neurons are synaptically excited into phasic activity by a stimulus which initiates ingestion: the localized warming of the prostomium by 2-5°C. To determine whether the simultaneous activation of these neurons measureably decreases 5-HT, ganglia were dissected from leeches (0.5±0.1g) before and within 3 hours of ingesting a blood meal. Serotonin was extracted and measured by HPLC-EC throughout the 32 segments of the leech. The C.N.S. comprises a supraesophageal ganglion (non-segmental), a subesophageal ganglion (SubEG, 4), iterated segmental ganglia (g1-g21) and a caudal ganglion (7).

Anterior ganglia from the SubEG to g10 contain 13-17 pmol 5-HT/ganglion, the level decreases to 8.5 pmols in g17-20 and to 2.5 in the caudal ganglion. The 2 fold rostro-caudal gradient in 5-HT cell number/ganglion accounts only partially for this 5-6 fold neurochemical gradient. Serotonin is reduced significantly following the 30 min blood meal in all ganglionic samples, except the caudal ganglion. The decreases range from 13 to 35% and are greatest anteriorly.

Warming the lip synaptically activates the Retzius cells (RZ) at all times, but in spring and summer, it evokes high-frequency impulse bursts. To examine the effects of bursting upon the 3-5 pmol of 5-HT in RZ, physiological preparations were thermally stimulated 8-10 times in 30 min experiments. Each 5°C stimulus lasted 2 min and evoked bursts, after which RZ somata were dissected. The 5-HT of 6 RZ from 3 leeches was reduced by at least 95%, suggesting that bursting rapidly mobilizes 5-HT from somata of effector neurons.

Ingesting blood averaging 890% of their weight distends leeches, terminates ingestion and inhibits biting for many months. Body wall distension tonically hyperpolarizes and inhibits RZ reversibly. To examine the effects of distension upon serotonin levels, 10 leeches were fed satiating blood meals. The body walls of 5 were cut and the blood removed from their crops, while the posterior suckers of the remaining 5 were cut similarly. After 6 weeks, 5-HT was extracted and measured from g4, g7 & g8. Leeches which were distended had 19.9±0.6(9) pmol 5-HT/ganglion. Leeches whose blood was removed and were not distended had 25% more, 24.2±1.2(9) pmols ($p<0.05$, t test).

The reduction in ganglionic serotonin by ingestion can be attributed primarily to decreases in serotonin from the somata of effector neurons. These data indicate that synaptic activation mobilizes their serotonin into the periphery and suggest that their inhibition during distension may hinder serotonin synthesis.

147.3 DEMONSTRATION OF STEREOSELECTIVE L-[^{3}H]QNB BINDING SITES IN NERVOUS TISSUE OF APLYSIA CALIFORNICA AND PLEUROBRANCHAEA CALIFORNICA. T.F. Murray, G.J. Mpitsos, J.F. Siebenaller* and D.L. Barker. Coll. of Pharmacy, Coll. of Oceanography and Dept. of Biochemistry and Biophysics, Oregon State Univ., M.O. Hatfield Marine Science Center, Newport, OR 97365.

In order to ascertain whether muscarinic (M) cholinergic mechanisms may be present in the nervous system of gastropod molluscs, we have characterized the specific binding of the M antagonist L-[^{3}H]QNB in membranes from Aplysia and Pleurobranchaea. L-[^{3}H]QNB bound with a high affinity (K_d=0.77±0.08 nM) to a single population of specific sites (B_{max}=47±2.1 fmol/mg prot.) in nervous tissue of Aplysia. An investigation of the subcellular distribution of L-[^{3}H]QNB binding sites demonstrated that the specific binding was enriched in fractions consisting predominantly of synaptosomes together with mitochondria. The specific binding of L-[^{3}H]QNB was displaced stereoselectively by the enantiomers of benzetimide, dexetimide and levetimide. The pharmacologically active enantiomer, dexetimide, was greater than 100x more potent than levetimide as an inhibitor of L-[^{3}H]QNB binding. Moreover, the M cholinergic ligands, scopolamine, atropine, oxotremorine and pilocarpine were effective inhibitors of specific L-[^{3}H]QNB binding. In contrast, the nicotinic receptor antagonists, decamethonium and d-tubocurarine, were virtually inactive as inhibitors of specific binding. The pharmacological characteristics of the L-[^{3}H]QNB binding site provide evidence for classical M receptors in Aplysia nervous tissue. The physiological relevance of the dexetimide-displaceable L-[^{3}H]QNB binding site was supported by the demonstration of the sensitivity of the specific binding to thermal denaturation. We have also demonstrated dexetimide-displaceable L-[^{3}H]QNB binding sites in nervous tissue of Pleurobranchaea. At a concentration of L-[^{3}H]QNB of 1.8 nM, nervous tissue of Pleurobranchaea bound 62 fmol/mg prot. The characteristics of the Aplysia L-[^{3}H]QNB binding site are in accordance with studies of numerous vertebrate and invertebrate tissues indicating that the M cholinergic receptor has been highly conserved through evolution. Toward the goal of establishing a behavioral assay for M action, we have preliminary evidence showing that M agents, when injected into Pleurobranchaea in doses that do not affect normal feeding, affect the ability of animals to learn food-aversion behavior.

147.4 HPLC AND IMMUNOCYTOCHEMICAL ANALYSES OF SEROTONIN IN HERMISSENDA CENTRAL NERVOUS SYSTEMS. S.Auerbach, L.Grover*, and J.Farley. Prog. in Neurosci. and Behav., Princeton Univ., Princeton, NJ.

Associative pairings of light and rotation result in pairing-specific long-term reductions of two K^+ currents (I_A and $I_{K\text{-}Ca}$), and enhancement of a voltage-dependent calcium current (I_{Ca}), in Hermissenda Type B photoreceptors. Pharmacological evidence indicates that serotonin (5-HT) effects these same ionic conductance changes. We have attempted to determine whether 5-HT is a neurotransmitter which may mediate significant portions of the associative neural and behavioral changes. We have asked: 1) Is 5-HT localized within areas rich in fine processes and cell bodies presynaptic to B cells, 2) Is 5-HT released during training, 3) Do 5-HT reuptake inhibitors substantially reduce short-term electrophysiological changes of B cells resulting from in vitro simulations of associative training?

Optical ganglia were dissected from 6 animals, and monoamines assayed by HPLC-EC. Sensitivity was 5-10 pg for NE, DA and 5-HT. 5-HT content was 33 ng/mg protein in optic ganglia and 95 ng/mg in remaining brain (mean of 3 replications). DA was 11 ng/mg in optic ganglion and 287 ng/mg protein in remaining brain (mean of 4 replications). NE was below detection limits in samples pooled from 6 optic ganglia as well as whole brains. 5-HT release was measured after paired light and rotation of whole-mounted brains. Whole brains released 17 ng/mg protein during a 2 hr incubation in ASW containing 10uM imipramine a 5-HT reuptake blocker. Experiments to determine if associative and random pairings have different effects on 5-HT release are in progress.

Location of 5-HT cell bodies and processes was determined by whole-mount immunocytochemistry using a fluorescent 2° antibody. The higest densities of stained cell bodies were observed in pedal ganglia, including a giant cell (LPl). Processes were seen leaving all 3 major pedal nerves. Fewer cell bodies were stained in cerebro-pleural ganglia (PG). One large symmetrical cell body was stained which sent a process out the buccal nerve. Many fibers stained in the area of the CPG where photoreceptor terminals are located.

In vitro conditioning effects were substantially reduced in the presence of 10uM imipramine. Five in vitro conditioning trials in normal ASW produced a mean cumulative depolarization of 6.8 mV (n=4). In 10uM imipramine ASW, cumulative depolarization was 1.0 mV (n=3) but B cells were on average 6.0 mV more depolarized prior to conditioning. B cell EPSP and caudal hair cell IPSP amplitudes and durations appeared to be enhanced by imipramine. These results support the hypothesis that 5-HT is a transmitter involved in long-term training-induced changes in B photoreceptor light responses. Supported by NSF BNS 8316707 to JF.

147.5 CYCLIC AMP, A COMMON BIOCHEMICAL LOCUS FOR THE EFFECTS OF 5-HT AND SCP_B BUT NOT FMRFamide IN TAIL SENSORY NEURONS OF APLYSIA K.A. Ocorr, M. Tabata*, and J.H. Byrne, Univ. of Texas Med. Sch., Houston, Texas 77225.

Current evidence supports a role for serotonin (5-HT) and cAMP in modulating the electrophysiological properties of sensory neurons mediating defensive tail withdrawal in Aplysia. Specific serotonergic inputs to sensory neurons, however, have not been demonstrated. Recently, a neuroactive peptide, small cardioactive peptide (SCP_B), has been isolated from Aplysia neural tissue. SCP_B is present in the ganglion containing the tail sensory cells and has been shown to mimick the effects of 5-HT (Lloyd, et al, 1984; Castellucci, et al, 10, 510, 1984; Lukowiak, et al, 1984). It is possible that 5-HT is acting as an agonist for the natural, peptidergic transmitter; alternatively, there may be parallel aminergic and peptidergic pathways with similar actions. As a first step in distinguishing between these possibilites we previously compared the ability of 5-HT to enhance cAMP levels in isolated clusters of sensory neurons with that of SCP_B. Exposure of clusters to 5uM 5-HT or 5 uM SCP_B produced identical (34 ± 11%, N = 12; and 32 ± 12%, N = 16) increases in the cAMP content. 5-HT and SCP_B produced similar inward currents associated with decreases in input conductance in voltage clamped sensory neurons. In contrast, another neuroactive peptide, FMRFamide, had no effect on the cAMP content of isolated clusters but had opposite electrophysiological effects of 5-HT on membrane currents.

We have examined the effect of 5uM SCP_B on cAMP levels in the presence of 5uM 5-HT in order to determine whether these transmitters utilize the same receptors to stimulate cAMP production. Under these conditions SCP_B produced an additional 45 ± 22% (N = 10) increase in the cAMP content of isolated clusters compared to 5-HT alone. This increase is similar to that observed in response to treatment with SCP_B alone. By contrast, increasing the 5-HT concentration by 5uM (to 10uM) resulted in a 37 ± 9% (N = 12) increase in the cAMP content, a net increase of only 3% compared to 5uM 5-HT alone. These data indicate that 5-HT and SCP_B exert their effects via separate receptors and support the possibility of parallel pathways that regulate cAMP levels in the sensory neurons. We are examining the effects of their combined presence on the electrophysiological properties of these cells.

We also examined the combined effects of 5uM FMRFamide and 5uM 5-HT. While FMRFamide produced no change in basal levels of cAMP it was possible that it could modulate the effects of 5-HT on cAMP levels. We found that the addition of FMRFamide neither increased nor decreased the cAMP content expected in response to 5-HT alone (N = 10). Therefore, it appears that the electrophysiological effects of FMRFamide and those of 5-HT do not share a common biochemical basis.

147.6 **CO-LOCALIZATION OF α-BAG CELL PEPTIDE AND EGG-LAYING HORMONE IN BAG CELL NEURONS OF APLYSIA CALIFORNICA.** S.-M. Pulst^{+*}, D. Gusman$^{*=}$, B.S. Rothman$^+$ and E. Mayeri$^{+=}$. $^+$Dept. of Physiology, University of California, San Francisco, CA 94143 and $^=$Dept. of Basic Sciences, California College of Podiatric Medicine, San Francisco, CA 94115.

The bag cells neurons of Aplysia californica synthesize and release two or more peptide transmitters derived from a common 29 kD precursor protein. It is not known if all bag cells process this precursor uniformly or if alternative processing occurs. We studied the distribution of two of these transmitters, α-bag-cell-peptide (α-BCP)(1-9) and egg-laying hormone (ELH), using an immunocytochemical method that allowed simultaneous visualization of two antigens.

Highly specific antibodies (Ab's) were raised in goat against the N-terminal(1-12) portion of ELH and in rabbit against α-BCP(1-9). Both Ab's were affinity purified. Paraformaldehyde fixed tissue sections were incubated with a mixture of the two primary Ab's, rinsed and stained with a mixture of FITC-sheep-anti-goat-IgG and TRITC-sheep-anti-rabbit-IgG. Absorption controls with 50-100 uM ELH, α-BCP(1-9), α-BCP(1-8) and peptide A showed that the Ab's reacted only with ELH or α-BCP(1-9), respectively. The secondary Ab's reacted only with goat-IgG or rabbit-IgG. We also developed a solid phase assay for crossreactivity. Nanogram amounts of peptides were spotted on filter paper, stained with the primary Ab's and visualized with the direct peroxidase method. These studies confirmed the results of the absorption controls and also demonstrated that neither Ab reacted with the 29 kD precursor as purified from bag cell extracts.

The pattern of immunoreactivity (IR) in tissue sections was highly specific. Intense IR for α-BCP and ELH was seen in bag cell bodies and processes, but not in other cells of the ganglion. All cell bodies within the bag cell cluster stained, although some cells showed more IR for α-BCP or ELH. Immunoreactive processes extended into the connective tissue sheath overlying the abdominal ganglion, into the pleurovisceral connectives and into the neuropil of the ganglion. ELH and α-BCP IR were co-localized in most processes. However, a small percentage of processes stained for only one of the peptides. In the cerebral ganglion cells that were immunoreactive for ELH also showed IR for α-BCP.

These results suggest that most of the bag cells process the ELH/BCP precursor uniformly, but that alternative processing may occur in a small subpopulation. The precursor is probably also expressed in the cerebral ganglion.

Supported by NIH grants NS16033 and NS16490.

147.7 CO-RELEASE OF FIVE PEPTIDES, ELH, AP, α-, β- and γ-BCP, DERIVED FROM A COMMON PRECURSOR PROTEIN OF THE BAG CELLS OF APLYSIA. B.S. Rothman, K.A. Sigvardt and E. Mayeri. Dept. of Physiology, Univ. of Calif., San Francisco, 94143

A burst discharge of impulse activity in the bag cell neurons initiates egg-laying behavior in Aplysia. Based on biochemical and DNA sequence studies, the bag cells synthesize a precursor protein that encodes one copy each of as many as 11 cleavage products. Three peptides, ELH, AP and α-BCP are known end-products of the bag cell precursor. They are present in bag cell extracts, and ELH and AP are known to be released by bag cells. ELH and α-BCP are neurotransmitters in the abdominal ganglion, and ELH also functions as a neurohormone that releases eggs from the ovotestis. Other predicted end-products of the ELH/BCP precursor include β-, γ-, and δ-BCP.

To further define the end-products of precursor processing and explore the role of bag cell peptides as chemical messengers, we tested their release when the bag cells were electrically stimulated. An intact abdominal ganglion was placed in a low dead-volume chamber and perfused steadily with sea water containing protease inhibitors. Perfusates were pooled from 6 ganglia; they were analyzed and further purified by a reverse-phase HPLC system that can detect as little as 10 ng of peptide. Perfusate equivalent to a single bag cell burst, collected 0-30 min before the initiation of a burst, showed no material except protease inhibitors. An equal amount of perfusate collected 0-30 min after the start of a burst showed 20 additional peaks of material. Based on comigration on HPLC with standards, six peaks of material were identified: ELH, AP, α-BCP(1-9), its N-terminal fragment α-BCP(1-8), β-BCP and γ-BCP. The amount of each peptide recovered from 8 bag cell bursts was (nM): 4.6, 7.3, 0.5, 0.05, 0.9 and 2.0, respectively. Recovery of the α-BCPs, unlike the other peptides, was dependent on the presence of a specific aminopeptidase inhibitor in the perfusion medium. These six peptides were also present in bag cell extracts, and far more α-BCP(1-9) was found than α-BCP(1-8). Other, unidentified peptides were present in both perfusate and extracts. In contrast, δ-BCP was not found in perfusate nor in extracts.

This study shows that 1) five peptides, ELH, AP, α-BCP(1-9), β- and γ-BCP, encoded on the ELH/BCP precursor are co-released, 2) these five peptides, but not δ-BCP, are end-products of bag cell precursor processing; their locations on the precursor indicate that a minimum of 3 additional peptides are required to entirely account for precursor processing, and suggest that δ-BCP is processed as a C-terminally extended peptide, 3) peptides released by a single bag cell burst can be detected directly by analytical HPLC without resorting to more sensitive, but overly specific methods such as RIA, 4) large amounts of released peptide can be recovered by preparative HPLC; novel peptides can potentially be identified by amino acid sequencing. Supported by NIH grant NS16490.

147.8 **CO-LOCALIZATION OF THE SCPs AND FMRFamide TO MOTOR NEURONS INNERVATING APLYSIA BUCCAL MUSCLE.** **P.E. Lloyd*, M. Frankfurt, I. Kupfermann, K.R. Weiss.** Pharmacol. & Physiol. Sci., Univ. Chicago, Chicago, IL 60637; Neurobiol. Behav., Columbia P. & S., New York, NY 10032.

Three procedures were used to confirm the presence of authentic FMRFamide (Fa) in Aplysia buccal ganglia: i). Bioassay; fractions from reverse phase (RP)-HPLC of buccal ganglia extracts were assayed with a new and sensitive bioassay (isolated snail esophagus). The major peak of activity had the same retention time as Fa. ii). Radiolabeling; buccal ganglia were labeled with ^{35}S-methionine, extracted and run on one mode of RP-HPLC. The labeled material with the same retention time as Fa was then sequentially run through a second mode of RP-HPLC and ion-exchange HPLC. The retention time of the labeled peak in the final two HPLC runs was identical to Fa iii). Immunocytology; staining of buccal ganglia sections with Fa-directed antisera revealed immunoreactive fibers and varicosities, numerous small neurons, and several large neurons which are part of a cluster of cells known to be motor neurons to buccal muscle. Staining of fibers and varicosities in buccal muscle was also observed. These results confirm that authentic Fa is present in the buccal ganglia of Aplysia. The two Small Cardioactive Peptides (SCP_A & SCP_B) were originally purified from Aplysia tissue and SCP-like immunoreactivity has also been observed in the large buccal motor neurons (Lloyd et al., J. Neurosci., In Press). To confirm the presence of Fa and the SCPs in the large motor neurons, individual somata were dissected from ganglia labeled with ^{35}S-methionine in the presence of colchicine (added to prevent transport of labeled peptides to terminals on other cell bodies). The somata were extracted and run on RP-HPLC in the presence of excess unlabeled peptides. The results from this procedure confirmed that large individual motor neurons synthesized either the SCPs or Fa. In addition, some large neurons appeared to synthesize both the SCPs and Fa. Staining of alternate sections of the buccal ganglia provided independent evidence that individual neurons contained both SCP-like and Fa-like immunoreactivity. Neighboring neurons that contained only SCP-like or Fa-like immunoreactivity suggest that this staining is not due to cross-reactivity of the antisera. Although they have moderate similarities in sequence, Fa and the SCPs are members of two distinct peptide classes. In general, they are not found in the same neurons or fibers and often have opposite physiological actions. It will be interesting to determine the physiological interactions of these peptides at the muscles innervated by the neurons containing both the SCPs and Fa.

147.9 IMMUNOELECTRON MICROSCOPIC LOCALIZATION OF SMALL CARDIOACTIVE PEPTIDE B TO DENSE-CORE VESICLES IN THE BUCCAL GANGLION OF APLYSIA. W. Reed*, K.R. Weiss, P.E. Lloyd*, I. Kupfermann, M. Chen, and C.H. Bailey. Center for Neurobiology and Behavior, Columbia Univ., P&S, N. Y. S. Psychiatric Institute, New York, NY, and Dept. Pharm. Physiol., Univ. of Chicago, Chicago, IL.

Small cardioactive peptide B (SCP_B) is a potent gastropod neuropeptide that exerts modulatory effects both centrally and peripherally. SCP_B is distributed throughout the Aplysia CNS, but occurs in highest concentrations in the buccal ganglion (Lloyd et al., J. Neurosci., in press; Mahon et al., PNAS, in press). Previous immunofluorescence microscopy of the buccal ganglion revealed SCP_B immunoreactivity ($iSCP_B$) in fibers and varicosities of the neuropil as well as in a selected subset of cell somas, including the somas of two large identified neurons, B1 and B2 (I. Kupfermann et al., Soc. Neurosci. Abstr., 1984). Biochemical studies have demonstrated that SCP_B is synthesized and released by B1 and B2 (Weiss et al., Soc. Neurosci. Abstr., 1985). Here we report the ultrastructural distribution of $iSCP_B$ within the buccal ganglion and specifically in the somas of B1 and B2.

B1 and B2, identified by their size and location within the ganglion, were labeled by intrasomatic injection of ferritin permitting their unequivocal identification in thin sections. One hour after injection, the ganglion was fixed in glutaraldehyde, dehydrated in methanol at -15°C, and embedded in LR White resin. Thin sections were stained for $iSCP_B$ using the avidin-biotin complex-horseradish peroxidase method of Whitnall et al. (Science, 222:1137).

Immunostaining of ferritin-labeled B1 and B2 cell bodies reveals that $iSCP_B$ is found within the lumens of large somatic dense-core vesicles. No organelle other than the dense-core vesicle is labeled. Occasional neurites and synaptic varicosities in the neuropil, as well as a number of unidentified somas in the ganglion cortex are also labeled. In each case the reaction product is confined to dense-core vesicles similar to those found in the somatic cytoplasm of B1 and B2. Preabsorption of the primary antibody with SCP_B inhibits staining in a dose-dependent fashion suggesting that the staining is specific for SCP_B-like antigens. A number of neurons contain dense-core vesicles that show no $iSCP_B$. When a primary antibody to Phe-Met-Arg-Phe-amide (FMRF-amide), another bioactive peptide common in Aplysia, is used, the dense-core vesicles of some of the $iSCP_B$-negative neurons are stained. This demonstrates that the staining is dependent upon a cell-specific content of the dense-core vesicles. Together with the biochemical evidence, these data suggest that SCP_B in B1 and B2 is sequestered into dense-core vesicles.

147.10 CALCIUM DEPENDENT-RELEASE OF NEUROPEPTIDES (THE SCPs) EVOKED BY INTRACELLULAR STIMULATION OF SINGLE IDENTIFIED APLYSIA NEURONS IN CELL CULTURE. K.R. Weiss, S. Schacher, I. Kupfermann, and P.E. Lloyd*. Center for Neurobiology & Behavior, Columbia Univ., N.Y. State Psychiatric Inst., New York, N.Y. 10032; Dept. of Pharmacol. Physiol. Univ. Chicago, Chicago, IL. 60637.

A pair of large bilaterally symmetrical buccal neurons B1 and B2, in situ, contain and synthesize neuropeptides SCP_A and SCP_B. Individual B1 and B2 neurons, maintained in dissociated cell culture, were used to investigate whether these putative neurotransmitter peptides are released by spike activity. Immunocytological staining of cultured B1 and B2 neurons revealed the presence of SCP-like immunoreactivity in their somata, processes, and varicosities. The cell culture technique allowed us to separate neurites from somata, and bioassays of HPLC fractionated material demonstrated that these neurons contained authentic SCP_A and SCP_B, both in their neurites and somata. HPLC fractionation of material from cells cultured in the presence ^{35}S-methionine revealed that cultured neurons synthesize the SCPs and transport these peptides into their neurites. The release of ^{35}S labeled peptides, resulting from spike activity, was measured in the presence of normal and low levels of calcium. Cell activity was controlled by intracellular electrodes, which were used either to silence the cell or to stimulate trains of spikes (1000 to 2000 spikes per 10 minutes). Spike activity resulted in measurable release of SCP_A and SCP_B, and this release was calcium dependent. In favorable preparations, 3-5% of the total neuritic content of SCP_A and SCP_B was released. These results show that neurons grown in the absence of targets can release neuropeptides. The demonstration of spike dependent and calcium dependent release, taken together with other evidence for the subcellular localization and potent physiological actions of the SCPs, suggest that these neuropeptides serve as neurotransmitters or neuromodulators.

147.11 FMRF-AMIDE IN NEURON R2 OF APLYSIA: EVIDENCE FOR ITS ROLE AS A SECOND NEUROTRANSMITTER. R. T. Ambron, P. Lloyd, M. S. Flaster, and S. Schacher. Ctr. for Neurobiol. & Behav., Depts. Anat. and Cell Biol., Columbia Univ., College of P&S, and NYS Psychiat. Instit., New York, NY, and Dept. of Physiol. & Pharm., Univ. of Chicago, Chicago, IL.

R2, the giant neuron of the abdominal ganglion, is cholinergic (Giller, E. & Schwartz, J., J. Neurophysiol., 34:93, 1971). We recently reported that R2 in vitro can regenerate neurites and form chemical connections with a variety of identified abdominal ganglion neurons including R15 (Schacher, S. et al., J. Neurosci., 5:1985, in press). R2 elicits both typical cholinergic as well as noncholinergic responses in these cells indicating that R2 releases both ACh and another transmitter.

Recently, R.O. Brown et al. (Soc. Neurosci. Abstr., 10:691, 1984) have reported finding molluscan peptide Phe-Met-Arg-Phe-amide (FMRFa)-like immunoreactivity in R2. We have extended these studies using both the intact ganglion preparation, and R2 synaptically connected to R15 in vitro, and present additional evidence for the role of FMRFa as a second neurotransmitter in R2.

To demonstrate that R2 makes FMRFa, we first exposed the isolated central nervous system to ^{35}S-methionine for 24h. Examination of R2's cell body and peripheral axons by HPLC showed that each contained a single radiolabeled peak that eluted with authentic FMRFa. The peptide is conveyed to the periphery by rapid axonal transport since it moves at a rate exceeding 60 mm/day and its transport was blocked by 2.5 mM colchicine.

HPLC analysis also demonstrated that radiolabeled FMRFa was synthesized by R2 growing in vitro and was transported into the neurites. The distribution was examined more closely using anti-FMRFa antibody and indirect immunofluorescence. The neuritic varicosities and growth cones of R2 growing in vitro with or without targets showed intense staining while cell bodies and non-varicose segment of neurites stained weakly. Furthermore, bath application of 5×10^{-7} M FMRFa produced an increased conductance hyperpolarization of long duration in R15 in vitro that mimicked the noncholinergic response evoked by spike activity in R2.

Like other Aplysia neurons in culture, R2 synthesizes, processes, and transports peptide transmitter even when grown in the absence of target cells (Flaster et al. and Weiss et al., these abstracts). The electrophysiological data demonstrate that R2 releases a second transmitter with FMRFa-like activity. Thus, the cell culture of R2 with and without target cells from the abdominal ganglion will be useful for studying the formation and maintenance of a dual-transmitter synapse.

CNS NEURONS: VERTEBRATE AND INVERTEBRATE

148.1 PAIRED-PULSE ANALYSIS OF NEUROPILE UNIT DISCHARGE EVOKED BY SLOW CONDUCTING FIBERS IN THE VENTRAL NERVE CORD OF LUMBRICUS TERRESTRIS J.L. Johnson. Dept. of Physiol. & Pharmacol., USD School of Medicine, Vermillion, S.D. 57069

The isolated ventral nerve cord (VNC) was stimulated as a site rostral to the clitellum. Intracord recordings of evoked responses were obtained at varying distances caudally using glass micropipette electrodes. In all cases, the stimulus pulse duration was 0.2 msec. All neuropile unit responses recorded were dependent upon activation of slow conducting intersegmental projections, and were not obtained at all if the dorsal giant fibers alone were activated. The earliest intersegmental small fiber system had a conduction velocity of 0.7-0.9 m/sec., and were activated at a stimulus strength of 2-2.5 volts. Increasing stimulus strength applied to the cord to higher levels activated additional intersegmental projections which could induce neuropile activity lasting for 50-100 msec. Neuropile unit responses were analyzed using paired-pulse (P1 - P2) stimulation of the rostral VNC at strengths sufficient to excite the slow intersegmental projections. Contrary to previous data (J. Exp. Biol., 45:141,1966),facilitation of the P2 response was clearly in evidence for most of the recorded neuropile units. The observed forms of facilitation of neuropile unit discharge include: (a) decreased latency for the P2 evoked response, (b) increased duration of P2 induced burst discharge, (c) shifting of the P2 induced discharge to a longer latency in the relative refractory period of the P1 stimulus (equivalent to preservation of response at short P-P2 interpulse delays), and (d) the sudden ability of the dorsal giant fibers to evoke neuropile discharge at the P2 stimulus at specific P1-P2 interpulse delays. For a total of 9 different neuropile units, the decrease in P2 response delay was 2.60 ± 0.42 (M ± SD) msec. using a P1-P2 interpulse delay of 5-26 msec. At rapid stimulation rates applied to the intersegmental projections, this form of facilitation could account for a highly significant phase-shift of response for these neuropile units which could be of physiological significance. In other neuropile units (such as b above) the increased duration of burst discharge with sustained activation could enhance the effectiveness of transmission at selected reflex circuits. Only one neuropile unit was recorded which was profoundly inhibited after the discharge induced by small fiber projections. This unit had a peak discharge rate of 20-25 Hz, and gave a single spike discharge after a latency of 45-52 msec with a 0.9 cm conduction distance.

It is anticipated that the differing forms of temporal interaction uncovered above will prove to be of central importance in the regulation of locomotion by the massive neuropile network of the earthworm VNC.

148.2 SNAIL GANGLIA PREPARATIONS RELEASE PROSTAGLANDINS. K.S. Madden* (SPON: W.G. Van der Kloot). Dept. of Pharmacology, New York Medical College, Valhalla, NY 10595.

In the A-cell of the snail, Helix aspersa, the action potential (AP) configuration and firing frequency can be systematically influenced by treatments known to increase or to decrease extracellular concentrations of prostaglandins([PG]$_{out}$)(1). The implied release of PGs from subesophageal ganglia has now been confirmed by radioimmunoassay(RIA). Thus, endogenous PGs may normally modulate cellular mechanisms determining APs in the A-cell.

Snails were fed or unfed for at least two months preceeding experiments. Ganglia (n=1 to 6) were dissected free of most connective tissue and placed in a holding bath. They were transferred to fresh snail saline (4 or 5 ml) at the start of an experiment. Samples of bathing medium (0.5 ml) were stored at -20°C until assayed. Derivatives of arachidonic acid(AA) formed by the action of cyclooxygenase(CO) were studied using standard RIA techniques and antisera for PGE_2, $PGF_{2\alpha}$, thromboxane(TX)B_2 and 6-keto-$PGF_{1\alpha}$. Indomethacin-Na$^+$(INDO, 3-12 μM)(2), an inhibitor of AA metabolism, was used in some experiments.

PGE_2, $PGF_{2\alpha}$ and TXB_2 were detected but 6-keto-$PGF_{1\alpha}$ was not. Extracellular concentrations of the predominant derivative, PGE_2, increased with time and through a process that was blocked by INDO. CO appears to metabolize AA in subesophageal ganglia.

Ganglia from fed snails released doses of PGE_2 that could exceed 3 nM which can account for changes in the AP. Ganglia from unfed snails released 10-fold less PGE_2. In these cases, synthesis may be reduced owing to decreased availability of AA, an essential fatty acid. Reduced synthesis may help to explain alterations in the A-cell activity that are associated with extended estivation.

PG synthesis is a Ca^{++}-dependent process involving the rearrangement of membrane phospholipids. In snail ganglia, manipulating the PG biosynthetic pathway also affects APs in the A-cell. This may be owing to direct changes in the membrane mechanisms mediating the cell's electrical excitability, to indirect effects of altering $[PG]_{in}$ and/or $[PG]_{out}$ or to some balance of these effects.

PG release from human and other vertebrate central nervous system(CNS) tissues is well-documented, but its function is not clear. The results of these studies suggest that the activity of certain vertebrate CNS neurons may be similarly modulated by PGs. Conditions that alter the PG biosynthetic capacity may enhance or depress CNS processes influenced by the activity of these neurons.

148.3 REGIONAL DISTRIBUTION OF CALCIUM INFLUX INTO BURSTING NEURONS DETECTED WITH ARSENAZO III. W.N. Ross and K. Graubard. Dept. of Physiology, New York Medical College, Valhalla, NY 10595, Dept. of Zoology, Univ. of Washington, Seattle WA 98195, and Marine Biological Laboratories, Woods Hole, MA 02543.

Absorbance changes of the metallochromic indicator Arsenazo III were used in conjunction with an array of 100 photodiodes to measure changes in intracellular calcium at many positions simultaneously in identified neurons of the crab stomatogastric ganglion. The ganglion was dissected, desheathed and mounted on the stage of a Zeiss Universal Microscope. In some preparations the esophageal and paired commissural ganglia were left attached to enhance the voltage oscillations and to aid in cell identification. Normal saline was used. Arsenazo III was injected iontophoretically into the soma and spread rapidly throughout the cell. Calcium changes were monitored as changes in absorbance at 640 ± 30 nm. Using a 25X water-immersion lens, each pixel in the array detected from an area of 63 x 63 μm^2, allowing a clear separation of signals from the soma, neuropil, and axonal regions. The exact shape of these regions was determined by filling the neuron with Lucifer Yellow after the experiment.

When stimulated intrasomatically, several neurons showed calcium changes all over the cell with approximately the same time to peak at each position. Since calcium diffuses slowly in cytoplasm the early changes in each position result from calcium entering through channels close to the location of the absorbance change. This indicates that calcium channels are distributed widely in the neuropil and on the soma. When cells were allowed to oscillate without stimulation, absorbance oscillations were detected all over the neuropil but not in the soma. A comparison between the membrane potential recorded in the soma and the calcium signal in the neuropil shows that the calcium changes followed the slow wave oscillation with peak calcium detected 50-150 msec after the end of the voltage plateau. In one pyloric LP neuron the calcium oscillations in the neuropil could be detected without signal averaging indicating that the magnitude of the calcium changes was substantial.

148.4 EFFECTS OF MONOVALENT CATIONS ON SUBSTANCE P-SENSITIVE INWARDLY RECTIFYING CURRENTS IN NUCLEUS BASALIS NEURONS. K. Yamaguchi*, Y. Nakajima, S. Nakajima and P.R. Stanfield. Dept. of Biological Sciences, Purdue University, West Lafayette, IN 47907.

Substance P (SP) produces a slow depolarization concomitant with an increase in the membrane resistance in cultured cholinergic neurons of the rat basal forebrain (1). The present study is concerned with the ionic mechanisms of this SP-induced depolarization. We used cholinergic neurons from the nucleus basalis in dissociated cell culture prepared as previously reported (1). The whole cell patch clamp was used for electrophysiology. Pressure ejection of SP (3 μM) onto the neurons (in TTX), while the cell was voltage-clamped at resting potential, produced a slow inward current. When the cell was clamped at a hyperpolarized level, SP elicited a decrease in the inward holding current, indicating a reversal in the SP induced current change. Current-voltage relations were measured before the application of SP (control), and immediately after the application of SP (while the SP effect was still persisting). The SP-sensitive current, obtained by subtracting the current during the SP-stimulation from the control current, revealed an inwardly rectifying property. This SP-sensitive current was nearly abolished by Rb^+. These results indicate that the SP-sensitive currents are inward rectifier K-currents (2). At large negative potentials, the inward currents started to decline during the hyperpolarizing pulse, suggesting a voltage- and time-dependent block of the rectification channels. SP application seemed to accelerate the time course of this blocking. However, the block of inwardly rectifying channels by hyperpolarization as well as the accelerating effect of SP on this block persisted without the presence of external Na ions (replaced by tetramethylammonium ions). When the external solution was replaced by isotonic 100 mM-K^+, 0 mM-Cl^- solution, large hyperpolarizing pulses produced large inward currents (presumably partly carried by inward rectification channels). SP decreased the magnitude of these inward currents. Application of Cs^+ (0.1, 0.5 mM) to the external solution diminished the inwardly rectifying currents. This effect became more pronounced as the membrane was more hyperpolarized, suggesting a voltage-dependent block of the channels by Cs^+. The SP effect became less in the Cs solution, and again this decrease of SP effects by Cs^+ became more pronounced at larger hyperpolarization. This result indicates that SP affects channels that are blocked by Cs^+ at large hyperpolarizations, strengthening the idea that SP has effects on the inward rectifier channels.

148.5 PROPERTIES OF A DEPOLARIZING AFTERPOTENTIAL IN RAT PIRIFORM NEURONS. N.W. Milgram and M. Segal*. Center for Neurosciences, The Weizmann Institute of Science, 76100 Rehovot, Israel.

Several lines of evidence have implicated the piriform cortex in the development of epilepsy. In the kindling model, spontaneous spiking appears first in the piriform region. Piriform cells also exhibit a special reactivity to excitatory neurotoxins as evidenced by the occurrence of extensive cell death in aminal models of status epilepticus. The present research sought to determine if the epileptogenic susceptibility of this region is reflected in unique cellular properties. Special attention was focused on depolarizing afterpotentials (DAP) recorded in these cells. Intracellular recordings were made from slices of rat piriform cortex cut parallel to the anterior-posterior course of the lateral olfactory tract and maintained in an interface chamber. Prominant DAPs were recorded in over 77% of 35 cells recorded in the superficial pyramidal layer. In every instance, the DAP originated off the falling phase of the action potential (AP). In most cases there were two distinguishable components: a small redepolarization to a level 14±1 mV above resting potential which had the appearance of a small bump and a slow decay (42.8±3.4 msec) back to the resting potential. The DAP was accompanied by an increase in membrane conductance, and had a sharply delineated reversal potential of 57.5±1.2 mV which was at the peak level of depolarization achieved. This DAP appears to represent an intrinsic property of piriform cells; the response has not been observed in the absence of an AP, and shows no decrement during high frequency firing. In the large majority of cases when APs were triggered by current injection, the DAP was the only afterpotential manifested. When action potentials were triggered by excitation of afferents, however, there were also hyperpolarizing afterpotentials. Experiments designed to analyze the ionic mechanism for generating DAPs indicate that neither Cl^- nor Ca^{++} are critical, but Ca^{++} is involved in the initial redepolarization.

Functionally the DAP increases the excitability of piriform cells as indicated by: 1. a decrease in AP threshold during the DAP; 2. the appearance of doublets or bursts off the DAP which could be triggered by brief pulses and which occurred spontaneously; 3. the emergence of spontaneous bursting in cells injected with Cs which produced a marked enhancement of DAPs.

148.6 MAUTHNER AXON-EVOKED INHIBITION OF AN INDENTIFIABLE FOLLOWER NEURON REQUIRING AN UNUSUAL SYNAPTIC MECHANISM. J.T. Hackett and L.J. Greenfield, Jr*. Dept. of Physiol., Univ. of Virginia, Charlottesville, VA 22908

A single impulse evoked in a goldfish Mauthner (M) axon can synchronize a unilateral contraction of the body and a bilateral contraction of the cranial muscles. Several neurons, each postsynaptic to both M-axons, relay impulses to the cranial motoneurons on one side. We now report a separate pathway through a follower neuron which is inhibited by the ipsilateral M-axon and excited by the contralateral one.

Two microelectrodes were used to obtain simultaneous intracellular recordings from a M-cell and a follower neuron. The latter were found under the facial lobe, parallel to and on the medial side of the M-axon, and overlapping the caudal extent of the cranial relay neurons (CRNs). Follower neurons were distinguished by a hyperpolarizing IPSP evoked by ipsilateral M-axon stimulation. The IPSP could be inverted by hyperpolarizing current injections or by injecting Cl^- into the neurons. Injections of depolarizing currents into these neurons evoked repetitive firing without a response in the cranial muscles. Impulses in CRNs failed to produce either the EPSPs or IPSPs in the follower neurons and measurements of synaptic delay were consistent with this finding. The synaptic delays measured from the rising phase of the M-axon spike to the ipsilateral IPSP was 0.51 ± 0.09 msec (n=14), to the contralateral EPSPs was 0.45 ± 0.035 msec (n=4), and to the CRN-EPSP was 0.44 ± 0.02 msec (n=8). These data indicate the possibility that the M-axon transmitter produces several synaptic actions, which we examined pharmacologically. The IPSP was blocked by strychnine applied either topically to the fourth ventricle (3 μl, 2.7 mM) or injected i.p. (3 μg/gm fish). At these concentrations, the EPSPs were not blocked. However, the EPSPs could be blocked by a 20 times higher dose. D-tubocurarine applied topically (3 μl, 14 mM) selectively blocked the EPSPs. Penicillin (3 μl, 250 mM) applied topically did not block the IPSP or the EPSP.

We conclude that a neuron can be individually identified which receives inhibitory and excitatory inputs from the ipsilateral and contralateral M-axons, respectively. The M-axon collaterals do not cross the midline; therefore, the follower neuron may be bilateral. The transmission time is too short for two chemical synapses, which raises three interesting possibilities: 1) the release of two transmitters from the M-axon, 2) a non-spiking inhibitory neuron excited by the M-axon via an electrical synapse, or 3) the differential sensitivity to pharmacological agents of functionally different postsynaptic receptors for the same transmitter. 148.7 CELLULAR AND SYNAPTIC PHYSIOLOGY OF TURTLE HIPPOCAMPUS. J.M. Shen and A.R. Kriegstein. Dept. of Neurology, Stanford University Med. School, Stanford, CA 94305.

The dorsal cortex of the turtle, Pseudemys scripta, consists of two principal classes of neurons that occupy three distinct layers. Morphological, pharmacological and physiological data suggest many similarities to mammalian neocortex, rendering it a favorable preparation for comparative studies. We have begun to investigate the cellular physiology of the turtle medial cortex, which is anatomically homologous to mammalian hippocampus. 500 μm-thick coronally vibratomed sections or intact cortical slabs were placed in a chamber and perfused with oxygenated saline at 22°C, and intracellular recordings were made from the region of the medial cortex with 3M K acetate-filled microelectrodes.

We found a group of spontaneously bursting neurons (mean membrane potential = -50 mV, mean input resistance = 84MΩ) confined to a restricted zone in the dorsal medial cortex (DMC). Cells with physiological properties resembling pyramidal or stellate neurons of dorsal cortex were also present in this region, but spontaneously bursting neurons were never encountered more laterally or medially. Bursts ranged from brief depolarizing events consisting of only two or three spikes to long (up to 3 seconds) depolarizations with multiple action potentials (APs). Interburst intervals (IBIs) also varied from cell to cell even within the same slice, lasting from 1 to 8 seconds; some cells had extremely constant IBIs. Most bursts seemed to be synaptically mediated since hyperpolarizing the cells revealed spontaneous underlying excitatory postsynaptic potentials (EPSPs).

Extracellular electric shocks elicited inhibitory postsynaptic potentials (IPSPs) in neurons medial to DMC that are reminiscent of dorsal cortical pyramidal cell responses. DMC neurons, however, responded to both medial and lateral stimulation with an initial burst of APs often followed by IPSPs lasting 1-20 seconds. IPSPs were usually more pronounced following medial stimulation and were often interrupted by bursts of APs or EPSPs.

Spontaneously active zones were marked with focal applications of pontamine sky blue. Subsequent histological studies localized these sites to a restricted area in DMC characterized by a loosely packed pyramidal cell layer. An antibody specific to rat limbic system (kindly provided by Dr. Pat Levitt) intensely labelled turtle DMC neurons. Neurons in more medial areas were lightly stained in comparison, while dorsal cortical neurons were completely unstained. Thus, turtle medial cortex contains distinct physiological, anatomical, and immunohistochemical regions remisiscent of subfields of mammalial hippocampus.

148.8 EXCITATORY SYNAPSES BETWEEN CA3 NEURONS IN THE GUINEA PIG HIPPOCAMPUS. R. Miles* and R.K.S. Wong (SPON: R.A. DiCaprio). Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

We have examined the properties of recurrent excitatory synapses in the CA2-CA3 region of the guinea pig hippocampal slices using two techniques. 1. simultaneous intracellular recordings from pairs of CA3 cells. 2. antidromic activation of CA2 pyramidal cells by stimulating CA1 stratum oriens. Recurrent epsp's were elicited in CA3 neurons separated from CA2 by a cut made from the alveus to the edge of the mossy fiber layer. Picrotoxin was used to suppress synaptic inhibition.

The amplitude of unitary mono-synaptic epsp's was 0.8-1.8 mV (n=6). Their rise time was 6-12 ms and duration at half amplitude 20-30 ms. Recurrent epsp's initially decayed more slowly than either step somatic depolarizations or epsps' evoked by mossy fiber stimulation. In Cs loaded neurons they reversed at more positive potentials than mossy fiber epsp's. Thus, some recurrent synapses apparently are made onto distal apical dendritic sites.

A slow voltage-dependent decay and an undershoot following unitary and antidromic recurrent epsp's suggested that intrinsic currents were activated. The undershoot, a 0.2-0.4 mV hyperpolarization of time to peak 60-80 ms from onset of unitary epsp's was blocked by intracellular injection of Cs and TEA. In these conditions epsp duration was greatly prolonged in a subthreshold potential range. This behavior seems to depend on intrinsic inward and outward currents since the voltage dependence of 2 mV - 5 ms intradendritic, depolarizing pulses mimicked that of recurrent epsp's.

A pre-synaptic burst lead to considerable temporal summation of unitary epsp's. A second epsp at interval 8-12 ms was strongly facilitated. Later epsp's at similar interval were facilitated less, possibly due to the growth of the intrinsic hyperpolarizing conductance. Thus a burst evokes a summed epsp of amplitude 2-5 mV, time to peak 25-50 ms with a falling phase of similar duration followed by an undershoot. Events of this time course were also elicited via multi-synaptic connections (n=28) revealed in the presence of picrotoxin. They were evoked at variable latency by pre-synaptic bursts but not by single spikes.

148.9 LOGIC OPERATIONS COULD BE MEDIATED BY INTERACTIONS BETWEEN EXCITABLE DENDRITIC SPINES. G.M. Shepherd and R.K. Brayton. Sect. of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510 and IBM Watson Res. Ctr., Yorktown Heights, NY 10598.

As part of an ongoing study of distal dendritic microcircuits, we have tested the hypothesis that excitable dendritic spine interactions (Shepherd, G.M., Proc. Nat. Acad. Sci., in press) could mediate logic operations. Using an electrical circuit analysis program, we have extended our previous compartmental model to include 4 spines arising from a length of dendritic branch. Each spine head included a model for an EPSP and a Hodgkin-Huxley action potential; the spine stems and dendritic compartments were electrically passive.

Three types of elementary logic operations have been analysed. An AND gate was simulated by simultaneous EPSPs in 2 adjacent spines. EPSP conductances (gEPSP) of 1 nS were sufficient in the model to trigger action potentials in spines 1 and 2, which then triggered saltatory conduction to 3 and 4. An OR gate was simulated by an EPSP in spine 1 or spine 2. In this case, a larger gEPSP of 2 nS was necessary to trigger an action potential, which then triggered the remaining 3 spines in sequence. Finally, an AND-NOT gate was simulated by combining an EPSP in spine 1 with an IPSP at different sites. When the IPSP was sited on the stem of spine 1, the spine impulse sequence fired when gIPSP was 2 nS, and was blocked by 3 nS. When the IPSP was sited on the dendritic branch near the origin of spine stem 1, a larger gIPSP of 7 nS was necessary to block the spine impulse sequence.

The results suggest that logic operations are inherent in the nonlinear interactions between excitable spines. They are consistent with conclusions (Rall, W. and Segev, I., in New Insights into Synaptic Function, ed. Edelman et al, New York: Wiley, in press) obtained from analysis of interactions between clusters of excitable spines, suggesting that the proportion of active spines in a distal dendritic tree would be limited, because their combined current would tend to fire the tree and override IPSPs in their path. It is possible that spines undergo dynamic turnover, and that their functional maturation can involve both synaptic and voltage-sensitive membrane channels, together with related metabolic, second messenger and cytoskeletal elements. If the proportion of mature excitable spines is thus limited, inhibitory synapses can be very effective in controlling their interactions, especially in thinner, more distal, dendrites. Thus, despite small numbers of inhibitory synapses on dendritic branches, their presence at strategic locations would give them powerful roles in establishing dendritic logic gates. The interactions between excitable spines were exquisitely sensitive to small changes in spine stem resistance, further supporting Rall's suggestion that these changes could provide a mechanism underlying learning and memory.

148.10 MODULATION OF EXCITABILITY OF FUNCTIONALLY RECONSTRUCTED CORTICAL PYRAMIDAL NEURONS BY DISTAL SYNAPTIC INPUT. T.M.McKenna, D.H.Perkel, N.M.Weinberger. Theoretical Neurobiology Facility, Dept. Psychobiology and Center for the Neurobiology of Learning and Memory, U.Cal. Irvine

A multi-compartmental neuron was constructed based on morphological and biophysical measurements from published data obtained in sensory and motor cortices. Neuronal time constants were obtained by injecting current pulses at the soma and peeling 2 or 3 time constants from the membrane potential decay. These time constants were found to depend upon the distribution of voltage dependent Na and K channels in the neuron.

We examined the pattern of action potentials (AP) produced by trains of inputs at the proximal apical dendrite and the modulation of this pattern by synaptic inputs placed on the distal apical dendrites or the basilar dendrites. The modulating input consisted of independent Poisson trains in three or more synaptic afferents. For a range of membrane specific conductances, the influence of the distal apical inputs on the probability of eliciting AP's from a regular input train at the proximal dendrite was found to be critically dependent on the duration of the delay between the beginning of the distal and the proximal input trains. The number of AP's produced was increased when the distal and proximal trains began within 60 ms of each other (either leading) and was maximally facilitated (>2X) when the two trains began simultaneously. When the distal train led the proximal train by more than 60 ms, the mean number of AP's was unchanged but the variance greatly increased. On trials when no spikes were produced, "recordings" of ion channel gates revealed that the tonic depolarization produced by the distal input resulted in Na inactivation. Distal trains that began more than 60 ms after the proximal train had no effect on the neuron's output. By contrast, input trains on the basilar dendrites could produce AP's at any time during the proximal train, depending on the precise relative timing of synaptic potentials.

Thus, electrotonically long dendrites can smooth synaptic potentials sufficiently so that sustained depolarizations may lead to lowered neuronal excitability. Furthermore, the relative time of onset of input trains in distal and proximal dendritic synapses is critical for increasing discharge probability.

148.11 TRANSFER FUNCTION AND INTEGRATION IN CENTRAL NEURONS. L. Moore, B. Christensen and K. Yoshii. Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

A first approximation to the integrative properties of a single neuron can be assessed by measuring the linear input-output transfer function for different regions of the cell. The transfer function at the soma is a critical determinant of output since the threshold level that triggers an impulse is generally reached here. In order to measure transfer functions at the soma and the tip of a dendrite a mouse neuroblastoma tissue culture cell (NG-108) was used. These cells have prominent somas with branching neurites containing large growth cones at their ends. A low resistance patch electrode was employed for whole cell voltage and current clamp admittance and impedance measurements (Moore & Christensen, 1985) from either growth cones or the soma of the cell. Morphological measurements were made from each cell and a branched cable model (Koch, 1984) containing voltage dependent conductances was used to interpret the frequency domain data from the same cell. These cultured cells show typical excitability properties for both somatic and growth cone recordings. Synaptic inputs were simulated by pressure application of transmitters or a high concentration of potassium ions through a microelectrode. Steady state depolarization of the cells activated the voltage dependent conductances which led to marked changes in the measured transfer functions. These results have consequences for neuronal integration and function. First of all, the neuron is not just a simple summing amplifier of synaptic input. The change in the bandpass characteristics during synaptic activation facilitates access to the soma those synaptic potentials with higher frequency components. The cell becomes "tuned" to conduct synaptic potentials with frequency components in a particular range and filter out the rest of the synaptic fluctuations. Also, the dendritic tree may either have different tuning curves or modulate the soma response depending on the synaptic input at any given time. Thus, the neuron has an inherent mechanism of filtering site specific synaptic input. In this sense, the neuron is also a spatial filter selecting preferentially for synaptic input located on particular portions of the dendritic tree.

PEPTIDES: BIOSYNTHESIS AND METABOLISM I

149.1 PURIFICATION, IDENTIFICATION AND LOCALIZATION OF BOMBESIN-LIKE IMMUNOREACTIVITY IN BOVINE ADRENAL MEDULLA. S. Lemaire. Département de Pharmacologie, Faculté de Médecine, Université de Sherbrooke, Sherbrooke, Québec, Canada J1H 5N4.

Immunoreactive bombesin (ir-BB) was found in acid (HCl) extracts of bovine adrenal medulla at a concentration of 27 pmoles per g of tissue. It was purified by successive chromatography through Sep Pak C-18 cartridges, Sephadex-G-50, partition chromatography and high pressure liquid chromatography. The latter purification step gave rise to four peaks of immunoreactivity (fractions I, II, III and IV). The major peak (fraction II) eluted closely to the amphibian synthetic peptide bombesin and a minor peak coeluted with synthetic porcine gastrin releasing peptide (GRP). The cellular and subcellular distributions of ir-BB were also analyzed. Bovine adrenal chromaffin cells were isolated by successive digestions with collagenase. Subpopulations of these cells were obtained by centrifugation through stepwise bovine serum albumin gradients. Three distinct cell layers (I, II and III) were obtained at the interfaces of the gradient: cell layer I was enriched in noradrenaline (adrenaline/noradrenaline ratio: 0.63) and its content in ir-BB was relatively high (1.64 pmoles/10^6 cells). On the other hand, cell layers II and III were enriched in adrenaline (adrenaline/noradrenaline ratios of 1.3 and 3.3, respectively) and their content in ir-BB was much lower (0.28 and 0.17 pmoles/10^6 cells, respectively). The subcellular fractions (granules, microsomes, mitochondria and cytosol) were obtained by differential centrifugations of an homogenate of bovine adrenal medulla. ir-BB was mostly concentrated in the secretory granules (0.65 pmoles/mg protein) as compared with the other cell constituents (from 0.06 to 0.19 pmoles /mg protein). These data indicate that bovine adrenal medulla contains various forms of bombesin-like material and that this material is more specifically localized in secretory granules along with catecholamines (most probably noradrenaline). The putative neuromodulator function of bombesin-like substances at this level remains to be investigated.

149.2 EFFECT OF SHORT TERM ELECTRICAL AND CHEMICAL STIMULATION ON THE CONTENT OF METHIONINE-ENKEPHALIN IN THE GUINEA PIG MYENTERIC PLEXUS. A. R. Gintzler, D. Clouet* and J. Glass*. Downstate Medical Center, Brooklyn, N.Y. 11203, and Res. Lab. New York State Off. Drug Abuse Serv., Brooklyn, N.Y. 11217.

Although the structure of both the enkephalin precursor, proenkephalin, and the gene that codes for it has been determined, the various physiological parameters that influence the rate at which proenkephalin is processed to enkephalin remain obscure. This report provides the first demonstration that the rate of enkephalin production is not fixed but is dependent on the degree of neuronal activity. The isolated longitudinal muscle with adherent myenteric plexus (LM-MP) preparation of the guinea pig ileum was chosen as a convenient source of enkephalin-containing neurons. The content of enkephalin in the myenteric plexus was determined by using a highly sensitive and specific radioimmunoassay (RIA) in combination with reverse phase High Pressure Liquid Chromatography (HPLC).

In the presence of Krebs buffer containing 2.5 mM calcium, electrical stimulation (20 Hz for 30 sec) or stimulation by high potassium (60 mM for 4 min) produced a significant increase (approximately 55%, $P<.02$) in the content of enkephalin-like immunoreactivity (ELI) in the myenteric plexus. The content of myenteric ELI was not altered when electrical stimulation was applied in the presence of a calcium free buffer containing the calcium chelator EGTA. Therefore, it appears that the effect of electrical stimulation is dependent on the presence of extracellular calcium. Electrically induced increases in ELI could also be abolished by pretreatment with tetrodotoxin indicating the need for intact functional sodium channels and the propagation of action potentials. Fractionation of LM-MP extract by reverse phase HPLC prior to analysis by RIA indicated that the increase in ELI was due to an elevation in the content of authentic methionine-enkephalin and not of some spurious peptide that cross reacts with the enkephalin antiserum.

These results indicate that tissue levels of enkephalin can fluctuate in response to changes in neuronal activity via a calcium dependent mechanism. The very brief time course for the increase following such stimulation (30 sec and 4 min following electrical and chemical stimulation, respectively) suggests that the elevation in content is due to an increase in the rate of processing of enkephalin precursor(s) to enkephalin and not to an increase in the rate of de novo synthesis of proenkephalin. Supported by a grant to ARG from the National Institute of Drug Abuse #DA02893.

149.3 AGE-RELATED INCREASE IN NEUROPEPTIDE Y-LIKE IMMUNOREACTIVITY IN RAT ADRENAL GLANDS. Hiroshi Higuchi* and Hsiu-Ying T. Yang. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Neuropeptide Y (NPY) is a 36 amino acid peptide, located in neurons of central and peripheral nervous system. Immunohistochemical studies indicate that NPY often colocalizes in catecholamine-containing neurons, suggesting a possible participation of this peptide in catecholaminergic transmission. In the adrenal glands of various species, NPY has been detected mainly in norepinephrine-containing chromaffin cells and also in nerve fibers penetrating through cortex and medulla. Since NPY-like immunoreactivity (NPY-IR) is stored in chromaffin granules, it might be co-released with catecholamines into circulation and function as a cotransmitter in various tissues. Interestingly, NPY appears to modulate the contractions of vascular and cardiac muscles. We show that the NPY content in rat adrenal gland increases with age, regardless of sex. Furthermore, another NPY-like immunoreactive peptide, which is more hydrophilic than NPY, was found to increase in the adrenal glands of aging rats. In contrast, similar age-dependent changes failed to occur in the cerebral cortex and hypothalamus, two brain regions with the highest concentrations of NPY, though injected NPY appears to exert various effects on the blood pressure, circadian rhythm and release of neuroendocrinal peptides in the CNS. The age-dependent changes of NPY-IR occurs specifically in the adrenal glands. Subsequently, we investigated the effects of the splanchnic nerve transection, because splanchnic nerve activity is known to modulate the various chromaffin cell constituents including tyrosine hydroxylase and enkephalins. Interestingly, the transection did not affect the adrenal NPY-IR content during the first week following transection, but abolished the age-dependent increases of NPY and the additional NPY-like immunoreactive peptide in rat adrenal gland. The high NPY content in adrenal gland may have physiologicla implications in adrenal function, and its age-related increase might be related to functional changes in aging animals. The appearance of another molecular form of NPY-IR in aging rats may be an important factor for future study in aging. In addition, the splanchnic nerve activity seems to regulate the NPY-IR content in the adrenal gland. Further investigations are in progress to explore the biosynthesis and functions of NPY and the additional NPY-IR peptide in the adrenal gland.

149.4 CEREBROVENTRICULAR AND VASCULAR METABOLISM OF ANGIOTENSINS IN RAT. J.W. Harding, M.S. Yoshida, R. Dilts, and J.W. Wright. Dept. of VCAPP, Washington State University, Pullman, WA 99164

Much of the data gathered to support a central role for angiotensins in cardiovascular control and body water balance has relied upon the intracerebroventricular injection of angiotensins (AII and AIII) and antagonists. Data gathered using this experimental approach, especially with regard to dose-response relationships, suffers from the unknown perturbation of ventricular metabolism. Initial studies, designed to address this potential problem, involved injection of ^{125}I-angiotensins (AII, AIII, Sar^1 Ile^8-AII) into the lateral ventrical followed by CSF collection via the fourth ventrical. HPLC analysis of collected CSF indicated nearly total metabolism of ^{125}I-AII and ^{125}I-AIII while approximately 50% of the ^{125}I-Sar^1 Ile^8-AII (SI-AII) remained. This degradation was shown to be dependent upon passage of the angiotensins through the ventricular space and not from direct CSF mediated action. Incubation of ^{125}I-AII and ^{125}I-SI-AII at 36°C for up to 90 minutes yield no significant degradation. However, ^{125}I-AIII was degraded by CSF but at a rate much slower than that measured subsequent to ventricular passage. In order to more accurately establish the rate of ventricular metabolism, rats were injected with labeled angiotensins and rapidly killed with focused microwave irradiation. This technique allowed the analysis of time points as short as 5 seconds after injection. The results of this study showed extremely rapid ventricular metabolism of angiotensins. AII had a t 1/2 = 22.5 sec while AII exhibited a t 1/2 = 6.5 sec.

Vascular metabolism of ^{125}I-angiotensins was also monitored and shown to be rapid with t 1/2's for AII = 9.1 sec and AIII = 8.9 sec. HPLC analysis of degradation products is consistent with an obligatory conversion of AII to AIII during the metabolic cascade. In total the results of this study encourage a reevaluation of the potency of various angiotensins (especially AIII) under conditions of reduced degradation and imply a significantly greater potency for AIII at the receptor level.

149.5 SUBSTANCE P CONTENT AND RELEASE IN DISSOCIATED AND MICROEXPLANT CULTURES OF RAT NODOSE GANGLION (VAGAL SENSORY) NEURONS. D.B. MacLean, P. Gulley and S.F. Lewis (SPON: J. Toole), Dept. of Medicine, Wake Forest Univ. Med. Ctr., Winston-Salem, NC 27103.

Substance P (SP), the widely distributed undecapeptide, is synthesized in cell bodies of vagal sensory ganglia and transported bidirectionally towards the medulla oblongata and peripheral sites of sensory innervation. The factors regulating its synthesis in and release from vagal neurons remain largely unknown. Although tissue culture is one promising model to study that regulation, culture of vagal sensory neurons has been limited. Recently, a successful dissociation technique has been described (Mathieu et al, Neuroscience 13:1373, 1984).

Nodose ganglia were removed from neonatal rats and either cut into 5-7 fragments each using fine scissors or dissociated in neutral protease (Dispase). Explants were maintained in enriched F-12/L-15 medium supplemented with adult rat and human placental serum; dissociates were maintained in enriched L-15, 5% rat serum. Seven to 10 ganglia equivalents were plated per 16mm well. Plating efficiency in dissociates was 15-30% at one week (3000-6000 neurons per well) and did not deline over the ensuing 10 days. Specific immunocytochemical staining of substance P was present in 30-40% of dissociated neurons by one week in culture; staining of microexplants was more variable. In microexplants, immunoreactive SP content per plated ganglion rose from 4.7 ± 1.2 pg/ganglion (G) (mean ± SD) at 1 week to 14.1 ± 3.6 pg/G at three weeks. In dissociates, after 5 days in culture SP content increased linearly with time: 9.0 ± 3.6 pg/G at 6 days, 64.7 ± 6.8 pg/G at 10 days and 128.0 ± 9.3 pg/G at 16 days (851 ± 61 pg/well). In both systems, 30 min epochs in 50mM K+ Kreb's buffer resulted in minimal release by 5-7 days in culture, whereas 10-20% of SP content was released at 14-21 days. Calcium-free, 0.125mM EGTA Kreb's inhibited both basal (low K+) and high K+ stimulated release. In preliminary studies of regulation of SP content, the addition of dibutyrl-cAMP (1mM) for one week resulted in a 4-fold increase in content ($p<.001$); cell number was unchanged. Phorbol ester (PMA), 20μM, had no effect.

Dissociated cultures of vagal sensory neurons produce large amounts of immunoreactive SP and may provide a powerful tool for the study of its regulation and release. Further releasing studies and co-culture with central and peripheral target tissues are in progress to assess specific differentiation of these neurons in culture.

These studies were supported by grant NS18705 from the National Institutes of Health.

149.6 RELEASE OF CORTICOTROPIN-RELEASING FACTOR (CRF)-LIKE IMMUNOREACTIVITY FROM RAT BRAIN REGIONS IN VITRO. C. B. Nemeroff, M. A. Smith, T. A. Slotkin, and G. Bissette. Departments of Psychiatry and Pharmacology, Duke University Medical Center, Durham, N.C. 27710.

Since the discovery of CRF in 1981 (Vale et al. Science 213:1394, 1981), considerable research has been conducted with this neuropeptide quite apart from its neuroendocrine role. It is of considerable interest to determine whether CRF fulfills the requisite criteria to be considered a neurotransmitter in the CNS. Thus, immunohistochemical and radioimmunoassay (RIA) studies have shown that the peptide is heterogeneously distributed in the mammalian CNS. After iontophoretic application, CRF produces alterations in neuronal firing rates in several brain areas. Moreover, intracerebrally administered CRF produces profound effects on the autonomic nervous system as well as on behavior. In the present study a sensitive and specific CRF RIA (Meth. Enzymol. 103:565-572, 1983), was used to measure in vitro secretion of CRF-LI from minced slices of hypothalamus, amygdala, cerebellum, midbrain and striatum. Minced tissue (8 mm^3) was incubated in modified Krebs-Henseleit buffer at 37°C that received 95% O_2/5% CO_2 and pH adjusted to 7.4. Addition of high concentrations (56 mM) of potassium resulted in a marked increase in CRF-LI release. This depolarization-induced release of CRF observed in all brain regions studied except cerebellum and frontal cortex, was calcium-dependent, as evidenced by the lack of effect of high (K^+) in both calcium-free media and in the presence of EGTA. Furthermore scorpion venom released CRF-LI and this release was also calcium-dependent. In the hypothalamic minces, neither 5HT (1-100 μM) norepinephrine (10 μM) or carbachol (0.1-100 mM) did not increase CRF release. The hypothalamus contained the highest concentrations of CRF-LI, but moderate concentrations were found in the midbrain and amygdala. Low concentrations were found in the striatum and cerebellum. These results confirm previous findings derived from use of CRF bioassay methods. The present findings provide further evidence for a neurotransmitter role for CRF in the mammalian CNS. (Supported by NIMH MH-39415)

149.7 DEVELOPMENTAL EXPRESSION OF THE RAT VASOPRESSIN GENE. H.H. Zingg, D. Lefebvre* and G. Almazan*. Laboratory of Molecular Endocrinology, Royal Victoria Hospital, McGill University, Montreal, Quebec, Canada, H3A 1A1.

The nonapeptide vasopressin (AVP) is synthesized as part of an AVP-neurophysin precursor molecule in magnocellular neurons of the hypothalamus. It has been demonstrated by immunocytochemical methods that these neurons acquire the capacity to synthesize AVP by embryonic day 16-18 (J. of Neuroscience 5: 98; 1985). On the other hand, the synaptic input connections regulating the activity of AVP neurons are only fully established by postnatal day 15 (Peptides 1, Suppl. 1: 27; 1980). To investigate the regulation of AVP gene expression during development, we determined the levels of mRNA encoding pre-proAVP-neurophysin in rat hypothalamus during embryogenesis and early postnatal life.

A 2.2 kb fragment encompassing the entire gene for pre-pro AVP-neurophysin was isolated from a rat genomic library (in collaboration with Drs. B.J. Cwickel and J.F. Habener, Boston). A 0.7 kb restriction fragment containing exon C of the AVP-gene was used as a probe. This sequence is specific for AVP mRNA and lacks homology with the oxytocin-neurophysin gene. The hypothalamus of early postnatal and adult Sprague Dawley rats and the midbrain region of fetal rats (7-20 days p.c.) was removed under a dissecting microscope and extracted in 4 M guanidine thiocyanate. RNA was purified by ultracentrifugation through 5.7 M CsCl. Following electrophoresis in 1.5% agarose, the RNA was transferred to a nylon membrane and hybridized with labeled AVP exon C probe. After autoradiography, the intensity of the bands was quantitated by densitometric scanning.

Using these methods, we found that a marked increase in AVP mRNA occurred postnatally: whereas AVP mRNA remained undetectable during fetal life, the levels attained at 0, 1, 2 and 4 weeks postnatally corresponded to <2%, 4%, 49% and 63% of the levels found in the adult. At all stages, a single band of AVP mRNA was detected, suggesting that only a single AVP gene is expressed throughout postnatal development.

The marked increase of AVP mRNA in hypothalamic magnocellular neurons following the 1st week of postnatal life coincides with the completion of synaptic development. These data therefore suggest that synaptic input plays an important role in the developmental regulation of neuronal AVP gene expression.

149.8 **CHARACTERIZING THE SITE OF IN VITRO CENTRAL AND PERIPHERAL PROCESSING OF PEPTIDE E TO ACTIVE FRAGMENTS.** G. L. Hoyer* and T. P. Davis (SPON: A. Dray). Dept. of Pharmacol., Univ. of AZ, Coll. of Med., Tucson, AZ 85724.

In previous studies we investigated the central and peripheral effects of the proenkephalin A derived opioid peptide, peptide E, and known processing fragments BAM-22P, BAM-12P, and met^5-enkephalin on gastrointestinal transit and contractility. These peptides increase intraluminal pressure when arterially perfused through canine small intestine segments and peptide E, BAM-22P and met^5-enkephalin inhibit gastrointestinal transit when administered i.c.v. to mice. Recent investigations have also shown that the opioid peptide β-endorphin may be processed both centrally and peripherally to peptide fragments with opposite effects in pharmacological tests. Therefore, a single peptide precursor, such as peptide E, may serve as a precursor for peptide fragments with different biological activities.

We have previously reported that crude membrane homogenates of whole rat brain and mucosa/muscularis of the canine small intestine process peptide E into biologically active fragments. The present study was designed to characterize the site of peptide E processing by studying various cellular fractions. Purified synaptosomal plasma membranes (SPM) were prepared by the method of Burbach et al (Biochem. Biophys. Res. Comm. 92, 1980). Brain microsomes were isolated by centrifugation of the SPM supernatant at 105,000 g for 80 min. Plasma membranes (mucosa and muscularis) were prepared by the method of Emmelot et al (Biochem. Biophys. Acta. 90, 1964). Each fraction was resuspended in 50 mM Na/K PO_4 buffer (pH 7.4) and time course incubated (37°C) with peptide E (8 nmol) (J. Pharm. Exp. Ther. 227, 1983). The supernatant was analyzed by HPLC for identification and quantitation of the peptide E related fragments (Peptides 5, 1984). Analysis of the data showed significant differences in the formation of peptide E related fragments between tissues. The purified SPM and microsomal fraction of the brain produce met^5-enkephalin preferentially as compared to other peptide E related fragments. The cellular fraction of the mucosa and muscularis of the small intestine produce leu-enkephalin at concentrations similar to met^5-enkephalin. All fractions produce BAM-12P and BAM-22P at significantly lower levels (pmol) than met^5- and leu-enkephalin except the muscularis plasma membrane where the concentration of BAM-12P is comparable (nmol) to that of met and leu-enkephalin.

The rank order of potency of i.c.v. administered peptide E and related fragments, on the inhibition of gastrointestinal transit was peptide E = BAM 22P > met-enkephalin, however BAM-12P was not active in this assay. In the arterially perfused intestinal segment the rank order of potency for increases in contractility was peptide E > BAM-22P = BAM-12P > met^5-enkephalin. It is of interest to note that BAM-12P showed significant activity in the intestinal segment model but not in the centrally mediated transit model. This correlates well with the finding that only the muscularis showed appreciable BAM-12P formation. In conclusion peptide E has been shown to be processed, both centrally and peripherally, to biologically active fragments by the SPM, microsomal fraction, and plasma membranes. The biological activity of these fragments differs from the activity of the parent compound, peptide E. Several other fragments of peptide E are currently being synthesized and tested to determine if peptide E, or one of the formed fragments is responsible for the potent opioid effects.

149.9 **EFFECT OF CENTRALLY ACTING DRUGS ON β-ENDORPHIN PROCESSING BY BRAIN SYNAPTIC MEMBRANE AND MICROSOMAL ASSOCIATED PEPTIDASES.** T. P. Davis and A. J. Culling-Berglund*. Dept. of Pharmacol., Univ. of AZ, Coll. of Med., Tucson, AZ 85724.

In recent years, evidence has accumulated to indicate that both in vivo and in vitro β-endorphin (β-E) serves as a precursor for various neuroactive β-E fragments and has a neurotramsitter or neuromodulator role also. The β-E 1-16 fragment, α-endorphin shows amphetamine-like effects in several pharmacological tests, whereas the β-E 1-17 fragment, γ-endorphin (γ E) shows antipsychotic effects in animal tests.

A previous study in our laboratory reported evidence that specific centrally acting drugs may alter in vitro β-E processing in crude, twice-washed membrane homogenates of whole rat brain after 8 day infusions by minipumps (Eur. J. Pharmacol. 100, 249. 1984). The infusion of the antipsychotic drugs haloperidol and chlorpromazine yielded a significant increase in the formation of γ-type endorphins but not α-type endorphins. Phenobarbital and promethazine showed no effect.

To determine if these drug induced enzymatic alterations were specific to the synaptosomal plasma membrane (SPM) or microsomal fraction we administered chlorpromazine (4.1 mg/kg/day), promethazine (5 mg/kg/day) and phenobarbital (20 mg/kg/day) for 8 days to male Sprague-Dawley rats (140-215 g; n = 5) using Alzet Model 2001 osmotic minipumps. The purified SPM was prepared using the method of Burbach et al (Biochem. Biophs. Res. Comm. 92, 2. 1980) and microsomal fraction was prepared by centrifugation of the final supernatant at 100,000 xg for 60 min. Each fraction was time course incubated (37°C) with β-E (10 nmol) for 30-120 min. Samples were boiled and centrifuged prior to HPLC analysis as previously described (Peptides 5, 6. 1984). Animals receiving the antipsychotic chlorpromazine had a significantly shorter half-life for β-E at the SPM (45.5 min) as compared to animals receiving saline (78.1 min), promethazine (65.8 min), or phenobarbital (83.7 min). The microsomal β-E half-life for promethazine (18.9 min) and phenobarbital (39.6 min) was significantly faster than chlorpromazine (85.5 min) or control (100 min). Together with the 2 to 3-fold increased production of both α- and γ-type endorphins, promethazine and phenobarbital had a significant influence upon the enzymatic activity or concentration in the microsomal fraction. After studying the formation rates of γ-type endorphins from purified SPM's it was further noted that chlorpromazine showed a significant decrease in the formation of des-tyrosine-γ-endorphin and γ-E when compared to either controls, promethazine, or phenobarbital treated rats. However, it was apparent that the formation of the putative antipsychotic peptide des-enkephalin-γ-endorphin was higher in the chlorpromazine treated animals. No significant difference was noted in formation of either α- or γ-type endorphins in the microsomal fraction as compared to controls.

These results suggest that the infusion of chlorpromazine alters membrane associated proteases at the purified synaptosomal membrane but not in the microsomal fraction. This alteration leads to a disruption in the formation of γ-type endorphins but not α-type endorphin although β-E turnover was significantly increased.

149.10 BRAIN EXTRACTS CONTAIN PEPTIDES RELATED TO THE NH_2-TERMINUS OF PROSOMATOSTATIN. R. Benoit and N. Ling. Montreal Gen Hospital Res Inst, Montreal, Que. and Salk Inst, San Diego, CA.

Four peptides derived from pre-prosomatostatin (pre-proSS) have been identified in nervous tissue and shown to be released in vitro: somatostatin-14, somatostatin-28, somatostatin-28(1-12) and pre-proSS(25-100). In order to detect new molecular forms derived from the NH_2-terminal portion of prosomatostatin, antisera were raised against pre-proSS(25-33)-Tyr conjugated to bovine serum albumin using bis-diazotized benzidine. From three antisera that were generated, the one with the lower titer (SMo5) detected the largest amount of immunoreactive material in brain and was selected as the primary antibody in radioimmunoassay (RIA). A sensitive RIA was obtained using pre-proSS(25-33)-Tyr as the cold antigen and pre-proSS (25-33)-Tyr labelled with ^{125}I as the tracer. Tissue from brain regions of adult rats (Sprague-Dawley, 345 g) were extracted with 2 M acetic acid containing pepstatin, PMSF and bacitracin. The extracts were lyophilized, the dried material dissolved in RIA buffer and the amount of proSS NH_2-terminus-like immunoreactivity (proSS-Nt-LI) was measured. Results obtained showed that the hypothalamus contained 7.1 ± 0.4 ng proSS-Nt-LI material per 100 mg wet weight. A uniform distribution was observed in different neocortical regions: 2.8 ± 0.3 ng in frontal cortex, 2.8 ± 0.2 in somato sensory cortex, 2.7 ±0.1 in visual cortex. Levels in pituitary and cerebellum were 1.7 ± 0.1 ng and 0.88 ± 0.04 ng.

In order to further characterize the proSS-Nt-LI, whole brains were extracted with 2 M acetic acid containing peptidase inhibitors and the extract was fractionated on Sephadex G-75. Monitoring of the column effluent by the above RIA revealed that the majority of the immunoreactive material did not coelute with prosomatostatin (M_r: 10.4 kilodaltons) nor with pre-proSS (25-100). It eluted mostly in three zones corresponding to peptides of 6, 3.5 and 1.4 kilodaltons. The 6 K peptide may correspond to pre-proSS(25-88) i.e. prosomatostatin without SS28 and the 3.5 K peptide to pre-proSS(25-56). However, the 1.4 K peptide represents a new entity. It is displaced from a carboxy-methyl cellulose cation-exchanger by 0.06 M ammonium acetate pH 4.6. On a reverse-phase HPLC system using a C_{18} column with 0.1% trifluoroacetic acid/acetonitrile as the mobile phase, the 1.4 K peptide is more hydrophobic than the pre-proSS(25-33)-Tyr standard and elutes at 27% acetonitrile.

These data suggest that post-translational modifications occur at the NH_2-terminus of prosomatostatin. Chemical characterization of the proSS-Nt-LI peptides is required in order to know their structure and their levels in brain and to confirm the precursor-product relationship between proSS and these peptides. Supported by FRSQ, Canadian MRC and NIH (AM18811).

149.11 THE ESTABLISHMENT OF A NOVEL RADIORECEPTOR ASSAY FOR THE MEASUREMENT OF NEURONAL CHOLECYSTOKININ. I.J.M. Beresford* C.R. Clark*, J. Hughes* (SPON: R.G. Hill). Parke Davis Research Unit, Addenbrookes Hospital, Cambridge CB2 2QB, UK

Cholecystokinin (CCK) is one of the most abundant neuropeptides. The measurement of CCK has relied on radioimmunoassay with significant problems experienced in the generation of specific CCK-directed antibodies due to the existence of multiple molecular forms. In view of this and related problems a novel radioreceptor assay (RRA) for CCK using the cerebral cortex CCK receptor is described.

Mice (CFLP) were decapitated, the cerebral cortex removed on ice and homogenised in 90% MeOH: 10% H_2O (10 vols). The supernatant was evaporated to dryness and the reconstituted aqueous extract subjected to C18 Sep-pak chromatography. The purified extracts were then resuspended in RRA incubation buffer (10mM HEPES; 130mM NaCl; 4.7mM KCl; 5mM $MgCl_2$; 1mM EGTA; 5mg/ml BSA; 0.25mg/ml bacitracin; pH 7.2). For the RRA, cortical membranes were homogenised in 10 vols Tris buffer (50mM; pH 7.4), washed twice by centrifugation and resuspended in RRA incubation buffer. A standard curve was obtained by incubating the membranes (10mg prot/ml) with [^{125}I]-CCK 26-33 (0.2nM) and increasing concentrations of CCK 26-33 (10^{-11} - 10^{-6}M) for 2h at 25°C. Reconstituted samples were incubated with membranes and [^{125}I]-CCK 26-33 under identical conditions. Bound and free radioligand were separated by vacuum filtration and the radioactivity counted. The extraction efficiency for CCK 26-33 was 68 ± 6% (n = 5). The RRA sensitivity was 50 fmoles per tube and linear between 50 and 1000 fmoles. The intra- and inter-assay coefficients of variation were 4 and 5% respectively. The inhibition constant for the CCK 26-33 standard curve was 3.13 ± 0.31nM (n = 6). Under these assay conditions, mouse cerebral cortex contained 318 ± 27 pmoles CCK/g tissue. Cerebellum, which lacks CCK, did not inhibit radioligand binding.

Assay of CCK by radioreceptor assay has a number of advantages but perhaps the most important is that the receptor assay will determine the amount of biologically relevant CCK activity in a given sample. This RRA offers the potential for measuring CCK in a variety of tissues, including brain, CSF and plasma.

149.12 ENKEPHALIN CONVERTASE LOCALIZATION IN SPECIFIC NEURONAL PATHWAYS. D.R. Lynch*, W. Clark Venable*, S.M. Strittmatter* and S.H. Snyder (SPON: S. Sato). Johns Hopkins Univ., Dept. of Neuroscience, Sch. of Med., Baltimore, MD 21205.

Enkephalin convertase (EC) is a carboxypeptidase B-like enzyme whose biochemical properties and tissue distribution suggest that it physiologically processes enkephalin precursors. It is specifically inhibited by guanidinoethylmercaptosuccinic acid (GEMSA), and autoradiography with ^{3}H-GEMSA has localized EC to enkephalin containing regions of rat brain. In the present study we have used lesioning techniques in conjuction with ^{3}H-GEMSA autoradiography to localize EC to specific neuronal pathways, some of which contain enkephalin and some of which do not. Previous studies have demonstrated the presence of enkephalins in the stria terminalis by showing that knife cut lesions deplete enkephalin from the stria anterior to the lesion and cause an increase in enkephalins posterior to the lesion. Knife cuts of the stria terminalis increase EC within the stria posterior to the lesion and deplete EC from the bed nucleus of the stria terminalis. These results show that, like enkephalins, EC is axonally transported in the stria terminalis. The hippocampal formation also contains high levels of EC but low levels of enkephalins. EC in the hippocampal formation is concentrated around the granule cells and around the pyramidal cells in layer CA 34. Selective lesions of the dentate gyrus with injections of colchicine into the area of the granule cells deplete EC in the dentate gyrus but do not affect EC levels in the hippocampus around the pyramidal cell layer CA 3-4. Lesions of the pyramidal cells with kainic acid deplete EC in CA 3-4. These results demonstrate the presence of EC in the granule cells, which contain proenkephalin B-derived peptides, as well as in the pyramidal cells, which express neither proenkephalin. The developmental course of EC in these cells also supports this conclusion. While the granule cells are not fully developed in the rat until after birth and do not contain enkephalin like immunoreactivity until approximately postnatal day 10, EC levels are high in the hippocampus several days before birth. This confirms that EC in the hippocampus is found within the pyramidal cells as suggested by the lesioning studies. We have also localized EC to sensory cells in the trigeminal ganglion, which are devoid of enkephalins but do contain the peptides substance P, VIP, and CGRP. Thus, EC distribution primarily parallels that of enkephalins and is found in enkephalinergic pathways, but also occurs in a few regions which do not contain enkephalins. Accordingly, EC may process other neuropeptide precursors in some regions of the nervous system.

CARDIOVASCULAR REGULATION: BULBAR MECHANISMS

150.1 **MECHANICAL CARDIAC INPUT ONTO MEDULLARY RETICULAR NEURONS IN THE CAT.** R.W. Blair. Dept. Physiology & Biophysics, Univ. OK Hlth. Sci. Ctr., Oklahoma City, OK 73190.

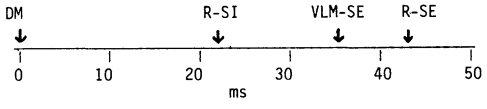
The medullary reticular formation is known to participate in cardiovascular "regulation", but most studies have concentrated on outflow from medullary reticular neurons (RN). Recent studies have indicated that RN also receive noxious input from the heart via sympathetic afferents. The present study was performed to determine whether innocuous stimuli applied to the heart affect the activity of RN. Cats were anesthetized with ketamine and chloralose, and were intermittently paralyzed with pancuronium. A bipolar electrode was attached to the left stellate ganglion (SG). Extracellular potentials were recorded from neurons in the reticular formation. The caudal medulla was searched with metal microelectrodes until a neuron responsive to stimulation of SG was found. These neurons were then tested for responses to aortic occlusion, to probing the heart, and to ventricular fibrillation. Of 41 RN tested, 8 (20%) increased their discharge rates, and 2 (5%) decreased their rates, during aortic occlusion. Of 16 RN tested, 9 (56%) were excited by touching the heart. Five of these RN had fairly distinct cardiac receptive fields. Probing one area of the heart would excite the cell, but the neuron would be insensitive to touching other areas. During fibrillation, 8 of 12 (67%) neurons were excited. Four cells responded at the onset of fibrillation, but the other four cells had a response latency of approximately 7 seconds. These data indicate that a variety of mechanical stimuli applied to the heart can influence the activity of RN. RN were also tested for noxious cardiac (coronary artery occlusion), somatic, auditory, and visual inputs. Various combinations of these additional inputs were found for different RN. In conclusion, RN receive innocous and noxious input from the heart, as well as input from other sensory modalities. (Supported by NIH grant HL 29618 and AHA Okla. Affiliate grant OK 83-G-25).

150.2 DORSOMEDIAL MEDULLARY NEURONS CONTROLLING SYMPATHETIC NERVE DISCHARGE. S.M. Barman and G.L. Gebber. Dept. of Pharmacol./Toxicol., Mich. State Univ., East Lansing, MI 48824.

The current study was initiated to test the hypothesis that the cat dorsomedial medulla contains the cell bodies of neurons involved in the control of sympathetic nerve discharge (SND). The spontaneous activity of 170 of 502 dorsomedial medullary (DM) neurons was temporally related to the 2- to 6-Hz cardiac-locked slow wave in inferior cardiac postganglionic SND. The discharges of these neurons remained synchronized to the 2- to 6-Hz component in SND when blood pressure, and thus baroreceptor nerve activity, were lowered to a level at which the phase relationship between the sympathetic nerve slow wave and the cardiac cycle was disrupted. Thus, the discharges of DM neurons were more closely associated with those of networks controlling SND than those of interneurons in the afferent limb of the baroreceptor reflex arc. Two observations indicated that the unit recordings were made from the region of the cell body. 1) DM neurons were excited by the iontophoresis of L-glutamate, an amino acid that depolarizes cell bodies but not axons. 2) An inflection on the rising phase of their extracellularly recorded spikes was observed. The inflection likely represents separation of the action potentials of the initial segment and soma-dendritic region.

Based on the results obtained using baroreceptor reflex activation, the dorsomedial medulla was found to contain a heterogeneous group of neurons with sympathetic nerve-related activity. DM neurons whose activity decreased in parallel with SND when carotid sinus pressure was elevated were considered to subserve a sympathoexcitatory (SE) function. Those DM neurons with sympathetic nerve-related activity whose firing rate increased during baroreceptor reflex activation were presumed to subserve a sympathoinhibitory (SI) function.

We compared the firing times of DM, rostral ventrolateral medullary (VLM), and raphe (R) neurons relative to the peak of the inferior cardiac sympathetic nerve slow wave. DM-SE neurons fired significantly earlier than their counterparts in the ventrolateral medulla and medullary raphe nuclei. DM-SI neurons fired significantly earlier than R-SI neurons. These data are summarized in the form of a time line which appears below.



These findings, together with the fact that VLM and R but not DM neurons project to the thoracic spinal cord (as determined by antidromic activation), support the view that DM neurons are closer to the region of origin of basal SND. (Supported by NIH grants HL-33266 and HL-13187.)

150.3 GABA and Serotonin Mediate the Sympathoinhibitory and Sympathoexcitatory Responses to Stimulation of Medullary Raphe Nuclei.
Robert B. McCall. Cardiovascular Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

Although it is widely appreciated that the medullary raphe nuclei play an integral role in the neural control of the cardiovascular system, there is surprisingly little data regarding the nature of the neurotransmitters which mediate the sympathoinhibitory and sympathoexcitatory responses elicited by stimulation of this area of the medulla. Recently, our laboratory found that serotonin antagonists blocked and serotonin uptake inhibitors potentiated the sympathoexcitatory response evoked from the medullary raphe nuclei (McCall, R.B., Brain Research, 311: 131, 1984). These data suggest that sympathoexcitatory responses elicited by raphe stimulation are mediated by serotonin. The present investigation was designed to extend this previous study and to determine the nature of the neurotransmitter mediating the sympathoinhibitory response evoked from medullary raphe nuclei. Computer summation techniques were employed to more accurately assess the effects of raphe electrical stimulation. The GABA antagonists picrotoxin (0.5-1.0 mg/kg, i.v.) and bicuculline (0.25-1.0 mg/kg, i.v.) blocked the sympathoinhibitory response evoked from the raphe in intact and mid-collicular transected, anesthetized cats. Mid-collicular transection blocked the high frequency spiking of sympathetic activity normally seen following GABA antagonist administration. Diazepam (0.3 mg/kg, i.v.) potentiated the sympathoinhibitory response elicited from the medullary raphe nuclei. Local application of picrotoxin to the dorsal surface of the lower brain stem, but not to the spinal cord, blocked raphe elicited sympathoinhibition. Picrotoxin often converted a sympathoinhibitory response into a sympathoexcitatory response. The sympathoexcitatory response to raphe stimulation could be blocked by intravenous or intrathecal administration of a serotonin antagonist. Finally, microinjections of L-glutamate into medullary raphe nuclei produced both pressor and depressor responses. These data suggest that the medullary raphe complex is heterogeneous with respect to autonomic function with sympathoinhibitory elements mediated at least in part by GABA and sympathoexcitatory pathways mediated by serotonin.

150.4 THE LINK BETWEEN NUCLEUS RETICULARIS GIGANTOCELLULARIS AND CARDIAC VAGAL MECHANISM IN THE RAT: ANATOMIC AND PHYSIOLOGIC STUDIES.
Samuel H.H. Chan, Julie Y.H. Chan, B.T. Ong* and Charles D. Barnes. Washington State Univ., Coll. of Vet. Med., Pullman, WA 99164-6520, and National Univ. of Singapore, Kent Ridge, Singapore 0511*.

Previous studies from our laboratory suggest that the nucleus reticularis gigantocellularis (NRGC) in the medulla oblongata may be intimately related to the physiologic and pharmacologic processes in circulatory regulation. That the cardiac vagal mechanism may serve as the output for this reticular nucleus to the heart is suggested by the observation that bilateral cervical vagotomy substantially eliminates the cardiovascular action of NRGC. The present study was undertaken to further investigate this NRGC-vagal link, using both anatomic and physiologic approaches. Since a controversy exists over the medullary origin of cardiac vagal innervations, we included nucleus ambiguus (NA), dorsal motor nucleus of vagus (DMV) and nucleus of tractus solitarius (NTS) in our experiments.

Wheat germ agglutinin-conjugated-horseradish peroxidase (WGA-HRP) was used in our anatomic studies to trace the connection between NA, DMV or NTS and NRGC in chloral hydrate-anesthetized rats. To ensure a discrete and localized injection, 15-20 nl of 1% WGA-HRP was infused into one of these cardiac vagal sites in each animal, via a micropipette (50-100 μm tip) over 5 min. Frozen 30 μm sections of the medulla were reacted with the TMB method and counterstained with thionin. Cells that conform with cytoarchitectural descriptions of NRGC neurons were heavily labelled with HRP granules 18-48 hrs following local application of the enzyme to NA, DMV and NTS. There was a bilateral representation, with a higher degree on the ipsilateral NRGC. HRP-labelled fibers could also be traced from the vagal sites to the vicinity of NRGC, signifying a reciprocal connection between them and the reticular nucleus.

Our physiologic experiments were performed on pentobarbital-anesthetized rats. A single NRGC locus in each animal capable of lowering the arterial pressure by at least 20 mm Hg upon electrical activation (10-s train of 1-ms, 20-50 μA rectangular pulses at 25 Hz) was first identified. The effect of stimulating this reticular locus, using single rectangular pulses (1-ms, 50-150 μA, 0.5 Hz) on NA, DMV or NTS was then evaluated. NRGC thus activated evoked field potentials or modified spontaneous single-neuron activities in the vicinity of these cardiac vagal sites. Furthermore, field potentials evoked by stimulating the cephalic end of the severed ipsilateral cervical vagus nerve in e.g. NA, were augmented, and the activated neuronal discharges enhanced, by NRGC.

The results from this study further reinforce the notion that the NRGC may utilize the cardiac vagal mechanism to exert its actions on the heart.

150.5 ^{3}H-PARA-AMINOCLONIDINE BINDING SITES IN VENTROLATERAL MEDULLA AND FRONTAL CORTEX DIFFER IN THEIR LIGAND SPECIFICITIES: IMIDAZOLE BINDING SITES IN THE VENTROLATERAL MEDULLA.
P. Ernsberger, M.P. Meeley and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Clonidine (CLON) is thought to inhibit vasomotor tone via alpha$_2$ receptors in the rostral ventrolateral medulla (RVL). However, the hypotensive effects of CLON in the RVL may, in fact, be mediated by a receptor type other than alpha$_2$, since depressor potency appears to depend upon an imidazole structure (Bousquet et al., JPET 232, 1984). We sought to establish whether CLON interacts with a putative imidazole binding site, as well as alpha$_2$ receptors, using radioligand binding.

Washed P$_2$ fractions from the ventrolateral quadrant of bovine medulla (VLM) and, for comparison, frontal cortex (FCx) were incubated in 50 mM Tris-HCl (pH 7.7) with 1.0 nM ^{3}H-p-aminoclonidine (^{3}H-PAC) at 25°C for 40 min prior to filtration; 10 uM phentolamine was used to define nonspecific binding.

(-)-Norepinephrine (NE) and epinephrine (up to 0.1 mM) inhibited approximately 75% of specific ^{3}H-PAC binding. However, the imidazolines CLON (> 100 nM), naphazoline (> 1 uM), and phentolamine (> 100 nM) displaced 100% of the specific binding. Thus, approximately 25% of specific ^{3}H-PAC binding sites as defined by phentolamine are non-adrenergic.

To further characterize ^{3}H-PAC sites, the competitive binding of a series of imidazole compounds was examined in VLM and in FCx. Unlike NE or CLON, the imidazoles histamine, cimetadine, and imidazole-4-acetic acid (IAA; a histamine metabolite) showed higher potency at ^{3}H-PAC sites in VLM versus FCx:

	IC_{50} in nM (% I_{max}) VLM	FCx
CLON	24 ± 8 (100)	5.6 ± 0.4 (100)
NE	166 ± 35 (70 + 1)	122 ± 31 (80 + 1)
Histamine	2,000 ± 1,000 (100)	38,000 ± 3,000 (100)
Cimetadine	480 ± 90 (68 + 9)	>30,000 (12 + 1)
IAA	22,000 ± 7,000 (72 + 3)	>300,000 (22 + 3)
*Extract	0.3 ± 0.1 U (100)	1.0 Units (100)

A methanol extract* of bovine brain (Meeley et al., this session) potently inhibited ^{3}H-PAC binding, particularly in VLM. In addition, studies of the binding specificity of non-adrenergic sites (10 uM NE added) in VLM showed that the extract had a high affinity for these sites (IC_{50} = 0.12 + 0.07 U), as did CLON (IC_{50} = 6 + 1 nM).

We conclude that: 1) CLON and related compounds may bind to a class of imidazole sites in brain; 2) these imidazole sites appear non-uniformly distributed in brain, being more apparent in VLM than FCx; and 3) an endogenous ligand present in brain may be involved in cardiovascular control through interaction with imidazole binding sites in the VLM. (Supported by NY Heart Association Fellowship and NIH Grant HL18974.)

150.6 ISOLATION OF CLONIDINE-DISPLACING SUBSTANCE FROM BOVINE BRAIN: FUNCTIONAL CHARACTERIZATION.
M.P. Meeley, P. Ernsberger, A.R. Granata and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Clonidine, a synthetic imidazole anti-hypertensive agent, has been shown to act centrally to lower blood pressure, specifically within the area of the rostral ventrolateral medulla (RVL) (Bousquet and Schwartz, Biochem. Pharm., 32, 1459, 1983). Recently, the presence of an endogenous substance in brain which potently displaces specifically-bound 3H-clonidine in rat brain membranes has been reported (Atlas and Burstein, Eur. J. Biochem., 144, 287, 1984). We sought to isolate clonidine-displacing substance (CDS) from bovine brain and further establish the physiological and neurochemical properties of partially-purified CDS.

CDS activity was determined using a 3H-p-aminoclonidine (3H-PAC) binding assay; unit activity is defined as that which displaces 50% of specific 3H-PAC binding (Ernsberger etal., this session). Fresh bovine brains (6) were homogenized in boiling distilled water, centrifuged at 100,000xg for 30 min, then heat-treated at 90-100°C for 5 min. The supernatant was dried and extracted with 20 vols of methanol, sonified for 3 min, filtered and concentrated. Further purification was obtained:

Purification Step	Spec. Activity (Units/g dry wt.)	Total Units/ 6 brains	Purif. (x-fold)	% Yield
Methanol extract	1565.	22,990.	---	100
Dialyzate	2553.	28,377.	1.6	123
$ChCl_3$/MeOH extract	3309.	19,776.	2.1	86

To determine if partially-purified CDS was physiologically active, rats were anaesthetized with urethane, paralyzed, and unilateral or bilateral microjections of CDS (0.02-2.4 Units/50nL vehicle) made in the C1 area of the RVL. CDS elicited a reversible (< 30 min) decrease in arterial pressure (AP) and heart rate (HR). Cardiovascular effects were dose-dependent (maximum Δ AP, -65+7mmHg; Δ HR, -40+8bpm; n=3) and restricted to the C1 area, as verified by PNMT immunocytochemistry. Neurochemically, an increase (2-fold) in the release of CDS activity over basal levels was observed when slices of rat ventral medulla were depolarized using Krebs' bicarbonate buffer, pH7.4 containing calcium and 56mM K+.

We conclude that (1) an endogenous clonidine-like compound (CDS) is present in brain; (2) partially-purified CDS, like clonidine, exhibits depressor activity when microinjected into RVL; (3) CDS in brain may be contained in nerve terminals and released with depolarization; and (4) CDS may be involved in neurotransmission related to central cardiovascular control. (Supported by NIH Grant NL18974.)

150.7 IMMUNOHISTOCHEMICAL LOCALIZATION OF DOPAMINE-β-HYDROXYLASE, PHENYLETHANOLAMINE-N-METHYL TRANSFERASE, SUBSTANCE P AND 5-HYDROXYTRYPTAMINE CONTAINING CELL BODIES IN THE VENTRAL MEDULLA OBLONGATA OF THE CAT. L. Marson* and A.D. Loewy (SPON: E.J. Cole). Dept. Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Neurones responsible for the maintenance of vasomotor tone are present within the ventral medulla. To define the transmitters that may be involved, knowledge is required of the precise locations of the cell bodies containing these various putative transmitters in this area. The distribution of substance P (SP) and catecholamine-containing neurones within the ventral medulla of the cat were studied.

Following injection of colchicine into the 4th ventricle, the distribution of SP, dopamine-β-hydroxylase (DβH), phenylethanolamine-N-methyltransferase (PNMT) and 5-hydroxytryptamine (5-HT) containing neurones were mapped in the cat medulla using the peroxidase-anti-peroxidase technique. DβH containing cells were found in the A1 and A5 cell groups as described in other species. Cells containing both SP or 5-HT were found in the raphe obscurus and raphe pallidus, while cells containing 5-HT alone were also found in the raphe magnus. Two groups of SP containing cells were found in the ventral medulla. The rostral group lie ventral to the facial nucleus and the caudal group was found to lie lateral to the inferior olivary nuclei. 5-HT containing cells were also found in the region lateral to the inferior olivary nuclei, in addition a number of 5-HT containing cells were found overlying the pyramidal tract. PNMT-containing cells were found in the ventral medulla, at the rostral extent of the inferior olives, corresponding to the C1 cell group.

150.8 AUTONOMIC PROJECTIONS OF MEDULLARY ADRENALINE SYNTHESIZING NEURONS. D.A. Ruggiero, M. Anwar, D.H. Park and D.J. Reis. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

In medulla, neurons containing the adrenaline synthesizing enzyme, PNMT (phenylethanolamine-N-methyltransferase), are located in areas of autonomic regulation. In this study we have mapped axon pathways of neurons containing PNMT in order to identify potential anatomical substrates of adrenergic function. Fiber projections of PNMT neurons were first mapped in 20 rats; animals were anesthetized, injected with colchicine (150 ug/10 ul), and the peroxidase-antiperoxidase method was applied to 40 um sections exposed for 24 hr. to antibodies to PNMT. In a second series of experiments (n=30) the cells of origin of these projections were mapped by injecting wheat germ agglutinin-horseradish peroxidase conjugate into PNMT-labeled terminal fields and combining the method of retrograde transport with immunocytochemical localization of tyrosine hydroxylase or PNMT.

C1 neurons in the ventrolateral medulla (VLM) give rise to two bundles of axons: 1) Most axons arch dorsally and form the principal tegmental bundle (PT). Descending fascicles in PT enter dorsal parts of the lateral funiculus to innervate preganglionic cells throughout the thoracic spinal cord. Ascending axons of PT innervate the parabrachial complex (PBC) and pontine raphe and, via the median forebrain bundle, dorsomedial, perifornical, ventral and paraventricular hypothalamic nuclei, amygdala, nucleus of stria terminalis, septal nuclei and preoptic area; 2) a small bidirectional C1 bundle, paralleling PT, projects in the ventral tegmentum. Local projections of C1 neurons terminate in raphe pallidus and nucleus tractus solitarii-dorsal motor vagus (NTS-X); C1 dendrites directly contact the ventral surface of the medulla.

C2 axons descend and ascend along the periventricular and central grey. Descending periventricular axons (and intrinsic fibers of C2 neurons in NTS) ramify within NTS-X. Ascending axons innervate periventricular nuclei (including locus ceruleus and dorsal lateral tegmental nucleus) and in midbrain give rise to a dorsal limb ending in the midline thalamus and two ventral limbs both terminating in hypothalamus. C2 dendrites ramify in the medullary raphe, and contact intraparenchymal blood vessels and the dorsal surface. Double label experiments verify that both C1 and C2 neurons contribute to terminal fields in hypothalamus and NTS-X, whereas adrenergic spinal projections derive primarily from C1 neurons in rostral VLM.

In conclusion, C1 and C2 neurons preferentially connect with nuclei of visceral control and may be differentiated functionally. Mechanisms coordinating their proposed roles in afferent modulation, chemoreception, cortical, vasomotor and neuroendocrine activities remain to be elucidated.

150.9 NEURONS OF THE C1 AREA MEDIATE PRESSOR RESPONSES TO CENTRALLY ACTING CHOLINERGIC AGONISTS IN THE RAT. E.E. Benarroch, R. Giuliano, P. Ernsberger and D.J. Reis. Cornell Univ. Med. Coll., New York, NY 10021.

In the rat microinjection of cholinomimetic agents into the rostral ventrolateral medulla (RVL) produces a sympathetically mediated increase in arterial pressure (AP) and heart rate (HR) (Willette et al., J. Pharmacol. Exp. Ther. 231:457, 1984). The neural substrate for these effects has not been identified. Studies from our laboratory indicate that the area of the RVL containing C1 epinephrine neurons (C1 area) plays a major role in the tonic and reflex control of AP and in cardiovascular responses to electrical or chemical stimulation of a restricted area on the ventral surface of the RVL. We sought to determine whether neurons of the C1 area also mediate changes in AP elicited by cholinergic stimulation of the RVL. Rats were anesthetized (urethane), paralyzed and ventilated. AP and HR were recorded. The exposed ventral medullary surface was explored for evoked pressor responses to topical application of L-glutamate (L-Glu 10 nmole) to identify the area overlying C1 neurons (Benarroch et al., Soc. Neurosci. Abstr. 10:35, 1984). Agonists were applied to this "Glu sensitive" area of the ventral surface of the RVL. Lesions (500 uA, anodal d-c current for 30 sec) were made and their location correlated with the distribution of C1 neurons as assessed immunocytochemically.

Physostigmine or carbachol (100 nl solution 10^{-5} to 10 M) applied to the Glu-sensitive area elicited a dose-dependent increase in AP and HR. The threshold dose was 10 pmole, maximal effects were obtained with 10 nmole, and at higher doses a profound fall in AP was observed. Previous application of atropine (1 nmole), but not hexamethonium (1 nmole), to the same area prevented the responses to cholinergic agonists, but not to L-Glu (10nmole). The responses to carbachol (1 nmole) applied to the Glu-sensitive area were abolished by ipsilateral application of 100 nmole GABA (from 160 ± 5 to 104 ± 8 mmHg, n=5, $p < 0.05$) or by ipsilateral electrolytic lesion restricted to the C1 area (from 170 ± 8 to 98 ± 4, n=5, $p < 0.01$), but not the adjacent raphe. The effects of carbachol applied contralaterally to the C1 lesions were unimpaired. The pressor effect of intravenous injection (i.v.) of physostigmine (100 ug/kg) was abolished by either bilateral application of GABA (100 nmole) to the Glu-sensitive area (from 150 ± 8 to 60 ± 4 mmHg, n=4, $p < 0.01$) or bilateral electrolytic lesions of the C1 area (from 150 ± 5 to 54 ± 3 mmHg, n=4, $p < 0.01$). Sections (10um) from untreated rats were incubated with ^{3}H-quinuclidinyl benzilate (2nM). A moderate density of muscarinic receptors was identified in a region overlapping the C1 area of the RVL. We conclude that neurons of the C1 area a) mediate pressor responses to muscarinic cholinergic stimulation of the RVL and b) are critical for the pressor response to i.v. physostigmine.

150.10 HEMODYNAMIC CHANGES INDUCE VARIATIONS IN CATECHOLAMINERGIC METABOLIC ACTIVITY WITHIN THE VENTROLATERAL MEDULLA. J.Y. Gillon*, L. Quintin, G. Hilaire*, M. Ghignone* and J.F. Pujol* (SPON: J.J. BOUYER) Neuropharmacology, Roussel Uclaf, 93230 Romainville, France.

In vivo voltammetry has recently been shown to be a sensitive and reliable technique to monitor pontine noradrenergic (NA) activity (Buda et al., Brain Res., 1983, 273 : 197-206 ; Gonon et al., Brain Res., 1983, 273 : 207-216). This study was undertaken to assess whether such a technique would evidence changes in medullary catechol (CA) oxidation current (Suaud-Chagny et al., submitted) in relation to hemodynamic variations. Male rats (OFA strain) were anesthetized (chloral 400 $mg.kg^{-1}$), ventilated with oxygen/air mixture and paralyzed. Temperature was maintained to 37.5 + 0.5°C. Acidosis, as checked by frequent arterial blood gases, was buffered with sodium bicarbonate. Treated carbon fibre electrodes were lowered to the ventrolateral medulla (VLM) (L 1.9 mm, P 0.3 mm to the obex, DV -2.5 mm) with a 30° angle to detect a catechol oxidation peak (+50-75 mV, differential normal pulse voltammetry). Sixty minutes were allowed to elapse in order to stabilize the catechol peak height and mean blood pressure (MBP, 110 + 20 mmHg). Results are expressed as % of baseline values of catechol signal. Volume expansion (4-6 ml) decreased catechol peak height to 80% of baseline value while MBP increased 10 to 30 mmHg. In contrast, blood withdrawal (BWD, 4-6 ml) increased catechol signal to 150% while MBP decreased to 30-50 mmHg (absolute value). These variations in catechol metabolic index are in keeping with electrophysiological variations evidenced in the locus coeruleus during similar hemodynamic manipulations (Elam et al., Brain Res., 1984, 290 : 281-297). Infusion of sodium nitroprusside increased catechol signal to 160% while MBP decreased to 40 mmHg. Prazosin 1 $mg.kg^{-1}$ i.p. increased catechol signal to 125% while MBP decreased to70-80 mmHg. This is in agreement with increased unitary activity in the A5 nucleus during controlled hypotension (Andrade et al., Brain Res., 1982, 242, 125-135). Clonidine 100-200 $ug.kg^{-1}$ i.p. decreased the catechol signal to 60-70%, and MBPto 70-80 mmHg. This may be related to the inhibitory action of this molecule on CA VLM structure (Cahusac et al., Neurosci. Lett., 1983, 42 : 279-284). Clonidine 100-200 $ug.kg^{-1}$ injected 30 min before hemorrhage reduced the catechol peak increase, secondary to BWD, to 115%. This is in keeping with the inhibitory action of clonidine on central NA neurons under nociceptive stimuli (Marwaha et al., J. Pharm. Exp. Ther. 1982, 222 : 287-293) or during stress (Quintin et al., Soc. Neurosci. Abstr., 1984, 10 : I, 679). That medullary CA activity is related to hemodynamic variations should be interpreted in view of the close anatomical association of adrenergic excitatory and NA inhibitory VLM structures.

150.11 TWO DISTINCT MEDULLOSPINAL SYMPATHOEXCITATORY PATHWAYS ORIGINATE IN THE RAT NUC. PARAGIGANTOCELLULARIS LATERALIS (PGCL). Patrice G. Guyenet, D. Les Brown and Miao-Kun Sun*. Univ. Virginia School of Medicine, Dept. of Pharmacology, Charlottesville, VA 22908.

The retrofacial portion of PGCL contains neurons with spinal projections and a strongly pulse-synchronous rate of discharge. Below a mean arterial pressure of 75 mm Hg (MAP), these neurons exhibit a high level of discharge independent of AP and their activity decreases linearly to zero when MAP is increased from 90 to 160 mm Hg. This inhibition results from the activity of arterial baroreceptors and is mediated by GABA (see following abstract).

The axonal conduction velocities of these neurons exhibit a bimodal distribution with peaks at 0.68 and 3.1 m/sec respectively (N=170 cells).

Clonidine (clo, 11 μg/kg i.v.) exerts a selective inhibitory effect on slow-conducting units while fast-conducting ones are unaffected. By the iontophoretic route, clo (100 nA) also selectively inhibits slow-conducting neurons.

Single or twin-pulse stimulation of the PGCL (0.5 msec, 150 μA, 0.5 Hz) evokes two peaks of activity at the level of the lumbar sympathetic chain (L2-L3) with latencies of 98 ± 2.5 msec (N=7) and 206 ± 9 msec respectively. Similar stimulations but delivered in the lumbar spinal cord (L2-L3) elicit a peak of activity 65 msec after the stimulus. The sympathoexcitatory effect of PGCL stimulation therefore results from the activation of two medullospinal pathways whose latency from PGCL to the upper lumbar IML averages 33 and 141 msec respectively. These latencies correspond to intraspinal conduction velocities of 3.2 and 0.68 m/sec respectively, figures which are identical to those exhibited by the spinal axons of PGCL pressure-sensitive neurons.

These experiments are consistent with the following interpretations: first, SND is in a large part maintained via the tonic discharge of medullospinal excitatory inputs originating in the retrofacial portion of PGCL; second, the baroreceptor reflex inhibition of SND is a disfacilitation involving the inhibition of PGCL sympathoexcitatory neurons; third, the medullospinal sympathoexcitatory projection of PGCL consists of at least two neuronal populations, a slow-conducting clonidine-sensitive one and a fast-conducting clonidine-insensitive other. (HL 28785, HL 33513, HL 01128).

150.12 THE ACTION OF GABA ON SYMPATHOEXCITATORY NEURONS IN THE RAT VENTROLATERAL MEDULLA. Miao-Kun Sun* and Patrice G. Guyenet. Univ. of Virginia School of Medicine, Dept. of Pharmacology, Charlottesville, VA 22908.

The retrofacial portion of nuc. paragigantocellularis lateralis (PGCL) contains a population of neurons which project to the intermediolateral cell column, discharge spontaneously at low levels of arterial blood pressure and receive a powerful inhibitory input originating from arterial baroreceptors. The nature of the transmitter released by this inhibitory input was investigated with single-unit recording techniques and ionophoresis in halothane-anesthetized rats. All PGCL cardiovascular neurons recorded could be silenced by GABA (0.8M; ≤ 50nA n=20), glycine (0.5M; ≤ 60nA n=10) or inhibited by taurine (1M, 60nA, n=5). The effects of gly and taurine were completely antagonized by strychnine (50 mM; 100nA, n=10). Gly-induced inhibitions were unaffected by bicuculline methiodide (BiC, 20mM, 100nA, n=5). Conversely BiC completely antagonized the effects of GABA but did not alter the inhibition caused by gly.

BiC (100nA) blocked completely and reversibly the inhibition of PGCL cardiovascular neurons produced by raising mean arterial pressure (MAP) to 160 mm Hg (n=14). During the period when the cells were insensitive to MAP elevations, they were still inhibitable by gly but were insensitive to doses of GABA previously sufficient to produce 100% inhibition in the absence of BiC.

Strychnine, when applied in an amount sufficient to completely antagonize the effects of gly did not impair the blood pressure sensitivity of the units (n=6).

BiC in doses sufficient to block the inhibition induced by elevations in MAP also increased the basal rate of discharge of PGCL CV units by 50% on average. Similar increases in the units activity could be produced by local applications of l-glu (0.2M, 100nA). Yet such elevations in the cells firing rate did not modify the inhibitory effects produced by raising MAP (n=6).

It is concluded that GABA or a related substance mediates the inhibition of PGCL sympathoexcitatory neurons produced by the activation of arterial baroreceptors. Moreover PGCL sympathoexcitatory neurons may be tonically inhibited by a GABA-ergic input even at MAP below the threshold for arterial baroreceptor activation (HL 28785, HL 33513, HL 011128).

LIMBIC SYSTEM: DEVELOPMENT AND PLASTICITY III

151.1 EFFECTS OF EXTRACELLULAR FIELDS ON NORMAL AND EPILEPTIFORM ACTIVITY IN ADULT AND IMMATURE RAT HIPPOCAMPAL SLICES. S.M. Bawin, T.J. Purtzer*, M.D. Mahoney*, A.R. Sheppard, S. Ashwal* and W.R. Adey. Departments of Physiology, Neurosurgery and Pediatrics, Loma Linda University and VAMC, Loma Linda, CA 92357.

We previously reported that oscillating extracellular fields in the range of EEG rhythms and epileptic afterdischarges (5-130 mV/cm in tissue) induced long-term increases in population spikes and EPSPs recorded in the CA1 cell layer and apical dendrites of adult rat hippocampal slices. These post-field effects were independent of the passive and instantaneous polarizations which occurred during DC and sinusoidal fields with amplitudes larger than 50 mV/cm. We have now compared field effects in slices from 8-25 day old pup rats with those observed in adult slices, studied concurrently in the same recording chamber. The perfusing solutions contained either 2 or 2.5 mM Ca^{++} and 5 or 7 mM K^+ ($[K^+]/[Ca^{++}]$ = 2.5). Immature and adult slices responded similarly to polarizing fields, but the long-lasting increases in excitability that followed oscillating fields (5 and 60 Hz) in mature tissue were never observed in animals younger than 16 days, and were rarely seen in the older pups. Increasing $[K^+]/[Ca^{++}]$ ratio from 2.5 to 3.5 in either solution resulted in epileptiform evoked potentials and afterdischarges, and facilitated field-induced lasting potentiations in adult and 16-25 d pups, but not in slices from younger animals. Measurements with K^+ sensitive microelectrodes in the CA1 pyramidal cell layer and apical dendrites showed increased K^+ activity during and following repetitive field stimulation (5 and 60 Hz) in slices from adult and 18-25 d rats, but not in the 8-13 d pups studied so far. Altogether these results suggest that although passive neuronal polarization by strong (greater than 50 mV/cm) extracellular fields occurs readily in the immature brain, the K^+ response of the tissue and its capability to sustain long-lasting field effects appear slowly, concurrent with the development of synaptic excitability. Once established, these last two mechanisms of field interaction with the tissue may have a significant influence on excitability, especially when the extracellular $[K^+]/[Ca^{++}]$ ratio is elevated, such as during seizures or intracerebral hemorrhage.

(Supported by Department of Energy, Southern California Edison Company and Department of Pediatrics, LLU.)

151.2 CYSTEAMINE SUPPRESSION OF KINDLED SEIZURES: DEPENDENCE ON INJECTION-TO-KINDLED SEIZURE INTERVAL. G.A. Cottrell and H.A. Robertson. Department of Pharmacology, Dalhousie University, Halifax, N.S., Canada B3H 4H7.

Higuchi et al. (Brain Res., 288:359, 1983) originally reported that cysteamine (β-mercaptoethylamine) suppressed amygdala kindled seizures at 24 and 48 hrs (with the suppression lasting up to 10 days in some animals) but not at 4 hrs. They attributed this suppression to brain somatostatin depletion. However, we feel that this explanation is unlikely as somatostatin depletion (Sagar, S.M. et al., J. Neurosci., 2:225, 1982; Srikant, C.B. and Patel, Y.C., Endocrinol., 115:990, 1984) and kindled seizure suppresson do not follow the same time course. Further, as we shall report, the injection to kindling interval is critically important for the suppression effect.

Male sprague-dawley rats were implanted with a twisted teflon-coated stainless-steel electrode in the left amydaloid complex or left dorsal hippocampus. The rats were kindled (2 sec, bipolar, 60 Hz, 340 μA to amygdala, 240 μA to hippocampus) on a daily schedule. Following kindling, rats were injected with cysteamine (200 mg/kg, IP). In the first experiment, we used the paradigm of Higuchi et al., i.e., injection 4 hrs prior to the kindling session. Our findings were essentially identical to those of Higuchi et al.: Four hrs after cysteamine administration, amygdala and hippocampal kindled rats exhibited kindled seizures. This suppression lasted for 4-10 days in individual rats. In the second experiment, we injected rats 2, 4 or 6 hrs after a kindled seizure. On the 24 hr kindling test, none of the rats in the 6 hr-post group exhibited suppression, i.e., they all had a stage 5 seizure. The effect of injection 2 or 4 hrs post was intermediate. In the 2 hr-post group, 2 out of 5 rats did not have a stage 5 seizure on the 24 hr test (the other 3 did). All these rats had a stage 5 seizure on the 48 hr test. In the 4 hr-post group, 3 out of 4 rats had a stage 5 seizure on the 24 hr test, 4 out of 4 on the 48 hr test. Thus, the percentage of rats exhibiting suppression and the duration of the suppression is dependent on the administration-to-kindled seizure interval. We therefore conclude that the suppression of kindled seizures following cysteamine administration is not due to the cysteamine per se, but must be due to an interaction of the cysteamine with the kindling process. One possibility is that it acts through glutamate receptors. Calcium-dependent glutamate binding is depressed by cysteamine (see poster of Robertson, H.A. and Cottrell, G.A., this meeting). (Supported by the Canadian MRC and the Dalhousie Medical Research Foundation).

151.3 THE EFFECT OF CHRONIC ETHANOL TREATMENT ON INHIBITION IN CA1 OF THE IN VITRO RAT HIPPOCAMPUS. C.J. Rogers and B.E. Hunter, Dept. of Neuroscience, Univ. of Fla., Coll. of Med. and V.A. Med. Cntr., Gainesville, FL. 32610

Chronic ethanol treatment (CET) produces an increase in the amplitude of the extracellular population spike (PS) with paired pulses in CA1 of the in vivo rat hippocampus (Abraham et al., 1981). The increase in PS amplitude was attributed to a decrease in recurrent inhibition (RI). It may also be possible that the increase in PS amplitude is the result of a decrease in recently described feedforward inhibition (FFI). Antidromic/orthodromic (A/O) and orthodromic/orthodromic (O/O) paired pulse techniques should allow for the relative dissociation of the influence of CET on RI and FFI. This study was designed to determine whether CET produced alterations in PS amplitudes in vitro as has been demonstrated in vivo and whether CET affects RI and FFI differentially.

Rats were fed a nutritionally complete ethanol (E) or sucrose-containing (S) liquid diet for 20 weeks. Ad lib lab chow and water were then given for at least eight weeks prior to acute electrophysiological in vitro manipulations. Stimulating electrodes were placed in stratum radiatum for orthodromic stimulation and in the alveus for antidromic stimulation. Extracellular field potentials were recorded at the pyramidal cell layer with micropipettes. Input/output (I/O) curves were collected followed by several paired pulse paradigms using different condition and test pulse current intensities as well as A/O and O/O configurations. Interpulse intervals (IPI) ranged from 20 msec to three seconds.

CET produced an enhancement of the PS using paired pulses in vitro as has been demonstrated in vivo. The increase in PS amplitude using O/O configurations is most pronounced with IPIs from 20 to 500 msec. A/O paired pulses at higher current intensities resulted in group S animals remaining moderately inhibited out to three seconds while group E animals showed only early inhibition. These results suggest that CET produces alterations in recurrent inhibition. The effect of CET on FFI is more difficult to interpret although it does not appear that the changes seen between groups with A/O paired pulses can account for the much larger differences observed between group S and group E animals with O/O data. These results suggest that CET alters the influence of FFI to a greater extent than it does RI.

151.4 POWER SPECTRAL ANALYSIS OF THE HIPPOCAMPAL EEG IN THE NORMALLY DEVELOPING RAT. J.D. Bronzino, C.J. Siok*, K. Austin*, R.J. Austin-LaFrance* and P.J. Morgane. Trinity College, Hartford, CT 06106 and Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

We have used power spectral analysis techniques to quantify the development of the EEG obtained from the frontal cortex and the hippocampal formation of normally developing rats during several different vigilance states. At 14,18,22,30 or 45 days of age, EEG recordings were obtained and computer analysis was performed during the vigilance states of quiet waking (QW), slow-wave sleep 1 (SWS1), slow-wave sleep 2 (SWS2) and REM sleep. In the power spectra derived from the hippocampal EEG it was found that in the 0.5-3.5 Hz frequency range during QW and REM sleep, the average power significantly decreased ($p<.02$ in QW; $p<.002$ in REM) as the animal matured from 14 to 45 days of age. A peak in the power spectra was also observed starting at 14 days of age in the 4-11 Hz (theta) frequency range during both QW and REM sleep. During REM the frequency at which the maxima of the peak occurred (peak theta frequency) significantly increased ($p<.001$) from 4.4 Hz at day 14 to 6.7 Hz by day 45. During QW the peak theta frequency at 14 days of age occurred at 4.3 Hz and its amplitude was 32% lower ($p<.01$) than that which occurred during REM. By day 45 the peak theta frequency during QW significantly increased ($p<.001$) to 5.9 Hz, but was significantly slower ($p<.01$) than the peak which occurred at the same age during REM. There was also a significant decrease ($p<.002$) in the amplitude of this peak when compared to the 14 day old animal. In the power spectra derived from the EEG of the frontal cortex, the average power of the predominant 0.5-3.5 Hz frequency band significantly increased ($p<.01$) during the states of SWS1 and SWS2 as the animal matured from 14 to 45 days of age. Our studies of normal electro-ontogenesis in these brain areas may serve as baseline values against which to assess the effects of neuronal insults on electrographic development in these regions. (Supported by NSF Grant ECS 8118440 and NIH Grant HD-06364).

151.5 AN INFORMATION/COMPUTATION THEORY OF HIPPOCAMPAL FUNCTION. W.B. Levy. Dept. Neurosurg., Univ. Virginia, Charlottesville, VA 22908.

It is the job of the nervous system to make good predictions about current and future states of the organism, the environment, and interactions between the two. Such predictions are constructed from predictions made by individual neurons. Indeed, parallel distributed theories of the nervous system interpret the activities of individual neurons as predictions. I.e., the activity of a neuron is its calculated probability that one of its best patterns currently exists. The calculation of this probability is conditioned on current afferent activity and the correlative history of the environment as stored in the connections between neurons. Additional neural circuitry predicts the overall current environment by selecting a subset of neurons that most strongly predict the existence of the features for which they are tuned. Optimally, the choice comes from predictions conditioned on all possible states of the environment.

Unfortunately, only a small subset of all possible conditional predictions can be generated by the brain because of the relatively limited number of neurons compared to possible configurations of the environment and the number of different ways predictions can be conditioned. This limitation is severe, i.e., most predictions will not be made. To minimize the damage of this constraint, afferents converging on a cell should be minimally redundant. Then each prediction is based on as much information as possible.

The hypothesis is that neurons of the dentate gyrus and CA3 remap the environment so that predictions made by CA1 neurons are based on minimally redundant information. This hypothesis restates the source coding problem in information theory, thus defining optimal performance: maximize the mutual information between the input and the output while minimizing the mutual information between the input lines with respect to themselves. In the model, the input lines are the layer II stellate cells of the entorhinal cortex which project to the DG and CA3, and the output lines are the CA3 pyramidal cells that project to CA1. The number of input and output lines is assumed equal. Septal inputs separate patterns in time. All other inputs are viewed as modulatory.

At least in one case there is a unique solution to this problem. For Gaussian environments the Karhunen-Loeve transformation is the optimal mapping. This transformation remaps the environment so that all output lines considered pairwise are independent and no higher order interactions exist. A more general solution suitable for optimally transforming more complex environments is desirable. The ultimate question is how and in what sense the natural constraints of anatomy and physiology produce a self-optimizing source coder.

151.6 DEATH OF CA1 PYRAMIDAL NEURONS FOLLOWING ELECTROLYTIC LESION OF THE ENTORHINAL CORTEX. Y.Theoret* and M.R. Krigman, Dept. of Pathology, Univ. of North Carolina at Chapel Hill, NC 27514.

Unilateral lesion of the entorhinal cortex results in a partial deafferentation of the perforant pathway excitatory terminals in the outer molecular layer of the dentate gyrus. Although this technique does not affect the granule cells viability, we have observed a massive neuronal death of the CA1 pyramidal neurons.

Long-Evans rats (300-350g) were anesthetized with pentobarbital and the head was immobilized in a stereotaxic frame with the incisor bar set at -3.9mm. The parameters involved in the fabrication of the lesioning electrode and in the application of the direct current were similar to those reported by Nadler and co-workers (Brain Res.,131:241,1977). Electrolytic current was applied in nine locations of the entorhinal cortex. Animals were sacrificed at 6, 12, 24, 48 and 96 hours after the surgery and the brains were processed for either light or electron microscopy.

Light microscopy 48 hours post-lesioning revealed extensive neuronal necrosis of the CA1 pyramidal neurons on the ipsilateral side; rare scattered pyknotic neurons were observed on the contralateral side. There was no effect on CA4 and CA3 pyramidal neurons nor on granule cells on either side. Neurons located in the subiculum and in the regions deep and superficial to the CA1 cell body layer were spared. Ipsilateral to the lesion side, necrotic neurons were not discernible 6 hours after the surgery but increasing number of dying CA1 pyramidal neurons were seen at 12 and 24 hours. Bielschowsky staining showed a correlation between the degeneration of fibers in the stratum lacunosum moleculare (temporo-ammonic tract) and the necrosis of the CA1 pyramidal neurons. Electron microscopy at 6 hours post-lesioning revealed numerous electron lucent dilated structures in the CA1 neuropil ; these may be altered glia or degenerative terminal boutons. At the same time, CA1 pyramidal neurons exhibited swollen mitochondria in the apical dendrites and to a lesser extent in the soma, and vacuolation within the cytoplasm. At later periods, the mitochondrial changes were less prominent but the cytoplasmic vacuoles increased in size and number and were now visible in the nuclei. Microtubules were less organized and cytoplasmic dense bodies were seen.

Although a direct electrolytic effect could sometimes be observed on the most caudal portion of the hippocampal formation, our findings indicate the absence of such an effect on the rostral CA1 pyramidal neurons. We propose that the acute necrotizing process is related to the degeneration of the entorhinal cortex terminals (possibly temporo-ammonic tract) in the hippocampal formation via mechanisms which remain to be elucidated. 151.7 EFFECTS OF CHOLINERGIC AGONISTS ON HIPPOCAMPAL NEURONS OF THE IMMATURE RAT. L. J. Reece* and P. A. Schwartzkroin (SPON: T. Kennedy). Dept. of Neurological Surgery, Univ. of Washington, Seattle, WA 98195.

Cholinergic agonists are known to facilitate the firing of hippocampal pyramidal cells in the adult rat through binding to receptors which are primarily muscarinic. This facilitation apparently occurs through two mechanisms: one a post-synaptic suppression of a voltage-dependent potassium current, the other a pre-synaptic suppression of inhibitory influences. In the adult rat, the pyramidal cell response to muscarinic agents has been characterized as a slow depolarization with concurrent increase in input resistance. We have previously demonstrated that in immature hippocampus the response to another neurotransmitter, GABA, differs significantly from that in the adult. We have therefore begun to examine the response of immature hippocampal pyramidal cells to acetylcholine.

Transverse slices (400 um) were taken from the hippocampus of rats from 5 to 60 days of age. Carbachol (5 mM) was applied from a micropipette in droplet form to the surface of the slice in the area of the cell body layer and the proximal dendrites. Preliminary evidence indicates that the response of immature animals to applied carbachol, while perhaps differing from the response in the adult in some respects, is basically similar. The pyramidal cells in slices from immature animals undergo a membrane depolarization on the average of 10 mv; this depolarization is associated with an increase in the cell's input resistance. Thus, immature pyramidal cells respond to cholinergic stimulation before their normal cholinergic afferents are well established.

The adult response, seen in animals older than 20 days, sometimes includes a brief hyperpolarization of 1-3 millivolts preceding the more commonly observed depolarization. In the cells in which the early hyperpolarization is seen, a brief decrease in the input resistance correlates temporally with the onset of the hyperpolarization. This hyperpolarization may be mediated by inhibitory interneurons, for we have shown that interneurons are excited by applied carbachol. This hyperpolarization is less apparent in the immature hippocampus, perhaps due to the slow development of inhibitory circuitry in these animals.

These studies were supported by NIH grants NS15317, NS20482, and GM07108.

151.8 ORGANIZATION AND DEVELOPMENT OF THE HIPPOCAMPAL COMMISSURE IN PRIMATES: OVERPRODUCTION AND ELIMINATION OF COMMISSURAL AXONS IN INFANT RHESUS MONKEYS. A-S. LaMantia and P. Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

We have examined the cytological and axonal organization of the interhemispheric fiber tract classically referred to as the corpus psalterium or the hippocampal commissure (HC) using electron microscopic (EM) and immunocytochemical techniques in nine rhesus monkeys ranging in age from birth to four years. The number of axons in the developing and adult HC was estimated using a quantitative EM method employed previously for the corpus callosum and anterior commissure (LaMantia and Rakic, Soc. Neurosci. Abstr. 10: 1080, 1984).

Three morphological features distinguish the HC from the adjacent corpus callosum (CC). First, a glial capsule surrounds the HC and separates it from the overlying splenium of the CC in infant and adult monkeys. The cells and processes which compose this capsule have ultrastructural characteristics of astrocytes: they have numerous bundles of intermediate filaments, and display strong immunoreactivity with antisera directed against glial fibrillary acidic protein. These cells are extensively interconnected by numerous desmosomal junctions. Second, the distribution of astrocytes and their processes within the HC is quite different from that in the CC. In the HC, glial cells are more numerous and after the third postnatal month their processes form a trabecular meshwork which separates bundles of axons into fasicles. In contrast, the incidence of glial cells is considerably lower in the CC and the processes of these cells do not divide groups of axons into fasicles. Third, the mean diameter of myelinated axons in the HC (0.7 um) is half that of axons in the splenium (1.4 um). Furthermore, myelination of the HC proceeds at a slower rate; however, in the adult HC 95% of the axons are myelinated as in the overlying CC.

There is at least a fivefold overproduction of axons in the developing HC. At birth there are over 1,000,000 axons in the HC. During the first two postnatal weeks this number drops to less than 400,000, and elimination of HC axons continues at a slower rate until the second postnatal month when the adult number of 200,000 is reached. The major wave of axon loss in the HC overlaps with that in the CC and the anterior commissure (LaMantia and Rakic, 1984); however, each commissure loses axons at a different rate. The omnipresence of axonal elimination during infancy in these three commissures, which connect several anatomically and functionally distinct cortical regions, suggests that this process may play a significant role in the formation of interhemispheric connections.

151.PO LACK OF PERSISTENCE OF ENVIRONMENTAL COMPLEXITY INDUCED INCREASE IN POSTSYNAPTIC RESPONSE TO PERFORANT PATH STIMULATION IN RAT DENTATE GYRUS FOLLOWING REHOUSING IN STANDARD LABORATORY CAGES. E. J. Green* and W. T. Greenough (Spon: C. L. Prosser). Neural and Behavioral Biol. Prog., and Depts. Psychol. and Anat. Sci., Univ. Illinois, Champaign, IL 61820

Several recent in vivo studies have found increased dentate gyrus field potential responses to perforant path stimulation following behavioral manipulations (e.g. Sharp et al., Soc. Neurosci. Abstr., 9(2), 1983). We recently reported that population epsp and spike responses were greater, in hippocampal slices maintained in vitro, from rats reared from weaning in a complex environment than in slices from individually cage-reared rats (Green and Greenough, Soc. Neurosci. Abstr., 10(1), 1984). The present study examined the persistence of this in vitro field potential response elevation during a subsequent period of re-housing in individual cages.

Rats in the environmental complexity initial condition (EC-I) were group reared from weaning in wire mesh cages containing a three dimensional lattice of wooden, metal and plastic objects which were changed daily, and were allowed free exploration in a separate play area containing a similar set of objects for 30 to 60 minutes each day. Rats in the isolated initial condition (IC-I) were housed singly in standard laboratory tubs. Following 30 days of differential rearing, both groups of rats were re-housed individually in plastic laboratory tubs for an additional 25-34 days. Hippocampal slices from littermate pairs were prepared for physiological investigation. Population responses were recorded in the stratum granulosum (ventral blade) of the dentate in response to stimulation of afferents in the middle molecular layer. Previously we found that slices from EC rats exhibited significantly larger population spikes and epsp's at the higher stimulus intensities in this region.

In contrast, in the present study, following 3-4weeks of additional housing in similar individual cage environments, there were no group differences in population spikes or epsp's across a range of stimulus intensities. Thus, the increased activation of granule cells in EC slices appears to be transient, persisting for less than 3-4 weeks in the absence of differential housing. 151.10 STUDY OF INFLUENCES FROM HYPOTHALAMUS AND LOCUS COERULEUS UPON THE ELECTRICAL ACTIVITY OF THE OLFACTORY TUBERCLE. R. Guevara-Aguilar, L.P. Solano-Flores+, M. Nájar Joa. Departamento de Fisiología, Facultad de Medicina, División de Investigación, UNAM. 04510, México, D. F.

The interaction of locus coeruleus (LC) and lateral hypothalamus (LH) stimulation over the electrical activity of the olfactory tubercle (OT) were studied. The experiments were conducted in 30 Wistar rats of either sex, anesthetized with chloral hydrate (400 mg/kg). Evoked potentials and/or unitary activity were recorded in the polymorphic layer of the olfactory tubercle using a single barrel glass capillary electrode filled with 2 M NaCl. Bipolar parallel stainless steel electrodes were used for stimulation. The LC stimulation electrode was placed in P8 to 9.4; L 0.8 to 1.1 and V -5.5 to -6.3. The LH stimulation electrode was placed in P 1.0 to 2.0; L 1.0 to 2.0 and V -7.0 to 8.0. All the electrode position were determined from bregma in the horizontal rat's skull and from the brain surface.

LH stimulation evoked a biphasic (positive-negative) potential in the OT, a similar potential had been previously recorded in cats. In the same experiment the latency of the first wave of the OT potential evoked after LC stimulation was longer than that of the first wave of the OT potential evoked after LH stimulation. Repetitive stimulation of LC (800 µA, 0.2 ms pulse, 300 Hz maintained during 5 s) previously to single test shocks to LH showed: while the positive wave of the evoked potential in the OT by LH stimulation was reduced with respect to the control, the negative wave was enhanced after a transient deppression.

We had previously reported that LC stimulation decreased the discharge frequency of the OT units, when we studied the effect of LH stimulation over the same cells responded to LC stimulation we observed that: 38/56 neurons (67.8%) initially increased their activity, 12/56 neurons (21,4%) initially decreased their activity and only 6/56 neurons (10.7) exhibited no effects following LH stimulation. These results suggest a convergence of LH fibers and LC fibers upon the OT neurons.

151.11 **BEHAVIORAL ACTIVATION IN 3-DAY-OLD RATS PRODUCED BY ELECTRICAL STIMULATION OF THE NUCLEUS ACCUMBENS BUT NOT THE NEOSTRIATUM.** Eunice H. Lee* and Gordon A. Barr* (SPON: Robert L. Thompson). Biopsychology Program, Hunter College, City University of New York and Dept. Psychiatry, Albert Einstein College of Medicine, Bronx, New York 10461.

Young rat pups become behaviorally activated, emitting a series of responses, that includes mouthing, licking, pawing, and locomotion, following either reinforcing exteroceptive stimuli such as milk, or brief electrical stimulation of the medial forebrain bundle (Hall, *J. Comp. Physiol. Psych.*, 1979, 93: 977; Lithgow and Barr, *Behav. Neurosci.*, 1984, 98: 479; Moran et al., *J. Neurosci.*, 1983, 3: 10). To further characterize the role of striatal and mesolimbic systems in the behavioral activation of infant rats, we observed the behavioral response of 3-day-old rats following brief electrical stimulation of the caudate nucleus (CD) or the nucleus accumbens (NA).

Bipolar teflon coated stainless steel electrodes, bared at the tip, were implanted in the CD or NA of 3-day-old pups. Testing occurred 16 to 20 hours after surgery. Following a 5 minute adaptation period and a 2 minute baseline observation period, behavior was recorded over 6-one minute intervals during which direct current biphasic square wave stimulation (500 msec train of 50 pulses with a pulse width of 2 msec) was delivered every 10 seconds during every other minute. Current was varied between 30 and 150 μA, although inactive sites were tested up to 1000 μA. The behavior of the pup was recorded during each minute. Following testing, pups were overdosed with a barbiturate and perfused intracardially. Frozen sections were stained for Nissl substance and the electrode placements verified without reference to the behavioral data.

Stimulation of the NA resulted in behavioral activation. Stimulation of the CD and other areas such as the diagonal band of Broca or the lateral septum were negative. The elicited behaviors occurred immediately after the onset of stimulation and decayed rapidly when the stimulation ended. The predominant behavioral responses elicited by stimulation of the NA were mouthing, licking and pawing. Locomotion, in contrast, was seen following stimulation of both the NA and the CD.

To assess first if dopamine antagonists would block stimulation induced behavioral activation, and second if typical and atypical neuroleptics would differentially affect striatal and mesolimbic systems, subsequent studies tested whether the behavioral activation elicited by electrical stimulation of the NA could be blocked by the dopamine antagonists haloperidol and clozapine. Haloperidol (0.2 mg/kg) and clozapine (2.5 mg/kg) produced comparable effects and blocked stimulation induced activation in the NA and stimulation induced locomotion in both the NA and CD. At these doses the drugs did not affect reflex behaviors (e.g. righting) or produce catalepsy or sedation.

These results suggest the involvement of the mesolimbic system in the behavioral activation that accompanies reinforcement in infant rats, and suggest a possible role of the dopamine system in behavioral activation and reinforcement in neonates.

151.PO MODEL OF DELAYED NEUROLOGIC DETERIORATION FROM ANOXIA: BRAIN PATHOLOGY AND METABOLISM. R.E. Myers, K.R. Wagner, and G. de Courten-Myers. Research Service, VA Medical Center, Cincinnati, OH 45220 and Departments of Neurology and Neuropathology, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Hyperglycemia at exposure to anoxia/ischemia provides the conditions for severe brain injury to develop. However, the time course and extent of deterioration of neurologic function and brain metabolism following anoxia/ischemia in such animals are less clear. We have respired hyperglycemic cats (30 to 50 mM serum glucose; control = 5 mM) with nitrogen for 8 minutes to produce a model of delayed neurologic deterioration. These animals initially develop fasiculations in tongue and facial muscles, hypersalivation and, in the absence of early cardiogenic shock, myoclonic jerks, seizures and coma. Widespread neuronal loss with diffuse capillary proliferation is present after several days survival. Cats that deteriorate earlier show moderate brain edema with cerebral and cerebellar herniation, and ischemic cell change, neuronal pyknosis and/or poor staining of nuclei. Similarly exposed saline infused cats show no such postexposure neurologic deterioration and no or substantially less marked lesions in brain.

At the end of exposure, glucose infused cats have significantly greater lactate concentrations in cortex (27 versus 20 μmoles/g), while the 2 groups show no differences in ATP (0.3 - 0.4 μmoles/g) or phosphocreatine (1 μmole/g). One hour following resuscitation, both groups have approximately control lactate concentrations, slightly reduced ATP (2 - 2.4 μmoles/g) but control phosphocreatine (5 to 6 μmoles/g). After 3 hours hyperglycemic cats trend toward elevated lactate and depressed ATP which reach significance by 5 hours (lactate = 8 and ATP = 1.7 μmoles/g). Saline and glucose infused control animals show no significant differences in metabolite concentrations. Electron microscopy 5 hours into recovery reveals severe cellular edema, with swollen mitochondria and damaged cellular membranes but only in hyperglycemic cats. In conclusion, hyperglycemia on exposure to anoxia leads to delayed development of severe neurologic injury, brain edema and widespread brain damage. Early following reoxygenation brain metabolism returns almost to normal, but, thereafter, in hyperglycemic animals slowly deteriorates with ATP declining and lactic acid accumulating in parallel with neurologic deterioration. (Supported by Veterans Administration Medical Research Service.)

NEUROETHOLOGY II

152.1 THE FEMALE'S OWN SINGINGS PROMOTE OVARIAN ACTIVITY: AUDITORY AND PROPRIOCEPTIVE FEEDBACK. M.-F. Cheng. Institute of Animal Behavior, Rutgers University, Newark, New Jersey 07102.

Hormonal control of the female reproductive system is strikingly similar among different species, including women. Similarly, social influence of the ovarian activity has been reported in many species. Most if not all the studies have been designed to ask which aspects of the social factors stimulate female reproductive functions. Clearly absent in these studies is a consideration of the dynamic nature of social interactions. In this study we report that in the ring dove it is the female's own singing in response to male courtship that directly stimulates her follicular development.

The male ring dove typically initiates courtship by singing two syllable notes (bow-cooing, nest-cooing) interspersed with chasing activity. The female joins in singing (nest-cooing) with the male at the nest site for a period of time. A few days later, the female lays a clutch of two eggs. Females stop singing abruptly after laying the 2nd egg.

Females muted by lesions in one of the neural control stations of nest-calls (medial portion of n. intercollicularis, mICo) or by cuts in motor nerves innervating syrinx blocked or reduced the effectiveness of the male's courtship to induce follicular response. These results led us to hypothesize that it is the female's own singing that promotes her follicular growth. To determine whether audiofeedback is involved in the female's endocrine response, a playback experiment was performed. Female doves were devocalized by inserting a 1½ inch polyethylene tubing (3/16" OD, 1/8" ID) into the interclavicular sac immediately surrounding the syrinx. Females were then assigned to the playback of different types of coos: male coos, the female's own coos, another female's coos; two other groups serve as controls, devocalized and sham-devocalized females without playback. The playback of the female's own coos resulted in significantly larger follicle size than if the playback was of male's coos. In another study, females were deafened by removal of both cochlea under anesthesia. Ten to twelve days after the surgery, these females and sham deafened females were paired with actively courting males, four out of 12 deafened females nest-cooed in response to male courtship; follicular development in these birds was comparable to sham-controlled females. Those deafened females that did not nest-coo showed little sign of follicular growth. We conclude therefore both auditory and proprioceptive feedback mediate the female's self-stimulation singing on follicular growth. Leucine autoradiography study suggests that efferent from mICo to n. periventricular region where LHRH neurons were found may mediate this self-stimulation effect. This work was supported by NSF grant BNS-8121495 and RSDA K02 MH70897.

152.2 IMPORTANCE OF MEDIAL FRONTOLIMBIC CORTEX IN PRODUCTION OF THE ISOLATION CALL OF SQUIRREL MONKEYS. J.D. Newman and P.D. MacLean. NICHD and NIMH, Bethesda, MD 20205

The isolation call may rank as the most basic mammalian vocalization, serving originally to ensure maternal-offspring contact. Our previous findings in the squirrel monkey showed that damage to the core of the brainstem at the thalamo-midbrain junction affected the structure and production of the isolation call. Since the medial frontolimbic cortex has proved to be the main cortical area for eliciting vocalization in the squirrel monkey, the question arises as to what effect damage to this area would have on the isolation call (reviewed by MacLean, P.D., Arch. Gen. Psychiatry, 42:405, 1985). For investigating this possibility, adult squirrel monkeys were tested for ability to produce isolation calls before and after ablations of different parts of the frontal lobe. Criterion performance was the production of 20 or more isolation calls during a 15-minute period of isolation in a sound-reducing chamber.

Whereas bilateral prefrontal lobectomy rostral to the cingulate gyrus had no effect on the production rate of isolation calls during a three-month period of testing, either a lobectomy or lobotomy just rostral to the knee of the corpus callosum resulted in an elimination of calls during a comparable follow-up period. Failure to produce isolation calls was also observed in monkeys in which ablations were confined to the medial walls of the frontal lobe, with the aspirations including the paragenual, subcallosal and preseptal limbic cortex, and adjoining presulcal medial neocortex. Cortical ablations restricted to the anterior supracallosal or subcallosal limbic cortex, or to the rostral supplementary area above the anterior cingulate gyrus, had either no effect, or only a transitory effect on rate of calling.

In the critical cases in which ablation of the medial frontolimbic cortex and adjoining neocortex eliminated the isolation call, there was but little retrograde thalamic degeneration, a finding perhaps owing to the preservation of sustaining collaterals of neurons innervating these areas.

152.3 FOREBRAIN INVOLVEMENT IN REPRODUCTIVE BEHAVIOR OF THE FEMALE FROG. C. Diakow, R. Shanley* and C. Scharff* Biology Dept., Adelphi University, Garden City, N.Y. 11530

When in breeding condition, female Rana pipiens are silent and show oviposition behavior if they are clasped by males. In contrast, unreceptive females emit a release call. The following experiments provide evidence that oviposition behavior is mediated by the forebrain but that inhibition of the call is not.

Exp. 1 tested for oviposition behavior in females with transections at the midbrain-diencephalic junction and in sham operates. Receptivity was induced in these autumn-collected animals with distension by cloaca ligation. There was a significant difference between the groups: 4/8 controls showed oviposition in response to clasps by male frogs; none of 14 transected females did. This indicates that the forebrain mediates oviposition.

Exp. 2 tested for oviposition behavior in POA-lesioned females and in sham operates. Subjects were collected in the spring and ovulation and receptivity were induced by administering exogenous pituitary glands and progesterone. There was no significant difference between the groups. All 6 sham-operates oviposited in response to clasp by male frogs, as did 4/8 POA-lesioned females. Histological analysis compares the lesion sites in females that oviposited with those that did not.

Exp. 3 tested for inhibition of the release call in females with lesions in the pre-optic area (POA) or with transections at the forebrain-midbrain junction. Sham-operated controls were also tested. Prostaglandin (PG) is known to silence intact females, so subjects received 5µ/gbw PGE_2(i.p.) and a control injection of the vehicle, deionized water (DI). Subjects were tested by means of a manual clasp around the trunk and PG and DI injections were administered in counter-balanced order 5 days apart. All lesioned and control females vocalized after DI injection but were silenced by PG, indicating that the POA and forebrain are not essential for the silence of the receptive female frog.

152.4 PHYSIOLOGICAL CHARACTERIZATION OF THE SEXUALLY DIMORPHIC LARYNX IN *XENOPUS LAEVIS* M. Tobias and D.B. Kelley, Dept. of Biol. Sci., Columbia Univ., New York, N.Y. 10027

Sex specific vocalizations coordinate reproductive behavior in the frog, *Xenopus laevis*. Male mate calls, used to attract and excite females, consist of alternating fast and slow trains of clicks. Female ticking, used to signal unreceptivity to the male, consists of a constant very slow train of clicks. Male and female calls are readily distinguishable on the basis of their temporal pattern. Production of the mate call depends upon circulating androgen in males. Females do not mate call. The purpose of this study was to determine whether male-like vocalizations could be elicited from an adult female larynx by stimulation of the laryngeal nerve with the appropriate temporal pattern. In addition, the effect of circulating androgens on laryngeal function was assayed in adult females.

We recorded electromyograms, tension, and actual sounds produced by an isolated larynx in response to stimulus trains delivered to the laryngeal nerve. The results reveal two sex differences in the physiological response of laryngeal muscle. One, there is a marked potentiation of muscle compound action potentials throughout the stimulus train in males but not in females. Two, male laryngeal muscle responds to stimulus trains identical to the mate call in frequency and duration by producing discrete twitches, each of which result in an audible click. In contrast, the female larynx produces a maintained contraction which results in a single click following the initiation of the contraction. Androgen-treated adult females produce a response intermediate between males and females; potentiation of compound action potentials and discrete twitch tension are both increased. However, discrete twitches are superimposed on a maintained contraction, which results in either aberrant clicks or no clicks.

In summary, stimulation of the laryngeal nerve with a train that mimics the temporal pattern of the mate call results in the generation of a "vocalization" comparable to an actual mate call in males. In females, even when androgen-treated, the same stimulus is ineffective in inducing the mate call. Thus, physiological characterization of the larynx has revealed that one rate limiting component in the production of male specific vocalizations resides in the periphery.

152.5 GAIN CONTROL IN A PRIMARY SENSORY PROCESSING AREA, THE ELECTROSENSORY LATERAL LINE LOBE, BY MEANS OF DESCENDING INPUT FROM THE MIDBRAIN. J. Bastian. Dept. of Zoology, University of Oklahoma, Norman, Ok 73019

The Electrosensory Lateral Line Lobe (ELLL) of gymnotiform weakly electric fish is the sole recipient of the electroreceptor afferent projection, and the output of this region projects to the midbrain torus semicircularis and nucleus praeeminentialis (NP). This latter structure projects back to the ELLL forming a feedback loop and descending neurons can influence the behavior of most of the ELLL interneurons as well as two categories of ELLL output neurons, E and I-cells. E-cells respond to an increase in electrosensory input with a phasic burst of activity which adapts rapidly, I-cells respond to this same stimulus with a decrease in activity. Responses of both cell types are graded with stimulus intensity, show preferential responsiveness or tuning to sinusoidal amplitude modulations of the electrosensory input and respond well to moving stimuli such as small conducting or non-conducting objects. The normal responses of E and I-cells are dependent upon the integrity of the descending input from the NP. A major source of this descending input is carried into the ELLL dorsal molecular layer by parallel fibers originating in the overlying posterior eminentia granularis. The NP projects to the eminentia granularis via the praeeminential-electrosensory tract, and this tract can be silenced via microinjection of Lidocaine or by small lesions. Either technique modifies the behavior of the ELLL E- and I-cells similarly. Removal of the descending input to the DML does not alter the E or I-cells' spontaneous firing frequency, threshold, or tuning to AM stimuli. This treatment does, however, change the gain of the electrosensory system and the receptive field sizes of individual neurons for moving electrolocation targets. In normal animals E-cell responses increase at a rate of about 1.5 spikes/s per dB increase in stimulus amplitude and I-cell responses increase at a similar rate for decreases in stimulus amplitude. Following descending input removal, E-cell responses increase at a rate of 4.6 spikes/s per dB increase in stimulus amplitude and I-cell responses increase by 3.8 spikes/s per dB decrease in amplitude. Receptive fields, or areas lateral to the fish within which a 12mm metal cylinder caused increases of at least 100% of an E-cell's resting frequency, averaged 2 cm^2 in normal fish and this increased to 7 cm^2 in fish with the descending input to the DML removed. Likewise, receptive field sizes for I-cells, stimulated with a 12mm plastic cylinder, increase from 1.3cm^2 to 4.6cm^2. E and I-cell responses to moving electrolocation targets also decrease rapidly as a function of the target's distance lateral to the fish. Removing the descending input increased the size of the responses at any given distance and also increased the rate of response decay as a function of distance.

152.6 TEMPORAL HYPERACUITY: NONLINEAR CONVERGENCE OF ELECTRORECEPTIVE AFFERENCES. G. Rose and W. Heiligenberg. Neurobiology Unit, Scripps Institution of Oceanography UCSD, La Jolla, CA 92093

The mechanism by which the weakly electric fish, Eigenmannia, detects time disparities of several hundred nanoseconds was explored.

Eigenmannia produces a nearly sinusoidal electric signal of an individual frequency (range, 250-500 Hz) via a specialized organ in the tail. The fish detects this signal using electroreceptors that are located throughout the body surface. A fish's electric organ discharge (EOD) can be "jammed" by the discharge of another fish if the two signals are of similar frequency. These EODs sum to form a signal which is amplitude and phase modulated at a rate equal to their frequency difference. In its Jamming Avoidance Response (JAR), Eigenmannia increases or decreases its frequency if the EOD frequency of the neighboring fish is lower or higher than its own, respectively. To determine which direction to shift its EOD frequency, the fish must detect the small amplitude modulations and modulations in the relative timing of signals received by different regions of its body surface (i.e. time disparity). At threshold, Eigenmannia can detect amplitude modulations of 0.1% and time disparities of 400 nanoseconds. Timing information is provided in the responses of "T-type" primary afferents. These nerve fibers mark the occurrence of each EOD by producing a single spike. To assess the capacity of T-type afferents to lock their spikes to a particular phase of the stimulus cycle, recordings were made from individual fibers. Even the most accurate phase coders time-locked their spikes with a standard deviation of approximately 37 microseconds. Thus, for time disparities of several hundreds of nanoseconds, it would be impossible for a fish, using the information gathered from any single afferent over 300 milliseconds (latency of the JAR), to reliably shift its EOD frequency in the correct direction. When the amplitude ratio between the jamming stimulus (S2) and signal that served as a replacement for the fish's own EOD (S1) was small (i.e. 0.0016), corresponding to a maximum time disparity of 1.8 microseconds, no JAR could be observed upon stimulation of specific body regions posterior to the gills; JARs could be elicited by stimulating only the head region using an S2/S1 ratio of 0.001. Simultaneous stimulation of three posterior regions with the S2/S1 ratio of 0.0016, however produced a strong JAR. Thus, our results indicate that electroreceptive afferent inputs converge in a nonlinear manner to generate sensitivity to time disparities of several hundred nanoseconds. In this process, inputs which are individually insufficient for eliciting a measurable JAR produce a strong response when combined.

152.7 EFFECT OF ABLATING THE CERCAL CHORDOTONAL ORGAN ON ESCAPE TURNS OF COCKROACHES. E. Gerzog,* A. Hahari* and J. Camhi. Dept. Zool, Hebrew Univ, Jerusalem, Israel. SPON: M. Devor

The cockroach Periplaneta americana turns away from the source of a wind puff, a response mediated by hair-like receptors on the cerci, paired posterior appendages. Rotation of one cercus medially by 60° from its normal lateral angle causes turning behavior to be shifted roughly 30° (mean of the one rotated and the one unrotated cercus). Underlying this behavioral change, the directional response curves are shifted for specific giant interneurons known to be heavily involved in mediating the turns (Comer and Camhi, J. Comp. Physiol. 155:31, 1984).

At the base of each cercus is a stretch-receptive chordotonal organ (CO) which senses cercal position (Bernard et. al., J. Comp. Physiol. 153:377, 1983). Given that cercal rotation leads to corresponding rotations of GI directional curves and turning behavior, the cockroach does not compensate immediately for imposed cercal rotations, respecifying wind angle with respect to body axis as occurs in crickets (Rozhkova et. al., J. Comp. Physiol. 137:287, 1980). Thus the CO, though apparently designed for registering the required sensory information, appears not to serve this function. It would seem, then, that the encoding of cercal position by the CO does not play a role in specifying the direction of the escape turn.

To test this idea, we ablated the CO from the right cercus and tested the cockroaches' turning behavior over the next 2-30 days. Wind stimuli received from within the angular range from head-on to 30° right of head-on evoked 69% turns to the right (wrong direction). Turns for wind from other angles were normal. The wrong turns persisted for at least 30 days. Sham operated controls gave significantly fewer wrong turns, 39% ($p<0.02$). CO ablation, but not the sham operation, caused large areas of degeneration in the lateral cercal nerve, through which the CO axons run. Neither operation produced any visible degeneration in the medial cercal nerve, through which the axons of cercal wind receptors run. We also counted the axons in the left and right medial cercal nerves. There was no significant difference on the two sides following either CO ablation or sham operation. The pronounced effect seen after CO removal was not produced by ablating other nearby sensory structures, such as the stylus. Thus CO removal appears to have a specific effect on the direction of escape turns. The substantial percentage of incorrect turns in sham-operated controls may result from a mechanical disturbance of the cercal base. We are testing effects of CO removal on wind responses of the GI's.

152.8 EFFECT OF ABLATING NON-CERCAL RECEPTORS ON CERCAL-MEDIATED ESCAPE BEHAVIOR IN THE COCKROACH. J. Camhi and L. Leibowitz.* Dept. Zoology, Hebrew Univ., Jerusalem, Israel

The cockroach Periplaneta americana responds to wind puffs, such as those resulting from the rapid approach of a predator, by turning away and running. The wind is detected by filiform hair receptors on the cerci, two posterior appendages. The cercal sensory axons project to the last abdominal ganglion (A6), where they excite giant interneurons (GI's), known to largely mediate the escape turns. If one ablates the cercus of one side, wind puffs from near the front on that side evoke turns toward, rather than away from, the wind source. Underlying this, the GI's on the side of the ablation are now almost silent in response to wind. Within one month, the turning behavior is largely corrected, and the GI's of the ablated side are now strongly activated by the opposite cercus (Vardi and Camhi, J. Comp. Physiol 146:299).

In studying such directional errors and their corrections, we ablated, in control animals, other posterior sensory structures but not the cerci. Ablating some structures, such as an anal stylus, caused little or no change in the turning behavior. However, after ablating unilaterally the tergites and sternites of abdominal segments 7-10 (whose sensory innervation derives from ganglion A6), wind puffs from a 40° frontal angular range on the ablated side evoked turns toward the wind source (incorrect turns) on 60% of the trials. This was significantly different from the 6% incorrect turns for normal animals. It was as though the cerci themselves had been ablated, though these were actually intact. The ablated areas contain no filiform hairs, and no receptors which, when stimulated by wind, evoke any action potentials in the GI's. Retests after two weeks showed that the incorrect turns persisted (65% wrong turns), though by 4 weeks there was significant correction (25% wrong turns). The corrected behavior persisted till at least 6 weeks. This time course parallels that of behavioral correction following unilateral cercal ablation. Ablating unilaterally just one segment (No. 7) leads to a similar number of wrong turns on day 1 (57%) and similar correction at 4 weeks (25%).

To determine whether these specific behavioral deficits and their corrections involve changes in the GI responses, we have recorded simultaneously from the GI's of both sides, both before and after ablating unilaterally segments A7-10. The ablation grossly alters the balance in left vs right GI activity, a property important in the motor decision whether to turn left or right.

152.9 TEMPORAL PATTERN RECOGNITION AND 'TRADE-OFF' PHENOMENA IN ACOUSTIC COMMUNICATION IN CRICKETS (GRYLLIDAE). J.A. Doherty* (SPON: M. Nelson), Sect of Neurobiology and Behavior, Cornell University, Ithaca, New York 14850

Behavioral studies of animal communication systems often have sought to specify the minimal physical properties of the sender's signal that are both necessary and sufficient for eliciting responses in the receiver. In systems where relatively few properties are involved, this strategy can be useful for directing studies of the neural correlates of signal detection and recognition. However, in more complex systems in which several signal properties are involved, such a strategy may not be adequate for elucidating more complex neuronal mechanisms of signal recognition. In some cricket acoustic communication systems, for instance, the recognition of male calling song and the elicitation of positive phonotaxis in responsive females during mating appears to involve the evaluation of several calling song temporal properties that have different weightings in the recognition process. These interactions can be described by a 'trade-off' in which several temporal properties contribute to the total attractiveness of the calling song. When the phonotactic efficacy of one temporal property is lowered, the attractiveness of the entire acoustic stimulus can be maintained by raising the attractiveness of other temporal properties. Some properties may have much higher weightings than others, leading one to believe that these other properties are 'nonessential' in the recognition process. However, when the attractiveness and weightings of the most potent temporal properties are lowered, the effects of other, less attractive properties become more evident. In this paper I will present results of ongoing behavioral investigations into trade-off phenomena and weighting factors in several species of crickets that have different calling song morphologies (i.e. trilling, chirping, and chirp-trilling species of crickets). The results of several phonotaxis asseys will be considered, including phonotaxis in arenas, in flight, and on a locomotion compensator. The behavioral results indicate that in addition to searching for necessity and sufficiency of temporal properties in acoustic communication systems, we should also consider how the nervous system encodes and recognizes certain combinations of temporal properties, each of which has a different weighting in the recognition process. 152.10 PREDATOR EVASION AND THE ORIGIN OF INSECT FLIGHT: AN EXERCISE IN EVOLUTIONARY NEUROETHOLOGY. John S. Edwards, Department of Zoology, University of Washington, Seattle, WA 98105

One of the major events in the evolution of terrestrial life was the monophyletic origin of flight in the Insecta. Current hypotheses concerning the origin of flight emphasise the emergence of a capacity for dispersal in patchy environments of the Palaeozoic. An alternative view stresses predation as a factor favoring the acquisition of flight. Paleontological evidence indicates that arachnids (scorpions and spiders) were present in the Devonian terrestrial environment when the first terrestrial hexapods arose. Predation pressure must thus have been a significant factor in the early evolution of the hexapods, favoring evasive strategies.

Our studies of the cercal sensory system and associated giant interneurons in the primitively wingless insect Thermobia domestica (Thysanura), the firebrat, and other apterygote insects indicate precise homology of their cercal sensory-giant interneuron systems with that of the well known orthopteroid insects. The system is a major component occupying comparable fractions of the total volume of the abdominal CNS (ca. 25%) in both groups.

Some apterygote insects and some orthopteroid insects run in response to cercal stimulation. Others jump. The critical introduction of a motor pattern in which the legs were extended simultaneously, to jump rather than sequentially, to run, was the predisposing factor for flight. The same muscle sets are used in running, jumping and flying; a longer jump is a better evasive response. Flight is generally preceded by a jump in modern insects, and it is plausible that in the refinement of the evasive jump, aerodynamic properties of the thorax were modified. Whatever the source of aerofoils leading to active wing surfaces, it is proposed that they arose inthe refinement of evasive jumping primed by cercal sensory input to abdominal giant interneurons. The emergent capacity for aerial exploitation of patchy environments was a consequence which led to the elaboration of active flight. Flight and vision subsequently interacted to drive the visual coordination of flight and replaced the original, slower mechanoreceptive cercal sensory system with descending visual giant interneurons, as found in some orthopteroids with minimal cercal systems and in most Holometabola.

152.11 FROM FEATURE DETECTION TO BEHAVIORAL ACTION: A CELLULAR ANALYSIS IN THE LOCUST.
H. Reichert and C.H.F. Rowell*. Dept. of Zoology, Univ. of Basel, CH-4051 Basel, Switzerland.

Animals abstract relevant information from the profusion of diverse stimuli they encounter and then organize appropriate behavioral responses. How is this done? A partial answer comes from studies showing that the CNS of higher animals are equipped with feature detectors. These are individual neurons, each tuned to a complex stimulus configuration indicative of a relevant natural situation. In a few cases, some insight into the neural mechanisms involved in feature extraction has been gained. However, we know little about the subsequent processing of feature detector activity.

Here we report the identification and characterization of several unique feature detector interneurons in the locust CNS, which integrate information from the compound eyes, ocelli and cephalic windhairs to detect course deviations in flight. Furthermore, we describe the cellular organization of the subsequent integrative circuitry, which translates feature recognition into appropriate behavior. Our studies show that segmental interneurons play important roles in the two neural systems which transform deviation detector activity into corrective steering behavior. First, thoracic interneurons are central to the fast course correction system which acts directly on wingbeat. There these interneurons, gated by the central pattern generator for flight, convert the deviation signal of the descending detector interneurons into phase-coupled premotor drive and apply this drive to appropriate flight motoneurons. Second, similar segmental interneurons are key elements of the slower feedback system for course correction. There premotor interneurons are involved both in the translation of course deviation information into corrective repositioning of the head and in the transformation of the resulting proprioceptive mismatch between head and thorax into compensatory flight steering behavior.

152.12 HEAD-BODY COORDINATION IN FREE FLYING HOUSEFLIES: AERODYNAMIC PERFORMANCE AND VISUAL FLOW.
H. Wagner* and C. Wehrhahn (SPON: M. Konishi). Max-Planck-Institut fuer biologische Kybernetik, Spemannstrasse 38, D-7400 Tuebingen, FRG.

Houseflies were simultaneously filmed from two sides at 75 frames/s and the angular movements of the body were analyzed with respect to the three orthogonal body axes (long (roll), transverse (pitch) and vertical (yaw) axis). In some cases also the position of the head relative to body could be seen.

The flights are characterized by quick, saccade-like body rotations about the vertical and transverse axis separated by much longer periods of little or no turning. Smooth, long-lasting angular movements about the vertical as well as the transverse axis do not play an important role. Rotations about the long axis are more frequent, may last longer and may be smoother than the rotations about the other two axes.

While the fly turns its body during a banked turn the head may compensate for the roll movements of the body up to about 90 degrees (see also Hengstenberg, in: Varju and Schnitzler, (eds) Localization and Orientation in Biology and Engineering, Springer, Berlin, 1984). The head's movement about the vertical axis is restricted to about +/-10 degrees relative to the body (Geiger and Poggio, Biol. Cybern. 25: 141, 1977). Thus the head is forced to make similar yaw movements as the body. The orientation of the vertical axis to gravity easily allows 360 degrees and more rotation about this axis, whereas roll movements seem to be restricted to about +/-90 degrees. The different orientation of these two axes to gravity may be the reason for both, the different time course of the turns and the different restriction of the movement of head and body relative to each other.

We speculate that on the one hand the movements in flight are coordinated to achieve maximal adaptation of the body movements to the requirements determined by the aerodynamic forces during flight. On the other hand the movements of the head (which is aerodynamically not very important) seem to be adapted to the constraints posed for the eyes which are fixed to the head to perceive the visual flow generated by the translational displacement of the fly in space with as little rotatory disturbances as possible.

152.13 A BIOCHEMICAL FEATURE GENERATOR FOR A FIXED ACTION PATTERN OF BEHAVIOR.
R.Gillette and D.J.Green. Department of Physiology and Biophysics and the Neural and Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

Fixed action patterns (FAPs) are stereotyped and rigid episodes of behavior usually triggered by specific sensory releasors, and are characteristically insensitive to further sensory stimuli during their expression. In the predatory mollusk Pleurobranchaea we have studied a FAP whose distinctive features are encoded in enzymic interactions with intracellular ion fluctuations and modifiable conductances in single command neurons.

The paired ventral white cell (VWCs) of the buccal ganglion are activated by tonic food stimuli in the buccal cavity to fire minutes-long recurrent bursts of broadening action potentials, driving recurrent episodes of vigorous ingestion. The effects of food stimuli are mimicked by cAMP, its agonists and its inhibitors of degradation; presumably neuromodulatory pathways from the buccal cavity cause enhanced cAMP synthesis in the VWCs. The burst episode is initiated and sustained by cAMP- stimulated voltage dependent Na^+ current.

We find that the duration, intensity, and interval between recurrent VWC bursts is in large part influenced by a pH sensitive and Ca^{2+}/calmodulin-activated cAMP phosphodiesterase (PDE). PDE activity increases during the burst and falls during the refractory, interburst interval over a time period paralleling the recovery of the neuron's ability to generate another burst. Both in vitro (Brain Res. 271, 371) and in vivo assays (Green and Gillette, this volume) show that PDE activity is a sensitive function of intracellular pH and Ca^{2+} fluctuations such as occur during the burst cycle. Calcium-activated K^+ currents are not demonstrable in the VWCs and probably have no role in the burst.

Thus, the features of the intensity, decay, duration of the burst, the interburst interval, and the consequent behavior of the FAP are satisfied in the following model. An increased level of cAMP causes increased inward current and burst initiation., Intracellular accumulation of Ca^{2+} and H^+ due to spike calcium current and proton generating processes lead to net increasing PDE activation which causes a fall in cAMP and consequent fall in inward current, leading eventually to burst termination. The slow recovery of Ca^{2+} and H^+ levels through the buffering processes of the cell determines interburst interval through the rate of fall of PDE activity. The fall of PDE activity itself is the major factor in the rate of recovery of cAMP levels to the next burst threshold, given a constant rate of cAMP synthesis. The interactions of cAMP, PDE, Ca^{2+}, and H^+ form a negative feedback circuit with the basic characteristics of a single phase oscillator.

153.1 **IN VIVO MEASUREMENT OF CATECHOLAMINE RELEASE IN PRIMATE VISUAL AND SOMATOSENSORY CORTEX.** J.W. McClurkin, C.D. Blaha, R.F. Lane, and R.T. Marrocco, Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403

We have used electrochemical techniques in combination with standard electrophysiological recording methods to assess visually evoked catecholamine (CA) release from nerve terminals in the striate (area VI) and somatosensory (area 3B) cortex of N_2O anesthetized macaques. Chronoamperometric measurements using stearate-modified graphite recording electrodes (Blaha and Lane, Brain Res. Bull. 1983, 10:861) selective for the CAs were used to monitor changes in CA release in the vicinity of cells electrophysiologically recorded with tungsten microelectrodes by cementing the electrodes together flush at their tips. Receptive field locations of cells near the graphite electrode were mapped by recording unit activity with the adjacent tungsten electrode. In vivo changes in CA release were assessed by post-in vivo calibration of each graphite recording electrode in standard solutions of norepinephrine and dopamine.

Exposure to bright room or strobe light following a 20 min period of dark adaptation caused a rapid increase (ca. 2-3 μM) in CA release in the visual cortex. The same effect was seen when a 20 deg diameter radial grating, previously shown to activate cortical neurons (McClurkin and Marrocco, J. Physiol. 348:135) was projected onto a tangent screen and rotated radially around the visual receptive field locations of the neurons recorded with the microelectrode. Returning the animal to the dark caused a decrease in CA release to dark adapted levels with a time course similar to the light-evoked increase.

The visual cortex receives diffuse noradrenergic input from the locus coeruleus, which has been suggested to trigger REM sleep. Light-induced changes in CA release were not simply a reflection of concomitant changes in behavioral arousal since no significant changes in EEG patterns, heart rate, CO_2, or rectal temperature were observed. Moreover, under identical conditions, CA release in the somatosensory cortex was unaffected by manipulation of the light level or by tactile stimulation of the skin surface. However, administration of the short acting barbiturate Suritol (10 mg/kg i.v.) decreased CA release in both brain regions.

Since there is little evidence for a CA containing neuronal input from the lateral geniculate, our results suggest the existence of a modality-specific, CA-mediated activation of visual cortical neurons not originating from the geniculo-cortical pathway. We conclude that the combined application of in vivo electrochemical and electrophysiological techniques will provide a useful tool in assessing the role of CA transmitter function in the primate cerebral cortex. Supported by NSF 82-07531, NS 13556, and MH 17148.

153.2 SENSITIZATION TO AMPHETAMINE IS ACCOMPANIED BY ENHANCED STRIATAL DOPAMINE RELEASE. E. Castañeda*, J.B. Becker, R. Wilcox* and T.E. Robinson (SPON: C.M. Butter). Department of Psychology and Neuroscience Laboratory Bldg., The University of Michigan, Ann Arbor, MI 48104-1687

The repeated intermittent administration of amphetamine (AMP) produces an enduring hypersensitivity ("sensitization") to its motor stimulant effects in nonhuman animals, and to its psychotomimetic effects in humans. It has been hypothesized that sensitization to AMP may be due to long-lasting changes in brain dopamine (DA) systems. In support of this, we previously reported that in rats AMP pretreatment in vivo produces an enduring enhancement in AMP-stimulated striatal DA release measured in vitro (Robinson & Becker, Eur. J. Pharmacol., 85:253, 1982). The present experiments were conducted to replicate and extend these findings.

Ovariectomized (OVX) female rats were used because: (1) females show more robust behavioral sensitization than males (Robinson, Psychopharmacol., 84:466, 1984); and (2) OVX females show less variation in DA activity than intact females. One week after OVX the animals received 6 daily injections of 3.0 mg/kg d-AMP or were left undisturbed. Seven days after the last injection they were decapitated. Each striatum was removed, diced into 1 mm^3 fragments and placed into superfusion chambers through which medium flowed at 100 μl/min (Becker et al, J. Neurosci. Meth., 11:19, 1984). Following a 1 hr equilibration period effluent samples were collected over 5 min intervals in chilled tubes containing 0.05 N $HClO_4$. Following the collection of 3 baseline samples DA release was stimulated by infusing medium containing 0.5 to 10 μM d-AMP for 2.5 or 5 min, and samples collected for an additional 5 intervals. The samples were later assayed for DA with HPLC-EC.

The addition of AMP to the medium stimulated endogenous DA release in all cases. However, striatal tissue from sensitized rats showed a significantly greater enhancement in DA release than tissue from control animals, when DA release was stimulated with 5 μM d-AMP over 5 min or 10 μM over 2.5 min. This effect was also obtained in a second independent experiment by R. Wilcox in which rats received 3.0 mg/kg AMP daily for 5 days, were withdrawn for 10 days, and DA release stimulated with 10 μM of AMP over 2.5 min. In contrast, low doses of AMP (0.5-2.75 μM over 5 min; 5.5 μM over 2.5 min) stimulated the same amount of DA release from sensitized and control tissue.

In summary, the repeated intermittent administration of AMP in vivo produces an enduring enhancement in AMP-stimulated endogenous DA release from striatal tissue in vitro. We suggest that this increased responsiveness of the striatum to AMP may be at least partially responsible for the long-lasting hypersensitivity to AMP seen in animals and humans previously exposed to AMP.

153.3 ENDURING ENHANCEMENT IN MESOCORTICAL DOPAMINE UTILIZATION IN AN ANIMAL MODEL OF AMPHETAMINE PSYCHOSIS. T.E. Robinson, J.B. Becker, C.J. Moore*, E. Castañeda* and G. Mittleman*. Department of Psychology and Neuroscience Laboratory, The University of Michigan, Ann Arbor, MI 48104-1687

In nonhuman animals the repeated intermittent administration of amphetamine (AMP) produces a progressive and enduring enhancement in many AMP-induced behaviors, and this "behavioral sensitization" is thought to be an animal analogue of AMP psychosis. There have therefore been many attempts to identify a neural correlate of behavioral sensitization, and most of these have focused on the nigrostriatal dopamine (DA) system. For example, we previously reported that AMP pretreatment produces an enduring enhancement in AMP-stimulated DA release from striatal tissue in vitro (Robinson & Becker, Eur. J. Pharmacol., 85:253, 1982). However, it is possible that AMP produces long-lasting changes in other mesotelencephalic DA systems as well.

To test this hypothesis we examined DA utilization in ovariectomized (OVX) female rats given 7-9 i.p. injections of 3.0 mg/kg of d-AMP or saline. The injections were given either daily or once every 3-4 days. OVX rats were used because they show, (1) more robust behavioral sensitization than males (Robinson, Psychopharm., 84:466, 1984) and (2) less variation in DA activity than intact cycling females. Eight to 10 days after the last injection of AMP or saline the rats received an i.p. injection of α-methyl-p-tyrosine (MPT; 200 mg/kg), and were killed by decapitation 30 min later. The medial frontal cortex, striatum and nucleus accumbens were assayed for DA with HPLC-EC, and the rate of decline in DA (relative to control animals that did not receive MPT) was used as an index of DA utilization. In addition, to assess the acute effects of stress on forebrain DA utilization some rats received 20 min of mild footshock prior to decapitation.

In two independent experiments, pretreatment with AMP produced an enduring (at least 10 days) enhancement in medial frontal cortex DA utilization (23-40%), but not in striatal or nucleus accumbens DA utilization. As reported previously, acute footshock stress also selectively enhanced mesocortical DA utilization.

These experiments show for the first time that the repeated intermittent exposure to AMP produces an enduring enhancement in mesocortical DA utilization. It is not clear why this method failed to reveal an effect on striatal DA utilization, because with other methods we have consistently found enhanced striatal DA utilization and release in sensitized animals. Nevertheless, the evidence reported here suggests that enhanced mesocortical DA activity may be involved in the behavioral changes associated with AMP sensitization in nonhuman animals, and the cognitive abnormalities (AMP psychosis) associated with stimulant drug abuse in humans.

153.4 **CHRONIC ANTIPSYCHOTIC DRUG EFFECTS ON DOPAMINE RELEASE IN VIVO: REGIONAL SPECIFICITY AND MECHANISMS OF ACTION.** C.D. Blaha and R.F. Lane, Inst. of Neuroscience, Univ. of Oregon, Eugene OR 97403

We have previously shown that repeated (21 day) treatment with typical, e.g. haloperidol (HAL), and atypical, e.g. clozapine (CLOZ) and thioridazine (THIO), neuroleptic drugs will decrease basal dopamine (DA) release and produce a tolerance to neuroleptic-induced release of DA differentially in rat striatum and nucleus accumbens (Fed.Proc. 1985 44:892). In order to investigate the possibility that the decreases in DA release may be partly due to neuroleptic-induced DA cell depolarization inactivation we examined the effects of apomorphine (APO) on DA release after repeated neuroleptic treatment. To examine the importance of the anticholinergic properties of the atypical neuroleptics, both basal and neuroleptic-induced DA release were also examined after repeated administration of HAL in combination with the anticholinergic trihexyphenidyl (THP, 1 mg/kg s.c.).

Chronoamperometric measurements using stearate modified electrodes (Blaha and Lane, Brain Res. Bull. 1983 10:861) implanted in both striatum and accumbens were performed in anesthetized rats. Administration of APO (5, 10, and 50 μg/kg i.v.) caused a dose-related increase in the release of DA in both brain regions when given 24 hr after repeated treatment with HAL. In contrast, APO increased DA release only in the accumbens after repeated CLOZ or THIO while decreasing release in the striatum (opposite effects of APO were observed after repeated treatment with the substituted benzamide metoclopramide). Repeated treatment with HAL in combination with THP completely and selectively prevented the decrease in basal and HAL-induced release of DA in striatum, normally seen after repeated treatment with HAL alone. Additionally, APO produced a typical dose-related decrease only in the striatum after administration of this drug combination.

Our results provide direct in vivo evidence that (1) the reduction in basal DA release, APO-induced increase in DA release, and tolerance to neuroleptic-induced release of DA after repeated treatment is predominantly due to the development of a state of tonic depolarization of DA neurons (2) the anticholinergic properties of atypical neuroleptics are partly responsible for their inability to alter DA release in the striatum after repeated administration and (3) suggests that the delayed onset of extrapyramidal dysfunctions and therapeutic effects during neuroleptic treatment are mediated, respectively, by selective inactivation of the nigrostriatal and mesolimbic DA systems. These results provide evidence that in vivo electrochemical methods employed to monitor changes in endogenous DA release during repeated neuroleptic treatment may serve as a model system in evaluating the therapeutic and neurological side effect potential of new pharmacological agents. Supported by USPHS Grants NS 13556 and MH 17148.

153.5 EFFECT OF CALCIUM CONCENTRATION ON THE MELATONIN-INDUCED INHIBITION OF ^{3}H-DOPAMINE RELEASE FROM RABBIT RETINA. Margarita L. Dubocovich and Julie G. Hensler, Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The hormone melatonin inhibits at picomolar concentrations the calcium-dependent release of ^{3}H-dopamine from the rabbit retina in vitro through activation of putative melatonin receptor sites (Dubocovich, Nature 306, 782, 1983; J. Pharmacol. Exp. Ther., in press). The aim of this study was to determine the involvement of calcium in the inhibition of dopamine release by melatonin at different frequencies of stimulation. Retinas from albino rabbits were labeled in vitro with ^{3}H-dopamine and superfused with Krebs solution. The release of tritium was elicited by field stimulation at either 1 Hz, 3 Hz or 6 Hz (360 pulses, 20 mA, 2 msec) twice within each experiment. The percent of total tissue radioactivity released above spontaneous levels during the first period of stimulation (S_1) for controls was: 2.09 + 0.23% (n=5) at 1 Hz, 2.63 + 0.29% (n=6) at 3 Hz, 2.71 + 0.4% (n=5) at 6 Hz in the presence of 1.3 mM calcium, and 0.73 + 0.08% (n=4) at 1 Hz, 0.85 + 0.14% (n=6) at 3 Hz, 1.37 + 0.13% (n=4) at 6 Hz in the presence of 0.65 mM calcium in the superfusion medium. When the calcium concentration in the Krebs' solution was 1.3 mM, melatonin (10 pM - 10 nM) inhibited in a concentration-dependent manner the release of ^{3}H-dopamine elicited by field stimulation at 1 Hz (IC_{50} = 50 pM), at 3 Hz (IC_{50} = 60 pM) and at 6 Hz (IC_{50} = 50 pM). The inhibitory effect of melatonin was potentiated when the calcium concentration was reduced in the superfusion medium to 0.65 mM. Under these conditions the IC_{50} for melatonin was 8 pM at 1 Hz, 13 pM at 3 Hz, and 16 pM at 6 Hz. When the D-2 dopamine autoreceptors were blocked by S-sulpiride (0.1 uM), in the presence of low calcium (0.65 mM), the potency of melatonin to inhibit dopamine release remained unchanged. Taken together these results suggest that regardless of the calcium concentration, the inhibitory effect of melatonin on dopamine release did not depend on the frequency of stimulation or on the activation of D-2 dopamine autoreceptors. The lack of effect of melatonin on the calcium-dependent release of dopamine from the rabbit striatum (Dubocovich, Nature 306, 782, 1983) would exclude an effect of melatonin on a presynaptic component directly involved with neurotransmitter release. We conclude that in the rabbit retina, as reported in the rat hypothalamus (Zisapel and Laudon, Brain Res., 272, 378, 1983), the potency of melatonin to inhibit dopamine release depends on the external concentration of calcium, suggesting an effect of this hormone through its receptor on the entry of calcium into the presynaptic nerve terminal. Supported by USPHS grant EY 04788 and MH 09215.

153.6 PROLACTIN (PRL) AUGMENTS DOPAMINE (DA) RELEASE FROM MEDIAN EMINENCE (ME) SYNAPTOSOMES BY A MECHANISM INDEPENDENT OF EXTERNAL Ca^{2+}. K.A. Gregerson and M. Selmanoff. Dept. of Physiology, Univ. of Maryland, Sch. of Medicine, Baltimore, MD 21201

We have previously reported that depolarization-induced release of preaccumulated ^{3}H-DA from ME synaptosomes prepared from male rats is enhanced following in vivo treatment with ovine PRL (Soc Neurosci Abstr 9:319). In the present studies, we explored the mechanism of action of this PRL-induced effect on DA release from ME nerve terminals. Synaptosomes were prepared from intact male rats treated with ovine PRL for 48h (4mg/kg, sc, every 8h) and from vehicle-treated controls. Synaptosomes were loaded by incubation in 0.1uM ^{3}H-DA for 30 min at 30°C and release was subsequently measured over 1- to 20-second time intervals under basal and depolarizing conditions using a rapid filtration technique.

Confirming our previous findings, pretreatment with PRL selectively increased the fractional release of ^{3}H-DA from ME terminals during depolarization while basal (5mM K^+_o) efflux was unchanged from controls. The difference in evoked release between PRL-treated and control ME terminals occurred when depolarization was induced with either high K^+_o (75mM) or veratridine (75uM). This effect of hyperprolactinemia appeared to be specific to the tubero-infundibular dopaminergic (TIDA) terminals since PRL treatment did not alter fractional release of DA under basal or depolarizing conditions in synaptosome preparations of caudate nucleus, nucleus accumbens or olfactory tubercle. The PRL-induced enhancement of DA efflux from ME synaptosomes during depolarization was evident over a wide range of external Ca^{2+} concentrations (0.01-3.0mM), suggesting that this effect of PRL is on a release mechanism independent of Ca^{2+}_o influx. This hypothesis was supported by the observation that 20mM Ni^{2+} (a competitive Ca^{2+} channel blocker), while blocking the graded dose response of DA release to increasing [Ca^{2+}_o], did not block the PRL-induced elevation in evoked DA release from ME synaptosomes. Furthermore, the effect of PRL did not appear to be due to carrier-mediated efflux of DA since the elevation in evoked DA release from ME terminals following PRL treatment was neither blocked nor reduced by binding up the carrier with the potent blocker, nomifensine (25uM).

In summary, the PRL-induced augmentation of DA release is specific to the ME and is coupled to depolarization via a mechanism other than activation of Ca^{2+}_o influx or "reverse" carrier transport. Possibilities for PRL modulation of this signal transduction include mobilization of Ca^{2+} from intraterminal sources or effects on secretory granules of TIDA terminals.

153.7 THE MECHANISM OF DOPAMINERGIC ACTIVATION INDUCED BY A NEW PSYCHOSTIMULANT PIPERAZINE DERIVATIVE. F. Battaini, L. Lucchi*, S. Govoni, P.F. Spano and M. Trabucchi. Inst. Pharmacol and Pharmacognosy, University of Milan, 20129 - Milan and Chair of Toxicol., II[nd] Univ. of Rome, Italy.

Fipexide, a piperazine derivative, has in vivo psychostimulant properties; some of the behavioral, neurochemical and clinical effects of this drug are reminiscent of a dopaminergic activation. In particular, fipexide, acutely administered, strenghtens amphetamine induced behaviors, induces a decrease of striatal dihydroxyphenylacetic acid concentrations and inhibits the release of prolactin. On the other hand, fipexide has very weak or none direct displacing activity in in vitro binding studies using dopamine receptor tritiated ligands. On this line the present study investigates the effect of acute and chronic fipexide administration on both pre- and postsynaptic markers of dopaminergic activity. Male Sprague Dawley rats were used; fipexide was administered per os as a suspension with 2% starch. Dopamine uptake and release, met-enkephalin content, binding studies with the various ligands were performed according to published procedures. Fipexide acutely injected (30 mg/kg, 3 hrs) induces a significant decrease in dopamine uptake measured in striatal slices of treated animals. The drug has an inhibitory action also when directly added in vitro. In contrast no significant effect was observed on dopamine release after in vivo administration although a small increase in the amine release was noticed after in vitro addition of the drug to striatal slices. In line with the uptake data the acute administration of the drug induces a decrease in the Na^+-dependent binding of ^{3}H-Cocaine, a regulatory site located on dopaminergic terminals for a putative endogenous peptide active on dopamine uptake. After chronic treatment (20 mg/kg, twice a day for 15 days) tolerance developed to the effect of fipexide on dopamine uptake. On the other hand the ^{3}H-Cocaine binding is still reduced when killing the animals three hours after the last treatment. In addition, the drug, both acutely and chronically administered, induces a decrease of striatal met-enkephalin concentrations. Fipexide seems therefore to indirectly act at regulatory sites of dopaminergic presynaptic function. The drug may represent an useful tool for studying the mechanisms of dopaminergic activation.

153.8 DOPAMINE AUTORECEPTOR ACTIVITY OF CGS 15855A. B.S. Glaeser, J.C. Berry*, W.C. Boyar*, R.A. Lovell, A.Braunwalder*, P. Loo*, G. Stone*, H. Kalinsky*, A.J. Hutchison*. Neuroscience Research, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, N.J. 07901

CGS 15855A has a profile of a potent and selective dopamine autoreceptor agonist. Dopamine autoreceptor activity for this compound was demonstrated by in vitro and in vivo test systems. For in vitro studies CGS 15855A displaced the dopamine agonist ligand ^{3}H-ADTN with an IC_{50} of 2 x 10^{-8}M - a value equipotent to other compounds having dopamine agonist activity (e.g. apomorphine 2 x 10^{-8}M, NPNA 2 x 10^{-9}M, and 3-PPP 4 x 10^{-7}M). CGS 15855A was relatively weak as a dopamine receptor antagonist with an IC_{50} of 1 x 10^{-6}M in ^{3}H-spiroperidol binding and was inactive in other receptor binding assays-serotonin (5HT-1, 5HT-2) clonidine (α_2), prazosin (α_1), QNB (muscarininc cholinergic). In vivo biochemical tests complemented the in vitro receptor assays showing CGS 15855A to be a specific autoreceptor agonist. In the gamma-butyrolactone (GBL) model for dopamine autoreceptors, CGS 15855A had an ED_{50} of 0.16 mg/kg ip and 0.39 mg/kg po, which was relatively more potent than apomorphine (ED_{50} = 0.56 mg/kg ip), TL-99 (ED_{50} = 1.60 mg/kg ip) and 3-PPP (ED_{50} = 2.11 mg/kg ip). In DOPA accumulation studies, CGS 15855A significantly decreased the accumulation of DOPA in the striatum. CGS 15855A (1 mg/kg ip or 10 mg/kg po) had a short to moderate duration of action (30-60 min) on the reduction of the dopamine metabolites, DOPAC and HVA, in the striatum. CGS 15855A did not alter the striatal concentrations of dopamine, serotonin or 5-HIAA. Similar effects were observed for apomorphine (2.0 mg/kg ip), while an elevation of dopamine metabolites was observed for haloperidol. In other studies, CGS 15855A (2 mg/kg ip) decreased DOPAC and/or HVA in the olfactory tubercles, nucleus accumbens and striatum. In conclusion, CGS 15855A has the profile of a dopamine autoreceptor agonist as demonstrated by in vitro and in vivo biochemical studies.

153.9 DOPAMINE AUTORECEPTOR AGONISTS DECREASE DOPAMINE RELEASE IN MOUSE AND RAT. W. C. Boyar*, P. L. Wood, A. Hutchison and C. A. Altar. (SPON: R. Lovell). Neurosci. Research, Pharm. Div., CIBA-GEIGY Corp., Summit, NJ, 07901.

Administration of dopamine agonists decreases in vivo dopamine (DA) synthesis and release (W. Kehr et al, J. Pharm. Pharmacol. 24:24,744, 1972). Static levels of the O-methylated DA catabolite, 3-methoxytyramine (3-MT), which reflect DA release (A. Groppetti et al, Life Sci. 23:1763, 1978), are also decreased by a DA agonist, apomorphine (B. H. C. Westerink et al, J. Neurochem. 38:680, 1982). We determined effects of DA autoreceptor agonists, including a new agonist, CGS 15855A, on levels of 3-MT, DOPAC, HVA, and DA in the olfactory tubercle (OT) or caudate-putamen (CP) of mice with GC/MF using selected ion monitoring (P. L. Wood, Biomed. Mass Spec. 9:302, 1982).

CGS 15855A (4 mg/kg i.p.) suppressed dopamine release in the mouse or rat 0.5 hr post-injection (*p < 0.05; ** p < 0.01 versus vehicle; n = 6-9/group):

		CAUDATE-PUTAMEN CONC. (pmol/mg protein)			
		3-MT	DOPAC	HVA	DA
Mouse	Vehicle	7.5	35	58	651
	CGS 15855A	3.4**	22*	41*	808
Rat	Vehicle	2.7	85	83	456
	CGS 15855A	1.4**	59**	52**	593

TL-99, apomorphine, N-propylnorapomorphine and CGS 15855A decreased 3-MT, DOPAC, and HVA in accord with their rank-order potency in the GBL model for DA autoreceptors. In contrast, the D_2 antagonists haloperidol or chlorpromazine markedly increased 3-MT in the mouse. The mouse was used in all subsequent studies. CGS 15855A produced a dose-related decrease in 3-MT to 35% of control values in the OT and CP whereas DOPAC or HVA were decreased to a lesser extent. The (+) but not (-) isomer decreased 3-MT, DOPAC, and HVA for up to 1 hr post-injection. Tolerance to the dopamine release-suppressing effects of multiple CGS 15855A injections did not develop during 3 hr, whereas striatal DA increased following repeated injections.

We conclude that (1) the mouse CP and OT contain dopamine autoreceptors; (2) 3-MT (DA release) is suppressed more than DOPAC or HVA (DA turnover) by dopamine autoreceptor agonists, and (3) CGS 15855A decreases DA release without the acute development of tolerance.

153.10 DIRECT EFFECTS OF PROGESTERONE INFUSION UPON IN VITRO AMPHETAMINE STIMULATED DOPAMINE RELEASE FROM THE CORPUS STRIATUM OF FEMALE RATS. D.E.Dluzen* (SPON: V.D.Ramirez). Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

We examined the effects of differing modes of direct infusions and doses of progesterone (P) upon in vitro amphetamine (AMPH) evoked dopamine (DA) release from superfused corpus striatal (CS) fragments from ovariectomized-estrogen primed female rats. Rats received four daily injections of estradiol benzoate (5µg/rat). On the fifth day, rats were decapitated, the CS removed and superfused in a modified Krebs-Ringer phosphate buffer medium (pH 7.4, containing .1% albumin, .18% glucose, .1% ascorbic acid and 3.5 x 10^{-4}M pargyline) at a flow rate of 30µl/min. Perfusate samples were collected at 10 min intervals for 24 intervals, acidified to a final concentration of .1N $HClO_4$ and DA determined with a radioenzymatic assay. At interval five, P, diluted in medium, was infused directly (either in short infusions - four discrete 10 min infusions each seaprated by 20 min or in long infusions - a continuous 40 min infusion) and at interval 19, AMPH (10^{-5}M) was infused for 10 min. The short infusion mode of P at 2 ng/ml resulted in a significant increase in AMPH-stimulated DA release as revealed in the area under the curve compared to control superfusions ($\bar{X}$±SE=2619±457 vs 912±105 pg/50 min, N=4) or to those receiving lower (.2 ng/ml) or higher (50 ng/ml) doses of P. When P was administered in long infusions, with identical total amounts, no significant increase in the AMPH-stimulated DA response was observed at any of the three doses tested and the higher doses actively inhibited this response (642±151 and 619 pg/50 min for the 2 and 50 ng/ml doses, N=4 and 2, respectively). We also used a progesterone metabolite-5αDHP (N=4), a synthetic progestin -R5020 (N=4), cholesterol (N=4) and estradiol (N=4) in short infusions at 2 ng/ml. The 5αDHP was also somewhat effective in enhancing the AMPH-stimulated DA response (1728±499 pg/50 min), however responses to the remaining substances were lower and did not differ from controls (1362±331,1092±452 and 908±257 pg/50 min for R5020, cholesterol and estradiol, respectively). The post-superfusion DA concentrations of CS receiving short infusions of 2 ng/ml P (1.17±.27 ng/mg) were significantly greater than controls (.71±.1 ng/mg). Long P infusions significantly lower tissue DA concentrations. Values for 5αDHP and R5020 were significantly higher, while those for cholesterol and estradiol were significantly lower. None of these compounds altered spontaneous DA release. These results demonstrate that a short infusion of 2 ng/ml P to CS tissue from ovariectomized-estrogen primed female rats can augment the in vitro AMPH-stimulated DA release and post-superfusion DA concentrations while a long infusion at this dose actively inhibited these paramters, indicating differential effects of P on CS tissue.

STRUCTURE AND FUNCTION: CORTICAL AND SUBCORTICAL ORGANIZATION II

154.1 DEVELOPMENT OF ACETYLCHOLINESTERASE ACTIVITY IN LAYER IV OF RAT VISUAL CORTEX: COMPARISON OF EFFECTS OF NEONATAL MONOCULAR AND BINOCULAR ENUCLEATION. Richard T. Robertson and Alberto A. Tijerina*. Department of Anatomy, College of Medicine, University of California, Irvine, CA 92717.

The presence of a transient pattern of acetylcholinesterase (AChE) activity appears to be characteristic of some developing thalamocortical systems, including the geniculocortical system of the rat. The appearance of the AChE histochemical reaction product suggests that the AChE is found in terminals of geniculocortical axons. The purpose of the present study was to determine the effects of neonatal monocular or binocular enucleation on the development of cortical patterns of AChE.

Subjects were laboratory born Long-Evans or Sprague-Dawley rats of 0-18 post-natal days (DPN) of age. Animals were anesthetized by hypothermia on 0 DPN and one or both eyes removed surgically. Animals were sacrificed by aldehyde perfusion on 6-18 DPN. AChE activity was detected histochemically in series of 50 um frozen sections by a modified version of the method of Koelle. Non-specific cholinesterase activity was inhibited by 10^{-4}M iso-OMPA. Adjacent sections were processed for a Nissl stain.

AChE activity appears in normal animals as a fine fiber-like plexus in layer IV of cortical area 17 at about 7 DPN. AChE reaction product reaches peak intensity in animals sacrificed at 10-12 DPN and declines until adult levels are reached by 21 DPN. The areal and laminar extent of the AChE plexus corresponds precisely to the terminal field of geniculocortical projections.

Neonatal monocular enucleation results in a marked loss of AChE in the medial sector of layer IV of cortical area 17 contralateral to the enucleated orbit, without detectable loss of AChE in the lateral sector of the contralateral hemisphere or in the hemisphere ipsilateral to the enucleated orbit. The cortical region sustaining the loss of AChE corresponds to the monocular segment of area 17. Neonatal binocular enucleation results in a complete absence of the band of AChE normally found in layer IV of area 17. The loss of AChE occurs in both hemispheres. The neonatal enucleation does not affect the transient bands of AChE in somatosensory or auditory cortex.

These data indicate the transient patterns of AChE activity normally found in developing rat visual cortex are dependent on normal afferent innervation and/or stimulation.

154.2 SYNAPTOGENESIS IN THE PREFRONTAL CORTEX: QUANTITATIVE EM ANALYSIS IN PRE- AND POSTNATAL RHESUS MONKEYS. J.-P. Bourgeois, P.S. Goldman-Rakic and P. Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

In order to relate neural maturation to the development of cognitive functions mediated by the prefrontal association cortex, synaptogenesis in the upper bank of the principal sulcus (Walker's area 46) was analyzed by electron microscopy (EM) in 18 rhesus monkeys ranging from the 47th embryonic day (E47) to 20 years of age. Two to four EM probes consisting of 100-120 consecutive electron micrographs were taken across the full cortical thickness in each specimen. The number of synapses per 100um^2 of neuropil and their classification into symmetric or asymmetric types and their localization on dendritic spines or dendritic shafts was determined in each probe.

Analysis of the E47 embryo failed to reveal any synaptic contacts within the prospective prefrontal cortex. By E78, synapses are present in the marginal zone (prospective layer I) and also in the subplate zone below the cortical plate. During the next fetal month synaptogenesis proceeds more rapidly in layer I than in the cortical plate itself. During the remaining two months of gestation, synaptogenesis increases exponentially in all cortical layers, and by birth (E165) the density of synapses is equivalent to that in the adult prefrontal cortex (15/100um^2). However, synaptogenesis continues at a high rate during infancy, attaining a peak of about 25/100um^2 between birth and the third postnatal month. Thereafter, synaptic density decreases slowly until puberty (3-5 years) when it again reaches the adult level of 15/100um^2. The changes in synaptic densities are predominately associated with the production and elimination of synapses situated on dendritic spines which form 60-70% of synapses at all ages. Synapses on dendritic shafts (30-40%) and cell somas (<1%) are less involved in age-related changes. The proportion of asymmetric to symmetric synapses also shows a transient increase, rising from about 4:1 at E89 and birth, to 7:1 at the peak, before decreasing back to 4:1 at maturity. The time of onset and the rate of synaptogenesis in the prefrontal association cortex are similar to that recorded in the primary visual cortex of the same animals (Bourgeois and Rakic, Neurosci. Abst. '83). In contrast, synaptic density during the stage of transient overproduction is lower in the prefrontal than in the visual cortex. Furthermore, unlike in the visual cortex, the excess of synapses within the prefrontal cortex is most pronounced in the supragranular (I-IV) layers, less in layer V, and absent in layer VI. Studies are in progress to examine how the period of elimination of excess synaptic contacts in the principal sulcus relates to the emergence and development of cognitive functions that depend on this area in the rhesus monkey (Diamond and Goldman-Rakic, Neurosci. Abst. '85). Supported by the U.S. Public Health Service.

154.3 A COMPUTER SYSTEM FOR REGIONAL VOLUME DETERMINATION OF PRIMATE AND HUMAN CEREBRAL CORTEX. W.K. Smith, M.C. de Lacoste, D.S. Schlusselberg, B.G. Culter* and D.J. Woodward. Dept. Cell Biology, Univ. Texas Health Science Ctr., Dallas, TX, 75235.

One aim in quantitative neuroanatomy is to determine regional volumes of brain structures from serial sections. A major problem is the number of sections to be processed. Representative data sets include 2000 fetal brain sections from the Yakovlev collection, 1500 adult sections from the UTHSCD Willed Body Program and 7000 primate sections from Dr. Stephan's collection at the Max Planck Inst. Brain Res. (Frankfurt). Efficient information handling strategies have been developed as part of the Computer Aided Reconstruction Package (CARP) to acquire perimeters, create solid-body models, calculate quantitative measures and display graphical data in three dimensions.

Perimeters are obtained in one of two ways: 1) contours are manually traced from photographic projections onto a graphics tablet attached to a time-sharing computer or 2) contours are semi-automatically collected from video digitized sections stored in a frame buffer using a high-speed graphics processor. After transformation into a biological coordinate system, the entire set of contours from a single brain is stored in one file. Tablet-based menus and terminal keystroke sequences are optimized for user interaction. Hardcopy output on standard pen plotters and electrostatic plotters is available.

CARP executes an interpreted command language which allows user specification of subsequent data processing. Arithmetic, database manipulation, graphical display and flow control operations are its commands. Three forms of output are provided: 1) graphical display of original and modeled data, 2) printed summaries of all quantitative information and 3) card image output formats suitable for input to SPSS-X and other statistical packages. This flexible command language has a major impact on user time required to process large amounts of data.

Quantitative values are obtained for each region. The region delimiters employed neocortical, allocortical and subcortical landmarks such as the rostrum of the corpus callosum, hippocampus and calcarine sulcus. The contour data facilitates generation of solid-body models of the regional volumes. Errors and artifacts not observed in the statistical analysis can be visualized in a solid surface display. Graphical imaging of modeled data allows the use of dividing planes and other methods for specifying regional boundaries. Supported by NSF BNS8316764 (MC de L) and the Biological Humanics Foundation (DJW).

154.4 FERRITIN LOCALIZATION IN RAT BRAIN BY IMMUNOCYTOCHEMISTRY. T.L. Martin*, R.C. Switzer, III, J. Joshi*†, and A. Zimmerman (SPON: N. Greenberg). University of Tennessee, Depts. of Medical Biology and †Biochemistry, Knoxville, TN 37920.

The presence of appreciable amounts of iron in the brain has long been known and is easily demonstrated histologically with the Perls method. Since the presence of iron in a cell triggers the synthesis of ferritin, an iron "storage" protein, the distribution of ferritin in brain might be expected to follow that of iron.

To determine the locations of ferritin in rat brain, freeze-cut sections were treated with immune serum containing antibody against rat ferritin. The antibody was raised in rabbits by injecting them with ferritin obtained from rat liver and spleen. The presence of antiferritin in the immune serum was checked by standard immunodiffusion. After application of the primary antibody, the sections were treated with the HRP-avidin-biotin (Vectastain) procedure to visualize the sites of antibody binding.

The regions of brain displaying ferritin-like immunoreactivity (herein, "ferritin staining") in general matched the description of iron containing areas in rat brain (Hill & Switzer, *Neurosci.* 11: 595, 1984). However, in those areas with positive immunoreactivity for ferritin, it was the neuron cell bodies and dendrites that were stained. This is in contrast to sections treated with the Perls method in which the glial cells are predominantly stained for iron and only a few neuronal populations are stained. In the neuronal populations with iron-positive cell bodies, i.e., central nucleus of amygdala, supraoptic nucleus, bed nucleus of stria terminalis, ferritin stained cell bodies were also found.

In the areas especially rich in iron, globus pallidus and substantia nigra, ferritin staining of neurons was particularly intense. The most striking pattern, however, was seen in layer 5 of cortex, where not only did neuron cell bodies stain but also the entire apical dendrite. In cingulate and entorhinal cortex, stained neurons were found in layers 2-5. The cerebellar purkinje cell bodies and dendrites were also stained except for those in the paraflocculus.

In our frozen sections, few glia stained for ferritin, but in preliminary results with vibratome sections, staining of glia was prominent in addition to neuronal staining. This suggests that freezing the tissue affects the state of ferritin in glia cells.

It is enticing to speculate on the presence of ferritin in neurons in which iron is not histologically demonstrable. Perhaps it is a strategy for those neurons in an iron-rich matrix to provide a means of preventing iron from participating in reactions that generate cytotoxic free radicals. This work was supported by the Robert H. Cole Neuroscience Foundation.

154.5 Neurochemical markers for subsets of inhibitory neurons in cerebral cortex: is neuropeptide Y a marker for a small subset of basket cells? A.J. Hodgson and J. Oliver. Centre for Neuroscience, Depts Immunology, Dept of Medicine. Flinders Univ. med. Sch. Flinders med. Centre Bedford Park, S. Australia 5042.

Inhibitory neurons in cerebral cortex have been divided into different subsets on the basis of their morphological criteria The majority of inhibitory neurons are thought to be GABA-ergic and can be identified by the Immunocytochemical localisation of markers glutamic acid decarboxylase (GAD) or the neurotransmitter GABA itself. Recently it has been shown that neurons containing GABA or GAD also contain neuropeptides and these delineats subsets of neurons:e.g. Somatostatin and cholecystokinin mark subsets that are distinct whereas somatostatin and neuropeptide Y (NPY) overlap in a high proportion of cells To further characterise these subset of cells we used a newly characterised antiserum to NPY. Rat brains were fixed by perfusion either with formaldehyde (4%), glutaraldehyde (0.1%) and picric acid (0.2%) or with glutaraldehyde (2%) Vibrotome sections were treated to enhance the penetration of antibodies (Llewelyn-Smith et al J. Histochem Cytochem, in press (1985) by incubation in 50% ethanol (3x30 min) and cyanoborohydride (0.1%,30min) NPY like immunoreactivity was detected by using an antiserum raised in sheep (Oliver.J. and Blessing W.W. unpublished), using the avidin-biotin technique. After reaction in diaminobenzidine the sections fixed in 1% osmium tetroxide then 2% aqueous uranyl acetate and flat embedded in TAAB resin on glass slides. Selected regions were re-embedded and examined in the electron-microscope. Certain sections were stained either as semithin sections on slides or as ultrahtin sections on grids with antisera to GABA using immunogold. The NPY antiserum stained a rich plexus of immunoreactive fibres and terminals as well as cell bodies and dendrites. most of these cell soma were small with patchy staining of the perikaryon. In the light microscope a small but significant proportion of the terminals appeared to form pericellular baskets consisting of a few fibres which had 3-10 boutons in apposition with the cell soma and what appeared to be proximal dendrites. In some cases the cell contacted also stained for NPY. In the electron microscope it was confirmed that the boutons that contacted the soma made synaptic contact with a Gray type II synapse. The same cell was contacted by numerous non-immunoreactive boutons. It was also possible to show that some of the cells contacted contained GABA. These results indicate that some NPY cells make contact with cell somata and proximal dendrites and on this basis appear to be similar to cells classically described as basket cells. From this study it is impossible to determine the cells of origin of the NPY terminals.

154.6 AN IMMUNOHISTOCHEMICAL CHARACTERIZATION OF THE DOPAMINERGIC (DA), NORADRENERGIC (NA), AND SEROTONERGIC (5HT) INNERVATION OF PRIMATE PREFRONTAL AND TEMPORAL CORTICAL REGIONS. D.A. Lewis*, M.J. Campbell, S.L. Foote, M. Goldstein and J.H. Morrison (SPON: E.L.F. Battenberg). Scripps Clinic and Res. Fdn., La Jolla, CA 92037 and N.Y.U. Med. Ctr., N.Y., N.Y.

The expansion and differentiation of the prefrontal (PFC) and temporal cortical (TC) regions is a distinguishing feature of primate brain. Using antisera against tyrosine hydroxylase and dopamine-B-hydroxylase, which visualize DA and NA fibers respectively, and anti-5HT, we characterized the innervation patterns of these three monoamines in PFC and TC of cynomolgus and squirrel monkey. Marked species differences in innervation patterns were observed. For example, relative to the supragranular layers, 5HT innervation in the infragranular layers of PFC was more dense in cynomolgus than squirrel monkey. Our findings in cynomolgus can be summarized as follows: 1) All three monoamine systems exhibited regional heterogeneity in fiber density. In PFC, DA fibers were most dense in area 9 and there was a medial to lateral decrease in fiber density on the dorsal surface. In TC, there was a superior to inferior increase in DA fiber density. NA innervation of PFC and TC was sparse compared to DA. The density of NA fibers increased from the rostral to caudal portions of PFC. 5HT innervation was generally denser in TC than in PFC. 2) Each monoamine system had distinctive laminar patterns of staining. In area 9 there was a dense arborization of DA fibers in layers I-III and decreased staining in the infragranular layers, whereas in the more sparsely innervated dorsolateral areas of PFC, DA fibers were more dense in the infragranular layers than in layer III. NA fibers were generally most dense in the infragranular layers of PFC. 3) There was a striking complementarity of the different monoamine laminar patterns. In TC, 5HT innervation was most dense in layer IV, whereas both DA and NA fibers were least dense in layer IV. There was also a complementary relationship between DA and NA fibers in layer I. DA fibers were dense in deep I and superficial II; in contrast, NA fibers were sparse in these layers and dense in superficial I. 4) Distinctive morphologic specializations, such as the 5HT "baskets" described by Tork and Mulligan (Neurosci. Abs., 1984), were seen. In summary, we used antisera which visualize DA, NA and 5HT axons to demonstrate that the monoamines have regional and laminar innervation patterns which are heterogeneous, distinctive and, in some cases, complementary or species-specific. These findings suggest specific differences in the functional roles of the monoamine systems in primate neocortex. Supported by K1-00519, AG0513, MacArthur Fdn., Sam and Rose Stein Charitable Trust, AA 07456-01.

154.7 NORADRENERGIC AND SEROTONERGIC INNERVATION OF CORTICAL, THALAMIC, AND TECTAL VISUAL STRUCTURES IN OLD AND NEW WORLD MONKEYS. Stephen L. Foote and John H. Morrison. Department of Psychiatry, University of California, La Jolla, CA 92093 and Department of Basic and Clinical Research, Research Institute of the Scripps Clinic, La Jolla, CA.

Antisera directed against human dopamine-beta-hydroxylase and against serotonin were used to characterize the noradrenergic (NA) and serotonergic (5-HT) innervation of several cortical and subcortical visual areas in squirrel monkey and cynomolgus monkey. Few species differences were observed for either monoamine. Cortical areas 17 and 18, as well as visual areas in the temporal and parietal lobe were found to exhibit regional specialization of both 5-HT and NA innervation. At the border between areas 17 and 18, the laminar innervation patterns characteristic of NA fibers in area 17 shift such that layer IV of area 18 contains more fibers than layer IV of area 17 ,and the overall density of fibers in area 18 is higher. For 5-HT, the laminated patterns characteristic of area 17 become less striking in area 18, and the overall density of fibers decreases. Visual areas of inferotemporal cortex were found to exhibit sparse NA fibers and very dense 5-HT fibers. Area 7 of the parietal lobule was more densely innervated by NA fibers, and less densely innervated by 5-HT fibers, than any other visual cortical region examined. Visual thalamic nuclei exhibited even greater regional differences in NA innervation. The lateral geniculate was found to be virtually devoid of NA fibers, while the pulvinar-lateral posterior complex was densely innervated. The density of 5-HT fibers was more uniform across these structures; all exhibited a moderate to high density of immunoreactive fibers. The superficial layers of the superior colliculus were found to be densely innervated by NA fibers, whereas 5-HT fibers were most dense in the intermediate layers. These observations suggest that functionally related visual regions share common and distinguishable densities of NA innervation. Specifically, tecto-pulvinar-juxtastriate structures are more densely innervated than geniculo-striate and inferotemporal structures, suggesting that, within the visual system, NA fibers preferentially innervate regions involved in spatial analysis and visuomotor response rather than those involved in feature extraction and pattern analysis. This is especially interesting given the proposed involvement of the locus coeruleus/NA system in cortical sensory processing and attentional mechanisms. The 5-HT innervation of visual areas was generally of high density and exhibited less specialization than was evident for NA innervation. 154.8 EFFECTS OF REVERSIBLE COLD LESIONS IN PRESTRIATE CORTEX ON PERFORMANCE OF VISUAL TASKS. Carol L. Martin-Elkins* and James A. Horel (SPON: J. Robson). Department of Anatomy and Cell Biology, SUNY, Upstate Medical Center, Syracuse, NY 13210.

It is well known that the inferotemporal cortex plays an important role in visual learning and retention. The principle visual input to this cortex is from a fairly circumscribed part of the prestriate area (Desimone & Gross). The particular role of this portion of the prestriate cortex in these processes has not been determined. In this experiment we used reversible cryogenic lesions to study the possibility that this prestriate input to inferotemporal cortex may participate in visual learning or retention.

Loops of stainless-steel tubing were shaped to fit over the preoccipital and fusiform gyri in the lateral and ventral aspects of prestriate cortex bilaterally. During experimental trials, cooled methanol was pumped through the cryodes which were maintained at -5°C. The cold produces a functional suppression of the area underlying the cryodes. During this suppression, the animals were tested on acquisition and retention of visual discriminations and performance on a delayed match-to-sample (DMS) task. The visual discrimination required the animal to respond to only one member of a stimulus pair in order to receive a juice reward. The stimuli consisted of photographs of monkey faces, objects or black-white patterns. The DMS task required the animal to respond to a sample photograph of an object and then, after a delay of several seconds up to several minutes, to a photograph of the same object now paired with another non-match object. Monkeys were tested with delays of 10 seconds and 45 seconds between the sample and match while cooling for two 20-trial blocks interspersed with control blocks. Also, a 6-minute delay was used in which cooling was administered either during presentation of the sample when the information is stored or the match when it is retrieved, or throughout the entire trial including both sample and match.

Cooling the lateral and ventral surface of prestriate cortex resulted in deficits in retention of black-white patterns and monkey faces, but not in retention of objects on visual discrimination tasks. However, acquisition did not appear to be affected. A more interesting finding was that while cooling throughout the entire trial, DMS performance at delays of 10 and 45 sec. was not impaired, but it was severely disrupted when the delay was increased to 6 min. An impairment also appeared when the cooling was limited to the match portion on 6 min. trials. There was a weaker effect when cold was applied only during sample. These results suggest that the prestriate cortex may be involved in long-term retention of visual information, but is not as important in short-term retention or learning. Supported by NINCDS grant NS 1829-03.

154.9 LAMINAR AND TANGENTIAL VARIATION IN THE MORPHOLOGY AND DISTRIBUTION OF GABA-CONTAINING NEURONS IN RHESUS MONKEY PREFRONTAL CORTEX. M.L. Schwartz, D.S. Zheng and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale University, School of Medicine, New Haven, CT 06510.

The distribution and morphology of GABAergic neurons in sensory and motor cortices suggest that this transmitter is restricted to local circuit neurons and is uneven in its radial distribution. In the present study we examined the organization and morphology of GABA-containing neurons in primate frontal association cortex to determine whether areal differences in the localization of this transmitter may provide information on the functional differences between cortical regions. Neurons in area 46 were labeled immunocytochemically for GABA (Immunonuclear Corp.) or for the synthetic enzyme GAD (Oertel et al., Neurosci. 6: 2715, 1981) and their distributions were mapped. GABA and GAD positive neurons are found in all cortical layers. Unlike the sensory areas of the monkey in which the highest concentration of GABA-containing neurons is in layer IV, in prefrontal cortex these cells are most numerous in layer II and superficial layer III. In addition, GABA-positive neurons exhibit a disjunctive tangential distribution: regions containing a high density of labeled neurons occur in 100-150 um wide zones that are separated by regions of lower density ranging from 100-300 um in width. In contrast to columns of cortico-cortical neurons, the tangential distribution of GABA neurons does not exhibit a regularly repeating periodicity. A more detailed examination of this distribution in serial sections is in progress to determine whether the GABA containing cells line up in stripes or are clustered into blobs. The size and morphology of GABA positive neurons show laminar variations. Stellate or multipolar cells with an average diameter of approximately 10 um are the predominant cell type in all cortical layers. Other cell types include bitufted and fusiform cells (10 um) that are prominent in large numbers in layers III, V and VI, and a small population of basket cells (12-18 um) found in layers III and V.

These results reveal that GABA-positive cells in prefrontal cortex are distributed in a specific laminar and tangential pattern. The laminar pattern is clearly different from that of several sensory cortices, but we do not yet know whether sensory regions exhibit a disjunctive tangential distribution. In prefrontal cortex, the tangential variations may be relevant to the modular patterns of afferent and efferent connections and functional activity of this area. It is likely that a similar relationship exists in many other regions of the cortex.

154.10 CONTINUITY BETWEEN VENTRAL PALLIDUM AND OLFACTORY TUBERCLE ILLUSTRATED BY PROMINENT PATTERNS OF GLUCOSE UTILIZATION DURING CHEMICALLY-INDUCED SEIZURES. L. Churchill, T. Pazdernik*, R. Cross*, M. Giesler*, F. Samson and S. Nelson. R.L. Smith Res. Center, Univ. of Kansas Med. Center, KC, KS 66103.

Changes in 2-deoxyglucose uptake during chemically-induced seizures provides clues to the anatomical regions functionally related in seizure pathways. Basal forebrain activation assessed by the 2-deoxyglucose method has been compared during seizures induced by bicuculline (0.6 mg/kg, i.v.), penicillin G (500 units, intrahippocampal), soman (0.1 mg/kg, s.c.) and kainic acid (12 mg/kg, i.p.). During seizures induced by bicuculline, penicillin G and kainic acid, the pattern of prominent increase in glucose use illustrates a connection between ventral pallidum and olfactory tubercle in agreement with anatomical connections between these brain areas demonstrated by the distribution of ferric iron content and acetylcholinesterase-positive neurons (Switzer, R.C., III, Hill, J. & Heimer, L., Neurosci., 7:1891-1904, 1982) and enkephalin-positive immunoreactivity (Haber, S.N. & Nauta, W.J.H., Neurosci., 9: 245-260, 1983). The connection is illustrated here by a bridge of increased glucose use between the dome-shaped ventral pallidum and the olfactory tubercle during bicuculline- and penicillin-induced seizures and by many multiple bridges in kainic acid-induced seizures. In bicuculline- and penicillin-induced seizures, the bridge is parallel to the fundus striatum connecting the ventrolateral edges of the ventral pallidum and olfactory tubercle. In kainic acid-induced seizures the many bridges lay parallel to each other and are perpendicular to the ventral border of the pallidum and dorsal to the olfactory tubercle. On the other hand with soman, activation is observed in these areas but the bridge between olfactory tubercle and ventral pallidum is not as prominent. Seizures induced by all 4 convulsants increased glucose use more rostrally to form a continuous, wide band from olfactory tubercle to anterior commissure. This band includes ventromedial nucleus accumbens and ventral pallidum. With soman and kainic acid the continuous band of increased glucose utilization continues through bed nucleus of stria terminalis and lateral septum. The prominence of the glucose use pattern in ventral pallidum and olfactory tubercle during repetitive, generalized motor seizures induced by a variety of different agents suggests a functional role of these brain regions in seizure pathways. Supported in part by U.S.Army DAMD17-83-C-3242.

154.11 IBOTENIC ACID LESIONS OF MEDIAL SEPTUM ABOLISH ATROPINE-SENSITIVE HIPPOCAMPAL RSA BUT SPARE ATROPINE-RESISTANT RSA. D. J. Stewart and C. H. Vanderwolf. Dept. of Psychology, Univ. Western Ontario, London, Ontario, Canada, N6A 5C2.

Previous experiments have suggested that hippocampal rhythmical slow activity (RSA) can be produced by activity in either of two ascending pathways. Activity in a serotonergic pathway (Vanderwolf and Baker, this meeting) may be responsible for the atropine resistant RSA seen during Type 1 behavior (e.g., walking, rearing, struggling during handling) and muscular twitches during rapid eye movement (REM) sleep. Activity in neurons in the medial septum and diagonal band may provide a cholinergic input during both Type 1 and Type 2 behavior (e.g., waking immobility, face washing, tremor) and REM sleep. This input may produce the atropine-sensitive RSA seen in the intertwitch intervals of REM sleep and also appears to be responsible for all the RSA present in urethane anesthetized animals. The role of the septal nuclei in atropine-sensitive (presumably cholinergic) RSA was studied in rats that received injections of ibotenic acid (5, 10 or 20 µg, dissolved in Locke's solution) in the medial septal region. Hippocampal RSA was quantified by passage through a band-pass filter (6-12 Hz for undrugged and atropine conditions, 4-10 Hz for urethane anesthetized conditions) followed by rectification and integration. Following at least two weeks recovery, all lesioned rats displayed RSA during Type 1 behavior both before and after atropine (50 mg/kg, i.p.). Following urethane anesthesia (1.0-2.0 g/kg, i.p.) RSA could be elicited by a tail pinch in the control group (vehicle alone) and the group receiving 5 µg of ibotenic acid but not in the groups receiving 10 or 20 µg. Analysis of REM sleep periods in the 20 µg treated group suggested that the RSA normally associated with the intertwitch intervals was also abolished, but the RSA associated with muscular twitches was preserved. Muscular activity during REM sleep was defined by EMG recording, a movement sensor and visual observation. Histological analysis revealed a dose related cell loss in the septohippocampal nucleus and the dorsal part of the lateral septal nucleus. Slight cell loss was also observed in the most dorsal part of the medial septal nucleus in some rats. Acetylcholinesterase staining of hippocampal sections appeared normal in all lesioned groups. Control injections produced virtually no damage. These results suggest that atropine sensitive (presumably cholinergic) RSA can be selectively disrupted by lesions which disrupt septal circuitry.

154.12 SLEEP-RELATED DISCHARGE OF BASAL FOREBRAIN NEURONS WHICH RESPOND TO CORTICAL ELECTRICAL STIMULATION. R. Szymusiak and D. McGinty. Neurophysiol. Res. (151A3), V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. Psychology, U.C.L.A., Los Angeles, CA 90024.

We have previously examined basal forebrain (BF) neuronal discharge in cats during sleep and waking using chronic microwire techniques. Fifty percent of the neurons studied had a "waking-active" discharge pattern, i.e., discharge rates during waking were much greater than those during nonREM sleep. Another 20% were classified as "sleep-active" neurons (sleeping rates >> waking rates). Sleep-active neurons were confined to the ventral BF and were distributed like cholinergic neurons. The remaining 30% of the cells were categorized as "state-indifferent" (waking rates ≃ sleeping rates). We have now examined the responses of these different BF cell types to electrical stimulation of various cortical and limbic system sites.

Three adult cats were prepared for chronic sleep recordings and with bundles of microwires (32µm tip diameters) aimed at various BF sites (diagonal bands of Broca, substantia innominata, and ventral globus pallidus). Stimulating electrodes were placed in sensorimotor cortex, orbitofrontal cortex, rostral cingulate cortex, and the fornix. Sleep-waking discharge patterns were determined for all cells which responded to stimulation.

A total of 20 BF neurons were influenced by stimulation; 16 were orthodromically activated and 4 were antidromically driven. Orthodromic responses typically consisted of a brief excitation followed by a much longer period of inhibition. Latencies ranged from 4 to 20 msec. Nine orthodromic responses were obtained from orbitofrontal cortex, 2 from cingulate cortex and 5 from the fornix. Of these 16 cells, 8 were state-indifferent, 5 were sleep-active, and only 3 were waking-active.

Of the 4 antidromically driven cells, 3 were activated from orbitofrontal cortex and 1 from the fornix. Latencies ranged from 5-18 msec. Three of the 4 cells were state-indifferent and the remaining cell was sleep-active.

These preliminary results indicate that the most common BF cell type (i.e., those with waking-active discharge profiles) are least likely to be influenced by electrical stimulation of the cortical and limbic system sites examined. Thus, sleep-waking discharge profiles may be correlated with the anatomical connectivity of BF neurons.

154.13 STUDIES ON ELECTRICAL RHYTHMS BETWEEN CEREBRAL CORTEX, SEPTAL AND LIMBIC AREAS. R.J. Morgan, G.T. Schneider*, C.C. Turbes, and T.N. Solie*. Dept. of Anatomy, Creighton Univ. Sch. of Med. Omaha, NE 68178

These studies are of the electrical activity of the extracellular space of the frontal, temporal and occipital cerebral cortex and the amygdala septal nucleus. These experiments show the interactions of the slow wave field potential of spatially distant neuron populations. Twelve cats are used in these studies. Chronic electrodes are surgically implanted in the cerebral and limbic brain areas previously mentioned. The analog signals are recorded on FM tape and analog to digitally converted and processed with a Varian V-72 minicomputer. Initial studies utilized coherence, partial coherence and cross phase spectral analysis. The same analog data is stored on a hard disc to facilitate comparison studies between brain regions.

These studies on coherence showed the percent coherence of the signals from two brain areas. Since many brain areas are synaptically interconnected, partial coherence analysis is used to remove a possible third signal from the other two signals. The synaptic interaction of a third signal from a third brain area is indicated when there is a decrease in coherence between the two signals in ordinary coherence when the third signal is removed in the partialization process. In some cases, removal of a noise term from one of the signals of the ordinary coherence pair of signals results in an increase in coherence following partialization. The changes in coherence varies with different frequencies following the partial coherence analyses. There are changes in the cross phase spectrum following partialization process. There are changes in phase evident at different frequencies and show increase or decrease in degrees of positive and negative phase. In some cases there is a complete phase reversal following removal of the third signal. These changes reflect the possible interaction of two or more synaptically interconnected brain areas. Certain brain rhythms (i.e., 40 Hz rhythm) show a complex interaction involving certain cortical and subcortical regions when partial coherence is used.

154.15 ELECTRICAL ACTIVITY OF THE CINGULATE CORTEX IN THE RAT: RELATIONS TO BEHAVIOR AND CHOLINERGIC INPUTS. L.S. Leung, J.G.G. Borst* and D.F. MacFabe*, Dept. of Psychology, Univ. Western Ontario, London, Ontario, Canada N6A 5C2.

The gross electrical activity of the cingulate cortex was studied in freely moving rats with chronically implanted electrodes. During waking immobility and slow-wave sleep, cingulate EEG showed a large amplitude irregular slow activity (<30 Hz, ISA), containing high amplitude, sharp events of about 20 msec duration (EEG spikes). During active movements (e.g.,walking and rearing), the EEG spikes were suppressed and theta rhythm and fast waves (30-100 Hz) predominated.

The cingulate EEG spikes appear to be behaviorally modulated by a cholinergic input. The low spike rate during walking (as compared to waking immobility) is increased by atropine sulfate (10-50 mg/kg i.p.) but not by atropine methyl nitrate. EEG spikes during immobility was suppressed by pilocarpine (25 mg/kg i.p.). Pilocarpine also enhanced the cingulate and hippocampal theta rhythms during immobility. Spectral analysis indicate that after atropine, ISA was increased and fast waves were decreased, but the absolute power of the theta rhythm in the cingulate remained unchanged.

Electrolytic lesion of the medial septal area (which usually spared the horizontal limb of the diagonal band) decreased the acetylcholinesterase (ACHE) staining in layers I,II,III and V of the cingulate and abolished the normal relation of cingulate EEG spikes with behavior, i.e. spikes appeared both during immobility and active movements. Medial septal lesions also paled the ACHE staining of the hippocampus and abolished the hippocampal theta rhythm. However, in some cases, the cingulate theta persisted or even increased after hippocampal theta was abolished, suggesting that theta rhythm can be generated intrinsically by the cingulate cortex, and is not due to hippocampal volume conduction. Substantia innominata lesion with kainic acid, whether unilateral or bilateral, did not affect the relation of cingulate spikes with behavior, even though ACHE stain in the cingulate layer IV and in the neocortex was paler than normal.

In conclusion, cingulate EEG spikes and EEG appear to be suppressed by a pathway which involves muscarinic cholinergic synapses and passes through the medial septum. Cingulate theta rhythm is probably driven by neurons in the diagonal band and medial septum which are partly distinct from those driving the hippocampal theta rhythm. (Supported by Canadian MRC and NSERC grants to L.S. Leung).

154.16 EVOKED POTENTIAL AND CURRENT SOURCE DENSITY (CSD) PROFILES IN RODENT NEOCORTEX IN VITRO. N.L.Chiaia, L.J.Cauller*and T.J.Teyler. Neurobiology Prog., NE Ohio Univ. Col. of Med., Rootstown, OH 44272.

In vitro brain slice preparations offer promise for investigations of information flow and microcircuitry within the CNS. Reduced slice preparations of several structures, including hippocampus, thalamus, striatum and amygdala, have already been reported and data from these investigations has advanced our understanding of the organization and path of information flow through these structures. The present investigation examines depth profiles of extracellular evoked protentials in slices taken from rodent visual and somatosensory cortex to identify prototypical response properties.

Coronal sections, 400 um thick, were prepared from the visual and somatosensory cortex of syrian hamsters in the manner described previously by Shaw and Teyler (Br.Res.,243:34 1982). To ensure stability, slices were incubated for a period of 1 hr following dissection before recording began. The tissue was stimulated via a 75 um concentric electrode placed at the white/gray matter boundry with single, .1ms, biphasic pulses, 20-30V. Evoked potentials were recorded via NaCl-filled micropipettes in a trajectory orthogonal to the surface.

In most cases, records were taken at distances of 300, 600 and 900 um from the white/gray border. Typical responses consisted of a triphasic waveform whose initial component was a pronounced negativity which occured approx. 1.5 ms post stimulus. This was followed by a positive inflection (peak latency 3.2 ms) and, finally, a second negative component (peak latency 5.0 ms). All three response components were observed at each of the three depths sampled. The latter two components diminished as recording approached the cortical surface. These late components could be abolished by incubation of the slice in a low calcium media, while the early component was found to be calcium insensitive.

In some cases, CSD profiles were constructed from averaged evoked potentials taken at 50 um steps from surface to depth. This analysis revealed the presence of two concurrent sinks at supra- and infra-granular layers which corresponded with maximal multiple unit activty. These layers were separated by a prominent current source through layer IV.

154.17 FIELD POTENTIAL AND CURRENT SOURCE DENSITY (CSD) PROFILES OF INTACT AND IN VITRO VISUAL CORTEX IN RATS. G.Vaknin, L.J.Cauller*and T.J.Teyler. Neurobiology Program, NE Ohio Univ.Col.of Med., Rootstown, OH 44272.

One-dimensional CSD analysis was applied to field potential depth profiles recorded perpendicular to the surface through visual cortex of rats. Strobe light visual-evoked profiles of the intact preparation are compared to profiles evoked by white matter stimulation of cortical slices. Both intact and in vitro recordings were from the same point on cortex, presumably area 17.

Coronal slices of cortex were prepared and maintained in the usual way (Shaw and Teyler,Br. Res., 243:35, 1982). The earliest (1-2 msec) response to white matter stimulation was an abrupt current sink in deep layers with a concurrent sink in adjacent superficial depths. This response probably represents the synchronous antidromic activation of pyramidal cells in layers V and VI. The antidromic dipole was immediately followed by a longer duration, reversed dipole with its source at the cell body depth and its sink above. The antidromic dipole consistently appeared to move upward from the cell body layer (0.2 m/s).

No sinks or sources were observed through the central 300-400 um region of the cortical slice. Somewhat later than the antidromic response (2-3 ms) was a massive current sink in upper cortical levels that lasted 10-40 ms.

The profile along a surface-to-depth trajectory that was recorded lateral to the point of stimulation revealed a pattern of sinks and sources that was virtually identical to the on-line profile described above. The off-line profile differed only in amplitude.

The CSD profile of the visual-evoked response in anesthetized rats resembled the pattern of activation observed in the slice but developed slower and lasted longer. The earliest response (35 ms) was a deep sink, superficial source dipole which migrated upward through the central layers (0.02 m/s). As in the slice, this initial response was shortly followed by a massive current sink in upper levels.

Although the ascending sink phenomenon was evident using the nearest neighbor method of CSD differentiation, the second-nearest neighbor method enhanced the appearance of sink movement.

154.18 THE NEURAL BASIS OF EVOKED FIELD POTENTIALS STUDIED BY CURRENT SOURCE DENSITY (CSD) ANALYSIS OF THE HIPPOCAMPAL SLICE AS A SIMPLE MODEL SYSTEM. L.J.Cauller*, N.Chiaia and T.J.Teyler, (SPON:T.Voneida) Neurobiology Prog., NE Ohio Col.of Med., Rootstown, OH 44272.

The well studied and relatively simple cytoarchitecture of hippocampus provides a model system in which to determine prototypical CSD profiles in relation to known sink/source generators. In vitro slices of rat hippocampus were prepared in the usual way (Teyler, Br.Res.Bull.,5:391, 1980). We sampled the profile of field potentials at 100 um steps through area CA1 along a trajectory perpendicular to the pyramidal cell body layer. CSD profiles were computed from profiles constructed from averages of these field potentials.

Separate profiles were evoked by: (i) antidromic stimulation of the alvear tract; (ii) orthodromic stimulation of stratum oriens and; (iii) orthodromic stimulation of discrete Schaffer collateral bundles through stratum radiatum.

The characteristic population spike evoked by antidromic activation of pyramidal cell bodies was generated by an abrupt current sink that was restricted to stratum pyramidale. The concurrent source was distributed over the most proximal apical dendrites and throughout statum oriens. The profile of the antidromic population spike was prototypical for all spikes including those evoked by orthodromic activation.

Discrete synaptic activation of apical dendrites via Shaffer collateral stimulation produced a large, but shallow current sink in stratum radiatum. This sink was surrounded by concurrent sources which extended both distally and proximally away from the activated sink. Sources extended to the distal extremities of the dendrites without decrement while the profile of sources along the apical shaft decayed exponentially with distance from the activated sink (population length constant: 100-150 um). Even though this somatopetal EPSP source usually decayed to extinction 200 um below the cell layer, apical EPSPs were always associated with large somatic current sources.

Synaptic activation of basilar dendrites via oriens stimulation evoked a massive sink throughout stratum oriens with a concurrent source that was restricted to the cell body layer.

155.1 ANGULAR DEPENDENCE OF THRESHOLDS FOR ELECTRIC FIELD EFFECTS ON FIRING RATES OF APLYSIA PACEMAKER CELLS. A.R. Sheppard, S.M. Bawin, M. Burton-Sagan* and W.R. Adey. VA Medical Center, and Loma Linda University, Loma Linda, CA 92357.

In order to gauge the importance of cell orientation and geometry in the effects of extracellular electric fields on neuronal excitability, Aplysia abdominal ganglia were exposed in vitro to alternating electric fields of 2 to 40 mV/cm rms over a range of angles defined by the field direction and the rostral-caudal axis of the ganglion. Alternating current at the natural firing frequency (ω1-3 Hz) was passed between orthogonal pairs of Ag-AgCl electrodes and adjusted to yield a vector sum that varied in 30° steps over a range of 180°. Intracellular records of cell firing were computer-analyzed for the temporal correspondence of action potentials with the phase of the sinusoidal waveform. The smallest detectable influence ("low threshold") and the level for strong synchronization ("high threshold") were found by statistical tests on the distribution of phase angles obtained from tests over all ranges of orientation angle and field magnitude. All cells showed significant angular dependence for both the "low" and "high threshold", often over the full 20:1 range. At optimal angles the "low and "high thresholds" were often as low as 2 and 20 mV/cm, respectively. Maximum and minimum sensitivities were frequently at right angles, but in several instances changes of 30° gave ten-fold changes in threshold, and multiple extremes of sensitivity sometimes occurred in one cell. For the RUQ "white" cells, maximum sensitivity was coincident with the rostral-caudal axis. Conductance of soma membrane is numerically dominant in these cells, but the data are consistent with effects at trigger zones in the axon (aligned along the axis). Cell L8 and others of the LLQ had more variable angular dependences, including maximum sensitivities perpendicular to the axis. Overall, the diversity of cell positions within the ganglion and cell morphology may account for great variations in angular responses. In low Ca++ solutions (1 vs 12 mM) field sensitivity was markedly greater but with the same angular dependence, suggesting these effects have little to do with synaptic coupling but depend on membrane status. (Research supported by the U.S. Department of Energy and Southern California Edison Company.)

155.2 **INTERNEURONAL AND INTERGLIAL GAP JUNCTIONS IN THE STOMATOGASTRIC GANGLION OF THE ROCK CRAB, CANCER BOREALIS.** **D.H. Hall, E. Marder, and M.V.L. Bennett, Dept. Neuroscience, Albert Einstein College of Medicine, Bronx, NY 01461, and Dept. Biology, Brandeis University, Waltham, MA 02254.**

Neurons of the crab stomatogatric ganglion (STG) which are connected by both electrical and chemical synapses were studied by thin section and freeze fracture electron microscopy. Although electrotonic coupling is common in invertebrate ganglia, gap junctions (gjs), the presumed morphological substrate, have often been difficult to demonstrate (e.g. King, J. Neurocytol. 5: 207-266, 1976). In crab STG, neurons contact each other via small gjs between secondary or tertiary neurites. The neuronal somata and primary neurites are sheathed by glial wrappings, so that primary neurites have only limited contact with other neuronal processes. Finer neuritic processes are segregated into glomeruli with little glial interposition where opportunities for synaptic contact are greater. Chemical synapses are common within glomeruli and are characterized by accumulations of vesicles, small pre-synaptic tufts, and post-synaptic densities. Terminals can be classified by their vesicle contents, small or large diameter clear vesicles. These vesicle classes may correspond to different transmitters used by intrinsic inhibitory neurons as in the lobster STG (King, op. cit.). Processes containing large dense core vesicles are also observed, perhaps deriving from extrinsic modulatory neurons.

Glial cells also form large gjs (often 1 micron in diameter) between their somata and between their processes in the outer glial sheath of the ganglion. Large desmosomes are also found between glia. Freeze fracture confirms an exceptionally high density of large gjs in the outer glial sheath. The individual particles (avg. 12.5 nm) are loosely organized. Most particles cleave with the P-face, but 10-30% are found with the E-face. This predominantly P-face association is unusual for arthropods.

As yet there is little freeze fracture evidence for gjs between neurons, due to difficulty in identifying neuronal membranes. The small size of neuronal gjs found thus far in the crab STG is typical of many invertebrate ganglia where there is electrotonic coupling (as shown in the mollusc, Navanax, Hall et al., J. Neurocytol. 12: 831-846, 1983), and the data from the crab STG provides further comparative data suggesting that electronic coupling in these invertebrate systems is mediated by the usual structure.

155.3 INTRACELLULAR CESIUM FLUORIDE LINEARIZES THE MEMBRANE PROPERTIES OF MAMMALIAN NEURONS FACILITATING THE EXPLORATION OF SYNAPTIC INPUTS. A.R. Kay*, R. Miles* R.K.S. Wong (SPON: C.R. Fourtner) Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

Electrotonic theory provides a means for estimating the distance of a chemical synapse from the soma; however, this body of theory is largely invalidated by the presence of channels that are activated in the subthreshold range of potentials (Llinas & Sugimori, Soc. Neurosci. Abstr., 10:193.7 (84); Masukawa & Prince, J. Neurosci., 4:217 (84); Stafstrom et al., J. Neurophysiol. 53:153 (85)), uncertainty as to the distribution of channels mitigate against a predictive nonlinear theory. Instead of applying restrictive theories we have attempted to linearize the membrane by suppressing voltage-dependant conductances using intracellular agents.

When recording intracellularly with microelectrodes it is possible to eliminate most of the outward current by the iontophoretic introduction of cesium, while most of the inward current borne by sodium can be annuled by the injection of local anaesthetic agents. Here we show that intracellular fluoride can be used to eliminate most of the calcium conductance.

Neurons were isolated from adult guinea pig hippocampi using trypsin digestion. The dynamics of inward current activation were studied in these neurons using the whole-cell patch clamp recording technique. When CsF was used as the predominant intracellular electrolyte, the noninactivating calcium channel, which activates at about -40 mV, was blocked by fluoride as has been previously reported in snail neurons by Kostyuk (Nature, 257:691 (75)), however, a low-threshold, inactivating calcium conductance, which activates between -70 and -60 mV was not affected by fluoride ions. This channel is similar in its kinetics to that described by Carbone & Lux in chick dorsal root ganglion cells (Biophys. J., 46:413 (84)).

In experiments on guinea pig hippocampal slices, recordings were made from the CA3 pyramidal cells with electrodes filled with fluoride (0.1 - 0.5 M) and EGTA (10 mM). Broadened, presumed Ca-dependent, action potentials were selectively suppressed after 5-10m recording with KF filled electrodes. The occurrence of both spontaneous and evoked synaptic potentials was maintained. With CsF filled electrodes membrane potential could be varied by intracellular current injection over a wide range to levels more positive than the epsp reversal. In contrast to our experience with electrodes containing Cs Acetate, slow large amplitude membrane potential shifts did not occur at potentials between -50 and -10 mV. Instead the membrane appeared to behave linearly at potentials above -50 mV.

155.4 DEVELOPMENT OF MINI-NETWORKS ON MULTIMICROELECTRODE PLATES: MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL ANALYSES. M. H. Hightower*, L. E. Czisny* and G. W. Gross, (SPON: J. Hines). Dept of Biology, The Texas Woman's University, Denton, TX 76204.

We are using glass multielectrode plates having 36 photoetched, transparent indium tin oxide conductors confined to a 1 mm x 0.5 mm recording area to monitor spontaneous activity from mouse spinal monolayer cultures. In order to limit the neuronal culture to the approximate size of the recording matrix, we have developed methods to generate adhesion islands of 1 to 2 mm diameters centered on the matrix and isolated from larger feeder areas that function to condition the medium (Hightower et al., Soc. Neurosci. Abstr. 9: 239, 1983). Under optimal conditions, these islands contain only a few hundred cells and provide spatially defined, simplified, and spontaneously active networks. Classification of cells according to size and morphology has so far revealed no distribution difference between the centered mini-network and large, peripheral feeder areas. Young cultures (1 to 2 weeks after seeding) usually exhibit random, uncoordinated activity that can be observed on many electrodes. Older cultures (3-6 wks) reveal primarily multisite, coordinated bursting that is often rhythmic. Cell counts after post-recording histology with Nissl or combined Bodian-Nissl stains (Hightower and Gross, Stain Technol., 1985, in press) suggest that a minimum neuronal density of approximately 100 neurons/mm^2 is necessary to ensure spontaneous, coordinated bursting. This required density reflects the random neuron adhesion relative to the fixed electrode matrix and probably also the "critical mass" of network components necessary to generate coordinated activity. In addition, 10 mM $MgCl_2$ has always terminated random spiking as well as coordinated bursting. This implies that chemical synapses are involved in the generation of the observed spontaneous activity. These requirements for a minimum cell density and for functional synapses support contentions that the observed activity is a network phenomenon. SEM analyses of specific cell-to-electrode coupling and pharmacological manipulation of synaptic activity are in progress.

155.5 DIFFERENCES IN THE PASSIVE MEMBRANE PROPERTIES OF HIPPOCAMPAL CA1 CELLS IN AGED AND YOUNG RATS A. D'Aguanno*, L. Takeuchi*, M.F. Davies, B.L. Bardakjian*, T.J. Blaxter* and P.L. Carlen. Playfair Neuroscience Unit, Toronto Western Hospital; Institute of Biomedical Engineering, Dept.'s of Physiology, Medicine, and Electrical Engineering, University of Toronto; Addiction Research Foundation, Clinical Institute; Ontario, Canada.

Aged rats (28-30 months) showed different passive membrane properties than young rats (6-8 months). Intracellular recordings were obtained from CA1 cells in hippocampal slices of Fischer 344 rats using 3M KAc or KCl electrodes. Results obtained from peeling analyses of the voltage decay produced by short hyperpolarizing constant current pulses (0.5 ms, 5 nA), showed that the aged animals had a significantly shorter (U-Test, $p<0.05$) neuronal time constant ($\bar{\tau}_0$=19.6 ms, n=14) than the young animals ($\bar{\tau}_0$=27.6 ms, n=14).

Préliminary spectral analysis using the Fast Fourier Transform supported the conclusions derived from the peeling analyses. In a resistive-capacitive network, the product of the time constant and the radian pole frequency is unity. Neuronal time constants derived from spectral analysis of voltage decay for aged neurons were significantly shorter (U-Test, $p<0.05$) ($\bar{\tau}_0$=19.4 ms, n=5) than the corresponding time constant of young neurons ($\bar{\tau}_0$=32.3 ms, n=5).

The input resistances derived from the peeling analyses were lower but not significant in aged versus young neurons ($\bar{R}_{in}$ aged=44.3 MΩ, $\bar{R}_{in}$ young=57.3 MΩ). Preliminary analyses of neuronal input capacitance (C_s) estimated from the coefficients and time constants of the exponential voltage decay, suggest that C_s in aged animals ($\bar{C}_s$=136 pF, n=6) is significantly smaller (U-Test $p<0.05$) than in young animals ($\bar{C}_s$=350 pF, n=6).

These data show that :

1) spectral and peeling analyses of voltage decay produced by short hyperpolarizing current pulses yield similar results.

2) neuronal time constant and input capacitance of hippocampal CA1 cells seem to decrease with age.

155.6 MORPHOLOGY AND ELECTROPHYSIOLOGICAL PROPERTIES OF RETICULARIS THALAMI NEURONS IN CAT. M. Deschênes, A. Madariaga* and C. Mulle*. Lab. of Neurophysiology, Sch. of Med., Laval Univ. Québec, Canada, G1K 7P4.

Reticularis thalami neurons (RE neurons) were identified morphologically and their electrophysiological properties were studied in cat under barbiturate anesthesia. Intracellular horseradish peroxidase injections showed that RE neurons possessed very long dendrites bearing numerous filopodia-like appendages and that their axon was directed toward main thalamic nuclei. As a rule, small axonal branches were also emitted within the RE nucleus itself. At rest, the membrane potential of RE neurons displayed two types of oscillations: a slow 0.1-0.2 Hz oscillation and fast 7-12 Hz oscillations occuring on the positive phase of the former. Episodes of spindle (7-12 Hz) waves lasted for 2-3 seconds and were characterized by rhythmic depolarizations and burst discharges. Intracellular current pulses injections revealed the presence in RE neurons of a large somatic persistent Na^+ current. After blockage of this current by QX314, rhythmic low-threshold depolarizing responses occured at the break of hyperpolarizing current pulses. These responses lasted for 70 msec and required large somatic hyperpolarizations (up to 30 mV) to be de-inactivated. It was then concluded that they represented low-threshold Ca^{2+} responses of dendritic origin. In QX314 injected cells, selective components of oscillations were abolished, among them, the positive phase of the slow oscillation and late depolarizing humps that followed burst discharges within spindle sequences. However, the rhythmic occurence of spindle episodes at 0.1-0.2 Hz were never affected by DC currents, QX314 or Cl^- injections, suggesting that oscillations within a particular RE neuron partly reflected the oscillatory behavior of a network of cells. On the basis of these electrophysiological results and on the basis of already-known morphological and neurochemical features of RE neurons a model is proposed to account for their rhythmic behavior.

155.7 PHARMACOLOGICAL AND KINETIC PROPERTIES OF OUTWARD CURRENTS OF HIPPOCAMPAL PYRAMIDAL CELLS. R.K.S. Wong, R. Numann* and A.R. Kay*, Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Voltage-dependent outward currents in the hippocampal pyramidal cells have been examined using acutely dissociated cells. Pharmacological agents including tetraethylammonium chloride (TEA), 4-aminopyridine (4AP), and Ca^{++} channel blockers (Mn^{++} and Cd^{++}) were used to characterize the different components of the outward currents. Under voltage-clamp at a holding potential of -50 mV, depolarizing steps of 10 mV increments elicited sustained outward currents followed by tail currents which decayed at a time constant of about 80 ms. When Mn^{++} (2 mM) or Cd^{++} was added to the perfusate, the outward current activated upon depolarization was suppressed and the amplitude of the current was not maintained for the duration of the depolarization. The tail current under this condition decayed more rapidly and its amplitude shows a Nernstian dependency on extracellular K^+ concentration. The transient outward current observed in Mn^{++} or Cd^{++} inactivates in two phases during maintained depolarizations: an initial fast rate of decay with time constants of about 50 ms followed by a slower decay with time constants of about 300 ms (at 0 mV membrane potential). TEA at 10 mM selectively suppressed the slowly inactivating outward current. At higher concentrations (15 mM) the initial fast decaying outward currents were also suppressed. 4AP at 1 mM suppressed both components of the outward current. The time constant of decay of the fast component was shortened. The 4AP action on the fast inactivating components also showed interesting voltage dependency with the blocking effect greatly enhanced upon increasing durations of hyperpolarizing prepulses. The effect of 4AP resembles that reported for the molluscan neurons (Thompson, J. Gen. Physiol. 80:1) and is consistent with the interpretation that 4AP in part acts on the closed but not inactivated potassium channels. Additional experiments also show that when cesium fluoride was used in the recording electrode, the outward current component dependent on Ca^{++} is largely suppressed.

Recent studies suggest that the outward current in the hippocampal pyramidal cells can be modulated by neurotransmitters. Characterization of the outward currents may provide the necessary information for a more detailed understanding on the mode of action of these transmitters.

155.8 SYNCHRONOUS CONDUCTION AMONG CLUSTERS OF PYRAMIDAL TRACT NEURONS. Antonio Canedo* and A. L. Towe. Dept. of Physiology and Biophysics, Univ. of Wash. Sch. of Med., Seattle, WA 98195.

The rules of impulse conduction on CNS fibers are usually taken to be the same as for PNS fibers. Each fiber is treated as though it were immersed in a large, external current-carrying medium, and hence conducts independently of its neighbors. Therefore, over a long conduction distance (e.g., cortex to spinal cord), any volley of activity evoked synchronously from the cell bodies must arrive desynchronized at its destination. However, there is increasing evidence that this might not always be true; central pathway fibers originating from a cluster of cell bodies may gather into bundles in such a manner that they all conduct at the same speed. This possibility has been tested by recording the antidromic responses of PT cells isolated several at a time from lateral pericruciate cortex of Domestic cats. Stimulating electrodes were placed on the medullary pyramid and dorsolateral funiculus at C4, and were placed stereotaxically into the cerebral peduncle, red nucleus, lateral hypothalamus, and medial thalamus. Bipolar needle electrodes were placed in the central footpad of each of the four paws for orthodromic activation of the cells (chloralose). It was thus possible to sort out the different PT cells by using spike collision tests along the main axon, between the axon and its collaterals, and between the axon and synaptically-evoked spikes. 'Large-seeing-distance' micropipettes were used to record the activity of several PT cells simultaneously.

Most antidromic 'unit' response obtained with these electrodes turned out on testing to consist of a stack of superimposed units. The size of the stack changed in discrete steps at specific, quite stable stimulus strengths. Collision testing showed each of these steps to reflect a discrete single unit with defineable properties. Although all units within a stack had the same antidromic latency (usually within 0.1 msec of each other), they did not all project to the same sites: some responded only to peduncle, some to both peduncle and pyramid, and some also to spinal cord. Furthermore, they did not all share the same collateral sites. Both fast and slow PT stacks were recorded, but all stacks that contained units responding only to peduncle were 'slow' stacks. Using a reference sample of 1,326 PT antidromic latencies recorded independently in the same cerebral region, it was possible to estimate the chance that any particular stack might be seen, under the assumptions of random dispersion of cells and independence of condutions. The highest probability stack we found had a chance of having been recorded randomly of 7.6×10^{-4}. Under the same rules, the chance of having obtained our overall experimental results was effectively zero ($p<10^{-240}$). There seems little doubt that the rules of CNS fiber conduction differ in important ways from those derived from study of peripheral nerves.

155.9 PROPERTIES OF CULTURED CEREBELLAR GRANULE CELLS MEASURED WITH WHOLE-CELL PATCH RECORDING AND IMAGING OF Ca^{2+} INDICATOR FLUORESCENCE. P. E. Hockberger and J. A. Connor. Dept. Molecular Biophysics, AT&T Bell Laboratories, Murray Hill, NJ 07974.

In preparation for studies on the role of cyclic nucleotides in cerebellar granule cell function, we have begun to characterize the properties of these cells grown in vitro under completely defined conditions. Explants of P3 to P10 rat cerebellum were cultured at 37°C on polylysine-coated glass coverslips and fed 3X per week with DMEM plus defined additives as detailed elsewhere (Ahmed, Z. et al., J. Neurosci. 3:2448,1983). Granule-like cells were identified using several criteria including soma size and shape, dendritic morphology, birthdate, survival in 10^{-4}M kainic acid, and response to GABA iontophoresis (also see Messer, A., Brain Res. 130: 1,1977). Intracellular and voltage clamp data were obtained using the whole-cell patch recording technique.

Granule cells were identifiable after 2-3 days in culture and increased in number throughout the first week. During that time the cells exhibited progressive changes in several membrane properties. Membrane resistance dropped (10^{-4} -> 10^{-3} Ω cm^2), resting potential increased (-30 -> -50 mV), and voltage-dependent conductances increased in amplitude. Small action potentials could be elicited after 7-10 days, and by 18 days in vitro overshooting action potentials were present. The following currents were recorded from these cells after 2-3 days in culture: (1) transient, 4-AP-sensitive outward current; (2) delayed outward current; (3) transient, TTX-sensitive inward current; and (4) GABA-activated current. The latter had a reversal potential around -50 mV (KAc-filled electrode) and was blocked by (+)-bicuculline or picrotoxin.

CCD imaging of cells loaded with the Ca-indicator dye fura-2 demonstrated that granule cells raised their cytoplasmic Ca^{2+} levels when exposed to either high potassium (25 mM) or 10^{-5}M GABA. The GABA response persisted in the presence of 0.3 µM TTX, a concentration sufficient to eliminate the inward current of these cells. The source of the Ca^{2+} elevation is presently under investigation.

That work not sponsored by AT&T Bell Laboratories was funded by a grant from AFOSR under contract F49620-85-C-0009.

155.10 ELECTROPHYSIOLOGICAL PROPERTIES OF NEURONS IN NEOCORTICAL EXPLANT CULTURES. M. Gutnick*, B. Wolfson* and F. Baldino,Jr. (Spon: G. Christoph) Central Research and Development Department, E. I. du Pont de Nemours and Co., Inc., Wilmington, DE 19898.

Previous studies have shown that although many of the membrane properties of neocortical neurons recorded in brain slices are similar to those recorded in vivo, there are some differences. The lack of spontaneous action potential firing in neocortical slice neurons may be an acute effect of axotomy, as in the case of acute undercut cortex recorded in situ. Similarly, the increased incidence of electrotonic coupling in neocortical slices has been attributed to the effects of partial dendrotomy of almost all neurons during the slicing procedure (Gutnick et al., Neuroscience, In Press). In the present study, we have examined the electrophysiological properties of neurons in organotypic explant cultures: an in vitro preparation that does not entail traumatic damage to neurons at the time of recording.

Explants of parietal cortex were prepared from newborn rats 3-5 weeks prior to experimentation and maintained in vitro on cover slips using tissue culture techniques which are standard in this laboratory (Baldino and Geller, J. Physiol. 327: 173-184, 1982). Intracellular recordings were made using micropipettes filled with 4M potassium acetate, and placed visually with the aid of an inverted phase-contrast microscope. For recording, cultures were maintained at 36 ± 0.5 °C in a chamber that was continuously perfused with balanced salt solution.

In general, properties of membrane potential and resistance, current-voltage relationships, synaptic potential generation and evoked spike firing in cultured cells were very similar to those previously reported in slices (Conners et al., J. Neurophysiol. 48: 1302-1320, 1982). However, unlike slice neurons, all neurons in culture spontaneously fired action potentials at rates between 0.5 and 5 Hz. Intracellular injection of lucifer yellow CH revealed stellate and pyramidal shaped neurons with long, branching, spiny dendrites. Following exposure to bicuculline (5-50 µM), cultures displayed paroxysmal burst discharges which occured spontaneously and could be triggered by electrical stimulation. Characteristics of the intracellularly recorded paroxysmal response were essentially the same as those previously reported in neocortical slices (Gutnick et al., J. Neurophysiol. 48: 1321-1335, 1982).

These data demonstrate that the properties of neurons in neocortical explant cultures are organotypic, and that the intrinsic circuitry of the culture is sufficient for generation of spontaneous and evoked epileptic discharges.

155.11 THE INVOLVEMENT OF CHLORIDE CONDUCTANCES IN THE LOW CALCIUM FIELD BURSTS OF RAT HIPPOCAMPAL SLICES MAINTAINED "IN VITRO". N. Agopyan* and M.Avoli.(SPON:P.Gloor). Montreal Neurological Inst. Dept.Neurol.& Neurosurg.,McGill Univ.,Montrêal,PQ, H3A 2B4, Can.

Rhythmic and synchronous bursts are recorded in the CA1 subfield of hippocampal slices maintained "in vitro" and bathed in Ringer containing low [Ca^{++}] (0.2mM), high [Mg^{++}] (4mM) (Jefferys and Haas, Nature 300:448,1982). Synaptic transmission and thus synaptic currents are theoretically blocked in this type of medium suggesting that: (i) neuronal synchronization during the bursts depends upon field effects (Taylor and Dudek, Science 218:810,1982); (ii) occurrence and duration of the bursts result mainly from a balance between inward Na^+ currents and repolarizing mechanisms such as non-synaptic K^+ conductances and an energy dependent pump. However, some role in this type of activity might still be played by residual Cl^- GABAergic phenomena as well as non-synaptic Cl^- currents. In these experiments we studied in slices of the rat hippocampus the effects induced by manipulation of Cl^- conductances on spontaneous (the frequency of occurrence being typical for each individual slice) and alveus-induced low Ca^{++} synchronous bursts. Both bursts were characterized in extracellular recordings in s. pyramidale by a negative long-lasting (3-10s) potential on top of which population spikes were generated. Addition of the disinhibitory drug bicuculline (20uM) into the Ringer increased the frequency of occurrence of spontaneous bursts and evoked a change in the morphology of both spontaneous and induced bursts which now consisted of two phases: a first one with decreased amplitude and increased frequency of the population spikes (first 1-2s) and a second one with increased amplitude of the population spikes. Modifying the low Ca^{++} high Mg^{++} Ringer by partially substituting Cl^- with acetate or proprionate (20mM) decreased the occurrece of spontaneous bursts while increasing the duration and amplitude of the negative slow potential and the number of associated population spikes. Cl^- substitution at higher concentrations (30-100mM) abolished the spontaneous bursts while the duration of the induced burst increased and spreading depression followed. Bicuculline applied to the Cl^- substituted medium (20mM) was capable of increasing the occurrence of the bursts and rendering these biphasic. These data show that Cl^- conductances play a role in modulating the excitability of hippocampal neurons in low Ca^{++}, high Mg^{++} Ringer. Also, bicuculline effects suggest that these currents are in part synaptic, although this drug might display some non-synaptic action as well(Heyer et al, Brain Res 232:41,1982).

155.12 NEURONAL BURSTING IN HUMAN EPILEPTOGENIC NEOCORTEX MAINTAINED "IN VITRO". M.Avoli and A.Olivier*. Montreal Neurological Institute, McGill Univ., Montrêal, PQ, H3A 2B4, Canada.

In presence of convulsants, neurons in "in vivo" and "in vitro" preparations display large amplitude membrane depolarizations associated with high frequency bursts of action potentials (aps). This phenomenon is considered to represent the underlying cellular feature of the focal epileptiform interictal discharge expressed in the EEG as a spike, thus knowledge of its genesis is important for understanding the mechanisms of focal epileptogenesis. In the present experiments I studied some features of the bursting displayed by human neocortical neurons in "in vitro" slices obtained from areas (2nd temporal gyrus) removed for the relief of seizures resistant to pharmacological treatment. These areas were considered epileptogenic since they displayed clear "spiking" when studied with implanted preoperative EEG electrodes and intraoperative ECoG. The techniques used were similar to those described by Schwartzkroin et al (Ann Neurol 13:249,1983) but Ringer containing 3.25mM K^+ was used as control medium. Intracellular recordings (K-acetate microelectrodes) were performed in neurons (5th and 6th layers) which were stimulated with tungsten cathodes placed in the white matter or within the cortex.

Low intensity stimuli evoked EPSPs rarely followed by hyperpolarizing potentials even at depolarized resting membrane potential (Vm). With higher strength stimulation nearly 70% of the neurons responded with large amplitude (up to 40mV) long lasting (half-width: 40-90ms) depolarizing potentials which could be associated with a burst of aps (up to 5) and/or fast prepotentials. By depo- or hyperpolarizing the Vm these giant stimulus-induced responses were decreased or increased as expected for a synaptic phenomenon, but voltage dependent potentials could be disclosed mainly during the late part comprising the repolarizing component. A dramatic increase in this late part could be obtained by increasing $[K^+]_o$ (up to 8.25mM) or applying 4 aminopyridine (10-20uM) in the Ringer. These procedures could lead to the appearance of spontaneous large amplitude depolarization with bursts of aps which responded to changes in Vm as expected for synaptic potentials, namely: (i) their frequency of occurrence was not dependent upon Vm; (ii) they increased or decreased in amplitude when Vm was decreased or increased respectively.

These data demonstrate that spontaneous bursting in human epileptogenic neocortex maintained "in vitro" (i) is modulated by K^+ outward currents and (ii) is synaptic in origin. These conclusions do also apply to the bursts elicited by strong focal extracellular stimuli. Using this paradigm, however, voltage dependent potentials can be observed during the late portion of the stimulus-induced response.

155.13 BURST GENERATION IN LATERAL HABENULAR NEURONS RECORDED IN VITRO K. S. Wilcox*, M. J. Gutnick* and G. R. Christoph* (Spon. J. E. Carnahan) Central Research and Development Department, E. I. du Pont de Nemours and Co. Inc., Wilmington, DE 19898

The lateral habenula nucleus (LHb) of the rat is a dorsal diencephalic structure which receives imput from limbic structures in the forebrain and projects to various midbrain areas. We have studied the electroresponsive properties of LHb neurons recorded intracellularly. Experiments were carried out in 400 µm coronal or saggital slices of the dorsal diencephalon prepared with a vibratome and maintained in vitro at 36°C. Most neurons in LHb exhibited two modes of spike-firing behavior. Depolarizing pulses applied from resting potential evoked normal repetitive firing with spike frequency a linear function of pulse amplitude. However, when depolarizing pulses were delivered from a background of current-induced hyperpolarization, they evoked large, all-or-none waves of depolarization, usually with superimposed bursts of fast spikes. Following a hyperpolarizing pulse these neurons generated an initial, brief (<50msec) burst which was followed by an afterhyperpolarization (50 - 150 msec) and a subsequent, prolonged (>500 msec) plateau depolarization that triggered repetitive spiking. All components of this response were sensitive to amplitude and duration of the hyperpolarizing pulse. Results of experiments with blockers of voltage-dependent Ca and Na currents indicated that the burst behavior released by hyperpolarization depends on Ca electrogenesis. The data suggest that in LHb neurons, as in neurons of some other diencephalic structures (cf. Jahnsen and Llinas, J. Physiol. 349: 205-226, 1984), patterns of spike firing are controlled, in part, by a low threshold, rapidly inactivating Ca conductance.

155.14 PHASIC MAGNOCELLULAR NEUROENDOCRINE CELLS CAN BE 'PACEMAKERS' OR 'FOLLOWERS'. R. David Andrew, Anatomy Dept., Queen's Univ., Kingston, Ont. Canada, K7L 3N6.

A burst of action potentials can arise in two distinct ways: as an intrinsic property of the recorded cell or as an emergent property of synaptic interactions. Intrinsic bursting is common in invertebrate neurons but has only recently been identified in magnocellular neuroendocrine cells (MNC's) of the hypothalamic slice (Andrew and Dudek, Science 221 1050, 1983). During steady depolarizing current injection, repetitive bursting may persist in tetrodotoxin which blocks spontaneous and evoked PSP's (Andrew, in preparation). This strongly supports the concept that endogenous 'pacemaker' neurons exist in mammalian CNS.

Recruitment of MNC's to a phasic burst pattern is associated with increased vasopressin secretion from neurohypophysial terminals. Apart from intrinsic mechanisms, we examined if cells might be driven by periodic synaptic input. Intracellular recordings from 5 of 23 phasic MNC's in supraoptic nucleus revealed a sinusoidal oscillation of the membrane potential, where each depolarizing phase could support a burst. The oscillation had a smooth trajectory and fixed period (range 6 to 18 s), similar to those waveforms generated presynaptically in certain motor and thalamic neurons. The following evidence suggests that this rhythmic oscillation has a synaptic origin independent of intrinsic mechanisms. 1) The oscillatory frequency was voltage-insensitive, i.e. periodicity was unaffected by steady current injection. 2) Oscillation amplitude and frequency was unaffected by spontaneous or evoked action potentials. 3) The oscillation could abate spontaneously, leaving intact the ability to fire an endogenous burst triggered with brief depolarizing current. 4) Perfusion with 10mM Mg^{2+}/.05mM Ca^{2+} immediately blocked both the oscillation and evoked PSP's (although it also simultaneously blocked intrinsic bursting in 10 of 10 phasic cells).

The rhythmic oscillation probably results from periodic synaptic input generated within the slice; its source is not yet identified. Presumably this input could promote and support phasic bursting in MNC's lacking a pacemaker ability, although the latter mechanism is more commonly observed in slices.

155.15 ELECTROPHYSIOLOGICAL CHARACTERISTICS OF PREOPTIC ANTERIOR HYPOTHALAMIC NEURONS IN EXPLANT CULTURES. B. Wolfson*, M.J. Gutnick*, and F. Baldino, Jr., (Spon. L. Liu-Chen) Central Research and Development Department, E. I. duPont de Nemours and Co. Inc., Wilmington, DE. 19898.

The preoptic anterior hypothalamus (POAH) of the rat particpates in a variety of regulatory functions including thermoregulation, endocrine homeostasis and autonomic functons. This region has been shown to possess a rich neurochemical diversity and a complex synaptic organization. We have previously shown that explant cultures are valid models of in situ POAH because they are organotypic with regard to cellular morphology, peptide content and extracellular unit responses to putative neurotransmitters. In this study, we describe some intrinsic electrophysiological properties of POAH neurons maintained in explant culture.

Explants of the POAH were prepared from newborn rats and maintained in vitro with standard tissue culture techniques for 3-5 weeks prior to experimentation. Intracellular recordings were made using micropipettes filled with 4M potassium acetate, and placed visually with the aid of an inverted phase-contrast microscope. For recording, cultures were maintained at 36 ± 0.5 °C in a chamber that was continuously perfused with balanced salt solution containing 2.0 mM Ca^{++} and 1.5 mM Mg^{++}.

In general, cells were characterized by resting potentials between -56 and -80 mV, and high apparent input resistances of between 70 and 200 Megohm. Current-voltage relationships were usually linear negative to resting potential; some neurons showed anomalous inward rectification upon depolarization. Depolarizing current pulses evoked trains of action potentials during which rapid spike broadening and frequency adaptation occurred. Usually these trains of action potentials were followed by hyperpolarizing afterpotentials which could last up to several seconds. Most neurons were spontaneously active and displayed spontaneous postsynaptic potentials.

Intracellular injection of lucifer yellow CH revealed neurons that were 20-25 µm in diameter and possessed 2-4 primary dendrites, most of which were spiny and extended up to 400 µm from the soma. Often, injection of dye into one neuron resulted in the staining of 2-6 cells, raising the possibility of electrotonic coupling.

These data demonstrate that the properties of neurons in POAH explant cultures are similar to those reported for other hypothalamic cells. We conclude that explant cultures are amenable to intracellular investigation of neuronal function in the POAH, and will be useful for gaining insight into the mechanisms of neurotransmitter action.

156.1 A KINEMATIC EXAMINATION OF THE DEFENSE RESPONSE IN CRAYFISH. T.M. Keliy* (SPON:G. Pilar). Department of Physiology and Neurobiology, University of Connecticut, Storrs, CT. 06268.

When a crayfish is confronted with a threatening visual stimulus, it reacts by rearing back and raising its claws (Glantz,1974, Wiersma,1952). The kinematics of this defense response were analyzed using an optical recording system that permitted unimpeded movement in 3 dimensions. LED's were glued to the dorsal thorax and coxa,merus,carpus, propus segments of the cheliped. Infrared light emitted from the 5 LED's was sampled at a rate of 50 Hz. by a position sensing photodiode and positional information was stored for later analysis by an LSI-11 microcomputer.

The presentation of a visual stimulus, a large black target moved rapidly towards the crayfish, resulted in the animal extending its anterior walking legs while raising and extending its chelae to assume a posture that was maintained for a variable length of time. This movement of the chelae was performed by elevating and rotating the merus at the thoracico-coxal and coxal-basal joints, and by extending the carpus at the merus-carpus (MC) joint. Movement was usually initiated at the proximal joints and was accompanied, after a short latency, by extension at the MC joint.

Although there was variation between animals, single animals tended to assume the defense posture by using a characteristic set of joint angles. Standard error of the mean for 95% confidence limits (SEM) in 4 different animals for elevation (SEM= 3^{o}, 2^{o}, 3^{o}, 2^{o}), rotation (SEM= 4^{o}, 4^{o}, 5^{o}, 3^{o}), and MC joint angle (SEM= 2^{o}, 2^{o}, 2^{o}, 1^{o}) indicated that these joint angles varied only within narrow limits. During movements other than the defense response, excursion at these joints was through a much greater range. Coefficients of variance (CV) for the 4 animals showed that during the defense response there was very little error in attaining the MC joint angle (CV= 5%,3%,4%,4%) and somewhat greater error in elevation (CV= 15%,10%,11%,19%) and rotation (CV= 12%,8%,11%,10%). These results suggest that joint angle is the parameter specified by the nervous system during this behavior.

156.2 *COORDINATION BETWEEN THORACIC OSCILLATORS FOR RHYTHMIC LIMB MOVEMENTS IN THE CRAYFISH PACIFASTACUS LENIUSCULUS.* *F. Clarac and K.T. Sillar*. Dept of Neurobiology, CNRS, Univ. of Bordeaux, 33120 - Arcachon, France & Dept of Physiology, Univ. of Bristol, Bristol BS1 5LS (U.K.).*

In intact crayfish during walking, coordination involves more-or-less antiphasic contractions of homologous limb muscles in adjacent leg. During 'waving' behaviour and after amputation of the distal limb, adjacent legs (or stumps) move in phase (Pasztor, V. & Clarac, F. J. exp. Biol., 102, 59-77, 1983). It is not known whether in phase activity results from proprioceptive input from the basal limb joints or from central coordinating pathways. To investigate this problem we have studied interganglionic coordination in semi-isolated and isolated preparations of the thoracic ganglia.

When isolated from the rest of the animal, each hemiganglion can produce patterns of rhythmic motor output which correspond to fictive forward locomotion (Skorupski, P ; Sillar, K.T. & Bush, B.M.H., Neurosci-Abst., 10, 627, 1984). During such rhythmic activity, adjacent hemiganglia display a preferred in phase pattern, while contralateral hemiganglia burst independently. Ipsilateral in phase coordination occurs in all sets of homologous motoneurones (MNs). Thus, remotor muscle MNs of the 4th ganglion (T4) discharge in phase with remotor MNs of the ipsilateral 3rd ganglion (T3) and in antiphase with promotor MNs of both T3 and T4. In non-rhythmic preparations, antidromic stimulation of the remotor muscle nerve can evoke rhythmic activity in the same ganglion and in the anterior (but not posterior) ganglion, suggesting that ipsi-segmental oscillators are coupled by ascending excitation. In rhythmic preparations the same stimulus can strengthen the degree of coupling between oscillators and reset their output.

Rhythmic output of one hemiganglion can be entrained by rhythmic proprioceptive input. Sinusoidal mechanical stimulation of a basal joint proprioceptive complex (comprising a chrodotonal organ and a muscle receptor of the thoracic coxal joint) will entrain oscillatory motor output at frequencies close to those occurring spontaneously. A similar stimulus also entrains the output of the next anterior ipsilateral oscillator.

In summary our results suggest that an ascending central pathway exists for in phase coordination of ipsilateral limb oscillators, and that proximal sensory structures, as well as some MNs, have access to that pathway. Future experiments will investigate the possibility that stimulation of more distal sensory structures monitoring loading of the limb can produce the alternating mode of coordination observed in intact walking crayfish.

156.3 CRAYFISH BACKWARDS-WALKING COMMAND NEURONS INHIBIT ELEMENTS OF THE TAILFLIP CIRCUITRY. Donald H. Edwards and Ted W. Simon, Department of Biology, Georgia State University, Atlanta, GA 30303.

Previous workers have shown that command neurons which mediate two different forms of escape tailflip inhibit each other and the abdominal postural motor system. We have found that command neurons that excite the abdominal postural motor system also inhibit elements of the escape tailflip circuitry.

We have demonstrated that backwards walking can be evoked by a pair of identified sensory afferents, the caudal photoreceptors (CPRs). These cells project into the rostral CNS, where they appear to excite a descending command pathway that can release backwards walking and cyclical abdominal flexion. CPR stimulation that evokes the abdominal flexion motor pattern also excites the Flexor Inhibitor (FI) motoneuron, which inhibits the abdominal fast flexor muscle that produces the tailflip. CPR stimulation that fails to evoke postural flexor activity also fails to excite FI.

Similar FI excitation is produced by direct stimulation of the command fiber pathway, which is a discrete group of fibers on the lateral ventral surface of the nerve cord. Repetitive stimulation of these fibers evokes bursting abdominal flexor activity and also reduces or eliminates the responses to sensory input of mechanosensory interneurons, the lateral giant command neuron, the fast flexor (FF) motoneurons and the extensor inhibitor (EI) motoneuron. The responses of the FF and EI motoneurons to direct lateral giant stimulation are unaffected by stimulation of the command fiber pathway. Our preliminary conclusion is that the inhibition is directed both at elements upstream from the motoneurons and, through excitation of the FIs, at the fast flexor muscle.

We would like to suggest that mutual inhibition among command systems may prove to be widespread. Such a system would serve to raise the threshold for incompatible behavior patterns when one pattern is released.

156.4 INTERNEURONAL COMMAND NETWORK CONTROLS PATTERN INITIATION IN THE CRAYFISH ABDOMEN. D. Moore* and J.L. Larimer. Dept. of Zoology, University of Texas, Austin, TX 78712.

During backwards terrestrial walking, the crayfish Procambarus clarkii exhibits a complex cyclical pattern of activity in its abdomen, characterized by alternating movements of the flexion and extension postural muscles (Kovac, M., J. Comp. Physiol., 95:61-78, 1974). Using extracellular and intracellular approaches, the neural elements "commanding" pattern generation were investigated.

Pattern generation in the cyclic postural system is partially an emergent property of a network of interganglionic pattern initiating interneurons and partially arises from the activation of discrete ganglionic oscillators. The cyclic pattern may be elicited in all of the abdominal ganglia by extracellular stimulation of any of the connectives, through which multiples of pattern initiating neurons project in parallel and in close association with one another. No single fiber traverses the entire length of the abdominal cord. The network is bilaterally symmetrical with strongest signal conduction in the rostral-to-caudal direction and weaker conduction in the caudal-to-rostral direction and laterally across ganglia. For normal patterned motor outputs to occur, each ganglion receives bilateral pattern initiating signals through the connectives; the signals are both descending and ascending. Removal of any of these input signals causes a deficit in the patterned outputs. Isolated ganglia are capable of oscillatory activity but at reduced strength. Unlike central pattern generators in many other systems, the cyclic postural behavior requires continuous stimulation in order to maintain rhythmicity.

Pattern initiating interneurons were characterized in a series of neuropilar impalements in ganglia 4, 5, and 6 of the isolated abdominal nerve cord using Lucifer yellow-filled microelectrodes. Intracellular stimulation of any one of several different morphological types evokes a cyclical pattern indistinguishable from that elicited extracellularly in the connectives. Hyperpolarization of the interneuron during pattern generation fails to affect the cyclical pattern, indicating redundancy of function. Suggestive of electrical coupling among pattern initiating elements, the interneurons typically show a burst of spikes of several different amplitudes that precede pattern generation as well as consistent dye-coupling among morphologically identifiable cells. Additional interneurons exist which, when depolarized, elicit a partial pattern. Hyperpolarization of these cells during pattern generation results in incomplete motor outputs.

Additional experiments demonstrated that pattern generation apparently occurs without the recruitment of typical flexion- and extension-producing interneurons which are the premotor elements controlling tonic postural behaviors.

156.5 **SEGREGATION OF PATHWAYS OF SLOW AND FAST FLEXOR MOTOR NEURONS WITHIN THE ABDOMINAL GANGLIA OF CRAYFISH.** E. M. Leise and B. Mulloney. Dept. of Zool., Univ. of Calif., Davis, CA 95616.

Within the abdomen of a crayfish are two sets of flexor muscles that participate in different motor activities. The fast flexor muscles generate the power-stroke for rapid tailflips. The slow flexor muscles maintain bodily posture; they help regulate the position of the abdomen on a moment-to-moment basis. To determine which ganglionic structures are important to the control of these behaviors, we made a series of cobalt backfills and intracellular HRP fills of the motor neurons to these muscles. We then traced the routes of the filled cells through the various axonal tracts, commissures and neuropilar areas of the abdominal ganglia (Skinner, 1985, J. comp. Neurol., in press).

The fast flexor motor neurons exit the abdominal ganglia through the main branches of the paired third roots. The slow flexor motor neurons exit through the superficial branches of the same nerve roots. The fast flexor motor neurons branch extensively in the dorsal commissures, in the dorsal-most layer of tracts just below the giant fibers, and also around the giant fibers. However, they bypass most of the ganglionic core - especially the large ventral horseshoe neuropil (HN) and lateral neuropils (LNs). In contrast, the slow flexor motorneurons arborize in both the ventral and dorsal commissure layers and in three of the four layers of axonal tracts. They also branch in the arms of the HN and within the LNs, where swimmeret pattern generation is thought to occur.

Several conclusions can be drawn from these data: slow and fast flexor motor neurons are known to receive input from the dorsal cord axons. These synapses probably occur in the neuropil of the dorsal axonal tracts. That the slow flexor neurons branch in more tracts, commissures and neuropils than the fast flexor motor neurons suggests that the slow flexors are components of many behavioral activities and that the fast flexors are active components of relatively few motor programs.

156.6 TACTILE STIMULATION OF THE SEXUALLY DIMORPHIC SWIMMERET AFFECTS THE ABDOMINAL POSTURAL PROGRAM IN THE LOBSTER, HOMARUS AMERICANUS. V.C. Kotak* and C.H. Page. Rutgers University, Bureau of Biological Research, Piscataway, NJ 08854.

The influence of mechanical stimulation of the swimmeret upon the abdominal tonic motor program was examined using a preparation with a second swimmeret remaining attached to an isolated abdominal nerve cord. Tactile stimulation was applied manually or by a probe fixed to a speaker cone. Extracellular recordings were made from the tonic flexor and extensor roots of the first 3 abdominal ganglia. Activity of the tonic flexor motor neurons (f1-f6) was analyzed based upon their relative spike amplitudes and firing patterns.

Strong stimulation--manual stroking of the swimmeret--produced vigorous extension responses in both sexes which included excitation of the peripheral inhibitor (f5), strong inhibition of all the flexor excitors (f1-f4 & f6) and a large increase in extensor activity. Preliminary intracellular recordings from flexor motorneurons confirm that f5 is excited and f3 inhibited following strong stimulation. Moderate stimulation (5g) in males excited f5 without changing flexor excitor activity. In 50% of the females, in addition to f5 excitation, there was significant inhibition of one or more of the small-medium (f2-f4) excitors. In the other females, f5 activity remained unaffected, while the firing frequency of f3 and f4 increased. The response latencies of the flexors to a moderate stimulus ranged from 75-100 msec. The first and third segments had latencies of 150-200 msec.

Although the sexual dimorphism of the first abdominal swimmerets has been described (Page 1985), the remaining four pairs of swimmerets also differ between the sexes. In the second segment, these differences include the presence of an accessory lobe on the endopodite of the male and differences in the structure and distribution of the cuticular sensilla. The accessory lobe is covered with many short "bristly spines". For the females long "smooth hairs" line the margin of both rami as well as forming 8-10 clusters on the coxa and proxial rami. Males completely lack smooth hairs. In both sexes "feathery hairs" line the entire margins of the rami. Stimulation of smooth hairs elicited an increase in f5 firing while the bristly spines in the male excited the flexor excitors. In contrast stimulation of the feathered hairs did not evoke any response in either sex.

156.7 EFFERENT NEURONS OF THE ABDOMINAL PLEOPODS IN THE LOBSTER, HOMARUS AMERICANUS: SEXUAL DIMORPHISM AND SEGMENTAL VARIATION. K. A. Killian*, C. H. Page and D. A. Cipolla* (SPON: R. Notvest). Bureau of Biological Research and Department of Biological Sciences, Rutgers University, Piscataway, NJ 08854

The efferents whose axons project in the first roots of the first through fifth abdominal ganglia were stained to examine segmental variation and sexual dimorphism in the innervation of the pleopod appendages. They were stained by backfilling the first root with an 80:20 mixture of 300 mM $NiCl_2$:$CoCl_2$. The somata are organized into two ipsilateral clusters, a large anterior cluster and a smaller posterior cluster. In addition two somata (one in the first ganglion) are located on the contralateral side of the ganglion. Because of the large number of somata stained in the second through fifth ganglia, the whole mounts were serial sectioned to count the number of dye-filled somata.

It has long been known that the first pair of abdominal appendages is sexually dimorphic in the lobster (Herrick, Bull. U. S. Bur. Fish., 29, 149-408, 1909). In the male the first pleopod forms an elongated stylet while it is a small uniramus appendage in the female. The second through fifth pairs of abdominal appendages form the swimmerets. Each swimmeret comprises a proximal coxal segment to which two leaf-like rami are attached--an endopodite and an exopodite. The second segment swimmerets are sexually dimorphic. In the male the endopodite has an accessory lobe that is absent in the female. In contrast to the more anterior segments, male and female swimmerets in the third through fifth segments have similar morphologies.

There is a correlation between pleopod structure and the number of efferents that innervate it. When compared to the swimmerets, the first segment pleopods are innervated by relatively few efferents. In 24 successful backfills of the first ganglion 27.3 (range = 23-31) somata were stained. In contrast almost four times as many efferents 109 (91-117) were stained in 48 backfills of the second through fifth ganglia.

The sexually dimorphic first and second pairs of pleopods contain about 10% more efferent somata in the female when compared with the male. For the male 25.8 (23-28) first segment and 100.5 (97-108) second segment efferents were stained while in the female 28.8 (26-31) first segment and 109.8 (106-113) second segment efferents were dye-filled. These differences are significant at the .01% level (Student t test). In contrast the numbers of efferents that were stained in male and female third, fourth and fifth ganglia did not differ statistically.

156.8 SIMULATION OF REGULATION OF DYNAMIC MUSCLE STIFFNESS IN A CRUSTACEAN SLOW MUSCLE. W. D. Chapple, Department of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06268.

Experiments on the stretch evoked reflex contraction of the ventral superficial muscles of the abdomen of the hermit crab, Pagurus pollicarus, indicate that dynamic muscle stiffness is constant over a range of stretch velocities (Chapple 1985). Since there is no tonic component to the reflex, and its latency is long (greater than 100 ms), negative feedback cannot be responsible for this control. An alternative explanation is that this graded slow muscle integrates the velocity dependent reflex burst of the motoneurons. The time constant of the muscle was experimentally determined to be about 470 ms; the time constant of the excitatory junction potentials (ejps) was about 40 ms. A model of neuromuscular system and muscle mechanics was simulated on a computer. Ejps with equilibrium potentials of +6mV were generated at varying frequencies. The resulting membrane depolarization was used to produce a contractile force proportional to the depolarization up to a value of -30 mV, beyond which point the contractile force was constant. This contractile force was in parallel with a viscous element and in series with an elastic element. Constant muscle stiffness in this model is found only when the time constant of muscle activation is about ten times that of the ejp time constant. In addition, reflex stiffness is not critically dependent upon the velocity dependence of the reflex burst in the motoneuron. A high sensitivity of the reflex to stretch velocity does not appear to be necessary to insure regulation of dynamic muscle stiffness.

156.9 COXAL AND BASAL LEG MUSCLES OF THE CRAB CARCINUS ARE INNERVATED BY THE COMMON INHIBITOR. Stacia Moffett, Daniel P. Yox and Linda B. Kahan*. Dept. of Zoology, Wash. State Univ., Pullman, Washington, 99164.

In the crab Carcinus maenas, a neuron has been described which innervates the basi-ischial levators and depressor and the coxal remotors and promotor (Yox and Moffett, 1983, Soc. Neurosci. Abs. 9:382; Bevengut et al., 1983, J. Comp. Neurol. 221:185-198). Working with the muscles and nerves of the fifth pereiopods of Carcinus maenas, we have now extended the description of this neuron to show that it is an inhibitor and that it corresponds in its distal branching pattern to the common inhibitor. In extracellular recordings from branches of the leg nerves, this neuron has a small spike and demonstrates a correspondingly high threshold to electrical stimulation. Tension levels in the anterior levator muscle drop dramatically when this unit is active. When the anterior levator nerve is stimulated at 100 Hz in increasing voltage steps, the tension developed by the excitors is abolished when the threshold for this unit is reached. We have not detected IPSP's in the superficial fibers of the posterior head of the anterior levator muscle, and we conclude that the major action of this neuron on the anterior levator is presynaptic inhibition.

Both electrophysiological mapping of the axon branches and mapping with cobalt and nickel dyes indicate that this neuron supplies not only the coxal and basal muscles but also distal leg muscles such as the dactyl opener. This is the only neuron we have found that innervates the muscles proximal to the autotomy fracture plane and also projects to the more distal muscles. The soma of this neuron is located near the midline of the ganglion. Bilateral backfills of the nerves of the coxal or basal muscles revealed that the bilaterally paired somata of these neurons are contralateral to their axonal projections in at least some crabs. We believe that the neuron we have described in Carcinus is the common inhibitor and that it corresponds to the ventral midline neurons described by Young and Govind (1983, Brain Res. 280:251-262) in backfills of cheliped nerve roots in fiddler crabs and also to the dorsal inhibitors of the claw closer muscles that undergo dramatic changes in both position and size during claw reversal in snapping shrimps (Mellon, 1981, Trends in Neurosci. 4:245-248).

156.10 LOCAL SPIKING INTERNEURONES AND THEIR ROLE IN THE CONTROL OF LEG MOVEMENTS OF THE LOCUST

M. Burrows, Department of Zoology, Downing Street, Cambridge, CB2 3EJ, England.

Spiking local interneurones provide the first integrative step in the processing of sensory information from the legs of a locust. Within a population of these interneurones that have cell bodies at the ventral midline of the thoracic ganglia, three classes are recognised. First, interneurones that receive inputs only from external mechanoreceptors. Second, interneurones with inputs only from external mechanoreceptors (proprioceptors), and third, interneurones with inputs from both internal and external mechanoreceptors. The first class receive direct inputs from afferents innervating hairs, and in turn make direct connections with some leg motor neurones. Their neuropilar branches are divided into two fields; one in a ventral region of neuropile to which the afferents project and possessing predominantly input synapses; the other in a dorsal region of neuropile to which the motor neurones project and possessing predominantly output synapses. Each interneurone is excited by a particular array of receptors on the leg that comprise its receptive field, so that the surface of the leg is mapped onto a population of these interneurones. The second and third classes show a spectrum of responses to movements of a single joint, that range from a maintained change in the frequency of their spikes for a particular position of the joint, to phasic changes to a movement of the joint in either direction. The inputs to these interneurones are derived from a variety of receptors at the joints, but for many of those monitoring the femoro-tibial joint, their responses can be mimicked by independent manipulation of the apodeme of a chordotonal organ.

The interneurones mediate local postural and compensatory reflexes of the leg, a role in which the organization of their sensory fields can most usefully be viewed. During voluntary movements of a leg the interneurones may signal the movement made, and contact with external objects or with other segments of the leg. They also respond in ways indicating that they are part of the neural machinery actually initiating the voluntary movement.

156.11 INTERNEURONS IN THE FLIGHT SYSTEM OF THE CRICKET, TELEOGRYLLUS OCEANICUS. R. Meldrum Robertson, Department of Biology, McGill University, Montreal, P.Q., H3A 1B1, Canada.

In the locust some important flight interneurons are located in abdominal neuromeres and are serially repeated in at least 4 of the 6 segmental neuromeres known to contain flight neurons. It has been proposed that these features support the pleural appendage theory for the evolutionary origin of insect wings (Robertson et al., Science 217:177, 1982). Given that insect wings are thought to have evolved only once it might be possible to find homologies in flight interneurons and their organization in related species. One such species is Teleogryllus oceanicus and I have intracellularly stained neurons phasically active during an expression of the flight rhythm of this animal. Adult female T. oceanicus of mixed ages post terminal moult were used. A dorsal approach was made to the thoracic ganglia which were deafferented and stabilized on a stainless steel probe. Thoracic neurons were filled with Lucifer Yellow after recording their activity during flight sequences.

The flight rhythm was initiated by blowing air over the head or the cerci of the animal. When this stimulus released a short duration flight sequence (5-20s) the cycle frequency was around 15 Hz. In some preparations a similar stimulus triggered a flight rhythm which lasted indefinitely (over 5 mins) with a cycle frequency greater than 20 Hz and in the normal range of wingbeat frequency. The basic properties of flight neurons are similar to those of the locust. During short flight sequences motoneurons fire bursts of large amplitude spikes with an intraburst frequency less than 100 impulses/s (during longer sequences at a higher cycle frequency motoneurons tend to fire only once per cycle) whereas interneurons fire bursts of smaller amplitude spikes at an intraburst frequency greater than 200 impulses/s. Activity in flight neurons was driven by excitatory and inhibitory synaptic input which set up membrane potential oscillations 10-20 mV in amplitude. Different interneurons fired bursts either in phase with elevator or with depressor motoneuron activity. Although the structure of some cricket interneurons appeared dissimilar, some other interneurons bore a marked similarity to locust flight interneurons; specifically to pattern generator interneurons that exist as sets of serially repeated homologues. This similarity is, to date, suggestive only and it remains to be discovered how far the similarities between individual interneurons extend in terms of both their physiology and their morphology. On these discoveries depends conclusions concerning which features in the flight systems of the cricket and the locust are a result of their common evolutionary heritage.

156.12 EFFECTS OF NEUROCHEMICAL AND NEUROANATOMICAL MUTANTS ON THE LANDING RESPONSE AND FLIGHT MUSCLE ACTIVITY OF *DROSOPHILA MELANOGASTER*. M Gorczyca and J C Hall. Brandeis University, Waltham, MA 02254

During tethered flight when an object approaches a fly from the front, a behavior termed the landing response is elicited. This consists of a down and outward movement of metathoracic and mesothoracic legs as well as a forward and upward extension of the prothoracic legs. If the approaching object has an upward component as well, the neural activity to the indirect flight muscles increases during and slightly after the approach and then briefly ceases. Normal activity returns shortly thereafter.

In mutant flies which were deficient for choline acetyltransferase (ChAT), the synthetic enzyme of ACh, both the landing and flight muscle responses disappeared. This occurred in Cha^{ts1} and Cha^{ts2}, the two temperature sensitive alleles studied and is correlated with the time dependent decrease in ChAT activity induced by pre-incubation at non-permissive temperature. A dopa decarboxylase temperature sensitive mutant (Ddc^{ts2}) was analyzed as well. It's responses were similar to that of wild-type.

A number of brain morphology mutants were also examined and two of these exhibited abnormal landing and flight muscle responses. The sol^{KS58} (*small optic lobes*) mutant responses were present but intermittent, and not as robust as in wild type. Other characteristics of the landing response have been reported to be aberrant in this variant. Visual stimuli which elicit strong responses in wild-type were ineffective in omb^{H31} (*optomotor blind*). In contrast, a stimulus that produces no response, or only a weak one, consistently gave strong landing responses.

The value of this simple assay system is to test the ever-increasing number of morphological and neurochemical mutants that exist for *Drosophila* and to do so in a way that reveals behavioral as well as physiological function. In this way the extent to which a particular genetic lesion disrupts the nervous system can be more fully determined.

156.13 GIANT VISUAL MOTION-SENSITIVE NEURONS ARE DIRECTLY CONNECTED TO NECK MUSCLE MOTORNEURONS IN FLIES: 1. STRUCTURAL ORGANIZATION. N.J.Strausfeld and J.J.Milde. EMBL, Meyerhofstraße 1, D-6900 Heidelberg, West Germany (FRG).

Flies move their heads in response to static or moving visual stimuli in a way that is reminiscent of optokinetic eye movements by crustacea and mammals (Land,M.S. In: Handbook of Psychobiology. Eds. M.Grazzaniga and C.Blakemore. Academic Press,49,1975). Two recent accounts describe the prominent role of eight giant vertical-motion-sensitive neurons (VS) of flies in connections between the brain and neck muscle motorneurons (Strausfeld,N.J. and Seyan,H.S.; Strausfeld,N.J. and Bassemir,U.K. Cell and Tiss. Res.,240,601 and 616,1985).

Using computer reconstructions of the head and body exoskeleton we have analysed the articulation between the head and prothorax and have determined how identified muscles insert into the rear head capsule, the articulating condyle and the prothoracic box. Reconstructions implicate certain of the 16 pairs of identified muscles in lateral, rotatory and vertical head movement.

By isolating each muscle, still attached to the CNS by its motorneuron axon, we have filled its motorneuron with cobalt ions. Two pairs of muscles, arranged so as to pull the head downwards, are each invested by a motorneuron whose dendrites in the brain are cobalt-coupled to two VS neurons viewing a frontal strip of the visual field. Another three pairs of muscles, arranged to pull the side of the head downwards (head rotation) are invested by three motorneurons that arise in the prothoracic ganglion where they are cobalt-coupled to a unique descending neuron originating in the brain. This cell (DNOVS 1) is, in turn, cobalt-coupled to six VS cells subtending the lateral part of the visual field. Other muscles are supplied by motorneurons whose dendrites interact with primary afferents from the organs of balance (halteres) or the wings. Certain other motorneurons interact with descending neurons that receive inputs from small-field visual neurons and horizontal-motion-sensitive neurons. These motorneurons invest oblique muscles that move the head around its vertical axis (side-to-side movement).

Cobalt coupling occurs between neurons that share gap junctions (Strausfeld,N.J. and Bassemir,U.K., J. Neurocytol.,12:971,1983). We conclude that control of head movement involves two sets of muscles directly connected to wide-field vertical-motion-sensitive neurons. Other muscles are separately invested by motorneurons that acquire their major inputs from halteres, wings and horizontal-motion-sensitive neurons.

156.14 GIANT VISUAL MOTION-SENSITIVE NEURONS ARE DIRECTLY CONNECTED TO NECK MUSCLE MOTORNEURONS IN FLIES: 2. PHYSIOLOGICAL ORGANIZATION. J.J.Milde and N.J.Strausfeld. EMBL, Meyerhofstraße 1, D-6900 Heidelberg, West Germany (FRG).

Visually induced optomotor responses of flies are supposed to be mediated by giant vertical- and horizontal-motion-sensitive neurons that originate in the lobula plate (Poggio, T. and Reichardt,W., Quart.Rev.Biophys.,9:377,1976). However, connexions between giant lobula plate cells and muscles involved in optomotor behaviour have not yet been established. We have recorded from motion-sensitive motorneurons in each of the four pairs of nerves that innervate head muscles. Each unit was most excited by a movement in a particular direction. Movement in the opposite direction elicited an inhibitory response or no response at all.

Response characteristics and directional selectivity of the motorneurons corresponded almost exactly with the well-documented properties of intracellularly recorded lobula plate giant neurons (Hausen,K., Biol.Cybern.,46:67,1982, Hengstenberg,R., J.Comp. Physiol.,149:179,1982, Eckert,H., J.Comp.Physiol., 149:195,1982). Moreover, presentation of stimuli to different parts of the visual field in combination with eye occlusions demonstrated the correspondence between the receptive fields of motorneurons and specific lobula plate giant neurons (VS and HS cells). For example, motorneurons supplying the cervical nerve (CN) responded maximally to downward movement of horizontal gratings in the frontal visual field as do the frontal-looking vertical cells (VS 2 and 3). Anatomical investigations reveal a direct connexion between VS 2,3 and the CN motorneurons (see N.J.Strausfeld and J.J.Milde, this issue). Stimulation by downward movement of horizontal gratings to the lateral visual field evoked best responses from motorneurons in the frontal nerve (FN). This result is in accordance with the response characteristic of VS 4-9 cells whose dendritic domains subtend the lateral retina. The connexion between VS 4-9 cells and the FN motorneurons has been confirmed anatomically (see N.J.Strausfeld and J.J.Milde). In the anterior dorsal nerve (ADN) and ventral cervical nerve (VCN) all recorded units preferred horizontal front-to-back movement in the ipsilateral visual field. None of these motorneurons are connected to VS cells. Rather, the response properties of ADN and VCN motorneurons suggest that they receive inputs from horizontal-motion-sensitive giant neurons. Our results are the first demonstration of direct connexions between so-called optomotor neurons and identified motor outputs. We suggest that giant visual neurons of the lobula plate directly control head attitude or head movement, or both.

156.15 MOTOR CORRELATES OF ASSOCIATIVE PHOTOTAXIC SUPPRESSION IN HERMISSENDA. W.G.Richards and J.Farley.Program in Neuroscience, Princeton University, Princeton, NJ 08544.

Light-rotation pairings result in increased latency and decreased velocity of light-evoked locomotor behavior in Hermissenda. Except for a single identified motoneuron (MN1, Goh & Alkon, J.Neurophys., 1984), little is known concerning the neural control of locomotion in this animal. We have examined motor correlates of phototaxic behavior and their modification by associative training using anatomical, lesion, and extracellular recording techniques. Bilateral lesions of either P1 or P2 (but not P3 & CP2) pedal nerves in untrained animals, which anatomical studies indicate innervate the pedal musculature, substantially reduced phototaxic behavior. Lesioned animals exhibited significantly longer light-evoked start and finish latencies and decreased locomotor velocities when compared to sham controls.

Extracellular suction electrode recordings from naive animals revealed net increases in total mulit-unit activity (MUA) of 10% during a 5-min light presentation for nerves P1, P2, P3, and CP2. A prominent component of nerve P2 activity patterns was synchronous, high frequency bursting in groups of cells evidenced as spindle-like peaks in PST histograms. Simultaneous recordings from pairs of nerves indicated that units within ipsilateral nerves P1 and P3 burst in phase with P2 spindle units, while spindle bursts in contralateral P2 nerves are typically out of phase. Spindle bursts (0.5-1/min frequency) were typically 3-15sec in duration in the dark adapted preparation. A 5-min presentation of light resulted in increases in frequency (42%) and duration (23%) of spindle bursts. Further increases in spindle frequency were noted during the initial 2-min period following light offset (+130% baseline rate; duration = +10%).

P2 nerve recordings were also obtained from behaviorally trained animals. Fifty paired or random light-rotation trials were administered on each of three days, and nerve recordings were made at 24 or 48 hour retention intervals, following behavioral tests. For random preparations (n=22), light resulted in increases in spindle burst frequency (+50%) and duration (+5%) comparable to those of untrained animals. Light offset responses were also similar (+55% freq.; +23% duration). By contrast, preparations from paired animals (n=22) exhibited light-induced reductions in spindle frequency (-8%) and duration (-6%). Spindle frequency increases following light offset were similar to those noted for random preparations (+54%), but the duration changes were absent (-3%). Thus, associative training resulted in a selective decrease in light-evoked spindle burst frequency and duration. These results suggest that associative training results in decreased visual excitation of pedal musculature.

156.16 WHOLE-BODY WITHDRAWAL OF THE POND SNAIL LYMNAEA STAGNALIS. G.P. Ferguson and P.R. Benjamin*. School of Biology, University of Sussex, England.

The whole-body withdrawal response of Lymnaea is induced by photic (light-off) and tactile sensory stimuli, and consists of the retraction of the head-foot of the animal into its shell.

This behavior is mediated by two muscle systems, the columellar muscle (CM) and the dorsal longitudinal muscle (DLM). The CM is innervated by the columellar nerves and contracts to longitudinally shorten the ventral head-foot and pull the shell down over the animal's body. The DLM is innervated by the superior and inferior cervical nerves, the left parietal nerve and the external right parietal nerve. Contraction of the DLM longitudinally shortens the dorsal head-foot and is synchronous with CM contraction.

The CM and DLM are both innervated by an electrotonically coupled network of withdrawal response motoneurons. The somata of these cells are located in all nine ganglia of the CNS, but are especially concentrated in the A clusters of the cerebral ganglia. The CM is innervated by cells in the cerebral and pedal ganglia and the DLM by cells in the cerebral, pedal, pleural and left parietal ganglia. Intracellular iontophoresis of Lucifer Yellow confirmed that the withdrawal response motoneurons project into the nerves innervating the CM and DLM. Individual motoneurons have large, but discrete, motor fields which often overlap with those of other motoneurons. Simultaneous intracellular recording from withdrawal response motoneurons and individual muscle fibers showed that motoneuron action potentials evoke one-for-one, non-facilitating excitatory junction potentials within muscle fibers. No all-or-nothing action potentials were recorded from the CM or DLM, neither was there any evidence of inhibitory innervation.

The withdrawal response motoneurons are high threshold cells which show little spontaneous activity. Most cells on one side of the CNS are electrotonically coupled strongly to each other, but only weakly coupled to cells on the contralateral side of the CNS.

Photic (light-off) and tactile stimulation of the body wall of reduced preparations evokes excitatory postsynaptic potentials (EPSPs) within withdrawal response motoneurons. These EPSPs usually depolarize the cells to above threshold value for action potential initiation, so causing contraction of the CM and DLM. Together, the synchronous reception of sensory input and the electrotonic coupling between the withdrawal response motoneurons are responsible for producing and coordinating the behavioral response.

156.17 ROLE OF THE PEDAL COMMISSURE IN THE COORDINATION OF NORMAL AND SEROTONIN-STIMULATED LOCOMOTION IN THE SNAIL MELAMPUS. Keith Snyder and Stacia Moffett, Department of Zoology, Washington State University, Pullman, WA 99164-4220

Locomotion in the pulmonate snail Melampus bidentatus has been characterized in intact and CNS-lesioned animals (Moffett, Biol. Bull. 157:306, 1979; Moffett and Snyder, Amer. Zool. 231:894, 1983). The latter study, a behavioral evaluation of snails recovering from operations, suggested that the bilaterally symmetrical coordination of the step cycle of pedal locomotion is mediated via either an intact cerebral commissure or an intact pedal commissure. However, recent evaluation of the effects of acute lesions in tethered, semi-intact snails using extracellular recording techniques contrasts with the behavioral observations. We found that transmission in the cerebral commissure does not suffice to coordinate movements on the right and left sides of the body after the pedal commissure has been cut. Transection of the pedal commissure uncouples the right and left pedal oscillators and typically changes the cycle rate of both.

Serotonin added to the bathing medium stimulates locomotion in Melampus as it does in Aplysia (Mackey and Carew, J. Neurosci. 3:1469, 1983). At concentrations below 5×10^{-6} M only sporatic pedal movements result. At 10^{-5} M, pedal waves that correspond to normal locomotion are reliably generated. Increases in serotonin concentration up to 10^{-3} M cause more exaggerated movements and the disappearance of some aspects of the normal behavior. The maximum rate for tethered locomotion is observed at 10^{-3} M serotonin and approaches the fastest locomotion seen in freely locomoting snails (18 step cycles per minute). Combining serotonin-stimulated locomotion with central lesions, we found that cutting the cerebro-pleural and cerebro-pedal connectives has no significant effect on pedal wave rate, although the rate almost doubles on the two sides when the pedal commissure is cut.

We conclude that locomotion is generated by right and left oscillators which control the corresponding sides of the foot. These are synchronized via connections in the pedal commissure. The rhythm of pedal movements generated by the individual oscillators is faster than the rhythm of the coupled oscillators.

156.18 RHYTHMIC MEMBRANE POTENTIAL OSCILLATIONS IN MOTORNEURONS OF ASCARIS: J.D. Angstadt* and A.O.W. Stretton (SPON: P. Smith). Neurosciences Training Program and Department of Zoology, University of Wisconsin, Madison WI 53706.

Our laboratory is investigating the neural basis of locomotion in the large parasitic nematode Ascaris. Intracellular recordings have revealed rhythmic oscillations in the membrane potential of Ascaris motorneurons. The presence of rhythmic activity is a common feature of many neurons involved in locomotor systems. We believe the observed oscillations may have an important role in the control of locomotion in Ascaris and have therefore begun to examine them in greater detail.

Rhythmic activity occurs most frequently in inhibitory motorneurons (type VI and DI) and consists of a slow depolarization followed by a faster depolarization-repolarization sequence. The activity has a peak-to-peak amplitude of 10-20 millivolts and a duration of several hundred milliseconds. The period of the rhythm ranges from 0.2 to 2 seconds. The phase of the rhythmic activity can be reset with intracellular or synaptic current, which suggests that the motorneurons are intimately involved in the generation of the oscillations and not simply following a rhythm imposed on them from another source. Phase response curves have been constructed for a variety of pulse durations and amplitudes and have been shown to predict the limits of entrainment of the rhythmic activity. The oscillations are blocked by removal of $CaCl_2$, Co^{++} substitution for Ca^{++}, or the addition of $CdCl_2$ to the saline solution. The loss of oscillatory activity in such salines can occur before the loss of neuromuscular transmission.

We believe these rhythmic oscillations are important for several reasons: (1) oscillations can be induced in quiescent inhibitory motorneurons by prolonged depolarization of presynaptic excitatory motorneurons; (2) synaptic input from excitatory motorneurons can produce changes in the frequency and amplitude of spontaneous oscillations; (3) oscillations in VI and DI motorneurons which innervate muscle on opposite sides of the worm (i.e. ventral vs. dorsal) maintain an antiphasic relationship. The above features are consistent with a model in which tonic drive to excitatory motorneurons results in the generation of oscillatory activity in inhibitory motorneurons. The activity in the inhibitors, and therefore in the dorsal and ventral muscle fields, is maintained in antiphase by the synaptic connections between the motorneurons.

PRESYNAPTIC MECHANISMS II

157.1 MEPP AMPLITUDE DISTRIBUTION IN FUNCTION OF THE RELEASE SITE POSITION ALONG THE FROG NEUROMUSCULAR JUNCTION. R. Robitaille*, G. Grenon* and J.P. Tremblay. Laboratory of Neurobiology, Laval University, Québec, Can G1J 5B3.

A new method, called the spatial decay method was used to evaluate 1) the position (X) along the frog neuromuscular junction (nmj) of the release site producing a MEPP and 2) this MEPP amplitude (Ar) before any spatial decay. The experiments were performed on the frog cutaneous pectoris muscle. The method requires simultaneous intracellular recording at both distal ends of a nmj. The electrodes were positioned using Nomarski optics. The assumptions that the MEPP amplitude is maximum in front of its release site and decays exponentially toward the recording electrodes placed distally permit the calculation of the position (X) of the release site producing each MEPP recorded intracellularly. The position (X) (i.e. the distance between electrode 1 and the release site of a given MEPP) is evaluated from the ratio of the MEPP amplitudes (A_1 and A_2) recorded respectively by electrodes 1 and 2, the distance (D) between these recording electrodes and the space constant λ of the muscle fibre.

$$X = (D - \lambda \ln (A_1/A_2))/2$$

By evaluating the release position of thousands of MEPPs recorded at a given nmj, we have already reported that the spontaneous release activity is not occurring uniformly along the frog nmj (Tremblay et al., Neur. Lett. 51, 247, 1984).

The spatial decay method also permits to evaluate the amplitude (Ar) of a MEPP before any spatial decay, i.e. the amplitude in front of its release site.

$$Ar = A_1/(e^{-X/\lambda})$$

The MEPP amplitude corrected for spatial decay are not normally distributed (Tremblay et al., Brain Res. 328, 170, 1985). We have now studied the relationship between the position of the release site (X) and the corrected amplitude (Ar). Our results indicate that the few MEPPs produced at the distal ends of the nmj are small MEPPs. Large size MEPPs are present only in the central region of the nmj. This central region does however also contain small and medium size MEPPs. Variations of MEPP amplitude may be due to either fluctuation in the amount of neurotransmitter liberated or to variation in the receptor density on the postsynaptic membrane in front of the release site. Our results do not permit to select one of these mechanisms. It is however interesting to point out that the distal region of the nmj which has a low probability of releasing neurotransmitter to produce a MEPP has also a low probability of producing large MEPP, whereas the central region which has a high probability of producing a MEPP has also a high probability of producing a large MEPP. Are these two phenomena interrelated?

157.2 QUANTAL RELEASE PARAMETERS COMPARED AT THE CRAYFISH NEUROMUSCULAR JUNCTION USING A NOVEL AND CONVENTIONAL METHOD. C.L. Keenan, G. Barrionuevo, D. Baxter, T.H. Brown. Div. of Neurosciences, Beckman Res. Inst. of the City of Hope, Duarte, CA 91010.

The quantum hypothesis and the analytical techniques derived therefrom have proven historically to be valuable in understanding mechanisms responsible for changes in synaptic efficacy. We have been developing (see Barrionuevo, et al., Soc. Neurosci. Abstr., 11: in press) a novel method of quantal analysis, based on a cepstral-like algorithm, that does not depend on the questionable assumption (Brown, et al., PNAS, 73:2913, 1976) that the actual quantal release process is well-approximated by a simple Poisson or binomial probability function.

Here we test this method on experimental data obtained from the crayfish opener-excitor neuromuscular synapse, using intracellular recording procedures (Baxter, et al., PNAS: in press). The mean quantal content m and the mean quantal size q were determined using both the novel method (based on the quantrum) and the conventional direct method (based on the amplitudes of spontaneous miniature excitatory postsynaptic potentials). Each method was applied without knowledge of the outcome of the other method; then the results were compared.

The values of m and q determined by the novel (quantral) and conventional (direct) methods were in excellent agreement. In the 10 synapses studied, the coefficient of determination (r^2) exceeded 0.9, and the slope of the regression was close to unity (see scattergram below). Based on these and other (Barrionuevo, et al., Soc. Neurosci. Abstr., 11: in press) results, we conclude that the quantral method offers new opportunities to understand changes in synaptic microphysiology.

157.3 SPONTANEOUS TRANSMITTER RELEASE FROM CHOLINERGIC RETINAL NEURONS IN CULTURE. N Stockbridge* & D.G. Puro (SPON: C.B. Smith), Laboratory of Vision Research, National Eye Institute, Bethesda, MD 20205.

Neurons dissociated from embryonic day 9 chickens were cocultured at a density of $10^6/cm^2$ on skeletal muscle from postnatal day 1 rat. Under these conditions cholinergic synapses form between retinal neurons and muscle cells within minutes and persist for several days (PNAS 74:4977, 1977). Such synapses reveal themselves in spontaneous postsynaptic potentials in electrical recordings from muscle fibers. In what sense are such synapses normal?

We have begun to investigate the electrophysiological properties of these synapses. To minimize cable effects on the amplitude and time course of these events, short fibers were selected for these studies and recordings were made from preparations cocultured for two to four hours to minimize the growth of processes.

Under these conditions, 10 - 50% of muscle cells are innervated and have events at rates from 1 to 10 per minute. These events are depolarizations ranging in amplitude from as small as can be detected above the noise (typically about 0.2 mV) to about 20 mV in the same muscle.

These events are distributed as would be expected for a random process; we find no evidence for temporal clustering.

The histogram of event amplitudes is not multimodal and shows no evidence that large events are multiples of small events. Small events are much more common than large events. If large events were composed of small events, it might be expected that large events would have slower rise times and slower decays due to asynchrony in release. We found no correlation between event amplitude and either of these parameters.

In order to diminish the probability that the events we observe are due to presynaptic electrical activity, we examined the effect of TTX on the event rate. We have also examined the effect of a calcium channel blocker alone and in concert with TTX. Neither 10 μM TTX nor 5 mM cadmium had any effect on the event rate or amplitude distribution.

We believe that transmitter release from recently formed synapses must be confined to one or a few closely spaced release sites and that the variation in amplitude of postsynaptic potentials results from variations in the amount of transmitter in individual 'quanta'.

157.4 DEVELOPMENT OF A MODEL SYSTEM TO STUDY ACETYLCHOLINE SECRETION. Joy A. Umbach and Cameron B. Gundersen. Dept. of Pharmacol. and Jerry Lewis Ctr., UCLA Sch. Med., Los Angeles, CA 90024.

The evoked release of acetylcholine (ACh) at vertebrate motor nerve terminals is dependent on calcium entry, but the events triggered by calcium are poorly understood. To approach this problem, we are examining whether components of the secretory machinery can be reconstituted in Xenopus oocytes. It has been established (Gundersen, et al. PNAS 82 608) that messenger RNA from the electric lobe of Torpedo induces these oocytes to produce functional choline acetyltransferase. This results in the synthesis of ACh in the mRNA-primed oocytes. We were curious whether these oocytes had also acquired a mechanism by which this ACh could be released in response to appropriate stimuli. Preliminary studies showed that the "leakage" of ACh (measured using a gas chromatographic-mass spectrometric assay), from oocytes containing 200-600pmole of ACh, was less than 0.5pmol-hr^{-1} (at 21°C in frog Ringer containing 0.1mM eserine or BW284-C51 as an anticholinesterase). By contrast, ACh efflux from frog sartorius muscle (with 40-60pmole of ACh) is about 2pmole-hr^{-1}. Thus, the background output of Ach from the mRNA-injected oocytes is relatively low. Several protocols (which evoke ACh release from motor nerve endings) were tested for their efficacy in inducing ACh release from these oocytes. Individual cells were bathed in Ringer solutions (with eserine, 0.1mM) containing either: high K^+, the calcium ionophore A-23187 (10μM), veratridine (25μM), ouabain (0.1mM), lanthanum (0.2mM) or a solution made hyper-osmotic by the addition of sucrose (to 50mM). None of these procedures enhanced the output of ACh from the oocytes. However, in parallel experiments we established that these treatments produced at least a temporary rise of ionized calcium in the cytoplasm of the oocyte (calcium-ion activity was monitored with a calcium ion-sensitive microelectrode). These data argue against the presence in these mRNA-injected oocytes of a calcium-activated process for the secretion of ACh. Paradoxically, when ACh-containing oocytes were bathed in a nominally calcium-free Ringer (no added calcium) ACh was released at a rate between 0.2 and 1.0pmole-min^{-1} per oocyte. This output of ACh in calcium-free Ringer was prevented by the addition of other divalent cations (Mg^{2+}, Ba^{2+}, Sr^{2+}) to the calcium-free Ringer; a result which suggests that the calcium-independent enhancement of ACh efflux is due to the removal of divalent cations which otherwise maintain a low permeability of the plasma membrane to ACh. In conclusion, our results indicate that mRNA from the electric lobe of Torpedo can give Xenopus oocytes the capacity to synthesize ACh, but it does not confer on them the ability to release this ACh in a fashion that mimics the release process at nerve endings in muscle or electric organ.

157.5 RELATIONSHIP BETWEEN EVOKED QUANTAL ACETYLCHOLINE RELEASE AND PRESYNAPTIC INTRAMEMBRANE PARTICLES. D. Muller*, M. Garcia-Segura*+ and Y. Dunant* (SPON : J.J. Dreifuss). Dept. of Pharmacology, CMU, 1211 Geneva 4, Switzerland, and +Inst. Cajal, 28006 Madrid, Spain.

A macro patch clamp technique (Dudel, J., Pflüger's Arch, 391:35, 1981) was used to analyse the evoked release of acetylcholine (ACh) at the Torpedo nerve-electroplaque junction. As at neuromuscular junctions, ACh release could be evoked in a quantal way with the amplitude of the first quantum corresponding to the amplitude of spontaneous miniature electroplaque currents. The amplitude distribution of evoked responses also closely followed a Poisson's law. A maximum rate of release has been estimated by electrodes of different sizes and was found to be of about 1.5 quanta/μm^2 of presynaptic innervating membrane.

When analysed by quick freezing techniques in similar physiological conditions (Dunant et al., C.R. Acad. Sc. Paris, 13:547, 1984), evoked ACh release could be correlated in its time course by a transient increase in the density of presynaptic intramembrane particles, but not with modifications in the number of endo-exocytotic images. The change in particle density could not be observed if calcium was omitted in the bathing solution, suggesting that it was not produced by the depolarization of the nerve endings. However, the maximum number of particles appearing simultaneously with the maximum rate of ACh release corresponded to approximately 400 particles/μm^2 of presynaptic innervating membrane. This does not allow a simple correlation between one such particle and a quantum of ACh or a molecule of ACh.

157.6 EFFECT OF CALCIUM ON SPONTANEOUS QUANTAL RELEASE IN FROG NEUROMUSCULAR JUNCTION. D. Kneifel* and M.I. Glavinovic (SPON: P. Braun), Departments of Research in Anaesthesia and Physiology, McGill University, Montreal, Quebec, Canada H3G 1Y6.

High concentrations of extracellular potassium are known to result in much increased frequency of miniature end-plate currents (MEPC-s). Morphological evidence shows that at high [K+]o (20 mM) quantal secretion occurs randomly, not only at but also in between the active zones (Ceccarelli, Grohovaz & Hurlbut, 1979, J. Cell Biol. 81, 163-177). Such changes in the spatial distribution of quantal release lead also to greater variability of MEPC amplitudes and faster clearance of ACh molecules in the synaptic cleft (Glavinovic, 1985, J. Physiol. 358, 85P). A high concentration of extracellular calcium counteracts the increase in frequency of MEPC's induced by high [K+]o but its mechanism is poorly understood. This study is an attempt to see how elevated [Ca2+]o affects other physiological changes induced by high [K+]o.

Experiments were done on the frog (Rana Pipiens) cutaneous pectoris preparation at room temperature (19-21°C) in physiological Ringer as well as in solution with elevated [K+]o (8 or 16 mM). Cholinesterase was either active or was inhibited by edrophonium chloride (20 μM; Roche).

The variability of MEPC amplitudes is decreased with high [Ca2+]o. The effect appears greater if extracellular K is high. Time constants of decay of MEPC-s are shortened with high [Ca2+]o if cholinesterase was active, indicating the action of [Ca2+]o on activated ionic channels, much in agreement with previous studies (Magleby & Weinstock, 1980, J. Physiol. 299, 203-218). MEPC-s are however usually marginally prolonged with high [Ca2+] if experiments are done in the presence of cholinesterase inhibitor showing that the clearance of ACh molecules in the synaptic cleft is slowed. High [Ca2+]o hence appears to counteract all major changes in spontaneous quantal secretion induced by high [K+]o (elevated frequency of miniature discharge, greater variability of MEPC amplitudes and faster ACh clearance).

Changes in spontaneous quantal discharge induced by high [Ca2+]o can be explained, assuming that at any potassium concentration [Ca2+]o enhances the miniature discharge at the active zones but depresses it in between. Alternatively it may be that [Ca2+] affects the frequency of MEPC-s, variability of their amplitudes and ACh clearance through different mechanisms.

Supported by MRC and MDA (Canada).

157.7 SYNAPTIC DEPRESSION IN FROG NEUROMUSCULAR JUNCTION. M.I. Glavinovic, Departments of Research in Anaesthesia and Physiology, McGill University, 3655 Drummond St, Montreal, Quebec, Canada H3G 1Y6.

According to currently held view, synaptic depression, observed during high frequency stimulation at high levels of quantal release, occurs because the number of quanta released is progressively diminished. However, evidence has been recently presented to suggested that newly formed acetylcholine (ACh) preferentially replenishes the store of quanta released by nerve stimulation, probably the immediately available store. In the absence of newly produced ACh, when ACh synthesis is impaired, nerve stimulation leads to release of partially filled quanta, although spontaneously released quanta appear almost normal (Glavinovic, 1985, J. Physiol. 361: 17P, 1985). This raises the possibility that even when ACh synthesis is not impaired the synaptic depression may be to a significant extent caused by a decrease in quantal size of nerve evoked quanta rather than by a lower quantal content.

Experiments were done on the frog (Rana Pipiens) 'cut' cutaneous pectoris preparation at room temperature (19-21^{o}C) using voltage clamp technique. Cholinesterase was inhibited by edrophonium chloride (20-25 μM; Roche).

As a result of prolonged high frequency stimulation (20 min; 5 Hz) end-plate current (EPC) amplitudes are diminished significantly (±SD) (42 ± 4%). The effect is predominantly presynaptic although a small decrease (8 ± 3%) of miniature end-plate current (MEPC) amplitudes is also observed. Shortening of EPC-s, which is also observed, is greater (31 ± 3%) than the shortening of MEPC-s (9 ± 2%) and results not from diminished spatial overlap of quantal events (that occurs because quantal content may be decreased) nor from lower 'lingering ACh' in the synaptic cleft, but from diminished quantal size of nerve evoked quanta. The contribution of such diminished quantal size to synaptic depression was estimated from the amplitude dependence of the time constants of decay of MEPC-s (Glavinovic, 1984, J. Physiol. 354, 43P) and known shortening of EPC-s that is of presynaptic origin and was found to be surprisingly high (67 + 13%). It appears that the synaptic depression occurs to a large extent because of decrease of quantal size of nerve evoked quanta.

Supported by MDA and MRC (Canada).

157.8 CHANGE IN PERITERMINAL IONIC ENVIRONMENT PRODUCED BY POLARIZING CURRENTS AND ITS EFFECT ON THE VOLTAGE DEPENDENCE OF AMPLITUDES AND TIME CONSTANTS OF DECAY OF END PLATE CURRENTS. R. Nissen* and M.I. Glavinovic (SPON: N. Lake), Depts. Anaesthesia Research & Physiology, McGill University, Montreal, Quebec, Canada H3G 1Y6.

Polarizing currents applied to change postsynaptic membrane potential are known to change periterminal ionic environment, change in potassium [K+] concentration being easiest to detect (Takeuchi & Takeuchi, 1961, J. Physiol. 155, 46). In this study such periterminal K+ concentration changes are estimated at different [K+]o and their effect on the voltage dependence of the amplitudes and the time constants of decay of end plate currents (EPC-s) examined.

Experiments were done on the frog (Rana pipiens) 'cut' cutaneous pectoris preparation. Membrane potentials were changed in a steplike manner from -50 mV to various levels but extreme being +50 or -150 mV. As a result of such membrane potential change the frequency of miniature end-plate currents (MEPC-s) changes slowly in solutions with high K+ concentrations. Periterminal K+ changes can be estimated from the change in frequency of miniature discharge. Absolute changes in periterminal K+ concentration are significant (~1 mM/25 mM) and are moreover only weakly dependent of [K+]o. This shows that the relative changes in periterminal K+ concentration are greater the lower [K+]o, and suggests that it may be increasingly less meaningful to examine the dependence of reversal potential on [K+]o if cleft K+ changes induced by polarizing currents are not taken into account.

Effect of such cleft K+ changes on the EPC vs Vm curve was also examined. As a result of a step like-change in membrane potential EPC amplitudes change rapidly. EPC vs Vm curve determined briefly after a membrane potential jump (20 - 500 msec) is only marginally different from that determined 1 min after such jump, even when extracellular K+ concentrations were elevated (~ 10 mM). The voltage dependence of the time constants of decay of EPC-s is found similarly independent of presumed periterminal K+ changes. These paradoxical findings can be explained by the fact that altering extracellular [K+] concentrations does not lead to any significant postsynaptic changes. Effect on nerve evoked quantal release is also small. Large increase in [K+]o (from 0.25 to 8 mM) leads to an increase in EPC amplitudes of only 25%.

Supported by MRC and MDA Canada.

ACTION POTENTIALS AND ION CHANNELS III

158.1 POLYCLONAL ANTIBODIES WITH SPECIFICITY FOR VOLTAGE-SENSITIVE CALCIUM CHANNEL PROTEINS. Hemin Chin, Karl Krueger*, Troy Beeler*†, and Marshall Nirenberg. NHLBI, NIH, Bethesda, MD and †Uniformed Services University of Health Sciences, Bethesda, MD

Rat skeletal muscle transverse tubule (T-tubule) membrane preparations were obtained that contained 50 pmoles of 1,4-dihydropyridine calcium channel antagonist binding sites per mg protein (H. Chin and T. Beeler, Biophys. J. 47, 265, 1985). T-tubule membranes were solubilized with 1% CHAPS, incubated with [^{3}H]PN-200-110, a potent dihydropyridine antagonist, and specific [Glycoprotein•[^{3}H]PN-200-110] complexes were purified 20-fold by wheat germ agglutinin (WGA) agarose column chromatography. The glycoprotein complexes were denatured, reduced with DTT, and fractionated further by SDS-polyacrylamide gel electrophoresis (5-15% gradient). Strips of gel were excised that contained the α, β, or γ protein subunits of the Ca^{2+} channel (Mr = 135,000, 50,000, and 32,000, respectively (B. Curtis and W. Catterall, Biochem. 23, 2113, 1984). Rabbits were injected with particles of polyacrylamide gel containing α, β or γ subunits of the Ca^{2+} channel and were boosted later with injections of Ca^{2+} channel subunit proteins that were electrophoretically eluted from portions of the gel. Antisera were obtained from 4 rabbits, HK-2, HK-9, HK-10, and HK-16. Analysis of transblots of protein from rat T-tubule membranes fractionated by SDS-PAGE showed that HK-2 antibodies recognize both the reduced and nonreduced forms of the 32,000 M_r γ-subunit, HK-9 and HK-10 recognize both the reduced and nonreduced 50,000 M_r β -subunit; whereas, HK-16 antibodies bind only to the reduced form of the 135,000 M_r α-subunit.

Antibody specificity for Ca^{2+} channel proteins solublized from human brain crude P2 membrane preparations was examined. HK-2 antibodies recognized on transblots a 34,000 M_r band of protein, and HK-9 and HK-10 recognized a 50,000 Mr band; however, HK-16 antibodies did not recognize α-Ca^{2+} channel subunits of human brain.

IgG purified from the antisera by protein A-Sepharose column chromatography was coupled to CNBr-activated Sepharose. Fractionation of solubilized T-tubule membrane proteins on affinity columns containing the HK-9 or HK-10 IgG yielded a single protein with an M_r of 50,000, the expected value for the β-Ca^{2+} channel subunit from solubilized T-tubule membrane protein preparations. These results show that the antibodies can be used for the identification and purification of voltage-sensitive Ca^{2+} channel proteins from skeletal muscle and brain. The antibodies also should be useful as probes for detecting the expression in E. coli of cloned recombinant cDNA for Ca^{2+} channel proteins.

158.2 [^{3}H]METHOXYVERAPAMIL ([^{3}H]D-600) AND [^{3}H]DESMETHOXY-VERAPAMIL ([^{3}H]D-888) LABEL MULTIPLE RECEPTORS IN BRAIN AND SKELETAL MUSCLE. Ian J. Reynolds, Adele M. Snowman* and Solomon H. Snyder. The Johns Hopkins University School of Medicine, Department of Neuroscience, Baltimore, MD 21205.

Numerous studies have demonstrated the presence of two or three separate receptors for calcium antagonist drugs associated with the voltage sensitive calcium channel (VSCC). The use of radiolabeled dihydropyridines such as nitrendipine indicate the presence of a single population of sites for these drugs. Such studies also show that a separate site exists for verapamil-like drugs. In the present study we have employed [^{3}H]D-600 and D-888 to label the verapamil receptor in brain and skeletal muscle microsome preparations.

In rat cortical microsomes [^{3}H]D-888 labels two populations of receptors with affinities of about 1.2 and 64 nM, with receptor concentration of 3.9 and 20 pMol/mg protein respectively. Binding to these sites is inhibited by low concentrations of nitrendipine (0.1 - 1 nM). [^{3}H]D-600 labels a similar population of nitrendipine sensitive sites. However, nitrendipine only displaces 30-50°/° of bound D-600 and D-888. By contrast analogues such as verapamil, tiapamil, and diltiazem completely inhibit binding.

Kinetic studies in rabbit skeletal muscle microsomes also indicate the presence of two sites for these drugs. Dissociation of [^{3}H]D-888 initiated by 80-fold dilution gives a biphasic dissociation curve. The addition of unlabeled D-888 and D-600 to the diluting buffer results in an accelerated dissociation rate. This indicates that the multiple sites are able to interact. Interestingly, the addition of dihydropyridines at the initiation of dissociation cause a marked slowing of the dissociation rate.

These results show that there are similar multiple interacting sites for verapamil-like drugs in brain and skeletal muscle, and that the interactions between receptor sites on the VSCC are complex.

158.3 A PEPTIDE TOXIN FROM CONUS GEOGRAPHUS BLOCKS VOLTAGE-GATED CALCIUM CHANNELS. D. H. Feldman and D. Yoshikami. Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

We previously reported (Kerr & Yoshikami, Nature 308:282-4, 1984) that omega-Conus geographus toxin (ω-CgTX), a 27-amino acid peptide purified from the venom of a marine snail (Olivera et al, Biochem 23:5087-90, 1984) irreversibly blocks evoked-release of transmitter in frog, and also attenuates the Ca^{2+} component of the action potential of chick dorsal root ganglion (DRG) neurons. Those results suggested that ω-CgTX interferes with Ca^{2+} influx into the presynaptic terminal, perhaps by blocking Ca^{2+} current or by augmenting K^+ current. We report here gigohm-seal whole-cell voltage clamp experiments which show that ω-CgTX specifically blocks voltage-gated Ca^{2+} channels.

Ca^{2+} currents in cultured, dissociated chick DRG neurons were pharmacologically isolated by using a bath containing 10mM Ca^{2+} and tetrodotoxin, and by recording with pipets containing CsCl and tetraethylammonium-Cl (TEA-Cl). ω-CgTX (5μM) was applied directly onto neurons by pressure ejection from a pipet.

Step depolarizations from -90 mV holding potentials elicited cobalt-blockable inward Ca^{2+} currents with 'transient' and 'prolonged' components (cf. Carbone & Lux, Nature 310:501-2, 1984; Nowycky et al, Biophys. J. 45:36a 1984). These currents were irreversibly blocked by ω-CgTX within a few seconds of its application.

In contrast to this striking effect on Ca^{2+} current, ω-CgTX had no discernible effect on K^+ currents (recorded with 10mM Co^{2+} instead of Ca^{2+} in the bath, and with KCl instead of CsCl and TEA-Cl in the recording pipet).

Thus, ω-CgTX rapidly, specifically, and irreversibly blocks neuronal Ca^{2+} currents. This action of ω-CgTX is sufficient to explain its inhibition of transmitter release. These findings indicate that ω-CgTX may be a useful tool to study neuronal and perhaps other Ca^{2+} channels.

Supported by NIH grants NS 15543, NS 00465 and NSF grant BNS 8316076. We thank B. M. Olivera and W. R. Gray for providing ω-CgTX, and L. M. Okun for advice on culture of DRG neurons.

158.4 D890: A NOVEL INTRACELLULAR CALCIUM ANTAGONIST IN PYRAMIDAL CELLS OF THE GUINEA PIG NEOCORTEX? R.A. Deisz* and D.A. Prince. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

D890, a quarternary methyl derivative of the Ca^{++} channel blocker D600, was proposed to act as a specific Ca^{++} current antagonist when applied intracellularly. We have examined the effects of D890 on pyramidal cells of guinea pig neocortical slices maintained in vitro under standard conditions at 37°C. Intracellular electrodes were filled with a suspension of nominal 10 μM D890 in 4M KAc. Only neurons with a stable E_m of at least -68 mV, APs of 90-110 mV and R_m exceeding 40 MΩ were considered. Brief depolarizing current pulses (20-150 msec) after topical application of 40 mM TEA and 10^{-6} M TTX invariably gave rise to Ca^{++} spikes lasting up to about 200 msec. About 20 min. after impalement with D890 electrodes the amplitude and duration of Ca^{++} spikes progressively decreased. In one neuron, where TEA was applied 70 min. after impalement with a D890 electrode no decrease was observed, perhaps because D890 already reached its full, but incomplete effect. The threshold for eliciting Ca^{++} spikes gradually shifted to more positive potentials and in 2 out of 9 neurons, Ca^{++} spikes no longer could be obtained. Recording with D890 containing electrodes in normal solutions also caused after about 10 min., a frequency-dependent decline of Na^+ AP amplitudes, an effect not seen in control cells. Moderate depolarizations eliciting 1-10 APs at frequencies above 0.5 Hz progressively reduced the AP amplitude. The first AP of a train was attenuated by about 20%, the last one by up to 40%. Unlike the effects of local anesthetics, the depression of AP amplitudes produced by D890 was not reversed by hyperpolarization. At frequencies below 0.25 Hz the decrement was below 10% (n=8). The burst of several APs at the beginning of depolarizing current pulses, seen in some cells was enhanced by hyperpolarization and decreased by depolarization, suggesting that they were due to activation of a low voltage activated Ca^{++} current. These events were little affected by D890. The slow envelope of the epileptiform depolarization shifts (DSs) induced by bath application of 10^{-5} M bicuculline were virtually unaltered by D890 (n=3). At frequencies of DS stimulation above 0.5 Hz the initial fast Na^+ spikes were reduced to a similar extent as those evoked by direct depolarizing current pulses. The effects described above are probably not due to cell deterioration since AP amplitudes remained constant and frequency independent for more than two hours in control cells and cessation of stimulation for 1-2 min. in cells impaled with D890 electrodes transiently restored the Na^+ AP amplitude. Our results show that intracellular D890 affects Na^+ dependent as well as some Ca^{++}-dependent events. A tentative explanation may be the positive charge of D890 due to quarternarization, may give rise to additional effects.

158.5 SOMATOSTATIN REDUCES VOLTAGE-DEPENDENT CALCIUM CURRENT IN AtT-20 MOUSE PITUITARY CELL LINE. Deborah L. Lewis and Forrest F. Weight. Lab of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

Somatostatin inhibits the secretion of ACTH evoked by secretagogues including corticotropin releasing factor, vasoactive intestinal peptide, isoproterenol, and forskolin in mouse pituitary tumor AtT-20 cells. In recent studies on AtT-20 cells Luini et al. (in preparation) have found that: (i) somatostatin decreases basal cytosolic Ca^{2+} levels and inhibits the cytosolic Ca^{2+} rise evoked by the above secretagogues; (ii) nifedipine reduces basal and secretagogue stimulated cytosolic Ca^{2+} levels; (iii) the effects of somatostatin and nifedipine are not additive; and (iv) TEA does not block the effect of somatostatin on cytosolic Ca^{2+}. These results raise the possibility that somatostatin may effect Ca^{2+} conductance. In view of this possibility, we used the patch-clamp method to study the effect of somatostatin on the Ca^{2+} current in these cells.

AtT-20 cells were cultured in Dulbecco's Modified Eagle Medium containing 10% fetal calf serum at 37°C in a humidified 10% CO_2 atmosphere. After subculturing 8-10 days, membrane currents were recorded using the patch-clamp method in the whole cell voltage-clamp mode. Currents were recorded in an external solution containing (in mM): 150 TEA, 0.8 $MgCl_2$, 5.4 KCl, 10 $CaCl_2$, 10 HEPES (pH 7.4), 45 glucose, 10^{-6}M TTX, and 1mg/ml albumin with an osmolarity of 340mOsm. The solution in the patch pipette contained (in mM): 120 CsCl, 11 EGTA, 2 TEA, 2 $MgCl_2$, 10 HEPES (pH 7.4), 4 Mg_2ATP, 20 creatine phosphate, and 50 units/ml creatine kinase with an osmolarity of 318mOsm. All recording was at room temperature.

Cells were voltage-clamped at a holding potential of -80mV and stepped from -120 to +80mV using steps 100ms in duration. Cell input resistance, measured between -120 and -60mV, was 2.0-7.9 Gohms. An inward current activated rapidly at potentials positive to -40mV, peaked in 6-7ms, inactivated slowly, was inhibited by 2mM Co^{2+}, and was present in 10mM Ba^{2+}. I-V curves for this voltage-dependent Ca^{2+} current (I_{Ca}) were obtained by measuring I_{Ca} at peak amplitude. Somatostatin (10^{-8} to 10^{-6}M) was applied from a macropipette lowered into the external solution near the cell under study. Somatostatin decreased peak I_{Ca} by 30.1±6.7% (n=6) during voltage steps eliciting maximum current amplitude (+10-15mV). Within two min after beginning somatostatin washout, I_{Ca} returned to control level. Control solutions of peptide vehicle (acidified bovine serum) diluted with external solution (identical to the peptide dilutions) had no apparent effect on I_{Ca}. These results suggest that reduction of peak I_{Ca} by somatostatin may contribute to the somatostatin induced inhibition of ACTH secretion.

158.6 ENKEPHALIN AND SOMATOSTATIN BLOCK OF CALCIUM CHANNEL IN NEUROBLASTOMA CELLS. A. Tsunoo*, M. Yoshii* and T. Narahashi (SPON: C.A. Berry). Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

We have previously found that neuroblastoma cells (N1E-115) have two types of voltage-gated Ca channels: one generates a transient Ca current (type I) and the other generates a long-lasting Ca current (type II)(Tsunoo et al., Soc. Neurosci. Abstr. 10, 527, 1984, Tsunoo et al., Biophys. J. 47, 433a, 1985; Yoshii et al., Biophys. J. 47, 433a, 1985). We have now examined the action of neuropeptides in modulating Ca channels. Ca channel currents as carried by Ba^{2+}(50 mM) were recorded using the whole-cell variation of patch clamp technique.

Leucine-enkephalin (Leu-Ek) (25 nM) caused a 70-80% reversible decrease in the amplitude of type II current associated with a step depolarization to 0 mV from a 10 sec prepulse at -30 mV without markedly changing its time course. This time-independent block was not voltage-dependent. However, with depolarizing pulses to potentials more positive than +10 mV, the Leu-Ek block was relaxed with an exponential time course during the depolarizing pulse. Naloxone (1 μM) antagonized the inhibitory effect of 25 nM Leu-Ek. Leu-Ek did not affect the type I current even at a concentration of 0.5 μM. Somatostatin (50 nM) also blocked type II current by 75% in a time-independent manner. With depolarizations to potentials more positive than +10 mV, the block was also relaxed in a time-dependent manner. Somatostatin did not affect type I current even at a concentration of 0.5 μM.

The selective block of type II Ca channel by enkephalin and somatostatin may provide the basis for presynaptic inhibition of transmitter release by these peptides.

Prepulse: -30 mV, 10 sec

158.7 PHENYTOIN SUPPRESSES CALCIUM CHANNEL CURRENTS IN NEUROBLASTOMA CELLS. D. Twombly* and T. Narahashi (SPON: S.-C. Cheng). Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

One of the suspected anticonvulsant modes of action of phenytoin (diphenylhydantoin, DPH) is its effect on calcium-dependent processes. Phenytoin inhibits post-tetanic potentiation in neuromuscular preparations, and suppresses calcium accumulation in synaptosomes and brain slices. The present study tested its ability to block calcium channels of N1E-115 neuroblastoma cells, neurons possessing both inactivating (type I) and non-inactivating (type II) calcium channels.

Voltage clamp experiments were performed on internally perfused neurons with the whole-cell/suction pipette technique. Barium (50 mM) was added to the external medium to serve as charge carrier through calcium channels. Phenytoin (100 uM) was bath applied at room temperature (23 C). Under control conditions, type I currents were activated at potentials positive to -40 mV, with maximum currents occurring at clamp steps to -10 mV or -20 mV. Time to peak of the type I currents ranged from 15 ms to 40 ms. Currents inactivated according to a single exponential time course (time constants: 30-55 ms). Type II currents, activated at potentials positive to 0 mV, displayed little or no inactivation during 200 ms test pulses. The amplitude of these currents was generally largest at potentials of +10 mV.

In the presence of phenytoin, peak type I currents were 35-80% of control amplitudes (62 +/- 17%, mean +/- s.d., n=9). This suppression of peak currents was not accompanied by changes in the kinetics of activation or inactivation. Holding potential significantly influenced drug potency; block of inward current was considerably greater at a holding potential of -60 mV than at -80 mV. At a given holding potential, however, the degree of block was comparable at all command potentials. These effects of phenytoin on type I currents were partially reversed during a ten minute washing period. In contrast to the inactivating currents, the non-inactivating currents were relatively insensitive to phenytoin. Neither the amplitudes nor kinetics of sustained, type II currents were substantially changed in the presence of phenytoin.

Calcium channels are considered important in regulating excitability of mildly depolarized cell membranes, and they are suspected to play a critical role in normal and pathological bursting activity. Through its effects on calcium channels, phenytoin could limit the rhythmic depolarization shifts associated with epileptogenesis, preventing the temporal and spatial propagation of seizure activity. (Supported by NIH grant NS14144).

158.8 NITRENDIPINE RESISTANT Ca^{++} CURRENTS AND VOLTAGE DEPENDENT INHIBITION OF NITRENDIPINE SENSITIVE Ca^{++} CURRENTS IN GH3 CELLS. Steven M. Simasko, Robert E. Oswald, and Gregory A. Weiland. Dept. of Pharmacology, New York State College of Veterinary Medicine, Cornell University, Ithaca, NY 14853.

Voltage sensitive Ca^{++} currents were examined in GH3 cells, a pituitary derived cell line, by use of the whole-cell voltage-clamp variation of the patch-clamp technique. The internal solution consisted of 154 mM CsCl, 2 mM $MgCl_2$, 2 mM ATP, 5 mM EGTA, and 10 mM HEPES (adjusted to pH 7.4 with NaOH). The bathing solution consisted of 120 mM tetraethylammonium, 1 mM MgCl, 19 mM glucose, 10 mM HEPES (adjusted to pH 7.4 with KOH), and either 25 mM $CaCl_2$ or 25 mM $BaCl_2$. These conditions isolated voltage-dependent Ca^{++} currents since there was no external Na^+ to flow through the voltage-sensitive Na^+ channel, and the internal Cs^+ and external tetraethylammonium blocked any current through K^+ channels. In most experiments external Ca^{++} was replaced by Ba^{++} because Ba^{++} resulted in larger current signals.

The effects of nitrendipine (NTD), a dihydropyridine Ca^{++} channel antagonist, were examined on the isolated Ca^{++} currents. NTD was applied via bath application after a successful whole-cell clamp had been achieved and allowed to stabilize. A dose-response relation was determined for NTD inhibition of Ca^{++} currents. When the cells were held at -80 mV before a test voltage of +10 mV was applied for 50 msec, NTD blocked the voltage-dependent current with an IC_{50} of 1 µM. However, the maximal block achieved was only 60-70% of the total Ca^{++} current. The effect was the same regardless of whether Ca^{++} or Ba^{++} was the current carrier. Inhibition of the current was found to be voltage dependent. When the cell was tested at a dose of 0.1 µM NTD and the holding potential was -80 mV virtually no blockade of current was observed with a test pulse to +10 mV. When the holding potential was -30 mV and the test potential +10 mV (this current was 30% of the current produced when holding at -80 mV), 0.1 uM NTD blocked 55% of the current.

The activation voltages of Ca^{++} currents when cells were held at -80 mV were examined in the presence and absence of 10 µM NTD. In the absence of NTD half-maximal activation was achieved at -20 mV. However, in the presence of 10 µM NTD, the half-maximal activation was shifted to -28 mV.

These data suggest that GH3 cells either possess two voltage dependent Ca^{++} channels, one sensitive to NTD and the other resistant to nitrendipine or that, rather than simply blocking a sub-population of NTD sensitive channels, NTD alters the open time and activation voltage of a single population of channels.

158.9 EFFECTS OF PYRETHROIDS AND VERATRIDINE ON TWO TYPES OF CA CHANNELS IN NEUROBLASTOMA CELLS. M. Yoshii*, A. Tsunoo* and T. Narahashi (SPON: E.M. Silinsky). Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611

It has recently been shown that a variety of neuronal membranes has two types of voltage-sensitive Ca channels: one generates a transient Ca current (type I), and the other generates a long-lasting Ca current (type II). Using a whole-cell variation of patch clamp technique in neuroblastoma cells (N1E-115), we have shown that these two channel types are distinguishable physiologically and pharmacologically (Tsunoo et al., Soc. Neurosci. Abstr. 10, 527, 1984; Tsunoo et al., Biophys. J. 47, 433a, 1985; Yoshii et al., Biophys. J. 47, 433a, 1985). Tetramethrin, a synthetic pyrethroid, is a potent Na channel modulator, and was found to block type I Ca channel preferentially. In the present study, the effects of two types of pyrethroids and veratridine, a Na channel modulator, on Ca channels were compared.

Tetramethrin (50 µM), a type I pyrethroid without containing a cyano group at the α position, caused a progressive block of type I and type II Ca channel currents over a 10-15 min period. When a steady state was achieved, type I current was blocked by 75% while type II current was blocked only by 30%. The tetramethrin block of both channel types was time-dependent, being enhanced during a 400 msec depolarizing pulse. The time-dependent component of block was easily reversible after washing with drug-free solution, while the time-independent component or resting block persisted for at least 40 min after washing. Deltamethrin and fenvalerate, type II pyrethroids containing a cyano group at the α position, are also potent Na channel modulators. Unlike tetramethrin, deltamethrin and fenvalerate (10 µM) had no effect on either type of Ca channel currents during 30 min of exposure. Veratridine (100 µM) did not alter type I current but decreased type II current by 40-50%. However, in veratridine, the reduced type II current was followed by a prolonged inward tail current upon repolarization. This suggests an increase in outward current rather than a decrease in type II current.

The results indicate that type I pyrethroids are Ca channel blockers as well as Na channel modulators. The two components of Ca channel block, a time-dependent reversible block and a time-independent irreversible block, suggest two separate sites of action of tetramethrin in Ca channels. However, type II pyrethroids modify Na channel only. This difference in action between type I pyrethroids and α-cyano type II pyrethroids may be partially responsible for the different symptoms of poisoning in animals.

158.10 BARBITURATE INHIBITION OF DIVALENT CATION POTENTIALS IN NOCICEPTIVE LEECH NEURONS. A.L. Kleinhaus and J. Johansen, Dept. Neurology Yale U. Sch. Med. New Haven, Ct. 06510

We have previously reported that barbiturates prolong the action potential of Retzius and nociceptive leech neurons, presumably by interfering with Ca-entry necessary for activation of repolarization mechanisms in these cells (Kleinhaus and Prichard, 1977;1979).

To verify this hypothesis directly we examined the actions of methohexital (MTX), pentobarbital (PTB) and phenobarbital (PNB) on divalent cation potentials evoked in medial (Nm) and lateral (Nl) nociceptive cells in Na-free, tetraethylammonium chloride (TEA) containing Ringer. The maximal rate of depolarization (Vmax) amplitude, and duration of the long-lasting (sec) regenerative potentials depended on $\{Ca\}_o$ and $\{Sr\}_o$; they were reversibly blocked by Mn and Co and were resistant to 50 uM tetrodotoxin, a concentration which abolished the Na-dependent potential. In both types of N cells, the three barbiturates reversibly and in a dose-dependent manner reduced the duration and Vmax of Ca- or Sr-dependent action potentials. The apparent K_I's for inhibition by the three drugs were estimated from the data points which could be fitted with reverse Langmuir adsorption isotherms. The order of potency of the barbiturates for inhibition of Vmax of the Sr-dependent action potentials was: MTV> PTB> PNB, the respective apparent K_I's being MTX: 560 uM, PTB: 800 uM and PNB: 3 mM. The inhibition of Vmax of the divalent cation potential occurred at concentrations which had little (PTB and PNB) or no (MTX) effect on the Vmax of the Na-dependent action potential recorded in the same cell-type in normal Ringer.

The barbiturates produced only minimal (<4mV) changes in resting membrane potential and conductance in Na-free, TEA-Ringer at the highest concentrations used in this study.

In contrast, in Na containing Ringer, MTX, PTB, and PNB depolarized the Nl cells whereas only PBN depolarized the Nm cell, the two other drugs having no effect. The drug-induced depolarization was accompanied by a large reduction in membrane input resistance. These effects may be related to the known excitatory properties of barbiturates which in these cells seem to be Na-dependent.

The results strongly suggest that barbiturates block Ca-entry through voltage-gated channels in identified leech neurons as they do in mammalian nerve terminal preparations and mammalian neurons in culture. Because leech neurons are easily identified and can be maintained in culture, the preparation is eminently suitable for the study of drug actions on Ca-permeability.

158.11 LACK OF VOLTAGE AND FREQUENCY-DEPENDENCE OF ETHANOL BLOCK OF CALCIUM CURRENT IN APLYSIA NEURONS. P. Camacho-Nasi and S.N. Treistman. Worcester Foundation for Experimental Biology, 222 Maple Avenue, Shrewsbury, MA 01545.

Among a variety of ionic currents that we have studied (I_{Na}, I_K, I_A) in isolated neurons of the marine mollusc, Aplysia californica, the calcium current (IC_a) is the most sensitive to ethanol (EtOH). At physiologically relevant concentrations (50mM) of EtOH, the amplitude of IC_a is reduced by 20% (Biophys. J.,47:435a,1985). Voltage clamp experiments show that the depression of current induced by EtOH is not accompanied by a shift along the voltage axis of IC_a activation, making it unlikely that the mechanism of blockade occurs by a surface charge screening effect. The efficacy of some anesthetics has been shown to be dependent on the prior activity of the channels which they interact with. We have done double pulse and pulse train experiments to determine whether the blockade of IC_a by EtOH is voltage and/or frequency-dependent. Either Ca^{++} or Ba^{++} served as charge carrier. Isolation of IC_a from competing sodium and potassium currents (Na replaced on equimolar basis with TMA; 140 mM TEA; 5 mM 4-AP) was successful within the range of voltages used in the present experiments and was confirmed by the absence of contaminating currents when Ca-channel blockers were added to the perfusion medium at the end of each experiment. In the control condition, the amplitude of IC_a during a test pulse was decreased by 70% when preceded by 10 pulses given at a frequency of one every 25 msec. EtOH did not change the amount of IC_a depression during these repetitive depolarizations (EtOH did not induce "use-dependent" block). Similarly, in double-pulse experiments in which a pre-pulse was made progressively more depolarized EtOH did not enhance the blockade of IC_a during a subsequent test pulse (EtOH did not induce voltage-dependent block). These results suggest that EtOH does not block the calcium channel by occlusion in a manner similar to that of some local anesthetics. (Supported by NIAAA grant No. AA05542).

158.12 Ca^{2+}-MEDIATED INACTIVATION OF Ca^{2+} SPIKES IN HIPPOCAMPAL NEURONS. T.A. Pitler* and P.W. Landfield (Spon: D.J. Goode), Dept. of Physiol. & Pharmacol., Bowman Gray School of Medicine, Winston-Salem, NC 27103.

In several invertebrate systems, Ca^{2+} currents have been shown to diminish following membrane depolarization, or other manipulations which increase the internal Ca^{2+} concentration ($[Ca^{2+}]i$) (cf. Eckert and Tillotson, J. Physiol., 1981). In addition, we recently found that some Ca^{2+}-dependent processes (e.g., Ca^{2+}-dependent K^+ conductance) also exhibit Ca^{2+}-dependent inactivation in mammalian hippocampal neurons (Pitler and Landfield, Soc. Neurosci. Abst., 1984). As yet, however, Ca^{2+}-mediated inactivation of Ca^{2+} currents in central vertebrate neurons has not been clearly demonstrated.

Using intracellular recording techniques in the rat hippocampal slice, we examined Ca^{2+} spikes in cesium-loaded, tetrodotoxin-treated pyramidal cells, in order to determine whether Ca^{2+} influx is modified by procedures that increase $[Ca^{2+}]i$. Control values for the Ca^{2+} spike (induced by 70 ms intracellular depolarizing pulses) were obtained and intracellular Ca^{2+} was then elevated by 4 Hz repetitive activation of the Ca^{2+} spike or by depolarizing pulses of varying durations (2, 5, and 10 sec.). In all experiments, membrane resistance and membrane potential were monitored to determine whether cesium-loading had completely blocked Ca^{2+}-dependent K^+ conductance, since such conductance can confound Ca^{2+} spike measures.

During brief repetitive activation or following long depolarizing pulses, the latency from the onset of the depolarization to the peak of the Ca^{2+} spike increased, and the amplitude and duration of the Ca^{2+} potential decreased. The magnitude of these changes was dependent on the degree of previous depolarization. Spike recovery was generally complete within 1-5 min following activation.

To ensure that the observed effects were mediated by an increase in $[Ca^{2+}]i$, the Ca^{2+}-chelator EGTA was leaked into the cell through the recording electrode. This procedure significantly reduced inactivation of the Ca^{2+} spike during repetitive activation.

Thus, these results indicate that Ca^{2+}-mediated inactivation of Ca^{2+} conductance is present in mammalian brain neurons, as well as in invertebrate cells, and may be a widespread regulatory mechanism for limiting deleterious elevations of intracellular Ca^{2+}. (Supported by AG 04207 and AG 04542).

158.13 EFFECTS OF DIHYDROPYRIDINE AGONISTS AND ANTAGONISTS ON Ca^{++} UPTAKE AND NEUROTRANSMITTER RELEASE BY RAT BRAIN SYNAPTOSOMES. T.J. Turner* and S.M. Goldin(Spon.D.Lester), Dept.of Pharmacology, Harvard Medical School, Boston, MA 02115.

The voltage-sensitive Ca^{++} channel is responsible for the depolarization-dependent entry of Ca^{++} into the nerve terminal. The resulting increase in intracellular $[Ca^{++}]$ is thought to initiate neurosecretion. We have determined that Ca^{++} channels are present in rat brain synaptosomes, and that they are sensitive to dihydropyridine Ca^{++} channel antagonists such as nitrendipine [NTP] and nifedipine [NFP](J. Neurosci. 5, 841-849 (1985)). In order to further characterize neuronal Ca^{++} channels, we have measured the effect of NTP and NFP on the depolarization-dependent release of ^{3}H-norepinephrine (NE) from preloaded synaptosomes, and have examined the effect of the dihydropyridine agonist Bay k8644 on depolarization-dependent Ca^{++} uptake and NE release by rat brain synaptosomes.

In order to study depolarization-dependent release of NE, we developed a superfusion apparatus that allows the superfusate to be switched from normal 5mM K^+ to 57.5 mM K^+. This increase in $[K^+]$ results in a transient, 5-10 fold increase in the rate of NE release. The release of NE during the first 10-20 sec. of depolarization is attenuated 40-60 % by including 1 uM NFP in the superfusate. However, at later times (20-60 sec.) NFP has no effect on the rate of NE release, suggesting that this secretion is mediated by Ca^{++} entry via potential-sensitive pathways other than the Ca^{++} channel, possibly the electrogenic Na/Ca exchange pathway. A dose-response relationship was obtained for the inhibition of NE release by NTP and NFP. The IC50 values of 75 and 90 nM, respectively, are approximately 50% greater than the values obtained previously for inhibition of depolarization-dependent Ca^{++} uptake into synaptosomes (56 and 63 nM).

The Ca^{++} channel agonist Bay k8644 was found to potentiate the ability of K+ to stimulate the uptake of Ca^{++} into synaptosomes. An increase in the depolarization-dependent Ca^{++} uptake was observed at all K+ concentrations above 5 mM, both in the presence and absence of external Na^+. This increase was blocked by NFP, indicating that the effect of Bay k8644 was mediated by Ca^{++} channels. However, Bay k8644 did not significantly alter the rate of depolarization-dependent NE release from synaptosomes at any level of depolarization tested.

The conclusion drawn from these studies is that the neuronal Ca^{++} channel has biochemical and pharmacological properties similar to those observed in other excitable tissues such as heart and smooth muscle. Synaptosomes present a viable system for the study of neuronal Ca^{++} channels.

158.14 DIHYDROPYRIDINE EFFECTS ON MAMMALIAN NEURONAL VOLTAGE-SENSITIVE CALCIUM CHANNELS. M.Jia* and M.J. Litzinger (SPON: P. Loh) Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda, MD. 20205

The dihydropyridines are believed to act on voltage-sensitive calcium channels as agonists or antagonists of calcium current based on their chemical structures. Previous microelectrode recordings in dorsal root ganglion neurons (DRG) taken from 12-14 day old fetal mice spinal cords and co-cultured with spinal cord neurons showed only mild inhibition of the calcium spike or dV/dt (30% of control) at concentrations of 1 μM nitrendipine (NTP), (Litzinger, et al., submitted,1985). Previous binding studies in these cultures showed a high affinity site (Kd = 1.1 nM) and a low affinity site (Kd=50nM) in 21 day old cells (Litzinger and Brenneman, BBRC 127, 112,1985). No correlation between NTP binding and electrophysiological recordings have been found thus far in our culture system.

In these experiments, two electrode voltage-clamp technique was used to study the effect of NTP and Bay K 8644 (Bay K) on calcium currents measured in DRG neurons. Recording solutions contained (mM):50 NaCl, 5 KCl, 5 $CaCl_2$, 1 $MgCl_2$, 10 glucose, 100 TEA-Br, 1 4-AP, 1 μM TTX and 10 HEPES adjusted pH to 7.35; sucrose was added to adjust the osmolarity to 325 m OSM. Experiments were performed routinely at 22°C. Electrodes (50-70 MΩ) contained 1M Cs_2SO_4, a potassium channel blocker. Perfusion pipettes had tip diameters of 5-10 μM and were positioned 30-50 μM from the cell. The membrane potential was held at -50 mV and 30 ms voltage jumps were used to activate calcium currents; at -10 mV the transient calcium current (T current) reached maximal amplitude while at 0 mV or +10 mV the slow noninactivating calcium current (L current) was maximal as others have described. Bay K at 1 μM consistently increased L current, while at 10 nM this effect was not observed in all cells. The peak transient current was also increased, but we could not determine whether this was due to an increase in the T current, or only to the increase in L current. NTP at 1 μM and 10 nM showed no difference from ethanol, the drug vehicle, in its effect on either component of the calcium current.

Our results suggest that Bay K is a potential calcium agonist in mammalian neurons, and that NTP is not effective as an antagonist of either voltage-sensitive calcium mechanism.

158.15 CALCIUM CHANNELS IN SARCOPLASMIC RETICULUM (SR) MEMBRANES ARE ACTIVATED BY CAFFEINE. Benjamin A. Suarez-Isla, Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, Maryland 20205.

Calcium channels have been detected in SR membranes from rabbit skeletal muscle (Orozco, Suarez-Isla, Froehlich and Heller, Biophys. J., 47, 57a, 1985) assembled at the tip of patch pipets with the double-dip method (Suarez-Isla et al., Biochemistry, 22, 2319, 1983). In 200 mM symmetric CaCl2 the single channel conductance was 5.6 ± 0.5 pS (mean ± S.E.M., n=8) and linear between +50 and +200 mV (positive inside the pipet). The conductance vs. Ca concentration relationship obtained between 50 to 200 mM CaCl2 (symmetric) showed saturation and could be fitted to a hyperbolic function giving a maximal single channel conductance of 7.9 pS and a $K_{0.5}$ of 83 mM Ca. Extrapolation to 5 mM (maximal estimated intraluminal concentration) gave a single channel conductance of 0.5 pS.

Barium could substitute for Ca as a current carrying species and the single channel conductance was 1.3 times larger than the conductance for Ca.

The channels appeared in bursts during application of steady polarizations of the patch pipet (+50 to +200 mV, positive inside). Bursts of activity lasted several seconds (mean 6.6 s) and were followed by longer silent periods of up to a minute. Bursts were prominent at all voltages studied and mean burst length did not show a significant voltage dependence in the few patches where possibly only one channel was present. During a burst, the channel fluctuated rapidly between open and closed states, showing rapid closures of 0.5 to 10 ms duration(mean = 1.8 ms).

However, addition of millimolar concentration of caffeine, a drug that produces a strong Ca release from the SR in both intact muscle and SR vesicles, produced a dramatic increase in mean burst length. In the absence of ATP and/or Mg, 1.6 mM caffeine increased burst length to minutes with concurrent appearance of several current levels, without change in single channel conductance. Activation took place within seconds but it decreased thereafter, even during sustained application of the drug. In contrast, ryanodine (1 mM) caused a transient inhibition of the Ca channel.

These results suggests that this Ca conductance may be associated with the postulated Ca release channel of sarcoplasmic reticulum.

158.16 VOLTAGE-CLAMP ANALYSIS OF INWARD CALCIUM CURRENT IN HIPPOCAMPAL CA3 PYRAMIDAL NEURONS. K.L. Zbicz and F.F. Weight. Laboratory of Preclinical Studies, DICBR, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

An inward Ca^{2+} current has been previously observed in CA3 hippocampal pyramidal neurons (Johnston, D. et al. Nature 286:391, 1980; Brown, D.A. and Griffith, W.H. J. Physiol. 337:303, 1983). This current was described as having a slow activation time course and no observable inactivation with maintained depolarization. We have further studied inward currents in hippocampal CA3 pyramidal neurons using the single microelectrode voltage-clamp (SEC) technique (Wilson, W.A. and Goldner, M.A. J. Neurobiol. 4:411, 1975). Thin slices (400-450u) of guinea pig hippocampus were held submersed in a transverse flow recording chamber and neurons in region CA3 were impaled with a single microelectrode (15-25 Mohm) containing 3M CsCl. Diffusion of Cs^+ into the neurons produced a large reduction in outward K^+ currents, revealing a depolarization activated inward current. This current could be reduced by the application of Co^{2+}, Mn^{2+}, or Ca^{2+}-free solutions, and is therefore presumed to be mediated by Ca^{2+}. In Cs^+ loaded neurons the inward current activated rapidly (<30 msec) and gradually decayed with maintained depolarization. This decline in inward current was incomplete, however, and the recorded current often remained net inward during a depolarization lasting several seconds. The decline in inward current was also observed when tetraethylammonium chloride (124 mM) was substituted for NaCl or Ba^{2+} was substituted for Ca^{2+} in the superfusing solution. In addition, the inward current that was activated during step depolarizations decreased as the holding potential was made more positive.

The inward Ca^{2+} current that was activated by a depolarizing step decayed with a complex time course upon return to a more hyperpolarized potential. This decay had both rapid and slow components. The rapid component was too fast to be accurately followed by the SEC. The slow component was observed as an inward tail current, the decay of which could be described by a single exponential function. The time constant for decay of this slow component was dependent upon the potential of the neuron, decreasing at more hyperpolarized potentials.

The data presented suggests that the inward Ca^{2+} current rapidly activates and that a fraction of this current inactivates with maintained depolarization. This inactivation may not be dependent on Ca^{2+} since it occurred when Ba^{2+} was substituted for Ca^{2+} in the artificial CSF used. The complex deactivation time course for the inward current suggests the possibility that two or more populations of Ca^{2+} channels are present in these cells.

158.17 CALCIUM CURRENTS IN SKELETAL MUSCLE OF THE RAT. I. Uribe* and R. F. Valdiosera* (SPON: J. E. Villarreal) Depts. of Physiology and Pharmacology. CINVESTAV-IPN, Apdo. Postal 14-740, México 07000,D.F.

Recently, Ca currents have been recorded from a fast twitch skeletal muscle of the rat (omohyoid), using the three-microelectrode voltage clamp technique (donaldson, P.L. and Beam, K.G. J. Gen. Physiol. 82: 449, 1983). Ca currents were preceded and followed by outward currents that remained even in the presence of K channel blockers. Although the early outward current seems to be carried by delayed rectifier channels not completely blocked by the TEA present in the bath, the late outward current seems to be less satisfactorily explained. For this reason, we have measured Ca currents of the omohyoid with the vaseline gap voltage clamp since this technique allows the control of the internal ionic composition. Recordings were made at room temperature (22-24°C) in an external solution that contained in mM: TMA or $TEACH_3SO_3$ 135, $CaCH_3SO_3$ 2 or 10, MOPS 5, glucose 12, and TTX 1 µM. Fibers ends were cut in intracellular medium containing TMA-aspartate 125, $(TMA)_2$EGTA 20 and MOPS 5, pH was adjusted to 7.35 in both solutions. This concentration of EGTA did not block contraction completely specially at strong depolarizations when Ca concentrations was high. We tried higher concentrations of EGTA (25-30 mM) but the fiber did not last long at this concentrations. Contraction was blocked when the internal solution contained 0.125 mM citrate in addition to the 20 mM EGTA. Citrate probably reduces Ca release from the sarcoplasmic reticulum since less EGTA is needed to block contraction when the external Ca is low (2 mM). Under these conditions, Ca currents are recorded with similar kinetics to the ones reported previously but without any noticeably outward currents. When Cs is substituted for TMA in the internal solution, inward currents are followed by a late outward current, these late outward currents are prominent when the external Ca concentration is low (2 mM) and are reversibly reduced or abolished by raising the Ca concentration to 10 mM. Both currents, are blocked by Cd (2 mM). On the other hand replacing Na for TEA in the external solution a second peak of inward current is recorded whose magnitude may be greater than the first, is more prominent in low Ca (2 mM) and is also reduced or abolished when Ca is raised to 10 mM. Again, both currents are blocked by 2 mM-Cd. Our results could be explained by recent findings showing that in frog muscle, Ca channel becomes permeant to monovalent cations in the absence of extracellular Ca (Almers, W., E.W. McCleskey and P. T. Palade, J. Physiol. 353: 565, 1984). If this were true in rat muscle, then Ca depletion in the tubular system could drop the Ca concentration to values low enough to activate non-selective conductance. A more systematic study in media of various pCa is needed.

This work was partially supported by CONACyT.

158.18 CALCIUM CURRENTS IN THE SECRETORY NEURON SOMA OF THE X-ORGAN OF THE CRAYFISH. U. García*, C. Onetti* and R.F. Valdiosera*. (SPON: P. Huizar). Depts. of Physiology and Pharmacology, CINVESTAV, Apdo. Postal 14-740, 07000 México, D.F. and CUIB, Universidad de Colima, Apdo. Postal 199, 28000, Colima, Colima, México.

Calcium currents in the soma of X-organ cells of the crayfish (Procambarus clarkii) were recorded at room temperature (22°C) with the whole cell clamp method. The cell bodies were exposed by gentle dissection of the connective tissue covering the X-organ and their axons were cut as close as possible to the cell bodies. The preparation was then perfused with van Harreveld's solution during 45-60 min. For recording, the bathing solution contained in mM: 195 choline-Cl, 20 $CaCl_2$, 2 $MgCl_2$2, 10 MOPS-CsOH and the pipette solution contained in mM: 217 CsCl, 2 $MgCl_2$, 0.2 $CaCl_2$, 5 Cs_2 EGTA and 10 MOPS-CsOH. The pH was 7.35 in both solutions. Cells chosen for recording were 20-30 micron diameter and no enzimatic treatment was necessary .

Depolarizing pulses every five second from a holding potential of -90 mV elicit inward currents starting at -30 mV that reach a maximum peak value of -40 µA/cm^2 at about 10 mV in 6 msec and inactivates with a relatively fast time course. The steady state inactivation curve of this current has a midpoint around -45 mV. These currents have the expected properties of a calcium current, they are stable for about 15 minutes, are not affected by 1 µM of TTX and are blocked by 2 mM Cd. No currents were recorded in axotomized neurons (n = 10) when Na (220 mM) and Cd (2 mM) were present in the bathing solution. In intact cells, however, uncontrolled inward currents were observed, that disappeared when TTX (1 µM) was added to the bath, These Na dependent currents seem to originate in the axon, since they are not present in axotomized neurons.

Our results suggest that the action potential in the soma of these neurons is calcium dependent and the sodium dependence observed in earlier studies with microelectrodes (Iwasaki, S. and Satow, Y. J. Gen. Physiol., 57: 216, 1971) was probably caused by sodium currents in the axon. More experiments are needed to settle this point.

159.1 INTRACELLULAR ZN, CU, AND FE IN CULTURED ASTROGLIA; LEAD-INDUCED CHANGES WITH AND WITHOUT THIAMIN. E. Tiffany-Castiglioni*, J. Zmudzki*, T.E. Rowles*, J.-N. Wu*, and G.R. Bratton* (SPON: A.J. Castiglioni, Jr.). Dept. of Veterinary Anatomy, Texas A&M University, College Station, TX 77843.

The effects of lead acetate on intracellular concentrations of zinc, copper, and iron were measured in cultured astroglia by atomic absorption spectroscopy. Results were correlated with lead uptake and viability. Our findings were as follows: first, astrocytes cultured for 10-15 days from newborn rats were resistant to lead toxicity (10^{-7} to 10^{-4} M lead acetate), as measured by trypan blue dye exclusion. However, the astrocytes took up and concentrated lead from the culture medium. For example, cultures treated with 10^{-5} M lead acetate had an intracellular lead concentration 55x that of the medium after 3 days. Intracellular Cu concentrations (µg/2 x 10^6 cells) were 4x that of controls in cultures given 10^{-4} M lead acetate for three days and harvested 2 weeks later. No consistent change was seen in Zn and Fe concentrations. Increased intracellular Cu is a hypothesized mechanism of lead toxicity (Niklowitz, Adv. Neurotoxicol., 1980). Though cell death was not increased by a 3-day exposure to lead, proliferation was significantly inhibited after two weeks by either 10^{-6} or 10^{-4} M lead acetate. Simultaneous administration of thiamin (10^{-4} M), which is used experimentally to treat lead intoxication, did not prevent either the intracellular accumulation of Cu or the loss of proliferation. We previously reported a similar lack of protection for SY5Y human neuroblastoma cells. These findings suggest that the mechanism by which thiamin protects the CNS from lead intoxication does not involve direct contact with target neural cells. The mechanism may reside in other processes, such as digestive or renal absorption.
Second, we found that oligodendrocyte cultures prepared from neonatal rat brain were much more sensitive to lead-induced loss of viability (permeability to trypan blue) than either astrocytes or meningeal fibroblasts at lead acetate concentrations of 10^{-5} to 10^{-3} M. This finding suggests that the hypomyelination observed in the CNS of lead-intoxicated young animals is, at least in part, a direct effect of lead upon the oligodendrocytes.

159.2 LEAD INTOXICATION IN THE DEVELOPING RAT CNS: BLOOD AND BRAIN CONCENTRATIONS. E.P. Finnerty, W.A. Anderson, and P. Kunkler. Univ. of Osteopathic Med. & Hlth. Sci., Des Moines, IA and Indiana Univ. Sch. of Med., Terre Haute Center for Med. Education, Terre Haute, IN.

Lead has been noted as being toxic to a number of organ and metabolic systems, though the developing CNS appears to be especially vulnerable. These observations represent a portion of an on going investigation of the toxic manifestations of lead ingestion in a rat model.

Animals were divided into 5 groups by litter. The control group received sodium acetate while each of the other groups received 2, 3, 4, or 5 doses of lead acetate (600 mg/kg/day) beginning on day 0 postnatally. The lead or sodium acetate was administered via gastric intubation. Animals were sacrificed on day 1, 2, 3, 5, 7, 9, 11, 13, 15, 17, 19, or 21 following the lead dosing. In each sacrifice group half the animals were selected for morphologic study while the other half were selected for blood and tissue lead analysis. Specimens obtained for lead analysis included: blood, kidney, liver, GI tract, brainstem, cerebellum, midbrain, and forebrain including cerebral cortex.

The lead concentration of the blood and other tissues was determined by standard methods using atomic absorption spectroscopy (Hitachi Model 170-70). This method allowed an analytical sensitivity of 15 µg/L and a percision of 8-15%.

Control animals were found to have blood lead concentrations of < 15 µg/L while the immediate post dose blood lead ranged from 10 (2 dose) to 16 (5 dose) mg/L. Thus demonstrating that gastric intubation is an effective means of administering lead and that there is a significant GI absorption in the rat pup. The elimination of lead from the blood displayed an apparent first-order elimination rate with the disappearance for all groups being parallel and requiring 15-17 days for 95% elimination, though at 21 days significant amounts of lead were detectable.

Hemoglobin concentrations were decreased in a dose-dependent fashion from days 1-14. Both body and brain weights of the lead-treated rats displayed a slower gain over the period than the controls.

This study demonstrates the effectiveness of the method using various doses for producing a model of lead intoxication in immature rat pups. This model is being used for further investigations of lead toxicity in the developing CNS.

We gratefully acknowledge the assistance of Dr. R. Serfass of Iowa St. Univ. for his technical expertise in the lead assays.

159.3 THE EFFECTS OF VARYING DOSES OF LEAD INITIATED AT DIFFERENT POSTNATAL INTERVALS. P.E. Kunkler*, W.J. Anderson, G.W. Patrick. Indiana Univ. Sch. Med., Terre Haute and Ft. Wayne Ctrs. for Med. Educ., Terre Haute.

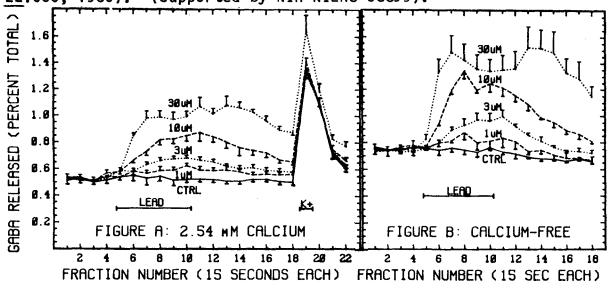
The brains of neonatal rats chronically exposed to lead, display vascular hemorrhages and stunted neuronal differentiation. The purpose of this study was to determine the effects of varying doses of lead acetate upon neuronal and vascular development when administration began at birth, 10 days of age, and 20 days of age. Rat pups from pregnant Long-Evans rats were given 600 mg lead acetate/kg body weight every 24 hours beginning at birth, at 10 days, and at 20 days of age. Cumulative doses of from one dose (600 mg/kg) through six doses (3600 mg/kg) were administered via stomach intubation. The pups were sacrificed every 24 hours after administration of the last dose. Five fixed sacrifice intervals were kept for comparison among all dose levels and different administration periods. These were at 10 days, 21 days, 25 days, 30 days, and 50 days. Animals receiving lead acetate beginning at birth displayed vascular hemorrhages throughout the brain, being most prominent in the cerebellum. A minimum of two doses were required to produce vascular effects. No significant body weight changes were found except in one lead treatment where there was a significant increase. Brain weight changes were significantly greater in all dose treatments. Blood lead concentrations were greatest 48 hours after the last dose and dropped ten-fold by 10 days of age. No significant body or brain weight changes occurred in any treatment group when treatment began at 10 or 20 days of age. When treatment began at 10 days of age, chromalytic neurons were present in large numbers in the nucleus gracilis and cuneatus and in smaller amounts in the dorsal horns of the spinal cord and the spinal trigeminal nucleus of 5 and 6 dose treatments. No hemorrhages nor obvious nerve degeneration was found. When treatment began at 20 days of age, no chromatolysis was found in sensory related neurons but peripheral degeneration was found in the sciatic nerve indicating a polyneuropathy was present. This study indicates that lead neurotoxicity may present different neurological deficits in the rat when exposed at different postnatal intervals.

159.4 RELATIONSHIP BETWEEN LOCOMOTOR ACTIVITY RESPONSE AND STRIATAL TYROSINE HYDROXYLASE ACTIVITY IN LEAD-EXPOSED RATS. PM McGinnis.* (SPON: GP Cooper). Dept. Environmental Health, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Childhood susceptibility to the adverse neurological and/or psychological effects associated with exposure to relatively low levels of lead may be mediated by a derangement in CNS synaptic function. The purpose of this study was to relate locomotor behavioral activity to alterations in dopamine neurochemistry (striatal tyrosine hydroxylase activity, TOH) in male rats exposed chronically to lead in a model simulating childhood lead exposure. Suckling pups were exposed to lead-contaminated milk during lactation then weaned onto 0.2% lead acetate in their drinking water. Control pups were exposed to non-contaminated milk during lactation then weaned onto distilled water. Body burden of lead was assessed on days 21 and 95 by analysis of lead concentration and erthyrocyte protoporphyrin. Blood lead was significantly elevated ($p<.0001$) on both days (day 21: 1.5 vs. 54.3 ug/dl; day 95: 2.8 vs. 84.8 ug/dl) in lead-treated rats relative to controls. Erthyrocyte protoporphyrin was also significantly increased ($p<.0001$) in the lead treatment group (day 21: 42.2 vs. 49.3; day 95: 53.0 vs. 84.7). At 91-95 days of age, locomotor activity was measured under red light in photocell activity chambers. The number of photocell breaks was measured at 5 minute intervals. d-Amphetamine sulfate (1mg/kg, sc) was administered after 30 minutes of habituation in the test chamber and then activity monitored for an additional 90 minutes. There was no difference in rate of habituation to the test environment between treatment groups. A significantly greater ($p<.05$) increase in activity 10 minutes following d-amphetamine was seen in the lead-treated rats. Animals in both treatment groups were chosen for subsequent quantitation of TOH activity by Z score criteria based on their activity at this 10 minute interval. The criteria produced 3 groups: low responders, normal responders and high activity responders to d-amphetamine. Animals were sacrificed at day 96-101 for determination of striatal TOH activity by accumulation of 3,4-dihydroxyphenylalanine (DOPA) following inhibition of aromatic-L-amino acid decarboxylase with NSD-1015 (75 mg/kg, ip). HPLC with electrochemical detection was adapted for measurement of DOPA. The use of various doses of α-methyl-p-tyrosine in conjunction with NSD-1015 showed the analytical methodology could discriminate a 22.6% decrease in TOH activity. There was no alteration in striatal TOH activity as measured by DOPA accumulation in adult male rats with a moderately raised body burden of lead due to chronic low level lead exposure since birth. There was no correlation between an individual's TOH activity and locomotor activity response to d-amphetamine nor to his lead body burden. These data suggest the CNS insult due to lead is not mediated by an alteration in striatal TOH activity. (Supported by ES-07073, & U.C. Graduate Studies & Research Office).

159.5 IN VITRO LEAD-INDUCED GABA RELEASE FROM SUPERFUSED RAT CORTICAL SYNAPTOSOMES. D.J. Minnema* and I.A. Michaelson. Dept. Environ. Hlth., U. Cinti. Coll. Med., Cincinnati, OH 45267

Previous studies have reported that inorganic lead (Pb) in vitro does not alter GABA release from rat brain synaptosomes (Silbergeld et al., J. Neurochem. 34:1712, 1980; Ramsey et al., Brain Res., 187:383, 1980). In contrast, the present study demonstrates that Pb (1-30 uM) added in vitro induces ^{3}H-GABA release from preloaded cortical synaptosomes in a dose-dependent manner. Purified synaptosomes (240 ug protein) were resuspended in physiological HEPES buffer and loaded with ^{3}H-GABA (250 nCi, 37°C, 30 min, under 95% O_2/5% CO_2) before being layered onto a 0.65 um pore-size cellulose acetate filter. The synaptosomal bed was superfused at 2 ml/min with HEPES buffer (37°C). After a 10 min washout, superfusate fractions were collected at 15 sec intervals. The first 4 fractions (F1-F4) served as a baseline to which the effects of Pb could be compared. Pb-acetate (1,3, 10 & 30 uM) or Na-acetate (20 uM) was added to the superfusing buffer during F5-F10; followed by normal HEPES buffer (F11-F18); followed by a 1 sec exposure to 61 mM KCl-buffer at the start of F19; then switched back to normal buffer for F20-F22. The amount of ^{3}H (dpms) in each fraction and that remaining on the filter was quantified by LSC spectroscopy. The Pb-induced GABA release was more pronounced in the absence (Figure B) than in the presence (Figure A) of calcium (2.54 mM) in the superfusing buffer. Similar effects of in vitro Pb on dopamine release (this lab) and ACh release (Suszkiw et al., Brain Res. 323:31, 1984) from rat brain synaptosomes have recently been observed. The present finding that Pb in vitro induces GABA release does not support the view that altered GABA release following chronic, neonatal Pb exposure can be explained solely by some factor other than Pb (i.e. elevated Δ-aminolevulinic acid) (Silbergeld & Lamon, J. Occup. Med., 22:680, 1980). (Supported by NIH-NIEHS-03399).



159.6 ZINC-LEAD INTERRELATIONSHIPS IN DEVELOPING RAT BRAIN. E.J. Kasarskis and T.M. Forrester* Depts. Neurology and Toxicology, VA and University of Kentucky Medical Centers, Lexington KY 40536.

Previous investigators have suggested that hippocampal Zn metabolism may be perturbed during postnatal Pb intoxication and may underlie the morphological and behavioral disturbances seen in this condition. Although this hypothesis is attractive and supported by the initial studies of Sato et al. (Soc Neurosci Abstr 9:936,1983), the regional susceptibility and dose-response relationships have not been established.

Female Sprague-Dawley rats (275-300g) were maintained on commercial rat chow and deionized water throughout gestation. After parturition and reduction of litters to 6, developing pups were exposed to Pb indirectly, by administering Pb acetate solutions (0%-4.5%) to groups of dams as their sole fluid source. Growth- and food-restricted groups were included to control for non-specific effects of inanition in the higher Pb groups. Pups were sacrificed at 21 days of age by barbiturate overdose. For each litter, individual brains were removed, dissected into 7 regions which were pooled, digested in nitric acid, and analyzed for Zn and Pb by atomic absorption spectrophotometry. With increasing Pb doses, Pb accumulated in all brain regions; the greatest relative enrichment (20-50 fold) was in brainstem and striatum. Despite near-lethal Pb intoxication and high regional Pb levels, the concentration of Zn was relatively unaffected (2%-15% decrease) in brainstem, midbrain/hypothalamus, striatum, and frontal and occipital cortex. In contrast, the Zn concentration in whole hippocampus and eye was reduced by 50-60% in the highest Pb group when compared to controls.

These data demonstrate marked regional differences in the magnitude of Pb/Zn interaction in brain and suggest that specific Zn pools may be preferentially affected by Pb exposure during CNS development. Greater differences may be detected by Zn analysis of individual hippocampal subfields and may disclose a specific antagonism of the mossy fiber-associated Zn pool by Pb. (Supported by the VA Research Service and the Muscular Dystrophy Association).

159.7 AREA SPECIFIC EFFECT OF LEAD ON ^{3}H-NITRENDIPINE BINDING IN RAT BRAIN. S.Govoni,R.A.Rius*,F.Battaini and M.Trabucchi.Inst. Pharmacol. and Pharmacognosy, Univ. of Milan and Chair of Toxicol., Univ. of Rome, Italy.

Lead (Pb) has been shown to interfere with Calcium (Ca) metabolism in brain (Silbergeld,E.K.,Life Sci.,20-:309,1977). The availability of Ca antagonists offers a biochemical probe for the study of the mechanisms regulating Ca transport in different experimental conditions. The present study investigates the binding of ^{3}H-Nitrendipine (^{3}H-ND) to synaptic membranes prepared from different brain areas after in vitro and in vivo Pb exposure. Females S.D. rats were exposed from day 16 of pregnancy to Pb acetate in the drinking water (2.5 mg/ml). The offspring received the same drinking solution which had been supplied to their mothers until they were killed (at 2-3 months of age). ^{3}H-ND binding was performed according to Gould et al. (P.N.A.S.,79:3656,1982). The in vivo exposure to Pb produced an increase in ^{3}H-ND binding to membranes prepared from striatum (ST; +48%) but not from hippocampus (HI). The increase in ^{3}H-ND binding in ST was not observed in EDTA-EGTA washed membranes, indicating that the effect was due to the persistence of Pb in the tissue. In order to further investigate the mechanisms leading to the different effect of Pb on ^{3}H-ND binding in ST and in HI, the in vitro action of Pb on ^{3}H-ND binding to membranes prepared from different brain areas was studied. Pb stimulated ^{3}H-ND binding in ST and cortex (CX) but not in HI. In addition, in hippocampus Pb inhibited the stimulation of the binding elicited by 200 uM Ca. The area-selective actions of Pb on ^{3}H-ND binding in brain are in line with previous data indicating that Pb displays regional selectivity in its effects on neurotransmitter metabolism (Govoni et al.,Toxicology,12:343,1979). More in general a differential sensitivity of Ca channels to ions of toxicological interest may explain the selective neurotoxic effects of some metal ions in different brain areas.

159.8 EFFECTS OF ALUMINUM ON NEUROTRANSMITTERS AND THE cAMP SYSTEM IN RAT BRAIN. S.A. Khatib, D.W. Allman* and P.A. Shea. Depts. of Biochemistry and Psychiatry, Indiana University School of Medicine, Indianapolis, IN 46223.

Aluminum (Al) has been implicated as the etiological agent in several clinical disorders including dialysis encephalopathy and osteomalacia. In animal studies, toxic amounts of Al caused liver and kidney necrosis, brain atrophy and death. These effects were dependent upon the form and dose of the administered Al. The mechanism(s) of Al toxicity in the CNS is still not known. However, in vitro studies have demonstrated an inhibitory effect of Al on neurotransmitter uptake by synaptosomes and Al was shown to interact with brain calmodulin.

To further investigate the effects of Al on the CNS, 3 groups of rats (7/group) were fed a normal diet for 4 weeks with Al (as $Al_2(SO_4)_3$) added to their drinking water as follows: control group (I) 0% Al (w/w), Al-group (II) 0.1% Al and Al-group (III) 0.5% Al. Rats were sacrificed by the near-freezing method and the dissected brain parts were prepared for the determination of cAMP and biogenic amine levels and adenylate cyclase (AC) and cAMP-phosphodiesterase (cAMP-PDE) activities. In addition, plasma Al concentration was determined. In different brain regions of the Al-treated rats (e.g., cerebral cortex, striatum and midbrain), significant increases compared to control were observed in their dopaminergic and serotonergic systems. Increases in cAMP levels were also observed in group III rats (cerebellum 125% of control, midbrain 75%, pons-medulla 66% and hippocampus 30%) and in group II rats (cerebellum 24% of control, pons-medulla 29% and midbrain 23%). The changes in cAMP levels are studied further by determining the activities of both AC and cAMP-PDE in the different brain regions. In vitro studies on the effect of Al on brain AC showed that in the presence of 5 mM NaF, 5 μM Al caused a significant increase in AC activity. In the absence of NaF, Al did not have any effect on enzyme activity. Plasma Al concentration was found to be elevated in the Al-treated rats when compared with the control group. (Supported by grants from Indiana Dept. of Mental Health and A-Mideast).

159.9 REVERSIBLE CHANGE IN THE BLOOD-BRAIN BARRIER PERMEABILITY INDUCED BY INTRAVENOUS ALUMINUM IN THE RAT. Yong Sun Kim, Moon H. Lee and Henry M. Wisniewski*. New York State Office of Mental Retardation and Developmental Disabilities, Institute for Basic Research in Developmental Disabilities, Staten Island, New York 10314

We have previously reported that an intraperitoneal injection of aluminum increased the permeability of the blood-brain barrier (BBB). The change, which lasted for a few hours after aluminum administration, appeared to be closely related to the blood aluminum concentration. In this experiment, we attempted to determine the time course of the BBB change in response to aluminum injected intravenously.

Adult Sprague-Dawley rats, under pentobarbital anesthesia, were given an injection of 10 mg/kg of aluminum lactate in a volume of 0.5 ml into the left femoral vein, followed by 0.5 ml of saline containing 5 μCi of ^{14}C-sucrose injected in the right femoral vein at either 5 min, 20 min, or 60 min post aluminum injection. The control animals received the same volume of ^{14}C-sucrose 5 min after 0.5 ml of an intravenous injection of isotonic saline. Plasma radioactivity was measured until the animals were decapitated 5 min after the tracer injection, at which time brain radioactivity was measured from five different brain regions. The cerebrovascular permeability and surface area (PA) were calculated using the Rapoport model (Brain Res.,150:653-657, 1978). As indicated in the table below, the BBB permeability became increased immediately (within 5 min) following the intravenous aluminum injection. The PAs remained elevated at 20 min post-injection. By 60 min, the BBB in the forebrain had returned to normal, while the brain stem still had an increased BBB permeability. The response of the BBB to aluminum at shorter time intervals is currently under investigation.

	Mean PA X $10^6 \cdot s^{-1}$			
Brain Regions	Control (n=7)	Al 5 min (n=5)	Al 20 min (n=4)	Al 60 min (n=5)
Cortex	54.4	77.1**	89.5**	66.6

159.10 DENTATE GYRUS GRANULE CELL RESPONSES TO LOCAL APPLICATION OF TRIMETHYLTIN. D.L. Armstrong, H.L. Read*, and M.J. Wayner. Division of Life Sciences, University of Texas at San Antonio, San Antonio, TX 78285

The mechanism of action of the neurotoxin trimethyltin (TMT) is still unknown despite extensive investigation. The high sensitivity of specific brain regions, particularly within the hippocampus, suggests that TMT is interacting with systems within these regions or affecting input to these regions and thus producing local necrosis. Our laboratory has utilized iontophoretic application of TMT to investigate the immediate response of mouse hippocampal neurons to toxin exposure. The present study employed the pressure ejection application method since this procedure has yielded much more reliable dose-response curves for this compound.

Two-, three-, and four-barrel microelectrodes were used to apply trimethyltin chloride in concentrations ranging from 10 to 100 mM. 1.0 M glutamate and 0.15 M NaCl applications were used as control ejections. Thirty-eight spontaneously active granule cells in mouse hippocampal slices were tested. Seventeen of these cells responded to TMT application with increases in spontaneous activity. Spikes per second records revealed a 100 to 200% increase in activity with a latency of 0.5 to 1.0 seconds. AT lower doses the duration of effect corresponded to the 5 sec period of toxin ejection, however, higher doses produced a more sustained increase in activity. Ten cells displayed a variable response to the toxin that included spontaneous bursting activity or biphasic increases then decreases in activity. Eleven cells displayed no response to the doses employed in this study. Direct postsynaptic interactions or alterations in interneuron inhibition of a subpopulation of granule appears to occur with a short latency following TMT application. The mechanism by which this immediate effect could lead to cell death is being investigated.

159.11 IRON-INITIATED LIPID PEROXIDATION IN MURINE SPINAL CORD CULTURES. D. K. Anderson & E. D. Means, VA Medical Center, Cincinnati, OH 45220.

We have previously demonstrated (Trans Am Soc Neurochem 15 (1): 130, 1984) that incubation of 50μM $FeCl_2$ with dissociated murine spinal cord cultures (11-13 day embryos) for 1 hr resulted in a significant decline in Na^+, K^+-ATPase activity; an effect that was partially reversed by methylprednisolone sodium succinate (MPSS), alpha tocopherol and mannitol. This suggested that iron inhibited Na^+, K^+-ATPase, at least in part, by initiating peroxidation in membrane lipids. The purpose of the present study was to confirm the occurrence of lipid peroxidation in cultures exposed to $FeCl_2$ by assaying for thiobarbaturic reactive (TBAR) materials and to correlate the TBAR material changes with those of Na^+, K^+-ATPase in untreated and MPSS, alpha tocopherol, or mannitol-treated cultures. TBAR materials were elevated 5.3 and 6.2-fold in cultures incubated with 50μM $FeCl_2$ for 1 and 2 hr, respectively. 100μM MPSS or 50μM alpha tocopherol, or 50μM mannitol partially blocked the rise in TBAR materials at both times. There was a strong negative correlation (r = -0.87) between levels of TBAR materials and Na^+, K^+-ATPase activity at both 1 and 2 hr. Additionally, incubation of cultures with either MPSS for 1 hr or alpha tocopherol for 24 hrs resulted in a 1.5 and 1.3-fold increase in Na^+, K^+-ATPase activity, respectively. After 120 min incubation with MPSS, there was an additional 1.3-fold increase in Na^+, K^+-ATPase activity but no further increase in Na^+, K^+-ATPase activity in cultures incubated with alpha tocopherol. This secondary MPSS stimulated increase in Na^+, K^+-ATPase activity was blocked by the protein synthesis inhibitor, cyclohexamide and the RNA synthesis inhibitor, actinomyosin D. These results suggest that iron initiates peroxidative reactions in neuronal membranes. Since both alpha tocopherol and MPSS are known antioxidants, these agents appear to protect by limiting the iron-initiated lipid peroxidation. The partial protection by mannitol suggests that $OH^\cdot$ may have been involved in the initiation of peroxidation. MPSS may also protect against the iron-initiated partial inactivation of Na^+, K^+-ATPase by inducing the formation of additional Na^+, K^+-ATPase molecules.

159.12 NEURONAL NECROSIS AND PHAGOCYTOSIS BY NEUTROPHILS AND PROSTANOID CHANGES FOLLOWING PEROXIDATION. E. D. Means, R. Saunders*, D. K. Anderson, and L. Horrocks. VAMC, Cincinnati, OH 45220 and Ohio State Univ. Col. Med., Columbus, OH 43210.

Murine spinal cord cultures were exposed to ADP/Fe^{2+} (0.5mM/0.1 mM) for 20 min after removal of the growth media. The media containing the ADP/Fe^{2+} was replaced and neutrophils were added ($0.5\text{-}1.0 \times 10^4$). Controls consisted of normal cultures, peroxidized cultures and cultures with neutrophils added. At 2, 4, 6 and 24 hr the media was removed and frozen at -70°C. The cultures were fixed and stained with cresyl violet. Other cultures were pretreated with alpha tocopherol (50μM), methylprednisolone sodium succinate (MPSS) (0.1mM) or mannitol (1%). Controls consisted of pretreated, pretreated-peroxidized, and pretreated peroxidized with neutrophils added. Peroxidized cultures showed minor fragmentation of processes and irregularity of the neuronal membrane. Peroxidized cultures with neutrophils showed significant neuronal necrosis and phagocytosis by neutrophils. Pretreated cultures showed cytological protection (alpha tocopherol > mannitol > MPSS). Radioimmunoassay (RIA) was performed on the individual media for prostaglandin E_2 (PGE_2), $F_{2\alpha}$, ($PGF_{2\alpha}$) & slow reactive substances (SRS; primarily leukotrienes C_4, D_4 and E_4). SRS's were undetectable in the media from all cultures. The lowest values for PGE_2 and $PGF_{2\alpha}$ (100-200pg) occurred in media from normal cultures and from cultures with neutrophils and with alpha tocopherol, mannitol and MPSS. Highest values (700-1000pg) were noted in media that had been pretreated with alpha tocopherol and peroxidized or pretreated with either alpha tocopherol, mannitol or MPSS, peroxidized and neutrophils added. These data suggest that (a) lipoxygenase may be inhibited making more arachidonate available for conversion to prostaglandins, or (b) high levels of lipid hydroperoxides inactivate cyclooxygenase while alpha tocopherol, mannitol and MPSS decrease the levels of lipid hydroperoxides resulting in higher concentration of PGE_2 and $PGF_{2\alpha}$.

159.13 TREMORGENIC MYCOTOXINS ENHANCE DIHYDROPYRIDINE BINDING IN RAT CORTEX. J.J. Valdes, R.J. Cole* and D.H. Ross. Biotechnology Div., Aberdeen Proving Ground, MD 21010; Dept. Agriculture, Dawson, GA 31742; Dept. Pharmacology, Univ. Texas Hlth. Sci. Ctr., San Antonio, TX 78284.

The flux of Ca++ through voltage-dependent channels is important for contractile processes in cardiac and smooth muscle and for transmitter release from nerve terminals. Although these channels may differ pharmacologically in their degree of coupling to dihydropyridine receptors and sensitivity to organic Ca++ channel blockers such as nifedipine, dihydropyridine receptor binding nevertheless has utility for the identification of compounds with potential consequences for Ca++ channel activity, and subsequent relevance to convulsive behaviors. Recently, economically important mycotoxins from the fungal genera Penicillium, Aspergillus and Claviceps have been found to induce tremors and seizures in humans and cattle. These tremorgens belong to several chemically distinct groups, including the fumitremorgens, the paspalitrems, and the tetramic acids. The best known compounds within these groups are verruculogen (P. verruculosum), aflatrem (A. flavus), and cyclopiazonic acid (P. cyclopium), respectively. The fumitremorgens and paspalitrems have, in common, an indole moiety derived from tryptophan, while the tetramic acids, though chemically related, are not considered true tremorgens. All three share, however, the ability to induce tremors and seizures which are similar to those induced by the naturally occurring marine toxin and Ca++ channel agonist, maitotoxin. Therefore, dihydropyridine receptor binding , defined as nifedipine displaceable 3H-nitrendipine binding, was assessed in cortical synaptic membranes from rats injected with a single intraperitoneal tremorgenic dose of verruculogen (1mg/kg), aflatrem (3mg/kg), cyclopiazonic acid (3 mg/kg), or DMSO vehicle, and decapitated 1 hr post-injection. There was an 88% increase in the number of binding sites following aflatrem treatment (Bmax = 100 fMol/mg protein), and a 43% increase in rats given cyclopiazonic acid (Bmax = 76 fMol/mg protein) relative to controls (Bmax = 53 fMol/mg protein). Verruculogen had only marginal effects (Bmax = 61 fMol/mg protein). These results suggest that aflatrem and cyclopiazonic acid act at dihydropyridine receptors and may, like maitotoxin, fix the Ca++ channel in an open configuration.

159.14 DIFFERENTIAL VULNERABILITY TO INSULT DURING THE BRAIN GROWTH SPURT IN RAT PUPS. J. Diaz,J. Hwang* and L. Jones*. Dept. of Psych., Univ. of Washington, Seattle, WA 98195.

The brain growth spurt (BGS) which occurs relatively late in mammallian brain development is thought to be a period of heightened vulnerability to a variety of insults. The BGS encompasses a long period of time, from mid-gestation to the fourth postnatal year in humans and approximately from postnatal day 4 through day 21 in rats. Few studies have examined insults which occur at different times within the BGS. The purpose of the present experiment is to describe the effects of RNA synthesis inhibition during the early accelerating phase, the peak velocity phase or the later decelerating phase of the BGS.

Long-Evans rats were assigned by weight on postnatal Day 4 to one of six groups: 1) pups injected with methlyazoxymethanol acetate (MAMA) daily from day 4 through day 7 (n=14); 2) pups injected daily with saline from day 4 through day 7 (n=16); 3) pups injected with MAMA daily from day 8 through day 11 (n=12); 4) pups injected daily with saline from day 8 through day 11 (n=15); 5) pups injected with MAMA daily from day 12 through day 15 (n=8); 6) pups injected daily with saline from day 12 through day 15 (n=15). MAMA was injected at a dose of 10 mg/kg (sub.cu.) and controls received an equal volume of saline. All the animals were weighed each morning . Each pup was sacrificed on the morning after its last injection, and its brain removed, dissected and weighed; and its liver, kidney, and spleen were also removed and weighed.

RNA synthesis inhibition suppressed whole brain weight and whole body weight equally at the three time periods. However, an examination of the individual components which comprise these weights revealed that : 1) cerebellar growth was depressed more during the early and peak periods of the BGS than during the late phase; 2) brain stem growth was depressed most during the peak of the BGS; 3) rostral brain growth was equally depressed during the three periods. The pattern of drug induced growth suppression in liver weight resembled that seen in the cerebellum, whereas kidney weight showed a significant linear increase over time in the drug animals when compared to the controls. Spleen growth showed a biphasic pattern over time in the drug groups.

These data indicate that within the period of the brain growth spurt different areas of the developing brain may have different corridors of vulnerability . The suppression of cerebellar growth exemplifies this point, since its growth spurt begins sooner and is faster than the rest of the brain. The description of individual growth patterns of specific brain areas as well as the persistence and functional significance of growth disruption at different times on the BGS must be determined. 159.15 OLFACTORY BULB DEVELOPMENT IN GUINEA PIGS EXPOSED TO ETHANOL DURING THE LATER HALF OF GESTATION. C. Nyquist Battie. School of Basic Life Sciences, Univ. of Missouri, Kansas City, MO 64108.

The olfactory bulb with its simple cortical organization and well-worked out anatomy and physiology is a good area in which to study teratogens. Decreased overall growth of the mouse olfactory bulb(OB) has been shown to result from perinatal exposure to ethanol (ETOH), although synaptic connections form normally (Int. J. Devel. Neurosci., in press). In that study ETOH was administered primarily after birth, which may not mimic human Fetal Alcohol Syndrome. To circumvent this problem, a guinea pig model was developed because of their longer gestation. An ETOH solution(30% v/v in ENSURE diet) was administered twice daily to 6 pregnant guinea pigs from day 35 of gestation to parturition at 69-70 days for a total of 6 gm ETOH/kg weight per day. Serum ETOH levels ranged from 170-200 mg% 1 hour after administration. The control group received the liquid diet but with isocaloric replacement of ETOH by sucrose.

No differences between the groups were found in food and water intake, nor in litter size, length of gestation and in offspring weight and length on the day of birth. No facial or somatic deformaties were seen in the ETOH newborns. Under barbiturate anesthesia, newborn guinea pigs were perfused, OBs were removed, embedded in glycol methacrylate, sectioned at 1μm and stained with cresyl violet. Histologic changes, attributable to ETOH, were seen. Abnormal clumping of granule cells, leaving larger than normal acellular areas, were common. In many sections mitral cells were in disarray, although most had the mature mitral shape. These changes could indicate abnormal migration. A few cells were swollen and had reduced nissl staining. In both control and ETOH OBs, glomeruli were not fully developed and migrating cells were seen in the external plexiform layer. The size of the mitral cell nucleus was examined in coronal sections, but no ethanol-induced change in size was noted. The percentage of mitral cells having more than 1 nucleoli was higher in ETOH OBs (53% vs. 44%), which may indicate a state of immaturity. ETOH also affected OB growth. The mean diameter of the glomeruli was lowered by ETOH (74.6± 2.0 vs. 83.8± 1.8) as was the width of the external plexiform layer (244± 8 vs. 272± 5.3 μm). It can be concluded that ETOH is detrimental to OB development in the guinea pig, a useful model of Fetal Alcohol Syndrome.

160.1 REINFORCEMENT-RELATED UNIT ACTIVITY IN BASAL FOREBRAIN AND AMYGDALA F.A.W. Wilson & E.T. Rolls, Department of Experimental Psychology, University of Oxford, Oxford, U.K.

Basal forebrain and amygdala unit activity reflecting the availability of reinforcement has been compared in behaving monkeys. In a visual discrimination task the monkeys could make a lick movement to obtain fruit juice when one stimulus (S+) was shown; responses to the other stimulus (S-) produced aversive saline. A reversal task required the monkey to respond to the former S- to obtain juice, and not to respond to the former S+ to avoid saline. In a serial recognition memory task stimuli were shown twice per day, once as novel and once as familiar. Lick responses to stimuli when novel produced saline and when familiar produced fruit juice.

A population of units (108/2004) in the substantia innominata and diagonal band of Broca responded differentially to the S+ and S-. 81 of these 108 units responded maximally to the S+ (and also to familiar stimuli) predicting fruit juice; 27 of these 108 units responded maximally to the S- (and novel stimuli) predicting saline. The differential response to novel and familiar stimuli was maintained when several trials (typically 8 tested) separated novel and familiar presentations of stimuli, reflecting memory for the stimuli. In the reversal task units responsive to the former S+ responded to the former S-; units responsive to the former S- changed response to the former S+.

Units (17/657) located mainly in the dorsal medial amygdala responded differentially to the S+ and S-. 16 of the 17 differential units responded maximally to the S+. 12/14 of these units did not respond differentially to novel and familiar stimuli, responding equally to these stimuli. Therefore when the reinforcement value of stimuli was determined by the novelty/familiarity of the stimuli, most amygdala units did not reflect the reinforcement value of the stimuli. Of the 2 units tested in the reversal task neither showed significant changes in response.

Both populations of differential units reflect the learned reinforcement value of the S+ and S-, but the responses of amygdala units are not entirely specified by the reinforcement value of the stimuli. In contrast, basal forebrain unit activity changes with changes of stimulus reinforcement value (the results from the recognition and reversal tasks); these units also reflect memory for stimulus novelty and familiarity important for specifying reinforcement within the task.

160.2 THE RESPONSES OF SINGLE NEURONS IN THE PRIMATE HIPPOCAMPUS RELATED TO THE PERFORMANCE OF MEMORY TASKS. E.T.Rolls, Y.Miyashita*, P.Cahusac* and R.P.Kesner. Dept. Exptl. Psychol., Oxford University, Oxford, England.

In order to analyze the functions of the hippocampus of the primate, the activity of 1510 single hippocampal neurons was recorded in rhesus monkeys performing memory tasks known to be impaired by damage to the hippocampus or fornix.

In an object-place memory task in which the monkey had to remember not only which object had been seen in the previous 7-15 trials, but also the position in which it had appeared on a video monitor, neurons were found which responded differentially depending on which place on the screen objects were shown. These neurons comprised 5.7 % of the population recorded. It is notable that these neurons responded to particular positions in space (whereas 'place' cells in the rat respond when the rat is in a particular place). In addition, 1.0 % of neurons responded to a combination of place and novelty, in that they responded more to a stimulus the first time it was shown in a particular position than the second time. Most of these neurons had response latencies in the range 100-200 ms, compared to typical behavioral response latencies of 350 ms.

In tasks in which the monkeys had to acquire associations between stimuli and motor responses, 10.6 % of neurons responded to particular combinations of stimuli and responses. For example, in a task in which the monkey had to perform a touch response 3 times when one visual stimulus was shown, but had to perform a witholding response for 3 sec to obtain reward when a different stimulus was shown (FR-DRO, Gaffan and Harrison, 1984, Quart. J. Exp. Psychol. 36B: 223-234), 9.2 % of neurons responded to one of the stimuli if it was linked to one of the responses in this task. The same neurons typically did not respond if the same stimuli or the same responses were used in different tasks.

In recognition memory tasks, a small proportion of neurons (0.7 %) responded differently to novel as compared to familiar stimuli. In addition, some further neurons responded to novel stimuli in other memory tasks such as a delayed match to sample.

These results show that hippocampal neurons in the primate have responses related to certain types of memory. Their responses appear to reflect holding information in memory for tasks which involve memory for where in the environment stimuli have been seen, and which motor responses should be made to particular stimuli.

160.3 VISUAL PROPERTIES OF PREFRONTAL CORTICAL NEURONS. S. Funahashi*, C.J. Bruce, and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven CT 06510.

According to previous reports, many prefrontal (PF) neurons respond to visual stimuli and have visual receptive fields (RFs). We further examined visual activity in PF cortex by studying single units there while monkeys performed a visual fixation task. Their heads were fixed and a magnetic search coil was used to monitor gaze. Both the fixation spot (0.2 degree diameter) and test stimuli (0.7 degree square) were presented on a monochrome CRT. Test stimuli were presented for 1 sec during the 3 sec fixation period and stimulus location was systematically varied within a polar coordinate framework. For directional tests, stimulus eccentricity was fixed and different angular directions, often spanning 360 degrees, were interspersed. For eccentricity tests, direction was fixed and different eccentricities out to 20 degrees were interspersed.

Of 135 PF neurons studied, 76 responded to peripheral test stimuli and visual RFs of 37 were mapped. Nearly all RFs (32/37) were bilateral; only 3 were ipsilateral and 2 contralateral. Most RFs subtended large portions of visual space, although some appeared to be discontinuous or patchy. Many RFs encompassed the center of gaze as judged both by responses to the fixation light and to test stimuli superimposed on it. Overall, these RFs differed somewhat from previous studies, which have found many visual RFs of PF neurons to be unilateral or discrete. We also examined the influence of direction of gaze on visual responses of PF neurons because PF cortex is reciprocally connected with posterior parietal cortex where visual activity can be influenced by direction of gaze. We simply moved the CRT 20 degrees to the left or right, and retested using the same fixation point and stimulus arrays, thereby stimulating the same retinal coordinates while the gaze was eccentric. For 7 PF neurons visual responses depended only on the retinal coordinates, but for 6 PF neurons responses depended upon direction of gaze as well in that visual responses from the same retinal locations were greater during eccentric fixation.

These visual properties of PF neurons indicate considerable convergence from the much smaller, exclusively contralateral visual RFs of neurons in striate and prestriate cortex, and suggest that visual processing in PF cortex might more resemble that described in higher-order visual association cortices such as posterior parietal and inferotemporal cortex. Supported by MH38546, EY04740, and a grant from the H.F. Guggenheim Foundation.

160.4 BEHAVIORAL RELEVANCE, A DECISIVE FACTOR IN THE RESPONSE OF PREFRONTAL NEURONS TO VISUAL STIMULI. J. Yajeya*, J. Quintana* and J.M. Fuster. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, CA 90024.

The activity of 150 single units was recorded from the monkey's lateral prefrontal cortex (sulcus principalis area) during performance of two visual discrimination tasks with delayed choice; in one task, the choice was between colors, in the other, between positions. In both, a trial was initiated by a diffuse low-intensity flash which served as a signal for ocular fixation (verified by EOG) on a centrally located 2.5-cm translucid disk (8°), on which 2 sec later a color light, the cue for the trial, was projected for 0.5 sec. After an 18-sec delay, the choice stimuli were presented on two lower disks. In one task, red or green cue called for the choice of that color when the two appeared after the delay; in the other task, yellow or blue cue called for choice of response side (right or left, respectively) between two white-light disks. A fifth color-cue, violet, was not followed by choice-stimuli. All cues were of equal brightness. Some of the units showed color- or task-differential reactions, but these were generally overshadowed by differences of reaction as a function of the behavioral significance of the cue. The behaviorally irrelevant stimulus (violet) tended to elicit unit responses of different magnitude than the other four. In a relatively inferior location of prefrontal cortex, the relevant stimuli induced protracted cell reactions lasting for much or all of the delay period. No such reactions were induced by the irrelevant stimulus. In conclusion, prefrontal units, at least within the area so far explored, seem to differentiate visual stimuli more by their behavioral significance than by their color or the particular task they cue. This is most evident during the delay period of delay tasks. It is well known that the functional integrity of the lateral prefrontal cortex is essential for normal performance of such tasks. The unit findings reported here provide further evidence of participation of the neurons of that cortex in the performance of these tasks and, thus, in the mediation of cross-temporal contingencies of behavior.

160.5 ADAPTIVE PLASTICITY IN THE PRIMATE SPINAL STRETCH REFLEX: PERSISTENCE. J. A. O'Keefe* and J. R. Wolpaw (SPON: A. J. Popp). Wadsworth Ctr. for Labs and Research, New York State Dept. of Health, Albany, NY 12201; and Depts. of Neurology and Anatomy, Albany Medical College, Albany, NY 12208.

Previous work (J. Neurophysiol. 50:1296-1319, 1983) showed that monkeys can gradually change the amplitude (amp) of the wholly segmental, largely monosynaptic, spinal stretch reflex (SSR) when confronted by a task requiring change. We studied the persistence of SSR change after non-performance periods of 2-38 days.

Eleven animals (Macaca nemestrina) with chronic EMG electrodes in biceps and related muscles learned to maintain elbow angle and a given level of biceps EMG against constant extension torque. At random times, a brief additional extension torque pulse elicited the biceps SSR. In the control mode, reward always followed. Under the SSR↑ or SSR↓ mode, reward occurred only if the absolute value of biceps EMG in the SSR interval (15-24 msec after the pulse) was above or below a set level. Animals completed 3,000-6,000 trials daily. Animals worked first under the control mode for up to 60 days and then under the SSR↑ or SSR↓ mode for up to 100 days. Some were then exposed to sequences including mode reversal (SSR↑ to SSR↓ or vice versa) and re-exposure to the previous mode. They responded to each SSR↑ or SSR↓ mode exposure with gradual mode-appropriate change in SSR amp. Mode exposures were interrupted by gaps in performance of 2-38 days.

Short gaps of 2-4 days had no discernible effects on SSR amp under any mode. Long gaps of 10-38 days produced transient 10-15% decrease in SSR amp under the control mode. This nonspecific decrease disappeared over the first post-gap week. Long gaps under the control mode had no other effects.

Under the SSR↑ mode, long gaps caused a significant loss of adaptive SSR increase. Pre-gap amp averaged 168% of control, while post-gap amp averaged 128%. Thus, in the absence of performance, SSR increase appeared to decay with a half-life of about 17 days. Unlike SSR↑ gaps, gaps during the SSR↓ mode had no consistent effect on SSR adaptive change. The average pre-gap amplitude of 63.6% of control was not significantly different from the average post-gap value of 66.4%. Thus, in the absence of performance, SSR decrease usually persisted without significant change for at least one month. The data did not show rapid adaptive change in the early post-gap period under either mode. SSR behavior in this period was a combination of recovery from the modest nonspecific gap-induced decrease and resumption of slow mode-appropriate adaptive change.

These results further support the hypothesis that adaptive SSR change involves persistent segmental alterations and thus may provide a technically accessible substrate of memory.

160.6 VISUAL RESPONSES IN MONKEY LATERAL HYPOTHALAMIC AREA DURING FEEDING BEHAVIOR. T. Ono, M. Fukuda* and H. Nishino. Dept. of Physiol., Fac. of Med., Toyama Med. & Pharmaceu. Univ., Sugitani, Toyama 930-01, JAPAN.

Single neuron activity was recorded from monkey lateral hypothalamus to investigate correlation of neuronal events with food discrimination and initiation of procurement motion in operant bar press feeding behavior. The operant feeding task consisted of discrimination of food, and bar pressing behavior to obtain food. These phases were separated by a forced wait of more than 2 sec before the animal could press the bar after the visual stimulus. Of 429 neurons tested, 68 (16%) responded during the visual phase. Of these, 30 (7%) responded selectively to the sight of a food or non-food object associated with the juice reward, but not to the sight of a meaningless or non-food object, or an object associated with aversive saline. The latency of food-related visual responses was 191±58 msec (mean±S.D., n=30), which was longer than that of non-discriminative visual responses (158±61 msec, n = 38) ($p<0.05$). In extinction tests, in which the monkey could not obtain food even he did press the bar, the animal pressed progressively later in successive trials. Of 11 food-related neurons tested, neuronal responses of 9 became weaker in successive trials and finally disappeared. The latency of the visual responses tended to become later in successive trials. The disappearance of food-related visual responses was also observed in reversal tests and upon satiation by food. The strength of the visual responses was correlated with the latency of the first bar press initiation and the speed of bar pressing. Also, there was highly significant correlation between the disappearance of the visual responses and the cessation of bar pressing behavior for food. The neuronal responses tended to disappear before the cessation of bar pressing behavior for food.

The data suggest that LHA neuron activity is intimately related to discrimination of reinforcement or non-reinforcement, and drive state to get food during operant feeding behavior. These are affected by learning and internal states such as hunger and satiety.

160.7 NEURONAL ACTIVITY OF PREFRONTAL CORTEX AND DORSOMEDIAL THALALMUS DURING A CONTINUOUS NONMATCHING-TO-SAMPLE TASK IN THE RAT. Y. SAKURAI. Dept. of Behavioral Sciences, Fac. of Integrated Arts and Sciences, Hiroshima Univ., Higashisenda-machi, Naka-ku, Hiroshima 730, Japan.

Prefrontal cortex (PFC) and dorsomedial thalamus (DMT) are thought to be involved in memory-based control of an operant response. By using a delayed go/no-go alternation task, we have suggested a functional hierarchy from DMT to PFC, that is a primary role of PFC in the response control function and that of DMT in the processing of working memory for responses (Sakurai & Sugimoto, Behav. Brain Res., in press). This study also focused attention on the memory-based control of response and elucidated the functions of PFC and DMT especially in the processing of working memory for external stimuli.

Rats were trained to perform a new delayed matching-to-sample task - the continuous nonmatching-to-sample task with Go/No-Go responses. A variable number of trials with low tone (1 kHz) stimulus alternated with trials with high tone (8 kHz) stimulus. A panelpress response (Go) on a trial following a stimulus change (nonmatch trial) was reinforced with food. Responses to repeated stimuli (match trials) were never reinforced. The animals were required to remember across the intertrial interval (delay period) which tone was presented on the previous trial and to emit or inhibit a response according to the memory process. Almost animals acquired the task with 3-sec of delay within 20 days of training. After the completion of training, the rats were chronically implanted with 25μ microwire electrodes into PFC and DMT and unit activity was recorded during performance of the task.

To the present four types of task-related neurons have been observed. 1) Retention-related type increased or decreased its activity during the delay period. 2) Response priming type responded to the tone presentation on a nonmatch trial for Go response. 3) Response inhibition type responded to the tone presentation on a match trial for No-Go response. 4) Tone recognition or retrieval type phasically responded to the tone both on match and nonmatch trials. We furthermore analyzed activity of those task-related neurons when the delay period was changed from 3 to 6 sec and after the animals had aquired the task with 6-sec of delay. The data from this experiment in conjunction with that from neuronal recording during a task which required working memory for responses, not external stimuli, (Sakurai & Sugimoto, Behav. Brain Res., in press) further delineates the role of PFC and DMT in working memory processing and control of an operant response.

This work was supported in part by a Grant-in-Aid for Scientific Research 59710072 from the Japanese Ministry of Education.

160.8 SEQUENTIAL DEPENDENCIES REGULATE SENSORY EVOKED RESPONSE OF SINGLE UNITS IN THE RAT HIPPOCAMPUS. R.E. Hampson*, T.C. Foster*, E.P. Christian, K.A. Campbell, and S.A. Deadwyler. Bowman Gray Sch. of Med., Winston-Salem, NC 27103

Past investigations have shown that preceding sequence of CS+/CS- trials in a 2-tone discrimination task affect the amplitude of auditory evoked potentials recorded in the outer molecular layer of the dentate gyrus. In this study, unit firing records from three major types of hippocampal cells were recorded from microdrive electrodes arranged to traverse the CA1, CA3 and dentate granule cell layers of the hippocampus. Classification of units as complex spike (ComSp), theta (T), and dentate granule cells (G) was according to criteria based on spontaneous and stimulus evoked firing characteristics. Single trial records for each cell type were collected from over 20 different sessions when behavioral performance was at criterion levels (n=15). Standard (Z) scores of pre- vs post-tone firing rate for each trial were analyzed by 2- and 3-way ANOVAs of cell type, CS+ vs CS- trials and preceding trial sequence.

Mean pre-tone firing rate for G cells was 17 spikes/sec., for T cells: 25 spikes/sec., and for ComSp cells: 1.5 spikes/sec. The mean post-stimulus histogram latency to peak discharge for CS+ trials was the same (90 msec.) for T, G and ComSp cells. Peak discharge occurred 100 msec after CS- trials for T and G cells and 80 msec for ComSp cells. All three cell types exhibited significant fluctuations in pre- vs post-tone firing rate (Z-scores) dependent on whether CS+ or CS- trials occurred. The main effect of preceding trial sequence on individual trial Z-scores was highly significant ($p<.001$). The Z-scores for runs of CS- trials were significantly decreased in relation to Z-scores for the CS+ run in all cells ($p<.01$). The average Z-scores for T and G cells decreased significantly during double alternation vs single alternation sequences ($p<.05$), and increased during runs of 3 or more CS+ or CS- trials ($p<.05$); however, T and G cells did not differ with respect to these sequences. In contrast to T and G cells, Z-scores for ComSp cells were significantly lower during single alternation and higher during double alternation sequences ($p<.01$). In addition ComSp cell Z-scores decreased to a significantly lower level than T and G cells during runs of 3 or more CS+ or CS- trials. When the current trial was not considered, ComSp cells were shown to be significantly affected by the preceding sequence of 3 to 5 trials ($p<.01$), whereas T and G cells were more strongly affected by the current trial.

Results showed a pronounced similarity between firing characteristics of G and T cells with respect to trial sequence. ComSp cells exhibited changes in firing characteristics which were opposite to T and G cells.

160.9 HIPPOCAMPECTOMY ALTERS CONDITIONED RESPONSE ONSET IN LONG DELAY CONDITIONING. A. L. Beggs, R. L. Port, A. G. Romano, and M. M. Patterson, Dept. of Psychology and Coll. of Osteopathic Medicine, Ohio Univ., Athens, OH 45701.

It has been demonstrated that the hippocampus generates a multiple-unit "model" of the classically conditioned rabbit nictitating membrane response (Berger & Thompson, 1978). However, hippocampectomy has no deleterious effect on the acquisition of conditioned responses (Schmaltz & Theios, 1972). Therefore, any involvement of the hippocampal "model" in classical conditioning must be nonessential to the basic substrate of the association. Hoehler and Thompson (1980) reported that the hippocampal "model" adjusts to a change in the CS-US interval more quickly than the behavioral response. Thus, the "model" may modulate temporal aspects of CRs dependent upon the parameters of the stimulus configuration. In an earlier study (Port, Mikhail & Patterson, 1985), we found that hippocampectomy influenced the rate of learning in short and long intervals but had no effect in a moderate interval. Hippocampectomy also decreased response onset latency in the short interval but had no statistically significant effect in the long interval. Recent evidence (Marek, McMaster, Harvey & Gormezano, 1984) suggests that the neural pathways mediating reflexive responses to corneal air puff and periorbital shock are somewhat different. If the hippocampus modifies temporal characteristics of conditioned responses, the effects of hippocampectomy on CR timing may be influenced by the US. The present experiment examined the effect of hippocampectomy on response onset in a long delay procedure. A corneal air puff was employed as the US; the preceding study utilized periorbital shock.

Rabbits were assigned to hippocampal lesion, cortical lesion and nonoperated control groups. Bilateral aspirations lesions of the hippocampus or neocortex were produced under fluothane anesthesia. Damaged animals were permitted two weeks to recover. Subjects were classically conditioned with a tone CS and air puff US. CS duration was 850 ms, US duration was 100 ms, and the CS-US interval was 750 ms. Sixty trials were given each day for four consecutive days. Hippocampectomy had no significant effect on the rate of acquisition. However, conditioned responses given by hippocampal damaged animals began earlier in the interval than responses given by cortically lesioned or nonoperated animals.

These results are consistent with the notion that the hippocampus modulates temporal characteristics of conditioned responses. The magnitude of hippocampal lesion effects on simple acquisition appears to be influenced by the response system as well as the CS-US interval. Nonetheless, the "model" of the CR which develops within the hippocampus appears to play a "purposive" role in classical conditioning.

160.10 HIPPOCAMPAL SUBSTRATE OF SENSORY-SENSORY ASSOCIATIONS: ELECTROPHYSIOLOGICAL AND LESION ANALYSES OF SENSORY PRECONDITIONING. R. L. Port, A. G. Romano, D. O. Berger*, and M. M. Patterson, Dept. of Psychology and Coll. of Osteopathic Med., Ohio Univ., Athens, OH 45701.

Many of the learning deficits exhibited by hippocampal lesioned animals occur in situations in which no reflexive motor response is present. Hippocampectomy impairs learning in latent inhibition (Solomon & Moore, 1975), reversal learning (Berger & Orr, 1983) and extinction (Schmaltz & Theios, 1972). However, simple CS-US associations are not impeded by hippocampal lesions (Port, Mikhail & Patterson, 1985). Since the absence of reflexive behavior appears to indicate the learning tasks in which hippocampal participation is vital, we have adopted Brogden's (1939) sensory preconditioning paradigm to study hippocampal involvement in plasticity. An earlier study (Port & Patterson, 1984) had revealed that electrolytic lesions of the fimbria abolished the CS-CS association but had no significant effect during CS-US training. The present research examined hippocampal multiple-unit activity during preconditioning and the effects of hippocampal lesions on the CS-CS association.

In the first experiment, rabbits were anesthetized with fluothane and implanted with chronic recording electrodes placed in the CA1 layer of the dorsal hippocampus. Multiple unit activity was recorded during paired presentations of light and tone for the preconditioned group, or during unpaired presentations for the control group. Animals were then classically conditioned with the light CS and a periorbital shock US. After CS-US training, ten nonreinforced presentations of the tone were used to assess the effects of preconditioning. Preconditioned subjects responded more frequently to the test stimulus than the control group, which failed to exceed spontaneous response rates. The amplitude of evoked hippocampal activity during preconditioning was highly correlated (r=+.85) with subsequent performance during the test session. In a second experiment, rabbits were lesioned with kainic acid placed in the dorsal hippocampus while under fluothane anesthesia. A control group received sham operations. Both groups were pretreated with diazepam. Training parameters were identical to those used for the preconditioned group in experiment 1. KA lesions had no deleterious effect during CS-US training, however, response rates to the test stimulus were reduced to spontaneous levels. Control animals exhibited significant effects of preconditioning.

These results suggest that the hippocampus is vital for sensory-sensory but not for sensory-motor learning. While the neural substrate underlying sensory preconditioning appears to include the hippocampus, the manner in which this structure influences response systems remains unknown.

160.11 THE ROLE OF OLFACTION IN CONDITIONED FOOD AVERSION DURING AND AFTER RECOVERY FROM OLFACTORY NERVE SECTION. N.E. Kinney, J.W. Wright and J.W. Harding. Dept. of Psych., SE Missouri State Univ., & Depts. of Psych. and Vet. Comp. Anat., Pharm., & Physiol., Washington State Univ., Pullman, WA. 99164

The role of olfaction in conditioned flavor aversion was investigated. Male albino mice underwent bilateral olfactory nerve section and were allowed 7 days for recovery. Animals were then food deprived for 8 hr before given access to a novel food (almond). During this first access, mice in the nerve sectioned group ate significantly more almond than did home cage, sham surgery/rotation, or rotation only controls. This could be interpreted as a failure to recognize the novelness of the novel food in the absence of the olfactory component of flavor detection/recognition. Nerve sectioned mice were then subjected to 50 min of body-rotation (60 rpm). Forty-eight hr later, all mice were given a second access to almond. This time, nerve sectioned and other rotation groups consummed significantly less than during the first access, demonstrating conditioned aversion to almonds.

On day 15 post-surgery, nerve sectioned mice were given a third access followed by body-rotation. During a fourth access 2 days later, these mice once again showed aversion to almond. However, subsequent repetition of the procedure resulted in virtually no consumption on day 25, and none on day 26. Home cage, sham surgery/rotation, and rotation only control groups consummed no novel food after first access.

Functional recovery (90% of controls) of a food odor mediated task was demonstrated on day 15 post-surgery in nerve sectioned mice (Harding & Wright, Brain Research Bulletin, 4:17-22, 1979), with complete recovery by day 21. It is suggested that nerve sectioned mice can form a taste mediated food aversion (following consumption of a novel food paired with rotation-induced gastrointestinal malaise) without olfactory input on day 7 post-surgery, and a second flavor (taste plus olfaction) mediated aversion on day 15. The retention of the flavor aversion on day 25 by the nerve sectioned group was as expected and did not differ from olfactory normal controls. Further, it appears that recognition of a food substance as novel is greatly hampered in the absence of normal olfactory functioning.

160.12 THE EFFECT OF ANTERIOR TEMPORAL LOBECTOMY ON ENDOGENOUS EPs RECORDED DURING VERBAL RECOGNITION MEMORY TESTING. M.E. Smith, J.M. Stapleton, K.A. Moreno* and E. Halgren, V.A. Southwest Reg. Epilepsy Ctr.; Brain Research Institute, UCLA, Los Angeles, CA, 90024.

We have previously reported the sequence of medial temporal lobe evoked potentials (EPs) recorded from depth electrodes during a verbal recognition memory task (Smith et al., 1984, Soc Neurosci Abs 10:846). The present study reports the results of scalp recordings during the same memory task in epileptics who had undergone either a left (L, N=7) or right (R, N=10) unilateral anterior temporal lobectomy (ATL), and in normal control subjects (N=9). EEG was recorded simultaneously from 22 channels (bandpass .1 to 100Hz.) and digitized on-line. Behavioral measures indicated that L-ATLs had a lower hit-rate on the recognition memory test than the R-ATLs or controls. However their performance was still substantially above chance levels and improved at a normal rate as words became more familiar with repetition. There were no differences between groups in false alarm rates or reaction times. Comparison of peak measures of the averaged EP waveforms also indicated differences among the groups. A negativity peaking around 400 msec. was largest to non-repeated words, but this difference in amplitude between repeated words and foils was only significant in the control group. In both lesion groups this N400 component was relatively attenuated compared to controls. No significant topographic differences were noted. The N400 was followed by a broad positivity (P550) which was biggest to repeated words. This difference between non-repeated and repeated items was significant for controls and R-ATLs but not L-ATLs. The L-ATLs exhibited the greatest reduction in amplitude for this component. The P550 was largest posteriorly across subjects. Small topographic lateral asymmetries were also noted. The exogenous components were similar across groups. These waveforms are compared to those evoked in simple auditory P300 tasks in the same patients, which show little difference between lesion and control groups. These data suggest that the contribution temporal lobe sources make to the scalp-recorded endogenous EPs may be highly task specific.

160.13 LONG-LATENCY COMPONENTS OF EVENT-RELATED POTENTIALS (ERPs) RECORDED FROM MONKEYS IN PASSIVE AND ACTIVE PARADIGMS DEMONSTRATE SIMILARITIES IN MORPHOLOGY AND FUNCTIONAL PROPERTIES TO THOSE RECORDED IN HUMANS. J. Pineda*, S. Foote, and H. Neville. Depts. of Neuroscience and Psychiatry, Univ. of California, San Diego, Salk Institute, and Scripps Clinic and Research Foundation, La Jolla, CA 92037.

A number of studies have revealed similarities between ERP components obtained in some animal species and those recorded in humans. In order to investigate whether long-latency components in monkey ERPs exhibit morphological and functional properties similar to those recorded in humans, ERPs were obtained from the brain surface of seven chair-restrained squirrel monkeys (Saimiri sciureus) chronically implanted with skull-screw electrodes at midline (Fz, Cz, Pz) and lateral (F3, F4, T3, T4, P3, P4) sites. Free field auditory stimuli (2KHz and 6KHz tones, 40 msec, 60 db above threshold) were presented in two types of paradigms resembling those in which specific ERP components have been studied in humans.

In the first paradigm, the same tone (either 2 KHz or 6 KHz) was presented on average every six seconds. A light signaled "time-in" periods, during which bar-press responses to the tones, occurring within a specific latency window, were rewarded, while no rewards occurred during "time-out". ERPs to the "time-in" tones exhibited a large, frontally distributed negativity that resembled the "O" (for Orienting) wave recorded in humans during the presentation of the same stimuli with long interstimulus intervals (Rohrbaugh and Gaillard, 1983).

In the "oddball" paradigm an active and a passive condition were used. A series of tones (2 KHz and 6 KHz) was presented with one tone occurring frequently (p=0.9) and the second one less frequently (p=0.1). In the active condition subjects were trained to respond to the less frequently occurring tone by pressing a lever to get a reward. In both conditions a large, positive polarity component (P3) was elicited by the infrequent tone. This component appears to be affected by changes in global stimulus probability and moment-to-moment variations in sequential order but not by variations in stimulus pitch or intensity.

These results suggest that long-latency components of monkey ERPs demonstrate morphological and functional properties similar to human long-latency components in analogous paradigms. Since components such as the P300 have been shown to covary with attentional, mnemonic, and semantic variables, these studies provide an animal model in which to investigate the mechanisms of these specific neural events.

ENDOCRINE CONTROL OF DEVELOPMENT I

161.1 ENVIRONMENTAL, BUT NOT SEX, DIFFERENCES EXIST IN THE GROSS SIZE OF THE RAT CORPUS CALLOSUM. J.M. Juraska and M. Meyer*. Dept. of Psychology, Indiana Univ., Bloomington, IN 47405.

Sex differences have been documented in the splenium of the human corpus callosum where females have a larger cross-sectional area than males (deLacoste-Utamsing and Holloway, Sci.,216:1431, 1982). An animal model for this dimorphism would be useful to understand its fine structural basis and possible hormonal origins. Thus we examined the rat for sex differences in the corpus callosum. However, we have previously reported that sex differences in the dendritic tree of visual cortical and hippocampal dentate neurons were dependent on the rearing environment. Szeligo (Anat. Rec.,187:726, 1977) has reported that rats raised in a complex environment have thicker white matter in the visual cortex than isolated rats. Therefore, we examined the size of the corpus callosum in rats of both sexes raised for one month post-weaning in either a complex (with toys and other rats) or an isolated environment. Measurements were taken in a manner similar to deLacoste-Utamsing and Holloway (1982) from projected slides of mid-sagittal, Weil stained sections from 10 litters.

No sex differences were found. Rats of both sexes that were from the complex environment had significantly larger (15-17%) middle and posterior (splenium) thirds of the corpus callosum than isolated rats. The anterior third was marginally in the same direction. While these results indicate that the rat will not serve as an animal model of human callosal dimorphism, they do demonstrate that the environment can alter the size of a major fiber pathway.

161.2 DENDRITIC PLASTICITY IN THE ANTERIOR CINGULATE CORTEX IN RESPONSE TO DIFFERENTIAL ENVIRONMENTS: SEX AND HEMISPHERIC DIFFERENCES. G. Carty, J.M. Juraska and D.L. Washburne*(SPON: G. Frommer). Dept. of Psychology, Indiana Univ., Bloomington, IN 47405.

We have found that the sexes differ in dendritic responses in the visual cortex and hippocampal dentate gyrus to rearing in complex and isolated environments. The anterior cingulate cortex may also be sexually dimorphic since it is reciprocally connected to both the visual cortex and dentate gyrus (through the entorhinal cortex) and contains a sizable number of estrogen receptors during development. An overall size asymmetry has also recently been reported. Therefore, we quantified the dendritic field in layer II-III pyramidal neurons in the anterior cingulate cortex (area 24b) in 6 litters of hooded rats of both sexes that were raised for one month postweaning in either a complex (with objects and other rats) or isolated environment. Neurons were sampled from coronal sections of Golgi-Cox stained tissue.

A concentric ring analysis revealed that the hemisphere in which the environmental effects were most pronounced varied with the sex of the animal (i.e., significant three-way interactions between sex, environment and hemisphere). In both the basilar and apical dendritic tree females showed greater differences between the environmental conditions in the right cortex and males showed greater differences in the left. Sex differences were most pronounced in the right hemisphere of the isolated rats where males had more dendritic material than females. In the left hemisphere, the presence and direction of sex differences were more variable. Further analyses examining the dendritic branching patterns in these groups are currently being performed. Although there were no hemispheric differences in the hippocampal dentate gyrus, the pattern of sex and environment differences in the right anterior cingulate cortex are similar to those previously found in the dentate granule cells.

161.3 HORMONAL CONTROL OF NEURON NUMBER IN SEXUALLY DIMORPHIC SPINAL NUCLEI IN THE RAT. D.R. Sengelaub, E.J. Nordeen, K.W. Nordeen*, and A.P. Arnold, Dept. of Psychology, UCLA, Los Angeles, CA 90024

The sexually dimorphic spinal nucleus of the bulbocavernosus (SNB) contains many more motoneurons in male rats than in females. Androgens produce this sex difference by regulating normally-occurring cell death, and perinatal treatment with testosterone propionate (TP) attenuates this death in females (Nordeen et al., 1984). Prenatally, before the differential decline in motoneuron number and development of the large sex difference, SNB motoneuron number increases dramatically. We have hypothesized that this increase is due to the migration of motoneurons into the SNB from the neighboring dorsolateral nucleus (DLN) (Sengelaub and Arnold, 1984), which is also sexually dimorphic. We thus examined the early development of the DLN in relation to the developing SNB in an effort to understand how androgens regulate cell survival and/or migration.

Timed pregnant females (Sprague-Dawley) received either 2 mg/day of TP in oil between embryonic days (E)16-22 or were left untreated (E23= day of birth= postnatal day (P)1). Pups born to TP-treated dams were cross-fostered to other lactating females and injected with 1 mg of TP on P1, P3, and P5. Lumbar spinal cords from males, females, and androgenized females (TP-female) were obtained at E18, E20, E22, P4, and P10, embedded in paraffin, sectioned and stained with cresylecht violet. DLN motoneurons were counted and corrections were made for split nucleoli.

At E18, when the number of motoneurons in the SNB is quite small, the DLN of all groups contains substantial numbers of motoneurons (1192-1244). However, by E22 when SNB motoneuron number for all groups has reached its maximum, the number of motoneurons in the DLN has declined, and males and androgenized females have significantly more DLN motoneurons than females (1140 vs. 884). DLN motoneuron number continues to decline to P10, especially in females, who lose 74% of their motoneurons compared to 54% in males. By P10 motoneuron numbers in males and females have reached their adult levels (552 vs. 320) and androgenized females do not differ significantly from males (596).

These results are consistent with the hypothesis that the SNB motoneurons originate in the DLN and migrate into position between E18 and E22. However, degenerating cells can also be seen in the DLN throughout this period, and thus it is possible that the decline in motoneuron number is the result of cell death. Furthermore, sex differences in DLN motoneuron number develop principally in the early postnatal period through a differential cell loss which can be attenuated by androgens, suggesting as in the SNB, an androgen regulated cell death.

(Supported by USPHS grant HD15021)

161.4 ANDROGENIC REGULATION OF DENDRITIC ARBOR IN A SEXUALLY DIMORPHIC RAT SPINAL NUCLEUS. E.M. Kurz, D.R. Sengelaub, and A.P. Arnold, Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The spinal nucleus of the bulbocavernosus (SNB) contains many more motoneurons in adult male rats than in females. The SNB innervates two sexually dimorphic muscles in the perineum, the bulbocavernosus and levator ani, and both the SNB motoneurons and their target muscles accumulate androgens. Castration of adult males results in a 13-17% decrease in SNB motoneuron soma size, but soma size can be maintained or returned to normal by treatment with testosterone. We examined the dendritic arbor of SNB motoneurons to determine whether testosterone's effect on soma size was also reflected in changes in the dendritic arbor following castration and hormone replacement.

Because it was necessary to examine the arbor of a comparable set of motoneurons in all groups over time, we used choleratoxin-horseradish peroxidase (CT-HRP) to retrogradely label only those motoneurons projecting to the bulbocavernosus. All injections consisted of .5 ul of .2% CT-HRP into the bulbocavernosus, which fills SNB motoneurons and their processes extensively, allowing a comprehensive description of the dendritic arbor of these cells. Intact male rats (Sprague-Dawley) were injected with CT-HRP at 8.5 or 18 weeks of age and males castrated or sham-castrated at 8.5 weeks were injected at 14 weeks. An additional set of animals castrated at 8.5 weeks, and implanted at 14 weeks with Silastic capsules either containing testosterone or left blank, were injected at 18 weeks. All rats were sacrificed 48 hours after injection and the spinal cords were removed, sectioned at 40 um, and processed with TMB. To estimate the length of SNB cell processes, every fourth section through the SNB region was examined under darkfield illumination and all HRP-filled fibers were drawn with a camera lucida. The lengths of all filled fibers were then measured and summed. The number of labeled cells and density of their labeling was also determined.

While it is possible that HRP transport efficiency was affected by the androgen depletion in castrates, we found no differences in the density of HRP labeling, or the maximal distance from the SNB at which labeled fibers could be observed. The length of the dendritic arbor per filled cell in intact males and sham castrates was similar, ranging from 4400-5500 um. At 14 weeks (5.5 weeks post-castration) dendritic length in the castrates was decreased to less than 50% of normal or sham levels. Castrated animals treated with testosterone for 4 weeks showed a substantial increase (50%) in dendritic length over that of castrates. These results suggest that androgens are critical for the maintenance of dendritic arbor in SNB motoneurons. (Supported by USPHS HD15021)

161.5 BRAIN GROWTH AND BEHAVIOR IN DEVELOPING FULLER BWS MICE: EFFECTS OF THYROID HORMONE. R. Benno, D. Desroches*, M. Hahn* and J. Salinas*. Dept. of Biol. Wm. Paterson College of N.J. 07470

Previous studies performed on Fuller Brain Weight Selected (BWS) mice have shown that the H-line (heavy brains) and L-line (light) differ on a variety of developmental tasks including surface righting and rotor rod riding ability, with L mice developing more rapidly (Chen and Fuller, Dev. Psychobiol., 8(4):355,1975). It was also shown that thyroid hormone (Th) administration decreased brain size and sped up development of behavior in both H and L mice. Our study investigated whether Th administration to H mice would make them similar to the L-line mice in terms of brain structure and behavior. We specifically focused on cerebellar related behaviors, e.g. righting reflex and rotor rod riding because of differences we have recently found in cerebellar foliation pattern between the two lines.

Three groups of H mice received daily subcutaneous injections of either 0.5 or 1.0µg L-thyroxine (Th-.5 and Th-1 groups) or saline (control), from day 1 to day 20. All were tested for surface righting and rotor rod riding ability, and the day of eye opening was recorded. On day 21, all mice were killed, total body, thyroid and brain weighed. Brains were immersion-fixed in formalin, cut in the mid-sagittal plane, stained with cresyl violet and analyzed for differences in cerebellar foliation patterns. The 1 µg treatment was effective in changing body and brain size. Th-1 mice had lower body weights ($p<.01$) and brain weights ($p<.01$) than the controls. The 0.5µg Th treatment had similar but smaller effects. Thyroid weights were unaffected by Th treatments. Brain partitions and anatomical features were also affected by Th treatments, particularly by 1.0µg Th. Th-1 mice had decreased total brain length ($p<.05$), cortical length ($p<.001$) and cerebellar width ($p<.002$). The number of cerebellar folia were also significantly reduced ($p<.0001$). Behavior was also found to be sensitive to Th treatments. All Th injected mice took less time to meet criterion for righting reflex ($p<.0003$) and rotor rod ($p<.02$). In addition, Th injections sped up the time of eye opening ($p<.0001$).

In conclusion, Th injections in the Fuller BWS H-line mice were shown to be effective in decreasing total body and brain size as well as in altering the cerebellar foliation pattern. In addition, the hormone was able to speed up the development of behavioral tasks dependent on a functional cerebellum possibly by increasing the rate of cellular maturation. These changes in brain structure and behavior make the H mice appear similar to control L mice both physically and behaviorally. It is therefore possible the Th sensitivity is involved in selective breeding for brain size. This hormonal difference may account for some of the differences in brain structure and development of behavior.

161.6 MORPHOMETRIC ANALYSES OF ALTERATIONS IN THE HYPOGASTRIC GANGLION SUBSEQUENT TO NEONATAL CASTRATION: ANDROGEN RECEPTOR REGULATION? J.E. Melvin, T.H. McNeill and R.W. Hamill. Depts of Anatomy and Neurology, Monroe Community Hospital, Univ. of Rochester Medical Center, Rochester, NY 14642.

Neonatal castration of male rats inhibits the development of postsynaptic tyrosine hydroxylase (T-OH) activity and diminishes the development of both presynaptic choline acetyltransferase (CAT) activity and total ganglion protein in the sympathetic hypogastric (HG) ganglion (Society for Neuroscience Abstract 10:457, 1984). To determine if the loss of neurotransmitter synthesizing enzyme activities and ganglion protein reflects decreased cell size and/or cell loss, morphometric analyses were performed. Additionally, cytosolic androgen receptor binding in the HG was studied according to the methods of McGinnis et al. (Brain Res. 275:75, 1983).

Neonatal male rats were castrated at 10-11 days of age and sham-operated littermates served as controls. Castration resulted in a significant decrease in both nuclear and cell body cross-sectional areas (nucleus, control $68 \pm 4\ \mu^2$, castrated $31 \pm 3\ \mu^2$, $P<.001$; cell body, control $293 \pm 17\ \mu^2$, castrated $124 \pm 12\ \mu^2$, $P<.001$). In contrast, there was no significant loss in the estimated total nerve cell population subsequent to neonatal castration (control 3700 ± 173, castrated 3262 ± 290).

To examine possible direct interactions between androgens and neurons of the HG, cytosolic receptor characteristics were studied. Castrated and adrenalectomized male rats, 65-75 days old, were maintained on 0.9% saline for 48 hours prior to assay. The HG and pituitary (Pit), which was previously shown to contain androgen receptors (McGinnis et al., 1983), were removed and immediately frozen in liquid nitrogen. HG and Pit from 18-21 rats were pooled for each assay and 4 nm ^{3}H-R1881 used as ligand. Competition studies suggested specific binding (10^{-9} - 10^{-5} M). DHT and testosterone inhibited receptor binding in the HG in a similar manner as the Pit. Corticosterone showed no tendency to compete with receptor binding, while progesterone and estradiol only competed at the highest concentrations.

These results suggest that the diminished development of presynaptic CAT activity and total ganglion protein in the HG is related to decreases in the size of neurons and not to the loss of neurons. Additionally, the lack of cell loss indicates that the inhibition of postsynaptic T-OH activity would reflect a loss of enzyme activity per cell. Furthermore, the presence of specific cytosolic androgen receptors in the HG possibly implies that altered morphological and biochemical development following neonatal castration is at least partially due to the loss of direct hormonal regulation.

161.7 SEX DIFFERENCES IN NEURONAL NUMBER OF TRIGEMINAL MOTOR NUCLEUS IN GUINEA PIGS BUT NOT RATS. Kate Townsend-Merino & S.M.Breedlove. Psychology Dept., U. of California, Berkeley, CA 94720.

In guinea pigs the temporal muscle is much larger in males than in females and castration of males drastically reduces masticatory muscle size. In fact, of the 46 muscles tested only the temporal, digastric and masseter respond as strongly to androgens as do perineal muscles. Masticatory muscle changes in castrated rats are merely proportional to changes in body weight (C.D.Kochakian, I. Pharm. Ther. B., 1 149). In rats the sexual dimorphism in perineal musculature is accompanied by a sex difference in the number and size of innervating motoneurons. We now report a sex difference in the number of neurons in the trigeminal motor nucleus (MoV) innervating the sexually dimorphic masticatory muscles of guinea pigs.

The brains of 5 male and 5 female age-matched (57-60 days) Simonsen-Hartley guinea pigs were frozen sectioned and alternate 40 µm sections were thionin stained. MoV was examined bilaterally for the number of motoneurons with visible nuclei in the dorsal and ventral subpopulations, as well as overall MoV. Cell counts were corrected for split-nuclei error. The temporal muscle is the most highly androgen sensitive of the masticatory muscles, so the magnitude of any sex difference might be greater in the dorsal half of MoV, which contains temporal motoneurons.

There were sex differences in the number of motoneurons in the dorsal half ($p<.05$, t-test), ventral half and the entire MoV nucleus ($p<.01$):

Mean # ±S.E.M.:	Dorsal half	Ventral half	Overall MoV neuron #
MALES:	1006.7 ±49.6	1254.0 ±37.3	2260.9 ±76.6
FEMALES:	793.0 ±20.5	913.0 ±32.6	1706.4 ±43.4

Male Hartley guinea pigs begin to outweigh females at 45 days. Accordingly, males were heavier than females in the present study, but there was no significant correlation within either sex between body weight and the number of MoV motoneurons (Males: r= -.09; Females: r= -.33). Rats also display a sex difference in body weight, but we found no sex differences in the number of MoV neurons in rats (M: 1292.5 ±50.5; F: 1125.6 ±63.8, N=16, $p>.05$). Guinea pig motoneurons in the dorsal half of MoV are larger than those in the ventral half, therefore the cross-sectional areas of 15 somata from each anatomical location were measured from each animal. No sex differences in mean cell size were found in either the dorsal or ventral portion of MoV:

MALES: Dorsal, 929.0 ±26.8; Ventral, 636.5 ±21.8 µm2.
FEMALES: Dorsal, 925.4 ±80.8; Ventral, 675.1 ±17.7 µm2.

There was no difference in neuronal density (# MoV neurons/total MoV volume) between males and females. However, there was a significant sex difference in the total volume of the MoV nucleus (M: 1.399 ±.05; F: 1.229 ±.01 mm3, $p<.05$), apparently because of a greater rostral-caudal extent in males. The sex difference in the number of MoV motoneurons and the androgen sensitivity of their target muscles suggest a sex-related behavioral function of these muscles.

161.8 NEONATAL ANDROGEN MAINTAINS SEXUALLY DIMORPHIC PERINEAL MUSCLES IN THE ABSENCE OF INNERVATION. Renata B. Fishman and S. Marc Breedlove, Department of Psychology, University of California, Berkeley, CA 94720.

The spinal nucleus of the bulbocavernosus (SNB) and its target muscles, the bulbocavernosus (BC) and levator ani (LA) are present in adult male, but not female, rats. SNB motoneurons and the BC/LA muscle complex are present in females at birth but disappear by the third week of life. Neonatal testosterone propionate (TP) treatment maintains SNB motoneurons and prevents involution of the BC/LA muscles. It is not yet determined whether androgen's primary site of action is the SNB motoneurons or BC/LA muscles. The purpose of the present study was to choose between these two alternatives by determining whether SNB motoneurons are necessary for the testosterone induced sparing of BC/LA muscles. We now report that removing SNB innervation to the BC/LA by neonatal lumbosacral spinalectomy does not prevent the androgenic maintenance of these muscles.

Sprague-Dawley female rats aged 0-24 hours received either a lumbosacral spinalectomy or sham operation. Spinalectomies were performed under a dissecting microscope by removing the dorsal surface of 2-3 mid-thoracic vertebrae, inserting a hypodermic needle down the vertebral column, and aspirating the entire lumbosacral spinal cord. Either TP (1mg) or sesame oil vechicle (.05cc) was injected s.c. immediately following surgery and again on the third day of life. At 26-30 days, rats were sacrificed and their spinal cords and perineal muscles were examined. Inspection of spinal cords indicated all lumbosacral spinalectomies were complete. BC/LA muscles were present in all TP (N=6), but none of the oil treated (N=6), spinalectomized females.

Additional experiments were conducted to determine whether or not BC/LA muscles were innervated by neurons replacing SNB cells. Spinalectomized (N=5) and sham operated (N=4) females were given additional TP on days 26 and 28 of life to increase muscle mass. Subsequently, perineal muscles were removed at day 30 and examined for motor endplates with either flourescently labeled alpha bungarotoxin (Sigma, N=3 spinalectomized and 2 sham) or an acetylcholinesterase stain (N=2 spinalectomized and 2 sham). Male BC/LA muscles were stained concurrently for comparison. The BC/LA muscles of both males and sham operated, TP treated females showed motor endplate band formations characteristic of innervated muscle. However, BC/LA muscles of spinalectomized animals showed only diffuse labeling with no evidence of a motor endplate banding pattern.

These results demonstrate that BC/LA muscles survive when neonatal females are treated with androgen immediately following complete denervation. Thus androgen can spare BC/LA muscles in the absence of SNB motoneurons, suggesting that androgen's primary site of action in maintaining SNB system structures may be the BC/LA muscles themselves.

Supported by NIH grant # NS19790 and March of Dimes grant # 5-447.

161.9 ONTOGENY OF FUNCTIONAL INNERVATION OF BULBOCAVERNOSUS MUSCLES IN MALE AND FEMALE RATS. Mark N. Rand & S. Marc Breedlove. Dept. Psychology, U. of California, Berkeley, CA 94720.

In male rats, the bulbocavernosus and levator ani muscles (BC/LA) are innervated by the spinal nucleus of the bulbocavernosus (SNB). Adult female rats lack both the SNB and its target muscles. However, both the SNB and its BC/LA targets are present in females at birth. Furthermore, the injection of retrograde markers into the BC labels SNB cells in newborn females, indicating that the motoneuron axons have reached their target. Nonetheless, both SNB cells and BC/LA muscles involute in females unless they are perinatally treated with androgen. It has not yet been determined how androgen maintains the SNB system, but a reasonable hypothesis is that androgen triggers or accelerates the maturation of the neuromuscular junction, and thereby prevents the dissolution of motoneurons and target. One measure of the status of the neuromuscular junction is the ability of SNB motoneurons to elicit contractions in BC/LA muscles. We have found that electrical stimulation of the appropriate ventral root elicits contractions of BC muscles in female rats perinatally.

Cesarean sections were performed on timed-pregnant Sprague-Dawley rats (Simonsen) under urethane anesthesia (1.6g/kg, im). Fetuses were rapidly decapitated and their viscera removed. The bodies were placed in a chamber with oxygenated Ringer's solution and carefully dissected under a microscope to reveal BC/LA and related structures. Ability of the muscles to contract could be confirmed by direct electrical stimulation. The ventral midline of the vertebral column was split to reveal the spinal cord, allowing access to the ventral roots. Proximal connections of individual ventral roots were cut and the roots were drawn into a suction electrode for electrical stimulation. Contraction of the BC muscles could be directly observed through the dissecting microscope, and was sometimes accompanied by isolated, ipsilateral deflection of the phallus to which the muscles attach. In some cases d-tubocurarine (Sigma) was added to the bath (.16mg/ml) to reversibly block BC/LA contractions.

BC/LA contraction could be reliably elicited in all newborn male rats by electrical stimulation of the sixth lumbar ventral root (L6). Stimulation of L5 and S1 also elicited weak contractions. Contractions of BC were observed as early as day 20 of gestation (d20g) in males. By d21g, medium to large contractions could be elicited in all males, and small but reliable contractions could be driven in the BC of females. On d22g all males showed strong responses and in 5 out of 5 females BC also clearly contracted following electrical stimulation of L6. By d23g (day of birth) BC contractions were weaker and less reliably elicited in female rats.

Our studies indicate that the BC/LA muscles of perinatal females can be functionally driven by SNB cells, yet both motoneurons and their target muscles will die without androgen. Thus it seems unlikely that androgen spares the SNB system by establishing functional contact between them, since that occurs to some extent in normal females. Apparently androgen averts dissolution of the SNB system by some other mechanism.

161.10 SEXUAL DIMORPHISM IN ONUF'S NUCLEUS OF DOGS: ANDROGEN REGULATION OF MOTONEURON NUMBER. F.A.Beach*, Nancy G. Forger & S.M.Breedlove (Spon:I.Zucker). Psych. Dept., U.C.Berkeley, CA 94720.

Onuf's nucleus in dogs, cats and primates is a slender column of small to medium-sized motoneurons in the ventrolateral aspect of the ventral horn in segments 1-2 of the sacral spinal cord. Retrograde labelling studies in cats and dogs demonstrate that the neurons in Onuf's nucleus innervate striated perineal muscles, including the external anal sphincter, ischiocavernosus and bulbocavernosus muscles. Onuf's nucleus may, then, be homologous to the spinal nucleus of the bulbocavernosus (SNB) and the dorsolateral nucleus (DLN) in rats which innervate the bulbocavernosus and ischiocavernosus muscles, respectively. In rats, the number of SNB and DLN motoneurons is greater in males than in females, which lack the target muscles. Perinatal androgen treatment of female rats spares SNB and DLN motoneurons as well as their target muscles. Here we describe a similar sexual dimorphism in Onuf's nucleus of dogs, and report that early androgen treatment of females reduces the dimorphism.

Spinal cords from purebred beagles were examined. Normal females (N=4) and males (N=4) were compared with five androgenized females born to dams that received 20 daily injections of testosterone propionate (1.1 mg/kg dam's body weight) during the middle third of pregnancy (day 24-43 post coitum). Four of these five treated females also received a 37.5 mg subcutaneous implant of crystalline testosterone on the day of birth. The dogs were sacrificed as adults (age 3-6yrs), and perfused with saline and formalin. The spinal cords were paraffin-embedded, serially sectioned at a thickness of 15 µm and treated with a Klüver-Barrera stain. As reported by others, Onuf's nucleus stands out sharply in this stain as a pale area demarcated from the surrounding network of myelinated fibers. Bilateral counts in every third section were made of all motoneurons within this pale, ovoid area. The resulting sum for each dog was tripled to estimate the total number of Onuf's nucleus motoneurons.

Male dogs had significantly more neurons in Onuf's nucleus than did females ($p<.02$, t-test). Androgen treated females were phenotypically masculinized; external genitalia consisted of a male-like phallus and no external vagina. Similarly, the number of motoneurons in Onuf's nucleus of androgenized females was not different from that of males ($p>.05$), and was greater than the number of motoneurons in normal females ($p<.05$).

	Males	Females	Androgenized Females
Mean # neurons ±SEM:	1407 ±133	823 ±122	1134 ±56

The sex difference in the number of perineal motoneurons is less pronounced in dogs than in rats, perhaps because female dogs normally retain perineal muscles in modified form. These results suggest that, as in rats, the number of motoneurons innervating dog perineal muscles is under early androgen control. Androgen rescues motoneurons of the rat SNB during the period of normal cell death; it may be anticipated that a similar mechanism operates on the neurons of Onuf's nucleus in dogs.

Supported by NIH grant # NS19790.

161.11 SEXUAL DIMORPHISM IN ONUF'S NUCLEUS OF HUMANS. Nancy G. Forger and S. M. Breedlove. Dept. Psychology, U.C. Berkeley, CA 94720.

Onuf described a spinal nucleus which, based on human neurological data, he believed to innervate striated perineal muscles. Onuf's nucleus is morphologically very similar in humans, cats, dogs and monkeys, consisting of small to medium-sized motoneurons in the ventrolateral aspect of the ventral horn of the sacral spinal cord. Retrograde labelling studies in cats and dogs confirm Onuf's suggestion that the nucleus innervates the external anal sphincter, m. bulbocavernosus and m. ischiocavernosus. We have recently demonstrated an androgen-regulated sexual dimorphism in Onuf's nucleus of dogs: males and androgenized females have a significantly greater number of motoneurons than do normal females (adjoining abstract). A sex difference in the number of HRP labelled pudendal motoneurons in Onuf's nucleus has also been described in macaque monkeys (Ueyama et al. JCN 232 '85). In the current study, we sought to establish whether a similar dimorphism exists in Onuf's nucleus of humans.

Spinal cords of 8 human females and 9 males from the Yakovlev collection of the Armed Forces Institute of Pathology were examined. Ages at autopsy ranged from 2-87 years in females (mean ± SEM, 22 ±10 yr), and 1.5 mos-60 yr in males (22 ±8 yr). Each cord was embedded in celloidin, cut coronally at 35 µm, and every 5th (N=1), 10th (N=10) or 20th (N=6) section was mounted and Nissl-stained. Adjacent Weigert-stained sections were also available to aid nucleus identification. The total number of Nissl-stained neurons in Onuf's nucleus for each subject was adjusted according to the sampling ratio in order to estimate the total motoneuronal number. In accord with previous reports, distinct dorsomedial (DM) and ventrolateral (VL) cell groups could be seen in Onuf's nucleus of humans. VL cells were small, dark and uniformly present, while medium-sized intermittently present cells characterized the DM division.

A sex difference was observed in the number of motoneurons of the VL group; males had significantly more motoneurons than did females ($p<.025$, t-test). The number of DM neurons was small and no sex difference was seen in this division or in the total number of motoneurons ($p>.05$).

Mean # neurons ±SEM	VL	DM	Total
Males:	2032 ±121	473 ±138	2505 ±212
Females:	1569 ±142	533 ±110	2102 ±165

A single additional spinal cord was examined in a case of amyotropic lateral sclerosis (female). As previously reported, the cells of Onuf's nucleus were preserved, despite widespread loss of other motoneurons.

The VL portion of Onuf's nucleus in cats innervates the ischiocavernosus. Onuf's nucleus is not present in rats, however in the homologous nuclei innervating the ischiocavernosus and bulbocavernosus muscles a sex difference in the number of motoneurons, favoring males, has been established. Perinatal androgen treatment of female rats reduces the dimorphism by sparing motoneurons from death during development. The present observation of a sex difference in motoneuronal number in VL Onuf's nucleus is the first description of sexual dimorphism at the cellular level in the human CNS, and one for which well established animal models are available. Supported by NIH grant # NS19790.

161.12 NEURAL CONTROL OF LORDOSIS AND EAR WIGGLING IN 6-DAY-OLD RATS. C.L. Williams and D. Lorange. Dept. of Psychol., Barnard College, Columbia Univ., NY, NY. 10025.

Six day old rats display lordosis and ear wiggling in response to tactile stimulation of the flanks and rump. These precocious behaviors are displayed by both male and female infants when they are deprived of their dam for 3-4 hrs and tested at (33 ± 2°C). The involvement of various brain regions in precocious lordosis and ear wiggling was examined by making transections along the neuraxis from the anterior hypothalamus to the pons in 6-day-old pups.

The transections were made by inserting a 30-ga., blunted, hypodermic needle through a hole in the skull on an angle so that it could be drawn laterally across the brain. A control operation was carried out in male and female pups from each litter; a hole was placed in the skull near lambda but no transection was made. Following the transection procedure, pups were placed in individual plastic tubs in an incubator for 4 hrs. Behavioral testing was conducted by stroking pups on the flanks and lower back for 30 sec every 30 min for 2 hr, and tests were videotaped. Following testing pups were sacrificed and the brains were sliced and stained. Sagittal sections were examined microscopically to determine the locus and extent of the brain cuts.

Using these techniques, we found: 1.) Cuts through the pons completely eliminated lordosis and severely reduced ear wiggling in both male and female rats. 2.) Cuts in the mesencephalon slightly reduced the frequency, duration and intensity of lordosis and the frequency of ear wiggling, however, this may have been due to an overall reduction in activity in these animals, rather than a specific effect on the neural systems underlying precocious sexual behaviors. 3.) Lordosis was severely reduced in pups with cuts in the diencephalon, while ear wiggling and overall activity were relatively normal.

These data suggest: 1.) In the infant as in the adult, supraspinal facilitation is required for the display of sexual responses. 2.) Hindbrain postural control centers support lordosis in the absence of input from the midbrain and forebrain. 3.) Hypothalamic facilitation in the infant occurs without the addition of exogenous estrogen.

161.13 EFFECT OF PRENATAL ESTROGEN DEPRIVATION ON THE DEVELOPMENT OF FEMININE SEXUAL BEHAVIOR IN FERRETS OF BOTH SEXES. M.J. Baum, S.A. Tobet and L.A. Lundell*, Dept. of Biology, Boston University, Boston, MA 02215

We tested the unorthodox hypothesis that estrogenic stimulation of the perinatal brain is required for the development of feminine proceptive and receptive coital capacity. On gestational day 30 pregnant ferrets were either ovariectomized and implanted s.c. with a Silastic capsule containing the aromatase inhibitor, 1,4,6-androstatriene-3,17-dione (ATD) or with ATD plus estradiol (E_2). A third group of pregnant ferrets was sham-ovariectomized. All groups received a Silastic capsule containing progesterone. Litters were delivered by cesarian section on gestational day 42. All offspring were cross-fostered to lactating mothers prior to being gonadectomized on postnatal day 5. In adulthood animals were injected s.c. daily with different dosages of estradiol benzoate (EB; 0,5,10 and 15 ug/kg) prior to tests of proceptive (approach latencies in a runway) and receptive (acceptance of neck grip) responsiveness to a sexually-active male ferret.

Ovariectomy and administration of ATD to pregnant ferrets caused significant reductions in plasma E_2 and hypothalmic aromatase activity in fetal offspring killed on gestational days 37 or 41.

Female ferrets displayed similar dose-dependent reductions in latency to approach a male after adult EB treatment (proceptivity), regardless of whether they had been deprived prenatally of estrogen. Normally male ferrets are proceptively defeminized, i.e., they show no EB-induced reduction in latency to approach a stimulus male. Prenatal estrogen deprivation caused males to run faster to a stimulus male in response to adult EB. This suggests that prenatal estrogenic stimulation normally contributes to proceptive defeminization in male ferrets.

Females deprived prenatally of estrogen were significantly less receptive than control females when tested with the 2 lower dosages of EB. This effect was reversed in females whose mothers received ATD + E_2. However, females in all three groups were equally receptive in response to the highest dosage of EB. Previous work showed that male ferrets are as receptive as females after gonadectomy and EB treatment in adulthood. Males deprived prenatally of estrogen were less receptive than control males in response to the lowest EB dosage whereas males exposed prenatally to ATD + E_2 were more receptive than controls in response to all three adult dosages of EB. The results suggest that estrogenic stimulation of the fetal brain enhances later receptive responsiveness to E_2; however, prenatal estrogen is not an absolute requirement for the development of receptive or proceptive coital capacity in ferrets of either sex.

161.14 SEXUALLY DIMORPHIC NUCLEUS OF THE MALE FERRET PREOPTIC/ANTERIOR HYPOTHALAMIC AREA IS DEPENDENT UPON PRENATAL EXPOSURE TO ESTROGEN S.A. Tobet, D.J. Zahniser* and M.J. Baum, Dept. of Biology, Boston University, Boston, MA 02215 and Image Analysis Laboratory, Tufts-NEMC Boston, MA 02111

Sex differences in brain morphology have been described in many species. In birds and rodents several sex differences in neural morphology depend on the developmental action of androgen or estrogen in the male. Similar developmental experiments have not been done in any higher mammalian species. In a carnivore, the ferret, a nucleus is present in the dorsal portion of the preoptic/anterior hypothalmic area (POA/AH) only in males. In the present experiments pregnant ferrets were administered different treatments to alter the fetal steroidal milieu. In an attempt to keep postnatal hormone exposure comparable in all groups, offspring were gonadectomized on day 5, the earliest age compatible with survival. After 18-20 days of testosterone-priming at 7-8 months of age, all animals were anesthetized with sodium pentobarbital before perfusion via the heart with saline followed by 10% neural buffered formalin. Coronal, 40-micron cryostat sections were cut through the POA/AH of all animals and stained with thionin. A bilateral, dorsal nucleus containing large cells, similar to that seen in males, was apparent in the POA/AH of female offspring of pregnant ferrets which received s.c. implants of testosterone over days 30-41 of gestation. A dorsal nucleus of the POA/AH was also present in males from litters treated with the anti-androgen, flutamide, over days 30-41 of gestation even though these males showed clear genital signs of androgen antagonism. By contrast, no dorsal nucleus was present in the POA/AH of males whose prenatal exposure to estrogen was reduced over days 30-42 of gestation by maternal ovariectomy and s.c. implantation of progesterone plus the aromatase inhibitor 1,4,6-androstatriene-3,17-dione (ATD). Male offspring of ovariectomized, ATD-treated mothers which received a low replacement dosage of estradiol also had no dorsal nucleus in adulthood. A higher dosage of estradiol was generally toxic; however, a dorsal nucleus was apparent in a single, surviving male whose mother received this treatment plus ATD. Thus, the development of a dorsal nucleus in the POA/AH of male ferrets depends upon prenatal exposure to estrogen derived form the neural aromatization of circulating androgen. Data from studies on the ferret as well as rodent species suggest that the neural aromatization of androgen to estrogen may be required in diverse orders of mammals for the development of sexually dimorphic features of the male forebrain.

161.15 DIRECT EVIDENCE THAT MALE AND FEMALE CELL DEATH RATES DIFFER IN THE DEVELOPING ZEBRA FINCH SONG SYSTEM. J. R. Kirn and T. J. DeVoogd, Psych. Dept., Cornell Univ., Ithaca, NY 14853

The zebra finch song system is sexually dimorphic in cell number, density, and dendritic elaboration, resulting from hormonal influences early in development (reviewed by (DeVoogd, 1984). To elucidate possible mechanisms by which hormones act, we have begun to investigate the normal development of the song system at a cellular level. A ubiquitous feature of nervous system development, including the telencephalon, is cell death (Finlay & Slattery, 1983). This report describes cell death in 3 components of the song system: Hyperstraitum ventrale pars caudale (HVc), and its principle targets, Robustus Archistriatalis (RA) and Area X. In 10-20μ cresylecht violet stained coronal brain sections from 15, 19 and 25 day old (post-hatch) finches, all cells in three representative sections through HVc and RA were counted. Degenerating cells, recognized by their pyknotic, darkly staining appearance, were counted in these and 3 additional sections. The total number of degenerating cells was expressed as a fraction of normal cells. Since Area X was visible in males but not females at all ages examined, it was analyzed differently. In males, the position of X in Lobus Parolfactorius (LPO) was determined and this was used to define putative X in same-age females. In 3 sections, the entire LPO, including X, was scanned for degenerating cells.

In 19 day old male HVc, a cell death rate of 1.4 degenerating cells/1000 normal was observed. The rate in females was substantially higher (7.6/1000). At 25 days old, HVc cell death rates increased in both sexes, but again were higher in females (♂ = 5.2/1000 normal; ♀ = 12.2/1000). In contrast, RA cell death rates were lower and not dimorphic at either 19 or 25 days (19, 25 day ♂ = 0.91, 2.2/1000 respectively; ♀ = 0.7, 3.3/1000). These results demonstrate that a) as in the rat spinal cord (Nordeen, et al., 1984), HVc undergoes subtantially more cell death in female finches compared to males; b). High, dimorphic cell death rates in HVc are coincident with low nondimorphic cell death rates in RA suggesting a possible temporal asynchrony in the development of sex differences in these structures that parallels asynchronious developmental changes in the volumes of these nuclei (Bottjer, et al., 1984). At day 15 and 19 more degenerating cells (dc) were found in LPO of females than in males (day 15-19 males = 16-22 dc; females = 40-36 dc). Although some dying cells were within male area X or its putative location in females, the majority were located outside of X and highest densities were adjacent to the ventricular zone in medial and dorsomedial LPO. This region may partially overlap with known hormone-concentrating areas in adult finches (Arnold, et al., 1976). Thus, the present data might indicate the death of hormone-sensitive cells in medial LPO. Alternatively, the survival of migrating cells may be dependent on hormones. The absence of a male-like endocrine milieu in the developing female might then increase cell death so as to create a spatially distant sexual dimorphism in area X.

161.16 MASCULINIZATION OF SONG-CONTROL NUCLEI MAY INVOLVE SELECTIVE RETENTION OF ANDROGEN TARGET CELLS. E.J. NORDEEN, K.W. NORDEEN* AND A.P. ARNOLD. DEPT. OF PSYCH, UCLA, LOS ANGELES, CA 90024.

Male zebra finches produce an androgen dependent courtship song that females lack. Consistent with this sex difference two neural song regions, magnocellular nucleus of the anterior neostriatum (MAN) and hyperstriatum ventrale pars caudale (HVc) have more androgen-accumulating cells in adult males than in females. Estradiol (E2) treatment of females shortly after hatching increases androgen target cell number in MAN and HVc to male-typical levels, and these masculinized females respond to androgens as adults with neural growth in song nuclei, and male-typical song. The critical period for this influence of E2 on androgen accumulation extends at least until 20 days after hatching, but not into adulthood. To help distinguish whether E2 masculinizes androgen accumulation in females by promoting the retention of androgen target cells or by promoting their development, we compared the numbers of androgen target cells present in MAN in 20-day-old females, and in adult females masculinized by E2 treatment on day 20.

Six females (ages 19-21 days) were implanted subcutaneously with silastic ropes containing 200 ug of E2. Three to six months later these E2 females and 4 normal females (ages 19-20 days) were gonadectomized. The following day, each bird was injected intramuscularly with 20 ng/gm body weight of 3H-dihydrotestosterone (DHT). The animals were decapitated 1 1/2 hours later and coronal brain sections (6 um) were processed for autoradiography. Reference sections (18 um) were taken at regular intervals and stained with thionin. Thin sections were exposed 4-8 weeks and stained with thionin. The reference sections indicated that in 3 of 6 E2-females, song nuclei were morphologically masculinized. The incidence of cells labelled by 3H-DHT or its metabolites was determined within MAN in these 3 masculinized females and in the juvenile females using the Poisson criterion. Neuronal density and total nuclear volume of MAN was also determined.

In E2-females 53% of MAN cells were labeled by 3H-DHT or its metabolites. This is significantly more than in normal adult females (17%, Soc. Neurosci. Abst., 10;454, '84). In juvenile females only 20% of MAN cells were labeled. However measurements of total nuclear volume and neuronal density indicated that MAN contains 3-4 times as many cells in juvenile females as compared to E2-females. Thus, young females possess more than enough androgen-accumulating cells in MAN than are necessary to account for the masculine pattern obtained in adult females treated with E2 early in life. These data are consistent with the hypothesis that during sexual differentiation, E2 regulates androgen target cell number in song related nuclei by promoting the retention of androgen-accumulating cells that would otherwise be lost.

161.17 LECTIN BINDING TO SEXUALLY DIMORPHIC BRAIN REGIONS INVOLVED IN SONG LEARNING THE THE ZEBRA FINCH. A.W. Coquelin, E.J. Nordeen, K.W. Nordeen*, and A.P. Arnold. Depts. Anatomy and Psychology, Lab. Neuroendocrinology, Brain Research Institute, UCLA, Los Angeles CA 90024.

To find markers for specific cells or tissue components which are sexually dimorphic and may be involved in song learning in zebra finches, we have incubated zebra finch brain sections with peanut agglutinin (PNA), a lectin which binds specifically to d-galactose moieties of glycoproteins. We find that many song control brain regions are bound by this lectin, as are some other brain regions. Binding in the song system is most distinct in MAN (magnocellular nucleus of the neostriatum), a nucleus which seems crucial for juvenile song learning but not for maintenance of song in adult zebra finches (Bottjer et al., Science, 1984).

Adult zebra finches were perfused with buffered 4% paraformaldehyde or buffered 10% formalin. Brains were removed and stored in fixative at 4°C until sectioning with a vibratome or frozen-sectioning with a sliding microtome at 30-40 um. Sections were incubated with bovine serum albumin and then with biotinylated PNA (20 ug/ml) overnight. Using the ABC technique (Vector), the lectin was localized with biotinylated HRP and diaminobenzidine and was viewed under the bright field microscope. We compared staining in adult males, adult females, and adult females which had been masculinized at hatching by an implant of Silastic containing 40 ug estradiol (E2).

In general, PNA lectin binding was associated with neuropil and not with cell bodies. Within the telencephaic song system, very distinct binding was seen in MAN, Area X, hyperstriatum ventrale pars caudale (HVc), and robust nucleus (RA), with heaviest labeling in MAN and RA. Other song or auditory nuclei showed distinct but light labeling (field L, nucleus interface, nucleus ovoidalis, lateral mesencephalic nucleus dorsomedial nucleus of intercollicularis). Outside the song system, heavy binding was seen in various nuclei including the ectostriatum, medial habenula, septum, nucleus of the stria terminalis, preoptic area, hypothalamic nuclei, and pretectal nucleus. In several brain regions, PNA binding formed very clear rings which closely apposed the cell surface of specific neurons. For example in Area X, such dense rings surrounded large cells (12-15um diam) in males and E2 females, but not in untreated females. Thus, PNA may bind to a specific synaptic structure which is sexually dimorphic. Dense rings were also seen in other brain regions (e.g., gigantocellular reticular formation) in both sexes. This technique promises to be useful for recognizing sexually dimorphic tissue components to study their differentiation and functional significance.

Supported by USPHS grants NS 19645 and HD 18859.

161.18 NEONATAL FOREBRAIN NOREPINEPHRINE(NE) AND REARING ENVIRONMENT INFLUENCE LASHLEY III MAZE PERFORMANCE IN RATS. DOPAMINE(DA) DEPLETION DOES NOT PROTECT AGAINST ISOLATION INDUCED MAZE DEFICITS. Matti Saari, Susan Murtha*, David Murray *, Ken Stange* and Bruce A. Pappas. Dept. of Psychol., Nipissing Univ. Coll., North Bay, Ontario, P1B 8L7, and Carleton Univ., Ottawa, Ontario, K1S 5B6.

We have previously suggested that neural and behavioural alterations induced by rearing environment may be mediated by central NE since NE depletion leads to lack of sensitivity to rearing conditions (O'Shea et al., Europ. J. Pharmacol., 1983).

We report on two experiments showing that: 1) neonatal NE depletion reduces the debilitating effects on maze performance of several kinds of rearing environments and 2) the debilitating effect of the isolation rearing condition is unaffected by neonatal DA depletion.

In experiment 1 newborn male Wistar rats were injected subcutaneously (s.c), either with 6-hydroxydopamine (6-OHDA, 50mg/kg) or vehicle (Veh, 1.0 mg/ml ascorbic acid in saline) twice within the first 24 hours after birth and cross fostered. At 24 days of age the rats were reared for 35 days in one of four environments: 1) large colony cages with rotated toys and daily 30 minute exposures to an open field 2) large colony cages with handling 3) large colony cages with no handling 4) isolated and undisturbed in single cages. At 60 days the rats were tested on four Lashley III mazes. Five trials per day were run with computer controlled randomization and data collection. Analysis of variance of the log median daily latencies revealed a significant drug treatment by environment by day interaction. This arose from the superior performance of the NE depleted rats in comparison to the vehicle injected rats from all but the enriched rearing conditions.

In experiment 2 one group with bilateral intraventricular injections of 6-OHDA (50 ug. in .5 ul. ascorbic acid/saline vehicle) and s.c. desmethylimipramine (DMI), 25mg./kg. was added to the above with their DMI-sham operated controls. These rats were all housed in isolation. The behavioural testing (as above) revealed a significant drug by control by day interaction with Ne depleted rats significantly faster and no differences among the other groups.

162.1 CHANGES ON MUSCARINIC RECEPTOR POPULATION IN SOME BRAIN AREAS OF RATS DURING AN AUTOSHAPED INSTRUMENTAL TASK. A. Ortega*, A. Meneses*, A. Oscós* and V. Alemán, Departamento de Neurociencias Centro de Investigación y Estudios Avanzados del IPN, México, D.F. 07000.

It is currently thought that the encode of learning is probably found in a modification of the organization or function a the synaptic level. Under certain demanding conditions, receptors localized at the postsynapsis could be a limiting factor in the synaptic function. Receptors in this region seems to be a plausible protein candidate regulating the synaptic function. Because of this, we have thought the possibility that during learning of an appetitive autoshaping lever pressing response paradigm, we could detect changes in the number of muscarinic receptors in different brain areas as compared with control animals. We used 30 female rats of 90 days of age. During a week, animals were fed ad libitum with tap water and Purina chow pellet diet. At this time 85% of the animals weight was programmed to be reach in the five subsequent days. Rats were divided ramdomly in 3 different groups: a passive control, a group trained during three sessions (one session of 50 associative trials per day) and a group overtrained during 10 sessions. Binding determinations were carried according to a previous report. (^{3}H)-scopolamine methyl chloride (Amersham) was used as the ligand. The amount of muscarinic receptors in hippocampus of control rats was 0.56 pmol/mg prot but this value statistically decreased to 0.40 pmol/mg prot in trained rats. There was not such difference in the overtrained group. Instead in the amygdala we found a statistic increase in the receptor number of trained animals 0.81 pmol/mg prot as compare to the value of the control group 0.39 pmol/mg prot. A similar change was not singificant in overtrained rats (0.64 and 0.60 pmol/mg prot respectively). In another brain area the septum, the population of receptors in trained animals decreased to 0.90 from 1.0 pmol/mg prot in the control group. This change was greater in overtrained rats, that is 0.34 pmol/mg prot from 0.86 pmol/mg prot in the control group. In the temporo-parietal cortex, as in the amygdala, the receptor population increased statistically from 0.48 pmol/mg prot in the control rats to 0.70 pmol/mg prot in trained animals. A similar but smaller change was found in overtrained animals that is 0.50 and 0.59 pmol/mg prot respectivelly. Finally in caudate nucleus we found a statistically significant decrease in the amount of receptors from 0.62 pmol/mg prot in control group to 0,53 pmol/mg prot in trained rats. A similar and significant change from 0.63 pmol/mg prot in the control rats to 0.50 pmol/mg prot in overtrained animals was also found. Affinity constants changes were only observed in caudate and septum of trained animals as well as in septum and temporo-parietal cortex of overtrained animals but these changes were rather small.

162.2 DSP4 ALTERS REARING ODOR EFFECTS ON DEVELOPING RATS. C.A. Cornwell-Jones, T. Giannulli* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717.

Odor preference modifiability declines in rats with depleted central and peripheral norepinephrine (NE), but investigation of novel object is not affected (Cornwell-Jones, C.A. et al., Behav. Neural Biol., 35:1982). In the present experiment, odor preference modifiability and general investigatory behavior were examined after depletion of central but not peripheral NE by the neurotoxin DSP4. Odor preferences of two-week and five-week old male rats were examined 10 days after systemic injection of 50 mg/kg of DSP4 or water. Seven days after injection, half the animals in each age group were placed in cedar shavings and the other animals remained in pine. Three days later, odor preferences were measured for both age groups, and on the day after preference testing investigatory behavior of the older rats was examined.

DSP4 treatment appeared to increase odor preference modifiability. Pine-reared rats in both treatment groups preferred pine to cedar odor at both developmental stages. Exposing water-treated rats to cedar induced indifference to the odors in the younger, but not the older group. In contrast, cedar-housed DSP4 rats were indifferent to the odors at both testing ages. Pine-reared infants in both treatment groups preferred the odor of soiled pine-nest shavings to the odor of clean pine shavings. Exposing rats to cedar eliminated this preference in pups injected with DSP4, but not water.

DSP4 treatment decreased rearing effects on general investigatory behavior. Exposure to cedar increased investigation of a novel cup for rats treated with water but not with DSP4. In addition, for water- but not DSP4-treated cedar-housed rats, the mean duration of investigatory bouts decreased during the testing session (i.e. habituation occurred).

NE depletion restricted to the central nervous system increased rearing-induced changes in odor preferences but reduced changes in investigatory behavior. The contrast with previously observed effects of combined central and peripheral NE depletion suggests that both NE sources normally help mediate experiential influences on these behaviors.

162.3 APPARENT MEMORY DEFICITS IN RATS TESTED FOR DELAYED ALTERNATION AFTER SELF-ADMINISTRATION OF DIAZEPAM. K.E. Gaston and M.A. Perrah*. Pitzer College, Claremont, CA 91711.

Acute treatment with diazepam produces transient anterograde amnesia in human subjects (Hinrichs et al, 1982, Pharm. Biochem. Beh., 17; Romney & Angus, 1984, Psychopharm. Bull., 20). Animals also show performance decrements on various tasks while under the influence of diazepam (Dantzer, 1977, Biobehavioral Reviews, 1). Most of these findings, however, do not unambiguously reflect memory dysfunction and can be interpreted in terms of other known properties (e.g., anxiolytic or disinhibitory) of the drug. The present study attempts to more directly examine the effects of diazepam on memory by testing rats on a delayed alternation task in which correct performance depends on the rat's remembering, over various periods of time, where it has just been.

The training and testing procedure was similar to that described by Roberts (1972, JCPP, 78). Each rat was pretrained to turn to opposite sides of a T-maze on successive trials in order to obtain food reward. When consistent alternation was established, nominal delays were introduced such that, after each trial, the rat was confined in the start box for 0, 5, 15, 30 or 60 sec. Each rat was given 5 test trials per day at each delay for several days. As expected, the percent of correct choices made was an inverse function of the delay, ranging from a high of about 95% at 0 sec to a low of about 65% at 60 sec. Next, on several separate occasions, each rat was allowed to drink a .625 mg/ml solution of diazepam in water and was tested for delayed alternation while under the influence of the drug. Self-administered doses of diazepam ranged from about 14 to about 39 mg/kg. The results showed that diazepam did not noticeably disrupt performance at the 0 sec delay, but that at each of the longer delays there was a dose-dependent decrement in percent of correct choices, as compared with pretest scores.

These findings suggest that the delayed alternation task is a useful paradigm for assessing the effects of diazepam on memory. The fact that diazepam did not interfere with alternation at the 0 sec delay indicates that the progressive decline in accuracy seen at the longer delays was due to diazepam-induced memory impairment and not to other, non-amnestic, properties of the drug. (Supported by Pitzer College Research & Awards Committee Grants.).

162.4 POST-LEARNING ETHANOL EFFECTS ON A WATER-FINDING TASK IN RATS. K.F.Melia*, C.L.Ehlers*, C.J.Lebrun*, and G.F.Koob. (SPON: L.Henderson). Div. of Neurosci., Alcohol Res. Ctr., Res. Inst. of Scripps Clinic, La Jolla, CA. 92037

In alcohol and cognition research, post-hoc administration of ethanol has been shown to enhance human memory for newly-learned material. Current animal research has replicated this phenomenon but with aversively-motivated tasks. Unfortunately, in such paradigms, ethanol's putative retroactive effects are potentially mediated by its lingering autonomic effects. An alternative paradigm, the water-finding task, offers the advantage of being an appetitively-motivated latent learning paradigm. Additionally, it has been used previously to study post-learning drug effects. To this end, the present study employed this paradigm to address the issue of post-hoc alcohol effects on memory enhancement.

Sixty male rats (138-264g) were assigned to one of three groups: control saline, a low dose ethanol (.75 mg/kg) and a higher dose ethanol (1.5 mg/kg). For latent learning, a rat was individually placed into the corner of an open field (37 x 64 x 46 cm) containing a drinking tube recessed into an alcove (11 x 13 x 46 cm). The subject was then allowed 5 min to explore the environment. During this time, the rat's initial latency to enter the alcove and lick the water tube was obtained (learning latency), and subsequent trips into the alcove accompanied by at least one lick were recorded (latent learning bouts). Immediately afterward, a subject was injected with one of the three doses and returned to its home cage. Approximately 30 minutes later, ad lib water was withdrawn, and 48 hours later, each animal was re-introduced to the open field and a second latency (test latency) to make contact with the drinking tube was measured.

A repeated measures analysis of variance revealed a statistically significant reduction in test latencies compared to learning latencies for all subjects ($p \leq .001$). The mean test latencies of the ethanol animals were the shortest, but not statistically significantly so (mean latencies = 42.44, 27.59 and 40.62 sec for control, low ethanol and higher dose ethanol, respectively). Linear regression analyses were performed on both test latency and the difference between learning and test latencies for each group. While the ethanol rats' behavior at time of test was significantly correlated with, and could be predicted from, behavior during latent learning, this was not true of the control animals. The control rats' test latencies were essentially random with respect to all measures of their previous behavior. Bouts and learning latency together were correlated significantly with test latency for the higher dose ethanol rats ($r=.81$, $p \leq .001$), and bouts were significantly correlated with the change in latency scores for the low dose ethanol rats ($r=.53$, $p \leq .05$). That is, for low dose ethanol, intraindividual latency reduction was predicted from the number of times the subject engaged in a drinking bout during latent learning.

These results indicate that ethanol administration can modify the effects of previous experience such that past behavior can come to more fully predict future behavior. It is suggested that the group-related orderly changes in behavior found may have implications for current research on the facilitating effects of post-learning ethanol on memory. 162.5 **EFFECTS OF CENTRAL DEPLETION OF NOREPINEPHRINE OR SEROTONIN UPON MEMORY TASKS USING THE RADIAL MAZE.** K. Pang[1], A. Chavez[2*] and G. Rose[1,2]. [1]Dept. of Pharmacology, University of Colorado Health Sciences Center and [2]Medical Research, VAMC, Denver, CO 80262

The hippocampal formation is known to play a critical role in the processes of learning and memory. One recent theory of hippocampal function suggests that this structure is particularly important in spatial memory; another theory suggests that the hippocampus participates in the recall of recent events (i.e., working memory). Both these types of memory may be demonstrated using the radial arm maze. Acquisition and performance of tasks using this maze are profoundly disrupted by damage to the hippocampus or its major afferents, but are unaffected by lesions of nonlimbic areas. Many studies have also implicated CNS monoaminergic systems in memory. However, the central site(s) of influence of monoamine neurotransmitters in learning or memory remain undefined, primarily because the brain loci governing performance in the tasks used have not been determined. In the present study, the effect of depletion of central norepinephrine (NE) or serotonin (5-HT) upon learning and memory was examined using the radial maze, since for such tasks CNS substrates are known.

Central NE or 5-HT were depleted by injection of N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine (DSP4; 2 injections of 50 mg/kg, i.p., at a 7 day interval) or 5,7-dihydroxytryptamine (5,7-DHT; 150 ug, i.c.v.), respectively. Rats treated with 5,7-DHT received prior treatment with desmethylimipramine (20 mg/kg, i.p.) to protect noradrenergic terminals. Control rats received equivalent injections of 0.9% NaCl. All animals were allowed 2-3 weeks to recover before maze training was begun. Rats were trained on the radial maze using the 8-arm spatial memory and the 4-arm working/reference memory paradigms; reversal learning in the 4-arm task was also examined. At the conclusion of behavioral testing, all rats were sacrificed and the hippocampus removed for analysis of tissue levels of monoamines using HPLC analysis.

Rats treated with 5,7-DHT (>70% depletion of 5-HT) had profound deficits in acquisition of the spatial and working/reference memory tasks. By contrast, treatment with DSP4 did not influence acquisition of these tasks; nor was performance of the spatial memory task or the work/reference reversal affected. NE depletions were, in all cases, greater than 90%. Thus, 5-HT, but not NE, is required for normal limbic system functioning in memory tasks using the radial maze. We are currently examining the effect of DSP4 and 5,7-DHT upon hippocampal long-term potentiation, a putative electrophysiological correlate of memory. 162.6 VINPOCETINE: NOOTROPIC EFFECTS ON DISRUPTED MEMORY RETRIEVAL IN RATS. V. J. DeNoble, L. W. Gelpke*, S. J. Repetti*, L. M. Wood*, and K. L. Keim. Dept. Pharmacology, Ayerst Laboratories Research Inc., Princeton, NJ 08540.

Vinpocetine (3α, 16α eburnamenine-14-carboxylic acid ethyl ester), vincamine, aniracetam and hydergine, compounds with purported cognitive activating profiles, were evaluated for their ability to prevent scopolamine-induced and hypoxia-induced impairment of retention of a step-through passive avoidance response. During the acquisition of the avoidance response, male Sprague-Dawley rats were placed in a lighted compartment and given access to a dark compartment. Two sec after entering the dark compartment, the rats were given a 2 sec inescapable 750 μA shock; retention was tested 24 hr later. For memory disruption, scopolamine (2 mg/kg sc) was administered 30 min prior to acquisition; all test drugs were given 90 min prior to acquisition.

Rats receiving scopolamine entered the dark compartment during the retention test with an average latency of 58 ± 7 sec, whereas vehicle control rats failed to enter (180 sec maximum latency). Vinpocetine (Peak Effect Dose [PED] = 200 mg/kg po) and aniracetam (PED = 100 mg/kg po), and hydergine (PED = 1 mg/kg po) prevented disruption by scopolamine of the passive avoidance retrieval. Hypoxia (7% O_2, 93% N_2) 20 min before and 20 min after avoidance training also impaired retention: > 75% of the rats did not retain the passive avoidance task. Vinpocetine (PED = 3 mg/kg po) and aniracetam (PED = 30 mg/kg po) were effective in preventing disruption of retrieval. Furthermore, in both tests the drug protection was dose-related in a typical inverted U-shaped manner. In contrast, hydergine (0.05 to 3 mg/kg po) and vincamine (0.3 to 100 mg/kg) were not effective against hypoxia-induced impairment. Hydergine at doses > 3 mg/kg po, markedly impaired motor function and could not be tested. The PED for vinpocetine and aniracetam in hypoxia impairment was significantly lower when compared to the doses effective in the scopolamine-impaired test. (-)-nicotine (0.1 to 0.4 mg/kg sc) and mecamylamine (1, 3, 10 mg/kg sc) given at various pretreatment times did not protect against memory impairment induced by either procedure.

These data support the view that vinpocetine has cognitive activating abilities as defined in models of both scopolamine-induced and hypoxia-induced memory impairment in rats. Disruption of retrieval by scopolamine is considered a specific antagonism of cholinergic neural substrates, whereas hypoxia-induced impairment is a more global brain insult. Since vinpocetine was active in both tests, this drug may be effective in a broad range of conditions which compromise memorial function.

162.7 THE ATTENUATION OF PAVLOVIAN EYEBLINK CONDITIONING BY PIZOTIFEN (BC-105) MAY BE DUE TO ITS EFFECTS ON AUTONOMIC SYSTEMS.* Sheryl R. Ginn and D. A. Powell. Neuroscience Lab., Dorn Veterans' Hospital, Columbia, SC 29201.

Experimentally naive New Zealand albino rabbits received Pavlovian eyeblink conditioning in which 75 db, 500 msec duration tones served as the conditioned stimulus (CS) and 200 msec paraorbital electric shock trains served as the unconditioned stimulus (UCS). Thirty-two animals, divided into four groups, received 0.0, 2.5, 5.0 or 10.0 mg/kg of the central serotonin (5-HT) antagonist pizotifen (BC-105) subcutaneously (s.c.) 15 minutes prior to session onset. Two pseudoconditioning control groups (N=16) received a random sequence of explicitly unpaired tones and shocks. These animals received 0.0 (n=8) or 5.0 (n=8) mg/kg BC-105 s.c., 15 min prior to session onset. Both heart rate (HR) and eyeblink (EB) conditioned responses (CRs) were assessed.

All three doses of pizotifen attenuated acquisition of the EB CR compared to animals which received saline injections, but these differences were not dose related. Both the 2.5 and 5.0 mg/kg groups showed significantly slower eyeblink acquisition than the saline group. The 10.0 mg/kg group also revealed fewer EB CRs than the saline group, but these differences were not significant. The cardiac CR, which accompanied EB conditioning, consisted of bradycardia and was attenuated in a dose-related fashion by BC-105. The groups which received explicitly unpaired tones and shocks showed virtually no EB or HR conditioning. The finding that the effects of BC-105 on the HR CR were dose related but its effects on EB conditioning were not, suggests that BC-105 may affect nonspecific processes related to autonomic conditioning, which in turn interferes with the acquisition of the somatomotor eyelid conditioned response. Interference with visceral systems by BC-105 may, for example, indirectly lead to cognitive impairments by causing confusion or motivational deficits in drugged animals.

162.8 EVIDENCE FOR MULTIPLE STAGES OF MEMORY FORMATION IN THE CHICK. T.A. PATTERSON, M.R. ROSENZWEIG, E.L. BENNETT, and S.E. LUCEY*. DEPARTMENT OF PSYCHOLOGY, UNIVERSITY OF CALIFORNIA, BERKELEY, CA. 94720.

Gibbs & Ng (1977) proposed a three stage model of memory formation based on work with the chick: short-term memory, due to hyperpolarization dependent upon K+ conductance changes; intermediate-term memory due to hyperpolarization dependent upon sodium pump activity and long-term memory, dependent upon protein synthesis. In preparation for further study in this field, we have attempted to replicate some key findings of Gibbs & Ng.

Two-day-old male Leghorn chicks were trained in a one-trial taste avoidance task. Dose response functions were determined for glutamate, a depolarizing agent; ouabain, a Na+/K+ ATPase inhibitor; and anisomycin (ANI), a protein synthesis inhibitor. Intracerebral injections (10 ul/hemisphere) of saline or drug were given 5 min pre-training, and chicks were tested 24 hr post-training. Compared to saline solution, 37.5mM- 75.0mM glutamate, .014mM-.041mM ouabain, and 11.3mM- 18.8mM ANI produced significant amnesia. Lower doses of each drug were not effective, while higher doses produced behavioral side-effects.

The duration of protein synthesis inhibition after intracerebral injection of ANI (10 ul/ hemisphere) was examined. A non-amnestic dose (7.5mM) produced 70% whole brain (minus cerebellum) inhibition 30 min after injection; this dropped to 50% by 2 hr. An amnestic dose (15.0mM) produced more than 80% inhibition from 30 min to 1 hr; inhibition dropped to 60% by 3 hr.

The development of amnesia following pre-training injection (10 ul/hemisphere) of glutamate, ouabain or ANI was determined. Glutamate (50mM) produced amnesia which developed by 10 min post-training. Ouabain (.027mM) produced amnesia which developed between 15 and 30 min post-training, while ANI (15.0mM) produced amnesia which developed by 90 minutes post-training. Amnesia produced by these agents appears permanent; chicks tested at later times are also amnesic.

These results are similar to those obtained by Gibbs and Ng and support a sequentially dependent three-stage model of memory formation. Doses required for amnesic effect, and the time which amnesia appears after injection of ouabain and ANI differ from their report; we are attempting to determine if these differences are due to training parameters or housing conditions.

162.9 DECREASE BY THC OF MEDIAL SEPTAL MEDIATED AUGMENTATION OF RESPONSE AT HIPPOCAMPAL CA1. N.J. Pontzer,* and D.M. Wilkison* (SPON: L.F. Tseng). Dept. of Pharm. and Tox., Medical College of Wisconsin, Milwaukee, WI 53226.

Decrements in learning and memory are among the most prominent behavioral effects of THC, the active constituent of marijuana. Both hippocampal lesions and anticholinergic drugs produce memory deficits similar to those observed after THC. THC has been shown to potently and specifically reduce spontaneous acetycholine turnover in the septo-hippocampal cholinergic system. This action is manifested by a decrease in cholinergic-mediated hippocampal theta rhythym. Pre-stimulation of the septum augments evoked monosynaptic discharge at the hippocampus in an atropine sensitive manner. We tested the hypothesis that THC would decrease evoked as well as spontaneous septo-hippocampal function.

Male Sprague-Dawley rats anesthetized with urethane (1.5 g/kg, ip) were implanted with 16 mil concentric bipolar stimulating electrodes in the medial septum (MS) and ventral hippocampal commissure (VHC). Semi-micro recording electrodes were positioned in the contralateral CA1 pyramidal cell layer. Eight successive CA1 responses (0.2 Hz) were averaged and digitally filtered to separate the cell discharge (spike) and synaptic (slow positive wave) components of the VHC-evoked field potential. Averaged responses were obtained for VHC stimulation levels which produced near-threshold, half-maximal and supramaximal spike amplitudes. The percentage increase in spike amplitude produced by septal pre-stimulation (400 Hz, 15 mS) was measured before and 15 min after THC given iv in cumulative doses of 0.3, 1.0 and 3.0 mg/kg.

Septal augmentation of CA1 spike amplitudes was greatest at near-threshold VHC stimulation (200 - 500%), much less for half-maximal (20 - 80%) and not detectable at supramaximal stimulation levels. There was little or no direct septal response or augmentation of synaptic components. THC reduced half-maximal VHC-mediated responses to levels at which greatly increased septal augmentation would be expected. THC also reduced the predicted septal augmentation of the spike response based on spike amplitude. This effect was sometimes seen at the lowest dose of THC when there was little change in spike amplitude. Physostigmine (0.3 mg/kg iv) produced a partial recovery of septal augmentation, but not VHC responses when given after THC. These actions of THC on septal augmentation at CA1 are similar to those we previously demonstrated for perforant path mediated responses in the dentate.

162.10 THE UTILITY OF A LATENT INHIBITION PARADIGM IN COMBINATION WITH A DELAYED REINFORCEMENT AUTOSHAPED BEHAVIOR. C.A.Cohen*and S.B. Sparber. Depts. of Psychology and Pharmacology, University of Minnesota, Minneapolis, MN 55455.

Latent inhibition is a term coined by Lublow and Moore which can be used to describe the inhibiting effect upon learning by exposing subjects to environmental cues, which will be used for conditioning stimuli, prior to the conditioning procedure (Lublow and Moore, J. Comp. Phys. Psych.,1959,52:415). It may be thought of as habituation or suppression of the saliency associated with novelty and/or the arousing effect of exposure to the novel cues. Acquisition of a forward autoshaped task is retarded by interposing a delay between the required lever-touch response and delivery of the food pellet reward (Messing,Kleven, and Sparber, submitted). Facilitatory effects of agents upon acquisition of autoshaped behavior may be due to nonspecific motoric or arousing properties, thus there is a need to establish a reliable task which requires response inhibition as a measure of learning, so that we can control for such variables.

During the delayed autoshape procedure, the retractable lever was extended into the chamber on a 45 second random time schedule and withdrawn either when the animal made a lever touch or 15 seconds had elapsed. When the lever was retracted under either of the above mentioned conditions, a food pellet was delivered 6 seconds later. Adult male Sprague-Dawley rats were randomly assigned and placed in modified Skinner boxes with retractable levers for 2 or 4 sessions of 24 trials without reinforcement. A third group was never placed in the operant chambers prior to the autoshape sessions. The animals placed in the chambers for the latent inhibition sessions were exposed to the identical procedure as in the subsequent autoshape sessions, except the food dispenser was disconnected. Three days after the last nonreinforced session, all subjects were presented with the delayed autoshape task for four consecutive sessions. A repeated measures ANOVA of the number of correct lever touch responses indicated that animals exposed to the chamber for 2 or 4 sessions prior to acquisition of the autoshape task did not acquire the response, as did the control subjects.

Exposure to Chamber	Acquisition Sessions (M±SE) 1	2	3	4
0	9.00± 1.07	8.50± 1.69	12.44±2.60	16.80± 2.92
2	6.73± 1.14	6.18± 2.23	5.70±2.63*	8.36± 2.78*
4	6.18± 1.15	4.09± 1.65	5.45±2.48*	7.64± 2.83*

162.11 AF64A IMPAIRS WORKING MEMORY IN RADIAL-ARM AND T-MAZE TASKS. J.J. Chrobak*, I. Hanin & T.J. Walsh* (SPON: R.A. King). Univ. of North Carolina, Chapel Hill, NC 27514 and Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Ethylcholine mustard aziridinium ion (AF64A) is a select cholinotoxin which produces a persistent reduction in presynaptic cholinergic markers (Mantione et al., Science, 213, 1981). This compound has been shown to impair retention of a passive avoidance response and disrupt acquisition of a radial-arm maze (RAM) task (Walsh et al., Brain Res., 321, 1984). The studies presented here attempted to further characterize the nature of the cognitive deficits produced by AF64A.

Male Fischer rats were trained in a modified RAM task. In this task rats had access to only 4 out of 8 maze arms during a predelay session. After entering these arms the rats were returned to their home cages for a 2 hr. delay period. Following the delay they were returned to the maze and allowed to freely choose among all 8 arms. Arms not previously entered were now baited and entry into previously visited arms constituted an error. Following 20 days of training rats were injected with AF64A (3 nmols/side/icv.) or an equivalent volume of saline and allowed 2 weeks to recover. Rats treated with Af64A performed at chance level, making 2 or more errors in their first 4 post-delay choices and making significantly more total choices in the post-delay session, throughout 20 post-operative trials (one per day, five days a week). The behavioral deficits were associated with a selective decrease (38%) of choline acetyltransferase activity in the hippocampus.

In a second experiment rats were trained on a modified T-maze task. Animals were placed into one of two start/goal boxes located on either arm of the maze. They were trained to run down the stem of the maze and return to the alternate start/goal box for food reward (i.e., a non-match to sample task). The location of the start box was randomly alternated on each trial. The different aspects of this task may be characterized as a) a reference memory component which involves an invariant response of running down the stem of the maze and b) a working memory component in which the animal must maintain some representation of the previous stimulus event (i.e., the start location) to perform accurately. Following training rats were injected with AF64A or saline according to the above protocol. Rats treated with AF64A were impaired on the working memory task, while their performance of the reference memory task, within the same trials, was unimpaired.

These data suggest that hippocampal cholinergic mechanisms are critical for allowing an animal to differentially respond on the basis of recently experienced stimulus events.

162.12 INTERACTIONS BETWEEN UNCONDITIONED STIMULI THAT PRODUCE TASTE AVERSION LEARNING. B. M. Rabin, W. A. Hunt* and J. Lee*. Behav. Sci. Dept., Armed Forces Radiobiol. Res. Inst., Bethesda, MD 20814-5145, and Dept. Psychol., Univ. Maryland Baltimore County, Catonsville, MD 21228.

A conditioned taste aversion (CTA) is produced when a novel tasting solution is paired with a wide variety of unconditioned stimuli, including injection of lithium chloride or amphetamine, or exposure to ionizing radiation. The diversity of unconditioned stimuli that can lead to CTA learning raises the question of whether or not there may be a common factor underlying the capacity of these stimuli to produce a CTA. This question was studied by investigating whether or not it would be possible to produce a CTA in rats by combining subthreshold doses of radiation, lithium chloride or amphetamine.

A CTA was established in rats using a two-bottle procedure with a 10% sucrose solution as the conditioned stimulus. The first experiment determined the doses that were just below threshold for producing a CTA: lithium chloride, 0.3 mEq/kg; amphetamine, 0.5 mg/kg; radiation, 15 rad (at 20 rad/min). These in turn became the standard doses for the second experiment. On the conditioning day, naive rats were treated with one unconditioned stimulus immediately following ingestion of the sucrose solution. 30 min later, without further access to the conditioned stimulus, they were given a second treatment with either the same or with a different unconditioned stimulus. Controls were treated with only a single unconditioned stimulus following sucrose ingestion followed by either saline injection or sham exposure 30 min later. In contrast to the controls, combining an initial subthreshold exposure to ionizing radiation with a second exposure 30 min later or with injection of a subthreshold dose of amphetamine or lithium chloride produced a significant decrease in test day sucrose preference. Similar results were obtained with combined subthreshold doses of amphetamine, but not with combined doses of lithium chloride.

The observation that two subthreshold doses of different unconditioned stimuli, following a single exposure to the conditioned stimulus, can be combined to produce a CTA suggests that there is a common factor underlying the capacity of lithium chloride, amphetamine and radiation to produce a CTA. The results also suggest that treating an organism with ionizing radiation or amphetamine produces a physiological change in the organism that remains active for at least 30 min following treatment.

162.13 EFFECTS OF TRIMETHYLTIN (TMT) ON THE LICL DOSE-RESPONSE FUNCTION FOR TASTE AVERSION LEARNING IN THE RAT. J. P. Mastropaolo, R. J. Dacanay & A. L. Riley. Psychopharmacology Lab, The American University, Washington, D.C. 20016

Recently, TMT has been shown to disrupt the acquisition of a conditioned taste aversion (CTA) when a delay is imposed between the presentation of the taste and the administration of a toxin (Riley, A., Dacanay, R., & Mastropaolo, J., Neurotox., 5:291-296, 1984). Specifically, TMT- and non-TMT-treated rats presented with a novel saccharin solution and injected with LiCl immediately, 3-h or 6-h post-saccharin ingestion displayed differential aversions. In both groups, the strength of the aversion decreased as the interval between ingestion and LiCl administration increased. Relative to the non-TMT-treated rats, however, aversions were weaker at the longer delays in the TMT-treated rats, a disruption consistent with memory deficits reported in other procedures (e.g. Walsh, T., Miller, D., & Dyer, R., Neurobehav. Toxicol. Teratol., 4:177-183, 1982). Concluding that this disruption is a memory deficit requires consideration of recent evidence that TMT also affects sensory systems (Dyer, R., Howell, W., & Wonderlin, F., Neurobehav. Toxicol. Teratol., 4:191-196, 1982; Howell, W., Walsh, T., & Dyer, R., Neurobehav. Toxicol. Teratol., 4:197-202, 1982). Since the acquisition of a CTA increases with the dose of the toxin, it might be that the effect reported by Riley et. al is due to changes in the intensity of the toxic effects of LiCl, which could interact with the delay gradient, rather than to memory impairment. The present experiment, therefore, assessed the effects of TMT on the ability of various doses of LiCl to produce CTAs. Specifically, 48 water-deprived rats were randomly assigned to two groups, one intragastrically administered TMT (6 mg/kg) and the other receiving an equivolume intubation of distilled water. Twenty one days following this treatment, all subjects were given 20-min access to a novel saccharin solution (0.1% w/v), followed immediately by an injection of either 0, 0.3, 0.6 or 1.8 mEq of LiCl. In total, there were four saccharin/LiCl pairings and a final saccharin aversion test. Three water recovery days separated successive exposures to saccharin. TMT- and non-TMT-treated rats showed equally large dose-related aversions, i.e., the higher the dose the greater the aversion. More importantly, no differences were found in the degree of CTA produced in TMT- and non-TMT- treated rats. Therefore, the earlier reported deficit in the acquisition of CTAs over long delays is not the result of changes in stimulus intensity. As such, the interpretation of this effect as a memory deficit is strengthened.

BIOLOGICAL RHYTHMS II

163.1 OLFACTORY BULBECTOMY PREVENTS THE ACYCLICITY ASSOCIATED WITH SHORT PHOTOPERIOD IN FEMALE GOLDEN HAMSTERS. D.R. Pieper and R.N. Heverly*, Department of Biology and Health Sciences, University of Detroit, Detroit, MI 48221

Exposure of golden hamsters to a short photoperiod (SP) for 10 weeks results in testicular regression in the male and acyclicity in the female. Exposure of rats to SP alone has no effect, but if the rats are pre-pubertally olfactory bulbectomized (BX) and then placed on SP or blinded and BX, the testes become smaller and the females have irregular estrous cycles. All of these effects in rats or hamsters are prevented if the animals are pinealectomized in addition to the other manipulations. We have recently shown that pre-pubertal BX of male golden hamsters will prevent the testicular regression associated with SP (Brain Res 321:183, 1984), an effect opposite that predicted by the results of BX in rats. The experiments described here test whether pre-pubertal or adult BX will prevent the acyclicity associated with SP in female hamsters. In the first experiment, 23 day old hamsters were divided into 4 groups: LD 14:10 sham BX; LD 14:10 BX; LD 6:18 sham BX; and LD 6:18 BX. Cells from vaginal washings were observed under the microscope for 11 weeks. At least 90% of both groups on LD 14:10 had regular estrous cycles for the last 7 weeks of the experiment. In the LD 6:18 sham BX group, 7 of the 19 animals (37%) were cycling regularly by 11 weeks after being placed in LD 6:18. On the other hand 21 of 23 (91%) of BX animals on LD 6:18 had regular estrous cycles. These results were very interesting and indicated that BX may prevent the acyclicity associated with SP. However it was somewhat perplexing that only 57% of the control group on LD 6:18 became acyclic. It was felt that this may have been due to the animals being exposed to the SP pre-pubertally. The experiment was therefore repeated except that this time the hamsters arrived in the laboratory at 63 days of age and they were sham BX or BX and placed in LD 6:18 at this age. This time, only 2 of 10 (20%) of the sham operated animals had regular estrous cycles 11 weeks after being placed in LD 6:18. On the other hand, 9 of 10 (90%) of the BX animals had regular estrous cycles. These results indicate that either pre-pubertal or adult BX will prevent the acyclicity associated with SP in female golden hamsters. The neural or humoral relationship between the olfactory bulb and the reproductive response to photoperiod is not clear at this time and is now being investigated.

163.2 HYPOTHALAMIC KNIFE CUTS THAT PREVENT SEASONAL REPRODUCTIVE CYCLES: DO THEY INTERRUPT HYPOTHALAMO-SPINAL CONNECTIONS IN HAMSTERS? M. H. Brown and A. A. Nunez. Dept. of Psychology and Neurosci. Prog. Michigan State University, E. Lansing, MI, 48824

Previous results from our laboratory (Nunez et al., submitted for publication) have shown that bilateral horizontal knife cuts placed ventral to, through, or dorsal to the paraventricular nucleus of the hypothalamus (PVN) prevent testicular regression in golden hamsters housed in a short photoperiod (6 hr light:18 hr dark) without disrupting entrainment of circadian activity patterns to the light-dark cycle. To further investigate the hypothalamic neural pathways involved in the gonadal response to photoperiod, an additional group of hamsters was given bilateral horizontal cuts aimed dorsal to the PVN and housed in short photoperiod (6L:18D). One group of control hamsters was also housed in short photoperiod while a second group was kept in long photoperiod (16L:8D). Begining 4 weeks after introduction of the hamsters to short photoperiod, biweekly measurements of the width and length of the right testis of each hamster were made. As in the previous experiment, most of the knife cuts were effective in blocking testicular regression. Possible explanations for the efficacy of the cuts dorsal to the PVN include:(i), interruption of projections from the SCN to the habenula (Neurosci. 6:2625,1981) which in turn projects to the pineal gland (Exptl. Neurol., 79:858,1983); (ii), severing of fibers that project from the PVN to the habenula (JCN., 169:221,1976) and/or pineal (Cell Tiss. Res., 205:11,1980); or (iii), interruption of efferent fibers that project dorsally out of the PVN and then caudally to preganglionic sympathetic cell bodies in the thoracic spinal cord. Support for the third possibility is provided by Luiten et al. (Br. Res., 329:374,1985) who described one bundle of paraventriculo-spinal fibers that leaves the nucleus laterally and then turns caudally near the medial forebrain bundle, and a second bundle of paraventriculo-spinal fibers that travels dorsally out of the PVN and passes dorsocaudally through the thalamus and the periaqueductal gray. To investigate the possibility that knife cuts dorsal to the PVN interrupt paraventriculo-spinal projections, we have employed unilateral horizontal knife cuts and subsequent bilateral injections of horseradish peroxidase (HRP) into the upper thoracic spinal cord. In one case, a knife cut just dorsal to the PVN and very near the dorsal boarder of the PVN substantially reduced the number of labelled cells in the PVN ipsilateral to the cut as compared to the contralateral PVN. Preliminary results obtained using bilateral injections of HRP into the spinal cord of hamsters in which bilateral cuts blocked gonadal regression indicate that the effective cuts interrupt some but not all of the paraventriculo-spinal projections. (Sponsored by NIMH grant MH 37877 to A. A. N.)

163.3 EFFECTS OF VENTROMEDIAL HYPOTHALAMIC LESIONS ON CIRCADIAN DRINKING AND TEMPERATURE RHYTHMS IN RATS. Stephen Kent* and Evelyn Satinoff. Dept. of Psych., Univ. of Illinois, Champaign, Il. 61820

Ventromedial hypothalamic (VMH) lesions eliminate the circadian rhythms of feeding (Kakolewski et al., 1971) and sleeping (Danguir and Nicolaidis, 1978). It has been suggested that they also eliminate the circadian temperature rhythm (CTR) (Krieger, 1980).

In this study we examined the effects of VMH lesions on body weight and circadian temperature and drinking rhythms in unrestrained female rats. Body temperature (Tb) was measured every 10 minutes through implanted telemetry devices and drinking via a drinkometer circuit. The rats were weighed 3-4 times a week for the first 2 months post-lesion and once a week after that. Tb retained its rhythmicity in all animals after VMH lesions in a 12:12 light-dark cycle, and the rhythm free-ran with a period of 24.12 ± .03 hours in constant dark (N=9). Some of the CTR parameters were altered postoperatively. During the dynamic stage of hyperphagia (days 6-20) (mean weight gain 4.77 ± .74 g/day) the acrophase advanced an average of 67 ± 19° compared to prelesion values ($p<.01$). The individual amount of phase advance was positively correlated with the maximum increase in body weight ($r=.844$, $p<.01$). This advance decreased slightly over time. Mean daily Tb slowly decreased after surgery so that by days 84-99 postsurgery, when the rats were in the static stage (mean weight gain 269 ± 30 g) it averaged 0.52 ± .16°C lower than prelesion values ($p<.02$). The amplitude increased slightly, but not significantly, over the post-lesion period.

Drinking became aperiodic in the six rats in which it was measured. In one animal drinking became rhythmic after 10 days, and in two others after 6-8 weeks. In the remaining three animals drinking remained arrhythmic for the duration of the study (4 months). Water intake increased 236 ± 25% over control levels ($p<.01$) during the dynamic stage and 133 ± 19% during the static stage.

When the rats were in the static stage, with body weights 238 ± 20% over controls, we tested their ability to maintain normal Tb in the heat (3 hrs. @ 40°C). They were removed from the heat earlier if their Tb increased above 41.75°C. Six of the seven lesioned rats had to be removed from the stress before 3 hours were up (avg. time = 117 ± 13 min.). In contrast, only 1 of the 7 controls had to be removed (avg. time = 177 ± 3 min.) ($p<.001$). Preliminary data with 4 VMH-lesioned animals reduced to pre-lesion weight levels suggest that this deficit may be due to the lesion and not to the increased weight.

These results indicate that in rats the CTR remains after VMH lesions with a decreased daily mean and a phase advance that is correlated with the weight gain. Neither the presence of the CTR nor any changes in it depend on the drinking rhythm.

163.4 Melatonin and Photoreceptor Metabolism: Interactions of Melatonin, Dopamine and GABA in the Regulation of Cone Movement. M.E. Pierce* and J.C. Besharse*. (SPON: J. Sutin). Dept. of Anatomy, Emory School of Medicine, Atlanta, GA 30322.

Using an in vitro eye cup preparation from Xenopus laevis, we have previously demonstrated that cone retinomotor movements are influenced by melatonin and by dopamine and have suggested that melatonin may regulate cone retinomotor movement via modulation of dopamine release. In eye cups from four day constant light-treated animals, melatonin mimics darkness and induces cone elongation. Dopamine not only mimics light and induces cone contraction, but also blocks melatonin-induced cone elongation. Dopamine also induces cone contraction in eye cups from cyclic light animals (12 hour light:12 hour dark), but melatonin does not reproducibly elongate cone in eye cups prepared at light offset from cyclic light-treated animals. The difference in melatonin sensitivity between cyclic and constant light-treated eye cups may be related to decreased melatonin biosynthesis and down-regulation of dopamine sensitivity expected in constant light (DeMello et al., PNAS 79: 5708, 1982; Lucas et al., Soc. Neurosci. Abstract 10(2):328.11, 1984). Another possibility is that an additional mechanism for the suppression of dopamine release is needed in cyclic-light animals.

There is considerable evidence that GABA-containing cells exert an inhibitory influence on dopaminergic amacrine cells in rat retina. Muscimol, the GABA agonist, inhibits the activation of tyrosine hydroxylase, a key enzyme in the synthesis of dopamine, and the GABA antagonists picrotoxin and bicuculline activate tyrosine hydroxylase and increase dopamine turnover in dark adapted retinas (Marshburn and Iuvone, Brain Res. 214:335, 1981). Therefore, we designed experiments to test the effects of GABA on cone movements. In eye cups prepared from constant light-treated animals, muscimol (50 µm) stimulates cone elongation which is blocked by the addition of dopamine. Muscimol does not stimulate cone elongation in eye cups prepared from cyclic light-treated animals. However, when both muscimol and melatonin are added to eye cups prepared at light offset from cyclic light animals cones elongate although this treatment is not as effective as darkness. In our cyclic light preparation, the GABA antagonist picrotoxin (100 µm) blocks dark induced cone elongation and induces cone contraction. These results are consistent with a model in which the suppression of dopamine is a necessary part of the dark signal for elongation. Melatonin and GABA may exert their influence through modulation of the dopaminergic system.

163.5 FLUCTUATIONS IN VISUAL SENSITIVITY OF GOLDFISH. C.J. Bassi* and M.K. Powers. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240

Although a number of species exhibit circadian rhythms in visual physiology, only a few have been shown to manifest such changes behaviorally (e.g. Limulus, rat and human). In this experiment, we measured fluctuations in the ability of goldfish, an animal that has long served as a model for retinal function, to detect a visual stimulus over prolonged periods of constant darkness.

Adult goldfish (9-15 cm standard body length) were maintained on a 12L:12D schedule for several weeks before the experiment began. They were classically conditioned to inhibit respiration when presented with a large, diffuse, 532 nm., 5 second stimulus.

Once trained a fish was placed in constant darkness and threshold was measured approximately every four hours for the duration of the experiment. Absolute threshold was measured by recording the probability of response to successively dimmer stimuli, in a staircase procedure. Threshold was determined by standard psychophysical techniques. The four fish tested so far remained in the dark for 40, 56, 92 or 168 continuous hours. During this time, the only light available was the dim, near-threshold stimulus.

All fish showed fluctuations in visual threshold over the course of the experiment. These fluctuations were periodic, with peak sensitivity occuring at approximately 24 hour intervals; five continuous cycles were observed in the fish tested for 168 hours. Maximum sensitivity generally occurred during the late subjective evening. The average change in sensitivity over the day was .50 log unit.

The rhythm in sensitivity observed in this psychophysical experiment does not correlate with our measurements of rod outer segment shedding under constant conditions. Nor does it match the patterns of locomotor activity that occur under constant conditions in this species. Nonetheless, the results are consistent with the hypothesis that the detectability of dim lights fluctuates on a circadian cycle; i.e., the rhythm in visual sensitivity persists for multiple cycles under constant conditions, with a period of approximately 24 hours.

163.6 SEROTONINERGIC INNERVATION OF MOLLUSCAN EYES CONTAINING CIRCADIAN PACEMAKERS. J.S. Takahashi AND A. Eskin. Dept. Neurobiol. and Physiol., Northwestern Univ., Evanston, Il. 60201; Biol. Dept., Univ. Houston-Univ. Park, Houston, TX., 77004.

Our previous studies indicated that 5-HT (Serotonin) is used as a transmitter of circadian information in the Aplysia eye. An important extension of these studies is to determine the anatomy of the 5-HT system. Goldstein et al (1984) examined 5-HT-immunoreactivity in whole mounts of juvenile Aplysia eyes. They observed a dense plexus of stained fibers surrounding the eye and in preliminary studies on adult sectioned eyes, found that most of the stained fibers were in the outermost region of the retina. The source of "5-HT" fibers in the eye appears to be somewhat controversial. Olson and Jacklet (1984) described accessory optic nerves (Acc. ON) carrying efferents up to the eye. Fluorescence studies indicated that the Acc. ONs contained some "5-HT" fibers and, based on other studies, Olson and Jacklet stated that the optic nerve probably did not contain "5-HT" fibers. On the other hand, Goldstein et al mentioned that the optic nerve contained two stained fibers.

Aplysia californica eyes were fixed in paraformaldehyde, sectioned on a cryostat, and then hydrated with porcine serum. Eyes were exposed to 5-HT antibody from either Immunonuclear or Accurate Scientific and then treated with a secondary antibody conjugated with FITC. A number of controls were performed to establish the specificity of the staining for 5-HT. No staining was observed when eyes were exposed only to the secondary antibody, only to normal rabbit serum, or to 5-HT antibodies pretreated with 5-HT. Also, the two different 5-HT antibodies gave similar patterns of staining. Antibody stained fibers were observed in the optic nerve, in the Acc. ONs, in the connective tissue capsule surrounding the eye, and within the eye itself. No stained cell bodies appeared in either the connective tissue sheath surrounding the eye or in the eye. We observed up to six large "5-HT" fibers in optic nerves and these "5-HT" ON fibers were continuous with "5-HT" fibers in the eye neuropil. "5-HT" fibers from Acc. ONs formed a dense network in connective tissue surrounding eyes. Some "5-HT" fibers in connective tissue were continuous with "5-HT" fibers within the retina. In the retina, "5-HT" fibers ran mainly around the periphery of the eye and penetrated not much beyond the cell body layer of photoreceptors. The retinal "5-HT" fibers did not appear to be restricted to certain "poles" or regions of the eye as described for certain cell types by Herman and Strumwasser, 1984. Our observations indicate that cells in the Aplysia retina receive 5-HT innervation from two sources, the optic nerves and the Acc. ONs, and that perhaps this anatomical separation correlates with different functions of 5-HT in the eye. Similar studies on Bulla eyes were performed. The connective tissue sheath surrounding Bulla eyes contain a network of "5-HT" fibers but no "5-HT" fibers were observed either within the optic nerves or within the retina.

163.7 SEROTONIN PHASE SHIFTS THE CIRCADIAN RHYTHM OF LOCOMOTOR ACTIVITY IN THE COCKROACH. Terry L. Page, Department of General Biology, Vanderbilt University, Nashville, TN 37235.

The pacemaker that regulates the circadian rhythm of activity in the cockroach Leucophaea maderae is composed of two oscillators, one located in each optic lobe of the brain. Two sources of input to each oscillator function in entrainment. The first is from the retina of the ipsilateral compound eye, and the second is from the oscillator in the contralateral optic lobe. On the hypothesis that at least one of the two entrainment pathways utilizes chemical synaptic transmission an effort was made to identify putative transmitters capable of phase shifting the pacemaking system.

Animals freerunning in darkness were removed from their activity monitors and restrained in a light-tight box. A small canula, placed in the head capsule near one optic lobe, was used to infuse putative transmitters in a series of 4 µl pulses (one pulse per 20 minutes) for a period of either 3 or 6 h. At the end of the infusion animals were returned to activity monitors and the phase of the freerunning activity rhythm was compared to the phase of the rhythm prior to treatment. Transmitters were dissolved (.05M) in physiological saline plus 1 mg/ml ascorbic acid. Three hour infusions were begun at circadian time (CT) 16-18; 6h infusions were initiated at CT 12-14.

For 3h infusions, serotonin (5HT) was the only substance tested that was found to generate phase shifts significantly different from saline controls ($p<.05$, t-test). The average phase shift for 5HT was -4.0 ± 1.29 h (mean+SD, N=6) while the average shift in controls was -1.4 ± 1.3 h ($\bar{N}=9$). Dopamine (N=6), norepinephrine (N=6), octopamine (N=7), carbachol (N=4), gamma-amino-n-butyric acid (N=4) and glutamate (N=4) had no phase shifting effect. Average shifts for these substances ranged from -0.2 h to -1.3 h.

Results were similar for 6 h pulses with the exception that dopamine as well as 5HT caused significant ($p<.05$) phase shifts compared to saline controls. Average phase shifts were: 5HT, -3.7 ± 1.11 h (n=7); dopamine, -3.8 ± 2.87 h (N=6); control, -0.9 ± 1.6 h ($\bar{N}=8$). Neither octopamine ($\bar{N}=6$), carbachol (N=4), norepinephrine (N=1), GABA (N=4) glutamate (N=5) or histamine (N=2) caused significant shifts.

Preliminary results indicate the effect of 5HT is dependent on concentration. Six hour treatments with .01M 5HT caused significantly smaller shifts (-1.33 ± 0.29 h, N=3) than the .05M 5HT infusions. Specificity of the 5HT effect was examined by treating animals with structurally related compounds. Neither tryptophan (N=3), tryptamine (N=3) or 5-hydroxyindole-3-acetic acid (N=3) caused average phase shifts greater than 1 h. (Supported by PHS-NIH Grant GM30039).

163.8 EFFECTS OF CONSTANT ILLUMINATION ON THE CIRCADIAN RHYTHM OF THE HORSESHOE CRAB Limulus polyphemus. A. Blaber, and P. Mack*
Biophysics Interdepartmental Group, University of Guelph, Guelph Ontario, Canada. N1G 2W1

Horseshoe crabs, Limulus polyphemus, are nocturnal animals and have endogenous circadian rhythms with free running periods of approximately 24 hours in constant darkness.

Monitoring of electroretinogram responses in the lateral eyes of four horseshoe crabs, under conditions of constant illumination, revealed a lengthening of the period in accordance with Aschoff's Rule. In all cases the length of the subjective day decreased by 1.2 to 2.7 hours and the length of the subjective night increased by 2.1 to 4.3 hours, giving total period changes of 0.9 to 1.6 hours, with respect to constant darkness.

These results contradict the velocity response curve hypothesis (Daan,S., and C.S.Pittendrigh, J.Comp.Physiol.,106:267-290,1976), developed to explain period changes in animal circadian rhythms under constant illumination, since it does not allow for changes in the length of subjective day. A new hypothesis is presented, using the phase response curve, which allows for changes of the lengths of both subjective day and subjective night.

163.9 A PROTOCEREBRAL CIRCADIAN PACEMAKER FOR HYPERGLYCEMIC HORMONE RELEASE IN THE CRAYFISH: Is there a common clock circadian system driving both light-adapting and crustacean hypergycemic hormones (CHH) from the sinus gland? B. Barrera-Mera, S. March-Mifsut*
Depto. de Neurociencias C.I.F.C., UNAM & Deptos. de Fisiología y Bioquímica, Fac. Medicina, UNAM A-Postal 70250 México, D. F.

A circadian clock is bilaterally located in the protocerebral eyestalk supraesophageal ganglion in crayfish (J. Interdiscipl. Cy. Res. 10, 79, 1979). By the surgical bilateral deafferentation of this structure from the rest of the nervous system we could isolate in vivo the main neuroendocrine complex of these animals. Its anatomical integrity and cyclical circadian ability for release the light-adapting hormone from the sinus gland of both eyestalks (Brain Res. Bull. 5, 667, 1980), offers us as an atractive model for the study of neuroendocrine circadian rhythms regulation. Aside from many other hormonal substances of the sinus gland-neurohemal complex in these crustaceans, the CHH also seem to be under the potent effects of a cephalic pacemaking system of glucose level regulation in the crayfish Astacus (J. Comp. Physiol. 89, 197, 1974). CHH is synthetized in specific neuronal elements of the eyestalk and the exact anatomical site controlling their cyclical release is presently unknown. Since the original publications, it is known that glycemic levels in crayfish readily increase not only by the action of stress, by toxic or pharmachologic substances, but also by the simple handling of the animals during experimental manipulation, by feeding, moulting, or by the action eyestalk extracts.

Nine in vivo protocerebral preparations were used. These preparations were daily feed with fresh or cooked chicken meat;4 mg/g of body weight. The retinal sensitivity measured as electroretinogram (ERG) was correlated with the haemolymphatic glucose concentration. For this purpose 25 µl haemolymph samples were obtained every 6 hours while ERG rhythm was continously recorded. Glucose was measured using a glucoxidase method. In all the animals tested an increase from 4.1-7.3 mg/% to 6.5 to 9.2 mg/% in haemolymphatic glucose concentration was obtained during the activity phase of ERG. Both the ERG rhythm and the cyclical variations of glucose concentration occurred with a periodicity of 26-27 hours. Glucose circadian variations dissappeared and the ERG rhythm became damped after the complete removal of protocerebrum.

Based in the present results we belive that protocerebral circadian pacemaker in crayfish would be driving among many others, the light adapting and CHH hormones from sinus gland. In accordance with the fact that both ERG and glycemic rhythmic variation show the same periodicity, we postulate that a single one pacemaking system command visual and glycemic circadian rhythms.

163.10 ONTOGENY OF LIGHT-DARK ENTRAINMENT IN THE RAT. M.J. Duncan*, M.J. Banister*, and S.M. Reppert (SPON: R.D. Hall). Children's Service, Massachusetts General Hospital, Boston, MA 02114.

Previous studies in rats indicate that the circadian system is functional and entrainable by the mother during the prenatal and early postnatal periods. The retinohypothalamic tract, which transmits light information for entrainment to the SCN in adults, is anatomically in place between postnatal days 3-6. We determined the onset of light-dark entrainment by using the rhythm of pineal N-acetyltransferase (NAT) activity to monitor the developing circadian system. This rhythm is the first readily measurable circadian rhythm overtly expressed in rats and is characterized by greatly elevated levels of enzyme activity during the dark period.

Timed pregnant Sprague-Dawley rats were exposed to a light-dark cycle (LD, lights on 0700-1900) throughout pregnancy. Following parturition, all dams were blinded. Groups of 6 dams and their litters were exposed to various lighting cycles postnatally. On postnatal day 10, pups (N=4-6/time point) were killed and their pineal glands removed for determination of NAT activity (method of Deguchi and Axelrod).

In Experiment 1, rats were exposed at birth to either constant darkness (DD) or to a reversed lighting cycle (DL, lights on 1900-0700) for 4, 6, or 8 days followed by DD. Pineal glands were collected at 2-h intervals throughout day 10 and the 24-h profiles of NAT activity were examined. For the DD group and the group exposed to DL from 0-4 days of age, the profiles were rhythmic and entrained to the prenatal LD cycle, with elevated levels from 2100-0500. In contrast, the NAT rhythm of the group exposed to DL from days 0-8 was re-entrained to the postnatal DL cycle (elevated NAT values from 0900-1700). The profile from the group exposed to DL from days 0-6 of age was arrhythmic, suggesting partial entrainment had occurred. Experiment 2 was conducted to determine more precisely the age at which LD entrainment begins. Animals were exposed from birth to a 6-h phase-delayed LD cycle for 4, 6, or 8 days followed by DD. The 6- and 8-day groups exhibited phase-shifted NAT rhythms, while the 4-day group did not. Furthermore, in another study, exposure to the phase shift from days 4-8 was sufficient to shift the NAT rhythm.

Thus, the data show that the potential for LD entrainment of the circadian system begins between postnatal days 4-6, the approximate age when the retinohypothalamic tract is innervating the SCN. (Supported by PHS Grant HD 14427)

163.11 ENTRAINMENT OF CIRCADIAN OSCILLATIONS IN THE HAMSTER FETUS BEFORE DAY 12 OF GESTATION. F.C. Davis, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

In rodents, circadian oscillations appear to already be present and entrainable in the fetus. As in adults, these oscillations are most likely generated by the suprachiasmatic nucleus (SCN) of the hypothalamus. This is based on day/night differences in metabolic activity of the fetal rat SCN on gestational day 19, three days before birth (Reppert and Schwartz, Science 220: 269, 1983), and on the observation that prenatal phase affects the postnatal phase of rhythms controlled by the SCN (e.g. hamster locomotor activity; Davis and Gorski, Neurosci. Abs. 8, 35, 1982). The activity rhythms of a hamster mother and her pups are approximately synchronous at weaning even when raised in dim constant light (LL). Davis and Gorski (Neurosci. Abs. 9: 625, 1983) found that lesions of the mother's SCN on day 7 of gestation disrupted the synchrony among pups, but that lesions on day 14, two days before birth, did not. This suggests that entrainment of fetal oscillations occurs before day 14. This age is just at the end of SCN neurogenesis (Davis and Gorski, unpublished; Crossland and Uchwat, Dev. Brain. Res. 5: 99, 1982). In the present study, lesions were performed on day 12 (when neurogenesis of the SCN is still occuring) to determine if the completion of SCN neurogenesis is required for entrainment of fetal oscillations. Locomotor activity records were used to select four lesioned mothers with severe disruption of their circadian rhythms. Seven pups from each of these litters were placed in individual cages to determine the phases of their freerunning activity rhythms. The within litter phase distributions were analyzed by the Raleigh test for orientation data. Three of the four litters were clearly synchronized ($P < 0.05$) while the fourth was not ($P=0.1$). Although the completeness of the maternal SCN lesions has not yet been histologically confirmed, it is unlikely that three of the four were incomplete, especially given the disruption of their activity rhythms. Therefore, it appears that by day 12 of gestation, before neurogenesis of the SCN is complete, entrainment of a fetal pacemaker has already occured. Either complete formation of the SCN is not required for it to generate oscillations and to become entrained, or entrainment of some other tissue occurs initially with phase being transferred to the SCN at some later age. Supported by NIH grant 5 R23 HD18686 to FCD and by the Joseph P. Riley Zoology Fund of the Univ. of Virginia.

163.12 CHARACTERIZATION OF THE CIRCADIAN TEMPERATURE RHYTHM (CTR) OF FEMALE AND MALE RATS. I. Rykaszewski* and E. Satinoff. (SPON: F. R. Brush). Dept. of Psychology, University of Illinois, Champaign, IL 61820.

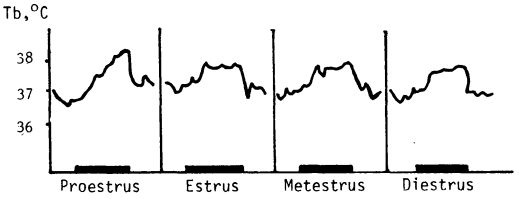
Adult rats have prominent 24-hour rhythms in body temperature (Tb), with the trough occurring during the lights-on portion of a 12:12 LD cycle, and the peak occurring during lights-off. Here we describe the CTR of cycling females and compare it to that of intact males.

Tb's were recorded at 10-min intervals from implanted telemetry devices in intact male and female hooded rats of the Blue Spruce strain. Data were collected for 5 estrous cycles in the females, and for 15-20 days in the males.

The amplitude of the CTR varied from about 2.7°C on proestrus to 2.2°C during metestrus, diestrus, and estrus. In 3 out of 4 females, the increased amplitude was produced by both an elevation in the peak Tb and a lowered trough. There was a less marked tendency for the trough of the CTR to be elevated on the day of vaginal estrus. These changes in amplitude resulted in a decrease and increase in mean daily Tb on proestrus and estrus, respectively.

There were changes in the waveform and phase of the CTR across the cycle (Fig). The peak of the CTR was phase-delayed on the night of proestrus, and the rhythm was sawtooth in shape when compared to the squarewave pattern observed during the other days of the cycle.

The characteristics of the the CTR of the males (mean daily Tb, amplitude, and phase) were most similar to that of diestrous females.



Averaged wave forms of hourly means of Tb across 5 estrous cycles of a female rat. Black bars = 12 hr lights off.

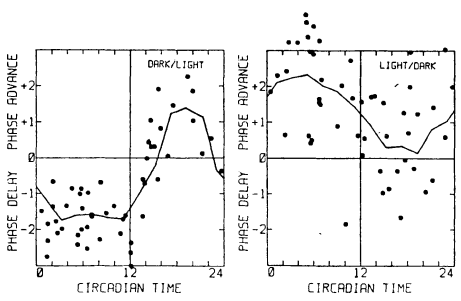
163.13 RESPONSE OF THE HAMSTER CIRCADIAN SYSTEM TO TRANSITIONS BETWEEN LIGHT AND DARK. H.E. Albers. Dept. of Physiol., Univ. of Mass. Med. Sch., Worcester, MA 01605.

Much of our current knowledge of how light-dark (LD) cycles entrain circadian clocks has come from studies documenting how brief pulses of light can phase shift circadian rhythms. However, the specific components of the light pulse, i.e. the transition between dark and light (D/L transition), light and the transition between light and dark (L/D transition) to which the circadian system responds have not been thoroughly defined. To determine how D/L and L/D transitions phase shift circadian rhythms, adult male hamsters were switched between constant light and constant dark at 10 day intervals at various times within the circadian cycle. When exposed to D/L transitions during the 12 hr prior to activity onset (subjective day) the activity rhythm was consistently phase delayed by approximately 1.5 hr. In contrast, L/D transitions provided during the subjective day produced phase advances ranging from approximately 1.5 to 2.0 hrs. During the early subjective night (until approx. 3 hrs. after activity onset) D/L transitions produced phase delays, however during the remainder of the night D/L transitions produced advances of up to 2 hrs. L/D transitions tended to produce small advance shifts during the subjective night. In summary, both D/L and L/D transitions produce distinct shifts in circadian phase throughout the circadian cycle. When combined additively, the phase shifts produced by D/L and L/D transitions mimic those produced by brief pulses of light. (Supported by NIH GM 34798).



163.14 CIRCADIAN PHASE-REPONSE CURVE BASED ON OSCILLATING VISUAL SENSITIVITY. Michael Terman and Jiuan Terman*. Dept. of Psychiatry, College of Physicians & Surgeons, Columbia Univ., and New York State Psychiatric Inst., New York, NY 10032.

Mammalian and avian circadian phase-response curves (PRCs) have typically been time-referenced to motor-activity rhythms measured in continuous darkness (DD). A discrete bright-light pulse presented early in the subjective night induces a lasting phase delay; late in subjective night, an advance; and during the subjective day, little or no response. This profile reveals the underlying mechanism of entrainment of non-24-hour free-running rhythms to daily light-dark cycles: animals with free-running periods greater than 24 hours, for example, adjust their daily pattern to accommodate phase-advances correcting for the deviation.

We have previously reported that visual sensitivity, measured in continuous signal-detection performance, shows circadian rhythmicity exclusive of motor-activity rhythms controlled by the suprachiasmatic nucleus (SCN) pacemaker (Terman, M. & Terman, J. Ann. N.Y. Acad. Sci., 1985, in press). Rats with and without SCN lesions show similar oscillations of dark-adapted detectability given dim light signals, under both DD and skeleton-photoperiod entrainment. The signals themselves are of insufficient intensity to induce phase responses.

In the present experiment, bright Vita-Lite fluorescent pulses (approx. 350 lux, 1-h duration) were occasionally presented against the DD background in unlesioned animals, at varying phases of free-running visual sensitivity, without reference to concurrent behavioral activity. Phase adjustments of the sensitivity rhythm were monitored for at least two weeks before another pulse was given. The resulting PRC is similar to that obtained by activity measurements.

Since ocular input induces phase responses in both motor activity and visual sensitivity, it is possible that there are redundant PRC processes governed by separable SCN and visual pacemakers. Alternatively, the two classes of PRC may be hierarchically organized, with SCN phase responses deriving from visual phase responses.

163.15 SUPPORT FOR THE NON-PARAMETRIC MODEL OF ENTRAINMENT IN THE DIURNAL PRIMATE Saimiri sciureus. J.S. Ferraro and F.M. Sulzman*. Dept. of Biol. Sci., SUNY-Binghamton, Binghamton, NY 13901.

Feedback lighting (LD_{FB}), which provides illumination only during the subjective night (i.e. the photosensitive portion of the circadian cycle) in response to a given behavior, has previously been used to test the non-parametric model of entrainment in nocturnal rodents (Ferraro, PhD Thesis, 1984). In three species (Rattus norvegicus, Mesocricetus auratus, and Mus Musculus), the free-running period (tau) of the locomotor activity rhythm was similar whether the animals were exposed to continuous light (LL) or discrete light pulses occuring only during the subjective night (i.e. LD_{FB}). The results of these experiments support the non-parametric model proposed by Pittendrigh and Daan (J. comp. Physiol. 106:291, 1976). In the current experiment, LD_{FB} was presented to 4 squirrel monkeys so that light fell predominately during the subjective night. LD_{FB} was linked to the drinking behavior in this diurnal primate so that when the animal drank the lights went out. Despite this seemingly adversive predicament the monkeys maintained regular circadian drinking rhythms. Furthermore, just as the free-running activity rhythms of nocturnal rodents exposed to LL or LD_{FB} were similar, the drinking rhythms of the squirrel monkeys in LL and LD_{FB} were comparable. Mean taus for squirrel monkeys exposed to LL and LD_{FB} were similar (25.6 and 25.8 respectively), despite a substantial decrease in the total amount of light exposure associated with LD_{FB}. Therefore, discrete light pulses given predominately during the subjective night are capable of simulating the effects of LL on the free-running period of the drinking rhythm of a diurnal primate as would be predicted by the non-parametric model and as was previously shown for three nocturnal rodents. These results thus lend support for the model and further suggest that the major entrainment mechanism are similar in nocturnal rodents and diurnal primates. (Supported by BRSG Grant SO7RR07149-11.)

163.16 ELECTROCONVULSIVE THERAPY: EFFECTS ON SPLIT CIRCADIAN ACTIVITY RHYTHMS OF HAMSTERS. J.D. Hallonquist and J.S. Brandes. Dept. of Psychiatry, Mount Sinai Hospital, Toronto, Ontario M5G 1X5, Canada.

Abnormal circadian organization has been reported in patients with severe mood disorders. An abnormally fast circadian oscillator and/or altered coupling between at least 2 oscillators may be present in some uni- and bipolar patients. If a causal relationship exists between mood disorders and circadian dysfunction, then clinically effective therapies should correct such abnormalities. Although lithium and antidepressant drugs are reported to slow or delay circadian rhythms in animals, no such reports exist for electroconvulsive therapy (ECT). This study examined effects of ECT on abnormal coupling between 2 oscillators that is sometimes observed in hamsters housed in constant light (LL).

Twenty-eight male hamsters had been individually housed in cages with activity wheels, in LL of approx. 75 lux, and had demonstrated a stable 180 degree split of the normal free-running activity rhythm for at least 1 month. Seventeen hamsters were randomly selected to receive a single administration of ECT (75 mA, 1 msec pulses @ 100 pps for 0.8 sec) via saline-soaked, gauze-covered ear clips. The remaining 11 hamsters received a single administration of sham-ECT during which no current was passed. Hamsters were anesthetized with a mixture of N_2O (2L/min) + O_2 (1L/min) passed over ethrane (2% V/V) during administration of ECT or sham-ECT, both of which were distributed over circadian time. Rhythms were then monitored for at least one additional month.

Overall, ECT had obvious chronotypic effects on the split activity rhythms of 10 (59%) of 17 hamsters, while sham-ECT had but a small effect (1 lengthening, 1 phase-delay) in only 2 (18%) of 11 hamsters -- a difference that is significant at the $p.05$ level (Chi-square). ECT lengthened (3), phase-delayed (2), phase-advanced (2) or actually fused (3) the split activity components. Most interesting was the fusing, which presumably reflected a differential effect on the 2 oscillators, never followed sham-ECT, and only very rarely occurs spontaneously in hamsters with split circadian rhythms. Further experiments are examining to what extent the type of response to ECT reflects the timing of its administration relative to the split components.

These results with ECT and our previous results with lithium (Soc Neurosci Abstr 1984, 10, 503) suggest that the split circadian rhythm preparation of hamsters may be particularly useful for assessment of chronotypic properties. The slowing of rhythms and normalization of coupling following ECT support the circadian dysfunction hypothesis of mood disorders. This work may contribute to a more effective clinical use of ECT, and the eventual development of less invasive therapies that correct circadian abnormalities (Supported by the Ontario Mental Health Foundation).

163.17 CIRCADIAN FACTORS IN MONKEY PERFORMANCE: EFFECTS OF TASK, PHASE SHIFTS AND CONSTANT LIGHT. W. N. Tapp*, B. H. Natelson, D. Creighton*. (SPON: S.D. Cook). Primate Neurobehavioral Unit, VA Medical Center & New Jersey Medical School, East Orange, NJ 07019.

We have developed a task where rhesus monkey performance exhibits important features of circadian influences on human performance. Monkey performance on this chained vigilance-discrimination task exhibits task dependent differences in the time of peak performance (discrimination peaks several hours before vigilance, $p<.01$) and in the time required to recover from performance deficits following a 6 hr phase shift (discrimination recovers significantly faster than vigilance, $p<0.01$). These task differences correspond to differences in humans where performance on "more cognitive" tasks peaks earlier during the day and recovers more rapidly after a phase shift than performance on simple repetitive tasks. Similarly, phase shifts produced the same sort of transient internal desynchronization in monkeys that they do in people, with activity resynchronizing significantly faster than temperature.

After characterizing performance in LD 12:12, we released the monkeys into constant light (LL). The task was available in LL from 0900 to 1700. Monkeys showed significant performance deficits in LL. Average vigilance performance was 15.1% worse in LL than in LD 12:12 ($p<.01$). Average discrimination performance was 14.6% worse in LL than in LD 12:12 ($p<.01$). While these deficits were not as severe as those associated with phase shifts, they were much longer lasting, persisting for over 100 days without sign of recovery. Performance deficits in LL were not due to internal desynchronization. During the period studied, the monkeys' circadian temperature and activity rhythms maintained stable periods and phase relationships. Indeed, both rhythms were synchronized to the time of the task with 24 hr periods and positive phase angles with respect to the task. Thus, LL represents a light schedule that produced significant performance deficits despite the fact that the monkeys were internally synchronized.

The pattern of behavioral change and physiological rephasal shown by rhesus monkeys after phase shift closely resembles that seen in humans. Thus, this model provides a unique opportunity to study performance and physiological function after chronobiological manipulations that would be too expensive or impossible to study in humans.

164.1 NORADRENERGIC INHIBITORS MODULATE THE CONCENTRATION OF FUNCTIONAL ESTROGEN RECEPTORS IN FEMALE RAT HYPOTHALAMUS. J.D. Blaustein, T.J. Brown* and E.S. Swearengen*. Division of Neuroscience and Behavior, University of Massachusetts, Amherst, MA 01003.

We have reported previously that after injection of the dopamine-β-hydroxylase (DBH) inhibitor, U-14,624, in ovariectomized female rats, the concentration of cytosol ERs in the mediobasal hypothalamus (MBH) and anterior pituitary gland (AP) decreased. This decrease, however, was mirrored by an increase in the concentration of cell nuclear ERs. U-14,624 appears to be anomalous in this action, because we now report that a variety of noradrenergic inhibitors decrease the concentration of cytosol ERs in the MBH (and in some cases the AP) without increasing the concentration of nuclear ERs. The DBH inhibitors, FLA 63 and diethyldithiocarbamate (DDC) both caused a biphasic effect on the concentration of cytosol ERs in MBH; the concentration first increased (by 13 - 27%) and then decreased (by approximately 21%), compared with the level in vehicle-injected rats. This biphasic effect occurred in the absence of any detectable change in the concentration of nuclear ERs. Inhibition of DBH decreased the concentration of cytosol ERs in the MBH and preoptic area-septum, but not in the amygdala, suggesting that the decrease is not due to a nonspecific effect on all cytosol ERs. Finally, an injection of estradiol-17β in rats that had been pretreated with either DDC or FLA 63 resulted in less accumulation of cell nuclear ERs than in vehicle-injected controls only in those tissues in which the drug first caused a decrease in the concentration of cytosol ERs. Therefore, under some conditions, pretreatment with a DBH inhibitor decreased the concentration of functional cytosol ERs resulting in subsequent decreased nuclear ER accumulation in response to an estradiol injection.

Treatment with the α_1-adrenergic antagonist, prazosin, also caused a decrease in the concentration of cytosol ERs in MBH and AP by 8 hours after injection, suggesting that the decrease seen after injection of DBH inhibitors is dependent on decreased α_1-adrenergic receptor stimulation. Similarly to the case using DBH inhibitors, injection of estradiol-17β caused a decreased cell nuclear accumulation of ERs in rats that had been pretreated with prazosin. The results of these experiments support the hypothesis that the catecholamines have a role in modulating the sensitivity to estradiol in some hypothalamic neurons and, in some circumstances, in the AP. (Supported by NS 19327 from the N.I.H.)

164.2 HORMONAL MODULATION OF NOREPINEPHRINE-INDUCED CYCLIC AMP ACCUMULATION IN SLICES FROM FEMALE RAT HYPOTHALAMUS AND PREOPTIC AREA. Anne M. Etgen and Nicola Petitti*. Department of Biological Sciences, Rutgers University, New Brunswick, NJ 08903.

To examine the interactions between ovarian hormones and brain noradrenergic systems, cyclic AMP (cAMP) accumulation in slices from the preoptic area (POA), anterior hypothalamus (AH), middle hypothalamus (MH), and posterior hypothalamus (PH) were incubated in vitro for 20 min in the presence or absence of 10 uM norepinephrine (NE). Prior to slice preparation, the endocrine state of the animals was varied. In the first experiment, slices were obtained from animals in mid to late diestrus or in proestrus (after the preovulatory LH surge). NE treatment of tissue from diestrous females produced robust increases in cellular cAMP content in slices from all regions except the PH. Of the remaining regions, the POA and AH showed significantly greater cAMP elevations than the MH. In contrast, slices taken from proestrous females showed small, statistically insignificant changes in cAMP content in all four brain regions. A second experiment evaluated NE-induced cAMP accumulation in ovariectomized (OVX) females. The basal level of cAMP in most slices from OVX rats was significantly higher than that observed in either diestrous or proestrous animals. NE treatment produced significant increases in cAMP in POA, AH and PH, but not in MH slices from OVX animals, but the levels were not as great as those in NE-treated slices from diestrous females. A third experiment evaluated the effects of estrogen and estrogen plus progestin treatment in OVX rats. Females which had been OVX for at least 4 days received 2 ug of estradiol benzoate 24 and 48 hr before sacrifice (EB) or this same estrogen treatment followed by 500 ug of progesterone 3.5 hr prior to sacrifice (EB+P). Basal levels of cAMP were reduced in both treatment groups when compared to OVX rats. As in the diestrous rats, POA, AH and MH slices from EB rats showed large NE-induced elevations in cAMP concentration. On the contrary, the EB+P rats, like the proestrous animals, showed little change in cAMP level following exposure to NE in vitro. These data suggest that ovarian steroids can alter neural responsiveness to NE in some diencephalic regions known to participate in the hormonal regulation of behavior and anterior pituitary hormone release. Supported by Grant No. MH36041 and a grant from the Charles and Johanna Busch Memorial Fund.

164.3 IMPACT OF ADRENALECTOMY ON α1 AND α2-NORADRENERGIC RECEPTORS IN THE RAT BRAIN: RELATION TO SPONTANEOUS FEEDING. M. Bailo*, M. Jhanwar-Uniyal*, A.D. Factor*, G. Beitmirza* and S.F. Leibowitz. (SPON: S. Berl) The Rockefeller University, New York, NY 10021.

Adrenalectomy (ADX) has been shown to down-regulate α2-noradrenergic receptors specifically in the paraventricular nucleus (PVN) (Jhanwar-Uniyal et al., 1984). Furthermore, α2-noradrenergic receptors of this nucleus are known to be involved in the stimulation of feeding behavior, and this effect requires the presence of circulating corticosterone(CORT) (Leibowitz et al., 1984). To investigate further the modulatory role of CORT on these PVN receptors and ultimately feeding, the present study was undertaken to investigate: 1) The influence of chronic ADX on α1 and α2-noradrenergic receptor density in brain regions analyzed via Scatchard analysis; 2) The impact of short term (6h and 12h) versus chronic (7 days) ADX on α2-noradrenergic receptors in the PVN; and 3) The effect of ADX on spontaneous food intake during the light versus dark period.

Male albino rats were sacrificed by decapitation 6h, 12h and 7 days after ADX or SHAM surgery. The brains were rapidly removed, frozen on dry ice, and the brain areas, either PVN, or medial hypothalamus, lateral hypothalamus, and frontal cortex, were microdissected. Standard radioligand binding procedures were employed using the α2-noradrenergic agonist [^{3}H]p-aminoclonidine ([^{3}H]PAC, 0.5-10.0 nM; 3.0 nM for discrete PVN) and the α1-noradrenergic antagonist [^{3}H]prazosin (0.1-1.4 nM). Nonspecific binding was determined in the presence of phentolamine (50 uM). For the spontaneous food intake study, daily food intake (lab chow pellets) was measured at 12h intervals over a period of 24h in pre-operative, SHAM and ADX rats.

The results indicate that: 1) Following ADX, high and low affinity [^{3}H]PAC binding were attenuated, respectively, by 28% and 21%, specifically in the medial hypothalamus; 2) The [^{3}H]prazosin binding (Bmax), as well as the K_D for both ligands, remained essentially unchanged in all brain areas examined; 3) ADX, at 6h, 12h, and 7 days, down-regulated α2-noradrenergic receptors in the PVN by 88%, 57% and 53%, respectively; 4) Compared to SHAM scores or pre-operative baselines, the ADX showed a significant attenuation (-51%) of food intake only in the dark period.

The results suggest that ADX influences the [^{3}H]PAC high affinity binding only in the medial hypothalamus, without affecting [^{3}H]prazosin binding. The present study also concludes that ADX down-regulates α2-noradrenergic receptors in the PVN, which may in turn cause a reduction in food intake in ADX rats. These findings suggest that PVN α2-noradrenergic receptors and circulating CORT have an important role in the regulation of food intake.
(This research was supported by NIH grant MH 22879.)

164.4 PROGESTERONE MODULATES CEREBELLAR PURKINJE CELL RESPONSIVENESS TO GAMMA-AMINOBUTYRIC ACID (GABA) AND GLUTAMATE (GLUT). Sheryl S. Smith, B.D. Waterhouse and D.J. Woodward. Cell Biology, UTHSC, Dallas, TX 75235.

In a previous report we have shown that both intravenous and iontophoretic application of 17 Beta-estradiol (E2) are capable of increasing cerebellar Purkinje (P) cell responsiveness to microiontophoretically applied GLUT in the halothane-anesthetized, ovariectomized adult rat. In the present study we have examined the effects of another sex steroid, progesterone (P) and combinations of varying doses of both E2 and P on responses of individual P cells to GABA and GLUT. Extracellular activity of single Purkinje neurons was recorded using multibarrel glass micropipets. Spontaneous firing rate and responses of neurons to microiontophoretic pulses (10s pulses every 40s) of GABA (10-50 nA) and GLUT (3-40 nA) were examined before and after jugular i.v. administration of P, E2 or E2/P. In some cases animals received s.c. injections of E2 (2 μgs) at 24 and 48 h before the day of recording. This injection schedule, when followed by P administration, induces reproductive behavior. Within 5-15 min after P administration (.5 mgs) to ovariectomized rats, P cell responses to GLUT were decreased by 45% (13 of 14 cells), and inhibitory responses to GABA were increased by 50% (6/6 cells), with no associated change in spontaneous firing rate. Complete recovery was observed 20-30 min after P administration (10/14). E2 pretreatment did not alter these P-induced effects; however, the latency of E2-induced increases in P cell responsiveness to GLUT was decreased by 15 min (8/8). Combinations of E2 (2 μgs) and P (.5 or 5 mgs) injected simultaneously resulted in effects similar to those seen with P alone (10/15), while effects similar to E2 alone were observed with administration of E2 plus P at 0.05 mgs (3/3). The administration of a protein synthesis inhibitor, anisomycin (30μg/kg,i.v.), 20 min before the recording session did not prevent any of the above steroid effects (3/3 per condition). The results indicate that sex steroids can act to alter neuronal responsiveness to putative neurotransmitters in a CNS region not known to contain steroid receptors. These findings further suggest that the observed steroid-induced alterations in P cell responsiveness may be due primarily to membrane effects and do not appear to require genomic mechanisms. (Supported by MH09010 to SSS; AA3901,DA02338 & Biological Humanics Foundation to DJW.)

164.5 CHANGES IN CORTICAL SEROTONIN RECEPTORS DURING THE FEMALE RAT ESTROUS CYCLE. L. Uphouse, J. Williams*, K. Eckols*, and V. Sierra*,Dept. Biology, Texas Woman's University, Denton, Texas. 76204

Neurotransmitter changes contribute significantly to the behavioral and neuroendocrine events characteristic of the female reproductive cycle. Most such changes have been seen in the hypothalamus and other basal forebrain areas with high densities of intracellular estrogen receptors. It is also these brain regions where steroidal modulation of neurotransmitter activity has been emphasized. However, estrogen can alter serotonin receptors in cortical tissue which has only minimal quantities of intracellular steroid receptors. It is, therefore, possible that estrogen can directly down-regulate cortical 5-HT receptors. If estrogen's modification of cortical 5-HT receptors is physiologically relevant to cyclic changes in behavior, then such changes should be evidenced during the estrous cycle. Such cyclicity is readily apparent in estrogen receptor rich regions, but cortical changes have not been seen previously. We have now identified cyclic changes in cortical serotonin receptors. The major change occurs between afternoon and evening on the day of proestrus which probably accounts for earlier failures to observe the cyclic variation. In our initial studies, Fisher F-344 female rats were sacrificed during the early afternoon of diestrus, proestrus, or estrus. Cortical serotonin-1 receptors (measured as the specific binding of ^{3}H5-HT) was 30-33% higher on estrus than on proestrus or diestrus. No changes were seen in either ^{3}H-spiroperidol or ^{3}H-ketanserin binding. ^{3}H-5-HT binding was then examined in proestrous and estrous females sacrificed during the afternoon, the early evening or near midnight. These studies demonstrated that a major increase in serotonin binding occurred between 2 and 4 p.m. on the day of proestrus. By 11:00 p.m., proestrous females were not significantly different from the estrous females but were approximately 30% higher than the proestrous females killed during early afternoon. Comparison by scatchard analysis of the increased binding during late proestrus and estrus suggested that the increased binding resulted from a significant increase in B_{max} and only a small change in K_D. The results of these studies are consistent with the reported ability of estrogens to down-regulate cortical serotonin-1 receptors. Cortical 5-HT binding was lowest on the morning of proestrus when estrogen levels are highest. There followed an upregulation of serotonin receptors in the cortex as estrogen levels decrease throughout the day. Such upregulation of serotonin receptors on the evening of proestrus and day of estrus may be a useful model system for the study of hormonally related behavioral disorders.

164.6 TRANSIENT CESSATION OF THE PERSISTENT ESTROUS AFTER NUCLEUS SUPRACHIASMATICUS LESION BY LOCUS COERULEUS DAMAGE. L.P. Solano-Flores*, H.U. Aguilar-Baturoni, O.A. Donatti-Albarrán*, C. Santos-Toledo* and R. Guevara-Aguilar. Depto. Fisiología, Fac. Medicina, U.N.A.M. Apdo. Postal 70250, 04510-México, D.F.

We have shown that the electrolytic damage of the noradrenergic nucleus locus coeruleus (LC) causes a transient cessation of the estrous cyclic activity of the non-previously manipulated female rat, effect which was caracterized by a diestrous aspect of the vaginal smears. It could be seen that the number of days after lesion in which diestrous smears were observed depended upon the amount of LC destroyed. Then, it seems that LC might be participating in the modulation of the normal expression of the estrous cyclic activity. Thus, we have in one side that a cyclic activity was disturbed by the anatomical impairment of the LC function. In the other side, we have the facts that the hypothalamic nucleus suprachiasmaticus (SCN) recieves direct retinal input, that the destruction of the SCN disrupts various physiological rhythms, that the lesion of the SCN induces a persistent estrous, and, that persistent estrous can be induced by exposure to constant bright light. Our laboratory has also already reported a transient supression of the persistent estrous induced by constant bright light by damage to the LC. This fact suggests a posible participation of the LC in the activity of those brain regions which mediate the persistent estrous response to constant bright illumination. This work was done with the aim to know whether the LC electrolytic damage disturbs the persistent estrous induced by lesion of the SCN. Vaginal smears were sampled daily during 100 days from mature and virgin Wistar rats. The samples were stained and analysed at 400x magnification. After at least four control cycles, the SCN area was electrolitically damaged bilaterally with a bipolar stainless steel electrode. Then, after at least ten days of a well stablished persistent estrous, the LC was electrolitically damaged monolaterally. Inmediately after the LC damage, the vaginal smears showed a diestrous aspect, situation which was maintained during some days before the smears showed an estrous aspect again. Two rats did not reinstalled the persistent estrous. The sham operated control animals continued cycling. The extension of both lesioned areas were evaluated. The present results suggest a possible functional interaction of the LC and the SCN in the regulation of the estrous cyclicity in the female rat.

164.7 EFFECTIVE ORAL ADMINISTRATION OF 17β-ESTRADIOL THROUGH THE DRINKING WATER OF FEMALE C57BL/6J MICE. M. N. Gordon, H. H. Osterburg*, P. C. May and C. E. Finch, Andrus Gerontology Center and Dept. of Biological Sciences, Univ. of Southern California, Los Angeles, CA 90089-0191.

17β-Estradiol (E_2) was added to the normally acidified drinking water of female C57BL/6J mice and presented ad libitum. This oral administration paradigm is effective, reliably producing a variety of E_2-sensitive responses in several different target tissues. Vaginal smear cytology changed from the predominantly leukocytic smear characteristic of ovariectomized control mice to a smear consisting entirely of cornified epithelial cells. Uterine wet weight, and the specific activities of two uterine enzymes, glucose-6-phosphate dehydrogenase and alkaline phosphatase were each elevated in a dose-dependent manner by E_2 administered through the drinking water. E_2 administration did not produce global alterations in all uterine proteins, as the specific activity of acid phosphatase was unaffected by E_2 in this dose range. Finally, the postovariectomy elevation in serum LH was suppressed in a dose-dependent manner after E_2 administration through the drinking water. A dose of 94 μg E_2/kg body weight/d administered through the drinking water for 7 d was sufficient to maximally elevate uterine wet weight 5.5-fold and uterine glucose-6-phosphate dehydrogenase specific activity 75%, and to maximally suppress serum LH to nondetectable levels.

Oral administration of E_2 through the drinking water did not produce tonic elevations of circulating E_2, but rather, produced a dynamic flux of serum E_2 qualitatively similar to that observed after subcutaneous injections of E_2. Thus, significant elevations of serum E_2 were observed when mice were sacrificed at night (2300-0300 h; lights out at 1700 h), 2-6 h after the peak in drinking rate occurred, but not when sacrificed in the late afternoon (1400-1800 h), 15-21 h after the peak drinking period.

The oral route of administration has advantages over the more conventional routes of E_2 administration, injection or surgical implantation of E_2-containing capsules, particularly for long-term experiments. Administration of E_2 through the drinking water is simpler and less labor-intensive, less stressful for experimental animals, does not require surgery, and may be more analogous to the normal, oral route of estrogen administration in women as oral contraceptives or as postmenopausal estrogen replacement therapy.

164.8 CASTRATION INDUCES NUCLEOLAR PROLIFERATION IN NEURONS OF THE MEDIAL AMYGDALOID NUCLEUS. S.W. Newman*, B. Bramoweth, and J.M. Swann, Department of Anatomy and Cell Biology, University of Michigan, Ann Arbor, MI.

The output of the medial nucleus of the amygdala (M) is essential for normal mating behavior in the male Syrian hamster. It is through this nucleus that chemosensory signals from the female drive sexual behavior. The chemosensory input to M is via direct projections from the accessory (vomeronasal) olfactory bulb and indirect projections from the main olfactory bulb. Circulating testosterone is also essential for normal male sexual behavior, and the neurons in M actively accumulate androgens. We have hypothesized that castration induces morphological changes in these neurons which might alter their ability to transmit chemosensory information.

Young adult male Syrian hamsters were castrated either 1 week (n=8) or 8 weeks (n=8) prior to sacrifice. Half of the males in each group were given testosterone propionate (TP) (500 ugm in peanut oil injected SQ every other day) before sacrifice. Brains of castrated males (with or without TP) and intact control animals (n=4) were dissected into small blocks containing the corticomedial amygdala. Blocks were embedded in glycolmethacrylate (Polysciences JB4), sectioned in the coronal plane at 6 um (av. size of nuclei of neurons in M=6-8um) and stained with hematoxylin and eosin. One section each from the rostral and caudal parts of M was chosen from each brain for analysis. On each section all neurons containing nucleoli (approximately 100 neurons per section) in each of 3 nonoverlapping grid areas within M were scored as containing single or multiple nucleoli. Our preliminary results show a significant increase in the number of neurons with multiple nucleoli 1 week after castration, followed by a reduction to slightly above control levels after 8 weeks. The TP treatment either prevents this change (in 1 week castrates) or restores the neurons to their precastration condition (when given for several weeks in the regimen described, which restores mating behavior in long term castrates).

Since multiple nucleoli normally occur in cells during periods of increased protein synthesis, these data suggest that protein synthesis in the neurons of M is enhanced for a limited period after castration. Further research is needed to determine whether this is a qualitative or quantitative change in protein synthesis and in what way this change influences the structural and functional integrity of these neurons.

164.9 QUANTITATION OF ANGIOTENSIN-1-CONVERTING ENZYME KINETICS IN INDIVIDUAL RAT PITUITARY AND ADRENAL GLANDS WITH ^{125}I-MK351A, A SPECIFIC ENZYME INHIBITOR.. L.M.Plunkett*, F.M.A.Correa and J.M.Saavedra. Section on Psychopharmacology, NIMH, Washington, D.C. 20205-1000.

We describe a quantitative autoradiographic technique which allows measurement of angiotensin-1-converting enzyme (ACE) levels as well as enzyme kinetics in discrete areas of the pituitary gland and adrenal gland in individual animals. Thin tissue sections (16μm) were incubated with ^{125}I-MK351A, a specific ACE inhibitor, and results were obtained with computerized densitometry followed by comparison of the optical densities generated with ^{125}I-standards. Compound 351A is a p-hydroxybenzamidine derivative of MK521, which is a Lys-Pro analog of MK422, the active form of the specific ACE inhibitor, Enalapril. By iodination of 351A, a specific marker for ACE is available for the compound will react in a one-to-one ratio with endogenous ACE, providing an estimate of availabe enzyme.

There were high levels of ACE present in both the anterior and posterior lobes of the rat pituitary gland. The maximum binding capacity (Bmax) was 920±62 fmol/mg protein for the anterior pituitary and 1162±67 fmol/mg protein in the posterior pituitary. The binding affinity constant (Ka) was 0.95±0.11 x 10^9M^{-1} and 1.20±0.19 x 10^9M^{-1} for the anterior and posterior lobes respectively. There was no detectable ACE binding with compound 351A in the intermediate lobe of the pituitary gland.

In the adrenal gland, there were two distinct areas of 351A binding, the adrenal medulla and the adrenal capsule-zona glomerulosa area. The Bmax for the medulla was 652±80 fmol/mg protein and 294±53 fmol/mg protein for the zona glomerulosa. The Ka for 351A was 1.04±0.19 x 10^9M^{-1} and 1.74±0.40 x 10^9M^{-1} for medulla and zona glomerulosa respectively. Other adrenal cortex areas showed no detectable ACE binding with compound 351A.

The results support the existence of a local ANG system in both the pituitary and adrenal glands. Each tissue had a distinct value for Bmax and Ka of the compound 351A/ACE interaction. With this method we can also make comparisons in ACE levels between individual animals in discrete tissue areas. Kinetic analysis of enzyme activity through an ACE-351A binding reaction provides even more information concerning ACE function.

64.10 NEURONAL CaATPase ACTIVITY AND CHANGES IN INTRACELLULAR Ca^{2+} INDUCED BY SHORT-TERM EXPOSURE TO THYROID HORMONE. L. Kragie-Ahmed*, Z. Ahmed, J. A. Connor and P. J. Davis*. Endocrin. Div. VAMC, Buffalo, NY 14215, Div. Neurobiol., SUNYAB, Buffalo, NY 14214 and Mol. Biophys., AT&T Bell Lab., Murray Hill, NJ 07974.

A thyroid hormone stimulable Ca^{2+}-dependent Mg^{2+} ATPase activity (CaATPase) has been described in RBC, reticulocyte and sarcolemma preparations. Here, we report for the first time, stimulation of a CaATPase activity by thyroxin (T_4) and triiodothyronine (T_3) in a membrane preparation obtained from a primary neuronal culture grown in serum-free, defined medium. Using Ca^{2+}-sensitive fluorescent indicators, quin 2 and fura 2, we also found a decrease in intracellular calcium upon short-term exposure to T_4. Whole cell voltage clamp experiments showed that the presence of 10^{-9} M T_3 or T_4 in the bath did not alter the primary membrane currents.

Four to six day old cultured neurons from fetal rat diencephalon and cerebral cortex were subjected to hypotonic lysis and mechanical shear. After removal of the nuclei (700xg pellet) "membrane fraction" (10Kxg pellet) was resuspended and aliquoted into isotonic saline containing 0.1 mM oubain, 1 mg/ml oligomycin, 1 mM $MgCl_2$, 0.1 mM EGTA and ± 0.1 mM $CaCl_2$. The incubation was 60 min at 37°C. The concentration of hormone was varied between 10^{-11} to 10^{-8} M. Membrane CaATPase activity in the presence of 10^{-11} M T_3 was 140% greater than the no TH control. Peak activity in presence of 10^{-10} M T_4 was 60% greater than control. Similar data were also obtained from mature rabbit synaptic plasma membrane. The CaATPase activity seems to show differential sensitivity to T_3 and T_4 according to region of origin.

Cells growing on polylysine coverslips were loaded with either quin 2 or fura 2. Fluorescence of small groups of cells was imaged using a CCD-based system (see Connor, J.A., these abstracts). Following 5 to 10 min. exposures to 10^{-9} M T_4, Ca^{2+} was significantly lower in a fraction of the cells on a given plate. In other cells on the same plate the $[Ca^{2+}]$ remained constant.

164.11 RENIN RELEASING PEPTIDE AND THE SEROTONERGIC REGULATION OF RENIN SECRETION. L.D. Van de Kar and J.H. Urban*, Department of Pharmacology, Loyola University School of Medicine, Maywood, Illinois 60153.

In previous studies (Fed. Proc. 44, 6774, 1985), we showed that administration of the serotonin releaser p-chloroamphetamine (PCA) leads to the appearance of a renin releasing factor in plasma. This factor is heat resistant and is in the molecular weight range of 500-10,000 daltons. Using an improved kidney slice method, we replicated these studies and observed that the molecular weight range is 5,000-10,000 daltons. When we fractionated plasma from PCA treated rats by ultrafiltration into two fractions, one with solutes in the 1,000-5,000 daltons and the other 5,000-10,000 dalton range, only the heavier fraction increased renin release from kidney slices. Incubation of this plasma fraction (5,000-10,000 daltons) with a non-specific protease (pronose) completely abolished its ablility to release renin from the kidney slices, suggesting that the renin releasing factor is a peptide. Co-incubation of the kidney slices with the renin releasing factor and propranolol (10^{-6} M) does not abolish the renin releasing ability of this renin releasing factor, suggesting that this effect is not mediated via a beta receptor. In conclusion, the present studies suggest that release of serotonin in the brain triggers the release of a peptide into the blood that directly stimulates renin release from the kidney. The source of this peptide is presently unknown.

164.12 EFFECT OF 1,25DIHYDROXYVITAMIN D_3 ON CHOLINERGIC ACTIVITY IN DISCRETE NUCLEI OF THE RAT BRAIN AND ON TESTOSTERONE IN PLASMA. J. Sonnenberg*†, V. N. Luine*, L. Krey* and S. Christakos†, †UMDNJ-New Jersey Medical School, Newark, NJ 07103 and The Rockefeller University, New York, NY 10021

In an effort to obtain a better understanding of the role of the calcium regulating hormone, 1,25dihydroxyvitamin D_3 (1,25$(OH)_2D_3$) in brain function, the activities of choline acetyl transferase (CAT) and monamine oxidase (MAO) were measured in discrete brain nuclei of vitamin D deficient and replete male rats. The nuclei sampled were those in which receptors for 1,25$(OH)_2D_3$ and/or vitamin dependent calcium binding protein (CaBP) have been identified. Significant elevations in CAT ($p < 0.05$) were observed in the arcuate-median eminence of the hypothalamus (A-ME) and in the bed nucleus of the stria terminalis (St) in rats made vitamin D replete by 8 daily intraperitoneal (i.p.) injections of 100 or 200 ng 1,25$(OH)_2D_3$ as well as by constant intraventricular infusion (i.v.i.) by ALZET minipumps of 25 ng 1,25$(OH)_2D_3$ for 7 days. The percent increase ranged from 12-45% and was related to the i.p. dose administered. Constant i.v.i. of 2 mM Ca^{++} or 125 ng 25$(OH)D_3$/day for 7 days did not alter CAT activity. No significant changes in MAO or CaBP in discrete brain nuclei were observed with vitamin D repletion. Since the A-ME is an important regulatory site in the neuroendocrine axis, serum testosterone was measured by radioimmunoassay (RIA). Serum testosterone was increased 2-5 fold ($p<0.05$) in rats made vitamin D replete by constant i.v.i. of 25 ng 1,25$(OH)_2D_3$ or by i.p. injection of 100 or 200 ng 1,25$(OH)_2D_3$. Testosterone treatment of gonadectomized male rats does not similarly alter CAT activity in these nuclei. Our results suggest that 1,25$(OH)_2D_3$ effects cholinergic activity in discrete brain regions and that 1,25$(OH)_2D_3$ may play a role in the regulation of certain neurohormones.

164.13 LOCALIZATION OF SEROTONIN IN THE CAUDAL NEUROSECRETORY SYSTEM. S.L. Cohen*, K.E. Miller, and R.M. Kriebel (SPON: M. Moffroid). Dept. of Anatomy & Neurobiology, Univ. of Vermont Col. of Med., Burlington, VT 05405, and Dept. of Anatomy, Univ. of Minnesota Med. Sch., Minneapolis, MN 55455.

Several neuroendocrine systems have been shown to receive projections containing serotonin, which has been implicated as a neurotransmitter in some of these nuclei. The caudal neurosecretory complex (CNC) of poecilids is an isolated neuroendocrine nucleus that is suited for study of the effects of putative neurotransmitters on neuroendocrine cells. This study describes the serotoninergic innervation of the CNC. Fish were anesthetized with MS-222 and perfused with 4% paraformaldehyde in 0.1M phosphate buffer. Cryostat sections (8 μm) or frozen sections (20 μm) were cut from the terminal spinal cord and processed for immunofluorescence or peroxidase anti-peroxidase immunohistochemistry respectively. Serotonin was identified with an antisera raised against a serotonin/BSA conjugate (Immunonuclear). Preabsorption of the antisera with this substance eliminated all labeling in the CNC. Sections for immunofluorescence were counterstained with ethidium bromide, and sections for immunoperoxidase were osmicated, in order to visualize anatomical relationships between labeled fibers and unlabeled cells. A dense network of long parallel fibers with multiple varicosities were observed within the CNC. Close appositional relationships were noted between these fibers and CNC neurosecretory cells, but most fibers were directed toward or located within the neuroendocrine axonal tract. The apparent origin of these fibers was rostral to the CNC. Several fish were sacrificed one week after the CNC was deafferented by lesioning the spinal cord one segment rostral to the nucleus. The dense plexus of serotonin fibers was absent in these specimens. However, a population of small (5-8 μm) labeled cells was present in both control and experimental animals. Many of these cells were intermingled with the neuroendocrine cells, and a few appeared to be located in the ependymal lining of the central canal. Labeled cells were also seen individually or in clusters on the lateral edge of the CNC, and abutting the ventral portion of the neuroendocrine tract. Most of these intrinsic neurons were round to fusiform with multiple processes. The processes were short and less varicose than the long labeled fibers. The source of some serotoninergic fibers appears to be extranuclear and some arise intrinsically. The source of the extrinsic projection and the role of serotonin in regulating CNC cells are being investigated. The results of this study imply that the CNC receives a dual serotoninergic innervation.

164.14 OXYTOCIN SECRETION FROM POSTERIOR PITUITARY LOBES OF LACTATING RATS INCUBATED IN VITRO. E. W. Haller and J. B. Gearns*. Dept. of Physiology, School of Medicine, Univ. of Minnesota, Duluth, MN 55812.

Neural lobes were excised from 2- to 10-day postpartum lactating Sprague-Dawley rats and incubated in a modified Locke's solution at 37° C. Oxytocin released into the medium during 10-minute incubation periods was measured by a radioimmunoassay using a specific antibody obtained from Dr. R. P. Elde, Dept. of Anatomy, University of Minnesota. Basal oxytocin output from the glands averaged about 60 pg/min. Cell membrane depolarization by raising K+ concentration of the incubation medium to 56 mM resulted in a 15-fold elevation of oxytocin secretion which was maintained at that level as long as incubation in high K+ was continued. When K+ concentration was restored to normal (5.6 mM), oxytocin secretion promptly returned to basal levels. Incubation of posterior pituitaries at normal K+ but in the presence of oxytocin at 200 pg/ml in the incubation medium produced a 40-fold increase of the oxytocin secretion rate during the first 10 min, which was elevated further during the subsequent five 10-min incubation periods, if oxytocin was present in the medium. On the other hand, incubation of posterior pituitaries in medium containing both 56 mM K+ and 200 pg/ml oxytocin responded in the same manner as in the presence of elevated K+ alone. The present data suggest that oxytocin may participate in the modulation of its own release not only at the level of oxytocinergic cell bodies (Freund-Mercier, M.-J. and Richard, P., J. Physiol. (London), 352: 447, 1984) but at the site of hormone release in the posterior pituitary, as well. The mechanism of such modulation remains to be elucidated. Supported by NIH NICHHD R01-13906.

164.15 Effects of hypophysectomy and arcuate and perifornical lesions on hypothalamic rat growth hormone-releasing factor. C.Y. CHIEN# and L.C. Terry (SPON: S. Berent). Neuroendocrine Lab., Univ. of Michigan and VA Medical Center, Ann Arbor, MI 48105.

The majority of growth hormone-releasing factor (GRF)-immunoreactive cell bodies in the rat brain were shown to be located in the arcuate nucleus and medial perifornical region (MPFX) of the lateral hypothalamus (Merchenthaler, I., et al., Endocrinology 114:1082, 1984). Fibers from the perifornical cell bodies form a fan-like projection to the median eminence (ME), where a dense accumulation of GRF-containing processes and terminals is found. The localization of GRF in the ME supports the hypothesis that this peptide is a regulator of growth hormone (GH) secretion. The objectives of this investigation were to determine (1) the origin of ME GRF, and (2) the effect of hypophysectomy on hypothalamic GRF. In experiment 1, adult male Sprague-Dawley rats (250g, 6-9/group) had thermal lesions placed bilaterally in the arcuate/ventromedial complex (ARC/VMN) or MPFX regions; sham controls had the electrode lowered 2 mm beneath the dura. Animals were sacrificed 7-10 days postoperatively, the ME was removed, sonicated in dist. water, placed in a boiling water bath for 10 min., centrifuged, and the supernatant and pellet were frozen (-80oC) for radioimmunoassay of rat GRF and protein, respectively. Lesion placement was verified histologically. In experiment 2, one hypophysectomized group received thyroxine/dexamethasone (HYPOX), the other received thyroxine/dexamethasone/GH (HYPOX/GH); controls received normal saline (CON) or GH (CON/GH) twice daily for 7 d, and animals were sacrificed on day 8. Hypothalami and ME were removed separately and processed as in experiment 1, except somatostatin (SS) was also assayed in the same samples. Antibodies to rat GRF were generated in rabbits, rat GRF was labelled with chloramine T and purified by HPLC. The antibody selected did not cross-react with human GRF, PHI, VIP, GIP, secretin, glucagon, or several other hypothalamic peptides, and bound 35% of labelled rat GRF at 1:60,000. ARC/VMN lesions decreased (p<.001) ME GRF by 96% (3.41 ± 0.29 vs 0.11 ± 0.08 pmole/mg protein, sham vs ARC, respectively), whereas, MPFX lesions had no effect (3.41 ± 0.29 vs 3.52 ± 0.21 pmole/mg protein, sham vs MPFX, respectively). Results of experiment 2 are tabulated below (#=p<.05).

GRF (fmole/mg prot)	CON	CON/GH	HYPOX	HYPOX/GH
ME	568 ± 61	706 ± 74#	468 ± 54	482 ± 54
Hypoth.	54.4 ± 1.9	57.1 ± 4.5	55.6 ± 6.7	45.0 ± 1.9
SS (pmole/mg prot)				
ME	3.1 ± .6	4.5 ± .4#	1.1 ± .2#	3.3 ± .7#
Hypoth.	.88 ± .11	.71 ± .08	.88 ± .07	.97 ± .08

Hypophysectomy had no effect on either ME or hypothalamic concentrations of GRF. However, the control group treated with rat GH (10 ug/kg bw twice daily ip) had increased levels of ME GRF. In contrast, hypophysectomy caused a significant decrease in ME SS levels; this effect was reversed by administration of GH, confirming previous studies. Similar to GRF, GH treatment in controls increased SS levels in the ME. Interestingly, hypothalamic levels of SS were not affected by hypophysectomy or GH administration.

These results indicate the following: 1. GRF-containing neurons in the hypothalamic ARC/VMN region project to the ME and contribute >95% of ME GRF, 2. GRF-containing cell bodies in the MPFX region do not project to the ME, and 3. hypophysectomy decreases ME somatostatin, but does not affect GRF. These findings support the hypothesis that GRF perikarya in the ARC/VMN nuclei are responsible for generation of episodic GH secretion, and that somatostatin is involved in feedback regulation of GH.

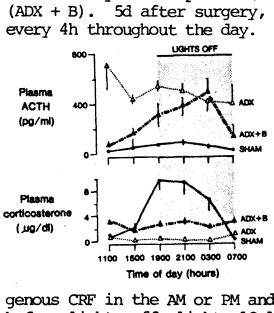
164.16 ACTH SENSITIVITY TO INHIBITION BY CORTICOSTERONE CHANGES BETWEEN MORNING AND EVENING. S.F. Akana*, C.S. Cascio*, N. Levin*, J. Shinsako*, M. Goodman*, and M.F. Dallman* (SPON: B. Libet). Dept. Physiol, UCSF, San Francisco, CA 94143.

Negative feedback regulation of ACTH by corticosterone (B) over the course of 24h is difficult to quantify because of the normally high amplitude circadian variation in plasma B in rats. Recently, we have implanted fused pellets of mixtures of B and cholesterol sc in adrenalectomized (ADX) rats and reported that constant B levels of approximately 5μg/dl provide good replacement based on restoration of AM ACTH levels, body weight and thymus weight to normal (Fed Proc 44,#3427). Furthermore, rats given either 0,20 or 40% B implants at ADX and killed 5d later either in the AM (2h after lights on) or in the PM (2h before lights off; lights 12:12h) showed a clear difference between AM and PM ACTH levels at constant plasma B levels of about 5μg/dl (20% pellet) with greater inhibition in the AM (Endocrine Soc., 1985). To further test the AM-PM shift in ACTH sensitivity to B feedback in rats with constant B levels we prepared groups of rats with either sham-adrenalectomy (SHAM), adrenalectomy + 0% B pellet (ADX) or adrenalectomy + 25% B pellet (ADX + B). 5d after surgery, 6 rats from each group were killed every 4h throughout the day. The figure clearly shows that plasma B in rats bearing the B pellet is constant and unchanging throughout the day. Plasma ACTH, while low and similar to SHAM levels in the morning, rises during the lights-out period and at peak values does not differ from ADX levels before returning to the morning low. Thus, a marked increase in PM ACTH occurs in the face of constant B levels. To test whether pituitary sensitivity to CRF varies between AM and PM, SHAM and ADX + B rats were treated with chlorpromazine-morphine-nembutal to block endogenous CRF in the AM or PM and 4h later (1h after lights on or 1h before lights off; lights 12:12h) were injected iv with either vehicle or 0.1 μg CRF. There was no AM/PM difference in the response to CRF in the SHAM (ΔACTH (pg/ml) AM:48+3, PM:58+8) or ADX + B (ΔACTH (pg/ml) AM:175+13, PM:157+15). Thus, there is greater negative feedback inhibition of ACTH by a given level of B in the AM than in the PM which is not explained by a concomitant shift in pituitary sensitivity to CRF. We conclude that operationally there is a daily "reset" of B feedback, but we postulate that functionally there is a shift in major feedback site from pituitary in the AM to brain in the PM.



(Supported in part by AM28172 and HL29714.)

164.17 RESISTANCE OF GLUCOCORTICOID RECEPTORS IN BRAIN TISSUES TO DOWN-REGULATION BY DEXAMETHASONE TREATMENT. B.B. Turner and J.E. Cole, II*. Dept. of Physiology, Quillen-Dishner Coll. of Med., East Tenn. State Univ., Johnson City, TN 37614.

Glucocorticoids are frequently used in high dosages for the treatment of a variety of pathological conditions. Despite the fact that numerous side effects of the steroid are receptor mediated, the effect of exogenous glucocorticoid on the autoregulation of receptors in different tissues has not been compared. We wished to test two hypotheses: 1) that the magnitude of cytosol receptor down-regulation is proportional to the receptor density in the tissue, 2) that receptor down-regulation is related to changes in the level of "transcortin-like" binding in the tissue. Dexamethasone (DEX; 1mg/1) was administered in the drinking water of adult male rats for 10 days. Both control and experimental animals were adrenalectomized 12 h before sacrifice. Rats were thoroughly perfused and the following tissues taken: liver, heart, kidney, pituitary, cerebral cortex, hippocampus, amygdala, and hypothalamus. The prepared cytosols were treated with charcoal to remove any remaining DEX. Aliquots of cytosol were incubated for 24 h at 4C with varying concentrations of 3H-DEX (0.5-30 nM). Bound steroid was separated from free by passage through LH-20 columns. "Transcortin-like" binding in tissues was defined as the specific binding of 3H-corticosterone occurring in the presence of excess unlabeled DEX.

The binding capacity of liver cytosol was markedly lower in the DEX-treated rats as compared with controls ($p<.01$). Decreases in the Bmax of heart and kidney cytosols were not significant. The results obtained in the brain tissues were unexpected: the four tissues were similar to each other in that the binding capacity of the DEX-treated rats was somewhat greater than that of the controls. Analysis of variance for the brain regions indicated a significant treatment effect ($p<.05$). "Transcortin-like" binding in liver, heart and kidney was significantly lower in the DEX-treated rats. No significant decrease in "transcortin-like" binding was observed in any of the brain tissues despite a decrease of 92% in plasma transcortin.

These data suggest that 1) in brain tissues, receptor binding capacity is increased, not decreased, by DEX treatment 2) the magnitude of receptor down-regulation varies markedly in peripheral tissues, and may be proportional to initial receptor density, 3) decreases in tissue transcortin are associated with glucocorticoid down-regulation. The anomolous finding in brain cytosols may be due to the inability of DEX to access or bind to these receptors in vivo. If this is the case, then glucocorticoid receptor up-regulation would result since the secretion of the endogenous corticoid, corticosterone is suppressed by DEX treatment. Supported by VA grant 1A (74) 111-430108.

164.18 PERFORMANCE OF TWO COMMERCIAL RADIOIMMUNOASSAYS (RIA) FOR PLASMA ACTH COMPARED WITH TWO REFERENCE LABORATORY ASSAYS. J.C. Ritchie, A.E. Kegelmeyer* and J.T. Walker*. Clinical Psychobiology Laboratory, Duke Univ., Durham, N.C., 27710.

Within the last year several commercial ACTH RIA's have appeared. All are performed on non-extracted human plasma and all claim to provide accurate measures of ACTH. In an attempt to verify these claims, we compared the ACTH assay kits of Radioassay Systems Laboratories, Inc. (Carson, CA.) and Immuno Nuclear Corp. (Stillwater, Minn.) with our well characterized, in-house extracted assay and the non-extracted assay of Dr. D. Orth (Div of Endo., Vanderbilt Univ.)

The determinations were performed on plasma samples (obtained from 7 normal at rest volunteers between 0800 and 1000) according to manufacturers specifications by technicians well versed in RIA methodologies. For our assay, samples and standards are extracted using a Sep-Pak cartridge (Waters, Inc.) and run in a homologous RIA using an antibody we developed against the 11 to 24 region of human ACTH 1 to 39. Details of Dr. Orth's assay have been published elsewhere (Clin. Chem. 30, #2, 259-265, 1984).

Results for the unknown plasmas (in pg/ml) are summarized below:

Sample	R.S.L.	Immuno Nuclear	Vanderbilt	C.P.B.L.
A	17	N.D.*	8	4
B	26	35	23	25
C	17	47	13	15
D	41	46	21	18
E	93	N.D.	37	49
F	51	757	38	32
G	39	N.D.	10	8

N.D.* = Not Done

As can be seen, both commercial assays gave higher values for all samples than either reference assay. This effect is probably due to the use of Bovine Serum Albumin (BSA) to "blank" out non-specific plasma interactions and is strictly dependent on the particular BSA preparation used in the assay.

We conclude that these two commercial RIA's should not be used in any area of research where measurement of absolute plasma ACTH concentrations is vital. When used in the clinical setting, (where the requirement for accuracy is not as high) samples should be run at several dilutions and checked for parallelism with the standard curve. Samples which generate binding curves that are not parallel should be referred to a reference laboratory.

164.19 BLOOD INDOLE AMINE LEVELS IN PREGNANT RATS FED TRYPTOPHAN DIETS.

M.Sakuma*, I.N.Mefford* and R.Grdy Jr.* (SPON:R.Gala). Dept. of Psychiatry, Wayne St. Univ.,Detroit MI 48207 and Dept. of Chemist. Boston Coll.,Boston,MA 02167.

We have previously shown that the blood levels of both tryptophan and 5-HT of pregnant rats were lower than prediet levels when animals fed by a 3% tryptophan diet during the third trimester, whereas in the age-matched non-pregnant rats a reduction was found only in the serotonin level (Neurosci. Ann. Meet.,1984). This suggests that pregnant and non-pregnant rats have a different response to 3% tryptophan diet. To confirm this, the effects of diets of various tryptophan contents were examined in the present project. 12 pregnant rats were assigned to 3%, 1%, 0.19% and 0.03% tryptophan containing diets. The pure tryptophan reagent (Sigma) was added to the base diet(Tryptophan Free Pregnant Rat Diet, Bio Serv.) by 3%, 1% and 0.19% by weight. Animals given each of the diets failed to show a dose dependent response in blood levels of tryptophan, 5-HT and 5-HIAA at all blood sampling times. The blood was sampled from the same animals consecutively at the time of the prediet (15th day of gestation), diet-end (delivery-end) and at weaning. Values of an analysis of variance for these sampling times revealed significant differences at 0.01% level. This was shown as sharp reductions of tryptophan and serotonin levels from prediet values throughout all diet groups, with small increases at weaning time. The levels of 5-HIAA of all diet groups showed no change at these sampling times. These results confirm those of the previous study and can be interpreted that during pregnancy of rats, both the levels of tryptophan and serotonin characteristically drop at the end of delivery. Namely, the influence of delivery is more powerful than the effects of tryptophan content in diet and able to produce some changes in blood parameters at the delivery end. The failure to show a dose dependent response to tryptophan in the diet suggests some regulatory mechanism occured at delivery end such as hemorrhage or hormone level changes. This warrants further studies. The reduction of serotonin levels from prediet values is evidence of the diet's effects which were similarly observed in the non-pregnant rat group of previous study.

165.1 BILATERAL SYRINGEAL INTERACTION IN THE VOCAL PRODUCTION OF AN OSCINE BIRD SOUND. S. Nowicki* and B. Capranica. Sect. of Neurobiol. and Behav., Cornell Univ., Ithaca, NY 14853.

The syrinx of oscine birds is two-parted and each side is presumed to operate independently of the other, enabling a bird to sing an "internal duet." Support for this theory comes both from spectrographic analyses revealing temporally-overlapping, non-harmonic acoustic elements in certain complex songs, and from the discovery that neural control of the syrinx is also highly lateralized. We here demonstrate one counter-example of a sound produced through a bilateral interaction of the two vocal sources.

The 'dee' syllable is the terminal note in the 'chick-a-dee' call of the black-capped chickadee (Parus atricapillus). It comprises 12-20 temporally-overlapping frequency components, evenly spaced at approximately 400 Hz intervals. The first and second spectral components having significant energy occur at about 1600 and 2000 Hz, with higher frequency components, spaced at the interval between these two peaks, occurring up to 7000 Hz. This orderly spectral structure resembles a harmonic series, but the lack of energy at lower frequencies and ambiguous estimates of fundamental frequencies based on the intervals between higher frequency components both suggested an alternative mechanism for production. In an effort to understand what role each side of the syrinx plays in the generation of this sound, we performed unilateral hypoglossal nerve sections on chickadees.

Sectioning either side gives rise to noise in which is embedded a true harmonic signal with a fundamental frequency in the range of 1500-2000 Hz. If the right hypoglossal nerve is sectioned, the fundamental frequency occurs at about 1600 Hz, corresponding to the first component of the intact signal; if the left nerve is sectioned, the post-operative fundamental occurs at about 2000 Hz, corresponding to the second component of the intact signal. Linear summation of post-operative signals from the left and right sides does not, however, give rise to the frequencies seen in the spectrum of a normal signal. Thus, the chickadee's two syringeal halves cannot be acting independently in the production of this sound, and must be coupled in some non-linear fashion.

The correspondence between the first two spectral components of the intact signal and the fundamental frequencies of the post-operative signals, as well as the fact that the frequency interval between all spectral components invariably equals the interval between these two frequencies, suggests that the additional spectral components of the intact call arise as sum and difference frequencies resulting from amplitude modulation between the two syringeal sources. Calculation of expected sum and difference products from the mathematical expression for such cross-modulation, using realistic values for post-operative harmonic signals, supports this hypothesis.

165.2 SIZE OF VOCAL CONTROL REGIONS CORRELATES WITH SONG COMPLEXITY ACROSS DUETTING BIRD SPECIES. E.A. Brenowitz and A.P. Arnold. Department of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024

Song in oscine birds is a learned behavior. It has previously been shown that 2 forebrain vocal control regions (VCRs), the caudal nucleus of the ventral hyperstriatum (HVc) and the robust nucleus of the archistriatum (RA), are large in male Canaries that produce a large repertoire of song syllables. Canaries with small song repertoires generally have small HVcs and RAs (Nottebohm et al. 1981). Similar correlations between VCR size and song complexity have also been reported for female Canaries induced to sing with testosterone (Nottebohm 1980), and between populations of Marsh Wrens having different song repertoire sizes (Canady et al. 1984). In the present study we wished to determine whether this correlation is also observed between closely related species. We compared VCRs and song complexity in 2 congeneric species of Panamanian wrens, the Bay Wren (Thryothorus nigricapillus) and the Rufous-and-white Wren (T. rufalbus). In both species males and females engage in elaborate song duets with each other. T. rufalbus has a slightly larger average body size (bill to tail = 14.6 cm.) than T. nigricapillus (14.0 cm.). Song repertoire size is about the same for male T. nigricapillus (X + SD = 16.5 + 6.4; R. Levin in prep.) and male T. rufalbus (14.0 + 3.3; Farabaugh 1983). However, repertoire size is much larger for female T. nigricapillus (15.2 + 0.5; Levin in prep.) than for female T. rufalbus (6.0 + 1.4; Farabaugh 1>

Brains from 5 males and 5 females of each species were sectioned and stained with cresyl violet or thionin. We measured volumes of 4 VCRs (RA, HVc, Area X, and the motor nucleus of the hypoglossal nerve, nXII), as well as of 2 thalamic nuclei not involved in vocal control (the rotund nucleus, Rt, and the pretectal nucleus, Pt).

RA, HVc, Area X, and nXII are an average of 78%, 55%, 43%, and 26% larger, respectively, in female T. nigricapillus than in female T. rufalbus ($P < .05$, Rank Sum test). Pt is the same size in females of both species ($P > .05$), while Rt is 78% larger in female T. rufalbus ($P < .05$). Conversely, there are no differences in the volumes of any of these brain nuclei between males of these 2 species ($P > .05$). This suggests that differences observed in the size of VCRs in female wrens are not due to differences in body size, phylogenetic history, or histological preparation, but rather are due to interspecific differences in female song repertoire size. These data support and extend the hypothesis that there is a causal connection between VCR size and the complexity of song behavior that can be learned by oscine birds.

165.3 INTRATELENCEPHALIC AUDITORY PATHWAYS IN THE BUDGERIGAR. C.M. McHale and S.E. Brauth. Department of Psychology, University of Maryland, College Park, Maryland, 20742.

In a previous study of auditory nuclei in the budgerigar, we have shown that the auditory relay nucleus of the thalamus, nucleus ovoidalis, is composed of two major subdivisions in this species. These are a central compact zone which projects to the primary auditory region of the telencephalon, Field "L" and a ventral and medial subdivision which projects both to Field "L" and to a dorsolateral auditory area located in the neostriatum intermedium (NIDL). As part of an ongoing study of the organization of these parallel pathways, we have investigated the efferent projections of both Field "L" and NIDL neurons. We find that neurons in both fields project laterally and ventrally to another telencephalic field located in the ventrolateral neostriatum intermedium (NIVL). Experiments utilizing 2-deoxy-D-glucose (2DG) autoradiography (Brauth et al, Neurosci. Abs., 10:401, 1984) have shown that NIVL is metabolically activated by acoustic stimuli including species-typical contact calls and warbles. Since NIVL neurons do not receive direct projections from the auditory thalamus, acoustic activation of NIVL is probably a result of projections to this region from auditory neurons in NIDL and Field "L".

All three telencephalic auditory fields (Field "L", NIDL and NIVL) project to selective portions of the archistriatum including portions of the posterior archistriatum and rostromedial archistriatum. In birds the archistriatum is a major source of descending telencephalic projections to brainstem nuclei. Of particular importance in the present context, we have found that projections derived from neurons in the posterior archistriatum terminate within both the MLd (nucleus mesencephalicus lateralis pars dorsalis - the avian inferior colliculus), and the ventral and medial subdivision of nucleus ovoidalis. Therefore pathways exist by which information processed by telencephalic auditory structures can influence brainstem auditory centers in this species. These pathways may provide a possible substrate for auditory discrimination or sensory learning processes.

Field "L" neurons also project to a small region directly abutting the medial border of nucleus archistriatalis robustus (RA). In budgerigars, RA is located within the rostromedial archistriatum (Paton et al, J. Neurosci., 1:1279-1288, 1981) and projects bilaterally to the motoneurons controlling the syrinx (nXIIts). RA therefore contains the upper motoneurons for the control of vocal behavior. Projections from Field "L" to a portion of the archistriatum immediately adjacent to RA may provide a mechanism by which information processed within the auditory nuclei of the telencephalon can provide feedback during vocal learning or vocal performance.

165.4 ELECTRORECEPTION AND ELECTROLOCATION IN PLATYPUS H. Scheich, G. Langner, Ch. Tidemann*, R. Coles, and A. Guppy* Zoological Institute, Technical University, 6100 Darmstadt, FRG, and Australian National University, Canberra, ACT 2601

The Australian monotreme platypus subsists entirely on live food caught during nightly dives in lakes and streams. Since eyes, nostrils, and ear canals are closed under water its ability to locate and catch rather mobile prey like crayfish, shrimp and small fish appeared to depend on the tactile sense of the bill which was known to be covered with mechanoreceptor organs (Poulton, E.B., Quart. J. Micr. Sci. 36: 143, 1894). We have conducted behavioral experiments showing that platypus can detect electric field gradients as small as 50 µV/cm and that it makes use of dipole fields to locate objects. Behavioral tests with 1 male and 3 females in a 3 m Ø pool involved: 1. locating small object which emitted DC fields and discrimination of identical mechanical objects, one emitting a field and the second not; 2. probing in hollow stones with and without electric fields; 3. avoidance of unexpected obstacles with and without electric fields; and 4. eliciting a reflex-like head jerk by switching on and off a homogeneous electric field. Complementary measurements of the compound action potentials from the tail flick of local freshwater shrimps gave values at the order of 1 mV/cm at a few cm distance, thus way above threshold for platypus. Since a tail flick yields only a few cm escape distance we consider the action potential a meanigful stimulus to guide prey catching.

Cortical evoked potentials with stimulation of the bill revealed an electrosensory field ventral to the auditory field and caudal to the mechanoreceptive bill map (Bohringer, R.C., Rowe, M.J., J. Comp. Neur. 174: 1, 1977). Evoked potential thresholds with pulses of 55 ms duration were at the order of 50 µV/cm. Electroreceptor candidates in the bill may be so-called gland duct receptors, unrelated to electroreceptors in lower vertebrates (Andres, K.H., v. Düring, M., In: Sensory Receptor Mechanisms. Hamann, W., Iggo, A., Eds., World Sci. Publ. Co., Singapore, pp. 81-99, 1984).

It is worth mentioning also that platypus showed a remarkable under-water-chemosensitivity. A drop of shrimp juice but not NaCl elicited vigorous search in the pool. Since nostrils are closed chemosensitivity may relate to the large size vomeronasal organ.

165.5 CENTRAL CONTROL OF FREQUENCY IN BIOSONAR VOCALIZATIONS OF THE MUSTACHED BAT. D.M. Gooler and W.E. O'Neill, Center for Brain Research, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

The biosonar system of the mustached bat, Pteronotus parnellii, has proven strategically advantageous for the study of audition and vocalization. In particular, this study exploits the fact that mustached bats control very precisely the frequency of their biosonar signals, based upon the frequency information present in echoes. This behavior, known as "Doppler-shift compensation", involves the production and reception of comparatively simple acoustic signals, which, however, contain acoustic elements similar to those used in human speech. These signals and their underlying motor patterns are stereotyped and repetitively produced, both in nature and via microstimulation of brain. The emphasis of this study is to examine the role of the anterior cingulate cortex (ACg) in the fine control of the frequency of emitted sounds, such as occur for Doppler-shift compensation during target-oriented flight.

Constant current cathodal pulses (20-30 μamps) were applied to a midline region of brain dorsal and anterior to the corpus callosum, presumably ACg,to elicit vocalizations. ACg appears to be divided into two areas based on the type of vocalization produced by microstimulation. The anterior portion is associated with echolocation sounds and the posterior section is associated with audible noise-bursts. The frequencies emitted by the bat during microstimulation of the anterior portion of ACg are most often 58-62 kHz, which is the normal range of frequencies dominant in the second harmonic of natural biosonar emissions in this species. This is in contrast to results of microstimulation in the midbrain periaqueductal gray where the frequencies of electrically elicited vocalizations are only near the resting frequency (61-62 kHz). Most interestingly, the frequencies of vocal pulses elicited by microstimulation of ACg vary depending on the position of the electrode. The frequency of emitted sound increases along a rostro-caudal axis. Thus, the ACg appears to be organized by place for the frequencies normally emitted during Doppler-shift compensation.

Studies are ongoing to examine the neural connections associated with elicited echolocation sounds from ACg. To date, retrograde transport of HRP from one injection site in ACg (frequency of elicited vocalization, CF_2=61 kHz) shows cell bodies of origin in the contralateral, reciprocal portion of ACg; ipsilateral, ventral ACg; ipsilateral auditory cortex; and two ipsilateral, midline thalamic nuclei. The results, thus far, indicate a potential source for an auditory influence on vocalization and thereby, potential for the control of emitted frequency of echolocation sounds in the bat.

165.6 AUDITORY LOCALIZATION AND VISUAL FIELDS IN MAMMALS. R. S. Heffner and H. E. Heffner. Lab. of Comparative Hearing, Bureau of Child Research, University of Kansas, Parsons, KS 67357.

Mammalian sound localization acuity has been shown to vary widely from 1^0 in man and elephants to over 20^0 in some rodents and hoofed mammals. In seeking possible causes of this variation we have begun to explore the relation between auditory localization and other ecological and morphological variables.

Because it has often been suggested that an important function of sound localization is to direct the eyes to the source of a sound, we have begun to explore the relation of sound localization to some simple visual parameters. As a first step, the size of both the binocular and panoramic visual fields was determined in 19 species of mammals whose sound localization acuity is known. It was found that the size of the binocular visual field is reliably correlated with sound localization acuity ($r=0.78$ $p<.01$). That is, animals with frontally directed eyes and wide binocular visual fields are better able to localize sounds in front of them than are animals whose vision is directed laterally.

The existence of such a correlation suggests a link between sound localization and vision. Whether this correlation indicates a causal link between the amount of binocular vision and localization acuity or whether both are related through some other factor cannot yet be determined. Nevertheless, the closeness of the relationship, when taken together with the recent discoveries of congruent maps of auditory and visual space in the superior colliculus, indicates that visual space and auditory space are functionally linked and merit further exploration.

165.7 AZIMUTHAL TRACKING ACCURACY OF MOVING TARGETS BY THE BIG BROWN BAT (EPTESICUS FUSCUS). W.M. Masters* and A.J.M. Moffat* (SPON: J.A. Simmons). Institute of Neuroscience, University of Oregon, Eugene, OR 97403

The Big Brown Bat (Eptesicus fuscus) detects and captures flying insects using its sonar (echolocation) system. Photographs of capture sequences show that soon after a bat has detected a potential prey target, it aims its head at it and keeps its head pointed at the target during the subsequent approach to and interception of the target. This behavior of keeping the head aimed at a moving target is useful experimentally, because a bat can be trained to perform a similar behavior in a laboratory setting, thereby permitting us to investigate some aspects of the bat's echolocation abilities. We trained bats to sit on a small platform and keep their head aimed at a small styrofoam ball suspended in space in front of the bat and moving irregularly along an arc a constant distance from the bat. We monitored the head aim of the bat by a specially built optoelectronic device, and simultaneously monitored the angular position of the target and the time of occurance of echolocation sounds. We were interested in two questions: how accurately can a bat keep its head aimed at a moving target, and what tracking strategy does it use to keep its head aimed at the target.

When tracking a moving target, a bat's head aim lags behind the target by about 60 to 100 ms, which, at any given instant, results in an error between the direction that the bat is aiming and the direction to the target. The error waveform (head aim minus target direction) averages $\pm4.7^0$ and is strongly correlated with the target's velocity waveform. If the bat's tracking lag is removed before the subtraction, the error waveform (now corrected for lag) is reduced to $\pm2.3^0$ and no longer correlates with target velocity. The lag-corrected error waveform does, however, correlate well with target angle. The explanation for this appears to be that the bat does not track the target with unity gain, but rather with a gain of roughly 0.9, so that the farther off the midline the target is, the larger is the bat's error. This error probably is not due to the bat's uncertainty as to the actual direction to the target, and if the bat's tendency to track with non-unity gain is compensated for by dividing the head-aim waveform by the tracking gain, the resulting lag- and gain-corrected error waveform averages $\pm1.6^0$ and no longer correlates with target angle or velocity. The residual error appears noise-like, as would be expected if it is due to the bat's uncertainty as to target direction and/or imprecision in aiming its head. The significance of these observations for the bat's head-aim tracking strategy will be discussed.

165.8 TIME OF DAY IS CRITICAL IN THE ASSESSMENT OF LESION-INDUCED DEFICITS IN VISUAL ORIENTING RESPONSES. B.A. Sabel, S.L. Ayres* and G.E. Schneider, Dept. of Psychol. and the Whitaker College, M.I.T., Cambridge, MA 02139.

Normal hamsters are remarkably different in their visual responsiveness during tests carried out at different times of the day (Ayres & Schneider, unpubl.). Our animals are kept on a 14 hr:10 hr light-dark cycle, with lights going off at 4 p.m. At this time, a period of greatest locomotor activity begins each day, which probably corresponds in the wild to a period of emergence from the burrows and foraging for food. However, in tests of visually elicited turning toward sunflower seeds presented in various parts of the visual field, normal laboratory hamsters are least responsive during this active period, whereas they are much more responsive when tested earlier in the day. The major reason for this appears to be that in the most active period, hamsters show the most predator-avoidance types of responses, including escape movements and freezing, to visual stimuli. (We have found that such responses can be abolished in hamsters by lesions of the superior colliculus (SC): Merker, '80; Schneider & Ayres, unpubl.)

These facts led us to test hamsters at two different times of day in a study of recovery of visually elicited turning movements after unilateral ablation of neocortex (on the right side) plus either exposure or exposure and removal of the opposite (left) SC. (Exposure of the left SC was done by removal of the overlying cortex.) Six adult hamsters comprised each of the two groups. Systematic variation in time of testing was begun 90 days after surgery, long after both groups had fully recovered visual orienting to seeds when tested in the morning, the time when our hamsters are generally most responsive. As in the case of normals, each group of brain-damaged animals showed significantly less orienting to seeds late in the day, during their active period ($p<.05$). However, in tests conducted during this late afternoon period a lesion-group difference appeared for presentations in the upper part of the left field, the field which had been affected by the cortical lesion. The group with the addition of an opposite sided (left) midbrain lesion showed less orienting in the left (as well as in the right) field ($<.02$). At the same time of day this group showed more freezing to an overhead "looming" stimulus, but this difference was not significant.

This appearance of a group difference at one time of day which was not present at another time of day leads us to suggest that time of day may account for some discrepancies found in the literature on brain lesion effects, and should be considered a critical variable in such studies, a variable which may be quite different for different species. (Supported by NIH grants EY00126 and EY02621.)

165.9 THE NEURAL SUBSTRATE FOR VOCALIZATION IN THE DOMESTIC CAT: A 2-DEOXYGLUCOSE ANALYSIS. N.C. de Lanerolle, Sections of Neurosurgery & Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT. 06510.

The neural substrate for vocalization in mammals is as yet only poorly understood. In order to determine the brain areas metabolically active during vocalization, the pattern of 14C-2-deoxyglucose (2DG) uptake was studied in the brains of anesthetized cats made to vocalize by electrical stimulation at a site in the ventrolateral pons. In these experiments each cat was injected with 100 uCi/kg of 2DG and stimulated for a period of 45 min with current intensities slightly above threshold for call evocation. The pattern of stimulation employed was 20 sec. current ON and 10 sec. OFF. Stimulation at such sites evoked mainly meow calls with some growls and meow-growls. Animals used as controls underwent all procedures except electrical stimulation.

The brain areas that were metabolically active in experimental animals alone were the following: In Medulla/pons: nu. of cranial nerve XI; caudal lateral nu.; hypoglosssal nu.; nu. ambiguus and adjacent medial reticular formation; facial nu. and adjacent medial reticular formation; main sensory nu. and motor nu. of cranial nerve V; cochlear nu. Midbrain: the ventromedial and dorsolateral edges of the periaqueductal gray; occulomotor nu.; medial geniculate nu.; red nu.; nu. Darkschewitsch and interstitial nu. The inferior colliculi and interpeduncular area were strongly labelled compared to controls. Diencephalon: medial mammillary nu.; ventral posterolateral nu; anterior ventral thalamic nu. Telencephalon: caudate nu and some cortical areas. All of the above areas were bilaterally active. The brain areas identified through this 2DG study correspond rather well with those areas found to be connected with this ventrolateral pontine call site in silver degeneration studies. It appears that in mediating vocalization induced by electrical stimulation at this site, several motor nuclei directly controlling sound production are active. In addition areas responsible for controlling head and eye movements, areas processing sensory inputs, some limbic structures, and areas intergating sensory/motor functions are also metabolically active.

165.10 BEHAVIOR PATTERNS EVOKED BY ELECTRICAL STIMULATION OF THE HAMSTER SUPERIOR COLLICULUS. D.P.M. Northmore* and G.E. Schneider (SPON: P. Hartline). Inst. for Neuroscience, Univ. of Delaware, Newark DE 19716 & Dept. of Psychology, M.I.T. Cambridge, MA 02139.

Evidence is accumulating that the rodent superior colliculus (SC) is involved not only in orienting movements of the body, head and eyes, but also plays a crucial role in avoidance of or escape from predators. Here we report on the variety of movements that can be evoked by electrical stimulation of SC in unrestrained hamsters.

Adult Syrian hamsters were implanted with 1-4 fixed electrodes made from teflon coated Pt-Ir wire (110μm diam) aimed at SC on the right side. The animals were observed in a circular walled arena while 1 sec trains of cathodal pulses (200 Hz, 0.1msec) were delivered to the electrodes by a constant current source.

The orienting movements evoked varied from quick turns resembling visual orienting to sunflower seeds, to slow, forced motor turns that continued for the duration of the stimulus. In either case, turning was contraversive (leftward). The most common defensive behavior evoked was freezing, ranging from a brief interruption of ongoing behavior, to prolonged immobility characteristic of one of the hamster's natural responses to visual threat. Other types of defensive behavior seen included ducking, backing and running escape.

Electrode tips were identified in sections stained for Nissl substance and degeneration. While all of the behavior patterns described could be observed from stimulation at different sites above the stratum opticum, relatively high currents (>500 μA) were required. Sites in the intermediate layers of SC yielded turns with low current thresholds (20 - 70 μA), and defensive behaviors at higher currents. Deep sites in SC tended to give brief arrests (12 - 90 μA), and other behavior patterns at higher currents.

The evocation of a range of defensive behaviors in addition to turning movements is consistent with previous observations (Merker, PhD Diss., MIT, 1980; Schneider & Ayres, unpubl.) that responses to visual threat in the hamster are diminished or abolished by SC lesions.

165.11 BENACTYZINE POTENTIATES ALARM CALLS IN THE SQUIRREL MONKEY J.R. Glowa and J.D. Newman. National Institute of Mental Health and National Institute of Child Health and Development, Bethesda, MD 20205.

An alarm call is a naturalistic response of many mammalian species to the presence of a predator. The study of possible neural mechanisms underlying this behavior is difficult because conditions appropriate for reliably eliciting alarm calls are not easily created in the laboratory. The present experiments were initiated following the serendipitous observation that benactyzine appeared to increase the frequency of alarm calling in squirrel monkeys when laboratory personnel were nearby. Benactyzine (Sigma) is a tertiary anticholinergic little studied for its behavioral effects. Squirrel monkeys are especially useful subjects for the study of this type of vocalization because they emit a species-specific alarm call (yap or cackle) under laboratory conditions. The effects of various combinations of benactyzine dose and stimulus conditions were studied on spectrographically analyzed vocalizations of isolated squirrel monkeys. Four monkeys, weighing between 700-1000 g, were tested individually in a quiet setting. The drug was not given more often than once a week. When given saline (0.1 ml/kg, i.m.), the intermittent presentation (30 sec on - 30 sec off, for 10 consecutive min) of a monkey puppet stimulus (Hanmee Trading Co., Flushing NY) resulted in a low level of alarm calling. Benactyzine (0.1-1 mg/kg, 0.1 ml/kg, i.m.), given 5 min before the start of recording, significantly increased the frequency of alarm calling in a dose-related manner following the onset of testing. In the absence of the stimulus, benactyzine resulted in little or no vocalization. These findings indicate that benactyzine can increase rates of alarm calling in the squirrel monkey under defined laboratory conditions. Such results suggest that benactyzine may serve as a useful pharmacological probe for the study of mechanisms mediating the alarm call and that in the squirrel monkey one such mechanism may involve a cholinergic substrate.

165.12 YAWNING AS A STEREOTYPED ACTION PATTERN AND RELEASING STIMULUS. R. R. Provine, Dept. of Psychology, Univ. of Maryland Baltimore County, Catonsville, MD 21228.

Yawning was induced by instructing subjects to "think about yawning." Such yawns were reported as normal by subjects. Yawns were consistent in duration ($X = 5.9$ sec $\neq$ 1.9 sec (SD)), periodic (X interyawn interval = 68.3 $\neq$ 33.7 sec) and within subject stability of yawn duration and frequency was maintained for at least several weeks. Yawns were "all-or-none" actions that went to completion once initiated; fractional yawns were seldom if ever produced and it was difficult for subjects to stifle a yawn. Yawns were complex, relatively long lasting, independent of the amplitude of the releasing stimulus and species typical. These and other characteristics qualify yawning as a stereotyped action pattern of the type described by ethologists.

Yawning was released both by observed yawns and by yet to be defined physiological states. Although visually observed yawns were potent yawn producing stimuli, thinking about or reading about yawning also elicited yawning. The wide variety of possible releasing stimuli contributes to the "infectiousness" of yawning.

Yawns may be the best example of stereotyped action pattern and releaser in humans. The study of yawning may provide insights both into yawn function and the more general issue of how releasers trigger behavior. Yawning also offers us the opportunity to experience the sensation of having a stereotyped action pattern released and performed. The prominence of yawning in human behavior and the advantages of yawning as a subject for neurobehavioral analysis are inconsistent with the current status of yawning as a minor behavioral curiosity.

166.1 REGIONAL NEUROTRANSMITTER TURNOVER FOLLOWING BRAIN STIMULATION REWARD John D. Lane, ǂMichael J. Blake and ǂElliot A. Stein, Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107 USA; ǂ Department of Biology, Marquette University, Milwaukee, WI 53233 USA

The apparent rewarding properties of intracranial self stimulation (ICSS) are presumably derived through the activation of specific anatomical and neurochemical pathways which are normally activated when presented with reinforcing stimuli. Furthermore, there is evidence that suggests that the rewarding aspect of ICSS is perceived only through active acquisition of the stimulation and that experimenter-applied or non-contingent stimulation does not possess rewarding qualities and may in fact be aversive. The sites which support this behavior have been well mapped and include areas from prefrontal cortex to the central gray. The results of lesion studies as well as other pharmacological manipulations suggest a role for dopamine in the mediation of this behavior, as well as for several other neurotransmitters and neuropeptides which may have a modulatory role. The aim of this experiment was to determine how several monoamine and amino acid neurotransmitters are involved in ICSS behavior and if a neurochemical distinction could be made between response-contingent and non-contingent ICSS. To achieve this end we have compared the regional turnover of several neurotransmitters (DA, NE, 5-HT, ASP, GLU and GABA) in rats receiving response-contingent ICSS and those receiving either no stimulation or non-contingent electrical stimulation. Male Holtzman rats were implanted with monopolar stimulating electrodes aimed at the ventral tegmental area. Following a one week recovery, rats were placed in stimulating chambers and primed to press for 100Hz, 300msec trains of 0.5msec cathodal electrical pulses. Those animals showing robust ICSS were implanted with chronic jugular catheters. After a three day recovery, the current range supporting ICSS for each rat was determined and used to match animals in the following three groups: 1) an active ICSS group; 2) a yoked group receiving a pulse train at the same time as the active group, at an intensity previously shown to support ICSS; and 3) a sham sedentary group receiving no stimulation. Animals were pulsed at 60 and 90 min prior to sacrifice with neurotransmitter precursors (^{3}H-tyrosine, ^{3}H-tryptophan and ^{14}C-glucose), and were totally frozen in liquid nitrogen. Discrete brain areas were assayed for neurotransmitter content and incorporation of radiolabel using HPLC tecnhiques, and turnover (mol/mg-hour) calculated. As observed by Porrino et al (Science, 224, 306, 1984) with the 2-DG technique, mesolimbic and mesocortical systems are activated by ICSS. Turnover in the nucleus accumbens and medial prefrontal cortex was correlated with the behavioral paradigm. (supported in part by DA-02234 and BRSG)

166.2 PRETREATMENT WITH A PRESYNAPTIC DOSE OF APOMORPHINE ENHANCES THE BEHAVIORAL RESPONSE TO AMPHETAMINE. A.E. Basse, M. Tsutsumi* and G.V. Rebec, Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Long-term administration of amphetamine (AMPH) produces a progressive augmentation of locomotion and some components of focused stereotypy in the rat. Recent biochemical (Muller, P. and Seeman, P., Eur. J. Pharmac.,55:149, 1979) and electrophysiological evidence (Kamata, K. and Rebec, G.V., Brain Res.,321:147, 1984; Kamata, K. and Rebec, G.V., Life Sci.,34:2419, 1984) suggests that the augmentation is mediated, in part, by a subsensitivity of dopamine (DA) autoreceptors. If this is the case, then an AMPH challenge administered to rats pretreated with a dose of apomorphine (APO) known to desensitize DA autoreceptors (Rebec, G.V. and Lee, E.H., Brain Res.,250:188, 1982) should produce the same behavioral alterations associated with multiple AMPH injections.

To test this hypothesis, rats were pretreated twice daily with injections of saline, 0.04 mg/kg APO or 1.0 mg/kg d-AMPH for 5 days. Twelve hours after the last injection, each animal received 1.0 mg/kg d-AMPH and individual components of the behavioral response were rated by independent observers.

As expected, pretreatment with 0.04 mg/kg APO caused a profile of sensitization to AMPH similar to that seen in rats pretreated chronically with the drug. Repetitive head movements were significantly increased in both the APO ($p<.05$) and AMPH ($p<.05$) treated groups with respect to controls. Sniffing also was augmented by both drug treatments, but this increase failed to reach significance in the AMPH group. The enhanced behavioral response to AMPH in rats pretreated with a presynaptic dose of APO suggests that subsensitive DA autoreceptors play a major role in the behavioral sensitization to AMPH during long-term treatment.

166.3 REGIONAL MONOAMINE ACTIVITY, SENSITIVITY TO AMPHETAMINE AND AGGRESSIVE BEHAVIOR IN MICE. K. Noda*, K.A. Miczek and R. Kream*. Dept. of Psychology, Tufts Univ., Medford, MA 02155, and Dept. Anesthesiology, N.E.M.C., Boston, MA 02111.

We have observed that the environmental conditions that modulate aggressive behavior in mice and the performance of aggression itself are associated with changes in levels of brain monoamines and their metabolites. These changes are also reflected in differential sensitivities of animals to sympathomimetic drugs. However, it is unclear whether or not these neurochemical changes are specific to aggressive behavior or of a more general nature. We have manipulated (1) the housing conditions which are thought to be important in the development of aggressive behavior, and (2) the amount of experience with aggressive behavior. Subsequently, either regional levels of brain monoamines or, alternatively, behavioral sensitivity to amphetamine was measured.

Mice were housed in different conditions for at least three weeks, and then sacrificed immediately after meeting an intruder in a resident- intruder confrontation. Dopamine (DA) and dihydroxyphenylacetic acid (DOPAC) concentrations were measured by HPLC-electrochemical detection in punched-out brain tissues. DA turnover as expressed by DOPAC/DA ratios in nucleus accumbens and amygdala of group-housed mice was increased compared to pair-housed counterparts. However, no change in turnover was observed in corpus striatum or tuberculum olfactorium.

The behavioral effects of d-amphetamine (0, 0.1, 1.0, 10 mg/kg i.p.) were assessed in three groups of male mice. Isolated or pair-housed mice with no prior fighting experience, as well as pair-housed mice with ten consecutive days of fighting experience, were given amphetamine and then confronted with an intruder. Various social, aggressive, and motor behaviors were analyzed. Isolated and pair-housed mice showed similar levels of attack behavior in the control condition; this behavior was enhanced slightly at the lower amphetamine doses and suppressed by the 10 mg/kg dose. The animals with prior daily fighting experience showed a higher level of fighting when given saline, with no enhancement by low doses of drug. Their fighting behavior was suppressed by all doses of amphetamine.

166.4 **LONG TERM SINGLE AND MULTIPLE UNIT RECORDINGS FROM BRAINSTEM REGION OF THE LOCUS COERULEUS IN AWAKE, BEHAVING NON-HUMAN PRIMATES.** **S.J. Grant, J.R. Taylor*, D.E. Redmond, Jr. Neurobehavior Lab., Yale Univ. Sch. Med., New Haven, CT 06510.**

Bundles of fine (32-64 um) wires have been successfully used in a number of species (mainly rodents and cats) to record single and multiple unit neuronal activity for extended periods (e.g. hours to days) from unanesthetized, freely moving subjects. This technique has not been used in primates, even though studies of awake, behaving primates may have advantages for investigations of cognitive and emotional functions. On the other hand, the technical difficulties and limitations (e.g. electrode deviation, sampling biases, limited penetrations) associated with fine wire electrodes may be greater in primates than in other species and thus limit the technique's usefulness.

We implanted three stump-tailed macaques (Macaca arctoides) with bilateral movable microdrives aimed at the region of the nucleus locus coeruleus. Bundles consisted of three 32 um diameter and three 64 um diameter wires. Some wires were etched to a micro-electrode type tip (>1 MegOhm), while others had low impedence blunt cut tips. Differential recordings through pairs of wires were amplified by a custom 6-channel FET headstage mounted on the subject's skull.

A variety of neurons were recorded through both the etched and blunt wires. Unit activity was tested for responsiveness to naturalistic stimuli, simple sensory stimuli, and tones paired with either orange juice delivery or mild air puffs directed at the face. Most activity remained stable for many hours, and in some cases days, even though the monkey's head and body were free to move within the constraints of a primate chair. Such long term stability permitted recordings to be maintained throughout the full time course of centrally acting agents, e.g., the alpha-2 adrenergic agonist clonidine (20-40 ug/kg, i.m.).

Compared with recordings from the same region of the brain stem using conventional glass coated tungsten microelectrodes, fine wires exhibited a lower signal to noise ratio, and a lower yield of neurons per penetration. On the other hand, stable recordings could be maintained longer and more consistently with fine wires than with microelectrodes. Fine wire electrodes have the potential to provide longer term recording from specific populations of neurons in awake, behaving primates with less restraint than is currently possible with other techniques.

166.5 REGIONAL EFFECTS OF AMPHETAMINE IN THE NEOSTRIATUM: SINGLE-UNIT RESPONSES IN FREELY-MOVING RATS. G.V. Rebec and T.W. Gardiner* (SPON: S.D. Curtis). Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

The neuronal response to amphetamine (AMPH) in immobilized (IMM) rats is both dose-dependent and regionally specific. Low doses ($\leq$ 2.5 mg/kg d-AMPH) typically suppress unit activity in the anteromedial neostriatum, whereas high doses ($\geq$ 5.0 mg/kg) produce the opposite effect. Neurons in the ventrolateral neostriatum, on the other hand, generally are excited by low and inhibited by high doses of d-AMPH. Multiple-unit recordings obtained from freely-moving (FM) rats, however, have indicated that both low and high doses of AMPH uniformly produce excitations in neostriatal activity. We have begun to examine these differences using single-unit recording techniques to determine the AMPH response in FM rats on a region-specific basis.

Differential recording of single-unit activity was obtained using a tungsten microelectrode, with the input signal fed into a lightweight headstage amplifier. This arrangement permitted free and unrestricted movement by the animal, without significant movement artifact. Thus far, in 7 different animals, the mean baseline firing rate (3.0 spikes/sec $\pm$ 1.8) of neurons in the anteromedial neostriatum was comparable to that previously obtained for IMM rats. No large variations were noted in the firing rates of individual neurons, although many cells (4 of 7) showed clear increases in activity associated with movement. Each rat then was challenged with an ip injection of 1.0 mg/kg d-AMPH. Within 20 minutes, the firing rate of 3 of 7 neurons increased by more than 300%; this response peaked at approximately the same time as the behavior. The remaining 4 neurons were clearly depressed by AMPH (by 50-80%). Although preliminary, these results contrast with both the single-unit recordings obtained from IMM rats and the multiple-unit recordings of FM animals. They suggest, however, that like the responses observed for IMM rats, AMPH may exert complex alterations in neostriatal unit activity, rather than uniform excitatory responses. Further work will extend these observations to other doses of AMPH and to other regions of the neostriatum.

Support by USPHS Grants DA 02451 and RR 7031.

166.6 ACTIONS OF d-AMPHETAMINE ON CEREBELLAR PURKINJE CELLS IN FREELY MOVING RATS. A.J. Michael, M.O. West, J.K. Chapin, B.D. Waterhouse, D.J. Woodward, Dept. Cell Biology, UTHSCD, Dallas, Texas 75235.

The present study was conducted to investigate the actions of d-amphetamine (d-A) on spontaneous discharge and GABA-induced inhibitory responses of cerebellar Purkinje (P) cells in the freely moving rat. Adult Long-Evans rats were prepared for chronic recording with a detachable microdrive positioned over the anterior cerebellum (midway between lambda and the occipital crest, 1 mm lateral to midline). Extracellular activity of P cells was recorded with multibarrel glass micropipettes during periods when the animal was motionless but alert. Drug response histograms collected before, during, and after d-A iontophoresis were used to quantitatively evaluate d-A effects on spontaneous discharge and inhibitory responses to microiontophoretic pulses (10 sec. duration, 40 sec. intervals) of gamma-aminobutyric acid (GABA). In 7 of 8 (88%) neurons, microiontophoretic application of d-A suppressed spontaneous discharge at currents ranging from 3 to 100 nA (mean=25 nA). In 6 of the 7 (86%) cells in which inhibition was observed, spontaneous firing rate returned toward control levels within minutes after cessation of d-A administration. In 2 of 3 units, d-A augmented GABA-mediated suppression of P cell discharge relative to changes in spontaneous activity. In both of these neurons, d-A caused a potentiation of GABA-induced inhibition at microiontophoretic doses which caused little or no change in spontaneous discharge.

These data support and extend our previous findings in anesthetized animals that iontophoretic doses of d-A can suppress spontaneous discharge of P cells, and that d-A can produce an augmentation of GABA-mediated inhibition of P cell activity. Previous investigations have demonstrated that norepinephrine iontophoresis and locus coeruleus stimulation can also potentiate GABA action in the cerebellum.

Thus, the data presented here provide a crucial link between studies in acute, anesthetized animals and studies in chronic, awake animals. Furthermore, these experiments serve as a foundation for the further evaluation of the actions of d-A and other drug substances on the physiology of neuronal circuits during behavior.

166.7 SEX DIFFERENCES IN AN ANIMAL MODEL OF AMPHETAMINE PSYCHOSIS Dianne M. Camp* and Terry E. Robinson (SPON: E. S. Valenstein). Department of Psychology and Neuroscience Laboratory, The University of Michigan, Ann Arbor, MI 48104-1687

The "behavioral sensitization" produced by the repeated intermittent administration of amphetamine (AMP) is thought to be an animal analogue of AMP psychosis. In studying the factors that influence the development of behavioral sensitization we recently found that female rats show a much more robust sensitization of AMP-induced rotational behavior than males. The present experiment was conducted to determine: (1) whether there are similar sex differences in the sensitization of other AMP-induced behaviors; and (2) whether there are sex differences in forebrain dopamine (DA) utilization in sensitized animals.

Adult Holtzman rats received an i.p. injection of AMP every 4 days, for a total of 10 injections. To compensate for sex differences in the metabolism of AMP male and female rats received different doses of AMP. Male rats received 3.0 mg/kg. Female rats received either 2.6 mg/kg (which produces brain levels equivalent to males receiving 3.0 mg/kg), or a lower challenge dose (1.78 mg/kg) that did not behaviorally distinguish males and females following the initial AMP treatment. AMP-induced stereotypy was quantified using a rating scale, and locomotor activity (distance traveled) was continuously monitored in automated activity monitors. All animals were killed 8-13 days following the last AMP injection and the medial frontal cortex and striatum assayed for DA and dihydroxyphenylacetic acid (DOPAC) using HPLC-EC. The ratio of DOPAC/DA was used as an index of DA utilization.

Both males and females showed a progressive enhancement in stereotyped behavior over the 10 test sessions. However, there were also significant sex differences. As predicted, female rats showed a greater sensitization of stereotyped behavior than males. The quality of stereotypy also differed in sensitized males and females, with females displaying a greater hyperactive component. There were sex differences in the sensitization of locomotor activity as well. Both female groups showed a significant change in locomotor activity across the 10 test sessions, whereas the activity of males did not.

Interestingly, there were also sex differences in DA utilization in sensitized animals. In female rats AMP pretreatment produced a significant increase in striatal DA utilization ($p=.02$), and a trend for enhanced frontal cortex DA utilization ($p=.075$), relative to non-AMP treated controls. In contrast, AMP sensitization had no measurable effect on striatal or frontal cortex DA utilization in male rats. We conclude that sex has a major influence on the development of behavioral sensitization and suggest that the neural correlates of behavioral sensitization may be easier to identify and study in female animals.

166.8 SIMULTANEOUS RECORDING OF DOPAMINE-CONTAINING NEURONS IN THE SUBSTANTIA NIGRA AND VOLTAMMETRIC RELEASE OF DOPAMINE IN THE CAUDATE NUCLEUS OF BEHAVING CATS. V.M. Trulson and M.E. Trulson. Department of Anatomy, College of Medicine, Texas A&M University, College Station, Texas 77843.

Electrophysiological recordings of single dopamine (DA)-containing neurons in the substantia nigra (SN) of anesthetized and/or immobilized animals have long been used as an index of functional activity of the central DA system. These neurons appear to possess autoreceptors which are sensitive to DA as well as DA agonists. More recently, a technique was developed for recording the electrophysiological activity of single DA-containing neurons in the SN of behaving cats. Drug manipulations under these conditions were similar to those observed in anesthetized and/or immobilized rats. However, examining the activity of DA-containing neurons in behaving cats revealed that, unlike other neurons in the brain, these cells showed no significant change in activity during sleep. Furthermore, these studies revealed that the activity of DA neurons increased by only a small amount (i.e., 15-20%) when the animal engaged in active movement. These latter data seem somewhat surprising in view of the postulated role of the nigral striatal DA system in movement. Since the introduction of the technique of *in vivo* voltammetry for measuring DA release it has become possible to examine the neurochemical turnover of DA in freely moving animals. Unit recordings were made using Formvar coated 32 micron diameter nichrome wires. DA release was measured using linear sweep voltammetry with semi-differentiation using electrodes that separate dopamine from ascorbic acid. Ag/AgCl electrodes and 27-gauge stainless steel needles were used as reference and auxiliary electrodes, respectively. The working electrodes were scanned at a rate of 10 mV/s over the range of -0.1 to +0.5 V every 5 min using a BAS CV37 voltammograph. *In vitro* recording using standards of DA revealed that peak for DA occurred at 0.28 V. The data revealed that, while unit activity was not changed across the sleep/waking cycle, the voltammetric release of DA was significantly decreased by approximately 35% during REM sleep. In addition, during episodes of active movement the activity of single DA-containing SN neurons increased only 15-20%, while the voltammetric release of dopamine in the caudate nucleus was increased by 40-50%. These data suggest that the measurement of single unit activity of DA-containing neurons does not accurately reflect the functional activity of central DA system under all conditions. Therefore, one must be extremly cautious of extrapolating from electrophysiological recordings of single DA neurons to the functional state of the central dopaminergic system.

166.9 BILATERAL 6-OHDA LESIONS OF MESOLIMBIC TERMINALS SELECTIVELY ENHANCE SPONTANEOUS AND SCOPOLAMINE-INDUCED LOCOMOTOR BEHAVIOR. M.R.Lynch and R.J.Carey. S.U.N.Y. Upstate Medical Ctr. and V.A. Medical Ctr., Syracuse, New York 13210.

A substantial amount of evidence exists to support a mesolimbic substrate for DA agonist-induced hyperactivity. However, bilateral 6-OHDA lesions of the nucleus accumbens (following DMI pretreatment) have produced both hyper- and hypoactivity. Most of these studies have employed only photocell measurement of spontaneous motor activity and yield overall session totals which are not useful for characterizing the post-lesion behavioral profile. Also, many reports are confounded by DA depletions in striatal areas as well. Therefore, the present study examined the habituation pattern of discrete locomotor responses in an open field both before and after bilateral 6-OHDA infusions made at deGroot coordinates AP +3.0, L +2.5 and DV -8.0 from dura. Subjects were six male Sprague-Dawley rats and all received 25 mg/kg DMI pretreatment. Cross-overs were recorded for five 2-min intervals over a 10-min observation session. Rearings were monitored in the same manner and total sec. grooming time was also recorded. Rats were tested at 48 hr intervals, between 1500 and 1800 hr. Further, as both dopaminergic and cholinergic systems appear to be intimately involved in the control of motor behavior, all animals were also tested with 1.0 mg/kg d-amphetamine, 0.1 mg/kg apomorphine and 0.5 mg/kg scopolamine-HCl, both prior to surgery and at 13-21 days post-lesion. All drugs were administered i.p. 30 min before testing, and return-to-baseline sessions were conducted between consecutive drug administrations.

Rats were allowed to recover for one week. From day 7 to 11 post-surgery, activity measures were not significantly altered from pre-surgery levels. From day 13 to 21 however, session totals for crossings revealed a significant increase over pre-lesion values. Examination of the within-session data indicated a significant habituation pattern, which was not apparent during pre-lesion testing. Pre- and post-lesion comparisons for the drug effects revealed differences between the three behaviors. Thus, both pre-lesion amphetamine-induced increases in rearing and decreases in grooming were abolished by the surgical manipulation. Apomorphine produced significantly greater decreases in grooming and scopolamine significantly increased crossings, (whereas only a slight increase was produced by this anticholinergic drug prior to the lesion), with no effect on the other two measures.

These findings indicate that, contrary to previous suggestions, the hyperactivity produced by bilateral 6-OHDA lesions of the nucleus accumbens is not due to a failure to habituate to the test environment. They also provide further indication of a dopaminergic-cholinergic interaction at the mesolimbic level which merits further investigation.

166.10 QUIPAZINE MALEATE, A 5HT AGONIST, POTENTIATES AMPHETAMINE-INDUCED LOCOMOTION IN THE MOUSE. E. Wanek and W.H. Riffee, Div. of Pharmacology, College of Pharmacy, Univ. of Texas, Austin, TX 78712

There is increasing evidence of a serotonergic component in the neural control of locomotion. Neurons with cell bodies in the raphe nuclei innervate higher dopaminergic brain areas concerned with locomotion, such as frontal cortex, nucleus accumbens and neostriatum (caudate-putamen). Alteration of central 5HT levels by l-tryptophan or parachlorophenylalanine, decreases or increases, respectively, spontaneous locomotor activity in rats. The aim of this study was to determine whether quipazine maleate, a putative serotonergic receptor agonist, has an effect on locomotion induced by a moderate (2.5 mg/kg) dose of amphetamine in the male CD-1 mouse. Mice were food-deprived for 24 hours prior to experimentation. Drugs were dissolved in saline and were given in a dose of 0.01ml/gram body weight. Doses were calculated and given as the salt. After a saline preinjection and a 60 minute habituation in the testing environment, a plexiglass cage monitored by infrared detectors, quipazine (2.5 mg/kg) was administered intraperitoneally, and the mouse replaced into the test cage. After 15 minutes, saline or amphetamine was given and activity monitored for the next 60 minutes. The parameter of activity measured was total distance moved per 5 minute periods. Activity was analyzed by a microprocessor which permitted only horizontal activity resulting from interruption of two successive infrared beams to be recorded. When quipazine was administered, there was a large, significant and sustained increase in amphetamine-induced locomotor activity compared to animals receiving a saline control injection. The apparent discrepancy between the results mentioned above using spontaneous locomotor activity in the rat and those of this study can be explained based on the habituated murine model utilized in this study. Earlier studies in our laboratory have shown that habituation in the test environment eliminates the exploratory (spontaneous) locomotor activity and permits the observation of direct effects of drugs on motoric behavior rather than including confounds such as handling and novel environment. The ability of quipazine to potentiate the amphetamine-induced locomotor activity shown in this study suggests that there may be direct or indirect serotonergic influences on dopaminergic systems underlying motor activity. These results also imply that the murine model utilizing habituation permits a clearer view of these drug interactions than those using non-habituated animals. (Supported by grant MH 33442 to W.H.R.)

166.11 EFFECTS OF DIETARY PROTEIN AND TYROSINE SUPPLEMENTATION ON STEREOTYPY AND BRAIN CATECHOLAMINES IN STREPTOZOTOCIN-DIABETIC RATS. L. L. Bellush and N. Rowland. Department of Psychology, University of Florida, Gainesville, Florida 32611.

Diabetic rats have been shown to have reductions of striatal dopamine synthesis (Trulson & Himmel, 1983) as well as increased dopamine receptor number (Lozovsky, Saller & Kopin, 1981). Attenuated responses to the dopaminergic agonists apomorphine and amphetamine have also been found (Marshall, 1978; Rowland, Joyce & Bellush, 1985). These alterations may, in part, be a consequence of reductions in brain concentrations of tyrosine, the amino acid precursor of dopamine known to occur in diabetes. In the present studies, we have examined whether dietary protein enrichment (exp. 1) or selective enrichment of synthetic diets (exp. 2) or powdered chow (exp. 3) with tyrosine will alleviate some of these abnormalities in diabetics. In all 3 experiments, behavioral stereotypy induced by amphetamine (3 mg/kg and 5 mg/kg) and apomorphine (1 mg/kg) were compared in diabetic and control rats on the various diets. In experiment 2, L-DOPA concentrations were measured in nucleus accumbens, hypothalamus and striatum following decarboxylase inhibition.

In experiment 1, high levels of dietary protein (46%) in combination with either carbohydrate or fat as the other major macronutrient, failed to restore the behavioral response of diabetic rats. In experiment 2, addition of 1% tyrosine (w/w) to synthetic diets containing casein (1% tyrosine) led to elevated L-DOPA concentrations in all three brain regions of diabetics, although only the elevation in nucleus accumbens was statistically significant. However, stereotypy was not modified by diet, nor were there correlations between L-DOPA concentrations and individual summed stereotypy scores. In experiment 3, enrichment of powdered chow (.68% tyrosine) with 1.36% or 4.08% additional tyrosine produced no modulations in the stereotypy of diabetics. The general conclusion from these findings seems to be that while dietary supplementation with tyrosine may enhance dopamine synthesis in some brain regions, this may not lead to enhanced release of transmitter which could actually correct performance deficits in diabetic rats.

Supported in part by training grant MH 15737 from NIMH.

166.12 THE EFFECTS OF INTRAVENTRICULAR INFUSIONS OF 5-HT AND TRYPTAMINE ON SELF-STIMULATION. J. Broadbent* and A.J. Greenshaw* (SPON: S. Richardson). Psychiat. Res. Div., Sask. Health, Univ, Sask., Saskatoon, Sask., Canada.

Previous reports have suggested that 5-HT may inhibit self-stimulation behaviour maintained by stimulation of the lateral hypothalamus. The effects of the structurally related 'trace amine' tryptamine has never been assessed in this paradigm. Tryptamine has recently been shown to be active in the rat CNS. Tryptamine binding sites which are distinctive from those of 5-HT have also been described. This study therefore assessed the effects of 5-HT and tryptamine infusions on lateral hypothalamic self-stimulation using rate-free measures of reinforcement to separate performance effects from specific reinforcement effects.

Male Wistar rats were implanted with 3rd ventricular cannulae and lateral hypothalamic twisted bipolar stimulating electrodes. Subjects were trained to lever press (60 HZ sine wave, 36-106 µA) on a fixed interval 3 sec. schedule. Duration of stimulation trains was determined by the length of time the lever was depressed. Rate of responses and duration of stimulation trains during the non-reinforced interval and during reinforcement were measured by an on-line micro-computer. After stable lever pressing was established subjects were tested with different current intensities and a working current chosen to allow changes in the duration of stimulation. Subjects were given daily 60 min. training sessions until less than 20% variation in baseline performance over 3 consecutive training sessions was observed. Clorgyline, a monoamine-oxidase inhibitor was given (5 mg/kg IP) 2 hours before the test session. Drug infusions of 10 µl of CSF, 5-HT (6.25 - 100 µg free base) or tryptamine (50 - 400 µg) were controlled by a Harvard infusion pump. Subjects were only used for one injection.

5-HT given intraventricularly induced a 50% inhibition of responding at doses of 12.5µg and above. An increase in the duration of non-reinforced lever presses was also observed, however, there was no change in the duration of stimulation trains. Tryptamine at doses of 200 µg and above also resulted in decreases in response rate . Again, non-reinforced duration was elevated but stimulation duration did not change.

As 5-HT did not affect the duration of stimulation trains, these changes were interpreted as non-specific performance effects. The results of tryptamine infusions were similarly interpreted. 5-HT and tryptamine did however result in similar effects on behaviour, although, a much higher dose of tryptamine was necessary.

It is concluded, therefore, that both 5-HT and tryptamine induce non-specific decreases in lateral hypothalamic self-stimulation on this schedule when infused into the third ventricle.

166.13 TRYPTAMINE INDUCES CONDITIONED TASTE AVERSION LEARNING IN THE RAT. P.J. Fletcher* (SPON: J.D. McQueen) . Psychiat. Res. Div., Sask. Health, Univ, Sask., Saskatoon, Sask., Canada.

It has been suggested that duration of action may be an important determinant of the formation of a drug induced CTA (Goudie and Dickins, 1978, Pharmac. Biochem. Behav. 9, 587). Several short acting compounds (eg., heroin, cocaine and phenylethylamine) are weak elicitors of a conditioned taste aversion (CTA) whereas longer acting related compounds (eg., morphine, amphetamine) reliably induce a CTA. Experiments in this report investigate the possible aversive stimulus properties of the short acting trace amine tryptamine (T). In addition since T may act at 5-HT receptor sites (see Jones, 1982, Prog. Neurobiol. 19, 117) the effects of T were compared to those induced by the 5-HT agonist quipazine.

Male Wistar rats were water deprived and presented with a 0.1% saccharin solution, followed by injection of T (20, 40, 60 or 80 mg/kg) or saline. A second group of rats were treated identically except that they received quipazine (2.5, 3.5, 5.0 or 7.1 mg/kg) or saline. On 4 retention trials rats were presented with saccharin and water, and the percentage preference for saccharin was calculated for each rat. On trial 1 all doses of T, except 20 mg/kg, induced an aversion to saccharin. By trial 4 this aversion was evident only in rats treated with 80 mg/kg T. These results differed from those obtained with quipazine. All doses of quipazine except 2.5 mg/kg produced a CTA which persisted over the 4 retention trials.

The effects of T were then examined in a single bottle, repeated injection paradigm. Water deprived rats were presented with saccharin and injected immediately afterwards with T (20, 40, 60 or 80 mg/kg) or saline. The saccharin-T pairings were administered 3 times at 4 day intervals. Although all doses of T except 20 mg/kg induced significant aversions to saccharin on 3 retention trials only rats treated with 80 mg/kg T exhibited a progressive decline in saccharin consumption across the retention trials.

The results show that T, like other agents altering indoleaminergic neurotransmission, produces a CTA. However, unlike these agents, T appears to be a relatively weak elicitor of a CTA. Since T is metabolised rapidly in rat brain (Wu and Boulton, 1973, Can. J. Biochem. 51, 1104) this may account for the weak action of T on CTA learning.

166.14 2-DG UPTAKE PATTERNS IN RAT CNS FOLLOWING ADMINISTRATION OF ABUSE POTENTIAL SUBSTANCES: A COMPUTER FACILITATED ANALYSIS. D.J. Woodward, Z.N. Stowe, W.K. Smith, D.L. McEachron, J.K. Chapin, and B.D. Waterhouse. Dept. of Cell Biology, UTHSCD, Dallas, TX 75235.

The ^{14}C-2-deoxyglucose (2-DG) method was used to examine glucose utilization patterns in animals receiving one of three abuse potential drugs; amphetamine, cocaine or ethanol. One week prior to experimental sessions, Long-Evans hooded rats were surgically implanted with stimulating electrodes under the toepad of each forepaw. For each experiment, animals received an i.p. injection of either: d-amphetamine sulphate, high dose = 10 mg/kg; low dose = 1 mg/kg; cocaine-HCl 10 mg/kg; ethanol 1.3g/kg or saline vehicle alone (control) followed 15 min. later by 2-DG (i.p., 14 mCi/100 gr). These drug dosages are known to produce behavioral effects in laboratory rats. The animals were then placed in a plexiglass enclosure for 60 min. prior to sacrifice. During this time both forepaws were continuously (0.25 Hz) stimulated at levels just subthreshold for limb withdrawal. Autoradiographs were prepared from brain sections (20 μm) according to standard procedures and then video digitized, linearized and color enhanced by a computer-based imaging system. Visual examination of autoradiographs indicated that all of the compounds caused increased 2-DG uptake in the cerebellar cortex, thalamus, caudate and cerebral cortex. Unlike amphetamine and cocaine, which caused increased 2-DG uptake in the inferior olive and surrounding brainstem, glucose utilization in these areas was reduced relative to controls after ethanol administration. High dose amphetamine produced a distinct pattern of alternating high and low glucose metabolic patches throughout the cerebellar hemispheres and vermis. Likewise, 2-DG uptake in several thalamic nuclei, particularly the ventral medial, intralaminar and lateral posterior, was clearly increased in autoradiographs from ethanol and cocaine brains and was highest in animals receiving high or low dose amphetamine. Glucose utilization was also increased above control levels in layer IV throughout the neocortex after amphetamine, cocaine and ethanol administration. For all drugs, glucose metabolism was not significantly different from controls in the hippocampus, inferior and superior colliculi and vestibular nuclei. In summary, these findings indicate that abuse potential compounds produce specific changes in glucose metabolism that are localized to discrete anatomical regions and probably reflect drug-induced enhancement or suppression of activity in local neuronal circuits. Overall, it appears that cocaine and amphetamine produced qualitatively similar changes in 2-DG uptake patterns which might be correlated with the similarity of their behavioral actions contrasted with those of ethanol. (Supported by AA3901, DA 02338, the Biological Humanics Foundation to DJW; AFOSR-85-0155 to BDW).

166.15 PHYSIOLOGY OF ABUSE POTENTIAL SUBSTANCES IN CENTRAL NEURONAL CIRCUITS: EFFECTS OF COCAINE ON SPONTANEOUS DISCHARGE AND GABA RESPONSIVENESS OF CEREBELLAR PURKINJE CELLS. B.D. Waterhouse, Z.N. Stowe*, J.-T. Cheng, A.J. Michael, D.J. Woodward, Dept. of Cell Biology, UTHSCD, Dallas, TX 75235.

Previous studies from this laboratory demonstrated that d-amphetamine could potentiate depressant responses of cerebellar Purkinje (P) neurons to microiontophoretic application of GABA as well as suppress P cell spontaneous firing rate. In the present experiments, we have examined the effects of cocaine, another widely abused CNS stimulant, on GABA-mediated inhibition and spontaneous discharge of cerebellar P neurons. Extracellular activity of single P cells was recorded from halothane-anesthetized rats during iontophoretic pulses (10s duration, 40s intervals) of GABA (16-50 nA). Peri-event histograms collected before, during and after microiontophoretic or i.p. administration of cocaine-HCl were used to quantitatively assess cocaine-induced changes in P cell spontaneous firing rate and GABA responsiveness. Parenteral doses of cocaine used here have been shown to produce alerting effects (10 mg/Kg) or increased locomotion (35 mg/kg) in laboratory rats (Scheel-Kruger et al., 1977). Following injection of high dose cocaine, P cell spontaneous discharge was routinely suppressed (n=5). In 4 of these 5 cases, inhibitory responses to GABA were reduced ($\bar{x}$ = 66%) from control levels. The onset of these effects was within 3 min. of cocaine injection and were maximal by 10 min. post-injection. Recovery toward the control level of GABA response was observed by 35-60 min. after cocaine application. Following injection of of low dose cocaine, P cell responses to GABA were consistently augmented an average of 63% (n=4) above control levels, while spontaneous firing rates were decreased (n=2), unchanged (n=1) or increased (n=1) from pre-cocaine levels. These drug-induced effects were observed within 3 min of cocaine injection, reached maximal levels by 25 min. and began to subside 30-40 min. post-injection. Enhancement of GABA-induced inhibitory responses and suppression of P neuron spontaneous activity were also observed with iontophoretic administration of cocaine (7-15nA). In summary, these results indicate that parenterally or iontophoretically applied cocaine has depressant effects on P cell spontaneous discharge. At low doses, both systemic and local administration of cocaine can also produce an enhancement of GABA-mediated inhibition similar to that observed with iontophoretic d-amphetamine. Such enhancement of neuronal responsiveness to GABA within local neuronal networks could facilitate the feature extraction function of brain circuits and might prove to be a common mode of CNS stimulant drug action. 166.16 EFFECTS OF ELEVATED CALCIUM ON LEARNED HELPLESSNESS AND BRAIN SEROTONIN METABOLISM IN RATS. K. Arasteh, D.W. Ray*[1] and M.E. Trulson. Department of Anatomy, College of Medicine, Texas A&M University, College Station, TX 77843, and [1]Department of Psychology, Marshall University, Huntington, WV 25701.

Mineral metabolism in depressive illness has been the subject of investigation for many decades. Calcium metabolism in mood disorders has been studied since the 1940's. Altered calcium homeostasis associated with depressive illness has been reported. However, since these studies are purely correlational in nature, they have not determined whether the altered calcium levels is a cause or a consequence of the disease state. Moreover, most of these studies have measured serum calcium levels, which do not necessarily reflect brain calcium concentrations. In addition to patients with the primary diagnosis of depression, patients with hyperparathyroidism also suffer from mood disturbances. The etiology of at least some of these disorders has been hypothesized to be related to abnormal calcium metabolism. Increased levels of calcium in the cerebral spinal fluid have been reported during the manifestation of depression in these patients, while the reverse occurs during recovery from such symptoms. Recent data from our laboratory revealed that small elevations of calcium ions (10-15%) significantly suppressed the activity of serotonin-containing dorsal raphe neurons by approximately 35% in vitro. Therefore, the abnormal levels of serotonin frequently found in depression may constitute a secondary effect rather than a primary one. In the present study, the effects of elevated calcium on learned helplessness in rats was tested by maintaining animals on either distilled water or water containing 2.5% calcium. Animals that were maintained on drinking water containing high calcium showed elevated levels of brain (+18%) and serum (+22%) calcium. Rats that were maintained on high calcium drinking water showed longer escape latencies (33.0 sec) than their non-calcium counterparts (18.3 sec) after they were pretreated with inescapable electric shocks ($p<0.025$). Lower levels of 5-hydroxyindolacetic acid associated with the state of "depression" were found in the forebrain (-26.3%) and brainstem (29.7%) of these animals. Therefore, elevated levels of calcium enhance learned helplessness and decrease brain serotonin turnover. These data suggest that the primary deficit in certain depressive states may be in calcium homeostasis rather than in serotonin metabolism.

166.17 STUDIES ON LOCOMOTOR ACTIVITY AND ROTATION AFTER LESIONS WITHIN OR LATERAL TO THE MEDIAN RAPHE NUCLEUS. D. Wirtshafter, W. Montana* and K.E. Asin. Dept. Psych., Univ. IL at Chicago, Chicago, IL 60680.

It has been well established that electrolytic lesions of the median raphe nucleus (MR) produce large increases in locomotor activity in most novel environments. The identity of the neural substrates underlying this effect, however, is not clear. Studies employing intra-MR injections of the serotonin (5HT) neurotoxin 5,7-DHT or injections of the excitotoxin ibotenic acid have suggested that MR-lesion induced hyperactivity may reflect damage to both nonserotonergic cells within the MR and to fibers of passage (Asin & Fibiger, Brain Res, 1983).

In the current study we attempted to more precisely characterize the substrate of MR-lesion induced hyperactivity by examing locomotion after placement of small lesions either within, or immediately lateral to, the MR. Lesions were produced by lowering a piece of 22 gauge stainless steel tubing. Midline "punches" passed directly through the MR and produced small, but significant, decreases in hippocampal 5HT. Punches 0.6mm lateral to the midline passed through the so-called predorsal bundles (tectospinal tracts) and failed to alter striatal or hippocampal 5HT levels. Both types of lesions produced equivalent increases in open field and tilt cage activity and equivalent decreases in running wheel activity in a 24 hour test compared to controls. These results demonstrate that it is possible to completely dissociate changes in locomotor activity and 5HT levels following lesions in the paramedian tegmentum. However, it is unclear whether the midline and lateral punches produce hyperactivity by damaging distinct neural systems, or whether they both damage a single system which passes diffusely through the MR and region lateral to it.

Since lesions of the superior colliculus have been reported to result in hyperactivity, we examined the possibility that the increases in activity produced by the lateral punches might have resulted from damage to the crossed component of the tectospinal tract. Therefore, we next examined locomotor activity following sagittal knife cuts through the dorsal tegmental decussation, through which descending tectospinal fibers pass. These cuts neither produced hyperactivity by themselves nor altered the effects of the lateral punches. It is unlikely, therefore, that damage to descending collicular fibers plays a significant role in the hyperactivity produced by electrolytic MR lesions.

It has also been reported that asymmetric MR lesions produce contralateral rotation. To further examine this effect, we placed unilateral punches .3,.6,.9 & 1.2mm lateral to the midline of the MR. On Day 2 post-op, rats with punches at .3 or .6 showed similar rates of rotation; on Day 10 post-op, only the most medial punch still produced significant rotation. These results suggest that the substrates of the rotation lie medial to the tectospinal tract.

166.18 MUSCARINIC CHOLINERGIC BINDING SITES REVERT DURING EXTINCTION OF CONDITIONED EMOTIONAL RESPONSE (CER) Angela K. Dolce* and John D. Lane (SPON: I.M. Korr), Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107 USA

Rats were classically conditioned to associate a conditioned stimulus (CS) with footshock, so that on test day, CS presentation alone produced suppression of food-reinforced responding and collateral 'emotional' behaviors reminiscent of anxiety (conditioned emotional response, CER). Previous studies (Lane et al., Europ. J. Pharmacol. 83, 183, 1982) demonstrated that this paradigm resulted in total behavioral suppression and a 40% reduction in cortical muscarinic cholinergic (quinuclidinyl benzilate—QNB) binding sites (change in Bmax and not Kd). These experiments were extended to assess the role of repeated CS presentations (extinction) on binding. After CER conditioning, rats were subjected to 15 additional once daily trials of 60 min food-reinforced responding, during which the CS was presented continuously during the final 15 min, but footshock was never delivered. At 2 day intervals groups of rats were sacrificed and cortical QNB binding assessed. Control groups for pre-CS and for no-CS (up to 11 trials) were run to ensure that baseline binding parameters did not vary over the entire course of the experiment. Behavioral suppression extinguished within 13 trials. Cortical QNB binding (changes in Bmax and not Kd) followed a parellel time course and returned to within normal limits. Benzodiazepine binding was also assessed. At trial 1, binding was decreased 25% (change in Bmax and not Kd) but was still decreased 11% after 15 trials of extinction. The operant chamber may represent a pseudo-CS for the animals. These transient phenomena are consistent with other behavioral paradigms, and suggest that the cholinergic system mediates or responds to conditioning-emotion. The effects of cholinergic agonists and antagonists, and AChE inhibitors on the behavior and binding parameters are now being assessed. (supported in part by MH-31835 to JDL).

166.19 BEHAVIORAL SEQUELAE FOLLOWING MPTP ADMINISTRATION IN THE MOUSE J.H. Kordower, S.Y. Felten, D.L. Felten, and D.M. Gash, Dept. of Anatomy, Univ. of Rochester Sch. Med. Den., Rochester, N.Y. 14642.

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) has received considerable attention with regards to inducing Parkinson's disease in humans and a Parkinsonian-like state in animals. Rats appear to be resistant to the neurotoxic effects of this compound. Systemic injections into mice cause long-lasting depletion of dopamine and its metabolite in the striatum (Neuropharm. 23: 711, 1984). While there have been observations of motor abnormalities reported, there has been little systematic assessment of the behavior in these animals. The present study examines the effects of MPTP upon motor and ingestive processes, two behaviors dependent upon nigrostriatal activity.

Mice were matched into groups based upon stable basal activity levels as measured by automated photocell activity meters. Group 1 (n=8) received a single subcutaneous injection of MPTP (30 mg/kg, methyl ester) daily for 5 days. Group 2 (n=8) received similar injections of vehicle (20% ethanol). Activity measurements were made for 30 min 1, 3, 5, and 7 days after drug treatement. Vehicle injections failed to alter activity levels. While the mice appeared hypoactive immediately following each injection, MPTP produced a significant hyperactivity 3, 5, and 7 days after drug treatment as compared to both baseline levels and vehicle treated mice. Activity levels in response to d-amphetamine and apomorphine were then assessed. Vehicle treated mice were hyperactive to amphetamine (1.5 mg/kg, sc). In contrast, MPTP mice were unaffected by d-amphetamine administration. Apomorphine (.1 mg/kg) produced a similar hypoactivity in both groups.

An additional two groups of mice were matched into groups based upon stable basal food intake and were administered MPTP (n=9) or vehicle (n=7) as before. Food intake, water intake, and body weights were then measured for 2 weeks. MPTP failed to produce any changes in any of these parameters. Following the 2 week period, mice were administered 2-deoxy-D-glucose (0, 300, 600, 900 mg/kg in ascending and descending order) to determine whether MPTP would alter the resulting hyperphagia. MPTP failed to affect the hyperphagia that resulted from the 600 and 900 mg dose.

High performance liquid chromatography is presently being carried out to determine the catecholamine and indolamine levels in the striatum, nucleus accumbens, medial basal hypothalamus, and substantia nigra of these mice.

In the present experiments MPTP produced a significant basal hyperactivity for at least one week following drug treatment. This may be due to increased activity of remaining dopaminergic neurons or due to MPTP's effects upon non-dopaminergic systems. MPTP eliminated d-amphetamine hyperactivity. This latter result suggests the inability of the remaining nigrostriatal fibers to increase their release of dopamine in response to d-amphetamine stimulation. In contrast to other animal models of Parkinson's disease, ingestive processes are unalterd by MPTP. (Supported by AGT32 107 (JHK), NIH NS15109 (DMG)).

167.1 THE EFFECTS OF AP-cmNTS LESIONS OR SUBDIAPHRAGMATIC VAGOTOMY ON SALT APPETITE

S. Uysal*, J. Schulkin* & T.M. Hyde* (SPON. E. Stellar)
New York University & University of Pennsylvania

There is evidence that lesions of the area postrema (a circumventricular organ) which in most cases also includes the caudal medial area of the nucleus of the solitary tract (AP-cmNTS) provoke changes in sodium homeostasis. Many abdominal vagal afferents terminate in this region; vagotomy at various levels is also known to provoke changes in sodium homeostasis. In the following study, the behavioral responsiveness to a salt appetite arousing treatment was studied in AP-cmNTS lesioned, or subdiaphragmatically vagotomized rats.

Adult male Sprague-Dawley rats were used. Five rats received AP-cmNTS aspiration lesions, 5 were subdiaphragmatically vagotomized and 10 were sham lesioned controls. Testing was performed one month after surgery. At testing the AP-cmNTS lesion group weighed 375 grams, the vagotomized group 330 and the control group 412 grams. Rats were adapted to a test chamber for 2 hrs. a day and given access to 3% NaCl and distilled water. Intakes in all 3 groups were negligible at this time. They were rendered salt hungry by being placed on a sodium deficient diet for 2 days; after the first 24 hrs. they were injected IP with 5 mg of furosemide to promote sodium loss. Twenty-four hours later the rats were placed in a test cage and saline and water intakes were noted for 30 minutes.

The results showed that all three groups increased their ingestion of the saline when rendered salt hungry. The AP-cmNTS group ingested a mean of 11.3 ± 4.8, vagotomized group ingested 5.8 ± 2.6 and the control group ingested 7.1 ± 2.5. On another trial (one week later) during a ten minute pre-ingestion access to the saline, the AP-cmNTS lesion group ingested 7.6 ± 3.6, the vagotomized group 4.5 ± 1.7 and the intact-control group 7.2 ± 2.5. When subsequently given access to the saline for an additional 30 minutes they ingested 6.5 ± 2.1 (AP-cmNTS) 2.6 ± 0.7 (vagotomized) and 2.3 ± 1.3 (intact-control)respectively.

The results revealed that AP-cmNTS and vagotomized rats increased their saline consumption in response to the salt appetite arousing treatment. However, the AP-cmNTS group tended to ingest more salt; the vagotomized group tended to ingest less salt. These results are consistent with other reports of elevated consumption of fluids in AP-cmNTS lesioned rats and decreased ingestion of subdiaphragmatic vagotomized rats.

167.2 NEONATAL SPONTANEOUSLY HYPERTENSIVE RATS SHOW AN EXAGGERATED NaCl PREFERENCE. K. E. Moe. Department of Psychology, Washington State University, Pullman, WA 99164-4830.

Spontaneously hypertensive rats (SHRs) of the Okamoto-Aoki strain show an exaggerated NaCl preference relative to normotensive Wistar-Kyoto (WKY) rats. In contrast, other animal models of arterial hypertension are associated with a reduced NaCl preference. It is not clear whether this higher NaCl preference precedes, accompanies or follows the development of SHR hypertension. Therefore, NaCl preference was assessed in SHR and WKY pups at 12-13 days of postnatal age (prehypertensive stage; Lais et al, Blood Vessels, 14:277,1977).

On the day of testing, pups were removed from their dams, implanted with an anterior mouth catheter, and then adapted to a warm, moist incubator. They were offered 2, 5 or 7% NaCl (0.34, 0.86, 1.20 M) or distilled water by pulsatile infusion through the mouth catheter for 30 minutes. Change of weight (to the nearest 0.01 g) over the course of the infusion provided the measure of intake.

As shown in the table below, the increased NaCl preference characteristic of adult SHRs is also demonstrated by prehypertensive SHR pups, relative to WKY pups. No differences were observed for water intake by pups of the two strains.

It has been hypothesized that chronically elevated activity or sensitivity of the brain renin-angiotensin system (BRAS) contributes to the development of hypertension in the SHR model. Such a perturbation might also explain the enhanced NaCl preference of SHRs, as (1) the brain renin-angiotensin system has been shown to be important for the arousal of NaCl appetite in normotensive rats (Moe et al, Am. J. Physiol., 247: R356, 1984) and (2) central administration of an angiotensin converting enzyme inhibitor reduces the exaggerated NaCl preference of adult SHRs (DiNicolantonio et al, Nature, 298: 846, 1982). The results reported here may be a behavioral indicator of BRAS perturbations in advance of the development of SHR hypertension.

	SHR pups	WKY pups
Water*	0.74 ± 0.09	0.74 ± 0.13
NaCl		
2% (0.34 M)	2.31 ± 0.26	1.09 ± 0.10
5% (0.86 M)	1.19 ± 0.08	0.58 ± 0.11
7% (1.20 M)	1.03 ± 0.09	0.17 ± 0.08

*Fluid intake is reported as mean ± SEM grams of fluid ingested per 100 grams body weight. Equal numbers of male and female pups were used; each value is based on at least 10 pups from at least 5 different litters.

167.3 CAPTOPRIL-INDUCED SODIUM APPETITE IN RATS: BRAIN SITES OF ACTION. J.Salisbury, N.E.Rowland, Z.King-Allen*and M.J.Fregly*(SPON: G.M.Hope). Departments of Psychology and Physiology, Univ. of Florida, Gainesville, FL 32611.

Captopril (CAP) is an orally active inhibitor of the enzyme which converts angiotensin I (AI) to angiotensin II (AII). Doses of CAP which inhibit the enzyme in the periphery also induce appetite for NaCl solution in rats. This may be due to increased AI in the periphery which enters the brain where it may still be converted to AII. Elfont et al (J.Physiol. 354: 11, 1984) found that this NaCl appetite could be inhibited not only by cerebroventricular (icv) infusion of CAP but also by implanting an empty cannula into the 3rd ventricle. In the first part of the present study we have confirmed that CAP, administered in food (1 mg/g food x 6 days), induces a robust appetite for 0.3M NaCl solution (given in a 2 bottle ad libitum choice with water) in intact rats. A similar magnitude of NaCl appetite was found in rats implanted 6 days beforehand with an indwelling 23 gauge stainless steel cannula into the lateral cerebral ventricle. A third group of rats similarly received an indwelling cannula, aimed obliquely to end in the anterior 3rd ventricle but missing midline structures. These rats increased NaCl intake relative to a no CAP control group, although their 3x increase in NaCl intake above their own no CAP baseline was not statistically significant. We thus find no marked impairment of CAP-induced NaCl appetite and believe that damage to the blood brain barrier cannot account for the previous failure (Elfont et al) to induce NaCl appetite soon after brain cannulation. Instead, specific tissue damage may occur with the implants, and recovery from such damage may underlie any return of NaCl appetite.

In a second study, rats received electrolytic lesions aimed at the subfornical organ (SFO, a central receptor site for AII), and rats with effective lesions were identified by reduced or absent drinking response (mean water intake 2.0 ml/h) to peripheral AII (200ug/kg, sc) relative to those with ineffective lesions (7.8 ml/h). When CAP was added to their food, as in the first study, the rats with effective lesions drank 11.4 ml 0.45M NaCl /24h after 5 days CAP, and the ineffective lesion group drank 15.1 ml (not significantly different). It thus appears that SFO lesions may impair, but not abolish CAP-induced NaCl appetite. These animals are still being tested in other NaCl appetite paradigms, the results of which will be reported. Supported by NIH AM31837-03.

167.4 MINERALOCORTICOID-INDUCED SALT APPETITE: CENTRAL SITE OF ACTION? J. Buggy, J. Valentine*, N.E. Rowland, J. Carlton, M.J. Fregly, and W.G. Luttge. Departments of Physiology, Psychology, and Neuroscience, University of South Carolina, Columbia, SC 29208 and University of Florida, Gainesville, FL 32611.

Both angiotensin and mineralocorticoids stimulate salt appetite and recently a synergy of these hormones in brain has been hypothesized. However, our results indicate that salt appetite induced in rats by systemic administration of deoxycorticosterone (DOC) does not depend on central angiotensin mechanisms. Intracerebroventricular (ICVT) injections of the angiotensin receptor antagonist saralasin block central responses to angiotensin and significantly inhibit salt appetite induced by sodium depletion but had no effect on intake of 1.8% NaCl aroused by subcutaneous DOC treatment (2.5 mg/day for 5 days).

Since many hormones act specifically in brain and since aldosterone binding sites have been described in brain, we next assessed whether mineralocorticoids administered directly to the brain rather than systemically would stimulate salt appetite in rats. One series of studies used microcrystalline implants of DOC tamped into 27 gauge inner cannula and bilaterally implanted into either perifornical hypothalamus or dorsal hippocampus, regions reported to contain aldosterone receptors; there was no increase compared to baseline in ad lib intake of 0.9% or 1.8% NaCl for up to 7 days of treatment. Another series of experiments used aldosterone tamped into 24 gauge inner cannula and bilaterally implanted into either posterior hypothalamus or ventral hippocampus; again, there were no immediate or delayed effects of the implants on ad lib NaCl intake. Another approach used DOC suspended in propylene glycol and physiological saline for ICVT injections at the level of the anteroventral third ventricle, an effective injection site for stimulation of salt appetite by angiotensin; compared to baseline intake, 2 or 4 ug/day of DOC for up to 5 consecutive days failed to stimulate intake of 1.8% NaCl. We cannot be sure that the site(s) or doses of mineralocorticoids delivered are appropriate but given the efficacy of intracerebral steroids to modify other brain functions and behavior, these may be taken as preliminary findings against these loci as central sites for action of mineralocorticoids in salt appetite.

In summary, our data indicate that salt appetite induced in rats by mineralocorticoids does not depend on central angiotensin mechanisms. Furthermore, we have failed to identify a central site of action for mineralocorticoids that stimulates salt appetite. Although brain regions not tested here may mediate salt appetite by mineralocorticoids, the possibility that salt appetite results from a peripheral effect of mineralocorticoids, perhaps on salivary sodium concentration, should be considered. Supported by NIH-AM 31837-03.

167.5 DIURESIS AND SUPPRESSION OF SALT APPETITE BY LATERAL VENTRICULAR INFUSIONS OF ATRIOPEPTIN II. R.L.Thunhorst, D.A.Fitts* and J.B. Simpson. Dept. of Psychology NI-25, Univ. of Washington, Seattle, WA 98195

Experiments were performed to determine the central nervous effects on hydromineral balance for atriopeptin II (APII), a peptide known to possess natriuretic and kaliuretic properties when injected intravenously. During tests, solutions were infused via a lateral ventricular cannula and water and 0.3M NaCl solutions were available from calibrated burettes. Urine was collected into tubes below the cages for measurement of volume as well as concentration of Na^+, K^+ and mOsm. Normally hydrated rats (n=9) fed Purina lab chow received isotonic saline vehicle (ISO), 30 pmol and 60 pmol/2 ul/hr APII on separate days. Neither dose of APII affected spontaneous water intake. However, APII infusions increased U_V(ISO=2.8±1.2, 30 pmol=4.0±1.5, 60=pmol 4.5±1.8 ml) and decreased U_{Osm}(ISO= 760±23, 30 pmol=559±150, 60 pmol=521±127 mOsm/kg) and U_{Na}(ISO=100±49, 30 pmol=66±33, 60 pmol=64±32 mmol/L). Rats (n=14) made sodium deplete following combined treatment with furosemide diuresis (25mg/kg) and low sodium diet overnight received 3hr infusions with either ISO, 6pmol or 60 pmol/hr APII. Control rats drank saline with a median latency of 7.7 min and consumed 7.7±3.7 ml in the first hr. The 60 pmol dose increased the latency to 44.3 min and suppressed intake in all 3hrs with less than 5.0 ml total drunk. Water intake was not affected. The 60 pmol group increased U_V in hr. 1(3.7±0.8 vs 1.8±1.1 ml for ISO) and had the lowest total osm over 3 hrs (442±175 vs 746±262 mosm/kg for Iso). Rats infused i.v. (n=19) with ISO, 60 or 600 pmol APII for 1 hr showed no differences on any variable measured, including U_{Osm}, U_{Na}, U_K, as well as total Na^+, K^+ and solute excretions. Fluids were not available for consumption here. Normally hydrated rats (n=15) were given a 7 hr infusion of either ISO, 120 pmol/ul/hr angiotensin II (AII) or AII in combination with 120 pmol/hr APII. The peptide infused groups drank both fluids with similar latencies but there was a suppression of total water and saline intakes in the combined infusion group vs the AII-alone infused group. We conclude that APII, when infused centrally, stimulates urine flow without increasing solute excretion and reduces salt appetite in sodium depleted and AII-stimulated rats.

167.6 DRINKING RESPONSES TO INTRACEREBROVENTRICULARLY (ICV) APPLIED DIPSOGENS AFTER AN AREA POSTREMA/CAUDAL MEDIAL NUCLEUS OF THE SOLITARY TRACT LESION M. Weiss, T. Hyde and R. Miselis. Dept of Biology, Animal Biology, School of Veterinary Medicine, Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, PA 19104.

The Area Postrema/ caudal medial Nucleus of the Solitary Tract lesion (AP-cmNTSX) causes a number of distrubances in rats' food and water intake: they become transiently hypophagic; chronically polydipsic, polyuric, and natriuretic; and develop an enhanced sodium intake (Hyde and Miselis,'83 & '84). It has been reported (Edwards and Ritter,'82) that rats over-respond to peripheral angiotensin II injection after AP/cmNTSX. We further characterized the AP/cmNTSX phenomenon by analyzing the effect of the lesion on the response to three different dipsogens injected directly into the third ventricle. We examined the drinking response induced by a pulse 1 ul ICV injection of either a low or high dose of angiotensin II (Ang II; 6 and 60 ng); the acetylcholine mimetic, carbachol (CARB, 40 ng); 3.4 % NaCl; or a control injection (0.9% sterile NaCl). The order of presentation was randomized and the animals received two injections of the low dose of Ang II and the control substance and one injection of the others. After the last injection the rats were given aspiration AP/cmNTS lesions and allowed to recover for two weeks. All animals recovered from the acute effects of the lesion, as determined from a daily body weight curve. Following re-adaptation to the cages, their drinking responses to the same treatments as stated above were measured. After AP/cmNTS lesion the animals drank more in response to CARB: 22.9 ± 4.7 ml/kg pre, 37.1 ± 6.7 ml/kg post. The intakes induced by other dipsogens were not affected by the lesion: Ang II 6 ng- 33.2 ± 4.9 ml/kg pre, 32.3 ± 3.7 ml/kg post; Ang II 60 ng- 39.5 ± 3.7 ml/kg pre, 47.1 ± 9.0 ml/kg post; 3.4% NaCl-4.3 ± 2.0 ml/kg pre, 2.6 ± 2.4 ml/kg post (intakes expressed as average water intake/ kg body weight ± S.E.; the control intakes have been subtracted out). Enhancement of drinking to peripheral but not centrally administered Ang II after this lesion suggests that there is a disinhibition of drinking by a peripheral mechanism, possibly of baroreceptors afferents (Robinson and Evered,'83). Supported by GM 277739 and MH 15092.

167.7 NEW AFFERENT AND EFFERENT NEURAL CONNECTIONS OF THE SUBFORNICAL ORGAN. R. W. Lind and L.W. Swanson. The Salk Institute, La Jolla, CA 92037.

Following the emergence of the subfornical organ (SFO) as the principal central site of action of circulating angiotensin II, attention was soon focused on the organization and functions of its neural connections. These early studies described a heavy efferent projection to the hypothalamus, with few reciprocating afferents, and these pathways are thought to be important for the central actions of circulating angiotensin II. Recent work using new and highly sensitive anterograde and retrograde tracing techniques suggests that (1) the subfornical organ sends efferent fibers to a number of targets that lie outside of the hypothalamus and which may be important for the arousal of behavioral responses to angiotensin II; and (2) the SFO receives direct and heavy neural inputs from circumscribed cell groups in the hypothalamus, limbic region, and pons.

Injections of the anterograde marker, PHA-L, into the SFO verified its known efferent projections to the hypothalamus, and injections of the retrogradely transported fluorescent dyes, true blue and fast blue, into these terminal fields, established the topographical organization of the cells of origin of these pathways. Employing a similar combination of anterograde and retrograde tracing techniques, the SFO was found to send additional fibers to the prefrontal cortex (infralimbic area), the rostral and ventral parts of the bed nucleus of the stria terminalis, the substantia innominata, the anteroventral periventricular nucleus of the preoptic region (Terasawa's nucleus), the arcuate nucleus, the lateral hypothalamic area, the dorsomedial hypothalamic nucleus, the zona incerta, the midline thalamus, and the dorsal and median nuclei of the midbrain raphe system.

Injections of retrogradely transported markers into the SFO resulted in the labeling of cell bodies in a number of locations that appear to receive SFO efferents. These include the median preoptic nucleus, the OVLT, the bed nucleus of the stria terminalis, Terasawa's nucleus, the lateral hypothalamic area, the dorsomedial hypothalamic nucleus, the zona incerta, the nucleus reuniens of the thalamus, and the dorsal and median raphe nuclei. Additionally, a few retrogradely labeled cells were found in the laterodorsal tegmental nucleus and in the lateral parabrachial nucleus.

These findings suggest that the current view of the SFO may underestimate its true importance. Thus, the SFO appears not to be simply a humoral sensory device in essentially one-way communication with the hypothalamus. Rather, there appear to be numerous routes for the input of neural information, as well as a rich array of efferent pathways allowing for the direct stimulation of arousal, somatomotor, and cognitive aspects of thirst.

167.8 SUPPRESSION OF FOOD INTAKE BY OPIOID ANTAGONISTS IN THE SHR/N-CORPULENT RAT. J.R. Andrade*, D. Padmore*, C.T. Hansen*, and M.J. Lewis (SPON: L. Hicks). Department of Psychology, Howard University, Washington D.C. 20059, and Veterinary Resources Branch, DRS, NIH, Bethesda, Maryland, 20205.

Endogenous opioids have been strongly implicated in the regulation of consumatory behavior in several animal models of obesity. In the Zucker rat and ob/ob mouse, very low doses of the opioid antagonists naloxone and naltrexone significantly suppress over-eating in obese animals, but not lean littermates. The purpose of this research was to investigate the effects on the opioid antagonists naloxone and naltrexone on food consumption in a newly developed cogenic strain of genetically obese rat, SHR/N-corpulent (cp).

The cogenic strain SHR/N-cp was developed by mating a Koletsky rat which was heterozygous for the cp gene to a spontaneously hypertensive rat (SHR). The homozygous (cp/cp) animal displays hyperphagia and manifests a hyperglycemic/hyperinsulinemic syndrome resembling insulin-dependent diabetes. SHR/N-cp and lean littermates were maintained on a six hour feeding schedule of ground Purina rat chow. Water was available ad lib. Following baseline measures of food intake, animals received acute injections (ip) of naloxone HCL (2.0 mg/kg saline). Analysis of the data revealed that the imposed six hour restricted feeding schedule resulted in no significant difference in baseline consumption between lean and obese rats. However, despite equal baseline consumption, both naloxone and naltrexone significantly suppressed feeding in obese rats but not lean littermates. These results suggest that the genetic obesity observed in the SHR/N-cp rat may be mediated by a similar endogenous opioid system which is believed to mediate excessive feeding and obesity in the Zucker obese rat and ob/ob mouse.

167.9 THE ANORECTIC EFFECT OF NALTREXONE: A LACK OF PHYSIOLOGICAL OR CONTINGENT TOLERANCE. M. Ferguson-Segall* and D.L. Margules. Dept. of Psychology, Temple Univ., Philadelphia, PA, 19144.

Food restricted rats develop tolerance to the anorectic effects of amphetamine (Carlton,P.L.,Phys. & Behav.,7:221, 1971), cocaine (Woolverton,W.R.,NIDA Res. Mono.,18:127, 1978), phenobarbital (Tang,M.,Ibid.,142, 1978), and quipazine (Rowland,N., Psychopharmacology,81:155, 1983) if they received the drug before, but not after, an opportunity to either drink a palatable solution (i.e. sweetened condensed milk) or eat lab chow. Carlton (1971) called this contingent tolerance to signify the importance of the timing between the drug injection and food presentation. Does contingent tolerance occur to the anorectic effects of opiate antagonists? The anorectic effects of naltrexone were tested for tolerance in ad lib female rats (Zucker). Thirty individually housed rats, 6 months old, were equally divided into three groups: naltrexone before (NB), naltrexone after (NA), and saline (S). All animals were injected twice, thirty minutes before and after a 10 minute presentation of apple juice (diluted with tap water 1:1). The NB group received .33 mg/kg of naltrexone before and saline after the apple juice, the NA group received saline before the apple juice and .33 mg/kg naltrexone after, and the S group was given two saline injections. After 2 sets of 6 daily injections, the NB group did not exhibit tolerance to the anorectic effects of naltrexone; during the last 6 days the NA and S groups were drinking an average of 5.8 ml while the NB group drank 2.7 ml. The drinking on the last day for each group was (mean+S.E.); NB - 2.7+.4, NA - 5.4+.7, and S - 5.9+.9. By the student t-test, the NB group was significantly different from both NA ($t=10.6$, $p<.001$) and S ($t=10.3$, $p<.001$). NA and S were not significantly different ($t=1.39$, $p>.05$). Because there is neither physiological nor contingent tolerance to naltrexone's anorectic effects, the mechanism by which naltrexone causes anorexia must be very different from the mechanisms by which amphetamine, cocaine, phenobarbital and quipazine cause anorexia.

167.10 TEMPERATURE-DEPENDENT DRINKING IN RATS WITH SEPTAL LESIONS. T. L. Steele and J. C. Mitchell. Dept. of Psychology, Kansas State Univ., Manhattan, KS 66506.

Research has shown that animals with septal lesions overrespond to sweet and bitter tastes. Yet no studies have established the effect of water temperature on water intake in such animals. The present experiments were performed to compare the drinking behavior of normal rats (n=12) to rats with septal lesions (n=6) when presented with water of different temperatures. Subjects were first given 35 days of ad libitum access to ambient temperature water in order to establish drinking baselines. They were next presented with cold (2°c), ambient (22°c), or warm (37°c), water in a 1-bottle, 6 hr access test (15 days), followed by a 2-bottle, 6 hr access test (9 days), a 1-bottle 30 min access test (25 days), and a 2-bottle, 30 min access test (9 days). Animals with septal lesions drank more water than normal animals when given ad libitum water access, but not when placed on the restricted water schedules. Both normal and septal animals drank more warm water than cold water in all four experiments, suggesting that warm water was less satiating than cold water. Septal lesions did not appear to have an effect on temperature-dependent drinking.

During the two 30 min studies, tongue contacts with the drinking tubes were recorded and each 1 min segment was analyzed according to whether or not the animals made contact for at least 10 sec. The data showed that normal animals generally confined warm water drinking to the beginning of the sessions. Drinking tube contacts dropped rapidly after the first 5-6 min of access, and little warm water was ingested thereafter. The majority of cold water was also consumed during the initial portion of the session, although cold water sampling decreased more gradually. Animals sampled from the cold water bottles more frequently than from the warm water bottles through the remainder of the session. The persistent sampling of cold water suggests that cold water was not aversive and may have been preferred to warm water during the last 2/3 of the sessions. Animals with septal lesions displayed similar drinking patterns, but differences between cold and warm water sampling were small. It appears that normal animals suppress warm water sampling during the final portion of the sessions while animals with septal lesions sample water of all temperatures at the same rate.

167.11 CONCURRENT REDUCTIONS IN APPETITIVE AND CARDIOVASCULAR VARIABLES T.A. McCaffrey*, J.A. Czaja, and E.A. Baronowsky*. Dept. Pathology, Cornell Univ. Medical School, New York, NY 10021 and Dept. Psychology, Miami University, Oxford, OH 45056

Previous experience in our laboratory has demonstrated that estradiol treated guinea pigs exhibit reduced drinking that is independent of a simultaneous decrease in food intake (Czaja, Butera, & McCaffrey, Behav. Neurosci. 97: 210-220, 1983). The reduced feeding and drinking are accompanied by a reversible decrease in carotid artery blood pressure and pressor response to exogenous norepinephrine (NE) measured in conscious, unrestrained animals. In addition, the 24 hour changes in blood pressure appear to be significantly correlated with the concurrent changes in water intake (McCaffrey & Czaja, Soc. Neurosci. Abst. 9: 544, 1983). We therefore designed 3 experiments to evaluate 1) additional parameters relevant to fluid regulation in estradiol treated females, 2) the cardiovascular effects of imposed changes in food and water intake similar to those observed during estradiol treatment, and 3) the potential role of changes in vascular smooth muscle as a factor in the reduced cardiovascular variables. In the first experiment 24, ovariectomized females guinea pigs were treated with 0, 3, or 30 µg of estradiol benzoate (EB) for 4 days. The estradiol treatments produced significant reductions (ANOV) in food intake, water intake, urine output, body weight, resting blood pressure, and the blood pressure response to NE. To simulate the effects of estradiol treatment, 7 subjects in experiment 2 were restricted to 70% of their normal food and water intake. By itself, this procedure produced no significant changes in the cardiovascular variables. In experiment 3, aortas of females pretreated for 4 days with either estradiol benzoate or the oil vehicle were tested for their responsiveness to NE in an isolated smooth muscle preparation. Relative to tissue from the oil (control) subjects, aortas of EB treated females were significantly less responsive to the contractile effects of NE. Altogether, results from these 3 experiments lead us to conclude that direct actions of estradiol on vascular tissue may mediate some of the cardiovascular changes produced by this hormone. If so, it is also possible that neural or hormonal changes resulting from these vascular alterations may provide stimuli for modification of thirst or other appetitive states.

This work was carried out under a Pre-Doctoral Research Fellowship to T.A.M. and a Grant-in-Aid to J.A.C., both grants from the American Heart Association, Indiana Affiliate, Inc.

167.12 SOYBEAN TRYPSIN INHIBITOR INCREASES PLASMA CHOLECYSTOKININ BUT DOES NOT DECREASE GASTRIC EMPTYING IN THE RAT. J.D.Falasco*, A.A.Avilion*, D.Greenberg*, G.P.Smith, J.Gibbs, R.A.Liddle*, J.A.Williams* (SPON: A.Strohmayer). Dept. of Psychiatry,Cornell University Medical College, Eating Disorders Institute and the E.W.Bourne Behavioral Research Laboratory, New York Hospital, White Plains, N.Y.,10605, and Cell Biology Laboratory, Mt. Zion Hospital and Dept. of Medicine, Univ. of California, San Francisco, CA, 94120.

Circulating levels of cholecystokinin (CCK) have been shown to increase following either intragastric (i.g.) preload of Soybean Trypsin Inhibitor (STI; Liddle, Goldfine and Williams, Gastroenterol., 87:542,1984), or intraperitoneal (i.p.) injection of CCK-8 (see abstract by G.P.Smith et al., this meeting). Gastric emptying has been shown to decrease following i.p. injection of CCK-8 (J.D.Falasco et al., Neurosc., 10:532,1984 abstract, Scarpignato et al., Archs. Int. Pharmacodynam., 246:286, 1980). To determine if endogenous release of CCK was sufficient for this effect, we measured gastric emptying following a preload of STI or injection of CCK-8 under conditions identical to those used by D.Greenberg et al. (see abstract this meeting) and G.P.Smith et al. (ibid).

Method Sprague-Dawley male rats (n=6), equipped with gastric cannulas were deprived of food overnight. Ten min prior to a gastric emptying test they were either: a) injected i.p. with CCK-8 (4 mcg/kg) or 0.15 M NaCl, or b) infused i.g. with 5 or 10 ml STI (20 mg/ml) or equivolumetric 0.15 M NaCl. Gastric emptying of 5 ml saline was measured over the subsequent 10 min period using a phenol red technique. The results are in the table:

Condition:	Saline inject	CCK-8 inject 4mcg/kg	Saline preload	STI preload 100mg	STI preload 200mg
Blood levels (pM equiv CCK)	---	3.2 ± 0.6	1.2 ± 0.2	9.5 ± 1.5	---
Gastric Emptying (ml/10 min)	4.56 ± 0.16	1.72 ± 0.16	4.30 ± 1.9	4.30 ± 0.19	4.28 ± 0.21

Exogenous CCK-8 decreased gastric emptying and increased plasma CCK, but endogenous CCK released by STI did not decrease gastric emptying despite increasing plasma CCK more than exogenous CCK-8 did. This failure of endogenous CCK to decrease gastric emptying parallels the similar failure of endogenous CCK released by STI to decrease real or sham feeding in the rat (see abstract by D.Greenberg et al., this meeting).

167.13 PLASMA LEVELS OF CHOLECYSTOKININ PRODUCED BY SATIATING DOSES OF EXOGENOUS CCK-8. G.P. Smith, D. Greenberg*, J.D. Falasco*, J. Gibbs, R.A. Liddle*, and J.A. Williams*. Dept. of Psychiatry, Cornell University Medical College, Eating Disorders Institute and E.W. Bourne Behavioral Research Laboratory, New York Hospital White Plains, NY 10605 and Cell Biology Laboratory, Mt. Zion Hospital and Dept. of Medicine University of California, San Francisco, CA 94120.

Administration of exogenous cholecystokinin (CCK) decreases feeding in the rat. It has been suggested that the circulating CCK levels produced by exogenous CCK in doses sufficient to decrease feeding are at pharmacological rather than physiological levels. Circulating levels of CCK in the rat are detectable with a bioassay utilizing pancreatic acini (Liddle, Goldfine & Williams, Gastroenterol. 87: 542, 1984). We used this assay to determine circulating CCK levels in rats administered exogenous CCK intraperitoneally (ip) and compared these levels to levels of endogenous CCK obtained after a test meal.

Plasma levels of CCK were determined in 17 hour food deprived male rats (Charles River) 10 minutes after ip administration of either 2 or 4 μg/kg CCK-8 (Squibb) or after eating a high carbohydrate liquid diet (BioServ, 40% v/v) for 10 minutes. The plasma CCK results are in the table.

Treatment	n	Plasma CCK (pM equiv CCK) Mean ± SEM	range
Test Meal	10	1.2 ± 0.2	(0.5 - 3.2)
CCK-8 (2 μg/kg)	8	0.9 ± 0.1	(0.5 - 1.25)
CCK-8 (4 μg/kg)	4	3.2 ± 0.6	(1.17 - 4.25)

Both doses of exogenous CCK-8 produced statistically significant decreases in food intake in separate experiments in these rats: 2 μg/kg produced a 23.3% inhibition and 4 μg/kg produced a 37.9% inhibition. Since the level of circulating CCK measured after 2 μg/kg of exogenous CCK-8 was not significantly larger than the level of circulating CCK measured near the end of a test meal, these data suggest that the satiating effect of exogenous CCK-8 can be obtained with doses that produce circulating levels of CCK that are within or near the range of circulating CCK produced by the ingestion of food.

167.14 SOYBEAN TRYPSIN INHIBITOR INCREASES PLASMA CHOLECYSTOKININ (CCK) BUT DOES NOT DECREASE FOOD INTAKE. D. Greenberg*, G.P. Smith, J. Gibbs, J.D. Falasco*, R.A. Liddle* and J.A. Williams* (SPON: J.A. Sechzer). Dept. of Psychiatry, Cornell Univ. Medical College, Eating Disorders Institute and E.W. Bourne Behavioral Research Laboratory, White Plains, NY 10605 and Cell Biology Laboratory, Mt. Zion Hospital and Dept. of Medicine Univ. of California, San Francisco, CA 94120.

Soybean trypsin inhibitor (STI) stimulates the release of endogenous CCK and leads to circulating CCK levels equal to or larger than those measured after the ingestion of a liquid meal in the rat. These plasma levels of CCK in the rat have been measured with a bioassay utilizing pancreatic acini (Liddle, Goldfine & Williams, Gastroent. 87:542, 1984). Thus STI can be used to increase circulating levels of endogenous CCK and therefore to determine the satiating effect of endogenous CCK.

STI (100mg/rat in 5 ml of 0.15M saline) was administered as an intragastric (ig) preload to 13 male Sprague Dawley rats (Charles River) 5 min prior to ingestion of a high-carbohydrate liquid diet (BioServ diluted to 40% v/v) for 30 min. The same dose of STI was also administered as an intraduodenal (id) preload to 7 rats 5 min prior to sham feeding the same liquid diet for 30 min. (Sham feeding was accomplished by having liquid diet drain out an open gastric fistula.) Equivolumetric preloads of 0.15M saline were used as controls in both conditions. After the effects of STI on real and sham feeding were measured, the effect of ig and id preloads of STI on plasma CCK were measured in a terminal experiment in most of these same rats.

The preloads of STI produced significant increases of plasma CCK, but STI failed to decrease either real feeding or sham feeding (see table).

Treatment	n	30 minute intakes (ml) mean ± SEM	n	Plasma CCK (pM equiv-CCK) mean ± SEM
Real feeding				
STI (ig)	13	25.7 ± 2.7	10	9.5 ± 1.5*
saline (ig)	13	24.1 ± 1.4	10	1.2 ± 0.2
Sham feeding				
STI (id)	7	57.3 ± 3.8	4	6.4 ± 0.9*
saline (id)	7	57.1 ± 3.1	4	0.6 ± 0.1

* $p < .001$ compared to saline preload

These results do not provide evidence for a satiating effect of endogenous CCK. Furthermore, they are puzzling because the levels of endogenous CCK produced by STI are significantly larger than the plasma levels of CCK produced by satiating doses of exogenous CCK-8 (see abstract by G.P. Smith et al. this meeting).

167.15 INTERRELATIONSHIPS BETWEEN CORTICOSTERONE AND VASOPRESSION DURING NORADRENERGIC FEEDING ELICITED VIA THE PARAVENTRICULAR NUCLEUS. B.L. Bogart*, Z.P. Pietrzak*, J.K. Nishita, and E.H. Ellinwood, Jr. Dept. of Psychiatry, Duke Univ. Med. Center, Durham, NC 27710.

Feeding behavior elicited by injection of norepinephrine (NE) into the paraventricular nucleus (PVN) of satieted rats has been shown to be dependent upon circulating corticosterone (Leibowitz, Roland, Hor, & Squillari, 1984). In contrast, feeding behavior elicited by injection of opiates into the PVN is not altered by circulating glucocorticoids (McLean & Hoebel, 1982). Recently, Crine (1983) has drawn attention to the possible role played by vasopressin (VP) in PVN-elicited feeding behavior. VP is known to potentiate the effects of CRF on the release of ACTH and is specifically co-localized with CRF in parvocellular neurons of the PVN. In addition, VP immunoreactivity has been shown to increase in parvocellular neurons following adrenalectomy (Kiss, Mezey, & Skirboll, 1984 ; Sawchenko, Swanson, & Vale, 1984). Since the parvocellular neurons project to the external zone of the median eminence, we have begun to study the relationships of VP on PVN-elicited feeding behavior and its possible neurochemical effects on the hypothalamic-pituitary-adrenal axis.

In our preliminary experiments, 12 male Sprague-Dawley rats (370.9 ± 7.25 g) were decapitated in pairs every 4 hrs over 24 hrs for baseline RIA assay of corticosterone (CORT). Beginning at 08:00 (lights on) these values were: 1.77, 1.41, 5.29, 18.96, 26.94, 13.42, and 1.77 ug.%. Adrenalectomy (ADX) reduced CORT to levels <1 ug.%. Subcutaneous 100 mg replacement pellets of 50% CORT restored CORT to 23.58 ug.% after 3 days.

Prior to ADX, experimental rats demonstrated NE-induced feeding (2.25 ± .5 g) after 24-nmole injections into the PVN. Three days after ADX, these same rats ate 2.60 ± .6 g (SHAM), 0.83 ± .09 g (ADX), and 1.17 ± .1 g (ADX + CORT). Adrenal weights and latencies for NE-induced feeding did not differ among the three groups. Immediately following the completion of the behavioral testing (Leibowitz procedure), each rat was decapitated, trunk blood was collected, and whole brains were rapidly frozen. VP and catecholamine levels were assessed from micropunched tissue samples taken from various brain regions using HPLC and RIA assays. Results of brain tissue assays are not yet completed.

Our preliminary results replicate those of Leibowitz et al. (1984) and further emphasize the permissive action of corticosterone on the NE-induced PVN feeding response.

167.16 SOMATIC, ENDOCRINE AND METABOLIC CORRELATES OF SET POINT RECOVERY IN WEANLING RATS WITH DORSOMEDIAL HYPOTHALAMIC LESIONS (DMNL RATS) AND SHAM-OPERATED CONTROLS (CON) AFTER BODY WEIGHT REDUCTION. L.L. Bernardis, G. McEwen* and M. Kodis*. Neurovisceral Lab. VA Med. Ctr. and Dept. of Med. SUNY at Buffalo, NY 14215.

DMNL rats and CON were food-restricted for 28 days and then refed. After restriction, both DMNL and CON rats had lost comparable weight relative to ad lib-fed DMNL and CON rats. Both formerly restricted (FORE) DMNL and CON rats had comparable reductions in plasma glucose, insulin and triglyceride but there was no difference among the groups in plasma glycerol, cholesterol and free fatty acids. However FORE DMNL rats had lower plasma protein than FORE CON. Restriction caused similar reductions of % carcass fat in DMNL and CON but FORE DMNL had lower % fat than ad lib DMNL. Per cent carcass protein was comparable in FORE and ad lib DMNL rats and FORE CON. However, ad lib CON had lower % protein than all other groups. Among 7 parameters of in vitro intermediary metabolism using U-14C-glucose as a tracer, FORE DMNL rats in general showed more robust responses than ad lib DMNL and CON. Among 8 parameters of in vitro intermediary metabolism of U-14C-glucose of liver, responses were varied but there was no difference among the groups in tracer incorporation into lipid, glycogen and glycogen/protein. FORE DMNL also had more robust tracer incorporation into lipid, and saponifiable lipid than ad lib DMNL rats. On refeeding, FORE DMNL rats ate more than ad lib DMNL rats whereas FORE CON ate as much as ad lib CON. This was still noticeable 9 days after refeeding. Efficiency of food utilization (EFU) was comparable among the groups prior to restriction, was greatly depressed during restriction in both DMNL and CON and was greatly increased in both FORE groups on realimentation; this too was still evident 9 days after refeeding. Body weight recovery paralleled food intake and EFU. After 4 days of refeeding, plasma glucose, insulin and triglyceride showed comparable increases over restriction levels and plasma protein in FORE DMNL normalized. Nine days after realimentation, EFU was still greatly increased in both FORE groups as were some of the parameters of epididymal fat pad and liver intermediary metabolism. Indeed, responses of liver parameters became more enhanced at that time. However, tracer incoporation into liver lipid, saponifiable lipid, total glycogen, glycogen/protein and glucose oxidation were comparable among groups at 9 days after refeeding. The data confirm a previous hypothesis that DMNL rats, despite their absolute hypophagia and hypodipsia and reduced ponderal and linear growth, normally defend their lesion-induced lower body weight set point. This set point is a "true" body weight and not a fat set point.

167.17 Short-term Food Intake Following Glucose in Intact and Vagotomized Rabbits. Paula J. Geiselman, Allon Shiff*, Lisa Culbreth*, and Donald Novin, Department of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

It previously was shown that oral intake of a small volume of glucose (10 ml of a .3M solution) increased later chow intake in the rabbit. The feeding-enhancement effect was potentiated by bilateral subdiaphragmatic vagotomy. These results have been extended to study the effects of repeated trials of glucose in intact and vagotomized rabbits.

Bilateral subdiaphragmatic vagotomy or sham laparotomy was performed on female New Zealand rabbits. Postoperatively, half of the sham-operated rabbits were fed ad libitum. The other half of the sham-operated rabbits were pair fed with the vagotomized rabbits during their recovery from surgery (1-3 weeks). Following recovery, rabbits were allowed to ingest 30 ml of a .3M glucose solution or were subjected to a mock procedure. The glucose and the mock procedures were repeated for five trials each.

Across trials, rabbits in the sham-ad libitum group ingested more chow following glucose than they ate in the mock condition. (Food ingested in the mock condition for this group was comparable to that observed in a control group given repeated mock procedures only.)

Rabbits in the sham-pair fed group also showed a feeding-enhancement effect following glucose. Further, in sham-pair fed rabbits, food intake increased with repeated trials in both the glucose and the mock conditions. This was not merely an effect of time because a sham-pair fed control group subjected to mock procedures only did not exhibit a change in food intake across trials.

In the vagotomized group, food intake was greater across trials in both the glucose and the mock conditions in comparison to food intake observed in vagotomized rabbits subjected to mock procedures only. Prior to glucose presentation, food intake for these two groups was comparable.

Thus, the feeding-enhancement effects following the oral intake of glucose do not subside, and may even increase, with repeated trials. It also is suggested that the feeding-enhancement effects of glucose may be generalized to other feeding conditions. The present results further have implications for gastrointestinal and metabolic mechanisms that may control feeding.

167.18 GUSTATORY INHIBITION AND OPIATE RECEPTOR UPREGULATION FOLLOWING CHRONIC NALOXONE TREATMENT IN RAT. W.C. Lynch, S. Krall,* B.Q. Fernandez* and C.M. Paden Departments of Psychology and Biology, Montana State Univ., Bozeman, MT 59717.

Chronic opiate receptor blockade can affect both opiate receptor binding (e.g., Tempel, A. et al., PNAS, 81: 3893, 1984) and behavioral sensitivity to opiate drugs (e.g., Snell, D., et al., Pharmacol. Exp. Ther., 221: 444, 1985). Inhibition of feeding and drinking by opiate antagonists is now well established and has been related to taste reactivity in nondeprived, nonstressed animals (Lynch, W.C., et al., Life Sci., 33: 1909, 1983) and to the localization of opiate receptors in CNS taste and feeding areas (Lynch, W.C., et al., Pharmacol. Biochem. Behav., in press).

The present study examined both gustatory and receptor-regulatory effects of chronic naloxone (NAL) in the same animals. Two groups of adult male (Sprague-Dawley) albino rats (N=12 each) initially received repeated access (30 min/day) to highly preferred solutions of sucrose, sucrose + quinine (S+Q), sucrose + HCl (S+H) or NaCl in 2-bottle tests. Once intake had stabilized, a subcutaneous Alzet minipump (Alza Model 2002) was implanted in each rat. Pumps contained either naloxone-HCl (150 mg/ml) or 0.9% NaCl. Intake tests continued for 2 weeks, after which pumps were removed; 24 hrs later autoradiographic assays for μ-receptors were performed (Modified from Herkenham, M. and Pert, C.B., J. Neurosci., 2:1129, 1982). Horizontal sections (20μ) of fresh frozen brain (N=3/grp) were cut, mounted (3/slide), and incubated with 1.5 nM [^{3}H]-dihydromorphine (DHM, 87.7 Ci/mM) in 0.17 M Tris (pH 7.4) for 30 min at 25°C. Every third section was incubated as above in the presence of excess levalorphan (1.0 uM) as nonspecific control. Slides were firmly apposed to LKB Ultrofilm for 45 days before developing.

Chronic NAL inhibited intake of sucrose ($p<.05$) and S+Q ($p<.01$) but neither S+H ($p>.10$) nor NaCl, although the latter effect approached significance ($p<.10$). Developed films were analyzed by quantitative densitometry using an Eye Com II image processor (Spatial Data Systems) and Amersham [^{3}H] Micro-scales standards. Highest receptor densities were found in areas previously reported for [^{3}H]-DHM binding. Chronic NAL produced a significant upregulation of receptors in most high-density areas, although this effect was not uniform. Largest increases in binding were seen in lateral N. amygdala, parts of the medial thalamus, N. accumbens and frontal cortex. Smaller increases were seen in interpenduncular nucleus, presubiculum, caudate/putamen, and inferior colliculus. These gustatory and receptor-regulatory effects of chronic NAL in the same animals, suggest a further possible link between opiate system function and gustatory/feeding behavior. (Supported by a grant from Procter and Gamble Co.)

167.19 EFFECTS OF HYPOTHALAMIC INJECTION OF PHENYLEPHRINE AND CLONIDINE ON WATER INTAKE CAUSED BY CENTRAL ANGIOTENSIN II AND WATER DEPRIVATION. L.A. DE LUCA JR.*; A. RENZI*; W.A. SAAD; L.A.A. CAMARGO* and J. V. MENANI*. Departamento de Fisiologia e Patologia, Faculdade de Odontologia de Araraquara-UNESP., Araraquara, SP, Brasil.

Norephinephrine and epinephrine injected into the lateral hypothalamus (LH) inhibit drinking in 24 hour water deprived rats (Grossmann, Am. J. Physiol. 202(5): 872, 1962). Fregly et al.(Brain. Res. Bull. vol. 7:661, 1981) showed that clonidine inhibited drinking caused by systemically injected angiotensin II (AII) and by water deprivation in rats. The purpose of this study was to test the effect of clonidine (α_2 agonist)and phenylephrine (α_1 agonist) injected into the LH (ILH) on drinking induced by AII-ILH and in water deprived rats. Exp. 1: Holtzman male rats were inplanted with one cannulae directed to the LH. Water intake was recorded 1 hour after injection of AII or isotonic saline. Isotonic saline (1 ul) ILH alone induced no drinking but 8.8±0.5 ml of water was ingested when AII (8 ng/ul) was injected into the LH 20 min after isotonic saline. When clonidine (5, 10, 20 and 40 nmol/ul) and phenylephrine (20, 40 and 80 nmol/ul) were injected into the LH 20 min before AII-ILH (8 ng/ul) the following dose response curves were obtained : 7.6 ± 1.3, 3.6 ± 0.8, 1.7 ± 0.4, 1.6 ± 0.4 ml and 7.4 ± 0.5, 3.9 ± 0.8, 0.6± 0.5 ml respectively. The results were significant for $P < 0.05$. Exp. 2: Other groups of rats were injected with clonidine, phenylephrine or isotonic saline (1 ul) into the LH after 30 h of water deprivation, and water intake was recorded for 1 h after injection. The results obtained were 10.4 ± 0.9 ml for isotonic saline only, 9.0 ± 0.9 ml and 9.6 ± 0.7 ml for phenylephryne (80 and 160 nmol/ul), respectively, and 2.3 ± 0,8 ml for clonidine (40 nmol/ul). The result for clonidine was significant for $P < 0.05$. In conclusion, Exp. 1 and Exp. 2 showed that both clonidine and phenylephrine were centrally effective in blocking centrally AII - induced drinking and that clonidine but not phenylephrine, was also centrally effective in blocking thirst in water deprived rats.Our data agree with those obtained by Rowland and Fregly (neurosc.Abstr. pg. 1011. 1984) and Fregly et al.(Brain. Res. 298, 1984).

167.20 BEHAVIORAL CHARACTERISTICS OF INBRED HYPERACTIVE RATS. R.E. Musty, L.H. Conti*, D.J. Wessel* and E.D. Hendley. Dept. of Psychology and Dept. of Physiology and Biophysics, University of Vermont Burlington, VT 05405

Hyperactive Rats (HA) were tested on several tasks to assess their behavioral characteristics. The HA rats were derived from recombinant breeding of the Spontaneously Hypertensive rat (SHR) and the Wistar-Kyoto rat (WKY), followed by brother sister mating of the offspring. These HA hybrids were selected for high spontaneous activity and low blood pressure. The F8 and F9 generations were tested on the following tasks: spontaneous activity, habituation of spontaneous activity, activity in an automated open field, habituation to novel (distracting) stimuli in the open field, learning and retention of a spatial maze (shock-motivated plus maze), retention of a passive avoidance response, and intra-specific aggressive behavior.

Spontaneous activity and activity in the open field was high in the HA rat relative to the WKY and was not different from the SHR. HA females were more active than HA males. Habituation of spontaneous activity in the HA was not different from that of the WKY, while the SHR displayed retarded habituation. In response to a novel stimulus in the open field, both the HA and the SHR were more active than the WKY, suggesting increased distractibility in the HA and the SHR. HA rats were not different from WKY or Wistar (Charles-River) rats in the acquisition and the retention of a spatial maze task (shock-motivated). When tested for the retention of a step-through passive avoidance response, the HA rat showed high retention, characterized by freezing in the start compartment, the WKY rats had normal retention scores, similar to those obtained from other strains of rats, and the SHR rats showed low retention of the avoidance response. In tests in intraspecific aggressive behavior, HA rats were paired with WKY rats in a testing arena. HA rats were more aggressive than WKY rats in this context, in terms of number of attacks and aggressive postures displayed.

The HA rat is similar to the SHR rat in terms of activity. The HA displays normal habituation of spontaneous activity, is hyperreactive to novel stimuli, and is highly emotional and aggressive. Further research is needed to clarify these differences. Supported by PHS 07125-118 and the Sugar Association, Inc.

167.21 SUCROSE FEEDING AND BEHAVIOR IN HYPERACTIVE RATS. E.D. Hendley, D.J. Wessel*, L.H. Conti* and R.E. Musty. Dept. of Physiol. & Biophys., and Dept. Psychol., Univ. VT., Burlington, VT 05405.

A newly developed inbred strain of hyperactive rats (HA) was used as subjects in behavioral studies designed to examine the effects of sucrose feeding on hyperactivity. HA rats were derived from a cross between Wistar-Kyoto Spontaneously Hypertensive Rats (SHR) and their normotensive control strain (WKY). The hybrids of this cross were inbred using selected brother/-sister matings, and breeding pairs were selected for high spontaneous activity and low blood pressure. The F8 and F9 inbred populations of HA rats were subjected to ad lib. feeding with sucrose-supplemented rat chow, or with chow alone in controls, either in acute (overnight) or chronic (14-18 d) feeding of the diets prior to behavioral testing. HA rats that are hyperactive without hypertension were compared with the parental strains: SHR that are hyperactive and hypertensive, and WKY that are neither.

Spontaneous activity, as measured in either an activity cage or in the open field test, was high in HA and SHR as compared with WKY, and sugar-feeding, either acute or chronic, had no effects on spontaneous activity in any of the strains. In a learning and memory task using the plus-maze and electric shock avoidance, no differences were observed in either learning acquisition or memory retention in any of the strains as a result of sucrose-feeding. Female HA and WKY controls paired in an arena for aggressiveness-testing similarly showed no changes in aggressive behaviors as a result of sugar-ingestion. In female HA rats and no other groups, we found a significant impairment in habituation to the small bare activity cage during 4 repeated 15-min trials, one hour interval between trials, as a result of sugar-feeding. Similarly, young (7-17 wk) HA females were impaired in habituation to a novel environment, the open field, whose features had been altered with distractors prior to a second exposure of the rats to the open field.

We concluded that sugar-feeding had no effects on a wide range of behaviors in hyperactive and non-hyperactive rats, including spontaneous activity, exploratory behavior, active avoidance learning, memory retention, and aggressiveness. However sugar did influence two habituative tasks, with and without distracting stimuli, in HA females alone, the most hyperactive group among these strains. The findings suggest that attentional/distractibility responding showed impairment with sucrose-feeding in this selected population of hyperactive rats. Supported by a grant from The Sugar Association, Inc.

SUBCORTICAL SOMATOSENSORY PATHWAYS II

168.1 ULTRASTRUCTURE OF RICIN INDUCED TRANSGANGLIONIC DEGENERATION IN FELINE DENTAL AFFERENTS. L.E. Westrum, M.A. Henry*, L.R. Johnson*, and R.C. Canfield* (SPON: A.H. Bunt-Milam). Depts. of Neurological Surgery, Biological Structure, and Restorative Dentistry, Univ. of Wash., Seattle, WA 98195.

Toxic ricin has recently been shown to be an extremely sensitive and exciting new tool for the demonstration of primary central afferents from peripheral nerves. The action of ricin involves its retrograde transport to the cell body where the ricin exerts its gangliolytic effect by inactivating ribosomal function thus causing the cell and its central processes to degenerate. An earlier light microscopic study was able to demonstrate with the use of ricin, the combined dorsal and ventral dental terminal fields that were previously seen only with either transganglionic horseradish peroxidase (HRP) transport or transganglionic degeneration following dental lesions.

The purpose of the present study was to characterize, using electron microscopy (EM), the type and the temporal sequence of degeneration. Also, the location and organization of primary dental afferents within partes caudalis (PC) and interpolaris (PI) of the trigeminal brain stem nuclear complex was investigated.

Toxic ricin (RCA II(60), E-Y Labs) was injected (1-3 µl/tooth) into the pulpal chambers of unilateral maxillary and mandibular posterior teeth and cuspids in adult cats. Following 7 days survival, typical electron dense degenerating terminals and axons were identified with ease, but were lucent enough so that the morphology of the affected terminal or axon could still be determined. Degenerating terminals were found in both the ventral and the dorsal regions of PC and PI. The terminals contained round synaptic vesicles, were presynaptic to small/medium dendrites and postsynaptic to other terminals with flat vesicles (F terminals). Small (0.5-2.0 µm) thinly myelinated axons were degenerating in both PC and PI. Other findings occasionally seen, included; 1) atypical forms of degeneration (vesicle depletion, increased glycogen content and/or neurofilamentous hyperplasia) which may represent early forms of typical dense degeneration or a unique form of degeneration and 2) degenerating F terminals, possibly representing selective transsynaptic degeneration. The results show; a) electron dense terminal and axonal degeneration occurs and is the EM correlate of argyrophilia seen with Fink-Heimer preparations, b) the types of profiles involved correspond to other EM studies of primary dental afferents but also involve structures not previously seen (F terminals) and c) with the use of a single technique, it is possible to reveal the dual dental projection that had previously only been shown by combining the results of both HRP and dental lesion studies.

Supported by NIH grants DE04942, NS07144 and NS20482. LEW is an affiliate of the CDMRC.

168.2 THE MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED HRP-FILLED VIBRISSA PRIMARY AFFERENT TERMINALS IN SUBNUCLEI PRINCIPALIS AND ORALIS OF THE RAT. W.E. Renehan, M.F. Jacquin, R.D. Mooney and R.W. Rhoades. Dept. of Anatomy, Univ. of Med. and Dent. of N.J.-SOM and RMS, Piscataway, N.J., 08854.

Standard intra-axonal recording and HRP injection techniques were used to study the terminal arborizations of 15 mystacial vibrissa primary afferents in trigeminal subnuclei principalis (PrV) and oralis (SpVo) of the normal adult rat. Labelled parent fibers did not bifurcate into an ascending and descending branch and no collaterals were observed in rostral PrV. In the caudal three-quarters of PrV and throughout SpVo, however, functionally distinct afferents gave rise to similarly shaped arbors (rapidly adapting, N=6; slowly adapting type I, N=6; slowly adapting type II, N=3). Multiple collaterals emanated from each fiber (2.75 ± 0.9 in PrV, 3.5 ± 2.12 in SpVo) and terminated in each subnucleus as a series of discontinuous, highly localized aggregates. The average diameter (in the widest dimension) of the terminal arbors in PrV was 125.5 ± 53.3 µm as compared to 112.7 ± 57.2 µm in SpVo. Collaterals terminated in a manner consistent with the topography recently demonstrated by HRP bulk labeling (Arvidsson J., JCN, 1982, 211:84-92).

Surprisingly, the morphology of a given vibrissa afferent terminal in PrV was not significantly different from the structure of the central arbors of the same fiber in SpVo. Cytochrome oxidase and succinic dehydrogenase staining of PrV in adult rodents (Ma and Woolsey, Brain Res., 1984, 306:374-379) both reveal a pattern (presumably reflecting primary afferent terminations) consistent with our single fiber data. No such pattern has been shown for SpVo. It is possible that the massive oral and perioral input to SpVo (Azerad, J., et al., Brain Res., 1982, 246:7-21) coupled with the relatively small size of this subnucleus (Jacquin, M.F. and R.W. Rhoades, JCN, 1985, 235:129-143) may "mask" the vibrissa terminations when this region is stained with these techniques. Supported by DE06528, EY04170, the March of Dimes, the UMDNJ Foundation (RWR) and NRSA NS07444 (WER).

WER and MFJ are currently at the Dept. of Neuroscience, NYCOM, Old Westbury, N.Y. 11568.

168.3 COMPARISONS OF THE DISTRIBUTION OF TRIGEMINOTHALAMIC AND TRIGEMINOTECTAL NEURONS STUDIED WITH FLUORESCENT DYES IN RAT, HAMSTER, AND MOUSE. L.L. Bruce, J.G. McHaffie* and B.E. Stein. Dept. Physiology, Medical College of VA, Richmond, VA 23298.

Comparisons of the distributions of neurons that project to superior colliculus (SC) and thalamus were made to determine if similar projection and collateralization patterns are present in different rodents. The retrogradely transported fluorescent dyes, fast blue and diamidino-dihydrochloride yellow were used. In each anesthetized animal, one dye was injected into the SC and the other into the thalamus in topographically congruent areas. Counts of yellow, blue, and double-labeled cells were made throughout the trigeminal complex: principalis (VP), pars oralis (Vo), pars interpolaris (Vi), and pars caudalis (Vc).

Trigeminothalamic projections were similar in each species. The densest concentration of retrogradely labeled cells was in Vp, with substantially fewer cells in Vi, and fewer still in Vo and Vc. A common pattern was also noted for trigeminotectal cells among for three species. Most trigeminotectal projections originated from cells in Vi, somewhat fewer from Vo, and least from Vp and Vc. Following paired injections of the tracers, double-labeled cells were scattered throughout the sensory trigeminal complex. Although comparatively few double-labeled cells were observed, most were in Vi. In mouse and rat, nearly all double-labeled cells were in Vi (80-95%), whereas in hamster only about 50% were in Vi. Double-labeled cells within Vi were restricted to the ventrolateral portion, corresponding to the representation of the vibrissae. These cells could be further distinguished morphologically because they were among the largest cells in the region of Vi. In hamster and mouse, only about 10% of all cells projecting to SC also projected to thalamus. In the rat, however, the proportion was doubled; about 20% of all cells projecting to SC also projected to thalamus.

These data indicate that distribution of trigeminotectal and trigeminothalamic cells are similar among different rodents. The vast majority of labeled trigeminal cells project either to SC or thalamus, and this might be expected on the basis of the very different behavioral roles these structures play. On the other hand, a subpopulation of trigeminal cells (principally in Vi) projects to both SC and thalamus. Since double-labeled cells in Vi correspond roughly with the vibrissae representation, it is likely that these collaterals convey the same information regarding vibrissae displacement. It is not yet clear, however, what specific physiological properties distinguish this subpopulation of double-labled cells from neighboring trigeminofugal cells. Supported by a grant from the Jeffress Foundation and NIH grant EY05612.

168.4 STUDIES OF ASCENDING INTRATRIGEMINAL PATHWAYS USING THE AUTORADIOGRAPHIC TECHNIQUE. W.M. Panneton and J.H. Haring, Dept. of Anatomy, St. Louis Univ. Sch. of Med., St. Louis, MO 63104

Previous studies using horseradish peroxidase as a retrograde marker have shown that numerous neurons within the subnucleus interpolaris, the paratrigeminal nucleus, and the medullary dorsal horn project into the dorsolateral pons, including the principal nucleus of the trigeminal sensory complex, the Kolliker-Fuse nucleus, and the parabrachial nucleus. However, since the effective area of uptake was difficult to determine in the retrograde studies, the present study was undertaken using the anterograde transport of tritiated leucine as a marker to determine the termination of caudal trigeminal neurons in the dorsolateral pons more accurately.

Anesthetized cats were secured in a stereotaxic apparatus, and the location of the trigeminal sensory complex was determined using electrophysiological mapping techniques. Injections of tritiated leucine were then placed within trigeminal and paratrigeminal areas. After 10 days, the animals were sacrificed and their brains processed for autoradiography and exposed for 2 to 6 weeks. Label was transported to the dorsolateral pons in all cases, but there were differences between cases. An injection centered in the dorsal aspect of the spinal trigeminal tract at the level of the obex and including the dorsal part of the paratrigeminal nucleus and the dorsal tip of the subnucleus interpolaris resulted in relatively dense label over neurons clustered in the lateral, rostral one-third of the principal nucleus and the dorsal rim of its dorsomedial subdivision; label over the Kolliker-Fuse and parabrachial nuclei was sparse to moderate in comparison and diffuse. Injections centered at the ventromedial tip of the spinal trigeminal tract and including neurons interstitial to the tract, the ventral medullary dorsal horn and the immediately adjacent reticular formation resulted in silver grains over the ventral tip of the principal nucleus, the Kolliker-Fuse nucleus, and dorsolateral parts of the parabrachial nucleus. Injections centered within the subnucleus interpolaris at the level of obex labeled all parts of the principal nucleus, the Kolliker-Fuse, the lateral parabrachial nucleus, and the medial parabrachial nucleus caudally. These data suggest that neurons found in the paratrigeminal nucleus dorsally have projections different than those found interstitially within the spinal trigeminal tract ventrally and implies that they are not functionally homogeneous. Supported by the American Heart Association, Missouri Affiliate.

168.5 A COMPARISON OF THE DISTRIBUTION AND MORPHOLOGY OF THALAMIC, CEREBELLAR AND SPINAL PROJECTING NEURONS WITHIN TRIGEMINAL NUCLEUS INTERPOLARIS OF THE RAT. K. D. Phelan and W. M. Falls. Department of Anatomy, Michigan State University, East Lansing, MI 48824.

It has been well established that trigeminal nucleus interpolaris (Vi) is the source of a number of secondary trigeminal projections to diverse targets along the neuraxis. Previous studies have suggested that the trigeminothalamic (TT), trigeminocerebellar (TC) and trigeminospinal (TS) projection neurons may represent separate cell populations within Vi. Although detailed analyses of the distribution and morphology of TT, TC and TS neurons have been conducted in the cat, comparable studies in the rat are conspicuously lacking. The present study utilizes the retrograde transport of HRP, following large injections into either the contralateral thalamus, the ipsilateral cerebellum or the ipsilateral upper cervical spinal cord, in order to determine the number, distribution and morphological types of TT, TC and TS neurons throughout the rostrocaudal extent of rat Vi.

As in the cat, TT and TC cell populations in the rat encompass similar size ranges and exhibit similar morphological varieties of neurons. However, TT and TC neurons are distributed along the entire rostrocaudal extent of rat Vi, while in the cat these same neuronal populations exhibit a partial spatial segregation along this axis. Although significant overlap occurs between TT and TC cell populations, some specific regional differences in their size, density, distribution and morphology are evident. For example, the TT neuronal population contains a larger number of smaller ($<$15 um) cells with round/oval-shaped somata distributed in medial and ventral parts of caudal Vi and in the dorsomedial part of rostral Vi. The majority of TC neurons in these same regions are medium-sized ($\approx$15-30 um) cells with oval/multipolar-shaped somata. Furthermore, the two spinal recipient zones, which border the spinal V tract (Soc. Neurosci. Abstr., 10:796, 1984) contain predominantly either TT cells (dorsolateral) or TC cells (ventrolateral). TS neurons, which comprise a smaller population of Vi cells, present a characteristic distribution pattern restricted to ventral and lateral regions of the nucleus. These neurons possess morphologies either similar to or distinctly different from TT and TC neurons depending upon their location within Vi. The results of the present study indicate the existence of several morphological types of TT, TC and TS neurons which exhibit some distinct differences in their regional distribution within Vi of the rat. This pattern of organization is distinctly different from that previously reported in the cat and possibly reflects a species difference in the functional organization of Vi.

168.6 POST-SYNAPTIC AFFERENT TERMINATIONS IN THE CAT DORSAL COLUMN NUCLEI VISUALIZED BY PHA-L BEAN LECTIN J. Pierce and A. Rustioni, Dept. of Anatomy, The University of North Carolina at Chapel Hill

The dorsal column (DC) system of the spinal cord is known to contain a mixture of fibers; including local spinal interconnections, 1° afferent collaterals, ascending post-synaptic afferents, and descending fibers. The post-synaptic dorsal column (PSDC) component can be differentiated both electrophysiologically and anatomically. The studies of Angaut-Petit (1975) and Brown et al. (1983) demonstrate that the information carried by these fibers displays a high degree of modality and somatotopic convergence. Moreover, they seem to project to brainstem regions that generally do not overlap with the main targets of 1° afferent collaterals. Studies using the successive degeneration technique (Rustioni, 1974), and spinal wheat germ agglutinin-horseradish peroxidase (WGA-HRP) injections following rhizotomy at cervical levels (Pierce et al., 1983) indicate that they probably terminate primarily in the ventral and rostral parts of the cuneate nucleus. However, neither of these approaches allowed one to a) discriminate between cut fibers of passage and terminal varicosities, and b) visualize individual fibers, with their pattern of collateral arborization.

With the use of the red kidney bean lectin phaseolus vulgaris leucoagglutinin (PHA-L) (Gerfen and Sawchenko, 1984) we are able now to address this problem. A laminectomy of the lower cervical region was performed, followed by a unilateral series of six iontophoretic PHA-L injections into the dorsal gray matter, from C6 to C7. 5μ amp pulsed positive current for 15 minutes was used to make each injection. Under these conditions PHA-L is thought to be taken up exclusively by cell bodies, and transported anterogradely. Three weeks later the animal was sacrificed, and the tissue prepared for light microscopy, after PHA-L immunohistochemistry.

This method also allows one to reconstruct cells involved in uptake. A subpopulation of the labelled cells we have seen have characteristics that correspond to those described by Brown et al. (1981) in their intracellular HRP study of PSDC cells. Often an axon could be followed into the DC's where most labelled fibers are observed. Terminal varicosities are seen, usually in "en passant" chains, distributed throughout the ventral and rostral cuneate nucleus. Patches of grouped terminals are also seen sporadically in the "cluster" zone of the cuneate, and in the external cuneate nucleus. In both of these regions WGA-HRP label has been seen in our previous studies (Pierce et al., 1983). Current work is underway to reconstruct individual terminal arbors in each of these target regions.

168.7 BRAINSTEM PROJECTIONS TO AND FROM THE CUNEATE NUCLEUS OF RATS AND CATS. R. J. Weinberg and A. Rustioni, Dept. of Anatomy, University of North Carolina, Chapel Hill, NC 27514.

The existence of GABAergic inhibitory mechanisms in the dorsal column nuclei of rats and cats has been firmly established by a variety of methods. Immunocytochemistry demonstrates that about 25% of neurons in the central core region ("MCd" of Cheema, et al, 1983) of the cat's cuneate nucleus (CUN) stain for glutamic acid decarboxylase (GAD). EM immunocytochemistry reveals numerous GAD-positive terminals of various morphologies. Recalling the electrophysiological demonstration that stimulation of the reticular brain stem core inhibits transmission through CUN (Cesa-Bianchi, et al.,1968, 1969), this finding of morphological heterogeneity raises the question whether GABAergic terminals in CUN originate exclusively from intrinsic neurons, or arise in part from extrinsic GABAergic neurons in the brainstem. The present experiments represent a first step toward answering this question, by investigating whether any significant input to CUN arises from other brainstem regions.

We made small injections of WGA-HRP into CUN of anesthetised rats and cats by iontophoresis (1-5 μA for 5-15 minutes) from fine glass pipettes (tip diameter 5-15 μm). After survival times of 24 hours, the animals were sacrificed. 40 μm frozen sections were processed for HRP using the TMB technique and examined with a Leitz microscope under bright- and dark-field illumination.

Our results to date indicate that small injections strictly confined to the dorsal part of the middle region of CUN in both rats and cats result in labeling of neurons in the vicinity of the injection, and virtually no retrograde labeling outside the nucleus. For cases in which the injection spread rostral to the middle region (in cats) or to the ventral fringe of the nucleus, retrograde labeling in the brainstem was relatively sparse and mainly confined to the rostral medullary tegmentum (n. magnocellularis, n. gigantocellularis, and raphe magnus) and to the contralateral red nucleus. We are now attempting double labeling experiments to investigate whether any of these projections might involve GABAergic neurons.

The sparseness of the retrograde labeling contrasted with the anterograde transport of WGA-HRP. Consistent with the results obtained by other investigators using degeneration techniques and autoradiography, we have observed a projection to the contralateral colliculi, pretectal area, and pontine nuclei. Ipsilateral to the injection site in rats, efferents were traced to the inferior cerebellar peduncle and to the superficial layers of the spinal trigeminal complex and of the dorsal cochlear nucleus, even when the injection was restricted to the central part of CUN.

This work was supported by NIH grants NS 07132 and NS 12440.

168.8 IMMUNOHISTOCHEMICAL DEMONSTRATION OF SEROTONIN-CONTAINING PROCESSES WITHIN THE CAT CUNEATE NUCLEUS. M.V. Trinh*, J.C. Pearson, M.D. Goldfinger, & K.S. Shalala. (SPON:G.Crampton) Depts. of Anatomy, Physiology, and Micro. & Immuno., Sch. Medicine and Col. Science & Engineering, Wright State University Dayton, OH 45435.

The cuneate nucleus is a somatosensory synaptic relay site involved with the transmission of mechanosensory information from forelimb afferent units. In addition to primary afferent input, the nucleus receives relayed projections from both spinal and supraspinal sources. Physiological studies have revealed excitatory and inhibitory influences on the transmission of afferent information. Recently, Goldfinger et al. (1) showed the presence of 5-hydroxyindoleacetic acid (5HIAA) in cuneate push/pull perfusates recovered during peripheral somatosensory stimulation; the presence of 5HIAA suggests the possibility of serotonergic (5HT) elements within the cuneate circuitry (as shown for the rat cuneate:2).

The present work tests for 5HT within the cat cuneate nucleus, using a sequential immunohistochemical procedure (3). Following fixation by perfusion with 4% paraformaldehyde in 0.1M phosphate buffer (pH 7.4), the brainstem tissue is frozen sectioned at 40um and incubated with a solution containing anti-5HT antibody (Polyscience, Warrington, PA). Biotinylated secondary antibody (antiIgG) is added to introduce biotinyl binding sites to the primary antibody. Next, an Avidin-biotinylated HRP complex (Vector Labs, Burlingame, CA) is added to bind to the secondary antibody. Reacted tissue is then incubated in a peroxidase solution. The cuneate nucleus is examined for 5HT reaction product, as defined by observation of reaction result within the Raphe nuclei of the same preparation.

The data reveal 5HT reaction product within thin processes which are axon-like in appearance. Labeled processes show spaced varicosities, and can be followed through the section depth. The spacing of process-contained varicosities suggests distributed contact points. These results are consistent with the recovery of extracellular 5HIAA, which could result from stimulus-elicited release of 5HT and subsequent enzymatic &/or thermal 5HT oxidation. These findings add to other evidence which suggest a role for serotonin in cuneate information processing.

168.9 RECOVERY AND DETECTION OF AMINO ACIDS RELEASED WITHIN THE CAT CUNEATE NUCLEUS. M.D. Goldfinger, S. Hensley*, and D. Schmalholz*. Dept. of Physiology, Wright State University, Dayton, Ohio 45435.

This work seeks to recover and detect primary amino acids released into the cuneate nucleus, using push-pull perfusion and HPLC (High Performance Liquid Chromatography) analysis, respectively.

Push-pull perfusion: The objective is to continuously sample the extracellular space containing cuneate relay neurons (located within 2 mm beneath the exposed brainstem surface). The push tube consists of a glass pipette drawn to a 100 um tip with a tungsten microelectrode fixed in the tip lumen. The push tube is positioned into the nucleus without engaging surface blood vessels. Artificial CSF vehicle solution is pushed through the tip at 20 ul/min and flows back towards the brainstem surface by capillarity and negative pressure applied via a second glass pipette at the brainstem surface next to the push tube entry site. Fluid is collected via the surface pipette into the negative pressure reservoir for subsequent HPLC analysis. Electrical activity is concurrently recorded from the microelectrode.

HPLC analysis (cf.ref.1): 25 ul of sample fluid is reacted with 100 ul of derivitizing solution (o-phthalaldehyde, mercapto-EtOH, 0.1M NaTetraBorate:1) for 2.5 min to form isoindole derivatives of primary amino acids. 20 ul of the reaction fluid is injected into the HPLC. System configuration parameters are: ODS-5 um reverse-phase column (T=34°C); isocratic mobile phase of 30% MeOH, 70% 0.1 M NaPhosphate; pump flow = 1.6 ml/min; Electrochemical Detector (BAS LC-4B, output filter = 1 Hz, oxidation mode); Electrodes - glassy-carbon working (V=+700 mV) and calomel reference. Testing with standards (L-amino acids in artif. CSF, pH=7.3-7.4) shows detector output with wide-range linearity (eg, 40-5000 pmole) and acceptably low variability (eg, $<$2%-elution times; $<$10%-peak heights). However, 10 of 22 amino acids could not be detected.

Preliminary study with 3 cats (prep.:2) sought samples from 5 minutes of continuous perfusion during periods with or without repetitive ipsilateral forepaw percutaneous electrical stimulation (0.1 ms-duration pulses at 10/sec.) Results showed that stimulation elicited an increase of baseline amino acid levels, with 4 to 6 readily discernible HPLC output peaks. GABA levels did not increase above baseline levels; yet, P-wave electrical activity (picrotoxin-sensitive:3) was concurrently recorded.

168.10 SENSORY PATHWAY SPECIALIZATION RELATED TO CALCITONIN GENE-RELATED PEPTIDE IMMUNOREACTIVITY IN THE RAT. L. Kruger, N. Brecha, C. Sternini and P. Mantyh. Depts of Anatomy, Anesthesiology and Medicine and Brain Research Institute, Center for Ulcer Research and Education, UCLA School of Medicine, LA, CA 90024 and VA Medical Center, Wadsworth, LA, CA 90073.

Calcitonin gene-related peptide (CGRP) has been localized to a variety of sensory, motor, autonomic and integrative structures (Nature, 304:129,1983). We report the distribution of CGRP immunoreactivity in sensory pathways of the rat using new CGRP antisera generated to [Tyr]-rat CGRP(23-37) coupled to keyhole limpet hemocyanin via glutaraldehyde. Normal and colchicine-treated rats were perfused with a paraformaldehyde solution. Brains were cut in transverse, horizontal or parasagittal axes. Sections were processed by the avidin-biotin peroxidase technique. Specificity was demonstrated in adjacent sections incubated in preimmune serum or in antiserum previously absorbed with 10 uM synthetic rat CGRP. CGRP immunoreactive axons in skin are numerous, especially within glabrous epidermis, in relation to a variety of dermal blood vessels and zones of nociceptor specialization. Small and medium sized sensory ganglion cells emitting thin axons are numerous and give rise to heavy bundles of presumptive nociceptor axons running in Lissauer and spinal V tracts terminating principally in marginal and gelatinosa layers. Small neural somata are present in cord gelatinosa and spinal V, and also unexpectedly, a few lemniscal neurons are labeled. Gustatory and visceral afferent axons are found in selected sectors of the solitary nuclei, medial parabrachial nuclei and the caudomedial thalamic ventral group, usually designated VM or VPMpc. Another fiber component can be traced through a sector of the posterior group and continues rostrad in the medial internal medullary lamina terminating in submedius and paracentralis nuclei, but not in the ventrobasal complex or other regions of the ventral group recipient of spinothalamic projections. Axons in the posterior group run medial to a peripedunclar cluster of labeled somata at the ventrocaudal border of the medial geniculate. Neurons of the thalamic reticular nucleus and sparse arrays of small neurons are labeled at the mesodiencephalic junction extending across the pretectal area and ventrally encompassing parts of periaqueductal gray and parafascicular, centromedial and reuniens nuclei- zones only indirectly implicated in pain mechanisms. A parsimonious principle accounting for the total pattern remains elusive. However, it may be relevant to note that in addition to CGRP in established chemosensory pathways (olfactory, gustatory and visceral) there is label in pathways related to polymodal nociceptor inputs; another class of sense organ for which chemically mediated excitation is suspected.

168.11 LOCAL CIRCUIT NEURONS IN THE RAT VENTROBASAL THALAMUS.
R.M. Harris and A.E. Hendrickson, Department of Biological Structure, University of Washington, Seattle, WA 98195.

Most thalamic nuclei contain a sizeable population of local circuit neurons. These neurons have been found to be inhibitory and to contain the neurotransmitter γ-aminobutyric acid (GABA). In the ventrobasal thalamus of the rat, a simpler circuitry appears to exist and few indications of any local circuit neurons have been found. In order to carry out a direct search for such neurons, an immunocytochemical study was made using a recently available antiserum to GABA.

Standard peroxidase-antiperoxidase techniques were used to show that a small population of cells in the rat ventrobasal complex (VB) does contain GABA. In order to determine if these were local circuit neurons, injections of horseradish peroxidase (HRP) were made into the primary somatosensory cortex. A band of cells in VB was retrogradely labeled. GABAergic cells were immunocytochemically labeled using carbazole as a chromagen, allowing a search for double labeled cells. No double labeled cells were found, indicating that the GABAergic cells did not project to the cortex. These probably represent a small population of local circuit neurons.

The GABA-labeled cells made up 0.4 ± 0.3% of the cells in rat VB. They were distributed throughout VB, with more cells along the lateral boundary of the nucleus and fewer medially. The average cross-sectional area of these cells was somewhat smaller than that of all cells in VB (81 ± 34 μm vs. 105 ± 36 μm). Aside from the number of cells, these properties are similar to local circuit neurons in other thalamic nuclei.

The functional significance of such a small population of local curcuit neurons is not clear. They are not likely to play a major role in this nucleus, indicating that the neuronal circuitry in the rat VB is particularly simple. Perhaps they play a role in processing a particular somatosensory modality, such as noxious stimuli.

168.12 MORPHOLOGY OF ELECTROPHYSIOLOGICALLY CHARACTERIZED NEURONS AND FIBERS IN THE MEDIAL AND LATERAL VENTROPOSTERIOR NUCLEI OF THE CAT'S THALAMUS. C.Vahle-Hinz*, K.-M.Gottschaldt †, L.M.Pubols, M.J. Friedlander and K.-D.Kniffki* (SPON: R.F.Schmidt). Physiologisches Institut der Univ., D-8700 Würzburg, FRG; Neurological Sciences Inst., Good Samaritan Hosp.& Med. Ctr., Portland, OR 97209 and Dept. Physiol.& Biophys., Univ. Alabama, Birmingham, AL 35294.

Horseradish peroxidase-filled micropipettes were used for intracellular recording and injection of single cells and lemniscal fibers in the thalamic face and body representation areas. Antidromic activation from the corresponding SI cortical fields was used to identify thalamocortical relay neurons; neurons activated transynaptically from the same cortical locations were classified as thalamic interneurons. Ascending fibers were identified by their spike form and unresponsiveness to cortical stimuli. Functional properties of neurons and fibers were determined with mechanical stimulation of fur, skin and sinus hairs. Vibratome sections were reacted with cobalt-intensified diaminobenzidine and the labeled neural elements reconstructed with camera lucida drawings.

Thalamocortical relay neurons with receptive fields on the face (n=5) have round somata of 10-30 μm diameter with 5 primary dendrites regularly spaced around the soma, giving the cell a star-like shape. The dendrites branch in a bushy fashion and cover a spherical volume 370-500 μm in diameter that is uncorrelated to soma size. Relay neurons with receptive fields on the body (n=4) have elongated somata 22-35 μm long and 8-13 μm wide. Three to 5 dendrites arise from the cell poles, two usually being larger, giving the arbor a medio-lateral orientation extending 300-550 μm.

Interneurons with face or body receptive fields (n=2) have large elongated somata, 25 and 33 μm long, and spherical dendritic arbors 560 and 570 μm in diameter, with spiny dendrites and large appendages (which however can also occur on relay neurons). A second type of interneuron (n=2) has been found that has a sinus hair receptive field and a small soma, 11 and 15 μm in diameter, and only a few irregular processes bearing bouton-like structures.

Fibers with face receptive fields (n=6) have one terminal arbor, and those with body receptive fields (n=4) one to three arbors spaced 100-700 μm apart rostro-caudally or medio-laterally. Most fibers' arborizations contain densely packed terminal boutons, but one fiber whose activity was inhibited by vibration was distinctly different; this had a loose terminal arborization with sparse boutons.

Thus, two types of thalamic interneurons have been observed. Both cells and fibers seem to have a distinct morphology in the medial and lateral ventroposterior nuclei. Specific functional properties may be expressed in the pattern of lemniscal fiber terminations.

168.13 *MULTIVARIATE STATISTICAL ANALYSIS OF NEURONAL STRUCTURE IN VENTRAL POSTERIOR THALAMUS.* *J. C. Pearson, B.L. Mann*, and J. R. Norris. Depts. of Anatomy and of Mathematics and Statistics, Sch of Med. and Col. of Science and Engineering, Wright State University, Dayton, OH 45435.*

Although physiological studies indicate considerable functional diversity among thalamocortical projection neurons in the ventral posterior (VP) nucleus in a variety of species, evidence for corresponding anatomical diversity is contradictory and incomplete. Some reports emphasize the similarity in relay cell structure while others present evidence which suggests grouping of relay cells into subcategories with morphological similarity.

The present study addresses the question of whether morphological variation among VP relay cells is sufficient to warrant subcategorization into anatomical classes by using morphometric procedures and multivariate statistical methods to describe Golgi-impregnated neurons in the VP of opossum, dog, and the lesser bushbaby, (Galago senegalensis). Relay cells are analyzed according to soma cross-sectional area, soma shape, number of major branch points (MBP), dendritic field shape and extent, and the number of appendages (spines) in defined dendritic branch zones. Principal components analysis is used to evaluate structural variation among cells in terms of the weighted sums of all variables. The data indicate that thalamocortical relay cells of opossum VP show some correlation in dendritic field extents, dendritic field shapes, and dendritic branch frequencies, but random variation in soma size and spine content. Thalamocortical relay cells of dog and bushbaby show strong correlation in soma and dendritic field parameters and in the number of spines located in the major branch zones. This pattern suggests that opossum VP cells form a single group of relay neurons in which some variation in structure is present, and that the diversity of relay cell structure in the VP of dog and bushbaby is great enough to acknowledge the presence of anatomical subcategories.

168.14 **SINGLE UNIT ANALYSIS OF THE FAR FIELD POTENTIAL.** **J.G. Blackburn, M.A. Cordova-Salinas* and S. Trojanowski*. Dept. of Physiology, Med. Univ. S.C., Charleston, SC 29425.**

Far field somatosensory evoked potentials (FFPs) and single unit responses were recorded in cats anesthetized with nitrous oxide. Far field potentials were recorded from a mid-line electrode at stereotaxic AP_O in response to electrical stimulation of the left superficial peroneal nerve (1 pps. 0.1 msec duration and 3 mA intensity). The reference electrode was located on the ipsilateral ear. The evoked potentials were amplified, filtered, summated with a microcomputer and displayed on a digital plotter. Single unit responses were recorded from the nucleus gracilis with tungsten microelectrodes, amplified, filtered and displayed on the digital plotter.

Eight stable components were identified in the FFP in response to superficial peroneal nerve stimulation: 4.80 ± 0.16, 5.66 ± 0.32, 6.39 ± 0.07, 8.35 ± 0.17, 9.15 ± 0.06, 9.61 ± 0.13, 10.41 ± 0.09, and 11.96 ± 0.15 msec. Unit responses appeared with an average latency of 9.04 ± 0.5 msec. The single unit responses appear to correlate in time with the fifth component of the FFP, indicating that this component may be generated in the brain stem. **This investigation was supported by NINCDS grant 2P01 NS 1106610.**

169.1 **DIFFERENT CATABOLIC PATHWAYS FOR THYROTROPIN RELEASING HORMONE (TRH) IN BRAIN AND SPINAL CORD OF NIH:N MICE**

B.R. Brooks, J. Turner, T. Schwartz, Neurology Service, Wm. S. Middleton VA Hosp. and Univ. Wisconsin Med. Sch., Madison, WI 53705

The catabolism of thyrotropin releasing hormone (TRH) in the hypothalamus and cerebral structures has been well elucidated. However, the biochemical and pharmacological effects of TRH are maximal in animal models of spinal cord disease - spinal cord motor neuron degeneration and spinal cord trauma. We have studied the comparative degradation of 3H-TRH and 125 I-TRH in cerebral cortex and spinal cord from NIH:N mice by reverse phase HPLC. Ten (w/v) percent homgenates were prepared in normal saline or 25 mM potassium phosphate buffer containing 2 mM dithiothreitol and 2 mM EDTA. Degradation of 3H-TRH occurred at a faster rate in fresh cortex homogenates (8.9 $\pm$ 0.1%/min) compared with fresh spinal cord homogenates (3.8 $\pm$ 0.2 %/min). Degradation rates of 125 I-TRH were decreased by 67% in the cortex (3.0 %/min) and by 82% in the spinal cord (0.7 %/min). One cycle of freeze/thawing resulted in a 60% decrease in degradation rate in the cortex and a 90% decrease in degradation rate in the spinal cord. HPLC analysis of degradation products indicated that deamido-TRH (TRH-OH) is the major product in the cortex while His-Pro-OH is the major product in the spinal cord. These results were confirmed by administration of bacitracin which increases His-Pro-OH production in cortex homogenates by inhibiting TRH-OH production but has no effect on the amount of His-Pro-OH produced in spinal cord homogenates. Cyclo-His-Pro production in the spinal cord under optimal buffer conditions is 20% higher than in the cortex. Catabolism of TRH in the spinal cord is slower and proceeds via a different metabolic pathway than in the cortex. These differences may be important in explaining the different biochemical and pharmacological effects of TRH on the spinal cord.

169.2 ELECTROCHEMICAL DETECTION OF NEUROTENSIN (NT) AND NT FRAGMENTS IN HUMAN CEREBROSPINAL FLUID (CSF) FOLLOWING ON-LINE TRACE ENRICHMENT AND GRADIENT ELUTION HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC).

D.L. Knight*, C.B. Nemeroff, and C.D. Kilts. (Spon: D.L. Kimmel, Jr.) Depts. Psychiat. and Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710.

A novel method for detection and chromatographic separation of NT and several of its major fragments has been developed. Gradient elution HPLC coupled with electrochemical detection (EC) was used to detect nanogram ($\geq$ 2 ng) quantities of NT, NT 1-6, NT 1-8, NT 1-10, NT 1-11, NT 9-13, and NT 8-13. EC detection is a more sensitive and specific method than typically used UV detection and allows the detection of NT and its fragments in biological matrices, i.e. CSF and brain tissue extracts. To maximize assay specificity, the significant retention of NT and its fragments by cation exchange and reverse phase HPLC was exploited by combining these two retention mechanisms in an on-line assay. The method yielding the best results involves using a Brownlee 3 cm cation exchange enrichment column with 20 mM potassium acetate (KAc), pH 3.5 and 10% acetonitrile (ACN) to enrich the samples, then back elution with 200 mM KAc, pH 6.4 , 0.75 mM heptane sulfonic acid (HSA) and 10% ACN onto a Waters C18, 10u reversed phase analytical column. Peptides were then resolved using a gradient elution from 10% ACN to 30% ACN in 20 minutes at 1.5 ml/min. Detection was accomplished by EC oxidation at +.850 V. Due to a decline in electrode sensitivity as a result of solvent gradient elution in combination with the matrix assayed and the use of relatively high oxidation potentials, the cell had to be polished daily. The EC oxidation of NT and its fragments is not merely a function of the presence of tyrosine or tryptophan, but apparently varies with the presence and relative position of basic amino acids (e.g., arginine). The chromatographic separation of NT and NT fragments was stable over a period of 6-9 months. When analytical column separation did begin to diminish it could be restored by adding HSA to the gradient mobile phases. Although this method is not as sensitive as most RIAs, it was utilized to specifically determine the nature of NT-like immunoreactivity in human CSF. Efforts to preconcentrate NT and its fragments by lyophilization or Sep-Pak chromatography and solvent evaporation indicated significant peptide degradation by these preparative techniques. The present method, which involves the chromatography of untreated CSF, permitted the specific qualitative determination of NT in human CSF. (Supported by NIMH MH-39415).

169.3 INSULIN-INDUCED HYPOGLYCEMIA ALTERS THE LEVELS OF PROENKEPHALIN A mRNA AND PROENKEPHALIN A RELATED PEPTIDES. T. Kanamatsu*, C.D. Unsworth†, E.J. Diliberto†, O.H. Viveros†, and J.S. Hong . †Laboratory of Behavioral and Neurological Toxicology, NIEHS/NIH, †Department of Medicinal Biochemistry, The Wellcome Research Laboratories, Research Triangle Park, NC 27709

The role of splanchnic innervation in the expression of opioid peptides (OP) in the rat adrenal medulla has been a matter of controversy (1,2). It has been proposed that the increase in OP level observed following both denervation and insulin-induced hypoglycemia results from an initial increase in the rate of splanchnic discharge (2). The measurement of mRNA levels of proenkephalin A ($mRNA^{enk}$) was used in this report as an index of OP biosynthesis and to establish the role of the innervation in OP gene expression.

Male Sprage-Dawley rats weighing 300 g were injected with insulin (IOU/kg, s.c.) to induce hypoglycemia and thus increase splanchnic nerve discharge. Insulin shock was stopped two hr later by oral administration with 1.5 ml 40% sucrose and rats were killed at various times thereafter. The levels of both NOP (native OP, without enzyme digestions) and COP (cryptic OP, with enzyme digestions) were determined by radioreceptor assay. The level of (Met^5)-enkephalin-like immunoreactivity (ME-LI) was determined by radioimmunoassay (RIA). The abundance of $mRNA^{enk}$ was measured by a blot hybridization method using a cDNA clone derived from rat brain.

Two hr of insulin-induced hypoglycemia decreased the level of catecholamines by approximately 55% and produced no significant alteration of the levels of COP and NOP in the adrenal medulla. The same treatment tripled the level of $mRNA^{enk}$. The increase in the level of $mRNA^{enk}$ reached a plateau 26 h after the injection of insulin (15-fold increase compared with controls), then the level declined with an approximate half life of 4 days. Significant increases in the levels of COP and NOP occurred 26 h after insulin treatment (COP, 6-fold; NOP 2-fold) and the increase reached maximal levels after 98 h (COP, 26-fold; NOP 18-fold). Seven days postdose, levels of OP were still higher than the controls (COP, 8-fold; NOP 5-fold). Results from RIA which measures ME-LI were consistent with those measured by radioreceptor assay. Pretreatment with ganglionic blocking agents, chlorosondamine (5 mg/kg, i.p.) plus atropine (1 mg/kg, i.p.) completely abolished insulin-induced increase in $mRNA^{enk}$. These data indicate that splanchnic discharge may stimulate OP biosynthesis, probably at the level of gene expression.

169.4 LITHIUM INCREASES (Met^5)-ENKEPHALIN LEVELS, PRECURSOR CONTENT AND PREPROENKEPHALIN mRNA ABUNDANCE IN THE RAT STRIATUM. S.P.Sivam and J.S. Hong. Laboratory of Behavioral and Neurological Toxicology, NIEHS/NIH, Research Triangle Park, NC 27709.

Lithium is a well-established drug for the treatment of manic-depressive illnesses though the mechanism of its action remains unknown. This report explores the influence of lithium on (Met^5)-enkephalin (ME) biosynthesis in the rat brain. Male Fischer 344 rats were treated with lithium chloride (4 mEq/kg/day, i.p.) for 1, 2, or 4 days and sacrificed 24 hr after the last dose; another group was sacrificed 2 hr following the dose to study the acute effect. Control animals received saline. The ME levels were determined by radioimmunoassay[1]. Lithium increased the ME level in the striatum in a time-dependent fashion reaching 76% of control value following four doses. No changes were observed in other brain regions studied such as hypothalamus, hippocampus, frontal cortex, brain-stem. In order to characterize the nature of this selective increase of ME level in the striatum, the precursor content as well as the preproenkephalin mRNA abundance were determined. The precursor content as reflected by the cryptic ME content following sequential digestion[2] with trypsin and carboxypeptidase-B was measured by radioimmunoassay. Lithium increased the precursor content in a time-dependent manner and this pattern closely paralleled with the increase in native ME content. The preproenkephalin mRNA abundance was quantitated by blot hybridization of total RNA (isolated by the guanidine thiocyanate extraction procedure[3]) with a ^{32}P labelled cDNA probe derived from rat brain[4]. Lithium increased the mRNA abundance following repeated doses for four days. These results confirm and extent the previous observations[5] in which case a cell-free translation method was used to estimate the preproenkephalin mRNA. The study suggests that repeated injections of lithium increase the biosynthesis of ME in the rat striatum.

169.5 *DETECTION OF RAT STRIATAL SUBSTANCE P AND SUBSTANCE K mRNA AND EFFECT OF HALOPERIDOL TREATMENT ON THE LEVEL OF SUBSTANCE P AND SUBSTANCE K MESSAGE.* J. Angulo*, K. Wilcox* B. Burkhart*, R. Lampe*, K. Lawrence*, R. Manning*, R. Arentzen*, L. Davis, and G. Christoph.* Central Research and Development Department, E. I. du Pont de Nemours and Co., Experimental Station, Wilmington, DE 19898.

Substance P (SP) is an endogenous brain peptide which has many properties expected of neurotransmitters in the central nervous system. In rat striatum, neuronal perikarya that contain SP project to the substantia nigra. This striatonigral pathway presumably plays a role in basal ganglia function. From published data on the sequence for bovine SP preprohormone mRNA and that of a related tachykinin peptide, substance K (SK), we have synthesized oligodeoxynucleotide probes (39-mers) which specifically hybridize to mRNA for SP and SK. After labeling the probes with 32-P, Northern gel analysis of total RNA from striatum shows one intense band for SP mRNA. The SK probe yields a signal of identical size, but one third as intense as that for SP. This may reflect the relative levels of SP and SK mRNA's or hnRNA's in striatum. No detectable SP or SK hybridization signal was detected with total RNA from cerebellum after 7 days of exposure to film (striatal SP and SK are routinely detected within 4 hours of exposure). Chronic treatment of rats with the dopamine antagonist haloperidol is known to decrease the concentration of SP in the substantia nigra. To determine whether this decrease in peptide concentration was due to reduced synthesis, we compared SP mRNA levels in striatal tissue from control rats and rats chronically treated with haloperidol (delivered by osmotic minipumps at 0.2 mg/Kg/hr for 5 days). The data indicate that chronic haloperidol reduces striatal SP mRNA suggesting that the drug induces a reduction in the expression of the SP gene.

169.6 **NEUROMEDIN B: A NEW BOMBESIN-LIKE PEPTIDE IN MAMMALIAN BRAIN.** **Robert T. Fremeau Jr.[1], Louis Y. Korman[2], Thomas L. O'Donohue[3] and Terry W. Moody[1]. [1]Dept. Biochemistry, George Washington Univ., School of Medicine, Wash., D.C. 20037, [2]VA Medical Center, Wash., D.C. 20901 and [3]Expt. Ther. Branch, NINCDS Bethesda, MD 20205.**

Bombesin, a tetradecapeptide initially isolated from frog skin, induces potent biological (hypothermia, hyperglycemia and satiety) and behavioral (grooming and analgesia) effects after central administration into the rat brain. Some of these actions may be mediated by the endogenous bombesin-like peptides which are present in certain brain regions such as the hypothalamus and spinal cord but not the hippocampus or cerebellum (Moody, T. et al., Peptides 2: 65, 1981). These endogenous bombesin-like peptides may interact with receptors which have been detected in discrete rat brain regions such as the periventricular and suprachiasmatic nuclei of the hypothalamus, dentate gyrus, hippocampus and dorsal horn of the spinal cord (Zarbin, M. et al., J. Neuroscience, 5: 429, 1985). Because receptors but not bombesin-like immunoreactivity are present in the hippocampus it is possible that these receptors are activated by some other peptide. Recently, Minamino, N. et al., (BBRC., 114: 541, 1983) isolated a decapeptide from porcine spinal cord (neuromedin B) which is structurally similar to bombesin (7 of the 10 C-terminal amino acid residues are identical). Here we report that neuromedin B-like peptides are present in certain rat brain regions such as the hippocampus.

A radioimmunoassay was developed for neuromedin B and the antisera did not cross react with bombesin or GRP. Immunoreactive neuromedin B was detected in high density in the spinal cord, hippocampus, hypothalamus and olfactory bulb. Intermediate levels of immunoreactivity were detected in the striatum, cortex, thalamus, midbrain, hindbrain and pituitary. Low levels of immunoreactivity were present in the cerebellum and pineal; the concentration of neuromedin B varied by approximately 2-orders of magnitude in high relative to low areas. Using gel filtration techniques one major peak of immunoreactivity was present which coeluted with neuromedin B. Using HPLC techniques, however, a major and minor peak of immunoreactivity was detected, the former of which eluted with neuromedin B. Also, receptors for bombesin-like peptides bound neuromedin B with high affinity (IC_{50} = 4 nM). Thus in certain brain regions, such as the hippocampus, receptors for bombesin-like peptides may be activated by endogenous neuromedin B-like peptides.

169.7 ETHANOL DECREASES B-ENDORPHIN RELEASE AND PRO-OPIOMELANOCORTIN mRNA LEVELS IN AtT-20 AND RAT PITUITARY CELLS IN CULTURE. J.R. Dave, L.E. Eiden and R.L. Eskay, (SPON: S. Sabol), Laboratory of Clinical Studies, DICBR, NIAAA and Laboratory of Clinical Science, NIMH, Bethesda, MD 20205.

Since ethanol is known to disrupt the hypothalamic-pituitary-adrenal axis, studies were undertaken to determine the effect of ethanol on release and synthesis of pro-opiomelanocortin (POMC)-derived peptides from AtT-20, rat anterior lobe (AP) and rat intermediate lobe (IP) pituitary cells in culture. Cells were preincubated for 24 hr with 0, 0.2 or 0.4% ethanol and basal release of B-endorphin (BE) was determined during an 1 hr release experiment in the presence of either 0.2 or 0.4% ethanol. Incubation of AtT-20 and AP cells with 0.4% ethanol resulted in a consistent 25% reduction in basal release of BE. However, the content of BE did not change in either AP or AtT-20 cells following 24 hr incubation with 0.4% ethanol. To determine the effect of ethanol exposure on POMC biosynthesis, the levels of POMC messenger RNA in AtT-20, AP and IP cells were quantified by Northern-blot and slot-blot techniques. Ethanol produced a dose- and time-dependent decrease in POMC mRNA levels in AtT-20 cells. 24 hr treatment of AtT-20 cells with 0.2, 0.4 or 0.6% ethanol produced approximately 0, 60 or 80% decrease in POMC mRNA levels, respectively. Treatment of AtT-20 cells with 0.4% ethanol for 8, 12 or 24 hr produced a 40, 50 or 60% decrease in POMC mRNA levels, respectively. Similarly, treatment of AP cells with 0.2, 0.4 or 0.6% ethanol for 24 hr produced a 40, 60 or 60% decrease in POMC mRNA levels, respectively. Treatment of primary cultures of IP cells with ethanol produced changes in mRNA levels which were similar in magnitude to those observed with AtT-20 cells. The time- and dose-dependent effect of ethanol on POMC mRNA levels and not on BE release from AtT-20 and rat pituitary cells suggest that the effect of ethanol on BE release may not be related to the decreased POMC mRNA levels. Ethanol may decrease POMC mRNA levels by reducing the transcription of the POMC gene in AtT-20 and rat pituitary cells.

169.8 THE ANTIPSYCHOTIC DRUG HALOPERIDOL DECREASES STRIATONIGRAL SUBSTANCE P, SUBSTANCE K AND PREPROTACHYKININ mRNA. M.J. Bannon, J.-M.Lee*, P. Giraud*, A. Young*, H.-U. Affolter* and T. Bonner*. Dept. of Psychiatry, Yale Univ., School of Medicine, New Haven, CT 06508 and Lab. of Cell Biology, N.I.M.H., Bethesda, MD 20205.

Striatonigral substance P (SP)-containing neurons may influence, and in turn be modulated by, nigrostriatal dopamine (DA) cells. However, in contrast to nonpeptidergic neurotransmitters, measures of the turnover of SP and other peptides have been lacking. Previous studies have shown that repeated administration of DA antagonists decreases substantia nigra SP concentrations. Although the relationship between SP concentrations and SP utilization remains obscure, it has been generally accepted that the net decrease in SP after DA antagonists results from an imbalance between increased SP synthesis and an even greater acceleration of SP release. Recently, the tachykinin substance K (SK) has been identified as a cotransmitter with SP, although the function of this peptide and its response to DA antagonists is unknown. Two mRNAs derived from the preprotachykinin (PPT) gene by alternate splicing encode for either SP (α PPT mRNA) or SP and SK (β PPT mRNA). Quantitating changes in the levels of neuropeptide-encoding mRNA may provide a useful index of changes in brain peptide synthesis and utilization. In the present study, we assessed the effects of acute and chronic administration of the DA antagonist haloperidol (HALO) on the levels of nigral and striatal SP, SK and PPT mRNAs in single rat striata.

Acutely, HALO (1 mg/kg) did not alter either striatal or nigral SP or SK concentrations. 24 hrs. after one dose of HALO, striatal SP and SK were decreased. After 3-10 d of treatment, both striatal and nigral SP and SK were decreased by ~ 20-30%. Thus SK peptide concentrations change in parallel with its co-transmitter SP. Total (α and β)PPT, quantitated using an exon 7-derived genomic probe, decreased significantly 24 hr after one dose of HALO. Further decreases (~30-45%) in PPT mRNA were seen after 3-10 d of HALO. When βPPT was specifically quantitated using an exon 6-containing probe, similar results were obtained. Thus both α PPT (SP encoding) mRNA and β PPT (SP/SK encoding) mRNA decrease in parallel with SP and SK peptides. Contrary to the commonly held hypothesis, chronically administered DA antagonists apparently decrease striatonigral SP/SK synthesis. Quantitation of neuropeptide-encoding mRNA in discrete brain areas may provide a dynamic index of brain peptide synthesis.

169.9 CHLORIDE TRANSPORT AND METABOLIC ENERGY ARE ESSENTIAL FOR COPPER STIMULATION OF LHRH RELEASE FROM MEDIAN EMINENCE EXPLANTS.

M. Colombani-Vidal, A. Barnea, Depts of Ob-Gyn, Physiol, and Cecil H. and Ida Green Ctr, Univ of Tex Health Sci Ctr, Dallas, Tx 75235

We have previously shown that chelated copper stimulates the release of luteinizing hormone releasing hormone (LHRH) from axonal terminals located in the ME by a mechanism involving a ligand (chelator) specific interaction with a limited number of sites on the LHRH neuron. This interaction leads to release of the peptide by a process that does not require extracellular calcium. In this study, we assessed the Na^+, Cl^- and energy requirements for this release process. ME obtained from 8 weeks old male rats were incubated at 37°C with 100 µM CuHis ($CuCl_2$: Histidine; 1:1) in Krebs Ringer-phosphate buffer, pH 7.4 for 15 min (Phase I) and then in copper-free buffer for 15 min (Phase II). LHRH released into the medium was assayed by RIA. The characteristics of the copper-stimulated release process is such that net stimulated release in Phase I is 9.8 and in Phase II it is 20.8 pg/15 min per ME. Thus, maximal rate of stimulated release is attained after transfer of the ME to copper-free medium. Substitution of Na^+ with $Choline^+$ did not alter the copper-stimulated release of LHRH. In contrast, substitution of Cl^- with isethionate (reducing the Cl^- concentration from 135.6 to 3.6 mM), completely abolished stimulated LHRH release in Phase II but not in Phase I. In addition, when copper-stimulated release was evaluated in the presence of 135.6 mM Cl^- and an anion transport inhibitor (SITS, 4-acetamido-4'-isothiocyano-2,2'disulfonic stilbene), stimulated release was completely inhibited in both Phase I and II. This result is suggestive that stimulated release seen in Phase I, in the presence of 3.6 mM Cl^- and absence of SITS, is due to Cl^- transport. To assess the energy requirement for copper-stimulated release of LHRH, ME were incubated either at 4°C or at 37°C in the presence of a metabolic inhibitor (4 mM NaF). Stimulated release in Phase I and II did not occur at 4°C and it was inhibited by NaF by 50%. In summary, we demonstrate that the process of copper-stimulated release of LHRH from axonal terminals requires metabolic energy and Cl^- but not Na^+. Although Cl^- transport is essential for the accomplishment of the entire release process, the differential Cl^- requirement for Phase I and II is indicative that uptake of copper and initiation of the process of LHRH release requires less Cl^- than the acceleration and attainment of maximal rates of release.

169.10 INTRASTRIATAL INJECTION OF KAINIC ACID INCREASES THE ABUNDANCE OF mRNA CODING FOR PREPROENKEPHALIN A IN RAT HIPPOCAMPUS.

J. S. Hong, T. Kanamatsu, J. Obie, K. Yoshikawa*, and S. Sabol*. Lab. Behavioral and Neurological Toxicology, NIEHS/NIH, Research Triangle Park, NC 27709
*Lab. Biochemical Genetics, NHLBI/NIH, Bethesda, MD 20205

We have previously reported that intracerebral injection of kainic acid (KA) causes a robust increase in the concentration of (Met^5)-enkephalin-like immunoreactivity (ME-LI) in the rat hippocampus. In order to understand whether KA-induced elevation in ME-LI is due to an increase in biosynthesis or to a decrease in release, we measured the abundance of mRNA coding for preproenkephalin A ($mRNA^{enk}$) as an index of biosynthesis in different brain regions. Male Fischer-344 rats (Wilmington, MA) between 12-14 weeks of age were used. The coordinates for intrastriatal injection were: A, 7.4; L, 2.8; V, 0. Rats were injected with KA (1 mg/ml dissolved in 0.9% NaCl) at constant rate (1 ml min^{-1}) for one min. Concentrations of native (without enzyme digestions) and cryptic (after enzyme digestions) ME-LI were measured by RIA. The abundance of $mRNA^{enk}$ was measured using a cDNA clone coding for preproenkephalin A derived from rat brain. A single striatal injection of KA caused recurrent seizure activities lasting 3-6 h. During this period, there was a 30-40% reduction in the level of native ME-LI in the hippocampus. The ME-LI returned to control value 12 h postdosing and then showed a large rebound 24 h after postdosing (200% of control values); there was a three fold increase in ME-LI 72 h postdosing. The reduction in ME-LI during the convulsing period suggests an increase in the release of this peptide and the rebound in ME-LI in later phase may be due to an overproduction of ME. This possibility was supported by a sharp increase in the abundance of $mRNA^{enk}$ during the phase of recurrent seizures. The level of $mRNA^{enk}$ reached a plateau (4 fold increase) 6 h postdosing then declined linearly and returned to normal value 72 h after injection. The increase in the level of $mRNA^{enk}$ suggests an increase in the biosynthetic rate of enkephalin-containing neurons triggered by the seizure activities. This idea was further supported by the increase of cryptic ME-LI in the hippocampus during the convulsing phase when there was a decrease in native ME-LI. The level of cryptic ME-LI reached a maximum 24 h postdosing then gradually declined, presumably being processed to give rise to native ME-LI. KA-induced alterations in the enkephalin system appeared limited only to the hippocampus and the entorhinal cortex (the location of cell bodies of enkephalin-containing neurons which project to the dentate gyrus), but not in the striatum or hypothalamus. The present demonstration of a robust increase in the metabolic activity of entorhinal-hippocampal enkephalin-containing neurons may be related to several KA-induced behavioral alterations, such as wet dog shake or post-ictal depression.

169.11 KAINIC ACID HAS A BIPHASIC EFFECT ON ENKEPHALIN AND DYNORPHIN IMMUNOREACTIVITY IN RAT HIPPOCAMPUS. J. Obie*, T. Kanamatsu*, J.F. McGinty and J.-S. Hong (SPON: E.M. Lieberman) Lab. Behav. Neurol. Toxicol. NIEHS/NIH Research Triangle Park, NC 27709 and Dept. of Anatomy, East Carolina Univ. Sch. Med. Greenville, NC 27834.

We have previously reported that intracerebroventricular or intrastriatal injections of the excitatory amino acid, kainic acid (KA), cause an increase in met^5- or leu^5-enkephalin immunoreactivity (IR) in the hippocampus (Hong, et al., Nature 258:231, 1980; McGinty, et al., PNAS 80:589, 1983). The maximal increase occurs by 3 days and is sustained for at least two weeks after a single KA injection. Immunocytochemistry (ICC) revealed that the increase in enkephalin (IR) was most apparent in hippocampal mossy fibers but was also noticeable in the perforant-temperoammonic pathway of the hippocampus. Four days post injection, no change in dynorphin A (1-17) (IR) was apparent by radioimmunoassay (RIA) or ICC. In the present study, we conducted a more detailed investigation of the time course of changes in enkephalin (IR) and dynorphin A (IR) in rat hippocampus after intrastriatal injections of kainic acid. Male Fischer 344 rats were anesthetized with Equithesin and injected stereotactically with KA (1 mg in 1 ml of 0.9% NaCl) at a constant flow rate (1 µl min^{-1}) for one minute. Recurrent motor seizures lasted for 3-6 h. during which time met-enkephalin (IR) decreased 30-40% and dynorphin A (1-8) (IR) decreased 78% in the hippocampus. Twelve hours after KA, enkephalin (IR) had returned to 87% of the control value whereas dynorphin A (IR) was still depressed by 63%. Immunocytochemistry performed on 6 h. samples revealed a marked depletion in mossy fiber dynorphin A (IR) and a less severe decrease in hippocampal enkephalin (IR) at this time point. No changes in enkephalin (IR) or dynorphin (IR) were apparent by RIA or ICC in hypothalamus or striatum (uninjected side). By 48 h., hippocampal enkephalin (IR) had increased to 270% whereas dynorphin (IR) had increased to 171% of control values. Both mossy fiber dynorphin immunostaining and enkephalin immunostaining were visibly increased at this time. An increase in enkephalin (IR) in the perforant-temperoammonic pathway, especially in the ventral hippocampal formation, was also apparent. By 72 h., dynorphin A (IR) had returned to control values but enkephalin (IR) was still elevated at 300% of control values. The biphasic changes in enkephalin and dynorphin (IR) subsequent to a single intracerebral KA injection suggest that an increase in the metabolic rate of the perforant path-mossy fiber circuitry during KA-induced seizures results in an initial release of opioid peptides followed by an overproduction of each opioid peptide, a response which is greater for enkephalin than for dynorphin. A rapid, four-fold increase in met-enkephalin mRNA in the hippocampus and entorhinal cortex within 6 h. after KA administration (see Hong, et al. this volume) supports the idea of an increase in biosynthetic activity in enkephalinergic neurons in the perforant pathway and in mossy fibers triggered by KA-induced seizures. Supported by NS 20451.

169.12 **EVIDENCE FOR A POSITIVE FEEDBACK OF GROWTH HORMONE ON HYPOTHALAMIC SOMATOSTATIN BIOSYNTHESIS.** K. D. Stewart and J. F. McKelvy, Dept. of Neurobiology and Behavior, SUNY Stony Brook, NY 11794

Somatostatin is known to inhibit growth hormone (GH) release from the anterior pituitary and physiological evidence has suggested that GH may act via a short loop feedback to regulate its own release. Thus, it is possible that GH may influence the expression of somatostatin in hypophysiotropic neurons. We have investigated this possibility by carrying out direct studies in vivo on the de novo biosynthesis of somatostatin in control, hypophysectomized (HYPOX), and HYPOX-GH-replaced rats.

We developed methods to examine the in vivo biosynthesis of three peptides generated from the somatostatin precursor: somatostatin-14 (SS-14), somatostatin-28 (SS-28), and somatostatin-28(1-12) (SS-28(1-12)). The peptides are radiolabeled by stereotaxic infusion of ^{35}S-cysteine and ^{3}H-proline into the periventricular area of the hypothalamus and transported to the median eminence from which the labeled peptides are extracted and purified to constant specific activity by sequential HPLC and chemical modification. Using this technique we have found that following hypophysectomy radiolabeled SS-28(1-12) was decreased by 56%, SS-28 by 25%, and SS-14 by 32% (compared to control rats). When GH was administered to HYPOX rats somatostatin was stimulated compared to HYPOX levels: SS-28(1-12) by 1.50 fold, SS-28 by 1.90 fold, and SS-14 by 1.72 fold. This stimulation resulted in a partial restoration of the biosynthetic values observed in control animals; such that when compared to control animals SS-28(1-12) was decreased by 84%, SS-28 by 43%, and SS-14 by 55%. The biosynthesis and transport to the median eminence of oxytocin and vasopressin were also assessed in the same experiments (by ^{35}S-cysteine incorporation) and showed no consistent response to the experimental manipulations.

Thus, the removal of GH causes a decrease in somatostatin biosynthesis while GH replacement partially restores somatostatin levels. Somatostatin may therefore be one factor by which GH regulates its own levels.

169.13 BIOSYNTHESIS OF POMC-DERIVED PEPTIDES IN A DIFFERENTIATED EMBRYONAL CARCINOMA CELL LINE. J.A. Fuller*, J.M. Levine* and J. F. McKelvy. Dept of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, New York, 11794

The murine embryonal carcinoma cell line, O1A1, responds to retinoic acid by differentiating into neuron-like cells (Edwards and McBurney, Dev. Bio., 98:187, 1983). This differentiation process has recently been shown to resemble the terminal differentiation of neuroectodermal cells (Levine and Flynn, this volume). To characterize the phenotype of the differentiated neurons, we have investigated the possible expression of neuropeptides by these cells. Pro-opiomelanocortin (POMC)-like material was detected in differentiated O1A1 cells by indirect immunoflouresence. To validate the expression of POMC peptides by this cell line, and to explore it's possible utility in studying POMC biosynthesis and processing and the induction of POMC gene expression, the de novo synthesis of POMC-derived peptides was studied.

Cells were induced to differentiate by treatment with retinoic acid and grown for 3-5 days in monolayer. They were then starved for 2 hrs in serum-free DME without methionine, and then 70 uCi/ml ^{35}S-methionine was added to the media. After a 6 hr. incubation, 50 ug of carrier peptides were added, the media harvested and the cells lysed in 5N formic acid. The acid-soluble lysate was added to the media, desalted and lyophilized.The material was then trypsin digested, oxidized, and subjected to sequential HPLC purification. After four HPLC separations the peptides were generally purified to constant specific radioactivity.

Both trypsin-digested Beta-Endorphin and acetylated and non-acetylated MSH's were detected. If all three peptides are digested with trypsin, then MSH- and Beta-Endorphin-like material is approximately equimolar, implying that a large amount of the material is in the precursor form. MSH and des-acetyl-MSH material occur in a ratio of 3:1. Non-differentiated cells produce some POMC related material, but show backround levels of immunoflouresence.

Thus, it appears possible to use an in vitro system to study the synthesis and processing of POMC related peptides resembling that found in the CNS and intermediate lobe. Studies are under way to determine this cell line's responsiveness to signals thought to regulate POMC expression, synthesis, and processing in neurons. (Supported by NIH NS 20372 and NS 21198)

169.14 MULTIPLE PRODUCTS DERIVED FROM OPIOID PEPTIDES. E.A. Young* and H. Akil. (SPON: S.Watson) Mental Health Research Institute, University of Michigan, Ann Arbor, MI, 48109

The presence of multiple active cores within the same peptide is well known. For example, the sequence of alpha-MSH is contained within the sequence of ACTH, the sequence of beta-endorphin is contained in beta-lipotropin, the sequence of dynorphin A 8 is contained in dynorphin A, and the enkephalin sequences are contained in all opioid peptides. Tissue-specific and species specific processing of precursor hormones to differing end products is well described. For instance, beta-lipotropin and ACTH are the preferred end products of pro-opiomelanocortin (POMC) processing in the anterior lobe of the pituitary, while beta-endorphin and alpha-MSH are the predominant products of POMC processing in the neurointermediate pituitary. Likewise, in pituitary and many regions of brain, dynorpin A is further processed to dynorphin A 8. Whether dynorphin A can be further processed to leu-enkephalin is still a matter of speculation. In addition to differences in forms released across tissues, there may be sub-populations of releasable pools within any particular tissue, so that the overall ratio of material stored does not necessarily correspond to what is released. Thus, tissue specific processing and different releasable pools are two different ways to encode multiple messages in the some precursor. Still another strategy exists, that is the conversion of one active peptide to another after release. Such post-release conversion has been seen in non-opioid systems such as the conversion of angiotensinogen to angiotensin I, and subsequently to angiotensin II and III in its target organ. Such post release conversion has not been well explored in opioid peptide systems. Using dynorphin A as a model system, we characterized the bio-transformation of dynorphin A to other biologically active peptide fragments in brain.

Radiolabelled ^{3}H dynorphin A was incubated with membrane fragments of rat whole brain at 0°C for varying time periods from 15 minutes to one hour. After incubation, the suspensions were microfuged and the supernatant pooled and lyophilized for subsequent application to HPLC. Using the radioactivity as a marker, as well as radioimmunoassay of the HPLC fractions, we were able to demonstrate the production of ^{3}H tyrosine from dynorphin A . In addition, a smal peak of radioactivity co-migrated with leu-enkephalin. *In vivo* injection of ^{3}H dynorphin A into the periaqueductal grey (PAG) in cannulated rats demonstrated extremely rapid conversion of dynorphin A to ^{3}H tyrosine and des-tyrosine dynorphin A (demonstrated by RIA of the HPLC fractions). Again, a small peak of radioactivity co-migrated with leu-enkephalin. We are currently seeking further indentification of this possible leu-enkephalin peak. Since both des-tyrosine dynorphin A and leu-enkephalin are biologically active peptides, it does appear that post-release conversion of one active peptide to another occurs in brain. We are also exploring another model system, that is the peripheral conversion in plasma of circulating opioid peptides to other biologically active peptides.

169.15 **MOLECULAR FORMS OF IMMUNOACTIVE ATRIAL NATRIURETIC PEPTIDE IN THE RAT HYPOTHALAMUS AND ATRIUM.** **G.M. Wildey*, T.R. Gibson*, and C.C. Glembotski.** Department of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Recent studies have demonstrated that mammalian atria contain peptides that are important diuretic, natriuretic, and vasodilatory agents. Several laboratories have isolated various forms of these atrial natriuretic peptides (ANP) which range in length from 21 to 125 amino acids. At the present time there exists little agreement on the major molecular forms of ANP that are present in the atrium or the plasma. All of these peptides possess a common COOH-terminal sequence, and are likely derived from a common precursor which has been sequenced in rats, mice and humans. The atrial peptides exert their effects on well-characterized receptors localized to the vascular smooth muscle cells, kidney, and adrenals. Extra-cardiac locations of the atrial peptides have been identified by immunohistochemistry; among these locations is rat hypothalamus. Receptors for ANP have also been localized to several brain regions and a role for ANP-related peptides in the CNS regulation of cardiovascular function has been implicated. Since the atrial peptides have potentially important endocrine and neurotransmitter activities, a study was undertaken to compare the molecular forms of these peptides derived from the heart and the hypothalamus. Acetic acid extracts of rat hypothalamus and atrium were prepared by a procedure previously shown to minimize proteolytic degradation of peptides. An antisera crossreactive with the COOH-terminal regions of ANP-related peptides was utilized to characterize molecular forms. The hypothalamic extracts contained about 13 ng of ANP per animal, whereas the atrial extracts contained about 30 µg of ANP per animal. The majority of the immunoactive material in the atrial extracts had a molecular weight of approximately 9,000 to 15,000 daltons when analyzed by HPSEC or Sephadex G-75 gel filtration. This suggests that few cleavages of pro-ANP (19,000 daltons) take place in the rat atrium. (These large molecular weight forms of ANP have been previously shown to possess full biological activity.) In hypothalamic extracts the major immunoactive species was about 1,500 to 1,800 daltons. The major molecular weight forms of ANP from each extract were further differentiated by RP-HPLC in a TFA/acetonitrile solvent system. The hypothalamic material eluted at 42% acetonitrile, while the atrial material eluted at 55% acetonitrile. These results suggest that the hypothalamus and atrium may differentially process pro-ANP to form tissue-specific product peptides. Supported by NIH Grant NS20396 and American Heart Grant-in-Aid 84 653

169.16 INFLUENCE OF MICROWAVE IRRADIATION ON ENDOGENOUS RAT BRAIN BRADYKININ LEVELS. K.E. Eason*, H. Okamoto*, L.M. Greenbaum* and J.J. Buccafusco. (SPON: D.S. Feldman). Dept. Pharmacology and Toxicology, Medical College of Georgia and Veterans Administration Medical Center, Augusta, GA 30912.

Bradykinin (BK) is a potent vasoactive peptide in the peripheral circulation. There also is considerable evidence to indicate that BK may function as a neurotransmitter in the brain. Current methods of measuring endogenous brain BK involve the aortic perfusion of a peptidase containing medium in anesthetized rats to 1) kill the animal and 2) prevent BK metabolism in brain tissue and cerebral blood. The tissue is removed and frozen in liquid N_2, followed by a multi-step extraction and chromatographic procedure. Levels of BK have been reported to be ~0.6 pmoles/g tissue (J. Neurochem. 43, 1072, 1984). The purpose of this study was to determine whether focused microwave irradiation could be employed to stabilize BK levels in postmortem tissue. Kallikrein and kininase activities were measured to assure complete inactivation of enzymes involved in release and destruction, respectively, of blood and brain BK. Male, Wistar rats were subjected to focused microwave irradiation (2450 MHz, 3.8 KW) directed at the skull for periods of 1.6, 1.8, 2.1, 2.45 and 2.9 sec. Whole brains were then removed and homogenized in 1M Tris-HCl, pH 8.0 containing 0.15M NaCl. Analysis of enzyme activity revealed that both enzymes were inactive when the irradiation period was at least 2.45 sec. Shorter periods and/or incomplete irradiation resulted in significant enzyme activity. Kininase was more heat-resistant than kallikrein, requiring longer and more thorough irradiation to be inactivated. Therefore, for the BK assay, animals were subjected to at least 2.45 sec of irradiation and the brains removed and homogenized in buffer containing ^{3}H-BK (to calculate recovery). NaCl was added to the supernatants obtained after centrifugation to salt out lipids prior to application to a reverse phase C_{18} extraction column and elution with 50%ACN : 1%TFA. After lyophillization, aliquots of reconstituted extracts were removed to determine % recovery and to measure levels of BK by radioimmunoassay. BK levels from individual brain samples were 0.7±0.075 pmoles/g with values ranging from 0.2 to 2 pmoles/g. Percent recovery of ^{3}H-BK was ~64%. These findings suggest that 1) adequate microwave irradiation of the brain allows the determination of values for BK in brain samples consistent with those obtained by employing more complex perfusion techniques, and avoids the use of anesthetics; and 2) the variability in BK levels obtained from individual animals is not related to incomplete inactivation of kininase or kallikrein. The nature of this variability is under investigation. Supported by HL30046 and the Veterans Administration.

169.17 CHOLECYSTOKININ GENE-RELATED PEPTIDES: THEIR SUBCELLULAR DISTRIBUTION IN RAT BRAIN. L.R. Allard* and M.C. Beinfeld* (SPON: M.H. Cooper). Department of Pharmacology, St. Louis University Medical Center, St. Louis, MO 63104.

Antisera raised against synthetic peptides D-10-Y comprising the carboxy-terminal extension of cholecystokinin (CCK) and V-9-M specific for the amino-terminus of pro-CCK were used in specific radioimmunoassays to study the subcellular distribution of such immunoreactive peptides in rat brain. Subcellular fractionation of whole rat brain determined what cellular component was enriched in these peptides. The molecular weights of D-10-Y-like and V-9-M-like immunoreactive peptides enriched in various subcellular fractions were determined by Sephadex G-50 chromatography.

Primary subcellular fractionation yielded a mitochondrial (P2) and microsomal (P3) fraction, both of which were enriched in D-10-Y and V-9-M-like peptides. Furthermore, a slight enrichment of V-9-M-like immunoreactivity was observed in the soluble fraction (S3). Further purification of the P2 fraction demonstrated an increase of D-10-Y-like and V-9-M-like immunoreactivity in purified synaptosomes. With the exception of the enrichment in the soluble fraction, V-9-M-like peptides as well as D-10-Y-like peptides follow a similar distribution to that of CCK 8-like peptides.

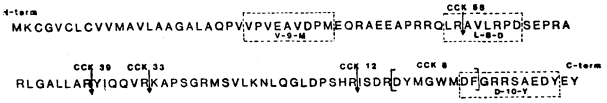
Sephadex chromatography of P2 and P3 fractions indicated the major forms of D-10-Y and V-9-M present. Whole rat brain contains two major molecular forms of D-10-Y-like immunoreactivity, one similar in size to CCK 33 and one slightly larger than CCK 8. In the P2 and P3 fractions, most of the D-10-Y-like immunoreactivity resembled the molecular form slightly larger than CCK 8. Rat brain contains three major V-9-M-like peptides with molecular weights of about 13,000, 8,000 and 2,700. The latter form predominates. The major form of V-9-M present in P2 and P3 fractions has a molecular weight of about 2,700.

It is likely that the D-10-Y-like immunoreactive peptide is an intermediate in the processing of CCK 8, and its enrichment in nerve endings is consistent with the final cleavage and amidation taking place in nerve terminals. The V-9-M-like peptide may represent an intermediate in the processing of CCK, and its presence in synaptosomes may indicate that the proteolytic cleavage of pro-CCK into CCK 58 and the 2,700 form takes place in synaptic vesicles. It is also possible that this amino-terminal portion of pro-CCK may be released along with CCK and play a role in synaptic transmission.

Supported by NS18335 and NS18667 (N.I.H.).

169.18 CHOLECYSTOKININ GENE-RELATED PEPTIDES: THEIR DISTRIBUTION, IMMUNOLOGIC, AND CHROMATOGRAPHIC CHARACTERIZATION IN RAT BRAIN AND SMALL INTESTINE. M.C. Beinfeld* and L.R. Allard* (SPON: N.A. Connors). Department of Pharmacology, St. Louis University Medical Center, St. Louis, MO 63104.

Utilizing the sequence of rat pre-pro cholecystokinin (CCK), synthetic peptides were produced which correspond to different portions of the pre-pro sequence. These peptides (illustrated below) have been used to develop specific radioimmunoassays (RIA) to detect CCK gene-related peptides (CGRP). These antisera detect substantial amounts of CGRP in both rat brain and small intestine. The molecular forms of these immunoreactive peptides have been characterized by Sephadex gel filtration chromatography and their distribution has been mapped with the peptide RIAs.



D-10-Y-like peptides: Antiserum against the fragment D-10-Y (which does not cross react with CCK 8 or related peptides) detects moderate amounts of immunoreactivity in brain (13.8 ng/g wet wt.) and intestine (53.8 mucosa, 15.8 muscle). Brain D-10-Y-like immunoreactivity emerged as two major peaks on Sephadex G-50 chromatography, one similar in size to CCK 33 and one slightly larger than CCK 8. It is likely that these D-10-Y-like peptides represent carboxyl-terminally extended forms of CCK 33 and CCK 8.

L-8-D-like peptides: Antiserum against L-8-D detects small amounts of immunoreactivity in brain (6.3), but larger amounts in intestine (in progress). In brain a single peak of immunoreactivity with molecular weight of about 1750 daltons was obtained, which probably represents the amino-terminal portion of CCK 58 remaining when CCK 39 is removed.

V-9-M-like peptides: Antiserum against V-9-M detects large amounts of peptide immunoreactivity in brain (104) and intestine (203 mucosa, 83 muscle). Several V-9-M-like immunoreactive peptides were detected in rat brain with molecular weights of about 13,000, 8,000, 2,700, and 1,700. The high molecular weight peaks probably represent different forms of pro-CCK, while the smaller forms are probably amino-terminal fragments of pro-CCK.

The CCK-gene-related peptides are present in both the brain and duodenum, and probably represent intermediates in the processing of CCK. Differences observed in molecular forms of CGRP in brain and intestine are consistent with differential processing of pro-CCK in brain and gut.

Supported by NS18335 and NS18667 (N.I.H.).

169.19 AN EVALUATION OF EXTRACTION TECHNIQUES FOR NEUROPEPTIDES IN HUMAN BRAIN. David W. Ellison, M. Flint Beal, Michael F. Mazurek and Joseph B. Martin. Dept. of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Several studies have shown alterations in neuropeptides in degenerative brain disorders. However, there has been no systematic study of the extraction techniques used in determining levels of neuropeptides. We measured the immunoreactivity of somatostatin (SS), neuropeptide Y (NPY) and vasopressin (AVP) in human parietal cortex after processing with one of five solvents: water, 90% methanol, 0.1 N hydrochloric acid (HCL), 0.1 N perchloric acid (PCA) and 2N acetic acid (HAc). The following procedures were evaluated alone or in combination: boiling, sonication, homgenization with mortar and pestle, freeze-thaw and polytron homogenization. Data are expressed per mg protein.

SS was extracted most efficiently by boiling in 0.1 N HCl (1.1 $\pm$ 0.09 ng) followed by boiling in 2N HAC (0.7 $\pm$ 0.07 ng) which both gave significantly better ($p<0.01$) results than boiling in water (0.1 $\pm$ 0.02 ng), homogenizing in 90% MEOH (0.1 $\pm$ 0.03 ng) or boiling in PCA (0.03 $\pm$ 0.001 ng). A similar pattern was seen for NPY, although 2N HAC (5.5 $\pm$ 0.34 ng) gave the best yield followed by 0.1 N HCl (4.6 $\pm$ 1.4 ng). When both these peptides were sonicated after boiling there was a marked and significant ($p<.001$) reduction in immunoreactivity (SS: 0.70 $\pm$ .07 to 0.32 $\pm$ 0.03 ng; NPY 5.5 $\pm$ .3 to 3.1 $\pm$ .2 ng). Increases in duration and intensity of sonication caused step-wise reductions in SS. HPLC characterization of somatostatin immunoreactivity showed that there was no alteration in the molecular weight species. Boiling followed by sonication had no effect on AVP. This peptide was extracted well in 0.1N PCA (0.21 $\pm$ 0.02 pg for boiling alone) in addition to 2N HAC and 0.1 N HCl; the best yield was produced by boiling and sonication in 0.1 N HCL (0.36 $\pm$ 0.04 pg). Extraction of protein, a frequent denominator in expressions of neuropeptide levels, varied relative to initial weight of tissue. Typically, extraction in HAc, HCl and PCA gave values of 8%, 10% and 12% mg prot/gm wet weight respectively.

The results suggest that careful evaluation of extraction procedures is critical in the determination of neuropeptide concentrations in human brain tissue. Sonication appears to be detrimental to extraction of several neuropeptides. The best solvents were 0.1N HCl and 2N HAC and simply boiling was as effective as any other procedure.

Dr. Ellison is a Wellcome Trust research fellow. Supported by NINCDS grant NS16367 and NIA grant IP50AG05134.

169.20 ISOLATION OF ADIPOKINETIC HORMONE-LIKE IMMUNOREACTIVE PEPTIDES FROM THE RAT MEDIAN EMINENCE. P.A. Schueler* and R. Elde. Dept. of Anatomy, University of Minnesota, Minneapolis, MN 55455

Adipokinetic hormone (pGlu-Leu-Asn-Phe-Thr-Pro-Asn-Trp-Gly-Thr-NH_2) was originally isolated from extracts of locust corpora cardiaca. In order to characterize the occurrence of neurons that produce this and similar peptides, we produced an antiserum against the Tyr^o analog of adipokinetic hormone. In addition to staining neurons in several arthropods, the antiserum stained a unique population of neuronal elements in rat median eminence, substantia gelantinosa and sacral parasympathetic nucleus of the spinal cord, and cerebral cortex, as well as certain cells of the pancreatic islet (Sasek, et al., Brain Res., in press). The antiserum also reacted with some cells in human pancreatic islets.

In order to characterize the molecular nature of the immunoreactive substance, 175 rat median eminences were extracted in 0.1% trifluoroacetic acid: 40% 1-propanol and chromatographed using reversed-phase high performance liquid chromatography (HPLC). Using the antiserum as the detection system in an immunoblotting paradigm, the HPLC fractions were screened for immunoreactivity. After repeated HPLC runs and high voltage electrophoresis the immunoreactive peaks were purified to homogenity. The amino acid compositions from each of the two peaks appeared to represent new neuropeptides, heretofore unidentified in the rat. Immunoreactive material with an identical retention time to that of the rat median eminence peptides was found in rat neonatal pancreas, and 2 cell lines; a rat medullary thyroid carcinoma (CA-77) and a clonal hamster beta cell line (HIT). This work further validates the approach of using antisera directed against invertebrate peptides to identify new neuropeptides in higher vertebrates.

Supported by the Graduate School, University of Minnesota, the Minnesota Medical Foundation and ImmunoNuclear Corporation.

170.1 SEROTONERGIC MODULATION OF DOPAMINE SYSTEM IN THE RAT NUCLEUS ACCUMBENS. H.S. Kim* and P.L. Wood, Neuroscience Research, Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, NJ 07901.

Electrolytic lesions of the dorsal (Neurosci. Lett. 15:127, 1979) and medial (Brain Res. 216:422, 1981) raphe have been reported to selectively elevate dihydroxyphenylacetic acid (DOPAC) in the rat nucleus accumbens. These data would suggest that the nucleus accumbens receives a tonic inhibitory input from the raphe. To test this hypothesis, we have evaluated the actions of the S-2 antagonist cinanserin on dopamine metabolism in the rat striatum and nucleus accumbens. The levels of dopamine, DOPAC, homovanillic acid and 3-methoxytyramine (3-MT) in tissue punches from 1 mm slices of microwaved rat brain were measured by gas chromatography-mass fragmentography (Biomed. Mass Spectrom. 9:302, 1982).

DOPAC levels were elevated (130 - 150% of control) 30 to 120 min after cinanserin (5 - 10 mg/kg i.p.). Homovanillic acid (140 - 160% of control) and 3-MT levels (200% of control) also were increased, with no change in dopamine steady-state levels. Using pargyline (75 mg/kg i.p.) to monitor the rate of accumulation of 3-MT and the decline in DOPAC, a 38% increase in the fractional rate constant for DOPAC was measured. Dopamine metabolites in the striatum were unaltered.

In summary, our data further support the hypothesis that the nucleus accumbens receives a tonic serotonergic inhibitory input to the dopamine cells innervating this forebrain nucleus. Furthermore, our data clearly indicate that when this input is disrupted both dopamine synthesis and release are augmented in the rat nucleus accumbens.

170.2 INTERACTION BETWEEN 5-HYDROXYTRYPTAMINE AND THYROTROPIN RELEASING HORMONE IN THE RAT SPINAL CORD. Louis E. Tremblay*, P.J. Bédard and R. Maheux* (SPON: C. Radouco-Thomas). Laboratory of Neurobiology, Hôpital de l'Enfant-Jésus, Québec, G1J 1Z4, Department of Anatomy, Laval University, QUEBEC, CANADA, G1K 7P4.

Thyrotropin releasing hormone (TRH) and 5-hydroxytryptamine (5-HT) coexist in descending bulbospinal pathways in the rat. (Hökfelt et al. Neural peptides and neural communication, 1-23, 1980). This coexistence suggests a functional relationship and indeed we have shown (Barbeau and Bédard, Neuropharmacology, 20: 477, 1981) that 5-HTP and TRH have a similar excitatory action on motoneuronal discharges and that the action of both compounds is enhanced by previous denervation by 5-7 Dihydroxytryptamine (5-7 DHT) and blocked by the 5-HT antagonist cyproheptadine. In the present work we have studied the effect of a single dose of TRH (10 mg/kg i.p.) or of chronic administration of the tripeptide (20 µg/2.5 µl/hour) with an intrathecal cannula and osmotic minipump on the subsequent response to 5-HTP 100 mg/kg i.p. The response studied and quantified was the spontaneous EMG activity of the hindlimb extensor muscles in rats spinalized twenty four hours before but pretreated or not twenty one days before with 5-7 DHT. Such denervation, by itself increased the response to 5-HTP to 160% of control. However, chronic treatment with TRH further increased the response to 5-HTP to 297% of controls. Animals treated chronically with vehicle showed no such increase. In such a denervated preparation, a single injection of 10 mg/kg i.p. of TRH had no potentiating effect on the response to 5-HTP one hour or twenty four hours later. Thus, in a chronically denervated spinal cord, chronic, but not acute treatment with TRH can increase the sensitivity of spinal neurons to 5-HT. The present results may help understand the functional reason for the coexistence of 5-HT and TRH in the same pathways. Supported by MRC of Canada, MT-5750.

170.3 REDUCTION AND RECOVERY OF THE CAT VISUAL EVOKED RESPONSE FOLLOWING ACETYLCHOLINESTERASE INHIBITION: INVOLVEMENT OF PUTATIVE NEUROTRANSMITTERS OTHER THAN ACETYLCHOLINE. A.W. Kirby and T.H. Harding* U.S. Army Aeromedical Research Laboratory, Ft. Rucker, AL 36362.

We previously have demonstrated a preferential loss in the VER to low spatial frequency stimulation with relative sparing of responses to higher spatial frequencies following physostigmine or diisopropyl fluorophosphate (DFP - an irreversible AChE inhibitor). Following DFP, the VER recovers to within a standard deviation of baseline measures within 10 to 20 hours without significant recovery of AChE activity. A second dose of DFP no longer reduces the VER, although administration of picrotoxin does. There is evidence in the literature that dopamine, GABA, and possibly other neurotransmitter systems might alter their activity to compensate for excess ACh. It also is likely that some neurotransmitter systems do not compensate for cholinergic hyperactivity, but are altered by increased activity in cholinergic interneurons. We report here results from HPLC analysis of retina and visual cortex following DFP administration.

Anesthetized and paralyzed adult cats were held in a stereotaxic headholder and fitted with appropriate corneal and auxiliary lenses to focus one eye onto a cathode ray tube. The other eye and a small sample of visual cortex were removed for determination of baseline neurotransmitter levels. VERs were recorded from stainless steel bone screws over visual and parietal cortex using phase alternated square wave luminance gratings as a stimulus. Following baseline response measures and initial determination of AChE activity, 4 mg/kg DFP was given i.v. over 1 minute. After a variable period of survival, animals were sacrificed and the other eye and additional visual cortex removed and prepared for HPLC analysis. Tissue was homogenized in 0.1M $HClO_4^-$ containing 0.1 mg/ml cysteine. The sample was centrifuged at 5000 rpm for 3 minutes after which the supernatant was removed, filtered through 0.45 micron filters, and injected through an HPLC system using electrochemical detection for catecholamines and indoleamines and precolumn derivitization with fluorescence detection for amino acids. The tissue pellet was resuspended in an equal volume of 1.0N NaOH and assayed for protein.

Our results demonstrate tremendous variation in catecholamines, indoleamines, and amino acids between different animals. However, using each animal as its own control, our results demonstrate a consistent increase in cortical GABA, a reduction in cortical serotonin (up to 4 and 5 times control levels, respectively), and little or no change in dopamine, following DFP. Our evidence suggests that the decrease in serotonin may be stress related. The increase in GABA certainly would explain our earlier results with picrotoxin. In retina there is a consistent decrease in dopamine (as much as 8 times), GABA (30%), and glycine (22%).

170.4 α-ADRENERGIC AND $GABA_B$ RECEPTOR-MEDIATED POTENTIATION OF cAMP ACCUMULATION IN RAT BRAIN SLICES: POSSIBLE INVOLVEMENT OF PHOSPHOLIPASE A_2. R.S Duman*, E.W. Karbon* and S.J. Enna (SPON: S.J. Strada). Depts. Pharmacol. and of Neurobiol. and Anat., Univ. Texas Med. School, Houston, Texas 77025.

Cyclic AMP production in brain slices appears to be regulated by at least two different receptor mechanisms. Receptors for isoproterenol (ISO), adenosine and VIP appear to be directly associated with adenylate cyclase through a guanine nucleotide binding protein. Other agents, such as the α-adrenergic agonist 6-fluoronorepinephrine (6-FNE) and the $GABA_B$ receptor agonist baclofen, appear to act at sites that are indirectly linked to this second messenger system. Thus, neither 6-FNE nor baclofen alone have any significant effect on cAMP production, although both greatly potentiate the responses to ISO, adenosine and VIP. Experiments were undertaken to define the mechanism whereby 6-FNE and baclofen facilitate cAMP formation. For the study, rat brain cerebral cortical slices were prelabeled with ^{3}H-adenine and ^{3}H-cAMP formation measured using a double column technique. Experiments with EGTA revealed that the ability of 6-FNE or baclofen to potentiate the cAMP response to ISO was totally dependent upon the presence of extracellular Ca++. Additional studies indicated that quinacrine, an inhibitor of the calcium-dependent enzyme phospholipase A_2 (PLA_2), abolished the potentiating responses to 6-FNE and baclofen in a noncompetitive manner. Systemic administration of corticosterone, a hormone known to reduce PLA_2 activity, significantly attenuated the cAMP potentiating action of 6-FNE in rat brain slices. Neither the lipoxygenase inhibitor nordihydroguaiaretic acid, nor a variety of cyclooxygenase inhibitors had any significant effect on the potentiating actions of 6-FNE and baclofen. The results suggest that α-adrenergic and $GABA_B$ receptors may influence neurotransmitter-stimulated cAMP formation by activating PLA_2 and enhancing fatty acid production. The negative results with the lipoxygenase and cyclooxygenase inhibitors suggests that fatty acid metabolites (e.g. prostaglandins and leukotrienes) may not be involved in this response. This implies that arachidonic acid itself may mediate the potentiating action of these substances on cAMP formation. (Supported in part by USPHS grants MH-35945 and MH-00501, and by grants from the National Science Foundation and Bristol-Myers, Inc.).

170.5 PHARMACOLOGICAL DIFFERENTIATION BETWEEN RECEPTORS COUPLED TO PHOSPHOINOSITIDE METABOLISM AND cAMP PRODUCTION IN BRAIN TISSUE. C. Chiappetta*, D.A. Kendall*, A. Pilc*, R.S. Duman* and S.J. Enna. (SPON: M.J. Schmidt). Depts. Pharmacol. and of Neurobiology and Anat., Univ. of Texas Med. School, Houston, Texas 77025, and Dept. Pharmacol., Univ. Leicester, Leicester, England.

Activation of α-adrenergic receptors by norepinephrine (NE) stimulates phospholipase C which catalizes the conversion of phosphoinositides to inositol phosphates (IP) and diacyglycerol. These latter agents serve as second messengers in a variety of tissues, including brain. Selective α-adrenergic receptor agonists such as 6-fluoronorepinephrine (6-FNE) increase IP formation and potentiate transmitter-stimulated cAMP production although they have little effect on cyclic nucleotide accumulation themselves. Experiments were undertaken to examine whether there may be a functional relationship between effects on phosphoinositide metabolism and cAMP formation in brain. cAMP and IP production were examined in rat brain cerebral cortical slices by prelabeling with either ^{3}H-adenine or ^{3}H-inositol. Concentration -response studies indicated that prazosin, a selective α_1-adrenergic antagonist, completely inhibited NE-stimulated IP formation with an EC_{50} of 30 nM. The α_2-adrenergic receptor antagonist yohimbine was ineffective up to a concentration of 1 μM. Conversely, a saturating concentration (10 μM) of prazosin inhibited only 25% of the α-adrenergic-potentiated cAMP formation in brain slices, whereas yohimbine completely abolished this response without influencing the β-adrenergic receptor component. Like 6-FNE, carbachol and serotonin enhance IP formation in this system but, unlike the α-agonist, neither potentiated the cAMP response to isoproterenol, adenosine or VIP. These results suggest that adrenergic receptors coupled to IP formation in rat brain cortex are prazosin-sensitive, whereas those associated with cAMP production are more sensitive to yohimbine. Furthermore, the lack of correspondence between carbachol and serotonin-stimulated IP production and cAMP formation indicates that either the receptors for these substances are not located on cerebral cortical cells possessing β-adrenergic, adenosine or VIP receptors, or that phosphoinositide metabolism is unrelated to cAMP production under these conditions. (Supported in part by USPHS grants MH-35945 and MH-00501).

170.6 EPINEPHRINE AND NOREPINEPHRINE SELECTIVELY ALTER RESPONSES TO EXCITATORY AMINO ACIDS IN THE FROG SPINAL CORD. C.J. Wohlberg, J.C. Hackman, and R.A. Davidoff. Depts. of Neurology and Pharmacology, Univ. of Miami Sch. of Medicine, and Neurophysiology Laboratory, V.A. Medical Center, Miami, Fl., 33101.

The reported ability of catecholamines (CAs) to modulate reflex transmission within the spinal cord may be caused by affecting neuronal responses to other transmitters. Since the excitatory amino acids (EAAs) L-glutamate (GLU) and L-aspartate (ASP) appear to mediate much of the excitatory synaptic activity in the cord, these compounds may be targets for the modulating actions of CAs. To explore this hypothesis, potentials were recorded from the ventral root (VR) of the in vitro, hemisected frog spinal cord utilizing sucrose gap techniques.

As expected, the bath application of either GLU or ASP (1 mM, 10-30 sec.) depolarized motoneurons (GLU: 6.3 +/- 0.1 mV; ASP 6.6 +/- 0.2 mV). Application of the selective EAA agonists N-methyl-D-aspartate (NMDA), kainate (KA) or quisqualate (QUIS) also resulted in large depolarizations of the membrane potential (NMDA, 100 uM, 8.5 +/- 0.05 mV; KA, 10 uM, 9.9 +/- 0.3 mV; QUIS, 10 uM, 7.9 +/- 0.7 mV; all 10 sec.). In contrast, the addition of NE or Epi (20 uM, 30 sec.) produced a dose dependent hyperpolarization of the membrane potential which was much slower in onset and longer in duration (NE, 0.66 +/- 0.1 mV; Epi, 0.79 +/- 0.1 mV). The difference in amplitude between NE and Epi was significant ($p<0.01$).

Exposure to Epi or NE prior to the application of the EAAs altered the amplitude of the EAA depolarization. Epi (20 uM, 30 sec.) diminished the amplitude of the depolarization resulting from the application of GLU, ASP, KA, and QUIS (25.5 +/- 3; 23.9 +/- 0.6; 17.2 +/- 3.2; 51 +/- 18.9 % reductions, respectively, $p<0.05$; GLU, 17 +/- 2.5; ASP, 7 +/- 0.5% reductions with 20 uM NE). On the other hand, prior addition of 20 uM Epi increased the area of the NMDA-induced depolarization (12.5 +/- 0.1% increase, $p<0.05$). This effect was also seen with the beta agonist isoproterenol (ISO, 10 - 100 uM, 30 sec., 24.6 +/- 0.1 % increase, $p<0.05$)

The use of selective adrenoceptor antagonists allowed us to study the effects of the CAs further. Yohimbine (10 uM,30 min.) or piperoxan (10 uM,30 min), both selective alpha$_2$-antagonists, blocked the Epi and NE induced diminution of the QUIS response, while propranolol, a beta-antagonist, blocked the potentiating effects of Epi and ISO on the NMDA response (10 uM, 30 min. PROP).

Thus, the application of Epi or NE to the cord prior to the EAAs GLU, ASP, KA or QUIS results in a decrease in the amplitude of the EAA-induced depolarization. This effect appears to operate through alpha$_2$-adrenoceptor activation. On the other hand, Epi and ISO potentiate the depolarizing effects of NMDA, apparently through activation of a beta receptor. Supported by NIH grants NS 17577, HL 07188T, and VA Medical Center Funds MRIS 1769 and MRIS 3369.

170.7 TRANSMITTER INTERACTIONS IN THE STRIATUM OF THE RAT STUDIED IN VIVO WITH PUSH-PULL CANNULA. M.T. Ciancone* and W.J. McBride (SPON: J.I. Nurnberger). Dept. Psychiatry, Inst. Psych. Res., Indiana Univ. Sch. Med., Indianapolis, IN 46223.

Studies were undertaken in our laboratory toward the development of a method for examining in vivo transmitter actions and interactions in the CNS of conscious, freely-moving rats. The push-pull cannula technique was employed to perfuse areas of the striatum both for adding test agents and for collecting perfusates for subsequent HPLC analysis of dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA).

Adult male Wistar rats were used in this study. Under pentobarbital anesthesia, a guide cannula was implanted stereotaxically over the left caudate nucleus. After a one-to two-day recovery period, a vented push-pull cannula was introduced via the guide into the caudate. An adjustable feature of the cannula allowed variable depths to be reached, thus renewing the site perfused in successive experiments with the same animal. Krebs-Ringer medium, equilibrated with 95% O_2/5% CO_2, was circulated through the system at a flow rate of 20 μl/min using a peristaltic pump. Experiments began after an initial 20-minute washout period. First, two 20-minute fractions were collected for baseline values. Initial baseline values for DA were 10-50 fmol/min. Initial baseline values for DOPAC and HVA were 200-700 fmol/min. Throughout the course of an experiment (4 or more hours) the baseline release of DA usually did not increase but did sometimes decrease below detectable levels. On the other hand, DOPAC and HVA efflux had a tendency to increase with time, sometimes reaching values of 1000 fmol/min and higher. At these later times, the efflux of DOPAC was usually 200-400 fmol/min higher than the efflux of HVA. In order to provide evidence that the site being perfused was viable, and to mimic certain in vitro conditions, 35 mM K^+ was added to the perfusion media (with a proportionate decrease in Na^+ concentration). Elevated K^+ markedly stimulated DA release to 50-140 fmol/min without causing a similar action on DOPAC and HVA efflux. Within an experiment, the amount of DA released by 35 mM K^+ was variable but not necessarily decremental with successive stimulations. In 3 out of 4 cases, 100 μM carbachol appeared to enhance the 35 mM K^+-stimulated release of DA. However, in the normal perfusion medium, 100 μM carbachol did not stimulate DA release. GABA (either 100 μM or 1 mM) did not alter the 35 mM K^+-induced release of DA. The efflux of DOPAC and HVA was not changed by GABA or carbachol. The data indicate that a qualitatively reproducible release of DA can be obtained with 35 mM K^+, both within the same experiment and with the same animal on successive days. However, additional data are needed to establish that this technique is useful for studying transmitter interactions in vivo. (Supported in part by MH 17107).

170.8 EFFECTS OF LY163502, A HIGHLY SELECTIVE D_2-DOPAMINERGIC RECEPTOR AGONIST, ON ACETYLCHOLINE AND DOPAMINE RELEASE FROM SUPERFUSED RAT CAUDATE SLICES. B. D. Sawyer* and M. M. Foreman (SPON:M. D. Hynes). Dept. of CNS and Endocrine Research, The Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN. 46285.

Stimulation of D_2 dopaminergic receptors has been shown to inhibit the postsynaptic release of acetylcholine (ACh) and the presynaptic release of dopamine (DA) from caudate tissue. The only known compound that appears to be selective for these D_2 receptors is LY171555, trans-(-)-4,4a,5,6,7,8,8a,9-octahydro-5-propyl-2H-pyrazol<3,4-g>quinoline monohydrochloride. However, this compound is much less potent than the less selective ergoline type dopaminergic agonists, such as pergolide. LY163502, trans-(-)-5,5a,6,7,8,9,9a,10-octahydro-6-propylpyrimido<4,5-g>quinolin-2-amine dihydrochloride, is a new, highly selective D_2 type agonist.

We have evaluated the effects of LY163502 on the potassium-induced release of tritium from rat caudate slices prelabeled with either ^{3}H-choline or ^{3}H-DA. Anterior caudate fragments were sliced to 300 μM thickness and subsequently incubated with either 100 nM ^{3}H-choline or ^{3}H-DA for 30 min at 37° C. Single slices were placed in 100 μl custom-made superfusion chambers and superfused at a rate of 400 μl/min at 37° C. Basal release buffer contained 118 mM NaCl, 4.2 mM KCl, 25 mM $NaHCO_3$, 1.0 mM $NaHPO_4$, 1.2 mM $MgCl_2$, 1.3 mM $CaCl_2$ and 11.1 mM β-D-glucose and was adjusted to pH 7.4 by gassing at 37° C with 95/5 percent O_2/CO_2. The stimulus buffer was identical to the basal release buffer except for the NaCl and KCl concentrations which were 102.2 mM and 20.0 mM, respectively. Tissues were superfused for 45 min with basal release buffer and then exposed to stimulus buffer for 1 min. The tissues were exposed to basal release buffer with drug starting at t=65 min and exposed to stimulus buffer with drug for 1 min at t=95 min. Superfusion was terminated at t=125 min. The concentration of LY163502 that elicited approximately 50 percent of maximal suppression of ^{3}H-DA or ^{3}H-ACh release was 3×10^{-9} M. The potency of LY163502 was greater than that observed with LY171555 in other experiments. The effects of LY171555 and LY163502 were found to be stereoselective and were blocked by sulpiride, a D_2 antagonist.

170.9 TONIC INHIBITORY INFLUENCE OF HABENULO-INTERPEDUNCULAR PATHWAYS ON ASCENDING DOPAMINERGIC NEURONS IN THE RAT BRAIN. T. NISHIKAWA*, D. FAGE* and B. SCATTON. Laboratoires d'Etudes et de Recherches Synthélabo (L.E.R.S.), Bagneux 92220, France.

Habenular nuclei receive afferents from several dopamine (DA)-rich forebrain areas via the stria medullaris and have (direct or indirect) connections with DA cell bodies located in the ventral tegmental area and substantia nigra through the habenulo-interpeduncular pathways. These anatomical relationships suggest a potential role for the habenula in the feed-back control of the activity of ascending dopaminergic systems. To explore this possibility we have studied firstly the effect of an acute interruption of impulse traffic into the habenulo-interpeduncular pathways (by means of a local infusion of tetrodotoxin into the fasciculus retroflexus). Secondly, we studied the effect of local injections of cholinergic, opioid and substance P ergic drugs into the interpeduncular nucleus (IPN) on DA metabolism in several DA-rich brain areas in the rat because the transmitter systems modulated by these drugs are known to exist within the habenulo-interpeduncular tract.

The bilateral infusion of tetrodotoxin (50 ng) into the fasciculus retroflexus of conscious rats (via indwelling cannulae) caused a marked increase in homovanillic acid levels, DA synthesis and utilization in the medial prefrontal cortex, nucleus accumbens, olfactory tubercle and striatum. Similar changes in DA metabolism were observed in these areas after bilateral infusion of tetrodotoxin (25 ng) into the stria medullaris. Infusion of atropine (0.4-1 µg) into the IPN increased homovanillic acid concentrations and DA utilization in the medial prefrontal cortex and nucleus accumbens but not in the olfactory tubercle and striatum. Intra-IPN injection of oxotremorine (17 µg) antagonized the increase in DA utilization in the nucleus accumbens (but not in the olfactory tubercle) induced by an intra-fasciculus retroflexus infusion of tetrodotoxin. Local infusion of naloxone (20 µg) into the IPN increased homovanillic acid concentrations in the nucleus accumbens and olfactory tubercle but not in the medial prefrontal cortex and striatum. In contrast, intra-IPN infusion of the substance P antagonist D-Arg^{1}, D-Pro^{2}, D-Trp^{7,9}, Leu^{11} or of substance P antiserum failed to alter homovanillic acid levels in the four DA-rich areas investigated. The present findings suggest that the habenulo-interpeduncular pathways exert a tonic inhibitory influence on meso-cortical, meso-limbic and meso-striatal dopaminergic neurons. Cholinergic and/or opioid peptidergic neurons coursing through the fasciculus retroflexus could take part in the inhibitory control of meso-cortico-limbic DA neurons.

170.10 ULTRASTRUCTURE AND SYNAPTIC INTERACTIONS OF ADRENERGIC AND GABA-ERGIC NEURONS IN THE RAT ROSTRAL VENTROLATERAL MEDULLA. T.A. Milner, J. Chan*, V.J. Massari[1], W.H. Oertel[2], D.H. Park, T.H. Joh, D.J. Reis and V.M. Pickel. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021, Dept. of Pharm., Howard Univ. Med. Coll., Washington, DC[1], and Technische Universitaet, Muenchen, Germany[2].

We sought to determine: (1) the ultrastructure of adrenergic neurons and (2) the synaptic interactions between adrenergic neurons and between adrenergic neurons and GABA-ergic terminals in the rostral ventrolateral medulla of the adult rat. The adrenergic and GABA-ergic neurons were identified by immunocytochemical labeling of antisera against their respective synthesizing enzymes, phenylethanolamine-N-methyl transferase (PNMT) and L-glutamate decarboxylase (GAD). The antisera were single labeled by the peroxidase anti-peroxidase (PAP) technique and dual labeled by combined PAP and immunogold methods.

Selective immunoreactivity for PNMT was detected throughout the cytoplasm of neuronal perikarya, dendrites, myelinated and unmyelinated axons and axon terminals. The perikarya were large (18-24µm), had a prominent nucleolus and a slightly infolded nuclear membrane. The most notable cytoplasmic organelles included numerous mitochondria, ribosomes and rough endoplasmic reticulum. The dendrites (0.8-2.0µm) received symmetric and asymmetric synapses from both PNMT-labeled and unlabeled terminals. The PNMT-labeled terminals (0.4-1.2µm) contained many small clear and a few dense core vesicles. Immunoreactivity for GAD was exclusively localized in axon terminals (0.4-2.0µm). The GAD labeled terminals formed primarily symmetric synapses with dendrites containing immunoreactivity for PNMT and with other unlabeled dendrites. We conclude that the adrenergic neurons have morphological features indicative of high metabolic activity and receive afferents from both adrenergic and GABA-ergic neurons. (Supported by NIH grants HL18974, MH0078, and fellowship NS 07340.)

170.11 SEROTONIN-BINDING PEPTIDES BIND MURAMYL DIPEPTIDE. F.C. Westall and R.S. Root-Bernstein*. Institute for Disease Research, Concord, CA 94518; Neurobiochemistry, V.A. Hospital, Brentwood, CA 90073.

Luteinizing hormone-releasing hormone (LHRH), adrenocorticotropic hormone (ACTH), melanocyte stimulating hormone (MSH), and the tryptophan peptide of myelin basic protein (trp peptide) contain structurally similar serotonin binding sites (Root-Bernstein, J. Theor. Biol. 100:373, 1983; Root-Bernstein, FEBS Lett. 168:208, 1984; Root-Bernstein and Westall, Brain Res. Bull. 12:425, 1984). The adjuvant peptide muramyl dipeptide has been found to have serotonin-like properties (Krueger, et al. PNAS 79: 6102, 1982; Masek and Kadlecova, Lancet 1:1277, 1983) and is known to cause experimental allergic encephalomyelitis (EAE) when injected with trp peptide (Nagai, et al. Cell. Immunol. 35:158, 1978) and experimental autoimmune castration when injected with LHRH (Carelli, et al. PNAS 79:5392, 1982). These observations led to the hypothesis that muramyl dipeptide might bind to serotonin binding sites (Westall and Root-Bernstein, Mol. Immunol. 20:169, 1983; Root-Bernstein and Westall, Lancet 1:653, 1983). We report here evidence from nuclear magnetic resonance spectroscopy and other physico-chemical methods demonstrating that muramyl dipeptide binds to the aforementioned serotonin-binding peptides. Muramyl dipeptide binds to LHRH, but not to LHRH 1-3 or 4-10 (indicating that the main binding site is located in the 2-5 region); and it binds to MSH-ACTH 4-10 but not ACTH 1-4. These data suggest that the binding site is composed of a "molecular sandwich" comprised of a Trp paired with a Phe or Tyr and accompanied by Ser or Glu and Arg. We also report data concerning the binding of various muramyl dipeptide analogues and control peptides, which demonstrate that the binding is relatively specific. In addition, we report results of experiments suggesting that muramyl dipeptide, but not control peptides, interferes with ACTH-induced release of corticosteroids from cultured adrenals. These results may be of importance to understanding both the mechanism of induction of autoimmune disease and some of the symptoms caused by bacterial infections, such as drowsiness. Perhaps most importantly, these results suggest a mechanism for the induction of post-vaccinal encephalopathies. It has long been known that vaccines should not be administered if the patient has a fever; perhaps the vaccines interact with bacterial breakdown products (such as muramyl dipeptide) to produce an autoimmune reaction similar to that produced by adjuvants with LHRH and trp peptide.

170.12 OPIATE PEPTIDES BIND CATECHOLAMINES. R.S. Root-Bernstein* and F.C. Westall (SPON: A. Yuwiler). Neurobiochemistry, V.A. Hospital, Brentwood, CA 90073; Institute for Disease Research, Concord, CA 94518.

Opiate actions appear to involve the catecholamines dopamine (DA) and norepinephrine (NE) (reviewed in Oliverio, et al., Int. Rev. Neurobiology 25: 276, 1984) and the endogenous opiate met-enkephalin is often co-stored and co-released with these amines (reviewed in Costa and Trobucchi, eds., Neural Peptides and Neural Communication, 1980). Based upon earlier research demonstrating that amines may bind specifically to peptides (Root-Bernstein and Westall, Brain Res. Bull. 12: 425, 1984) and to aromatic drugs (Root-Bernstein and Westall, Brain Res. Bull. 12:17, 1984), we hypothesized that both endogenous and exogenous opiates might specifically bind DA and NE. We recently presented evidence that morphine (but not naloxone, desipramine, pargyline, fenfluramine, etc.) binds NE and DA, but not serotonin, histamine, tyrosine, etc. (Root-Bernstein and Westall, Neurology 35 (Suppl. 1): 311, 1985). We report here evidence from nuclear magnetic resonance spectroscopy, colligative properties, pH titration studies and chromatography demonstrating that met-enkephalin, leu-enkephalin, and morphiceptin (Tyr-Pro-Phe-Pro-NH2) specifically bind NE and DA, but do not significantly bind serotonin, histamine, acetylcholine, tyrosine, etc. Control peptides, including enkephalin fragments and a number of serotonin binding peptides including LHRH and MSH and the tryptophan peptide of myelin basic protein, did not significantly bind NE or DA. Gastrin tetrapeptide (Trp-Met-Asp-Phe-NH2), however, binds DA, which may be significant since the same sequence occurs in the DA cotransmitter cholecystokinin (Voigt and Wang, Brain Res. 296: 189, 1984). Met-enkephalin and morphiceptin also bind naloxone. The dissociation constant, K, for the binding of both NE and naloxone to met-enkephalin is c. 10-4 per mole. These data suggest that endogenous opiates may act, at least in part, by binding up NE and DA in vivo; and that naloxone, which was found not to bind either DA or NE, may antagonize the opiates by directly binding to the opiate thereby preventing opiate binding to neurotransmitters. Model building also suggests that the opiate-catecholamine complexes may have significantly higher affinity for lipid membranes than either molecule alone. Like other anaesthetics (Franks and Lieb Nature 300: 487. 1982), the opiates may act by incorporating in a DA or NE-dependent manner into the lipid membranes of neurons, interfering with receptor conformations. We also report data from experiments on chronically cultured rat pineals testing for in vitro interactions of the peptide opiates with exogenously administered NE.

170.13 THE EFFECT OF ALTERATIONS IN CENTRAL DOPAMINERGIC ACTIVITY ON TRH CONTENT IN RAT BRAIN. T.M. Engber, M.S. Kreider, D. Lurie*, M. Zweben* and A. Winokur. Depts. of Pharmacology and Psychiatry, Univ. of PA, Philadelphia, PA 19104

Intraventricular administration of the catecholamine neurotoxin 6-hydroxydopamine (6-OHDA) to rats results in increases in the TRH content of olfactory bulb, hippocampus and amygdala. Pretreatment with bupropion to prevent destruction of DA terminals abolishes this increase in TRH. However, pretreatment with the NE uptake blocker DMI does not alter the effect of 6-OHDA on the TRH content of these regions. In order to further study the relationship between DA and TRH, the effects of various pharmacologic manipulations of DA systems on regional TRH content were examined.

Male S-D rats received i.p. injections of one of three drugs. Alpha-methyl-para-tyrosine (AMPT), an inhibitor of catecholamine synthesis, was given at a dose of 250 mg/kg once and then 100 mg/kg every 3 hrs; animals were sacrificed either 2 or 24 hrs after the initial injection. Bupropion, a DA uptake blocker, was given at a dose of 50 mg/kg, and animals were sacrificed 2, 24, or 72 hrs. after injection. Apomorphine, a DA receptor agonist, was given at a dose of 15 mg/kg, and animals were sacrificed 2, 24, or 72 hrs. after injection. Control animals received injections of PBS vehicle (The apomorphine vehicle also contained 0.4 mg/ml ascorbate). Following sacrifice, brains were removed and dissected on ice into 10 regions. The TRH content of each region was determined by radioimmunoassay.

The TRH content of all ten brain regions examined was unaffected by AMPT, bupropion, or apomorphine treatment at any of the time points studied. These results suggest that TRH content is not influenced by changes in DA activity alone. The effect of 6-OHDA must be due to loss of DA nerve terminals, not to loss of DA itself. It is possible that a cotransmitter or some other factor contained in DA nerve terminals is responsible for changes in TRH content.

170.14 IVT 6-HYDROXYDOPAMINE ENHANCES TRH IMMUNOREACTIVITY IN RAT DORSOMEDIAL HYPOTHALAMUS. M.S. Kreider, T.M. Engber, K. Cody* and A. Winokur. Depts. of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104

Administration of the catecholaminergic neurotoxin 6-hydroxydopamine has been shown to result in substantial elevations of the TRH content of several regions of the rat CNS. TRH content of regions of the limbic system were particularly influenced by this treatment; however, hypothalamic TRH appeared to be unaffected. Since the distribution of TRH within the various nuclei of the hypothalamus is not uniform and may be regulated by different factors, it was of interest to determine if 6-hydroxydopamine altered TRH localization in individual nuclei of the hypothalamus.

Male Sprague-Dawley rats received IVT injections of 6-hydroxydopamine hydrobromide, 400 ug in 10 ul of 0.9% NaCl containing 0.2 mg/ml ascorbic acid, or vehicle. Three days following 6-hydroxydopamine administration, rats were anesthetized with chloral hydrate, 400 mg/kg, and perfused intracardially with heparinized saline followed by lysine-periodate fixative. Brains were removed and coronal sections of 80 um through the entire hypothalamic region were cut on a cryostat. Sections were incubated for 48 hours at 4 C with a specific antiserum to TRH at a dilution of 1:500 and further processed for immunohistochemistry by the avidin-biotin immunoperoxidase method.

Exposure to 6-hydroxydopamine resulted in a striking increase in the intensity of the immunoperoxidase reaction in TRH containing fibers of the dorsomedial nucleus of the hypothalamus. The density of the TRH positive fibers in the dorsomedial nucleus appeared unchanged. Other nuclei of the hypothalamus known to contain high concentrations of TRH did not exhibit dramatic changes in the density or intensity of TRH staining.

These findings indicate that TRH in the dorsomedial nucleus can be regulated independently of the other TRH containing nuclei of the hypothalamus and may indicate different functions for TRH within the hypothalamus. These findings support the hypothesis that catecholamines play a role in the regulation of TRH systems in brain.

170.15 VASOACTIVE INTESTINAL PEPTIDE EFFECTS ON SEROTONIN TURNOVER IN THE HIPPOCAMPUS. J. Stuckey*, D. Allen* and B. McEwen. (SPON: D. Micco). Lab. of Neuroendocrinology, The Rockefeller University, New York, NY 10021.

Vasoactive intestinal peptide (VIP) is located throughout the brain, including the hippocampus. VIP has been shown to have several biological effects in the hippocampus. One of these is the apparent increase in the binding of serotonin to 5-HT1 receptors in homogenates of hippocampus after pre-incubation with VIP (Rostene et al., 1983). These results suggest that VIP can influence serotonergic neurotransmission in the hippocampus. To further investigate this possibility, we examined the effect of lateral ventricular injection of VIP on hippocampal serotonin (5-HT) turnover.

Male Sprague Dawley rats (275-325g) were anesthetized with Urethane. Twenty three gauge guide cannulas were lowered stereotaxically into each lateral ventricle. The rats then received an intraperitoneal injection of pargyline (75 mg/Kg) and bilateral lateral ventricular injections of 0.15N saline as vehicle control or VIP dissolved in 0.15N saline (75 ng/injection for a total dose of 150 ng). The injection volume was 0.5 ul. The rats were sacrificed immediately, 15 min. or 30 min after injection. The brains were removed and frozen on dry ice and later sliced into 300 um thick sections. Punches were taken from hippocampal areas and the serotonin levels were measured using HPLC.

VIP increased serotonin content in the dorsal subiculum without affecting serotonin content in any other hippocampal area.

Time	0	15	30
5-HT(pg/ug protein)			
Control	3.1±0.5	5.6±1.1	9.8±1.2
VIP	3.7±0.6	8.7±0.5	11.9±0.8

The VIP group differed significantly from the control group by analysis of variance [$F(1,30)=6.59, p<0.05$].

The increase in serotonin content after VIP injection suggests an increase in serotonergic turnover. It is of interest that the effect appears localized to the dorsal subiculum, since that is the area where the effect of VIP on 5-HT binding in the hippocampus is localized (Rostene et al., 1983). The present results provide further evidence that VIP may modulate serotonergic neurotransmission in the hippocampus.

171.1 ADENOSINE AFFECTS SYMPATHETIC NEUROTRANSMISSION AT MULTIPLE SITES IN VIVO. G.E.Evoniuk*, R.W.von Borstel*, and R.J.Wurtman. Lab. of Neuroendocrine Regulation, Department of Applied Biological Sciences, Massachusetts Institute of Technology, Cambridge, MA

We examined the effects of adenosine and its analogs on sympathomimetic responses of pithed rats to electrical stimulation of preganglionic nerves (ES) or to injections of nicotine, phenylephrine (PE), or isoproterenol (ISO). Four physiological indices of sympathetic neurotransmission were measured: blood pressure, heart rate, and contractions of smooth muscle in vas deferens and eyelid. Intravenous infusion of sufficient adenosine to elevate arterial levels from 1.5μM to 2-3μM caused a 2 to 3-fold potentiation of nicotine-induced increases in blood pressure, heart rate, and smooth muscle tension (in both vas deferens and eyelid). Higher adenosine concentrations (3-4μM) produced a smaller potentiation of nicotine's effects. At 2-3μM, adenosine had no effect on sympathomimetic responses to ES or PE. Higher concentrations (3-4μM) attenuated pressor responses to ES and PE and the contractile response of the vas deferens to ES; these levels also potentiated positive chronotropic responses to ISO. The adenosine analogs N-cyclopropylcarboxamidoadenosine (N-CPCA), 2-chloroadenosine (2-CLA) and L- and D-phenylisopropyladenosine (L-PIA, D-PIA) also reduced pressor responses to both ES and PE, exhibiting the potency order N-CPCA > L-PIA > 2-CLA > D-PIA. These analogs exhibited this same potency series in attenuating contractile responses to ES in the vas deferens. However, all four analogs potentiated, at the lower doses tested, the contractile responses of the vas deferens to PE; at higher doses, inhibition predominated. N-CPCA enhanced the chronotropic effects of ISO and ES, while 2-CLA, L-PIA and DPIA decreased heart rate responses to ES. The nonpurinergic vasodilator sodium nitroprusside had no significant effect on the sympathomimetic responses tested, indicating that non-specific vasodilatory actions were not responsible for adenosine's effects. These observations show that circulating adenosine, at levels within or near the physiological range, or synthetic adenosine analogs, can influence sympathetic transmission in vivo by interacting with at least three sites: sympathetic ganglia (where they amplify responses to nicotine), sympathetic nerve terminals (where they reduce evoked release of norepinephrine) and sympathetically-innervated end organs (where they may either reduce or enhance the influence of adrenoceptor agonists, depending on the particular tissue and probably its adenosine receptor subtypes). Adenosine's net effect in vivo represents a complex summation of its multiple actions at anatomically and pharmacologically distinct sites within the efferent sympathetic nervous system.

Supported by grants from NSF (BNS-8415761), USPHS (MH 09197-01) and the Center for Brain Sciences and Metabolism.

171.2 AUTORADIOGRAPHIC EXAMINATION OF ADENOSINE A-2 RECEPTORS IN RAT BRAIN USING [3H]-5'-ETHYL-CARBOXAMIDO ADENOSINE(NECA) E.W.Snowhill* and M.Williams.(SPON:D.J.Pettibone)Neuroscience/Cardiovascular Research, Pharmaceuticals Division,CIBA-GEIGY Corp.,Summit,NJ 07901

Adenosine receptors in mammalian tissues can be classified into A-1 and A-2 subtypes depending on the ability of agonists to inhibit and stimulate adenylate cyclase, respectively. Many adenosine and arylxanthine derivatives exhibit high selectivity for A-1 sites, such as cyclohexyladenosine(CHA),cyclopentyladenosine(CPA) and 1,3-diethyl-8-phenylxanthine(DPX).There are currently no known compounds which can be characterized as purely A-2 selective. This has previously prevented regional localization studies for the A-2 receptor. It was recently shown that the non-selective ligand [3H]-NECA,which has approximately equal affinity for both receptor subtypes in homogenates, when incubated in the presence of a concentration of unlabeled CPA which selectively blocks A-1 receptors, can be used to label A-2 receptors(Bruns et al.(1984)Soc.Neurosci.Abstr.10:957) In the present study, the regional binding characteristics of [3H]-NECA were examined in 20 micron thick sections of rat brain. Non-specific binding was determined in adjacent sections incubated in the presence of 10 uM 2-chloroadenosine(2-CADO) and represented less than 10% of total binding. Specific binding reached equilibrium at room temperature in 120 minutes and was reversible by dilution or by addition of excess 2-CADO. "A-2 specific" binding was determined by incubation of sections with [3H]-NECA and 50nM CPA. Autoradiograms of total, non-specific, and "A-2 specific" binding were generated by apposition of radiolabeled slides to tritium-sensitive film (Ultrofilm;LKB, Bromma) for 3-4 weeks. [3H]-NECA exhibited a heterogeneous distribution throughout the brain. Caudate-putamen showed the greatest density of binding, with quite high amounts in the zonal layer of superior colliculus and the molecular layers of hippocampus and cerebellar cortex. A moderate degree of binding was also apparent in cerebral cortex(minimal laminar distribution), granular layer of cerebellar cortex, and superficial grey layer of superior colliculus. Autoradiograms co-incubated with CPA to selectively displace A-1 binding showed a dramatic decrease in binding (to slightly above non-specific density) in all areas of the brain examined except caudate-putamen. This area retained a density of binding nearly equal to total binding (in the absence of CPA). This is the first quantitative visualization of adenosine A-2 sites in the brain, and emphasizes the importance of autoradiography to the study of receptor function. Studies are ongoing to evaluate the significance of this information on regional adenosine receptor subtype localization and its relevance in regard to physiological function and receptor pharmacology.

171.3 (^{3}H)-N^6-CYCLOPENTYLADENOSINE (CPA), A NEW LIGAND FOR ADENOSINE A-1 RECEPTORS. Michael Williams, Albert Braunwalder* and Thomas J. Erickson*#. Neuroscience Research, Research Dept.,Pharmaceuticals Div.,CIBA-GEIGY Corporation, Summit, NJ 07901 and # DuPont NEN, Boston, MA 02180.

CPA is an adenosine agonist with twice the selectivity of the prototypic ligand, N^6-cyclohexyladenosine (CHA) for adenosine A-1 receptors. In terms of in vitro binding activity, CPA is 700 times more selective for the A-1, as opposed to the A-2, receptor (Bruns et al., Soc.Neurosci.Abstr. 10 (1984) 282.2). High specific radioactivity CPA (46 Ci/mmole) binds with high affinity (Kd = 0.48 nM) to a single site in adenosine deaminase pretreated rat brain membranes. Specific binding was reversible, destroyed by boiling and, at a ligand concentration of 1 nM, represented 90-95% of the total counts bound. Pharmacologically, the specific binding of CPA was consistent with the labeling of an A-1 receptor. CPA, CHA and the R-diastereomer of N^6-phenylisopropyladenosine (PIA) were more active than the non-selective agonist, 5'N-ethylcarboxamidoadenosine (NECA) while the S-enantiomer of PIA was some sixteen times less active than R-PIA. In comparing the binding of (^{3}H)-CPA with that of (^{3}H)-CHA in identical membrane preparations, some discrete differences were observed. R- and S-PIA and the xanthine adenosine antagonist, PACPX (1,3-dipropyl-8-(4-amino-2-chloro)-phenylxanthine were more active in displacing 1 nM CHA than they were in displacing 1 nM CPA while the Kd for CHA was twice that of CPA. In addition, the apparent Bmax for the hexyl analog was some 60% greater than that observed for the pentyl analog. These findings provide further evidence for the possible existence of subclasses of the A-1 receptor and indicate that the increased selectivity of CPA for the A-1 receptor may be useful for the further delineation of such subclasses in vitro.

171.4 EFFECT OF CO-LOCALIZED PEPTIDES ON OXYTOCIN AND VASOPRESSIN RELEASE, IN VITRO. J.A. Schriefer* (Spon. F. Gonzalez-Lima), Dept. of Pharmacol., Ponce School of Medicine, Ponce, P.R. 00732

Recent evidence suggests that a number of other peptides are located in the oxytocin (OT) and vasopressin (VP) containing neurons of the hypothalamo-neurohypophysial system. Such peptides may modulate release of OT and VP from the neurohypophysis. The effects of methionine enkephalin and cholecystokinin, reported to exist in OT neurons, and leucine enkephalin, found in VP neurons, on OT and VP release were examined using the isolated hypothalmo-neurohypophysial preparation (HNS) of the rat.

Adult male rats were decapitated, the HNS removed as a tissue block and incubated under oxygen in a modified Krebs buffer at 37°C in the presence or absence of either D-Ala^2-leucine- (LENK) or D-Ala^2-methionine-enkephalinamide (MENK) or cholecystokinin octapeptide (10^{-10} - 10^{-6} M). OT and VP released into the media during 10 min incubation periods were quantitiated by specific radioimmunoassays. MENK (10^{-6} M) produced a significant decrease in the amount of both OT and VP released into the incubation media. However, LENK (10^{-8} - 10^{-6} M) produced a significant increase in the amount of VP released. OT release was not significantly altered by LENK. Cholecystokinin had no significant effect on OT or VP release at the concentrations tested.

These studies demonstrate that while MENK (present in OT neurons) inhibited both OT and VP release from the isolated HNS, LENK (present in VP neurons) stimulated VP release. This evidence suggests that the various co-localized peptides may have differential effects on neurohypophysial hormone release. Supported by a PMA Foundation Research Starter Grant.

171.5 ADENOSINE INHIBITS SPONTANEOUS FIRING OF RAT LOCUS COERULEUS NEURONS RECORDED INTRACELLULARLY IN BRAIN SLICES. S. A. Shefner and T. H. Chiu*. Dept. of Physiol. and Biophys., Univ. of Illinois at Chicago, Health Sciences Ctr., Chicago, IL 60680

Intracellular recording was used to study the effect of adenosine on rat locus coeruleus (LC) neurons, in a totally submerged brain slice preparation. Known concentrations of adenosine were applied in the bath by switching between control artificial cerebrospinal fluid (aCSF) and aCSF containing adenosine, by means of a valve system. LC neurons in the brain slice preparation show spontaneous firing in the absence of synaptic input; neurons in this study had firing rates ranging from 0.3 - 5 Hz. Concentrations of adenosine from 10 to 200 μM were tested. Adenosine reversibly decreased the spontaneous firing rate in 16 of 17 LC neurons tested. In those cells tested with more than one concentration, the effect was dose-dependent (n=4). Adenosine (100 μM) caused complete block of firing in 80% of cells tested (n=10); firing resumed upon washout, returning to the control rate.

In addition to the inhibition of spontaneous firing, adenosine (100 μM) also caused small hyperpolarizations (2-10 mV) in 10 of 11 cells. The size of the hyperpolarization appeared to be related to the resting membrane potential of the neurons (correlation coefficient = -0.75, n=10, sig. $p<.05$); those cells having the most negative resting potentials showed little or no hyperpolarization with adenosine. When input resistance was measured by passing constant current hyperpolarizing pulses across the cell membrane (n=3) only small reductions in input resistance (7-15%) were noted during the peak of the hyperpolarizing response.

The adenosine receptor antagonist theophylline (200-300 μM) was tested in 7 cells. In most cases theophylline alone increased the basal firing rate somewhat. Theophylline antagonized the adenosine-induced inhibition of firing, hyperpolarization and reduction in input resistance. The degree of antagonism varied from partial to complete, and depended on the respective concentrations of adenosine and theophylline used.

We conclude that adenosine has inhibitory actions when applied to LC neurons in the brain slice preparation. This inhibition may be due to a direct postsynaptic effect. Spontaneous firing of LC neurons in the slice does not seem to depend on synaptic input, therefore, it is unlikely that the adenosine-induced inhibition of this firing is due to inhibition of transmitter release. Adenosine's inhibitory effects on LC neurons appear to be mediated by adenosine receptors since they are antagonized by theophylline.

171.6 CHARACTERIZATION OF ADENOSINE RECEPTORS IN THE RAT SPINAL CORD. J. I. Choca, H. K. Proudfit, and R. D. Green*. Dept. of Pharmacology, University of Illinois at Chicago, College of Medicine, Chicago, IL 60612.

Adenosine mediates the activity of adenylate cyclase (AC) via two distinct receptors. The adenosine A_1 receptor mediates the inhibition of AC and displays nanomolar affinities for adenosine, whereas the A_2 receptor mediates stimulation of AC and displays micromolar affinities for adenosine. Adenosine A_1 sites have been characterized in both the ventral and dorsal halves of the rat spinal cord using N^6-[^{3}H]-cyclohexyladenosine ([^{3}H]-CHA), a specific ligand for A_1 receptors (Geiger et. al. J. Neurosci. 4: 2303, 1984). The present studies compare the binding characteristics of [3H]-N-ethylcarboxamide adenosine ([^{3}H]-NECA), an agonist with near equal potencies at A1 and at A2 sites, with those of [3H]-N^6-(L-phenylisopropyl)adenosine ([^{3}H]-L-PIA), an agonist with greater potency at the A_1 site than at the A_2 site (Yeung and Green, Naunyn-Schmiedeberg's Arch. Pharmacol. 325: 218, 1984).

Lysed crude mitochondrial fractions of the ventral and dorsal halves of the cervical and lumbar enlargements were utilized to study the binding characteristics of [^{3}H]-NECA and [^{3}H]-L-PIA. In the preliminary saturation studies [^{3}H]-NECA specifically bound more sites than [^{3}H]-L-PIA (VENTRAL: NECA = 251 + 18; L-PIA = 158 + 17 fmol/mg protein; DORSAL: NECA = 322 + 5; L-PIA = 241 + 11 fmol/mg protein). N^6-cyclopentyladenosine (CPA), which demonstrates a 350-fold greater potency at A_1 sites than at A_2 sites (Bruns et. al., Neurosci. Abstr. 10: 957, 1984), biphasically inhibited [^{3}H]-NECA binding with low Hill coefficients (n_H) and high IC_{50}'s in both ventral and dorsal halves (VENTRAL: n_H = 0.47 + 0.10; IC_{50} = 268 + 149 nM; DORSAL: n_H = 0.49 + 0.04; IC_{50} = 156 + 59 nM). In contrast CPA inhibition of [^{3}H]-L-PIA binding was statistically different with lower IC_{50}'s and Hill coefficients closer to 1 (VENTRAL: n_H = 0.84 + 0.07; IC_{50} = 4.97 + 0.15 nM; DORSAL: n_H = 0.79 + 0.04; IC_{50} = 4.23 + 0.13 nM). These saturation and inhibition data suggest the existence of A_1 and A_2 receptors in the rat spinal cord. Ultimate verification of this hypothesis will require the demonstration of adenylate cyclase inhibition and stimulation in the spinal cord, mediated by adenosine analogs. (Supported by PHS grant NS18636.)

171.7 EFFECTS OF SEROTONERGIC ACTING BETA-CARBOLINES UPON HIPPOCAMPAL DENTATE RESPONSES IN UNANESTHETIZED RATS. N.J.Leidenheimer*, J.W.Boja*, L.J.Cauller*, and E.Foldvary* (SPON: S.L.Stuesse), Pharmacology Program, NE Ohio Univ. Col. of Med., Rootstown, OH 44272.

1,2,3,4-tetrahydro-beta-Carbolines (THBC) exist endogenously (Barker et al., Biochem.Pharm.,30:9 1981) and have been shown to inhibit 5-HT reuptake and MAO type A activity (Buckholtz, N-S's Arch.Pharm.,314:215 1980). In addition, the substituted form, 6-MeO-THBC, also binds with high affinity to the 5-HT_1 receptor (Ho, et al., Can.J.Biochem.,51:482 1973; Taylor, et al., J.Pharm.Pharmacol.,36:125 1984).

The hippocampal dentate area receives heavy 5-HT input from midbrain raphe (Moore and Halaris, J.Comp.Neur.,164:171 1975). Stimulation of this 5-HT pathway facilitates the dentate responsiveness to stimulation of its primary afferents, the perforant path (PP), which are thought to be glutaminergic. This study examines the modulatory effects of THBC upon this serotonin-sensitive system.

Rats were permanently implanted with electrodes to stimulate the angular bundle of the PP and record the evoked field potential in the hilus of the dentate gyrus. This preparation provides stable recordings of the dentate response in freely-moving and sleeping rats.

THBC (20mg/kg IP) caused substantial changes in both the population excitatory postsynaptic potential (pEPSP) and population action potential (spike) components of the monosynaptic dentate response. The pEPSP was initially elevated and then fell to sub-baseline levels 1 hr after injection. The spike rose to 150% of the baseline level within 40 min and remained elevated. Both pEPSP and spike returned to baseline level approximately 3 hrs after injection. Dentate excitability was determined by plotting the spike output as a function of pEPSP input. Despite the biphasic nature of the changes in pEPSP, dentate excitability rose monophasically to a maximum 1 hr, and returned to baseline 3 hrs after injection.

This THBC-induced modulation of dentate excitability resembles the facilatory effect of stimulation of the serotonin system. These effects are consistent with a disinhibitory role of serotonin in the dentate where serotonin inhibits the activity of inhibitory interneurons.

171.8 **AGE-RELATED LOSS OF THE CAPACITY OF MUSCARINIC AGONISTS TO INHIBIT THE ACTIVATION OF ADENYLATE CYCLASE IN STRIATUM.** **J. Coupet, C.E. Rauh* and J.A. Joseph. Dept. of CNS Research, Lederle Labs, Pearl River, NY 10965.**

Previous experiments have demonstrated that muscarinic acetylcholine receptor (mAChr) agonists such as oxotremorine (OXO) and carbamylcholine (carbachol) inhibit dopamine (DA) stimulated adenylate cyclase (AC) in rat neostriatal preparations (Olianas et al., Mol. Pharmacol. 23, 393, 1983). Since diminution of striatal functioning seems to be a consistent finding in aged animals, resulting in such changes as declines in psychomotor performance, we sought to determine in the present experiment if the ability of these agonists to inhibit DA stimulated AC would be altered as a function of age. Two concentrations of oxotremorine (50 and 100 μM) and carbachol (0.5 and 1.0 mM) were used to inhibit AC activated by 30 μM DA in neostriatal broken cell preparations from young (3-6 mo) middle aged (13-15 mo) and old (22-26 mo) rats. Results showed that along with an age related decline in the activation of AC by dopamine, oxotremorine and carbachol inhibited DA-stimulated AC to the same extent in young (e.g., oxo at 100 μM inhibited DA stimulated AC by 30 + 0.2%) and middle aged (30 + 0.1%) but not old (9.8 + 0.2%) animals. These agonists had no effect on basal AC activity in any age group. The presence of atropine (10 μM) antagonized the effects of both agonists. For example, atropine reduced the degree of AC inhibition by oxotremorine to 4 + 0.1% in young animals and 3 + .1% in middle aged animals. These findings suggest that there may be specific age-related functional declines in AChr such that they are less responsive to agonist stimulation. It may also be that in the senescent animal mAChr agonists impinge upon uncoupled receptors and subsequent physiological control over other receptor systems (e.g. the striatal D_1 cyclase linked system) is be blunted.

171.9 DO OPIOID PEPTIDES MODULATE TRANSMITTER RELEASE IN THE CAT SUPERIOR CERVICAL GANGLION? D.M. Araujo* and B. Collier (SPON: R. Capek). Dept. Pharmacol. & Ther., McGill University, McIntyre Medical Bldg., Montreal, Quebec, Canada H3G 1Y6.

It has been suggested that enkephalins might have a functional role to modulate transmitter release at a variety of synapses. The present experiments sought to test this idea for acetylcholine (ACh) release in the cat superior cervical ganglion. Measures of ganglionic extracts by radioimmunoassay (RIA) with an antibody to [Met^5]-enkephalin (ME) showed the presence of immunoreactive material, but by HPLC this was separated into two main peaks. Ganglia contained 2209 ± 513 pmol (n = 5) of enkephalin-like immunoreactivity, of which 57.5 ± 11.6% migrated on HPLC as ME and 37.7 ± 13.4% as [Met^5]-enkephalin-Arg^6-Phe^7, the carboxyl terminal heptapeptide of the large preproenkephalin A.

To test whether these peptides efflux from ganglia, tissue was perfused and the effluents collected for RIA. The efflux of immunoreactive material was 700 ± 273 pmol/min (n = 3), of which 75.8 ± 10.1% was ME by HPLC and 24.2 ± 10.3% was MEAP. The addition of thiorphan, an "enkephalinase" inhibitor, to the perfusion medium increased measured efflux of enkephalin by 2.6-fold and MEAP by 1.5-fold.

To determine whether these peptides might modulate transmitter release, ganglia were perfused with medium containing physostigmine. ACh release was evoked by preganglionic nerve stimulation, and the effects of the stable ME analogue D-Ala^2-[Met^5]enkephalin amide (DAEA) or MEAP were tested. The enkephalin analogue, DAEA, did not affect ACh release when presented at 10^{-4}M, but MEAP reduced release in a dose-dependent way. The concentration of MEAP required to reduce ACh release to 50% of control was 8.9 x 10^{-8}M (n = 4).

It is concluded that MEAP may have a modulatory role on cholinergic transmission in the superior cervical ganglion and that this role is unrelated to its ability to serve as a precursor for ME. (Supported by MRC and FCAC, Canada.)

171.10 DIFFERENTIAL EFFECTS OF INTRACRANIAL INJECTIONS OF ADENOSINE ANALOGS ON KINDLED SEIZURES IN RATS. J.B. Rosen, L. Ellison*, and R.F. Berman. Dept. of Psychology, Wayne State University, Detroit, MI 48202.

Adenosine depresses neuronal firing and has both sedative and anticonvulsive properties. We have previously demonstrated that the adenosine agonists L-phenylisopropyladenosine (L-PIA) and N-ethylcarboxamido-adenosine (NECA) inhibit amygdaloid-kindled seizures when injected into the cerebral ventricles of rats. The present study extended these findings by (1) examining the effects of focal injections of adenosine agonists on hippocampal, caudate, and amygdaloid kindled seizures, and (2) comparing the anticonvulsive effects of two adenosine analogs, L-PIA and NECA, which show different receptor subtype specificity.

Chemitrodes were stereotaxically implanted in either the amygdala, hippocampus, or caudate nucleus of male Long-Evans rats. Upon recovery, rats were electrically stimulated via the chemitrode once daily with a current just sufficient to elicit an afterdischarge. Once rats were fully kindled (i.e., 3 consecutive generalized seizures), L-PIA or NECA (0.1 to 5.0 ug/0.5 ul) were injected via the chemitrode 5 min before electrical stimulation and the effects of these agents on amygdala, hippocampus, or caudate kindled seizures were determined.

The results demonstrated that adenosine analogs are potent anticonvulsants when injected intracranially into several kindled seizure foci. When injected into the amygdala, L-PIA and NECA were partially effective in blocking afterdischarges and behavioral seizures. When injected into the hippocampus or caudate nucleus, L-PIA displayed a biphasic effect. Low doses of L-PIA (0.2-0.5 ug) blocked seizures, intermediate doses (1.0-2.0 ug) were ineffective, and higher doses (5.0 ug) again blocked seizures. In contrast, low doses of NECA did not inhibit seizures while higher doses did.

The anticonvulsive effects of L-PIA and NECA suggest that adenosine receptors at the focus of kindled seizures can modulate both focal afterdischarge and behavioral seizures. This effect is more prominent in brain regions with high levels of adenosine receptors (i.e., hippocampus and caudate nucleus) than in a region with low levels (i.e., amygdala). In addition, the differences in the effects of L-PIA and NECA agree with other findings which suggest that L-PIA and NECA display differential adenosine receptor subtype activity.

171.11 MELATONIN-INDUCED CHANGES IN GABA AND MUSCIMOL BINDING IN RAT BRAIN. F.M. Coloma* and L.P. Niles. Department of Neurosciences, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

Similarities in the psychopharmacological actions of the benzodiazepines, barbiturates and the pineal hormone, melatonin, prompted an investigation of whether melatonin, like these drugs, acts by modulating the central activity of γ-aminobutyric acid (GABA). In earlier experiments, melatonin was found to enhance the high affinity binding of the GABA agonist, ^{3}H-muscimol by about 20% in rat synaptosomal membranes. The greater consistency of this effect in Tris-HCl as compared with Tris citrate and the ability of KCl to augment melatonin's effect, suggested a chloride ion dependency. In addition, treatment of rat cortical membranes with Triton X-100 decreased or abolished the enhancing effect of melatonin.

We now report that preincubation of synaptic membranes with melatonin at 4°C for 60 minutes, significantly enhances ^{3}H-GABA binding by 30-60%. Saturation studies of high affinity ^{3}H-muscimol (0.3-20 nM) binding indicate that melatonin (10^{-4}M) causes a decrease in binding affinity while enhancing the concentration of binding sites. Moreover, melatonin's enhancing effect on ^{3}H-muscimol binding is blocked by metergoline but not by the benzodiazepine antagonist, Ro 15-1788.

These preliminary findings suggest that melatonin's pharmacologic effects on GABA binding are not mediated via a benzodiazepine site but may involve a serotonergic binding site.

171.12 RELEASE OF ENDOGENOUS ADENOSINE FROM RAT BRAIN SYNAPTOSOMES. W.F. MacDonald* and T.D. White. Dept. of Pharmacology, Dalhousie University, Halifax, N.S., Canada B3H 4H7.

There is evidence that adenosine is an extracellular inhibitory modulator of neuronal activity in the brain. In order for adenosine to exert effects extracellularly it must first be released, either as the nucleoside or as a nucleotide which is subsequently broken down to adenosine. Radiolabel methods for studying nucleotide/nucleoside release suffer from the serious limitation that the actual amounts of nucleotide/nucleoside cannot be determined since one has no knowledge of the specific activities of the radiolabelled compounds being released. In the present study we investigated extrasynaptosomal accumulation of endogenous adenosine using HPLC with fluorescence detection to monitor the etheno adenosine derivative formed by reaction with chloroacetaldehyde.

When rat brain synaptosomes were incubated for 10 min at 37°C, a single peak was obtained following chromatography of the incubation medium. The peak had a retention time identical to an adenosine standard and was abolished when preincubated with adenosine deaminase, indicating it was adenosine. Basal accumulation of adenosine in the medium was 66 pmol per mg protein per 10 min. Elevated K^+ (24 mM) evoked an additional accumulation of 193 pmol per mg protein per 10 min and 50 μM veratridine evoked 583 pmol adenosine accumulation per mg protein per 10 min. K^+- and veratridine-evoked accumulation of adenosine did not arise from microsomal or mitochondrial contaminants of the synaptosomal preparation since purified microsomes and mitochondria did not exhibit evoked accumulation of adenosine in the medium. K^+-evoked accumulation of extrasynaptosomal adenosine was Ca^{2+}-dependent, whereas veratridine evoked accumulation of adenosine was increased in Ca^{2+}-free medium. In the presence of a combination of α, ß-methylene ADP and GMP, which inhibits ecto-5'-nucleotidase, conversion of added ATP and AMP to adenosine was inhibited by 90% in synaptosomal suspensions. However, inhibition of ecto-5'-nucleotidase only reduced basal extrasynaptosomal accumulation of adenosine by 74%, veratridine-evoked accumulation of adenosine by 46% and K^+-evoked accumulation by 33%. Most of the basal accumulation of extrasynaptosomal adenosine appears to be derived from released nucleotide, probably ATP, but about half of the veratridine-evoked accumulation of adenosine and most of the K^+-evoked accumulation may arise from adenosine released in its own right, rather than from a released nucleotide. (Supported by the MRC of Canada).

171.13 BUFOTENINE ANTAGONIZES SEROTONIN'S EFFECTS ON HERMISSENDA TYPE B PHOTORECEPTORS. R. Wu and J. Farley, Program in Neuroscience, Princeton University, Princeton, N.J. 08540

10^{-4} to 10^{-6} M concentrations of 5-HT enhance the peak and steady-state light-induced depolarizing generator potentials of B cells, through a reduction of two K^+ currents (I_A and I_{K-Ca}) and enhancement of a voltage-dependent calcium current (I_{Ca}) [Wu & Farley, Soc. Neurosci. Abstr., 1984]. Because these effects are similar to those produced by associative training of the animal, and 5-HT is an endogeneous neurotransmitter released during training (Auerbach et al., this volume), we have attempted to identify 5-HT antagonists with the eventual aim of determining how much of the training-produced change in B cells is attributeable to 5-HT's actions.

Pretreatment (8 min.) of Type B cells with 10^{-4} M bufotenine ASW blocked the usual response changes seen when 10^{-4} M 5-HT was subsequently added. Neither the steady-state light response nor membrane resistance were significantly increased under these conditions [$t(5)=1.02$, n.s.; $t(5)=0.0$, n.s.] However, the transient light-induced peak response decreased significantly [$t(6)=2.31$, $p < .05$].

10^{-4} M bufotenine alone (dissolved in methanol/ASW) had no significant effects on input resistance, membrane potential, peak, and steady-state light response of B cells, [$t(6)=0.0$, n.s.; $t(6)=-1.46$, n.s.; $t(8)=-.50$; $t(8)=-.55$] indicating that its effects upon B cells were relatively specific to its antagonism of 5-HT's actions.

Experiments to determine which of the 5-HT-induced ionic conductance changes are affected by bufotenine are in progress.

171.14 ACTIVATION OF ADENOSINE A_1 RECEPTORS ENHANCES Ca^{2+}-MEDIATED POTASSIUM CONDUCTANCE IN HIPPOCAMPAL CA_1 NEURONS. P.H. Wu,* N. Gurevich and P.L. Carlen, Neurology and Clinical Pharmacology Programs, Addiction Research Foundation; Playfair Neuroscience Unit, Toronto Western Hospital; and Departments of Medicine and Physiology, University of Toronto, Toronto, Canada.

Adenosine (AD) is known to be released both in the peripheral and central nervous system and AD receptors in the central nervous system have been identified. There are three extracellular AD receptors; A_1 (high affinity), A_2 (high affinity), A_2 (low affinity) (Daly, J., et al: Cell. Mol. Neurobiol. 3: 69-80, 1983) and intracellular AD receptors. Although pharmacologic characterization of A_1 receptors has been very successful, the electrophysiological function of A_1 receptors has not been demonstrated conclusively. In the present study, hippocampal slices from male Wistar rats (150-200 g) were prepared and perfused with standard artifical CSF or a Ca^{2+}-free medium containing 200 μ M $CdCl_2$. In some experiments, tetrodotoxin (TTX) 1 μ M and TEA 5 and 10 mM were added to the perfusate. 3 M K-acetate or KCl microelectrodes (50 to 180 Meg ohms) were used for intracellular recordings. AD, L-phenylisopropyl-adenosine (L-PIA), N-ethylcarboxamide adenosine (NECA), 8-para-sulfophenyl theophylline (8-PSPT) and caffeine were dissolved in the medium and subperfused onto the slice or focally applied by pressure ejection. AD (0.5 to 100 μ M), L-PIA (10 μ M) and NECA (1 μ M) applied onto stratum oriens (SO) consistently produced a hyperpolarizing response, especially when the cell was firing either spontaneously or from passive depolarization. The hyperpolarization induced by 5 μ M AD was completely blocked with 10 μ M 8-PSPT application which acts extracellularly. Similarly, adenosine deaminase (2 units/ml) also blocked AD hyperpolarizing responses, suggesting that the AD receptors associated with CA_1 cells and are extracellularly located. The ionic mechanism of the AD-mediated hyperpolarization was examined. The long-lasting afterhyperpolarization (AHP) following a train of spikes was elicited by a depolarizing current pulse. The early part of the AHP, which is a non-calcium-mediated potassium conductance, was not affected by AD or caffeine, whereas the later part of the AHP, which is mainly a calcium-mediated potassium conductance (Ca-gK), was enhanced by AD, and was blocked by 8-PSPT and caffeine (60 μ M). TTX and TEA block Na^+-dependent spikes and voltage-dependent K^+ conductance, bringing out higher threshold Ca^{2+} spikes. AD delayed the onset of Ca^{2+} spikes. We conclude that AD enhances Ca-gK by activating an extracellular, post-synaptic A_1 adenosine receptor. The parallel localization of AD receptors and the distribution of AD containing neurons in the hippocampus (Braas, K.M., et al: Neurosci. Abs. 165: 14, 1984), suggested that AD plays a significant role in the modulation of hippocampal neuronal excitability.

171.15 HETEROGENEITY OF RESPONSE TO SEROTONIN IN MECHANOAFFERENTS OF THE CEREBRAL GANGLION OF APLYSIA. S.C. Rosen*, A.J. Susswein, K.R. Weiss, and I. Kupfermann (SPON: H. Chiel). Center for Neurobiology & Behavior, Columbia Univ., New York, NY 10032; New York State Psychiatric Institute, N.Y., and Dept. Life Sci., Bar-Ilan Univ., Ramat-Gan, Israel 52100.

Each hemi-cerebral ganglion contains two adjacent clusters of small neurons, many or all of which are primary mechanoafferents with receptive fields on the skin of the head and/or muscles of the buccal mass (Rosen et al., J. Neurophysiol., 1979, 1982). In most respects, these neurons are very similar to other clusters of mechanoafferents that have been described in Aplysia. For instance, the EPSPs produced by cerebral mechanoafferents exhibit profound low frequency depression. A striking difference between at least some of these neurons and other mechanoafferents that are known is that the increase of synaptic effectiveness the cerebral mechanoafferents exhibit following strong nerve stimulation is due to a post-synaptic mechanism, rather than to presynaptic facilitation. Heterosynaptic facilitation of mechanoafferents in the abdominal and pleural ganglia is due to the presence of adenylate cyclase-linked receptors that are stimulated by serotonin (5-HT) which produces inactivation of K^+ channels, resulting in spike broadening. As a first step to examine whether cerebral mechanoafferents possess similar cellular properties, spike width in the presence of 50 mM tetraethylammonium was determined in the presence and absence of 5-HT and other neuromodulators. In contrast to other similar neurons, many of the cerebral neurons in the mechanoafferent cluster, including previously identified interganglionic mechanoafferents, exhibited marked spike-narrowing in the presence of 5-HT (threshold approximately 10^{-6}M). Another population of cells in the mechanoafferent cluster showed spike-broadening, and exhibited enhancement of the EPSP they evoked in follower cells located in the cerebral B-cluster. These results suggest the hypothesis that the mechanosensory cluster of the cerebral ganglion contains at least three types of neurons that may be differentially modulated in order to perform different functions associated with feeding behavior.

171.16 EFFECT OF HISTAMINE ON IPSPs IN RAT HIPPOCAMPAL CA1 PYRAMIDAL NEURONS, S. A. Springfield and H. M. Geller, Dept. of Biology, City College of CUNY, New York, NY 10031 and Dept. of Pharmacology, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854.

Investigations using extracellular recording techniques have indicated that one prominent action of histamine (HA) may be through a reduction in the potency of central GABAergic systems (Springfield et al., Neurosci. Abst., 9: 1154, 1983). To understand the mechanism of this action of HA we have studied its effect on the inhibitory postsynaptic potential (IPSP) and the accompanying conductance changes on hippocampal CA1 pyramidal neurons.

Hippocampal slices (350 μm) prepared from 125-200 g male rats were constantly superfused with Yamamotos' medium equilibrated with 95% O_2/5% CO_2 and maintained at 32-34°C. A bipolar stimulating electrode was placed in the alveus to antidromically activate the pyramidal neurons. Low intensity (0.1-10 V) stimuli evoked an IPSP. Intracellular recordings were made with glass micropipettes filled with 3 M KCl. Hyperpolarizing current pulses (4 nA, 10 msec) were passed at the peak of the IPSP to assess membrane resistance/conductance changes. Histamine (10^{-6} M) was added to the perfusate and changes in membrane resistance and IPSP noted. Histamine was then eliminated to assess the return to control conditions.

The pyramidal neurons had resting membrane potentials of -65.7 to -79.9 mV and input resistances of 35.2-52.8 Mohm. The IPSPs had amplitudes of 18-30 mV and durations of 70-120 msec. Histamine application resulted in a reduction in the potency of the IPSPs, made evident by a reduction in the conductance increase recorded near the peak of the IPSP as well as a reduction in the amplitude of the IPSP. In every instance the IPSP conductance increase was diminished by HA, the mean reduction being 52.6%. The amplitude of the evoked IPSP was reduced by 5 to 53% when HA was applied. All changes were reversed by elimination of HA from the perfusate.

By demonstrating a depression of the IPSP conductance increase, these intracellular experiments support the conclusions already drawn from the extracellular observations; that HA may be causing either a reduction in the release of GABA from local interneurons impinging on the pyramidal cell, or that HA may be causing a reduction in the sensitivity of the pyramidal cell membrane to GABA. In either case, the resultant effect at the postsynaptic membrane of the pyramidal cell, a reduction in the IPSP amplitude and the associated conductance change, can be interpreted as further evidence for modulatory actions by HA. Additional experiments are in progress to distinguish between these possibilities.

171.17 EFFECT OF REM SLEEP DEPRIVATION ON ADENOSINE A1 AND A2 RECEPTORS IN RAT BRAIN REGIONS. G. YANIK, N.M. PORTER, M. RADULOVACKI., DEPARTMENT OF PHARMACOLOGY, COLLEGE OF MEDICINE, UNIVERISITY OF ILLINOIS, CHICAGO,IL 60612

It has become increasingly clear that endogenous adenosine (Ado) may play a role in the regulation of the sleep-wake cycle. Studies in dogs, (Haulica et al. J. Neurochem. 21: 1019-20, 1973) together with studies from this laboratory in rats have shown that ado and synthetic ado analogs can increase deep slow wave sleep and REM sleep (Radulovacki et al., JPET 228: 268, 1984; Virus et al., Neuropharm. 22: 1401,1983). In addition, Ado A1 receptors have been shown to increase in specific rat brain regions following 48 h. of REM sleep deprivation (RD) by the "flower pot method" (Yanik et al., Soc. Neurosci. Abstr., Vol. 10 Part 2 p. 959, 1984). In order to differentiate between the effects of immobilization stress and RD we subjected rats in the present study to 96h of RD and added a large platform "stress control" group. In addition to the analysis of A1 receptors we also analyzed A2 receptors (assay adapted from Yeung and Green, Nuanyn-Schmeideberg's Arch Pharmacol. 325: 218-25, 1984) since stimulation of A2 receptors is thought to contribute to waking (Radulovacki et.al., 1984, op. cit.). Male Sprague Dawley rats (300-350 g) were assigned to one of three groups: cage controls (CC), large platform controls (LP) , or small platform REM sleep deprived group (SP). LP and SP groups were exposed to the REM deprivation set-up for 96 h while CC were housed in their home cages for the duration of the experiment. Following 96 h of RD, animals were killed by decapitation and their brains were rapidly removed and dissected. All brain samples (cortex, striatum, hippocampus, thalamus and cerebellum) were kept frozen at -70 C until assayed. A1 receptor binding was assayed using H3 PIA, and A2 receptor binding in corpus striatum was estimated using H3 PIA and H3 NECA. A statistically significant increase in Bmax was found only in the cortices ($p<.05$ as measured by Kruskal-Wallis nonparametric ANOVA) of RD animals while LP and CC groups were not significantly different. This finding confirms the previously reported A1 receptor changes seen after 48 hr RD. However, estimations of A1/A2 receptor populations in corpus striatum failed to elucidate any clear-cut role for A2 receptors in REM sleep deprivation. This study indicates that REM sleep deprivation produces increases in A1 receptors in rat brain, and suggests a role for these receptors in REM sleep. (Supported by ONR contract N000 14-79-C-0420)

171.18 EFFECTS OF CHRONIC INTRACEREBROVENTRICULAR INFUSION OF ADENOSINE AGONISTS AND DEOXYCOFORMYCIN ON BRAIN ADENOSINE RECEPTORS & SLEEP IN THE RAT. N.M. Porter, F.M. Clark*, R.D. Green, M. Radulovacki, Dept. Pharmacology, Univ. of Illinois at Chicago.

Two types of adenosine (Ado) receptors have been identified in the CNS: A1 receptors mediate the inhibition while A2 receptors the stimulation of adenylate cyclase (AC). Previous studies have demonstrated that chronic administration of Ado antagonists, such as caffeine and theophylline, up-regulate Ado A1 receptors in the CNS. The present studies were undertaken to determine the effects of chronic administration of Ado agonists on Ado receptors in the brain.

Male Sragues-Dawley rats (300-400 gm) were implanted with cannula into the lateral cerebral ventricle. ALZET osmotic pumps, implanted subcutaneously, were connected to the cannula and one of the following drugs administered: L-phenylisopropyladenosine (L-PIA, 0.50 nmoles/hr/2 wk), 5'-N-ethylcarboxamide adenosine (NECA, 0.04 nmoles/hr/2 wk) and deoxycoformycin (dCF, 5 nmoles/hr/1 wk). Each group had its own vehicle control. Rats were sacrificed 24 hr after the end of the infusions and ligand binding assays performed in cortex and striatum (ST). Ado A1 receptor binding was measured with ^{3}H-PIA, while A2 receptor binding was estimated by the NECA minus PIA binding assay performed in the presence of saturating concentrations of ^{3}H-PIA and ^{3}H-NECA (Yeung and Green, Naunyn-Schmiedeberg's Arch Pharmacol 325: 218, 1984). Chronic administration of L-PIA, an Ado A1 agonist, produced no change in A1 or A2 receptor binding. However, treatment with NECA, a mixed A1/A2 agonist, or with dCF, a potent inhibitor of endogenous adenosine metabolism, while producing no effect on A1 receptor binding, produced significant decreases in A2 receptor binding in ST (40% and 60%, respectively). Studies examining the effects of these treatments on AC activity are currently in progress. Preliminary results in rats treated with NECA suggest desensitization of the AC to the A2 stimulatory response.

In the second study, the effects of chronic administration of NECA on sleep were determined. Rats implanted with EEG and EMG electrodes were polygraphically recorded during the first 48 hr of drug withdrawal. During the first 24 hr, NECA withdrawn animals showed a significant decrease in wakefulness and an increase in deep slow-wave (SWS2) and REM sleep. The increase in SWS2 persisted during the second 24 hr of recording.

These data show that treatment with NECA and dCF results in a down-regulation of Ado A2 but not Ado A1 receptors. Furthermore, the results suggest that these Ado A2 binding sites may represent functional receptors since biochemical and behavioral changes are associated with the loss of these sites. (Supported by ONR contract N00014-79-C-0470)

171.19 THE EFFECTS OF SYSTEMIC AND LOCAL ADMINISTRATION OF ADENOSINE ANALOGS ON HIPPOCAMPAL EVOKED RESPONSES. T.V. Dunwiddie and M.S. Brodie, Dept. Pharmacol., Univ. Colorado Health Sci. Ctr. and Veterans Administration Medical Res. Service, Denver, CO 80262.

Adenosine and its analogs have potent depressant effects on the behavior and physiology of intact animals. Intraperitoneal (i.p.) and intracerebroventricular (i.c.v.) injections of adenosine analogs such as R-phenyl-isopropyladenosine (PIA) and N-ethylcarboxamidoadenosine (NECA) produce profound reductions in body temperature, heart rate, blood pressure and spontaneous locomotor activity. However, there has been no demonstration of a direct effect of systemically administered adenosine analogs on electrophysiological activity in the central nervous system. We examined the effect of i.p. and i.c.v. administration of adenosine analogs on the hippocampal evoked field EPSP (fEPSP), a response that is sensitive to the actions of adenosine in vitro.

Sprague-Dawley rats were anesthetized with urethane (1.2 g/kg) and surgically prepared for stereotaxic implantation of injection cannulae, recording and stimulating electrodes. The anterior hippocampal commissure was stimulated contralaterally to the recording electrode, which was located in the CA1 region of the hippocampus. Microinjection cannulae were implanted in either the anterior or posterior region of the lateral ventricle ipsilateral to the recording electrode. Adenosine analogs (PIA, NECA) were given i.p. in doses from 0.1 to 5.0 mg/kg, and NECA was injected i.c.v. in doses from 0.4 to 135 ug. Adenosine and PIA were also applied from multibarrel recording pipettes by micropressure ejection. The adenosine receptor antagonist theophylline was injected i.p. in doses from 50 to 150 mg/kg or applied directly via micropressure application.

Local ejection of adenosine (5 mM in the pipette) profoundly depressed the amplitude of the hippocampal fEPSP in a theophylline reversible fashion. The fEPSP amplitude was also reduced by local ejection of PIA; systemic or local injection of theophylline partially reversed this response. Similarly, i.c.v. injection of NECA into the posterior (but not anterior) aspect of the ipsilateral ventricle reduced the amplitude of the fEPSP. However, systemic injection of adenosine analogs had no significant effect on the fEPSP amplitude, even at doses up to 100X higher than those required to elicit behavioral responses.

These results demonstrate that although the hippocampus in situ is sensitive to the actions of locally applied purinergic agonists, systemic administration of these agents has no effect. This suggests that these drugs do not reach these sites following i.p. administration in physiologically significant amounts, and would indicate that the hippocampus is unlikely to mediate the behavioral actions of these drugs. (Supported by DA 02702 and the Veteran's Administration Medical Research Service).

171.20 DOPAMINE NEUROMODULATION WITHIN THE RAT CAUDATE NUCLEUS L.A. CHIODO AND T.W. BERGER. Lab. Neurophysiology, Center for Cell Biology, Sinai Hospital of Detroit, 6767 W. Outer Dr., Detroit, MI 48235 and Depts. Psychol. and Psych., Univ. of Pittsburgh, Pittsburgh, PA 15260.

Numerous studies have demonstrated that DA is the neurotransmitter released by nigral efferents within the caudate nucleus. Debate still exists, however, over the precise physiological role of DA at postsynaptic sites. A number of laboratories have reported excitatory effects of microiontophoretically applied DA and substantia nigra stimulation on caudate neuronal activity while other groups have demonstrated that DA inhibits the discharge of these cells. Recently, it has been suggested that DA may not act as a simple excitatory or inhibitory neurotransmitter but instead may exert a neuromodulator role on postsynaptic membranes. That is, as a neuromodulatory the primary physiological role of DA may be to alter the efficacy of other neurotransmitters impinging upon the same postsynaptic membrane. Given these observations, we examined the ability of microiontophoretically applied DA to modulate the co-iontophoretic application of either the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) or the excitatory amino acid glutamate (GLU). All spontaneously active rat caudate neurons sampled were of the type 1 previously described (Skirboll and Bunney, Life Sci., 1979). When GABA was iontophoresed onto these neurons (5-25 nA), there was a rapid decrease in the spontaneous activity (% inhibition = 44.6±1.9 [mean ± SEM]; n=20) while local application of GLU (0-5 nA) increased neuronal discharge (% excitation = 64.6±2.6; n=20). The co-iontophoresis of DA, at ejection currents which inhibited spontaneous activity (10-35 nA; % inhibition = 50.9±3.6; n=10), differentially altered the response of caudate neurons to these two neurotransmitters. While significantly increasing the effectiveness of iontophoretically applied GABA by 112% ($p < .001$; n=10), it decreased the response of caudate neurons to GLU application by 44% ($p < .001$; n=10). In contrast, when DA was microiontophoresed at currents which had no effect on spontaneous activity, there was an augmentation of the response of caudate neurons to both neurotransmitters. That is, the effectiveness of both GABA and GLU iontophoresis was increased by 96% and 186% respectively ($p < .001$; n=10 for both). These data agree with the previous findings which demonstrate that DA exerts a neuromodulatory role at postsynaptic sites within the mammalian CNS.

172.1 A DORSOLATERAL SPINOTHALAMIC PATHWAY IN SQUIRREL MONKEY. M.W. Jones*, A.V. Apkarian, R.T. Stevens and C.J. Hodge, Jr., Dept. of Neurosurgery, Upstate Medical Center, Syracuse, New York 13210.

Recent investigations in our laboratory have demonstrated a crossed dorsolateral spinothalamic pathway in cat which originates primarily from neurons within lamina I, and constitutes the primary lamina I projection to the thalamus. This study was designed to determine if a similar pathway exists in primates.

In 4 squirrel monkeys HRP-WGA (2%; 1µl total) was injected stereotactically into medial and lateral thalamic nuclei known to receive spinothalamic terminations. Just prior to the thalamic injection one of a series of lesions designed to block HRP-WGA transport through the dorsal columns, the ventral quadrant or the dorsolateral funiculus was made in the ipsilateral thoracic spinal cord. After a 5 day survival period tissue was processed for horseradish peroxidase histochemistry. Spinal lesions and thalamic injection sites were examined histologically. The HRP-WGA injection site did not include the midbrain. The locations of HRP-labeled spinothalamic neurons were plotted from transverse sections of the lumbar enlargement (L6-S1).

In an animal that received no spinal lesion and served as a control, labeled neurons were found in laminae I-VIII, X (7.8 total cells/section). The main populations of labeled neurons were located contralaterally in lamina I (14%), the reticular and compacta zones of lamina V (38%) and in laminae VII, VIII (32%). In an animal that received a combined ventral quadrant-dorsal column lesion (1.6 total cells/section), the main HRP-labeled spinothalamic populations were found contralaterally in lamina I (37%) and in the pars compacta of lamina V (24%). In an animal with a lesion of the dorsolateral funiculus (3.6 total cells/section) there were very few labeled neurons in lamina I (3%) and the main HRP-labeled population was found contralaterally in the reticular zone of lamina V (34%) with smaller populations in the pars compacta of lamina V (17%) and in laminae VII, VIII (25%).

These findings demonstrate distinct ventral and dorsolateral spinothalamic projections in the primate which cross segmentally within the spinal cord. This is similar to the cat which also has distinct dorsolateral and ventral spinothalamic pathways. In the squirrel monkey the dorsolateral projection originates predominantly from neurons within lamina I and the pars compacta of lamina V and the ventral projection originates primarily from neurons within the pars reticulata and compacta of lamina V and laminae VII, VIII.

172.2 MEDIAL AND LATERAL THALAMIC TERMINATIONS OF THE DORSOLATERAL AND VENTRAL SPINOTHALAMIC PATHWAYS. R.T. Stevens, A.V. Apkarian, M.W. Jones* and C.J. Hodge, Jr., Dept. of Neurosurgery, Upstate Medical Center, Syracuse, New York 13210.

We have recently demonstrated in cat the presence of two distinct pathways contributing to the spinothalamic tract (STT): a dorsolateral spinothalamic pathway (DSTT) originating primarily within lamina I and a ventral spinothalamic pathway (VSTT) originating mainly within laminae IV, V, VII and VIII (Jones et al., accepted in Brain Res.). Both pathways cross segmentally and terminate within the thalamus. The purpose of this study was to determine the components of each pathway which terminate within the medial thalamus or the lateral thalamus and those which terminate in both the medial and lateral thalamus.

Cats were injected with two retrogradely transported fluorescent dyes. Evans Blue (10% W/V) was injected into the lateral thalamus to include the ventrobasal complex and the ventrolateral thalamus. Granular blue (2% W/V) was injected into the medial thalamus to include the centrolateral and centromedian nuclei and nucleus submedius. After a 10 day survival period, cats were perfused with 10% formalin, tissue was sectioned and viewed on a Zeiss epifluorescence microscope system.

Within the lumbar spinal cord, contralateral lamina I neurons, the primary component of the DSTT, terminated primarily within the lateral thalamus. The percentage of contralateral STT lamina I neurons which terminated with the lateral thalamus ranged from 54% to 78% while those projecting to the medial thalamus comprised 16% to 28%. The percentage of the contralateral STT, lamina I neurons which projected to both the medial and lateral thalamus ranged from 6% to 18%.

Cells of origin of the VSTT (contralateral laminae IV-VII, X) demonstrated approximately equal numbers of cells which projected exclusively to the medial thalamus or the lateral thalamus. Only within lamina VIII were cells identified which projected to both the medial and lateral thalamus (less than 5% of total lamina VIII).

These results show that cells of origin of both the DSTT and VSTT terminate within the medial and the lateral thalamus. Some cells within each pathway bifurcate and terminate within both the medial and lateral thalamus.

172.3 THALAMIC TERMINATIONS OF LAMINA I DORSAL HORN NEURONS IN THE CAT OBSERVED WITH THE PHASEOLUS VULGARIS LEUCOAGGLUTININ (PHA-L) ANTEROGRADE TRANSPORT METHOD. A. D. Craig. Physiologisches Institut der Universität, Röntgenring 9, D-8700 Würzburg, F.R.G.

Spinothalamic(STT) and trigeminothalamic(TrT) lamina I neurons include nociceptive-specific and thermoreceptive-specific cells, as well as multireceptive cells responsive to both modalities; in the cat's STT, these neurons project in a functionally specific manner to medial and/or lateral thalamus (Craig & Kniffki, J. Physiol. (London), in press). The need for an anterograde identification of the multiple lamina I termination sites in thalamus is emphasized by the widespread distribution of STT and TrT projections demonstrated previously. The resolution and sensitivity required for this analysis, which exceed those provided by current tracing methods, may be attainable with the recently introduced anterograde transport method based on the immunohistochemical localization of the lectin PHA-L (Gerfen & Sawchenko, Brain Res. 290:219, 1984).

In the present study, iontophoretic injections of PHA-L are made at sites of physiologically characterized lamina I neurons in the medullary or spinal dorsal horn in anesthetized cats. After a survival time of 1-3 wks, animals are perfused with 4% paraformaldehyde and 0.2% picric acid at low and high pH. Serial 40 µm frozen sections are processed with the indirect immunofluorescence method or with a biotin/avidin/Texas Red® marking procedure. Major incubation parameters are (23°C): 1st antibody 1 µg/ml, 40 hrs; 2nd antibody 5 µg/ml, 4 hrs; labeled avidin 5 µg/ml, 4 hrs.

Several injections have been restricted to lamina I, while some include laminae I and II. Although labeling of severed fibers has occurred, no evidence of retrograde or transneuronal labeling has been observed. In cases with injections at the site of nociceptive trigeminal lamina I neurons responsive to input from intra- and/or peri-oral structures (inc. teeth), bouton-bearing axonal branches or terminal arbors have been observed in several contralateral loci, including ZI, the caudal portion of Po_m, the ventral margin of VPM and VM_b, the region of the oral representation in VPM, and Sm_d. An injection at the site of a cold-responsive lamina I neuron resulted in additional terminations at the dorsomedial border of VPM. Morphologically distinct termination patterns have consistently been observed in several sites.

These results demonstrate that discrete analyses of ascending projections can be made with the PHA-L method in the cat. The direct identification of lamina I termination sites in the diencephalon provides a substantive basis for study of the functional organization of nociceptive and thermoreceptive input to thalamus.

172.4 ANATOMICAL BASIS FOR AN INTERACTION BETWEEN THE SPINOTHALAMIC AND LEMNISCAL SYSTEMS IN THE VENTROBASAL COMPLEX OF THE RAT THALAMUS. AN ELECTRON MICROSCOPIC STUDY. W. Ma*, M. Peschanski and H.J. Ralston III, Dept. of Anatomy, University of California, San Francisco, CA 94143 and INSERM, U 161, 2 rue d'Alesia, 75014 Paris, France.

In a recent light microscopic study (Neurosc. Abst., 10, 1984, 143-10), we have demonstrated the existence of a somatotopically organized overlap of the projections originating from the spinal cord and the dorsal column nuclei (DCN) in the ventrobasal complex of the rat thalamus (VB). Such an overlap, visualized at the light microscopic level, suggested that some interactioin between the two systems might occur at the level of single VB neurons receiving afferents from the two sources. The present experiment was designed to test this hypothesis by determining the existence of differentially labeled terminals impinging upon the same neuron in a study using a double-labeling anterograde strategy at the ultrastructural level.

Anesthetized Male Sprague-Dawley albino rats received an injection of a 10% solution of wheat-germ agglutinin conjugated to HRP (WGA-HRP) in the left side of the lumbar or cervical enlargements of the spinal cord 48 hours before sacrifice. In the same time, or 24 hours later, the left DCN were lesioned. One to two days later, the animals were perfused transcardially with heparinized saline followed by a phosphate buffered solution (0.1 M, pH 7.4) of 3% glutaraldehyde, 1% paraformaldehyde and 4% sucrose. Vibratome sections of the right VB were cut (50 µm-thick) and reacted using benzidine dihydrochloride as a chromogen then osmicated, dehydrated and flat-embedded. VB areas containing HRP labeled terminals originating from the spinal cord were trimmed out and cut on an ultramicrotome for further analysis with the electron microscope. As expected from previous studies, labeled spinothalamic terminals were large (2 to 7 µm in diameter), contained numerous round vesicles and formed several asymmetrical (Gray type I) synapses with large dendrites and, more rarely, somas of VB neurons. In the same fields, electron-dense, electron-lucent and neurofilamentous degenerating large terminals were visible. The degenerating terminals (0.5 to 3 µm in diameter) were often seen to contain round vesicles and to form asymmetrical Type I synapses with large dendrites and somas of VB neurons. Terminals from the cord or the DCN were sometimes close from each other, less than 1 µm apart, and in a few cases they were observed contacting the same post-synaptic element.

This study confirms at the ultrastructural level that terminals from the spinothalamic tract and the lemniscal system are present in the same areas of the VB. The existence of some convergence has been demonstrated which provides an anatomical basis for a direct effect of the two systems on single thalamic neurons. These results are in agreement with electrophysiological studies demonstrating the presence of noxious and non noxious responsive neurons in the VB of the rat. (Supported by NS 11614 to HJR, and by INSERM, France).

172.5 THE SPINO-RETICULO-DIENCEPHALIC PATHWAY IN THE CAT. A. Blomqvist* and K.J. Berkley. Dept. of Psychology, Florida St. Univ., Tallahassee, FL 32306.

A pathway from the spinal cord to the diencephalon via the reticular formation is generally believed to be of importance for the emotional and motivational aspects of pain sensation. However, little is known about the organization of this spino-reticulo-diencephalic pathway. The purpose of the present experiment was to examine this pathway in the cat by comparing the termination pattern of the spinal projection to the reticular formation with the distribution of the reticular neurons projecting to the diencephalon, using a variety of single and double orthograde and retrograde tracing techniques. Our preliminary results show that whereas several brainstem regions, not generally associated with the reticular formation, receive a dense spinal input, the spinal projection to the reticular formation is sparse, and overlaps only to a limited extent with the location of the reticulo-thalamic neurons. Furthermore, the reticular neurons projecting to the intralaminar nuclei and the zona incerta, two main rostral targets of the reticular formation, seem at least in part to be differently distributed. The findings thus suggest that 1) few reticulo-thalamic neurons receive a direct spinal input and 2) that the information transmitted from the reticular formation to the intralaminar nuclei and the zona incerta, respectively, may be different in character.

172.6 **Interstitial Nucleus of the Spinal Trigeminal Tract: A Specific Nociceptive Relay for Oral and Perioral Structures?** **R.C. Shults, A.R. Light, and S. Donaghy* Univ. of North Carolina Sch. of Medicine, Chapel Hill, NC 27514**

As part of an investigation of intra-oral and peri-oral sensory/nociceptive pathways in the trigeminal system of adult cats, peroxidase-anti-peroxidase immunohistochemistry and diaminobenzedine were used to visualize antibodies specific for substance P (S-P), leu enkephalin (L-ENK), 5-hydroxytryptamine (5-HT), somatostatin (SRIF) and vasoactive intestinal protein (VIP). As previously reported for nucleus caudalis (medullary dorsal horn) and spinal dorsal horn, S-P was located primarily in layers I and II-outer (IIo), L-ENK in layers I, IIo, II-inner (IIi), and III, and SRIF in layers IIo, IIi and III. S-P and L-ENK reactivity were also observed superficial to the spinal trigeminal tract (SVT) in the paratrigeminal nuclei. In more rostral sections, where nucleus caudalis is continuous with nucleus interpolaris, layers I and II are penetrated and dispersed by deep axon bundles. In the overlying SVT, islands of neuropil become evident as the interstitial nucleus of SVT (Falls and Phelan, Soc. Neurosci. Abs. 10: 482, 1984). These islands stain darkly for S-P, L-ENK and 5-HT. It is important to stress that these islands appear as layers I and II disappear from the underlying nucleus as if layers I and II had migrated into the tract overlying nucleus interpolaris and nucleus oralis. Islands of neuropil were observed with increasing frequency from the nucleus caudalis-interpolaris border, rostrally, to mid levels of nucleus interpolaris. More rostral sections contain progressively fewer islands in the tract over nucleus oralis.

While the interstitial nucleus of SVT (IN-SVT) may represent a novel structure with an unknown function, we would like to propose that it is homologous to layers I and II (marginal zone and substantia gelatinosa) in nucleus caudalis and the spinal dorsal horn and that it may represent a specific nociceptive relay for pulpal, intra- and peri-oral inputs. The following facts support this hypothesis: 1) patterns of localization of S-P, L-ENK and 5-HT are similar for IN-SVT, and layers I and II of nucleus caudalis and the spinal dorsal horn; 2) nociceptive primary afferent fibers have been shown to terminate in IN-SVT (Jacquin, M. personal communication) in a pattern similar to nociceptive afferent terminations in layers I and II of nucleus caudalis and the spinal dorsal horn; 3) close proximity of IN-SVT to major pulpal projection pathways (Westrum et al., Soc. Neurosci. Abs. 10: 993, 1984); and 4) projections to the thalamus from IN-SVT (Falls and Phelan, Soc. Neurosci. Abs. 10: 482, 1984). This projection pathway may explain sparing of oral and peri-oral pain and recurrence of pain following trigeminal tractotomies caudal to obex. Supported by NINCDS grants NS-16433 and NS-00534.

172.7 ULTRASTRUCTURAL ANALYSIS OF SUBSTANCE P AND OTHER SYNAPTIC PROFILES INNERVATING AN IDENTIFIED PRIMATE SPINOTHALAMIC TRACT NEURON. S.M.Carlton, C.C.LaMotte, C.N.Honda, D.J.Surmeier, N.C. deLanerolle and W.D.Willis. Mar. Biomed. Inst., Univ. Texas Med. Branch, Galveston, TX 77550 and Neurosurg. Sec., Yale Univ. School Med., New Haven, CT 06510.

In an effort to define the terminations of primary afferent and modulating systems onto spinothalamic tract (STT) neurons, we have combined intracellular staining of identified STT neurons with immunohistochemistry. STT cells in the lumbosacral cord of anesthetized monkeys (M. fascicularis) were antidromically activated from the contralateral thalamus, and after physiological characterization were intracellularly marked with HRP. Following perfusion with 2.5% paraformaldehyde, serial vibratome sections (50μm) were reacted for HRP and then immunohistochemically labeled for substance P using the PAP technique. Sections were flat embedded for light microscopic reconstructions. For ultrastructural analysis, serial EM sections were collected on formvar coated slot grids.

The one cell analyzed to date was a WDR neuron responsive to activation of low and high threshold cutaneous afferents innervating the foot. The soma was located at the lateral border of lamina V; the dendritic tree extended 700μm dorsoventrally, 1500 μm mediolaterally, and 1300μm in the rostrocaudal plane. The cell was characterized by numerous somatic and dendritic spines. Several types of terminals contacted the STT neuron, including: R terminals with small, clear, round, and occasionally dense core vesicles; DCV terminals with several dense core and clear, round vesicles; LGV terminals with numerous larger granular vesicles; P terminals with pleomorphic vesicles; and F terminals with flattened vesicles. Although examples of each type of terminal were found to contact the STT soma, dendrites, and somatic and dendritic spines, the frequency of each varied. The R terminal was by far the most common contact onto each STT structure, comprising 30-40% of the sample. The DCV and P types each accounted for about 20-35% of the terminals.

Most SP synaptic profiles were R terminals (with or without 1 or 2 dense core vesicles); they were found in contact with the STT somata, somatic spines and dendrites. Other SP profiles were LGV terminals usually observed in long varicose chains along the lateral V border; they contacted STT dendrites. A few SP profiles were DCV terminals, contacting STT dendrites and spines.

The results indicate that the entire soma of this WDR neuron, as well as its dendritic tree, is subject to a large variety of synaptic inputs, including different types of SP terminals which probably arise from several sources. (Supported by NIH grants NS13335, NS11255, NS09743, NS07185, NS07062, NS07216 and NS07574.)

172.8 ULTRASTRUCTURE OF PEPTIDERGIC AND SEROTONERGIC SYNAPTIC TERMINALS CONTACTING SPINOTHALAMIC AND OTHER LAMINA V NEURONS OF THE MONKEY CERVICAL CORD. C.C. LaMotte, Section of Neurosurgery, Yale Univ. School of Medicine, New Haven, CT. 06510.

The lateral reticulated border of lamina V contains both spinothalamic neurons and a high concentration of several peptides as well as serotonin. This study describes terminals in this region that are immunoreactive to a variety of peptides or 5-HT, and their synaptic contacts with spinothalamic neurons.

Spinothalamic neurons and their processes were retrogradely labelled following sterotaxic injections of HRP into the VPL region of the thalamus. Immunoreactive terminals were identified with specific antibodies to the neurochemicals, using the avidin biotin complex (ABC) method.

Substance P terminals are of three types. The most common are R terminals, containing small round clear vesicles and forming synaptic contacts onto the soma and dendrites of dorsal horn neurons. Some SP-R terminals are simultaneously presynaptic to another R terminal as well as a dendrite. A few SP terminals contain several dense core vesicles (DCV) as well as round vesicles. Other SP terminals contain many large granular vesicles (LGV) and are part of long varicose chains located along the lateral edge, in a region continuous dorsally with the marginal zone.

Somatostatin (SS) terminals are R terminals and contact somata, large and small dendrites, and spines. Some SS dorsal horn terminals are large and contain many mitochondria. Some SS terminals are postsynaptic to unlabelled R terminals.

Met-enkephalin terminals contain pleomorphic clear vesicles and several dense core vesicles; they form asymmetrical junctions on somata, large dendrites, and, more frequently, synapse on small dendrites and spines. Some ENK terminals are presynaptic to R or pleomorphic terminals.

Serotonin terminals are R type. However, 5-HT terminals contact somata and proximal dendrites with symmetrical junctions, but contact small dendrites with asymmetrical junctions. A few 5-HT terminals are large glomerular C terminals with round clear vesicles and scalloped edges. 5-HT terminals of either type rarely contain dense core vesicles.

Many of the above types of SP, SS, ENK and 5-HT terminals are found in synaptic contact with the soma and dendrites of retrogradely labelled spinothalamic tract neurons. Some of these STT neurons have somatic and dendritic spines that are also postsynaptic to some of these terminals. Although lateral lamina V contains many of the same neurochemicals identified in the superficial dorsal horn, its synaptic organization is quite different from that which we have previously described for laminae I and II. Furthermore, each of these neurochemical systems directly impinges onto STT cells. (Supported by NINCDS NS13335).

172.9 LIGHT AND ELECTRON MICROSCOPIC OBSERVATIONS OF ENKEPHALIN-IMMUNOREACTIVE PROFILES IN THE NUCLEUS SUBMEDIUS OF THE CAT THALAMUS. J.A. Coffield* and V. Miletic. Dept. of Struct. & Funct. Sci., School of Vet. Med., Univ. of Wisconsin, Madison, WI 53706.

The nucleus submedius (Sm) of the cat thalamus reportedly receives direct projections from neurons located in lamina I of the medullary and spinal dorsal horns (Craig and Burton, J. Neurophysiol., 45:443-466, 1981). Since lamina I neurons respond principally or exclusively to noxious cutaneous stimulation, the nucleus submedius might be a thalamic relay center for the processing of nociceptive information. In the present study we have employed the peroxidase-antiperoxidase (PAP) immunohistochemical technique to study the presence and distribution of enkephalin (ENK) in the Sm.

Adult cats were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde in 0.1M phosphate buffer. Fifty μm coronal and parasagittal Vibratome sections were processed for ENK with the PAP technique. For light microscopy (LM), 0.75% Triton X100 was added to the 1^{o}, 2^{o} and PAP incubations to improve antibody penetration. No detergents were added to the material used for electron microscopy (EM).

The ENK immunoreactive fibers appear confined to a small area (100-200μm in diameter) in the dorsal and caudal part of the Sm, and are located from 40 to 100μm from the dorsal edge of the Sm. This area appears to overlap at least in part with the Sm area shown by Craig and Burton to contain projections from the lamina I neurons. At the LM level at least two different types of immunoreactive axons could be seen based on the size of their varicosities. At the EM level preliminary results show that the ENK immunoreactive endings predominantly contact cell bodies and dendrites.

These data indicate a limited and concentrated presence of ENK immunoreactive fibers in the cat Sm. It remains to be established whether any of these fibers originate from lamina I, and what their possible function in sensory information processing might be.

172.10 IMMUNOCYTOCHEMICAL INVESTIGATION OF MONOAMINERGIC INTERACTION IN BRAIN STEM RAPHE NUCLEI OF THE CAT. S. Pretel and M.A. Ruda. Neurobiology & Anesthesiology Br., NIDR, NIH, Bethesda, MD 20205.

The serotonergic (5-HT) neurons of the raphe nuclei are involved in the modulation of sensory, motor and autonomic functions at the spinal level. The neurochemical identity of the afferents which innervate these raphe neurons is not known, however, behavorial data suggest an interaction between noradrenaline afferents and 5-HT neurons in the raphe nuclei. We examined the possible interaction between these two monoamines in n. raphe magnus (NRM) obscurus (NRo) and pallidus (NRp) using a double-label immunocytochemical method.

Cats were perfused with 4% paraformaldehyde. Following cryoprotection, 18 μm transverse or sagittal sections of the brain stem were cut with a cryostat. Monoamines were identified using antisera to 5-HT, dopamine-ß-hydroxylase (DBH, the synthesizing enzyme for noradrenaline which is present in noradrenaline and adrenaline neurons) and tyrosine hydroxylase (TH, an enzyme present in dopamine, noradrenaline and adrenaline neurons). Since there is little evidence for the presence of a catecholamine other than noradrenaline in axons of the caudal raphe nuclei, it is likely that most of our DBH and TH immunoreactive axons contained noradrenaline. The tissue was processed sequentially for each antigen, using first the PAP immunocytochemical method and second the indirect immunofluorescence method with FITC as the fluorochrome. Both labels could be viewed simultaneously using epi-fluorescence and a blue fluorescence filter combination.

Numerous 5-HT cell bodies with labeled proximal dendrites were seen in the NRM, NRo and NRp as well as DBH or TH immunoreactive axons. Some 5-HT labeled axons were also visible. When viewed under high magnification with differential focusing, some of the DBH-immunoreactive varicosities appeared to make contact with 5-HT neurons and proximal dendrites. These contacts were found more often on the cell bodies than proximal dendrites. In addition, we observed 5-HT axons which appeared to contact 5-HT neurons in the NRM, NRo and NRp, but these were found less frequently than DBH varicosities contacting the 5-HT neurons.

These observations suggest that 5-HT neurons in the NRM, NRo and NRp receive input from NA and 5-HT afferents and that these two monoaminergic systems interact within the raphe nuclei. Since afferents from NRM likely distribute to the dorsal horn while the more caudal NRo and NRp afferents terminate mainly in the ventral horn, noradrenergic modulation of 5-HT neurons in the brain stem presumably effects the activity of sensory as well as motor systems.

172.11 IMMUNOHISTOCHEMICAL LOCALIZATION OF GLUTAMATE, GLUTAMINASE AND ASPARTYL AMINOTRANSFERASE NEURONS IN THE SPINAL TRIGEMINAL NUCLEUS OF THE RAT. K.R. Magnusson*, A.J. Beitz, A.A. Larson, J.E. Madl* and R. Altschuler. (SPON: G.W. King). University of Minnesota, St. Paul, MN 55108 and NINCDS, Bethesda, MD 20205.

In an attempt to identify glutamatergic neurons in the spinal trigeminal nucleus (STN), three different glutamate markers were compared using immunohistochemical techniques. Polyclonal antibodies against glutaminase (GLNase) and aspartate aminotransferase (AATase) and a monoclonal antibody to carbodiimide-fixed glutamate (Glu) were used. STN glutamatergic neurons projecting to the thalamus were identified by a combined retrograde transport-immunohistochemical technique. Three Sprague-Dawley male rats were perfused intracardially with paraformaldehyde (4%) and glutaraldehyde (0.1-0.2%) and sections were subsequently reacted with either the GLNase or AATase antibody. Three additional rats were perfused with a solution of 5% carbodiimide and 0.5% glutaraldehyde in phosphate buffer followed by 5% glutaraldehyde. The sections were post-fixed in 5% glutaraldehyde, washed and then reacted with the monoclonal glutamate antibody. Sections incubated with either the polyclonal antisera or the monoclonal antibody were subsequently processed utilizing the avidin-biotinylated peroxidase technique and reacted with diaminobenzidine to visualize the immunoreactive cells. Horseradish peroxidase (HRP) was injected into the ventroposterior nucleus of the thalamus and the combined retrograde transport-immunohistochemical procedure was performed as previously described (Beitz, A.J., Neurosci, 7:2753, 1982). Immunohistochemically reactive neuronal profiles were found in all three subnuclei of STN with each of the three markers. The caudal nucleus of STN (Sp5C) had the highest number of immunoreactive profiles, followed by the interpositus nucleus of STN (Sp5I) and the oral nucleus of STN (Sp5O). The AATase antiserum was found to label more neuronal profiles than GLNase and Glu. This may suggest that the AATase antiserum is staining another population of cells in addition to glutamate. Following large HRP injections into the thalamus, HRP labeled cells were found in all three of the trigeminal subnuclei. Retrogradely labeled neurons were most prominent in the Sp5I and Sp5O. Neurons containing both retrogradely transported HRP and glutamate or glutaminase immunoreactivity were evident predominantly in Sp5I and rostral Sp5O. Approximately 20-35% of HRP labeled neurons were double-labeled. These results suggest that glutamatergic neurons are present throughout the STN and that some of these neurons project to the thalamus. Supported by NIH grants DE06682 and NS19208 to A.J.B. and NIH grant NS17407 to A.A.L.

172.12 DISTRIBUTION OF PONTOSPINAL NORADRENERGIC AXONS IN RAT LOWER CERVICAL SPINAL CORD. R.M. Fay and D.J. Mayer. Dept. of Physiology, Med. Coll. of Virginia/Va. Commonwealth Univ., Richmond VA 23298.

A powerful bulbospinal antinociceptive system is known to descend via the dorsolateral funiculus (DLF), but its neurochemical nature is a matter of controversy. Noradrenaline (NA) is a neurotransmitter candidate for this system because pontine noradrenergic (NAc) cell groups are known to project to the spinal cord, and NA has been shown to play a role in descending inhibitory systems. In order to determine the spinal funicular distribution of descending NAc fibers, we have developed a sensitive procedure which involves combined retrograde and immunohistochemical labelling. Some features of this procedure are: (1) implanting 30% horseradish-peroxidase (HRP) slow release gel in a selected cord target area (appropriate lesions and/or a specialized delivery apparatus is used to minimize undesired labelling when implanting areas deep within the cord); (2) cutting and staining cords for HRP to verify actual labelling; (3) use of a diaminobenzidene-stabilized tetramethylbenzidene (TMB) reaction to optimize retrograde-HRP staining in combined-labelling sections (Rye, J. Histochem. Cytochem. 32:1145); (4) use of the peroxidase-anti-peroxidase technique for immunohistochemical staining; and (5) use of the ultra-sensitive TMB stain for retrograde HRP on alternating sections in order to evaluate the efficacy, and extrapolate the maximum expected amount, of retrograde staining in the combined-labelling sections. All areas of spinal-cord white matter have been selectively implanted, with results as follows. Implantation of the dorsal columns, the lateral funiculus (LF) adjacent to lamina V, and the outer margin (approx. one-third of their depth) of the LF and ventrolateral funiculus (VLF) resulted in practically no combined labelling. Implantation of the ventral funiculus (VF) and the internal two-thirds of the VLF and LF, however, resulted in consistent, strong labelling of the ventral locus coeruleus (primarily ipsilateral), the subcoeruleus nucleus (ipsilateral only), A5 (ipsilateral only), and A7 (bilateral) cell groups. DLF implants, on the other hand, produced a consistent but light combined label in a smaller percentage of NA cells in the same general locations as LF, VLF, and VF implants. Although it is clear that the majority of NAc fibers descends in a crescent-shaped bundle within the LF and VLF (the distribution pattern in the VF is yet to be determined), these findings alone are insufficient to distinguish whether the NAc DLF fibers arise from disparate pontospinal NAc cells or arise as collaterals from NAc axons in the more-ventral funiculi. Resolution of the cause of this difference may provide information on the role of the DLF in antinociception.

Supported in part by PHS grant DA 00576.

172.13 **THE EFFECTS OF SEROTONIN AND SUBSTANCE P ON SPINAL PAIN REFLEXES.** R.M. Murphy* and F.P. Zemlan (SPON: R.J. Hitzemann). Dept. Psychiatry, University of Cincinnati College of Medicine, Cincinnati, OH 45267-0559.

Several lines of evidence indicate that the descending bulbospinal serotonin system suppresses incoming noxious input to the spinal cord and mediates narcotic analgesia. Recent immunohistochemical studies have shown that 5-HT and substance P (SP) coexist in the same bulbospinal neurons, and are colocalized in the same spinal cord dense core vesicles. The present behavioral studies examined the relationship(s) of 5-HT and SP in the control of three spinal pain reflexes.

Two days after spinal transection, 5-HT_1 receptors were stimulated by ip administration of the 5-HT agonist 5-MeODMT (1.5 mg/kg) which resulted in the expansion of the receptive field (RF) area for all three spinal pain reflexes (ventro-, 16% increase from baseline; dorsi-, 51% increase; lateral, 219% increase). Intrathecal SP administraion (0,0.25,1.25, 7.5 ng) in rats pretreated with 5-MeODMT, produced a significant reduction of pain reflex RF area for all three spinal reflexes at all three doses of SP. The largest reduction occurred with the 0.25 ng dose of SP (ventro-, 54% decrease; dorsi-, 55% decrease; lateral, 65% decrease). However, intrathecal SP administration in rats not pretreated with 5-MeODMT produced a dose-response related expansion of pain reflex RF area for all three reflexes (eg. ventro-, 80% increase; dorsi-, 110% increase; lateral-, 275% increase after the 7.5 ng SP dose).

The present data, consistent with other studies in intact animals, indicate that administration of SP alone facilitates spinal cord pain transmission probably by activation of SP primary afferent receptors. Similarly, 5-HT agonist administration facilitated pain transmission in the present study consistent with earlier reports. However, SP inhibited the effect of 5-MeODMT on spinal reflexes when administered after the 5-HT agonists. Thus, SP demonstrated the opposite effect following 5-MeODMT treatment suggesting a second mechanism of action. This second mechanism may be related to the descending 5-HT/SP system. At this meeting, we report electrophysiological data suggesting a functional interaction of 5-HT and SP released from bulbospinal 5-HT/SP neurons. Also, we report an apparent coupling of a subpopulation of spinal 5-HT and SP receptors suggested by receptor binding studies. In the present study, the inhibition by SP of the 5-MeODMT induced facilitation of spinal pain transmission may be related to an interaction between 5-HT and SP associated with the bulbospinal 5-HT/SP system.

(Supported by NS 18326).

OPIOID RECEPTORS II

173.1 DERIVATIVES OF 7α-AMINOMETHYL-6,14-endo-ETHENOTETRAHYDROTHEBAINE AS POTENTIAL PHOTOAFFINITY LABELS OF OPIOID RECEPTORS. J.C.Schaeffer, J.J. Kopcho* and M.A. Byer*. Department of Chemistry, California State University, Northridge, California 91330.

Considerable pharmacological and biochemical evidence indicates the presence of multiple opioid receptors in the brain. In order to establish whether these apparently different receptors are either simply different conformations of the same molecule stabilized by different membrane environments, different binding sites on a single stable molecular conformation, or totally different molecular species, specific irreversible labels would be most useful. Toward this end, a series of potential photoaffinity labels derived from 7α-aminomethyl-6,14-endo-ethenotetrahydrothebaine (I) containing an 4-azido-2-nitroanilino moiety that can be photoactivated at wavelengths greater than 350nm has been synthesized. The relative binding potencies of these compounds were ascertained by a binding assay using a crude rat brain membrane preparation and 1nM naloxone ± 1μM levallorphan in the presence or absence of sodium.

Compound I was synthesized from thebaine in three steps. It was converted to 7α-N-(4-azido-2-nitrophenyl)aminomethyl-6,14-endo-ethenotetrahydrothebaine (II) by reaction with 4-azido-2-nitrofluorobenzene. Compound II had an I_{50} of 1000nM. Monodemethylation of II at the 6 or 3 (III) position gave analogs with I_{50}s (100mM Na) of 320nM and 5.6nM, respectively. Demethylation at both the 3 and 6 positions gave an analog (IV) with an I_{50} (100mM Na) of 1.7nM, while replacing the N-methyl group in III with a cyclopropylmethyl group gave analog V that had an I_{50} (100mM Na) of 3.7nM. The 3-demethylation of I afforded the corresponding oripavine derivative (VI). The reaction of VI with N-hydroxysuccinimidyl N-(4-azido-2-nitrophenyl)-3-aminopropionate gave the corresponding 7α-amide derivative (VII) that had an I_{50} (100mM Na) of 0.32nM. In the absence of sodium the I_{50}s of III, IV, V, and VII were 0.6nM, 0.4nM, 2.1nM, and 0.38nM, respectively. The sodium ratios suggest that III is probably a pure agonist, IV and V are mixed agonists/antagonists, and VII is a pure antagonist.

Compounds III,IV,V, and VII are potent inhibitors either in the absence or presence of sodium of tritiated naloxone binding, and thus are excellent candidates for further evaluation as photoaffinity labels.

173.2 HIGH RESOLUTION RADIOAUTOGRAPHIC VISUALIZATION OF DELTA OPIOID RECEPTORS IN RAT BRAIN USING IODO-AZIDO DTLET, A HIGHLY SELECTIVE PHOTOAFFINITY PROBE. F Pasquini*. A Beaudet. P. Bochet*, C. Pharmac. et Biol.. Univ. René Descartes, 4, ave. de l'Observatoire, 75270 Paris, France.

^{125}I-azido DTLET is a pure monoiodinated derivative of the δ opioid selective photoaffinity ligand azido DTLET (Tyr-DThr-Gly-pN_3Phe-Leu-Thr), which binds specifically and with high affinity to rat brain membrane preparations (Kd=14 nM) and shows a displacement profile by DAGO (Ki=370 nM) and DTLET (Ki=2 nM) similar to that of (^{3}H)DTLET (Bochet et al., INRC, 1985). The possibility of applying this selective photoaffinity probe to the high resolution radioautographic detection of brain δ opioid receptors was investigated using 20 μm-thick cryostat sections from rat neostriatum. Incubation of unfixed tissue sections for 45 min at room t°, with 0.2-0.7 nM ^{125}I-azido DTLET yielded remarkably high specific/total binding ratios (> 90%). Pre-fixation of the brain with fixative solutions containing 0.75-2% paraformaldehyde or 0.1% acroleine almost totally abolished this specific binding. However, in sections pre-fixed with weak concentrations of glutaraldehyde (0.3-0.5%) associated or not with 0.2% paraformaldehyde and 1% tannic acid up to 65% of the original specific binding was still detectable. The radioautographic distribution of the bound radioactivity was characterized in both fresh and pre-fixed sections by a dense and homogeneous labeling of the caudate-putamen, similar to that observed using other δ selective ligands. Irradiation of the labeled sections (pre-fixed or not) with a single 254 nm U.V. flash allowed retention of 20-30% of the specifically bound radioactivity during subsequent post-fixation and dehydration steps, irrespective of the nature (glutaraldehyde, paraformaldehyde or a mixture of both) and concentration (1-4%) of the post-fixative used. In contrast, in sections that were not exposed to U.V. light, the radioactivity was totally washed out from the sections in the course of fixation and dehydration. Similar patterns of radioautographic labeling were observed before and after U.V. flashing followed by histological processing, suggesting that the radiolabeled molecules had been cross-linked onto or in the vicinity of their specific binding sites during irradiation Finally, the topographic distribution of covalently bound ^{125}I-azido DTLET observed in radioautographs prepared by classical dipping techniques was similar to that revealed by film radioautography. These results indicate that ^{125}I-azido DTLET is an ideal tool for the selective light microscopic radioautographic localization of brain δ opioid receptors and should be applicable to the visualization of these sites at the electron microscopic level. Supported by the C.N.R.S. (France) and the MRC (Canada).

173.3 CYCLOFOXY, A FLUORINATED OPIATE RECEPTOR LIGAND: HIGHLY SELECTIVE LABELING OF BRAIN OPIATE RECEPTORS, IN VIVO. N.L. Ostrowski, T. Burke*, K.C. Rice*, A. Pert and C.B. Pert+. Section on Behavioral Pharmacology, Biological Psychiatry Branch, NIMH, *Section on Medicinal Chemistry, Laboratory of Chemistry, NIADDK, +Section on Brain Biochemistry, Clinical Neuroscience Branch, NIMH, 9000 Rockville Pike, Bethesda, MD 20205 U.S.A.

Cyclofoxy, a fluoro-analogue of naltrexone, has been designed specifically to permit labeling of opiate receptors in living animals and humans (Burke, Rice & Pert, Heterocycles, Vol. 23, p. 99, 1985). Recently, using positron emission tomography (PET) 3-[^{18}F]-acetylcyclofoxy was shown to accumulate in opiate receptor-rich brain regions of a live baboon and to be stereospecifically displaced by injections of (-)- but not (+)-naloxone (Pert, et al., FEBS Letters., Vol. 177, p. 281, 1984). We now present autoradiographic evidence that ^{3}H-cyclofoxy labels a population of opiate receptors in brain that is virtually identical to that labeled by ^{3}H-naloxone. Furthermore, the binding patterns of ^{3}H-cyclofoxy in brain are similar after injections into live rats and under in vitro binding conditions. Intraveous injections of ^{3}H-cyclofoxy into rats yielded optimal brain to cerebellar binding ratios in homogenates, supernatants and in 24-micron thick brain sections 60 minutes after 30μCi per animal (s.a. = 16.4 Ci/mmol). Autoradiographs revealed the typical opiate-antagonist binding profile with marked retention of ^{3}H-cyclofoxy in striatal patches, the subcallosal streak, thalamus and medial habenula and little retention of label in the cerebellum. ^{3}H-cyclofoxy binding was reversible; that is, radioactivity could be removed from brain slices by washing slide-mounted sections for 30 minutes. The same brain sections, after washing, again bound ^{3}H-cyclofoxy or ^{3}H-naloxone in the same pattern, in vitro. However, when pre-washed brain sections were incubated in the presence of cold naloxone, ^{3}H-cyclofoxy binding was reduced to background levels. These data show that ^{3}H-cyclofoxy labels the well-described naloxone-sensitive opiate receptor in vivo and in vitro. The present results combined with evidence that cyclofoxy demonstrates low levels of toxicity in animals suggest that cyclofoxy is an excellent tool with which to study the physiological role of opiate receptors in living animals and humans using in vivo autoradiography and PET.

173.4 BINDING PROPERTIES OF [^{3}H] DIPRENORPHINE AND [^{3}H] ETHYLKETOCYCLAZOCINE IN GUINEA PIG BRAIN. Hurlbut, D.E.* and Leslie, F.M. Department of Pharmacology, University of California, Irvine, CA 92717, U.S.A.

The pharmacological characteristics of [^{3}H] diprenorphine (^{3}HDIP) and [^{3}H] ethylketocyclazocine (^{3}HEKC) binding to the putative kappa opioid receptor in guinea pig brain have been examined. Well washed membrane preparations were incubated at 22°C for 90 min in 50 mM Tris buffer (pH 7.4) containing enzymatic inhibitors (bacitracin, 1 mM and bestatin, 10 µM) and appropriate labelled and unlabelled drugs. Specific binding was defined in the absence and presence of levallorphan (1µM). The affinity of the two radioligands was determined by Scatchard analysis. Dose response curves for inhibition of radioligand binding by a number of unlabelled drugs were then generated and compared. Two methods were used to analyze the pharmacological properties of radioligand binding sites in anatomically defined brain regions: regional dissection and autoradiographic analysis. For autoradiography, brain sections were cryostat cut and incubated as described above. Radioligand binding was then visualized by exposure to tritium-sensitive film. Grain density was quantified by computerized image analysis (Altar et al, Science 228:597, 1985). In guinea pig cerebellum, ^{3}HDIP and ^{3}HEKC exhibited monophasic Scatchard plots with similar Bmax values. Selective µ and δ blockers did not displace radioligand binding, confirming previous reports that this tissue contains only "kappa" opioid binding sites (Robson, L.E. et al, Neuroscience 12:621, 1984). A number of other inhibitors, including dynorphin A, exhibited biphasic inhibition curves, with Hill coefficients significantly less than 1. Similar biphasic inhibition curves were obtained in guinea pig whole brain homogenate in the presence of selective µ and δ blockers (D-Pro4-morphiceptin, 300 nM, and DSLET, 100 nM). Curves could be fitted to a two site receptor model using computerized non-linear least squares analysis. There were two lines of evidence to suggest that these high and low affinity sites were independent, rather than interconverting forms of the same receptor: 1) various opioid drugs exhibited different rank orders of potency for inhibition of the two binding sites and 2) proportions of the two binding sites were found to vary in different regions of the brain. These data suggest possible heterogeneity of "kappa" opioid binding sites in guinea pig brain.

173.5 N-ETHYLMALEIMIDE TREATMENT PREVENTS FORMATION OF A HIGH AFFINITY δ OPIOID AGONIST RECEPTOR COMPLEX WITHOUT ATTENUATING GUANINE NUCLEOTIDE INHIBITION. J.W. Spain* and C.J. Coscia, Dept. Biochem., St. Louis Univ. Sch. Med., St. Louis, MO 63104, U.S.A.

Previously, we demonstrated multi-step association of both µ and δ opioid agonists to partially purified bovine hippocampal synaptic membranes (SPM's) (Scheibe et al., J. Biol. Chem. 259, 13298-13303, 1984). Subsequent experiments suggested the involvement of a GTP binding protein (N_i) in the formation of a high affinity complex for the δ selective agonist, D-ala^2-D-leu^5-enkephalin (DADL). In the present study, NEM was used to alkylate bovine hippocampal SPM's in an attempt to gain additional insight into the mechanism of GTP action. Dissociation of ^{3}H-DADL (in the presence of 20 nM D-ala^2-mephe^4-gly-ol^5 enkephalin) from SPM's pretreated with 0.2 mM NEM for 20 min (quenched with 2 mM DTT) was compared to controls. Computerized analysis of kinetic data indicated that NEM treatment prevents the association-time dependent formation of the slowly dissociating state which has been attributed to a putative ternary complex of receptor-ligand-N_i. This interpretation is consistent with the known ability of NEM to block receptor mediated inhibition of adenylate cyclase. Computer modeling of the multi-step association, with or without NEM uncoupling, simulated binding patterns for dissociation and association that were comparable to those observed experimentally.

The effect of the GTP analog, Gpp(NH)p, on steady state DADL binding to the NEM treated SPM's differed from that previously reported for less specific enkephalins in tissue containing more µ than δ sites. The observed enhancement of Gpp(NH)p inhibition at δ sites following NEM treatment resulted in 15-20% decreased binding at 1-10 µM while in controls the same effect required 50-100 µM Gpp(NH)p. In parallel experiments the expected decrease in potency of Gpp(NH)p with µ-specific ligands was observed. If Gpp(NH)p was added to NEM-treated SPM's at the onset of dissociation, the off-rate was significantly increased and proved to be association time-independent. In control membranes, the effect of Gpp(NH)p upon dissociation was most prominent following prolonged association time periods and was negligible after a brief association. Within the framework of the ternary complex theory, these results suggest the existence of a discrete GTP binding site in addition to the GTPase present on N_i. This site, when occupied by guanine nucleotide, causes the dissociation of δ agonist. As evidenced by independent studies in our labs, this binding attenuation is reversible by divalent cations. Supported in part by NSF BNS 81-14947 and NIH HL 07050 grants.

173.6 INTERACTION OF RELATIVELY SELECTIVE DELTA OPIOID LIGANDS WITH HIGH AFFINITY MU$_1$ OPIOID BINDING SITES. Y. Itzhak and G. W. Pasternak, The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021 U.S.A.

Previous pharmacological and biochemical studies indicated that both opiate alkaloids and enkephalins which cross react with mu and delta sites display similar high affinity to mu$_1$ opioid binding sites. This study was undertaken in order to elucidate whether relatively selective delta-ligands: DSTL, [D-Pen^2, L-Pen^5] - and [D-Pen^2, L-cys^5]enkephalins display affinity for mu$_1$ sites in addition to their interaction with delta sites.

Control and naloxonazine (NAZ) treated rat brain membranes were washed extensively and binding of ^{3}H-DSTL and ^{3}H-DAGO (mu) was tested. Saturation analysis of ^{3}H-DSTL binding to control membranes revealed a biphasic Scatchard plot K_D = 0.2 nM; Bmax = 0.7 fmole/mg tissue and K_D = 3.9 nM; Bmax = 7.4 fmole/mg tissue. In contrast a linear Scatchard plot was obtained in NAZ-treated membranes (K_D = 4.4 nM, Bmax = 7.5 fmole/mg tissue). Inhibition of ^{3}H-DAGO binding by delta-ligands or ^{3}H-DSTL mu-ligands (DAGO and morphine) was biphasic, i.e. low contractions (0.5-10 nM) inhibit 5-25% of the corresponding ^{3}H-ligand binding while considerably higher concentrations were required to inhibit the rest of that binding. However, treating NAZ eliminated the inhibition of binding observed with low concentrations leaving a monophasic inhibition of ^{3}H-ligand binding.

The results presented in this study indicate that selective delta-ligands still display high affinity for mu$_1$ sites.

173.7 SYNTHESIS AND BIOLOGICAL ACTIVITY OF POTENT ANALOGS OF DYNORPHIN-(1-13) WITH HIGH AFFINITY FOR THE κ OPIOID RECEPTOR. M. Dumont, L. Lachance* and S. Lemaire. Département de Pharmacologie, Faculté de Médecine, Université de Sherbrooke, Sherbrooke, Québec, Canada J1H 5N4.

Various analogs of Dynorphin-(1-13) (Dyn-(1-13)) substituted in position 8 or 10 were synthesized by the solid-phase method and their specific activity was measured by their binding potency to κ opioid receptors on guinea pig cerebellum and their ability to inhibit the electrically-induced contractions of the guinea pig ileum and the mouse vas deferens. The synthetic peptides were cleaved from the resin with liquid HF and purified by successive chromatographies on Sephadex G-10 and Nucleosil C-18. Their purity was assessed by thin layer chromatography on silica gel, analytical high pressure liquid chromatography on μ-Bondapak C-18 and amino acid analysis. Binding assays were performed at 22°C for 30 min with 2 ml aliquots of the membrane preparation (Ca 1 mg wet weight) and 2 nM [^{3}H]-ethylketocyclazocine ([^{3}H]-EKC). Bacitracin (2.5 x 10^{-5} M) was added to the incubation medium to protect the peptides from enzymatic degradation. The bound ligand was separated from free by filtration though GF/B Whatman filters. Introduction of Ala in position 8 produced a marked increase in the activity of the peptide on the κ sites (Ki:0.05 nM as compared with 0.11 nM for Dyn-(1-13)) and in the mouse vas deferens (IC_{50}:11 nM as compared with 21 nM for Dyn-(1-13)). Its activity on the guinea pig ileum was slightly decreased as compared with that of the parent peptide. Other substitutions in position 8 such as the introduction of D-Ala, Trp or D-Trp caused either no change or slight decreases in the biological activity of the peptide. On the other hand, the introduction of D-Pro in position 10 of Dyn-(1-13) induced no change in the potency of the peptide for the κ receptor while its activity on the guinea pig ileum was lesser than that of the parent peptide. Finally, replacement of position 10 by Trp or D-Trp caused important decreases in the activity of the peptide in all assays. It is concluded that more potent analogs of Dyn-(1-13) with high affinity for the κ opioid receptor can be obtained by modification of the hydrophobicity and steric bulkiness of the residue in position 8.

173.8 BINDING SITE SPECIFICITY OF ANTI-IDIOTYPIC ANTI-OPIATE RECEPTOR ANTIBODIES TO NEUROBLASTOMA x GLIOMA OPIATE RECEPTORS J.A. Glasel and W.E. Myers, University of Connecticut Health Center, Farmington, CT 06032

We have recently reported the production and purification of rabbit polyclonal anti-idiotypic (anti-Id) anti-opiate receptor antibodies (Glasel & Myers, Life Sci., *in press*). Following affinity purification, these antibodies competitively, and reversibly inhibit binding of ^{3}H-morphine to rat neural membranes. In addition, the anti-Ids displace ^{3}H-naloxone, and ^{3}H-DADLE in a binding site-specific manner (unpublished results).

As an approach to investigating similarities between rat brain opiate receptors, and opiate receptors expressed by neuroblastoma x glioma hybrid cells, we have examined the effects of our antibodies on opiate binding to the hybrid cell receptors.

Mouse neuroblastoma x rat glioma (NG-108-15) hybrid cells were grown to confluency in culture flasks. ^{3}H-morphine, ^{3}H-naloxone and ^{3}H-DADLE binding to whole cells was determined using the standard filter assay. The effect of our antibodies on opiate binding was established by the addition of 20ug of the affinity purified antibodies to the incubation mixtures following pre-incubation with radioligand.

The anti-Id antibodies completely blocked ^{3}H-morphine binding, reduced ^{3}H-naloxone binding by greater than 50%, but had no effect on binding of ^{3}H-DADLE. This is in contrast to what we have observed in rat neural membrane assays, suggesting receptor subclass differences between the two sources.

173.9 OPIATE RECEPTORS IN RAT PITUITARY ARE CONFINED TO THE NEURAL LOBE AND ARE EXCLUSIVELY KAPPA. M. Herkenham, K. C. Rice*, A. E. Jacobson*, V. Bykov* and R. B. Rothman. Lab. Neurophysiol., NIMH (MH), Lab. Chemistry, NIADDK (KR and AJ), Bethesda, MD 20205 and Lab. Preclinical Pharmacol., St. Elizabeths Hospital, NIMH, Washington, DC 20032 (VB and RR).

The distribution, density, and subtype specificity of opiate receptors in the rat pituitary were examined by quantitative autoradiography after in vitro binding optimized to label mu, delta or kappa opiate receptors. After pre-incubation, sections for mu and delta binding were respectively incubated at room temperature for 90 min in 2 nM [^{3}H]D-ala^2-MePhe^4-Gly-ol^5-enkephalin or 5 nM [^{3}H]D-ala^2-D-leu^5-enkephalin plus 30 nM oxymorphone. Sections for kappa binding were pretreated with etonitazene and fentanyl derivatives, BIT and FIT, to irreversibly alkylate the mu and delta sites, washed, and incubated at 0°C for 3 hrs in 2 nM [^{3}H]bremazocine plus 0.4 M NaCl. Binding to BIT and FIT treated brain membranes in the 0°C/NaCl condition gave an apparent single class of receptors with a Kd of 0.45 nM, a Bmax of 378 fmole/mg prot, and a kappa profile of ligand displacement by opiate analogs. To replicate earlier studies, some sections were incubated at 0°C in 2.5 nM [^{3}H]naloxone plus 100 mM NaCl. All sections were washed, dried and apposed to LKB film for two months.

Film densitometry showed that mu and delta binding was undetectable in the pituitary but showed characteristic subtype patterns in co-processed rat brain sections. On the other hand, [^{3}H]bremazocine bound moderately densely (about the same density as in the substantia nigra and periaqueductal gray) to the neural lobe. A thin outer rim of binding had about 3-fold higher density than the central portion of the neural lobe. Binding in the anterior and intermediate lobes was not significantly higher than the blank (generated by adding 1 μM etorphine). [^{3}H]naloxone binding showed the same pattern as did [^{3}H]bremazocine, but with only about one-tenth the density.

These results indicate that opiate receptors are confined to the neural (posterior) lobe and are exclusively kappa. Specific [^{3}H]naloxone binding can be attributed to its affinity for the kappa receptor. Morphine and enkephalin bind weakly in neural lobe homogenates compared to brain (Simantov and Snyder, Brain Res., 1977, 124: 178), supporting the selective presence of kappa receptors in the pituitary. The kappa-preferring endogenous ligand, dynorphin, is densely localized to nerve terminals in the neural lobe. Future studies may show the functional relationship of kappa receptors to the endogenous peptides. In the meantime the rat pituitary, because it contains only kappa receptors, is a useful tissue for biochemical characterization of opiate receptor subtypes.

173.10 THE LABELING IN VIVO OF SIGMA OPIOID RECEPTORS IN MOUSE BRAIN WITH (+)-[^{3}H]-SKF10047. R.M. Ferris, A. Russell, F.L.M. Tang and R.A. Maxwell. Dept. of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

The sigma opioid receptor, so named because of the distinct pharmacological profile produced by its prototypic agonist SKF 10047 (N-allynormetazocine), is believed to mediate mania and other psychotomimetic effects in man. Recently, a site that binds (+)-[^{3}H]-SKF10047 has been identified in guinea pig and rat brains in vitro. While this sigma receptor has received extensive biochemical and pharmacological characterization in vitro, little information is available on the nature of the sigma site in vivo. In the present study, we describe the in vivo labeling of sigma opioid receptors in mouse brain using (+)-[^{3}H]-SKF10047 as a ligand, and have attempted to compare the relative potencies of various drugs on sigma sites in vivo and in vitro. Mice were injected with 5 μCi of (+)-[^{3}H]-SKF10047 into the tail vein. After various time intervals, the mice were decapitated, their brains were rapidly removed, weighed and homogenized in 50 mM Tris-HCl buffer, pH 7.7 and total and particulate (specific and nonspecific) bound radioactivity were determined (detailed methodology will be presented). Specifically bound (+)-[^{3}H]-SKF10047 in the particulate fraction was defined as the difference in total radioactivity in the particulate fraction obtained from vehicle injected mice minus the radioactivity in the particulate fraction from haldol (2 mg/kg i.p.) injected mice. Specifically bound (+)-[^{3}H]-SKF10047 in the particulate fraction reached peak levels 30 min. after i.v. injection declined rapidly over the next 120 min., and constituted 87% of the total particulate radioactivity. Labeling of the sigma opioid sites could be blocked in vivo by injecting mice i.p. with the drug 30 min. before the i.v. injection of the ^{3}H ligand. Under these conditions, haldol was found to be the most potent compound in reducing specific (+)-[^{3}H]-SKF10047 binding with an ID_{50} of 0.75 ± 0.024 mg/kg. Other neuroleptics such as thioridazine and chlorpromazine had good potency with ID_{50} values of 8.9 ± 2.02 mg/kg i.p. and 19.2 ± 1.4 mg/kg i.p. Clozapine and spiperone were very weak inhibitors in vivo. Specific (+)-[^{3}H]-SKF10047 binding was also reduced in vivo by imipramine, dl-propranolol, bupropion, BW 234U, and (+)-EKC; but was not reduced by apomorphine, clozapine, sulpiride, naloxone and SCH23390 at doses of 50 mg/kg i.p. Phencyclidine at doses as high as 10 mg/kg i.p. only produced 36% inhibition of (+)-[^{3}H]-SKF10047 binding. The relative potencies of these agents obtained in vivo correspond well with their relative affinities obtained in vitro. One exception was noted, (+)-butaclamol was found to be approximately 300X weaker than its (-)-isomer in vitro but 8X more potent than its (-)-isomer in vivo. Thus, this in vivo binding assay should be a useful new technique for studying the effects of drugs on sigma sites in the intact animal.

173.11 DIFFERENCES IN THE MU$_1$ BINDING OF ^{3}H-DADL-ENKEPHALIN IN THE CORTEX AND THALAMUS. B. Adler, R. R. Goodman and G. W. Pasternak. The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

Considerable work has been directed towards the biochemical and pharmacological characterization of mu$_1$ receptors. One difficulty in these studies has been the relatively low percentage of total binding corresponding to mu$_1$ sites. Autoradiographical studies have indicated that a large portion of the binding of radiolabeled enkephalins to the thalamus is easily displaced by low concentrations of morphine sulfate, suggesting that morphine-sensitive mu$_1$ binding represents a high percentage of total ^{3}H-enkephalin binding in this region. In contrast, radiolabeled enkephalin labels predominently delta sites in cortex. We therefore compared the binding of radiolabeled enkephalins to homogenates of the rat thalamus and cortex. Competition studies indicate that 40-60% of ^{3}H-DADL-enkephalin binding in the thalamus is inhibited by low concentrations of morphine (2-5 nM). In contrast, morphine lowered ^{3}H-DADL-enkephalin binding by only approximately 5-15% in the cortex. IC_{50} determinations of morphine against ^{3}H-DADL-enkephalin from 5 independent experiments show values of 3.4 nM in the thalamus and 60 nM in the cortex. These results support the previous observations noted in autoradiography studies and illustrate the differing ratios of mu$_1$ to delta binding in these two brain regions. These differing ratios may prove useful in the development of mu$_1$ binding assays and emphasize the advantages of using tissue regions in the characterization of opiate receptor subtypes.

173.12 EFFECTS OF SIGMA AGONISTS ON LOCAL CEREBRAL GLUCOSE UTILIZATION. M. R. Kozlowski and M. J. Higgins*. Department of Medicinal Sciences, Pfizer Inc., Groton, CT 06340

The 14C-2-deoxyglucose technique has been used by several investigators to determine the effects of drug action on local cerebral glucose utilization (LCGU). In the present report, this technique is used to examine the effects of sigma receptor agonist compounds on brain activity in the rat. In order to insure that the effects observed were due to sigma receptor stimulation alone, 3 structurally different sigma agonist compounds were used: the phenylcylohexylamine, phencyclidine (PCP); the benzomorphan, SKF-10,047 (SKF) and the dioxolanylpiperidine, dexoxadrol (DEX).

PCP, SKF and DEX (3.2 umol/kg, s.c.) produced qualitatively similar patterns of altered LCGU. The largest increases in LCGU occurred in the frontal cortex, nucleus accumbens, anterior cingulate cortex, anterior caudate and the ventromedial thalamic nucleus. Smaller, but still statistically significant increases in LCGU were found in the motor and sensory cortices, sibiculum, and hippocampus. LCGU levels were also elevated in the majority of other structures examined, however these increases did not reach statistical significance. In addition to the common pattern of altered brain activity produced by all sigma agonists, increases in LCGU not common to all 3 compounds were seen in several structures including the subcallosal cortex (PCP only), posterior caudate (PCP only), posterior cingulate cortex (PCP and DEX), entopeduncular nucleus (SKF only) and inferior colliculus (SKF only).

We propose that the common pattern of altered LCGU seen in this study is the result of sigma receptor stimulation, the biochemical action shared by all of these compounds, whereas the effects not common to all 3 compounds are due to other mechanisms.

173.13 ISOLATION, PURIFICATION, AND CHARACTERIZATION OF RAT BRAIN OPIATE RECEPTORS. (SPON: N. Buckholtz). C.C. Smith, J.B. O'Neill, B. Zipser*, S.M. Shreeve, C.M. Fraser, J.C. Venter, R.J. Weber and C.B. Pert*. Neuroimmunology Unit, Section on Brain Biochemistry, Clinical Neuroscience Branch, National Institute of Mental Health, Building 10, Room 3N256, 9000 Rockville Pike, Bethesda, Maryland 20205-1000.

We have used (3-[^{125}I]iodotryosyl^{27}) β-endorphin (^{125}I-βE) as a high specific activity ligand probe to study rat brain opiate receptors. Binding of ^{125}I-βE is reversible (approximately 90%), stereospecific, and saturable. Competition experiments with [D-Ala^2, D-Leu^5]enkephalin, dynorphin$^{1-13}$, morphine, and etorphine demonstrate that ^{125}I-βE binds to opiate receptors with mu, delta, and kappa type characteristics. ^{125}I-βE was bound to rat brain membranes which where then solubilized in 1% digitonin, resulting in a relatively stable (t/½ for dissociation approximately 40 hours) ^{125}I-βE opiate receptor complex, which could be assayed on Whatman GF/C filters coated with polyethyleneimine. We then used a combination of lectin affinity chromatography, preparative isoelectric focusing and high-performance size exclusion chromatography to characterize the ^{125}I-βE opiate receptor complex and isolate it in increasingly pure form. These procedures demonstrate that the digitonin solubilized opiate receptor ^{125}I-βE complex adheres to wheat germ agglutinin:sepharose and can be eluted off with 0.2 M N-acetylglucosamine, has an isoelectric point of 4.55 ± 0.1, and a Stoke's radius of approximately 72 Angstroms. SDS gel electrophoresis of the radioiodinated isoelectrically focused, wheat germ agglutinized fraction, for example, revealed several minor bands at 14 and 19 Kd, major bands at 34 and 40 Kd and at 58 Kd, which corresponds to the molecular weight of the opiate receptor in agreement with previous reports (Klee, W.A., et al., FEBS Lett. 150: 125-128, 1982; Newman, E.L. and Barnard, E.A. Biochemistry 23: 5385-5389, 1984) and Zipser, et al., this meeting.

173.14 COMPARISON OF THE BINDING AND REGIONAL DISTRIBUTION OF SIGMA OPIOID AND PHENCYCLIDINE RECEPTORS. Patricia C. Contreras, Remi Quirion and Thomas L. O'Donohue, Exper. Ther. Branch, NINCDS, NIH, Bethesda, MD 20205 and Douglas Hosp. Res. Ctr., Verdun, Quebec, Canada H4H1R3.

The similarities between the psychotomimetic effects of sigma opioids, such as SKF10,047 and cyclazocine, and phencyclidine (PCP) support the suggestion that PCP receptors and sigma opioid receptors represent the same binding site. However, recent studies by Tam (Proc.Natl.Acad.Sci. USA 80:6703,1983) and Martin et al.(J. Pharmacol. Exp. Ther. 231:539,1984) have shown differences in the binding of PCP and SKF10,047. It has also been suggested that haloperidol, a dopamine antagonist, and N-n-propyl-3-(3-hydroxyphenyl)-piperidine (3-PPP), a dopamine agonist, exert some of their effects by binding to sigma opioid receptors. The purpose of our investigations was to examine whether PCP and sigma opioid receptors represent one class of receptors and whether haloperidol and 3-PPP bind to sigma/PCP receptors by comparing the binding and regional distribution of ^{3}H-TCP (1-(1-(2-thienyl)cyclohexyl) piperidine), ^{3}H-PCP, ^{3}H-dexoxadrol, ^{3}H-(+)SKF10,047, ^{3}H-haloperidol and ^{3}H-3-PPP. ^{3}H-TCP was found to label the same binding sites as ^{3}H-PCP because the order of potency of PCP analogs and sigma opioids for inhibition of binding of ^{3}H-PCP and ^{3}H-TCP were the same. Also, a high density of binding sites were labeled by both ^{3}H-PCP and ^{3}H-TCP in the cortex, hippocampus. and dentate gyrus. Moderate densities were found in the medial geniculate nucleus, nucleus accumbens, caudate nucleus, interpeduncular nucleus, superior colliculus, periaqueductal grey and cerebellum. Very little binding of ^{3}H-TCP and ^{3}H-PCP were found in the spinal cord, most of branstem and hypothalamus. Dexoxadrol produced PCP-like stereotyped behavior and ataxia, but the binding of ^{3}H-dexoxadrol was different from that of ^{3}H-PCP as there were different orders of potency for inhibition of binding of each labeled ligand. Also, unlike ^{3}H-TCP, ^{3}H-dexoxadrol labeled binding sites in the hypothalams. The binding sites labeled by ^{3}H-dexoxadrol in the hypothalamus and cortex were different as measured by the potency of drugs to displace ^{3}H-dexoxadrol. Also, haloperidol only displaced the binding of ^{3}H-dexoxadrol in the hypothalamus and not in the cortex. The binding of ^{3}H-(+)SKF10,047 was determined because only the (+) isomer produces stereotyped behavior. ^{3}H-(+)SKF 10,047 did not label υ,κ or δ receptors as naloxone, ethylketocyclazocine and dynorphin did not inhibit the binding of ^{3}H-(+)SKF10,047. The order of potency of drugs for displcing ^{3}H-(+)SKF10,047 was different from that found with ^{3}H-PCP or ^{3}H-dexoxadrol. The binding and regional distribution of ^{3}H-haloperidol and ^{3}H-3-PPP was also determined. These results suggest that PCP and sigma opioids bind to a heterogeneous population of receptors and that PCP and sigma opioid receptors are different.

173.15 QUANTITATIVE LIGHT MICROSCOPIC VISUALIZATION OF SIGMA OPIOID/PCP RECEPTORS WITH [^{3}H]TCP, [^{3}H](+)SKF10,047 AND [^{3}H]PCP. S.R. Zukin and R. Sircar. Departments of Psychiatry and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Phencyclidine (PCP), its active analogs including N-(1-[2-thienyl]cyclohexyl)piperidine (TCP) and sigma opioids such as N-allyl-normetazocine (SKF10,047) exert unique behavioral effects in animals and psychotomimetic effects in humans. Drugs of these classes have been shown by ourselves and others to bind saturably, reversibly and with high affinity to the same specific brain receptors. These receptors exhibit a characteristic heterogeneous regional distribution pattern distinct from that of any other receptor type. In binding as well as behavioral experiments, the PCP analog TCP (N-(1-[2-thienyl]cyclohexyl)piperidine) has been demonstrated to be significantly more potent than SKF10,047 or PCP. In the present study quantitative autoradiographic patterns of [^{3}H]TCP, [^{3}H]PCP and [^{3}H](+)SKF10,047 binding were determined in rat brain in order to assess the relative specificities of these ligands for sigma opioid/PCP receptors. 20 micron thick sections of fresh-frozen rat brains were incubated with 5 nM [^{3}H]TCP (58.2 Ci/mM), 10 nM [^{3}H](+)SKF10,047 (25.5 Ci/mM) or 10 nM [^{3}H]PCP (49.9 Ci/mM) respectively in 5 mM Tris-HCl, pH 7.4 for 45 min to one hr. Adjacent sections were incubated under the same conditions but in the presence of excess nonradiolabeled ligand. Slides were washed, dried and tightly juxtaposed against tritium-sensitive film for 2-6 weeks. 10 micron sections were cut from a tritium standard block ([^{3}H]Microscale, Amersham) and dry-fixed to slides; one such slide was placed against each film. Densitometric readings of each brain region as well as each standard of the microscale were recorded. Receptor densities were expressed as fmol/ mg tissue. Distribution patterns of [^{3}H]TCP, [^{3}H](+)SKF10,047 and [^{3}H]PCP binding were very similar. The highest binding densities of all three tritiated ligands were found in CA_1, CA_2 and dentate gyrus of the hippocampus. Certain brain regions rich in mu opioid receptors, including central gray, substantia nigra and interpeduncular nucleus displayed lower levels of [^{3}H]TCP than of [^{3}H]PCP or [^{3}H](+)SKF10,047 binding, suggesting higher specificity of [^{3}H]TCP for sigma opioid/PCP receptors and little cross-reactivity at other receptor classes. On the basis of its greater specificity as well as potency, [^{3}H]TCP appears superior to [^{3}H]PCP or [^{3}H](+)SKF10,047 as a molecular probe of brain sigma opioid/PCP receptors.

173.16 DOPAMINE RECEPTOR-REGULATED MU- AND DELTA-PROFILE OF AN OPIOID RECEPTOR COMPLEX COUPLED TO ADENYLATE CYCLASE. A.N.M. Schoffelmeer*, J.C. Stoof* and A.H. Mulder* (SPON: H.W.M. Steinbusch). Dept. of Pharmacol. and Neurol. (JCS), Med.Fac., Free University, van der Boechorststraat 7 1081 BT Amsterdam, The Netherlands.

Adenylate cyclase activity (determined as the efflux of cAMP) in rat neostriatal slices is regulated by stimulatory D-1 dopamine receptors and inhibitory D-2 receptors (Stoof, J.C. and Kebabian, J. W., Nature 294, 366-368 (1981)). Recent studies, examining ligand binding to rat brain homogenates (Rothman, R.B. and Westfall, T.C., J. Neurobiol. 14, 341-351 (1983)) as well as smooth muscle bioassays (Lee, N.M. et al., Biochem. Psychopharmacol. 33, 75-89 (1982)) have suggested that mu- and delta-opioid receptors might not always be independent entities, but different recognition sites of an opioid receptor complex. Here we report on the inhibitory effects of mu- and delta-opioid receptor activation on dopamine receptor regulated cAMP efflux from rat neostriatal slices. Both morphine and D-ala^2-D-leu^5-enkephalin (DADLE) inhibited D-1 receptor induced cAMP efflux (30/uM dopamine + 10/uM (-)sulpiride) with an EC_{50} of 800 and 3 nM, respectively. The mu-opioid receptor antagonist naloxone was more potent in reversing the inhibitory effect of morphine, whereas the delta-opioid receptor antagonist ICI 174864 was a much more potent antagonist for DADLE, suggesting the involvement of mu- and delta-opioid receptors. Upon simultaneous activation of D-1 and D-2 receptors (by 30/uM dopamine in the absence of (-)sulpiride) the EC_{50} of morphine remained unchanged, while that of DADLE was strongly enhanced to 100 nM. In this case, naloxone was an equipotent antagonist for both opioid receptor agonists, suggesting the involvement of mu-opioid receptors only. Similar results were obtained upon stimulation of D-1 receptors with the D-1 agonist SKF 38393 and stimulation of D-2 receptors with the D-2 agonist LY 141865. Moreover mu-opioid receptor efficacy appeared to be strongly diminished upon activation of delta-opioid receptors. Therefore these mu- and delta-opioid receptors cannot be regarded as independent entities, but appear to be functionally coupled. Our data provide functional evidence for the existence in the neostriatum of an opioid receptor complex with closely associated mu- and delta-recognition sites. The pharmacological profile of this receptor complex appears to be regulated by dopamine receptors.

PROCESS OUTGROWTH: GUIDANCE MECHANISMS, GROWTH CONES

174.1 REARRANGEMENT OF AXON FASCICLES IN THE DECUSSATION OF THE PYRAMIDAL TRACT. K. Kalil and C. Norris*. Dept. of Anatomy and Neurosciences Training Program, University of Wisconsin, Madison, WI 53706.

Axons of the hamster pyramidal tract are grouped into well-defined fascicles along their entire trajectory from the sensorimotor cortex to the spinal cord, an arrangement particularly striking in young animals. We were interested in whether axons maintain the same spatial relationships along this pathway such that selective fasciculation could play a role in target innervation.

In one series of experiments, HRP was injected into the sensorimotor cortex of animals 1-4 days of age. In some cases small lesions were made in the center of a large injection site. Labeled axons within the internal capsule are arranged in fascicles that reflect the topography of their cortical neurons, as shown by the fact that within the internal capsule the lesions create empty unlabeled spaces normally occupied by several contiguous fascicles. Small injections of HRP in the opposite hemisphere (corresponding to the location of the ipsilateral lesion) resulted in the labeling of a small contiguous group of fascicles similar in position to the unlabeled regions of the other side. This topographic order is maintained until the pyramidal tract enters the decussation in the caudal medulla at 40-44 hours after birth. As fibers cross, the overall pattern of axon fascicles is rearranged, reversing the order of fascicles from right to left as they enter the dorsal column.

In further experiments, HRP-coated glass pipettes applied to the medullary pyramid filled axons locally in the region of the decussation in animals 2 days to 2 weeks of age. At the decussation individual fibers do not maintain their original positions but join new fascicles. Some axons pass over many fascicles before finding the appropriate partners. When axons are followed into the rostral spinal cord, it is apparent that those that were contiguous in the medullary pyramidal tract are now widely separated in the dorsal column. Thus, the spatial order of axon fascicles in the spinal cord is not determined by merely passive channeling of axons to their targets in the same topographic order in which they leave the cortex. Further, temporal order does not seem to be a factor in determining nearest neighbor relationships in the decussation, since lead fibers are often widely separated from later-arriving axons. The results suggest that fibers actively seek out specific fascicles at the decussation, a process which may play a role in their ability to find appropriate targets in the spinal cord.

174.2 PHYSICAL AND MOLECULAR FACTORS THAT INFLUENCE AXONAL GUIDANCE AT THE DEVELOPING OPTIC CHIASM. M. Poston*, U. Rutishauser and J. Silver (SPON: I.R. Kaiserman-Abramof). Dept. of Developmental Genetics and Anatomy, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

We are interested in the physical and molecular characteristics of boundaries that may play a role in axonal guidance along the optic pathway in the developing vertebrate embryo. We have studied the development of the presumptive optic chiasm in 2-5 day chicken embryos. When pioneering optic fibers approach the chiasm they never grow rostrally into the olfactory region of the telencephalon, even though a potential avenue of tissue joins these two areas. Conversely, olfactory tract axons grow as far caudally as, but never cross, the forward boundary of the optic chiasm.

A region of specialized neuroepithelium immediately rostral to the optic chiasm, first described by Silver (J.C.N. 223, 1984) in the mouse embryo and called the "knot", exhibits unusual cellular and molecular properties which may influence axonal guidance at this major intersection. The "knot" consists of a very dense cluster of cells which lack long radial processes and whose cell bodies are situated immediately along the basal lamina of the neuroepithelium, thus eliminating the marginal zone where axons tend to grow. We saw no indication that the neural cell adhesion molecule (NCAM), an adhesion promoting membrane glycoprotein that is expressed elsewhere along neuroepithelial endfeet within the optic pathway (Silver and Rutishauser, Dev. Bio. 106, 1984), was expressed by the cells in the knot region. NCAM is produced by cells of the presumptive chiasm (both before and after the arrival of optic axons on day 4) and by the ventrocaudal telencephalon (presumptive olfactory tract) rostral to the knot. The absence of NCAM staining at the knot was consistent across the diencephalic/telencephalic junction. A tremendous amount of cell death was also observed pre-axonally and precisely in the pre-knot region.

We propose that the knot, through its elimination of the marginal zone endfeet and its lack of NCAM, functions as an axon-refractory, physiochemical barrier which effectively separates the optic and olfactory systems. If correct, this proposal would offer a possible explanation of a fundamental observation concerning forebrain sensory projections, that retinal ganglion cell axons do not normally directly innervate the telencephalon and that olfactory axons do not travel caudally into the diencephalon to form direct connections with the thalamus.
