The spike at 10 pm of the striatal $D_2$ receptors Bmax ($P=0.0016$, $DF=4.4$) and Kd ($P=0.049$, $DF=2.3$) was significantly higher in old than young animals. These preliminary results show that aged animals exhibit more prominent circadian rhythms in Bmax and Kd of striatal $D_2$ receptors when compared to young animals, indicating that both age and time are important variables to be considered for drug response.

**280.5** LOW LEVEL (SUBNORMAL) CHRONIC DIETARY CHOLINE SUSTAINS RETENTION OF LEARNING IN AGING MICE. Ronald F. Mervis. Division of Neuropathology, The Ohio State University College of Medicine, Columbus, Ohio 43210

The affect of chronic choline availability on behavior in aging C57Bl mice (/6J and /6NNIA strains) was evaluated using a passive-avoidance paradigm to assess 24 hour retention of learning. A diet containing very low levels of choline (0.9 mg/gm) was found to result in impaired retention of learning. However, an isocaloric and isonitrogenous diet containing 1.5 mg/gm of choline -- well below the levels in standard rodent chow preparations (2.3 mg/gm) -- was found to result in an improvement of retention of learning that was at least equal to or even surpassed the performance of mice on various choline enriched diets (2.4, 4.8 or 10.8 mg/gm of choline). Wecker and Trommer (J. Neurochem. 43:1762-1765, 1984) have proposed that transport of choline through the blood-brain barrier may be modulated by a choline stimulated inhibitory substance in serum. This suggests that the subnormal levels of dietary choline which are approximately equivalent to minimal dietary requirements may be too low to stimulate production of the inhibitory factor, and hence are transported rapidly into the brain. Higher levels of dietary choline, however, could result in the formation of the inhibitory factor which would lower transport of available choline to the brain. Therefore, higher levels of dietary choline did not produce comparable improvement in passive-avoidance retention.

**280.6** Behavioral Responsiveness to Estrogen in Female Rats: Influence of Strain and of Aging.
L.J. Fitten*, J. Shryne*, R. Gorski Dept. of Psychiatry-Biobehav. Sci. and Dept. of Medicine; Dept. of Anatomy and Brain Res. Inst. UCLA School of Medicine, Los Angeles, California 90024.

There have been conflicting reports on the female rat regarding aging lordosis behavior and sensitivity to gonadal steroids. While investigating these relationships in Fischer (F) rats it became apparent that a substantial percentage (43%) of our aged CDF F-344 (Charles River) rats (20 mo.) were unusually sensitive to doses of Estradiol Benzoate (EB) previously used in this lab on another strain. We therefore decided to compare estrogen sensitivity in young (3-4 mo.)(N=17) and aged (21-22 mo.)(N=18) female F rats. To explore strain differences we also included young Sprague-Dawley (SD) rats from another supplier (Simonsen)(3-4 mo.)(N=13). All subjects were ovariectomized and placed in a reverse light room for 2 wks. Subjects were then randomly assigned to either a low dose EB (0.5ug x 3 days) or a higher dose EB (2.0ug x 3 days) and tested for lordosis behavior in a plexiglass arena under red light illumination with two sexually vigorous males on the 4th day. Behavior was scored by two independent investigators. A 2 wk. gonadal steroid free period followed, then the animals were re-tested in the same manner to note experiential effects. After testing, all subjects were weighed and sacrificed. Organs were inspected and weighed to evaluate general health status.

| | | Test One | | Test Two | |
|---|---|---|---|---|---|
| EB x 3 days | | 0.5ug | 2.0ug | 0.5ug | 2.0ug |
| S.D. | $\bar{X}$ | 2.50 | 17.86 | 5.83 | 19.00 |
| 3-4 mo. | ± | 2.28 | 4.61 | 3.80 | 6.66 |
| Fischer | $\bar{X}$ | 19.38 | 44.89 | 56.13 | 84.56 |
| 3-4 mo. | ± | 4.00 | 7.14 | 7.87 | 2.62 |
| Fischer | $\bar{X}$ | 33.13 | 49.20 | 70.83 | 76.60 |
| 21-22 mo. | ± | 10.28 | 11.07 | 6.69 | 8.48 |

Although F old subjects were more sensitive to EB (higher Lordosis Quotient, LQ) than young F, differences were not statistically significant. However, in all cases SD young were significantly less sensitive than both young and old F rats. Furthermore, both F young and old showed a significant increase in LQ for both dosages in the second test, while the SD did not.

This study suggests that aging does not decrease estrogen sensitivity in the F rat, but does point to a significant strain difference in estrogen sensitivity between F and SD rats. Furthermore, only F rats show significant increase in EB sensitivity with repeated testing at these doses, which may reflect their higher sensitivity.

**280.7** CIRCADIAN RHYTHM OF LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) IN ESTRADIOL-TREATED OVARIECTOMIZED RATS: EFFECTS OF AGE. P.M. Wise[1], E.D. London[2], I.R. Cohen-Becker[1], and N.G. Weiland[1]. [1]Dept. of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201 and [2]Neuropharmacology Lab., NIDA Addiction Research Center, Baltimore, MD 21224.

Previous reports have demonstrated the presence of a circadian rhythm in LCGU in the suprachiasmatic nucleus (SCN) of male rats (Schwartz, W. et al., J. Comp. Neurol., 189:157,1980). The ability of estradiol to induce LH surges depends upon an intact SCN and is altered during middle-age. To determine whether changes in the circadian pattern of neural function could account for age-related differences in the pattern of LH surges, we measured LCGU in several brain areas, with particular emphasis on hypothalamic areas involved in cyclic LH release.

Young (3-4 mo) and middle-aged (11-14 mo) cycling rats were ovariectomized. One week later (day 0), they were implanted with Silastic capsules containing estradiol, which produced physiological concentrations of estradiol in serum. On day 1, the external jugular vein was cannulated to the level of the right atrium, and the cannula was externalized through the nape of the neck. LCGU was measured by the autoradiographic 2-deoxy-D-[1-$^{14}$C] glucose method (Sokoloff, L. et al., J. Neurochem., 28:897,1977) in undisturbed, unrestrained rats at 0300, 0500, 1000, 1200, 1400, 1700, 1900 and 2300h (lights on between 0400-1800h). We observed a circadian LCGU pattern in the SCN of young rats: LCGU was higher during the light phase compared with the dark period. At 1000h there was a transient decline. This decline occurred at a time just prior to the previously reported initiation of LH surges and increases in norepinephrine activity (Wise, P.M., Endocrinol., 115:801,1984). In contrast, although middle-aged rats exhibited a circadian rhythm in SCN-LCGU, there was no decrement at 1000h, and LCGU decreased to a lower level at 1400 and 1700h as compared with young rats. Similar trends in circadian rhythmicity were observed in the medial preoptic nucleus, suprachiasmatic preoptic nucleus and paraventricular nucleus. LCGU in middle-aged rats was lower during the afternoon in these hypothalamic nuclei. Other brain areas which exhibited an age-related decline in LCGU were: cortical areas, corpus striatum, corpus callosum, nucleus accumbens, bed nucleus of the stria terminalis, amygdala, dorso- and ventromedial nucleus and lateral aspect of the medial mammillary nucleus.

These data indicate that there are changes in the circadian pattern of LCGU in the suprachiasmatic nucleus which relate to the timing and amplitude of estradiol-induced LH surges in middle-aged rats. The data suggest that a change in the biological clock occurs with age and that this change affects the ability of rats to exhibit cyclic reproductive function. (Supported in part by NIH AG-02224 and AG-00168 to PMW)

**280.8** PROGESTERONE PREVENTS AGE-ASSOCIATED LENGTHENING OF ESTROUS CYCLES AND ATTENUATION OF PREOVULATORY GONADOTROPIN SURGES IN FEMALE RATS. L.V. De Paolo* and K.L. Rowlands* (SPON: B. Brooks). Dept. of Physiol. Univ. of TX. Hlth. Sci. Ctr., San Antonio, TX 78284.

Recently, Nass et al. (Biol. Reprod. 27:609, 1982) reported that mating delayed the age-associated decline in reproductive function of female rats. Since circulating progesterone (P) levels are elevated for a 2-3 week interval during pregnancy, the following study was conducted to determine whether intermittent elevations in P levels can alter the rate of reproductive aging in female rats. Beginning at 2 mos of age, 4-day cycling rats were divided into two groups. In one group (n=22), each rat was inserted s.c. with 3 Silastic capsules containing crystalline P while rats in another group (n=45) received 1 empty capsule. After 2 weeks, the capsules were removed for 2 weeks. Thereafter, implantation and removal of capsules were repeated 5 additional times. Rats receiving P capsules became acyclic 3-4 days after exposure to P and resumed cyclicity 4-7 days after P-capsule removal. One month after removal of the last series of capsules (rats approximately 8-mos old), rats exhibiting consecutive 4-day cycles were bled at 4-h intervals from 1400h on proestrus (Pr) to 1000h on estrus (E). At 1600h E, rats were sacrificed and trunk blood was collected. Plasma levels of LH and FSH were determined by RIA. For comparison, a group of 3-mo-old rats (n=14) was bled on Pr and E. In 8-mo rats who received empty capsules, 26.7% of these rats exhibited 4-day cycles compared to 65.6% of 3-mo rats. However, in contrast to rats who received empty capsules, 63.1% of P-treated rats exhibited 4-day cycles. In comparison to 3-mo rats, preovulatory LH and FSH surges were attenuated in 8-mo rats given empty capsules. Furthermore, plasma FSH levels in these 8-mo rats were lower at 2200h Pr and during the secondary FSH surge at 0200 and 0600h E than levels observed at these times in 3-mo rats. However, by 1600h E, plasma FSH levels were higher in 8-mo rats not receiving P than in 3-mo rats. In striking contrast, preovulatory LH and FSH surges were indistinguishable between 3-mo rats and P-treated rats. Moreover, profiles of plasma FSH levels were similar on Pr and E in these two groups except at 1000 and 1600h E when plasma FSH levels were higher in P-treated rats. These results demonstrate that age-associated lengthening of estrous cycles and impairments in neuroendocrine mechanisms regulating preovulatory LH/FSH surges can be prevented at least temporarily by previous intermittent exposure to P and suggest that the disruption of estrous cycles and preovulatory surges in older rats are not related to chronological age per se. In contrast, the inability of P to prevent altered FSH secretion during the latter portion of the secondary FSH surge suggests that impairments in the mechanisms controlling this rise are attributed to aging per se. (Supported by NIH grant AG-03764).

280.9 IN LIFESPAN RESEARCH, ONE HOUR OF ENVIRONMENTAL ENRICHMENT PER MONTH HAD CUMULATIVE EFFECTS ON MARKING BEHAVIOR IN GERBILS AFTER TEN MONTHS OF AGE. MaryLou Cheal. Department of Psychology, Arizona State University, Tempe, AZ 85287.

In many experiments, housing conditions have been shown to influence behavior of experimental animals. Plasticity of the brain of young animals due to environmental factors has been clearly demonstrated. More recently, even the brains of old animals have been shown to be susceptible to change after environmental stimulation. In this research, the effects of repeated short exposures to environmental enrichment across the lifespan were studied. In a longitudinal study, 62 gerbils were reared in groups housed in identical cages with climbing apparatus and food and water ad libitum. Half of the gerbils were placed outdoors in a large desert environment for one hour each month from two months of age throughout the lifespan. No behavioral differences were found between gerbils given enrichment and gerbils in the indoor control condition during development and young adult life. However, starting at ten months of age, gerbils given the outdoor experience made more marks with the ventral gland than did controls. This species-specific behavior pattern is sexually dichotomous; i.e., male gerbils mark more than female gerbils. Nonetheless, the enrichment effect occurred in both male and female gerbils. The ventral glands of these gerbils developed at younger ages than those of controls (Soc. Neurosci. Abst., 1984, 10, 452), but there were no differences in the size of the ventral glands at the ages when marking behavior was enhanced. This is the first demonstration of cumulative effects of brief outdoor exposures on behavior. Because this behavior is known to be dependent on gonadal hormones, these data also suggest that neuroendocrine events can be modified by the environment in adult animals.

280.10 HIGHER-ORDER MOTOR FUNCTIONS IN ALZHEIMER'S DISEASE. S. Stockmeyer,* S. Corkin, & J. H. Growdon. MIT, Cambridge, MA 02139, Massachusetts General Hospital, Boston, MA 02114.

Primary motor disorders are not common in Alzheimer's disease (AD), but deficits in higher-order control functions have been described. Corkin, Growdon, & Sullivan, 1981, found that patients with AD were impaired on a coordinated tapping task but not on repetitious fine-finger motions. In order to extend this observation, we used two types of tasks that could reveal problems in planning or organizing motor acts.

Patients with AD ( N = 34 ) and healthy control subjects subjects ( N = 20 ) were examined for the presence and severity of mirror synkinesia in the hands during finger movements. The subject depressed keys attached to potentiometers that signaled any release of pressure. The keys were held depressed by the fingers of one hand while one finger of the opposite hand was either actively lifted or performed a tapping movement. As expected, control subjects showed a small amount of synkinesia; in contrast, patients with AD demonstrated significantly greater synkinesia in both hands ( $P < .05$ ). The presence of excessive mirror synkinesia indicates a lack of inhibition of the ipsilateral pyramidal tract.

In a modification of the Thurstone Tapping Test subjects were required to coordinate both hands temporally and spatially as they tapped in circular, vertical, and horizontal movements. Mirror and nonmirror movements in clockwise and counterclockwise directions were included in the task variations. The same movements were also performed unilterally. The ratios of unilateral to bilateral tapping on six task variations were significantly higher for patients with AD than for control subjects ( $P < .05$ ). Although most patients with AD could perform the task unilaterally, many were noticeably impaired in speed and coordination in the bilateral condition. Control subjects reduced their speed in the bilateral condition as expected, but were able to maintain the coordination required by the task. These observations indicate that patients with AD are unable to monitor the sensory cues and motor output for both hands simultaneously.

280.11 HIPPOCAMPAL PYRAMIDAL CELLS AND AGING: A NEURONOMETRIC STUDY. D.V. Jeste, T. Bryant, C. Owen and J.B. Lohr. (SPON: R.J. Wyatt). Neuropsychiatry Branch, NIMH, Intramural Research Program, Saint Elizabeths Hospital, Washington, D.C. 20032.

**Introduction:** It is now generally believed that certain regions of the brain manifest a selective vulnerability to the effects of aging. Previous studies of age-related neuronal loss in hippocampus have yielded conflicting results. Whereas Ball (Acta Neuropath. 5:249, 1977) and Dam (J. Neuropath. Appl. Neurobiol. 5:249, 1979) found a loss of hippocampal pyramidal cells with aging, Devaney and Johnson (Gerontology 30:100, 1984) reported an apparent increase in the density of hippocampal neurons with age. The present study was undertaken to determine aging-associated changes in density and size of pyramidal cells in each of the four sectors (CA1 thru CA4) of right and left hippocampi.

**Material and Methods:** We examined brains of 20 subjects (11 females, 9 males, age range 6-94, mean 48 ± 29 years) from the "normative" series in the Yakovlev Collection, at the Armed Forces Institute of Pathology, Washington, D.C. We chose sections of right and left hippocampi according to specified atlas criteria. Using Zeiss Videoplan-II (a computerized planimeter), we measured areal density, neuronal cross-sectional area and nuclear area in sectors CA1 thru CA4. These measurements were done "blind" with respect to the clinical data.

**Results:** There were no significant differences in the parameters studied, between males and females or between right and left hippocampi. There was no significant correlation between age and neuronal density, cell cross sectional area or nuclear size in any of the 4 sectors. Subjects over 65 (n=6) had lower mean neuronal density than those under 65 (n=14), although this difference was significant only for CA4 (23.2 ± 5.5 vs 29.4 ± 5.7 cells/unit area; two-tailed $t = 2.101$; $p < 0.05$).

**Comment:** Our study does not support the reports of significant alterations in hippocampal pyramidal cells with aging, with a possible exception of neuronal density in CA4. This is in sharp contrast to our earlier work suggesting a significant decrease in the density of cerebellar Purkinje cells with age (Jeste, Lohr, Mani, et al., In "Current Perspectives on Dementias" ed. DV Jeste, American Psychiatric Press, Washington, D.C., in press). We will discuss limitations and possible implications of our results.

280.12 HIRANO BODY FILAMENTS CONTAIN ACTIN AND TROPOMYOSIN. P.G. Galloway*, G. Perry* and P. Gambetti. Division of Neuropathology, Institute of Pathology, CWRU, Cleveland, Ohio 44106.

Hirano bodies, rod-shaped eosinophilic inclusions found in the hippocampus and other parts of the nervous system, occur in normal aging but are increased in Alzheimer's disease and other neurological disorders. At the ultrastructural level, the Hirano body is composed of lamellar filaments similar in size to actin filaments. The presence of actin in Hirano bodies has been previously described at the light microscopic level. The present study was undertaken to determine the ultrastructural localization of actin and actin binding proteins in the Hirano body. Immunoperoxidase staining of paraffin-embedded hippocampal tissue with a poly- and a monoclonal antibody to chicken gizzard actin confirmed the presence of actin antigen in the Hirano body at the light microscope level. For ultrastructural analysis, free-floating vibratome sections were stained with both antibodies by using the peroxidase-antiperoxidase and indirect immunogold procedures. Sections were osmicated, embedded in Spurr's medium and thin sectioned. At the electron microscope level, immunostaining of Hirano body filaments was observed with the actin antibodies. Staining could be blocked by adsorbtion with a chicken gizzard actin preparation. The presence of actin binding proteins in the Hirano body was investigated using antibodies to tropomyosin, spectrin and myosin. The antiserum to tropomyosin stained the Hirano body. Further investigation as to the arrangement of actin and tropomyosin antigen sites within the Hirano body will clarify the participation of these proteins in the formation of this cytoplasmic inclusion.

280.13 MULTIPLE TRANSMITTER-SPECIFIC MARKERS IN SENILE PLAQUES IN ALZHEIMER'S DISEASE. R. G. Struble, R. E. Powers*, M. F. Casanova*, C. A. Kitt, D. T. O'Connor*† and D. L. Price. Neuropathology Laboratory, The Johns Hopkins University School of Medicine, Baltimore, MD 21205; †Department of Medicine, University of California, San Diego School of Medicine, San Diego, CA 92093.

Senile plaques, one of the major histopathological hallmarks of Alzheimer's disease (AD), are composed of neurites and amyloid. Neurites are enlarged axons, terminals, and dendrites, and some have been shown to be derived from cholinergic-, somatostatinergic-, or substance P-containing neurons. However, the transmitter specificity of neurites in specific regions of brain have not been systematically examined for multiple neurotransmitter markers.

In the present immunohistochemical study, we examined the character and distribution of fibers stained for dopamine ß-hydroxylase, somatostatin-14, substance P, cholecystokinin, neurotensin, vasoactive intestinal peptide, bombesin, and leucine-enkephalin in the hippocampi and adjacent cortical regions of five patients with clinical and pathological diagnoses of AD and five controls, ranging in age from 35-78 years. In controls, we plotted the normal distribution of stained cells/fibers. To date, in the AD cases, we have observed neurites showing all of the above transmitter-specific markers. Some neurites were in proximity to amyloid, suggesting that these neurites were associated with senile plaques. Hence, fiber abnormalities and neurites in senile plaques were seen with antibodies directed against a variety of transmitter markers. The distribution of stained neurites was roughly comparable to the density of fibers in the particular transmitter system in normal tissues, i.e., where fibers of a particular system were normally abundant, there appeared to be a greater possibility that the system participated in the formation of plaques. Adjacent silver-stained sections disclosed many more plaques than seen by immunocytochemical methods, suggesting that neurites of a variety of other transmitter systems may show similar structural pathology. Mechanisms leading to the formation of plaques are not known but could represent a local response to loss of specific transmitter systems arising from subcortical regions (e.g., basal forebrain or brainstem) or reflect local cortical abnormalities. These observations, that neurites expressing epitopes of transmitter systems known to be at risk in AD (e.g., somatostatin or substance P) and systems not reported to be decreased (e.g., cholecystokinin) in AD, suggest that neurites in plaques may represent both degenerating systems and possibly abortive attempts at regeneration by local neuronal processes.

## ACTION POTENTIALS AND ION CHANNELS VII

281.1 DIVALENT CATION EFFECTS ON NMDA-ACTIVATED CHANNELS CAN BE DESCRIBED AS Mg-LIKE OR Ca-LIKE. L.M. Nowak and P. Ascher*, Dept. Pharmacology, Cornell U.,Ithaca, NY and *Lab. de Neurobiologie, Ecole Normale Supérieure, Paris 75005.

N-methyl-D-aspartate (NMDA) activates a class of glutamate receptors in vertebrate CNS and increases a cationic conductance. In physiological solutions the current-voltage (I-V) relationship has a distinct non-linearity, such that responses at -60mV are smaller than those at -40mV despite the reversal potential being at 0mV. Previously we demonstrated that this region of negative-slope conductance in the I-V curve actually was due to a voltage-dependent blockade of the channels by extracellular $Mg^{++}$ions ($[Mg^{++}]_o$ ≤1mM)(Nowak et al.1984, Nature 307:462). We have extended these studies, examining the actions of other divalent cations on NMDA-activated single channels.

Outside-out membrane patches were excised from somata of mouse brain neurones grown in primary dissociated cell culture. Patch pipettes contained (in mM): 140 CsCl, 5 EGTA-K, 0.5 $CaCl_2$, 10 Hepes-K (pH7.2). 10mM EGTA and 1mM $CaCl_2$ were used in some experiments. The outside surface was superfused with a solution containing (in mM): 140 NaCl, 2.8 KCl and 10 Hepes-Na (pH7.2) to which was added 10µM NMDA to stimulate channel openings and various amounts of divalent cations.

Without divalent cations NMDA-activated channels had a mean open time near 5ms (20-24°) and a linear conductance of 50pS. Although all divalent cations tested reduced the currents measured at negative potentials the results obtained were clearly separated into two groups of effects which could be termed Mg-like and Ca-like. As previously reported, $[Mg^{++}]_o$ alters the kinetics of NMDA-activated channels. Addition of 10-100µM $[Mg^{++}]_o$ resulted in channel openings which were interrupted by brief, fast, closures giving the impression of bursts. Rapid closures were longer with hyperpolarization. The burst duration and the number of bursts decreased with increasing $[Mg^{++}]_o$ and with increasing hyperpolarization. For low $[Mg^{++}]_o$ channel conductance was unchanged. In contrast $Ca^{++}$ was only effective at high concentrations (5-10mM) where its major action was to decrease single channel conductance. Channel kinetics were unchanged between -60 and +60mV. The decrease in channel conductance was slight at positive potentials, pronounced between 0 and -60mV, and moderate below -60mV. The $Mg^{++}$ effects were mimicked by $Co^{++}$, $Mn^{++}$, and $Ni^{++}$at similar concentrations (10-100µ M) while 10mM $Ba^{++}$ exhibited the Ca-like effect.

LMN was supported by a grant from the Fondation Simone et Cino del Duca.

281.2 A NEW PATCH-CLAMP CONFIGURATION: SLOW WHOLE CELL. M. Lindau*, J.M. Fernandez* and E. Neher*. (Spon. W. Almers). Abt. Membranbiophysik, Max-Planck-Institut für biophysikalische Chemie, D-3400 Göttingen, W.-Germany.

Cells, internally dialyzed with patch pipette solutions very often lose some of their functional properties. It is suspected that this is due to the loss of regulatory proteins or other cellular components that are essential to the regulation of cell function by second (intracellular) messengers. For example, intact rat peritoneal mast cells respond to antigens or substances like compound 48/80 by degranulating violently, releasing histamine and other mediators. But dialyzed mast cells invariably failed to degranulate in response to external stimuli, when, in the whole cell mode, the access resistance was 1 - 20 MΩ.

If a cell-attached patch was formed with pipette solutions containing Ca buffers, ATP and no added Ca, the patch very often became leaky within several minutes of recording. A voltage pulse applied to the pipette then induced a current transient similar to the capacitive transient obtained in fast whole cell, but about 100 times slower and smaller. As in the whole cell configuration the capacitance and conductance of the cell could be measured from this transient, revealing normal values for capacitance of 5 - 10 pF and a cell input resistance typically between 20 - 100 GΩ; the pipette series resistance ranged between 100 - 5000 MΩ which is still more than an order of magnitude smaller than the cell input resistance. We call this configuration "slow whole cell" as opposed to the usual "fast whole cell". We believe this configuration is obtained when the plasma membrane (normally 100 kΩ·cm²) is damaged upon patch formation, however is not entirely disrupted thus keeping the intracellular environment unchanged.

Mast cells monitored in the slow whole cell mode, degranulated in response to antigens and 48/80, showing a 3-fold increase in the cell capacitance and frequently showing no increase in the specific membrane conductance. The latter result questions the view that the opening of Ca-channels mediate antigen-induced histamine release from mast cells.

Preliminary experiments indicate that the slow whole-cell configuration can be reached in a variety of cell types by including in the pipette solution α-toxin from staphylococcus aureus which is known to produce well defined holes in membranes.

We thank Prof. S. Bhakdi, University of Giessen, F.R.G., for a sample of purified α-toxin.

281.3 IONIC INTERACTIONS WITHIN THE VESTIBULES OF ION CHANNELS

John A. Dani*. (SPON: William James). Section of Molecular Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510.

Many channels have wide, funnel-shaped vestibules that lead to a more selective, narrow region. The AChR pore, for example, has a large vestibule and is thought to be lined by hydrophilic amino acids which include tens of negatively and positively charged residues, but has only a small net charge. Due to the size and net charge it is likely that the vestibule contains many ions, and in the widest areas the molecular behavior is much like bulk solution. As the vestibule funnel narrows, ions experience a driving force due to the potential difference across the membrane, and near the narrow region ion-ion and ion-channel interactions become more intense. These considerations suggest a progressive shift from a bulk-like to a selectivity-filter situation, with the funnel-shaped vestibule serving as the transition zone. Most effort has been directed at describing interaction within the narrow region, because it is the place where the ion must closely approach the pore walls. Here, however, attention is focused on the vestibule, which is considered to have net charge, a funnel shape, and to be in equilibrium with the bulk solution. Ion size, ionic screening of the net charge, binding, and blockage of current are considered in determining how the vestibule provides a "conditioned" environment for the narrow, selective region.

Depending on the experimental conditions, the vestibule gives varied effects: 1. One benefit of a wide vestibule is that the narrow, restrictive region can be very short, permitting the channel's maximum conductance (Gmax) to be larger. 2. Net charge inside the vestibule creates a local potential that confers some cation vs. anion and divalent vs. monovalent selectivity. 3. Large organic ions cannot fit into the vestibule at as high a concentration as small ions, so they are less effective at screening the potential due to the vestibule's charge. Therefore, at an equivalent bulk concentration of large ions the vestibule's attractive potential is larger, causing these ions to saturate sites inside the channel at a lower bulk concentration. This factor may contribute to the relatively high affinity block of current by large impermeant cations such as TEA+ or some local anesthetics. 4. The potential produced by a net charge in the vestibule varies as a function of ionic concentration. This produces conductances at low concentrations that are larger than expected from measurements at high concentrations, an effect that also can be produced by multiple-ion occupancy of the narrow region. 5. The apparent Gmax and Kd of a permeant ion can change due to interactions in the vestibule caused by adding mM concentrations of divalent or large ions to the bulk solution.

Supported by NIRA NS 21229.

281.4 TWO PHARMACOLOGICALLY DISTINCT $Ca^{++}$-ACTIVATED $K^+$ CURRENTS ARE PRESENT IN THE GH3 ANTERIOR PITUITARY CELL LINE.

A.K. Ritchie* (SPON: Lawrence W. Haynes). Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

The single electrode, patch voltage clamp technique was used to study whole cell currents in the GH3 anterior pituitary cell line. GH3 cells have an outward current that is activated by the voltage dependent entry of $Ca^{++}$ ions into the cell. This outward current is absent in $Ca^{++}$-free, EGTA saline and is inhibited by $Ca^{++}$ channel blockers such as 0.5 mM $Cd^{++}$ (Dubinsky, J.M. and G.S. Oxford, J. Gen. Physiol. 83:309-339, 1984). Tail current analysis reveals that this $Ca^{++}$-activated outward current has a reversal potential of -72 ± 2 mV ($\bar{x}$ ± SEM, N = 7) in standard saline (5.6 mM KCl, 150 mM NaCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM glucose, 10 mM HEPES, 5 mM 4-aminopyridine, 3 μM TTX, pH 7.3) when using an intracellular electrode that contains 150 mM KCl and 3 mM HEPES, pH 7.3. At room temperature the tail current reversal potential changes by 56 mV/decade change in external $K^+$ concentration thus confirming that the $Ca^{++}$-activated outward current is mediated by a selective increase in $K^+$ ion permeability. The majority of the $Ca^{++}$-activated $K^+$ current that is elicited by a 400 mS step to +20 mV is inhibited by extracellular TEA with a half maximal inhibitory concentration of 0.8 mM. However, in the presence of a maximally effective concentration of TEA (30 mM), a small portion (10-20%) of the $Cd^{++}$ inhibitable outward current persists. The following evidence indicates that this $Cd^{++}$ inhibitable, but TEA resistant, outward current is also a $Ca^{++}$-activated $K^+$ current: 1) the tail current amplitude measured upon returned to the holding potential of -50 mV and plotted as a function of the voltage used to elicit this outward current has a voltage dependence that is similar to that of the inward $Ca^{++}$ current in GH3 cells and 2) the reversal potential of the tail current for this outward current is -72 mV.

The TEA resistant $Ca^{++}$-activated $K^+$ current is inhibited by 100 nM apamin. Apamin is a polypeptide component of bee venom which has been shown by others to be an inhibitor of a relatively TEA resistant component of the $Ca^{++}$-activated $K^+$ conductance in rat myotubes (Romey, G. and M. Lazdunski. Biochem. Biophys. Res. Comm. 118: 669-674, 1984) and bullfrog sympathetic ganglion cells (Pennefather, P., B. Lancaster and P.R. Adams. Soc. Neurosci. Abs. 10: 147, 1984). In the absence of TEA, apamin inhibits 10 to 20% of the total $Cd^{++}$ sensitive outward current that is elicited by a voltage step to +20 mV. Both the TEA and apamin sensitive $Ca^{++}$-activated $K^+$ currents can also be activated at -50 mV in a $Ca^{++}$-free, EGTA saline by application of 50 nM thyrotropin releasing hormone, a tripeptide which has been shown in GH3 cells to cause the release of $Ca^{++}$ from intracellular stores.

281.5 PATCH CLAMP ANALYSIS OF INACTIVATING OUTWARD CURRENTS IN DISSOCIATED CNS NEURONS OF WILD-TYPE AND *SHAKER*$^5$ *DROSOPHILA*.

C.K. Solc* and R.W. Aldrich. Dept. of Physiology and Sect. of Mol. Neurobiol., Yale Univ. Sch. of Med., New Haven, CT 06510. and Dept. of Neurobiol., Stanford Univ. Sch. of Med., Stanford, CA 94305.

Patch clamp analysis of ion channel mutants in *Drosophila* affords a powerful approach to the correlation of structure and function in membrane channel proteins. Previous voltage clamp studies of the dorsal longitudinal flight muscles (DLM) have shown that the $Sh^5$ locus mutation alters the kinetic properties of the fast transient potassium current $I_A$ (Salkoff and Wyman, TINS. 6:128, 1983). We report here experiments using the whole-cell and cell-attached patch clamp techniques to record inactivating outward currents in dissociated CNS neurons from wild-type and $Sh^5$ mutant flies.

Primary CNS cultures were prepared from late third instar larvae as described previously (Wu et al., J. Neurosci. 3:1888, 1983). Experiments were performed on type II and type III neurons from one to eight day old cultures in a *Drosophila* Ringer supplemented with 10% Schneider's medium. Pipettes were filled with the same solution for cell attached experiments, or with a high $K^+$ low $Ca^{++}$ internal solution for whole-cell experiments.

Whole cell outward currents were recorded from both wild type and $Sh^5$ neurons. Cells from cultures less than two days old tended to have only the delayed current while cells from older cultures usually exhibited robust fast transient currents that were sometimes accompanied by delayed currents.

The fast transient outward current activated at -35 to -45 mV with a rapid, sigmoid and sharply voltage dependent time course, reaching its peak within 1.5 to 6 ms and then inactivating. The midpoint of the steady state inactivation curve was between -75 and -80 mV. The voltage dependence of activation was similar to values reported in the DLM, but the steady state inactivation curve was shifted in the hyperpolarizing direction by about 35 mV. In cell-attached patches, we have recorded ensembles of small, flickery single-channel events whose averages had kinetics consistent with the fast outward current.

The delayed outward currents appeared to be made up of more than one channel type. Prepulses to potentials depolarized from rest inactivated a component of the delayed current, but long test pulses failed to produce a falling phase in the current. Single channels with first latencies consistent with the characteristics of the inactivating component of the delayed current were observed in cell attached patches.

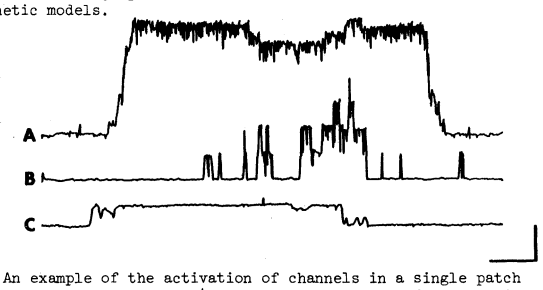
281.6 ACTIVATION OF POTASSIUM CHANNELS BY RAPID APPLICATION OF CALCIUM TO INSIDE-OUT PATCHES OF CULTURED HIPPOCAMPAL NEURONS.

R.S. Brett and B. Lancaster. Depts. of Anesthesiology and Neurobiology & Behavior, SUNY at Stony Brook, New York 11794

Ca-activated K channels mediate spike repolarization and after-hyperpolarization in a variety of excitable cells. To investigate the activation of K current by Ca at the single channel level, we are applying a method for the rapid (<10 ms) exchange of solutions bathing the cytoplasmic face of inside-out patches of cultured hippocampal neurons (cf. Brett, R.S., Dilger, J.P. & Adams, P.R., Neurosci. abstr. #71.1, 1984). Applications of 1-100 μM Ca for 200-1000 ms caused the appearance of 1-16 large-conductance (140-200 pS) channels. The latency and number of openings were dependent upon the Ca concentration (see figure). The probability of opening was also increased by depolarization. In symmetrical K solutions, the current reversed at zero mV. At negative pipette potentials, application of $BaCl_2$ (1 mM) to the cytoplasmic face rapidly and reversibly abolished Ca-activated channel openings. In occasional patches we have observed, together with events of the type shown, a second Ca-activated channel having lower conductance and different kinetics. The ability to make rapid Ca concentration jumps should allow new statistical tests of detailed kinetic models.



An example of the activation of channels in a single patch (pipette potential -50 mV) by rapid application of 1 and 100 μM Ca. Trace A, 100 μM Ca; calibration bar = 100 pA; Trace B, 1 μM Ca; calibration bar = 25 pA. Trace C, representation of the solution exchange profile after rupture of the patch, using a pulse of 70 mM KCl solution to alter the pipette tip potential. The horizontal bar = 100 ms.

281.7 A VOLTAGE-DEPENDENT, 4-AMINOPYRIDINE SENSITIVE, OUTWARD CURRENT STUDIED IN VIVO IN CORTICAL NEURONS OF AWAKE CATS BY VOLTAGE SQUEEZE TECHNIQUES. C.D. Woody, V. Nenov*, E. Gruen*, P.Donley*, M.Vivian*, and W. Holmes. Depts. of Anatomy and Psychiatry, MRRC and BRI, UCLA Med. Ctr., Los Angeles, CA 90024.

Studies of 47 neurons of the precruciate cortex disclosed fast, outward currents that increased with increasing, positive step voltage commands from holding potentials set between -60 and -80 mV. Preceding depolarizing pulses reduced the currents while preceding hyperpolarizing pulses potentiated them. In 12 cells given pressure injection of 4-aminopyridine, all but one showed reduction of the outward current. The degree of reduction varied from cell to cell.

Electrodes used in these experiments were prepared from theta-capillaries and were tested for non-rectifying passage of + and - currents of >>20 nA prior to use. They were filled either with 3M KCl or with 1.5 - 2M 4-aminopyridine in 2.25M KAcetate. A Dagan 8100 amplifier was used for single electrode pulse clamping.

The measurements of changes in current corresponded with previous in vitro measurements in other cortical cells (Gustafsson, B., et al., Nature 299:252, 1982), and in Tritonia (cf. Thompson, S.H., J. Physiol. (Lond.) 265:465, 1977). The cable properties of neocortical pyramidal cells are such that an actual voltage clamp is unrealizable with control of but 1-10% of a space constant estimated from previous modeling of theoretical cable properties in cells of known morphology. Also, the fast sodium currents are incompletely controlled. Further, the large number of active synaptic conductances along the cable length results in a kind of counter clamping toward the normal resting potential of the cell. Hence, the potentials are squeezed away from the normal resting potential and towards the desired holding and command potentials.

Nonetheless, the preparation affords qualitative examination of currents and time courses found in the actual in vivo state and semi-quantitative measurements of sufficient precision and sensitivity to detect changes in outward currents upon administration of pharmacologic blocking agents.

Changes in outward currents have been linked to membrane changes supporting conditioning in invertebrates and potassium currents have been linked indirectly to ACh - cGMP dependent changes in membrane properties of the cells of this cortical region (which has been found necessary for some forms of mammalian conditioning). Thus, the present technical advance affords a possible means for detecting changes in currents related to mammalian conditioning. (Supported by AFOSR and NICHHD. We thank Dr. D. Alkon for invaluable help in beginning these studies.)

281.8 A SODIUM-ACTIVATED POTASSIUM CURRENT IN CULTURED VERTEBRATE NEURONES. D. Bertrand*, C.R. Bader and L. Bernheim* Dept of Physiology, University Medical Center, 1 rue Michel-Servet, CH-1211 Geneva 4, Switzerland.

Cultured neurones from dissociated avian parasympathetic and sensory ganglia were studied in voltage clamp with the whole cell recording technique. An outward current carried by potassium ions and suppressible by extracellular 4AP and TEA was found to be initiated whenever a sodium current entered the cell. This potassium current had the following characteristics : 1) it was suppressed by TTX at a concentration which blocked the fast inward sodium current, 2) it was suppressed by removal of extracellular sodium, 3) it could not be detected at voltages more depolarized than the sodium reversal potential, 4) inhibition of inactivation of the sodium current increased the duration of this potassium current, 5) it was strongly activated when the intracellular fluid contained 50 mM NaCl. These observations were made in the absence of extracellular calcium and in the presence of 5 mM EGTA and 5 mM ATP in the intracellular fluid.

We conclude that this potassium current is activated by an increase in the intracellular sodium concentration. Our results suggest that the quantity of sodium entering a cell during a single action potential is sufficient to activate this potassium current.

281.9 SINGLE TRANSIENT POTASSIUM CURRENTS IN MAMMALIAN SENSORY NEURONS STUDIED USING PATCH-CLAMP TECHNIQUES. H. KASAI* (SPON: K. TANAKA). Dept. of Physiol., Faculty of Medicine, Univ. of Tokyo, Tokyo 113, Japan.

A single-channel which carried transient outward current (A-current) was isolated in an extracellular patch-clamp electrode. Dorsal root ganglion cells isolated from adult guinea pigs were grown on poly-L-lysine coated plastic dishes for up to two weeks. Nerve cells were bathed in an isotonic KCl solution during the patch-clamp experiments (150mM KCl, 1mM $MgCl_2$, 1mM EGTA, 5mM Na-Hepes, 5.5mM glucose at pH7.4, 20-24°C), so that the resting membrane potential was close to 0mV. The patch pipette contained a Na-free Tris-solution (150mM Tris-HCl, 5mM KCl, 1mM $CaCl_2$, 1mM $MgCl_2$, at pH7.4). We chose those membrane patches from which A-current was purely recorded; when membrane potential was depolarized to 0mV for 30sec., A-current was completely inactivated, and thus, contamination of the patch with other channel currents was easily discriminated. The single-channel currents was elicited shortly after the membrane depolarization from hyperpolarized potential (-100mV). The appearance of the currents tended to reduce in time. The mean conductance of the K channel was 20.1±3.7 pS (mean±SD, n=15). The major charge carrier through the channel was determined as K ions. Mean open time was 6.8ms at 0mV. A closed time histogram was approximately fitted by two exponential curves with time constants 1ms and 3.4ms. A latency histogram for the first openings of the channel showed a peak at 2.5ms. These observations indicated the presence of two closed states in the process of activation of the channel. The activation and inactivation kinetics of this channel was studied at various membrane potential using ensemble averaged currents. The activation of the channel was started at potential>-60mV. The channel was inactivated by depolarization with two time constants, 100msec and 4sec. The complete inactivation was attained at potential>-40mV with slow time constant (4sec). Properties of the channel were not affected when mebrane patch was exposed to the Ca-free solution containing 1mM EGTA (inside-out patch). Effects of 4-aminopyridine (4-AP) were studied using the inside-out patch configuration; 1) 4-AP reduced the single-channel conductance (a half-reduction was attained at 12mM); 2) the reduction in the single-channel conductance was dependent on the membrane potential: it was larger at depolarized membrane potential; 3) 4-AP reduced the opening probabilty (a half-reduction was attained at 12mM at 0mV); 4) 4-AP shifted voltage-dependence of both the activation and inactivation of the channel in a depolarizing direction; 5) all of the effects were reversible.

281.10 OUTWARD CURRENTS INDUCED IN XENOPUS OOCYTES FOLLOWING INJECTION OF RNA FROM APLYSIA AND RAT BRAIN. M.B. Boyle, E. Azhderian* and L.K. Kaczmarek. Department of Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510.

It has been shown that when RNA isolated from vertebrate tissues is injected into oocytes of Xenopus laevis, the translation of the foreign mRNA may lead to the appearance of novel ion channels. We have examined the ability of the oocyte translation system to express ion channels after injection of RNA from the nervous system of the mollusc Aplysia. We have tested the electrical properties of Xenopus oocytes after injection of 1) poly(A+)-enriched RNA from rat brain; 2) total RNA from pooled cerebral, pedal, and pleural ganglia of Aplysia; and 3) total RNA from the peptidergic bag cell neurons of Aplysia. Total RNA was obtained by homogenization of the tissue in guanidine thiocyanate and centrifugation through a 5M CsCl cushion. The yield of total RNA per gram of starting material was 50 to 100 ug for Aplysia central ganglia. Oocytes were treated with 2 mg/ml collagenase at room temperature for 1 to 1.5 hours soon after isolation. Oocytes were later injected with 20 to 100 ng of RNA in water or 20 to 100 nl of sterile water. Ionic currents were measured 3 to 7 days after injection using 500 ms depolarizing steps from -40 or -100 mV. In oocytes injected with poly(A+)-enriched RNA isolated from rat brain, transient outward currents reaching peak in about 100 to 200 ms were observed, in agreement with the report of Gundersen et al. (Proc. Roy. Soc. Lond. B 220:131, 1983). In oocytes injected with RNA from pooled cerebral, pleural and pedal ganglia from the CNS of Aplysia, we observed delayed outward currents which activated during the first 50 to 200 ms and which showed no apparent inactivation with time. We have never observed similar currents in non-injected or water-injected controls. The injection of total RNA isolated from the peptidergic bag cells of Aplysia resulted in the appearance of a new transient outward current in 16 out of 26 oocytes from 3 frogs. This current was seen when the cells were held at either -40 or -100 mV. This current shows a faster activation than the transient current found in oocytes injected with RNA from rat brain. The amplitude of the current showed a monotonic increase with depolarization up to +60 mV. The current was not present in non-injected cells or in 8 water-injected controls from these frogs. However, in one animal not used in these experiments, a similar current was seen in non-injected cells. Thus, it remains to be determined whether these currents represent novel ion channels coded for by the injected RNA from Aplysia or whether the injections promote expression of native oocyte channels.

281.11 TWO TYPES OF DELAYED POTASSIUM CHANNELS: INACTIVATING AND NON-INACTIVATING CHANNELS. J. L. Ram & D. Dagan. Dept. of Physiology, Wayne State Univ., Detroit, MI 48201 & Rappaport Fam. Inst., Technion, Haifa, Israel.

Under voltage clamp of long duration, neurons show partial inactivation of voltage dependent delayed potassium current (IK). Channels and currents underlying IK were analysed in cell-attached patches of Helix neuronal cell bodies. Results indicate at least two principal types of IK channels, one which inactivates almost completely (IK,ID: inactivating delayed channels), and a second which does not show time-dependent inactivation (IK,ND: non-inactivating delayed channels). Fast outward transient (IA) channels have also been studied.

ID channels: Delay from onset of depolarization until peak number of open channels was >70 ms (mean=115 ms). Inactivation time constants averaged 350 ms. Opening probability decreased to near zero for long (1 s) depolarizations. Activation was voltage dependent and required >45 mV above rest. Single channel conductance was 45±12 pS. There are at least 2 closed states. With single channel patches, about half the responses were "blanks," consistent with a model in which channels can enter the inactive state directly without a previous opening. ID channels are not likely to be Ca-dep. K channels (IC), since ID channels are seen with 0 Ca ringer in the patch pipet. In other studies, Helix IC channels consistently have conductances of 15-20 pS, less than half the conductance of ID channels.

ND channels: Previous studies in Helix using fluctuation analysis (Reuter & Stevens, 1980) indicate non-inactivating channels of 2.5 pS, which would be too small to be seen as distinct channel openings and closings in our single channel records; however, one would expect a voltage dependent increase in patch mean conductance and an increase in current fluctuations with depolarization. This is exactly what is seen. This voltage dependent current begins to activate at about 50 mV above rest and does not inactivate over the course of 1 s. Steady state current is reached within 50 ms.

Thus, we propose that IK is due to at least two types of channels. Essentially all of the inactivating fraction of the current is due to ID channels; whereas, most of the non-inactivating current is due to ND channels.

IA channels: These have a low probability of activation from holding potential at rest but can be activated when holding potential is hyperpolarized 25 and 50 mV below rest. Peak opening probability at 75 mV above rest (from a holding potential 25 mV below rest) is reached in <15 ms and the inactivation time constant is <100 ms. Single channel conductance is 10-15 pS.

We thank the Lady Davis Trust for financial assistance to JLR.

281.12 $Ca^{2+}$-MEDIATED REDUCTION OF $K^+$ CURRENTS IS ENHANCED BY INJECTION OF $IP_3$ OR NEURONAL $Ca^{2+}$/CALMODULIN KINASE TYPE II. M.Sakakibara*, D.L.Alkon, J.T.Neary, R.DeLorenzo†, R.Gould¶, and E.Heldman§. Lab. Biophysics, NINCDS-NIH, MBL, Woods Hole, MA 02543; †Dept. Neurol., Yale Univ. Sch. Med., New Haven, CT 06510; ¶NY State Inst. Basic Res., Staten Island, NY 10314; §Dept. Pharmacol., Israel Inst. Biol. Sci., Ness-Ziona, Israel.

Elevation of intracellular $Ca^{2+}$, $[Ca^{2+}]c$, in the isolated soma of the Hermissenda type B cell has been shown to cause reduction of the early voltage-dependent outward current, $I_A$ (Alkon et al., Biophys. J. 40:245, 1982) and the $Ca^{2+}$-dependent outward current $I_C$ (Alkon and Sakakibara, Biophys. J., in press). The prolonged duration of $I_A$ and $I_C$ reduction (1-5 min) suggested that biochemical steps may be responsible for reduction which may outlast $[Ca^{2+}]c$ elevation itself and could lead to the $I_A$ and $I_C$ reduction (lasting days) which encodes associative memory. Previous studies showed that iontophoretic injection of one type of a $Ca^{2+}$/calmodulin (CaM) dependent protein kinase (PK), phosphorylase kinase, enhances and prolongs $Ca^{2+}$-mediated $I_A$ and $I_C$ reduction (Acosta-Urquidi et al., Science 224:1254, 1984). In the present study iontophoretic injection of neuronal $Ca^{2+}$/CaM-PK type II under isopotential conditions was found to cause significant $I_A$ (n=8, $p<.01$) and $I_C$ (n=8, $p<.02$) reduction lasting 20 min or longer. This reduction did not occur unless preceded by voltage-clamp conditions which caused significant $[Ca^{2+}]c$ elevation (25 sec depolarization paired with a 2 sec light of $\sim 10^4$ ergs/cm$^2$·sec). No such reduction occurred when the $Ca^{2+}$/CaM-PK was first inactivated before injection. $Ca^{2+}$/CaM-PK injection followed by $Ca^{2+}$ loads did not significantly alter $I_{Ca^{2+}}$ measured at 0 mV (in 0-$Na^+$, 300 mM $K^+$-ASW) the $K^+$ equilibrium potential, or the light-induced inward $Na^+$ current, $I_{Na^+}$. Trifluoperazine (10 μM) in the ASW caused increase of both $I_A$ and $I_C$ and shortening of $Ca^{2+}$-mediated reduction of outward $K^+$ current, measured as an apparently inward current (just opposite to the effects of $Ca^{2+}$/CaM-PK). Iontophoretic injection of inositol trisphosphate ($IP_3$) but not $IP_1$ produced $I_A$ and $I_C$ reduction even in the absence of $Ca^{2+}$ load conditions. $IP_3$-induced reduction of $I_A$ and $I_C$ also persisted for the recording duration. $IP_3$ injection caused a similar reduction of $I_A$ (n=8, $p<.005$) and $I_C$ (n=9, $p<.01$) measured across the isolated soma of the type A photoreceptor, but had no effect on $I_{Ca^{2+}}$ of either type B or A somata. $IP_3$ injection had no effect on $I_{Na^+}$ of type B cell but caused a clear increase of the type A $I_{Na^+}$ ($p<.001$). $IP_3$ injection, by mobilizing $[Ca^{2+}]c$, may produce its effects on $I_A$ and $I_C$ via activation of endogenous $Ca^{2+}$/CaM-PK and possibly endogenous C-kinase as well. The differences in $IP_3$ effects on type B and A $I_{Na^+}$ may reflect differences in endogenous enzyme levels which, in turn, might explain differences in receptor sensitivity during light and dark adaptation.

## DEVELOPMENT OF INVERTEBRATES II

282.1 TISSUE INTERACTIONS DURING MIGRATION OF NEURAL PRECURSORS IN LEECH EMBRYOS. S.A. Torrence* (SPON: D.K. Stuart) Dept. of Molecular Biology, U. of CA., Berkeley, Berkeley CA. 94720

In glossiphoniid leech embryos, neuroblasts and glioblasts that arise outside the prospective CNS migrate in small clusters along stereotyped pathways to reach their characteristic positions in and near the ventral ganglia. To examine the role of intercellular interactions in guiding migrating cells to their destinations and controlling their final positions, tissues offering potential guidance cues have been identified and ablated.

In each right or left hemisegment two groups of neural precursors belonging to the Q cell line migrate from the lateral edge of the body-wall rudiment toward the ventral midline where they produce the glia of the interganglionic connective, an antero-ventral cluster of central neurons, a single ventro-lateral central interneuron and a small cluster of peripheral neurons along one of the segmental nerve roots.

Among cells along the routes of migration that might provide guidance or positional cues are cells derived from two ectodermal cell lines (O and P) and from the mesoderm: several peripheral neurons, the nephridiopore, epidermal specializations called cell florets, and circular and longitudinal muscle fibers. In addition, cells of the N cell line, which gives rise to the majority of central neurons, have been proposed to play an important role in organizing the ganglia by Blair & Weisblat (1982, Dev. Biol. 91:64-72).

To learn which tissues are necessary for normal migration and positioning of neural precursors of the Q cell line, progenitor cells of various parts of the ectoderm or mesoderm have been ablated before the onset of migration, either by intracellular injection of the lethal enzyme DNase or by laser irradiation of cells labeled with a photosensitizing lineage tracer dye. Ectodermal ablations did not prevent migration and produced only subtle alterations in final cellular positions. Such alterations are probably a simple consequence of the overall reduction in ganglionic size. By contrast, partial ablations of the mesoderm produced substantial abnormalities in the positioning of cells after migration or prevented migration altogether, depending on the severity of the lesion. Thus normal migration and positioning of neural precursors from the Q cell line do not require specific interactions with other ectodermal cell lines but do depend on interactions with the mesoderm.

282.2 MORPHOGENESIS OF SEGMENT-SPECIFIC INNERVATION PATTERNS IN AN IDENTIFIED LEECH NEURON. J. Jellies, C.M. Loer and W.B. Kristan, Jr., Department of Biology, B-022, U.C.S.D., La Jolla, CA, 92093.

Although most of the midbody segments of the medicinal leech (Hirudo medicinalis) are essentially identical, segments 5 and 6 are specialized for reproduction and contain the male and female tissue. Many of the neurons in these segments are correspondingly specialized and hence different from those in the more "standard" ganglia. We have been examining the morphogenesis of one such pair of neurons, the serotonergic Retzius cells, in order to gain insight into the mechanisms by which identified neurons acquire their particular innervation patterns.

One example of a segment-specific difference is that the standard neurons project central axons to adjacent ganglia while those in segments 5 and 6 have no such projections. However, these axons are initiated early in embryogenesis, but later cease extending (A. Mason, J. Glover and W. Kristan, 1984, Soc. Neurosci. Abst., 10:1033). A second obvious difference in Retzius cells is that in the 5th and 6th segments they innervate reproductive tissue, but not body-wall as they do in the standard segments. We used intracellular injections of Lucifer Yellow in embryonic Hirudo to determine whether the peripheral axons in segments 5 and 6 also followed the standard pattern initially, and whether contact with reproductive tissue was correlated with the development of morphological differences.

We found that all Retzius cells extend peripheral axons into the body-wall for almost 72 hours after the processes are initiated. This involves a primarily lateral growth along apparently identical trajectories until late in the 9th day when the axons in segments 5 and 6 come into close association with the reproductive tissue. From that point on, the processes in these segments grow medially to acquire their characteristic patterns while those in standard segments continue lateral growth into the body-wall. The timing of target contact is well correlated with the initiation of changing innervation patterns and the other segment-specific morphological differences in these cells. Thus, we hypothesize that contact with the reproductive tissue signals the neurons in segments 5 and 6 to change their morphogenetic patterns. The predictions of this hypothesis are currently being tested.

This work was supported by grants from NIH.

282.3 THE POSSIBLE ROLE OF TARGET INTERACTIONS IN THE DEVELOPMENT OF SEGMENT-SPECIFIC DIFFERENCES OF AN IDENTIFIED NEURON. C.M. Loer, J. Jellies, and W.B. Kristan, Jr.. Dept. of Biol., U.C., San Diego, La Jolla, CA 92093.

We are interested in the mechanisms by which a neuron assumes its unique identity during development. Segmentally homologous neurons often acquire very different properties, perhaps due in part to the unique segmental environments in which they develop. In standard midbody segments of the leech, Hirudo medicinalis, the large serotonergic Retzius cells innervate the entire skin and body musculature. In contrast, the Retzius cells in segments 5 and 6 do not innervate the body wall; rather, they heavily innervate the male and female reproductive organs found only in those segments. In addition, Retzius cells in segments 5 and 6 differ from all other Retzius cells in soma size, interganglionic branching pattern, neuropilar arborization, and connectivity. We and others (A. Mason and J.G. Glover, submitted) have found that the early development of the Retzius cells in all segments is similar. Differences in the morphology of Retzius 5,6 arise only after their growth cones appear to contact the developing reproductive tissue. At this time, the cells stop extending neurites both laterally into the body wall and into the intersegmental connectives, appearing rather to devote their entire peripheral innervation to the developing reproductive tissue. These observations suggest that interaction with the reproductive tissue is important in the development of the unique characteristics of the Retzius cells in segments 5 and 6.

We are testing this hypothesis with manipulations of leech embryos to ask two questions:

1. Can Retzius 5,6 become like standard Retzius cells in the absence of reproductive tissue? To address this question, we will have ablated the reproductive primordia early in development, before the Retzius cells have contacted the tissue.
2. Can Retzius cells from other segments be induced to become like those in segments 5 and 6? We have addressed this question with two different experiments. We have ablated the Retzius cells in 5 and 6 to see whether Retzius cells from adjacent ganglia, which normally innervate the body wall in these segments, are capable of innervating the reproductive primordia. We have also transplanted reproductive primordia into other segments of the leech embryo. Preliminary results indicate that the Retzius cells of other segments are capable of making a heavy innervation of the reproductive tissue and that this tissue is attractive for Retzius cell processes.

We are continuing experiments to ask whether the development of other unique characteristics of Retzius 5,6 is brought about by interaction with the reproductive tissue.

282.4 HOMOLOGS OF THE HEART ACCESSORY NEURONS IN THE LEECH ARE REVEALED BY DYE FILLING AND ANTIBODY LABELING. Wei-Qiang Gao*, R.R. Stewart and E.R. Macagno (SPON: S. DeRiemer). Dept. of Biological Sciences, Columbia University, New York, NY, 10027.

Several identified neurons, such as the Lateral and Rostral Penile Evertors of Zipser (J. Neurophysiol. 42:455, 1979) or the Heart Accessory (HA) cells of Calabrese & Maranto (J. Comp. Physiol. A154:393, 1984), seem to exist only in the sex segmental ganglia (SG5 and SG6) of the leech nerve cord. Since these ganglia have several hundred more neurons than other SG (Macagno, E.R., J. Comp. Neurol. 190:283, 1980), it is possible that the above-mentioned identified neurons arise uniquely in these SG. Alternately, other ganglia could have homologs of these cells at some point in development, and these later degenerate, or homologs remain but assume different identifies.

Our examination of the HA neurons in SG5 and SG6 [HA(5) and HA(6)] and cells in similar positions within adjacent ganglia in embryos and in adults using dye-filling with Lucifer Yellow and immunocytochemistry with the monoclonal antibody Laz1-1 (kindly provided to us by Dr. Birgit Zipser) lends support to the last of these alternatives. The branching patterns of HA(5) and of HA(6) are very similar in that both have primary processes that extend across the midline and branch into the contralateral roots, but they differ in that HA(5) extends a thick process into the contralateral anterior connective while HA(6) does the same but in the posterior direction. These characteristic branching patterns were seen in the adult and in embryos 20 to 30 days old. Dye fills of cells in very similar positions in adjacent SG revealed cells in SG4 and SG7 with morphologies that closely resemble those of the HA neurons. These cells were designated cells 158 based on their position on the generally accepted map of the leech ganglion. In both embryos and adults, cells 158 in SG4 show the same branching pattern as the HA neurons in SG6, while cells 158 in SG7 look like the HA neurons in SG5.

Cells 158 were also found to label with the mAB Laz1-1, whereas the HA neurons did not. This was shown by double-labeling cells 158 and HA neurons with Lucifer Yellow and Laz1-1 in embryos and adults. In addition, HA neurons of adults label with FMRFamide antibody, but cells 158 do not (J. Kuhlman & R. Calabrese, personal communication.

Developmentally, cells 158 and HA neurons initially share similar branching patterns, extending neurites in both directions along the connective nerves. As development proceeds, however, specific branches of these neurons become large whereas others cease to grow or are eliminated, giving rise to the asymmetric branching seen in the connectives. This observation, the similarity in branching pattern and the similarity in cell body position lead us to postulate that cells 158 and the HAs are homologs. (Supported in part by NIH Grant NS-20336.)

282.5 DIFFERENTIATION AND DEATH OF CELLS IN THE LEECH CNS. I. THE BIPOLAR CELLS. R.R. Stewart and E.R. Macagno. Dept. of Biological Sciences, Columbia University, New York, NY 10027.

To help assess how the adult complement of neurons is achieved during the development of individual segmental ganglia (SG) in the leech CNS, we are examining the antibody labeling of individual cells in embryonic and postembryonic developmental stages of hirudinid leeches. The monoclonal antibody Laz1-1, kindly provided to us by Dr. Birgit Zipser, was raised in mice against the adult nerve cord of Haemopis. It labels between 20 and 35 cells per SG of the adult nerve cord and labels fewer neurons within the sex ganglia (SG5 and SG6) than it does in adjacent ganglia, e.g., SG4 or SG7, in both adults and in embryos. The differences in labeling pattern appear as early as 12 days of development at 24 °C. However, when embryos are labeled between 7 and 12 days, a pair of cells not seen in older embryos is labeled in many ganglia. These cells are medially located on the dorso-posterior aspect of each ganglion. Since two processes appear to project from each cell, one anteriorly and the other posteriorly along the ipsilateral side of the ganglion, we have named these the bipolar cells. Their processes travel within what seem to be well-defined longitudinal tracts.

Bipolar cells are the first to label with Laz1-1, labeling initially in more anterior ganglia (at 7 days), and gradually over the next two days in more posterior ganglia (a new pair begins to label every approximately three hours). By 9 days, when bipolars are labeled in nearly all 32 ganglia, those in the anterior SG , but not those in the head ganglia, begin to die. The first sign of degeneration is the loss of labeling from the anterior and posterior processes. As degeneration of a cell continues, its intensity of labeling decreases in comparison to other bipolars judged to be healthy, and the cell is seen to fragment. Interestingly, the fragments of the dying cell still retain some immunoreactivity as they gradually disappear. As development proceeds, bipolar cells begin to die in more posterior segments as well as in the head, and by 12 days all the bipolars have degenerated.

The function of the bipolar cells is not known, although their early appearance during ganglion formation suggests that they might be responsible for establishing the first longitudinal tracts within the CNS. It is also unknown at present whether these are glial, neuronal or muscle cells. Their degeneration, however, occurs after they have begun to differentiate and during a period in which cell number is decreasing in the SG from an initially higher value than is found in the adult.

(Supported in part by NIH Grant NS-20336.)

282.6 DIFFERENTIATION AND DEATH OF CELLS IN THE LEECH CNS. II. THE UNPAIRED MEDIAL SEROTONERGIC NEURONS. E.R. Macagno, R.R. Stewart and D. Spergel*. Dept. of Biological Sciences, Columbia University New York, NY 10027.

Of the four types of serotonergic neurons found in the majority of the segmental ganglia of the leech, three are paired (Retzius, Dorso-lateral and Ventro-lateral cells) and one is unpaired (the medial or M cell) in all but a few of the most anterior ganglia. In early embryogenesis the M cells first appear as a pair in each ganglion, as seen in Helobdella by glyoxylic acid induced fluorescence of monoamines (Duncan Stuart, personal communication) and in Haemopis and Hirudo by serotonin antibody labeling (this antibody was kindly provided to us by Dr. Jean Lauder). Is it the case that one M cell simply stops producing serotonin, so that it can no longer be detected with the antibody, or does one of the M cells degenerate in those ganglia where a single M cell is found?

We have obtained evidence in hirudinid leeches which indicates that, in each ganglion with a single M cell, one cell of the original pair dies. As do the bipolar cells discussed in the preceding abstract, the degenerating M cells break appart into many fragments which retain immunoreactivity. Eventually no trace of the cell is seen. In Hirudo, the species that we have examined in more detail, one or two M cells are seen labeling at 9 days of embryogenesis from the first segmental ganglion (SG1) (we did not examine the head ganglia) to between SG5 and SG12. At later times both members of the pair label in all SG. Observations on seven embryos of 11 to 13 days of age revealed that M cells become unpaired gradually from anterior to posterior, with as few as one and as many as seven dying cells observed in individual embryos. By 20 days all SG, with the exception of SG1 and SG2, possess unpaired M cells. Among those cells that were clearly assignable to one side or the other of the midline (some sit right on the midline), as seen in six embryos aged 12 to 20 days, 39 cells were on the left side and 40 on the right side (data pooled for all embryos). Thus, which M cell dies appears to be randomly determined. A possible mechanism of M cell death is competition for the same synaptic targets, with the loser being eliminated. Support for this hypothesis has been provided by the observation (Duncan Stuart, in preparation) that, in Helobdella, killing of the N teloblast, which eliminates all the M cells that arise on the same side, results in the survival of all the M cells generated by the teloblast on the other side.

282.7 HORMONAL REGULATION OF POSTEMBRYONIC NEUROGENESIS IN THE MOTH MANDUCA SEXTA. R. Booker* and J. Truman (SPON: M. Murray). Univ. of Washington, Seattle, Wash. 98195

All the segmental ganglia of M. sexta larvae contain neuroblasts, which generate discrete clusters of partially differentiated neurons, the preganglion cells (PGCs). During metamorphosis a wave of cell death sweeps through the clusters eliminating 10-100% of the PGCs. At about the same time the surviving PGCs begin the process of terminal differentiation to mature neurons. Manduca's postembryonic development is controlled by a few developmentally important hormones. Using a combination of histological and endocrine techniques, the developmental regulation of postembryonic neurogenesis in Manduca by the steroid hormone ecdysone was examined.

Larvae were ligated between the thorax (the source of ecdysone) and the abdomen during the early phases of metamorphosis. The fourth abdominal ganglia (A4) of the isolated abdomens were then examined at a point corresponding to two days after pupation. The development of the abdomens ligated during the first days of metamorphosis was incomplete; in A4 minimal cell death and differentiation were observed within the clusters of PGCs. When the ligature was applied later in development, both the extent of cell death and differentiation of the PGCs increased. The adult cell number and morphology were observed only if the abdomens were ligated on or after the day of pupation.

A direct effect of ecdysone on neurogenesis was shown by combining ligation with hormonal replacement. Abdomens were ligated at the onset of metamorphosis. The ligated abdomens were then infused with ecdysone and examined six days later. Both cell death and differentiation were triggered in the isolated abdomens in response to the infused ecdysone. The magnitude of the responses observed was dose dependent. While ecdysone may trigger these developmental events the extent of the cell death and the morphology of the mature neurons was found to be cluster specific.

282.8 SEROTONERGIC CELLS IN *Drosophila*. A.M. Valles* and K. White*. (SPON: J. Hall). Dept. of Biology, Brandeis University, Waltham, MA 02254.

The study of the distribution of the neurotransmitter serotonin (5HT) in *Drosophila melanogaster* has been initiated in an attempt toward understanding the extent of the role of this neurotransmitter in the ontogeny of the nervous system. Genetic variants allow one to alter the levels of 5HT and thereby probe the impact of 5HT on neuronal development.

Immunocytochemical techniques have been used to identify 5HT-containing cells in the central nervous system (CNS) (White and Vallés, *Molecular Bases of Neural Develop.*, Ed. G.Edelman, W.Gall and W.Cowan, 1985). In the present study, we extend the localization of 5HT immunoreactivity during development and demonstrate that a) the onset of staining of 5HT cells appears in the CNS during late embryogenesis, b) the 5HT stereotypic pattern persists post-embryonically and c) additional post-embryonic cells appear during pupation. In the neuropilar region, extensive immunoreactive processes and axonal arborizations are observed. The larval nervous system shows peripheral 5HT immunoreactive innervations to the ring gland and the cephalopharyngeal muscles.

In *Drosophila*, the gene *Ddc* encodes the enzyme dopa decarboxylase (Wright et al, Genetics,84:287, 1976) which catalyzes the decarboxylation of 5HTP to 5HT as well as l-dopa to dopamine (Livingstone and Temple, Nature, 303:67,1983). The effect of *Ddc* mutations on 5HT cells was studied by deleting the *Ddc* gene. *Ddc* deficient animals can survive until early pupal period. The CNS of the *Ddc* deficiency larvae were characterized by a complete absence of immunoreactive cells. However, 5HT neurons are still present since incubating the tissue in exogenous 5HT results in the reappearance of the immunoreactive pattern. Work is currently being conducted to determine the effect of *Ddc* mutations on dopaminergic cells (see Budnik et al, this volume). (Supported by NIH Grant GM31503).

282.9 DEVELOPMENT OF AMINE AND PEPTIDE NEURON SYSTEMS IN EMBRYONIC AND LARVAL LOBSTERS-E. Kravitz, B. Beltz and K. Siwicki* Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

We have begun a study of the appearance of the amines, serotonin and octopamine, and the peptide proctolin, in embryonic and larval lobsters. The aim is to examine when in development identified neurons first express these substances, what controls this expression, and when these neurons first become functional, and then to correlate these events with the emergence of aspects of lobster behavior.

Female lobsters carry on their swimmerets between 10,000 and 100,000 eggs,all fertilized within a few days of each other. Embryonic development is slow(up to 9 months in the wild), but can be speeded up by keeping eggs in warm water.The first stage, free-swimming larvae, have no claws, walking legs or swimmerets, are top-dwellers that move towards light and show no "hiding" behavior. 2 to 3 weeks and 3 molts later,4th stage larvae hatch that resemble miniature lobsters.They descend to the bottom, burrow and hide, and begin the solitary existence of young lobsters.4th stage larvae swim in a fully extended posture, similar to one induced in older animals by injection of octopamine.

We have mapped the patterns of immunocytochemical staining for the 3 substances in animals half-way through embryonic development, in later embryos, and in various larval stages. Staining for serotonin appears early in development (see Taghert and Goodman, J. Neurosci.4,989) and the full complement of neurons staining for serotonin in adults can be identified in the earliest embryos we examined. The serotonin-staining neurons are among the largest cells in the embryo. A pair of brain cells are about 30$\mu$m in diameter in early embryos and about 60$\mu$m at hatching. The identified serotonin-proctolin cell pairs in the T5 and A1 ganglia of adult lobsters (Beltz and Kravitz, Soc. Neurosci. Abstr.10,152) also are easily found in embryos. They are large (15$\mu$m) neurons found in characteristic midline locations and their major neuropil branches can be recognized in early embryos. In contrast proctolin staining (seen in about 1500 neurons in adult lobsters) is observed in only a few hundred cell bodies in embryos, mainly in regions of the nervous system that regulate feeding. During the lst to 4th larval stages, staining appears in the remaining neurons. This includes the T5-A1 serotonin-proctolin neurons, which therefore express their amine and peptide functions at widely different times in development. In certain neurons, staining for proctolin is seen only in embryos. Preliminary studies with an antibody to octopamine show a proctolin-like pattern of staining: well stained neurons only in the anterior part of the nervous system in embryos, and an adult-like pattern by the 4th larval stage. Biochemical studies to complement the immunocytochemical investigations are presently under way. (supported by the Klingenstein Fund and NIH)

282.10 COMPETITION CONTROLS QUANTAL RELEASE AT AN IDENTIFIED INSECT SYNAPSE. D.Shepherd* and R.K.Murphey Neurobiology Research Center, SUNY Albany, Albany, NY 12222.

A small group of sensory hairs on the cricket cercus are innervated by neurons (x-neurons) that terminate in both the ipsilateral and contralateral halves of the terminal abdominal ganglion. Recent anatomical studies have demonstrated that long term removal of the left cercus causes a distortion of the remaining right, x-neuron, it adds arbors on the side of the amputation and decreases the number of arbors on the side opposite to the amputation (Murphey & Lemere.Science.224. 1352-1355.1984).

Simultaneous recording from 2 bilaterally homologous interneurons and the right x-neuron have demonstrated that following deafferentation the synaptic connections of the x-neurons are reorganised. In untreated animals the right x-neuron produces a monosynaptic e.p.s.p. in both medial giant interneurons (MGI). In unilaterally deafferented animals, the x-neuron fails to produce a detectable e.p.s.p. in the right MGI, suggesting that as a result of deafferentation the x-neurons have retracted synapses from the right MGI. In the left MGI the same x-neuron produces an e.p.s.p. twice the size of the e.p.s.p. seen in normal animals, indicating an increased efficacy of the synaptic connection. These changes in connectivity are entirely consistent with the anatomical changes seen in the x-neurons.

Using quantal analysis of the inputs to the left MGI it has been possible to further examine the presynaptic changes produced by the reorganisation of the x-neuron. Using binomial statistics to determine m, the mean quantal content, it was demonstrated that m=0.9 in untreated animals and m=2.37 in experimental animals. This increase in m indicates that a change in the presynaptic neuron contributes to the enhanced contact and is correlated with the shift of the x-neuron terminals in the region near MGI. Further, the binomial product n in experimental animals (n=6.3) is nearly twice that seen in normal specimens (n=3.14). Recent studies have suggested that n is directly correlated with the number of contacts between pre and postsynaptic neurons (Korn et.al.,Science.213, 898-901.1981). Preliminary light microscope studies of our material suggest that the number of contacts is low (fewer than 10) in control animals and is increased in treated specimens. In conclusion, the removal of neighboring presynaptic cells alters the structure of neuron-x and this has a direct correlate in changes of synaptic efficacy.

282.11 SYNAPTIC PLASTICITY IN RESPONSE TO PARTIAL DEAFFERENTATION OF GIANT INTERNEURONS IN THE AMERICAN COCKROACH. Susan Volman. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

The giant interneurons (GI's) of the cockroach escape system receive input from a bilateral pair of sensory organs, the cerci, which contain an array of wind-sensitive sensilla. Within one month after unilateral cercal lesions, GI's which received their major input from the ablated cercus become more responsive to stimulation of the remaining cercus. This enhanced responsivity underlies functional plasticity in the escape behavior which also occurs after unilateral cercal ablations (Vardi and Camhi, J. Comp. Physiol. 146: 299, 1982).

In order to study the physiological basis for enhancement, recordings were made from the GI somata which are located across the ganglionic midline from the axons. Small dendrites arise ipsilateral to the soma, whereas the major dendrites and integrating zone are ipsilateral to the axon. The size and shape of compound EPSP's, as well as recordings from GI's in ganglia which had been split along the midline, showed that each set of cercal inputs connects mainly ipsilaterally to areas of the neuropil which are about 100μm apart. After long-term ablations of the major input, there was no indication that the location of connections from the intact cercus had changed, although this input was now more likely to evoke action potentials. There was also no evidence for any changes in the cable properties of the GI's.

I next looked for changes in unitary EPSP's evoked by stimulation of single afferents. The filiform hairs on the cerci are arranged in distinct rows and columns and each hair is associated with a single sensory neuron. Thus it is possible to reidentify single afferent neurons from one animal to the next. I confined this study to 4 afferents (hairs 3-6 from column h on the cercus ipsilateral to the soma) which make a large contribution to the receptive fields of GI's 1 and 2 after ablation of the contralateral cercus. Unitary EPSP's, correlated one-to-one with action potentials in individual afferents, were recorded from 8 intact animals and 6 animals at least 30 days after unilateral cercal ablation. For GI 2, these EPSP's were significantly larger in the deafferented animals, averaging 4.3mV as compared to 1.8mV in the intact animals. For GI 1, however, there was no significant difference between the size of EPSP's in the two groups, perhaps because these hairs play a less important role in the enhanced response of this GI.

Cobalt fills of column h afferents showed that they arborized purely ipsilaterally. Thus the physiologcal results for GI 2 suggest that, after partial deafferentation, enhanced responsiveness may be accounted for by increased synaptic current at a site widely separated from the locus of deafferentation.

282.12 ADIPOKINETIC HORMONES IN LOCUSTS: SYNTHESIS AND DEVELOPMENTAL REGULATION: S. Hekimi* and M. O'Shea. Lab. of Neurobiology, Univ. of Geneva, CH-1211 Geneva 4, Switzerland.

Adipokinetic hormone (AKH) is a sequenced decapeptide (pGlu-Leu-Asn-Phe-Thr-Pro-Asn-Trp-Gly-Thr-$NH_2$) which functions in adult locusts (Schistocerca sp. and Locusta sp.) to mobilize lipids during flight (see Stone and Mordue in "Neurohormonal Techniques in Insects" Ed. T.A. Miller, Springer Verlag, 1980). It is found in high amounts (~ 500 pmol) in the corpus cardiacum (CC), a major insect neurosecretory structure. The CCs of locusts also contain a second AKH-activity (AKH II). The reported amino acid (a.a.) compositions of AKH II in Schistocerca and Locusta differ, whereas the structure of AKH I is the same. AKH II is related to AKH I (Carlson, Insect Biochem 9, 1979). A proposed sequence for Schistocerca AKH II is pGlu-Leu-Asn-Phe-Ser-Thr-Gly-Trp-$NH_2$. The a.a. composition of Locusta AKH II suggests that $Thr^6$ is substituted with Ala (Gäde, G. Hoppe-Seyler's Z. Physiol. Chem. 365, 1984). By incorporating tritiated amino acids into in vitro cultured CCs and by reverse phase HPLC we confirm that the two AKH IIs are different and that the a.a. composition of Schistocerca AKH II is correct. Using the in vitro system we can $^3H$ label AKH I and II to high specific activity (order of 1Ci/mmol/24 hr culture). We are currently using this method to study AKH biosynthesis and its regulation. It may also allow for receptor identification and for establishing RIAs that distinguish between AKH I and II.

Using molecular sieving and reverse phase HPLC we have isolated a CC protein ("X") that may be an AKH precursor. It has a molecular weight ≤10 Kd (AKH = 1 Kd). In in vitro culture "X" incorporates all the a.a.s present in AKH. It is the only compound to do so at a rate comparable to that for AKH. As expected for a precursor, "X" does not accumulate in the CC and contains Arg and Lys residues.

To study developmental regulation we have measured AKH I and II levels in different stages and sexes. There is a gradual but dramatic shift in the ratio of AKH II/AKH I from the adult (ratio ~0.2) to near equality in the late embryo or first instar (ratio ~ 0.8). From the 2nd instar on, the AKH ratio shows consistent sexual dimorphism; the female having the slightly higher ratio. Absolute amounts of AKH I and II appear not to change even normalized to body weight, except in adults. During adult maturation a steep increase of AKH I and II occurs and a difference between males and females by a factor of about 2. The presence of both AKH peptides throughout development and their differential regulation suggest functional roles not solely related to flight, an entirely adult behavior. Supported by E.I. du Pont de Nemours and Company.

282.13 TRANSNEURONAL INDUCTION OF MUSCLE ATROPHY IN GRASSHOPPERS. Mark Weidner*and Edmund A. Arbas. (SPON: E.Lasater).Northeastern University, Boston, and Biological Laboratories, Harvard Univ. 16 Divinity Ave. Cambridge, MA. 02138.

Autotomy is a process evolved in a number of animals whereby nonessential body parts are shed for defense or to abandon a damaged extremity. Grasshoppers and locusts often drop a jumping leg by autotomizing between the 2nd and 3rd leg segments (trochanter and femur). This severs branches of the leg nerve (N5), but does not damage muscles, as none span this joint. We find in the grasshopper, Barytettix psolus, that muscles intrinsic to the thorax that operate the coxa (1st leg joint) and that are neither damaged nor denervated by autotomy, atrophy to less than 15% of their normal mass following autotomy. Atrophy is localized to the side and body segment where autotomy occurs. Atrophy begins about 10 days after loss of a limb, is complete by about 30 days, and follows a similar timecourse whether induced in young adults or sexually mature grasshoppers.

In addition to severing N5, hindlimb autotomy reduces load on the coxal muscles, and alters coxal use in behavior, possibly via changes in motor outflow to its muscles. We have tested the possible contributions of these influences to muscle atrophy by: 1) cutting N5 near the metathoracic ganglion without inducing autotomy, 2) loading the coxal muscles after autotomy by re-attaching the limb (weighted to compensate for dehydration) in its natural position, 3) inducing abnormal postures of the coxa by cutting the tendon of the tibial extensor muscle and causing abnormal leg use during behavior. All procedures severing N5 caused maximal atrophy. Re-loading coxal muscles did not significantly prevent atrophy. Abnormal use of the leg did not result in any significant atrophy of coxal muscles. We conclude that the peripheral severing of the leg nerve that occurs during autotomy is the primary cause of atrophy of the coxal muscles. Neurons with projections in N5 thus appear to affect central neurons that separately innervate coxal muscles and through them induce atrophy. This effect may occur through degeneration or atrophy in the CNS of neurons projecting in N5, or through the alteration of their physiological activity and the subsequent influence of these changes on neurons innervating coxal muscles. Preliminary anatomical studies in which selected coxal muscle motorneurons were stained by backfilling with cobalt show no major changes in motorneuron morphology that accompany muscle atrophy and thereby point to changes in the physiological or biochemical activity of these neurons as the determinant of muscle atrophy.

We thank R.L. Calabrese for providing materials and facilities for this study.

283.1 ON THE ORDER OF 10,000 CONSTRAINTS ON NEURAL CONNECTION VALUES MUST APPARENTLY BE SATISFIED TO ENABLE CERTAIN ASPECTS OF CONCEPT REPRESENTATION AND PRODUCTION OF SEMANTIC ERRORS. R. Martin. Biochem. Lab., Chemistry Dept., Brooklyn Coll., Bklyn., NY 11210.

Among the most startling of mental errors are those that involve substitution of different concepts for one another. For example, a person who is asked to copy the sentence "Tigers growl" may write instead: "Lions growl." A key feature of such semantic errors is that words which replace one another are almost always related: "lion" and "cat" may replace "tiger" but not "orange" or other semantically unrelated words. Slightly more than 10,000 constraints on permissible connection values within a structurally homogeneous network enable -- and are apparently required for -- this type of mental error to be modelled in a manner that is consistent with other aspects of concept representation. These constraints include those that must be satisfied for novel and familiar examples of familiar categories to be appropriately named, for groups containing members of several categories to be named, for information to be correctly transferred from one concept to another, and for the severity of errors to be minimized when inappropriate names or labels are selected. The model involves only six learning rules that guide adjustment of connection strengths to values that generally satisfy the 10,000 constraints. The model is of interest because of recent experimental observations supporting key assumptions (1) and because the approach taken suggests explanations for a number of other cognitive abilities (2). Connection values are so highly constrained -- with several hundred constraints simultaneously limiting the permissible value of each connection -- that it may not be possible to formulate a qualitatively different, alternative explanation for these aspects of concept representation and production of semantic errors.

283.2 FREQUENCY ESTIMATES OF SELF-GENERATED AND EXAMINER-PROVIDED WORDS: EVIDENCE FOR A FRONTAL-LOBE CONTRIBUTION. M.L. Smith* and B. Milner. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A 2B4.

The "generation effect" refers to the finding that, in normal subjects, memory for self-generated words is better than memory for words that are externally presented (Jacoby, 1978; Slamecka & Graf, 1978; McFarland et al., 1980). The generation effect is strong across a variety of testing conditions and is independent of the depth of processing of the material. Raye, Johnson & Taylor (1980) extended these findings to frequency judgements, showing that people are more sensitive to the relative frequency of internally generated events than of externally presented events.

Smith (1985), and Smith & Milner (1983) have demonstrated deficits after frontal lobectomy in estimating the number of times words or abstract designs (provided by the examiner) appeared in lists. In view of the robustness of the generation effect in normal subjects, the question arose as to whether the impairments seen in patients with frontal-lobe lesions in sensitivity to frequency of occurrence would also be seen with words generated by the patients themselves.

Patients with excisions from the left frontal (LF), right frontal (RF), left temporal (LT), or right temporal (RT) lobe, and normal control subjects (NC) were given two tasks. In one, they were required to generate words in response to clues, whilst, in the other, they simply had to read responses that satisfied the clues. In both tasks, the target words appeard 1, 3, 5, 7, or 9 times. After generating, or reading, all the target words, the subjects were required to estimate the number of times each word had appeared.

The results indicated that all subjects gave higher frequency estimates overall to the words that they generated themselves than to those they had merely read. This effect did not interact with locus of lesion. However, across both tasks, the LF and RF groups underestimated frequency of occurrence relative to the LT, RT, and NC groups, at the higher frequency levels; the LF group was impaired at frequencies 5, 7, and 9, and the RF group was impaired at frequency 9.

These findings demonstrate a role for both frontal lobes in sensitivity to frequency of occurrence of both internally generated and external events. In keeping with the verbal nature of the test material, there appears to be a stronger contribution by the left than by the right frontal lobe to frequency estimates on this task.

283.3 STRUCTURAL AND FUNCTIONAL ABNORMALITIES OF FRONTAL LOBE IN SCHIZOPHRENIA. K.F. Berman*, R.C. Shelton*, R.F. Zec, and D.R. Weinberger*, Section on Clinical Neuropsychiatry, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Several observations suggest abnormalities of dorsolateral prefrontal cortex (DLPFC) in schizophrenia. These include clinical symptoms similar to those of frontal lobe disease, decreased relative DLPFC regional cerebral blood flow (rCBF), and animal studies suggesting a role for DLPFC in cognitive processes commonly impaired in patients with chronic schizophrenia. Recent research in schizophrenia has identified two relatively consistent brain abnormalities: 1)structural findings such as enlarged ventricles and cortical atrophy, especially of frontal lobes, on CT scan; and 2)functional abnormality of frontal cortex in studies employing techniques such as regional cerebral blood flow (rCBF) that investigate physiology of the living human brain. These findings of structural and functional abnormalities are potentially important to the understanding of schizophrenia, but it has not been clear whether they are related. The present study combines determinations of cortical function via Xenon133 inhalation rCBF with investigation of structure by computed tomography (CT) scan.

rCBF, an indicator of cortical metabolism, was measured during various cognitive tasks. First, to assess DLPFC function, 20 patients medication-free (DF) for at least four weeks, 24 patients treated with neuroleptic medication, and 25 normal subjects completed a three-test series: rCBF was determined initially during the resting state and then while subjects performed, in counterbalanced sequence, an automated version of the Wisconsin Card Sort (WCS) to selectively test DLPFC, and a simple numbers matching task (NM) to control for non-DLPFC-related aspects of the procedure. Next, to assess the roles of attention and task specificity in DLPFC function, rCBF was measured in 17 DF patients and 18 controls during two versions of a visual continuous performance task (CPT), an attentional task not specific for DLPFC. Finally, to further determine DLPFC function during complex, but non-DLPFC-linked, reasoning, rCBF studies were done while subjects solved Raven's Matrices (RM). Brain structure of 20 DF and 22 medicated patients who completed the WCS/NM paradigm was assessed with CT.

DLPFC rCBF, specifically, was lower in DF patients compared to normals during the WCS. Treatment with neuroleptic medication did not reverse this DLPFC inactivity. In contrast, during the non-DLPFC-specific CPT's, NM, and RM tasks, no difference in DLPFC blood flow between patients and controls was noted. Degree of DLPFC activation during the WCS was correlated with patients' performance on this task (r=.52, p .02) but not with their degree of autonomic arousal during the procedure. DLPFC rCBF correlated with several parameters of structural pathology in CT, including frontal atrophy and lateral ventricular size.

These data suggest a potential pathophysiological mechanism for the cognitive impairment in schizophrenia. These results also indicate that physiological observations of reduced DLPFC rCBF are related to structural pathology, that these abnormalities are linked, and that they are important biological underpinnings of this illness.

283.4 ALTERATIONS OF LOCAL CEREBRAL GLUCOSE METABOLISM IN MOOD DISORDERS. M.E. Phelps, L.R. Baxter, J.C. Mazziotta, J.M. Schwartz. Division of Nuclear Medicine and Biophysics, UCLA School of Medicine.

Studies of local cerebral glucose memtabolic rate (LCMRGlc) with (F-18) fluorodeoxyglucose (FDG) were performed with positron emission tomography (PET) in patients with unipolar depression (n=11), bipolar depression (n=8), hypomania (n=8), bipolar mixed states (n=3) and excessive compulsive disorder in depressed and non depressed states (n=5). Studies were carried out in drug free states as well as during spontaneous and drug induced changes in mood. Age/sex matched normals (n=12) were also studied. All studies were carried out in ambient ears/eyes open resting state. Major findings were: 1) bipolar depressed patients had lower ($p < 0.001$) supratentorial CMRGlc (16.7±1.3 SEM), than normals (23.6±0.7), hypomanic bipolar (24.7±1.6) or unipolar depressed (24.5±0.9). Values in parenthesis are CMRGlc in units of μmoles/min/100gms. Bipolar mixed patients had supratentorial CMRGlc values (16.4±2.8) that were not different from bipolar depressed patients but were lower than all other groups ($p < 0.02$). Bipolar depressed and mixed states showed increased (31%) supratentorial CMRGlc ($p < 0.02$) with elevated mood (euthymic or hypomanic). Three rapid cycling bipolar patients also showed consistent increases (35%) in supratentorial CMRGlc from depressed to elevated mood state. The agreement of CMRGlc in paired studies of the depressed state in 2 of these patients was ±8%. Unipolar depresssed patients had a low LCMRGlc ratio of caudate to hemisphere (Cd/Hem) (1.18 ±0.03 SEM) compared to bipolar depression (1.3 ±0.4) or normals (1.32 ±0.02). Four unipolar patients studied after drug induced recovery all showed corresponding return of Cd/Hem ratio to value in normals. Patients with excessive compulsive disorder had significant hypometabolism in the left frontal and anterior cingulate during the depressed state that return to normal levels and left/right symmetry in the non depressed state. Results of these studies show 1) delineation of bipolar depressed from unipolar depressed patients and normals by changes in supratentorial CMRGlc but no apparent focal changes in bipolar depression, 2) seperation of mixed bipolar from unipolar depression, 3) delineation of unipolar from bipolar depression and normals by focal changes in the caudate, 4) identification of focal (frontal and cingulate) changes in LCMRGlc in excessive compulsive /depressed state and 5) direct correspondence of changes in CMRGlc and mood state in these patients independent of whether changes in mood were drug induced or spontaneous.

283.5 EQUIVALENT PATTERN OF ORDER MEMORY PERFORMANCE IN RATS WITH NUCLEUS BASALIS MAGNOCELLULARIS LESIONS AND HUMANS WITH ALZHEIMER'S DISEASE. R. P. Kesner, K. A. Crutcher, and T. B. Adelstein* (SPON: S. W. Miller), Dept. of Psychology, Univ. of Utah, Salt Lake City, Utah 84112.

It has become of increasing importance to develop an animal model of mnemonic symptomatology associated with Alzheimer's disease in order to understand its underlying neuropathology and to develop therapeutic methods aimed at alleviating memory symptoms. In order to develop such a model, rats with ibotenic acid lesions of the nucleus basalis magnocellularis (NBM) were tested in an order memory task for an 8-item list of varying spatial locations within an 8-arm radial maze. Humans diagnosed as having Alzheimer's disease as well as healthy elderly subjects were also tested in an order memory task for a 6-item list of varying spatial locations with X's placed on a single sheet of paper containing twelve possible locations. The critical procedures used to test the NBM lesioned animals were identical to that used to test Alzheimer's patients. For each trial a list of pseudo-randomly selected locations was presented. After presentation NBM lesioned animals or Alzheimer's disease patients were given a single test with a choice between two locations (arms in maze or X's on a sheet of paper). The rule to be employed was to choose the location (arm or X) that ocurred earlier in the presentation sequence.

Rats with small NBM lesions resulting in small AchE depletion of parietal cortex and parts of frontal cortex had normal performance for the first, but impaired performance for the last choice orders of the list. Animals with large NBM lesions resulting in large AchE depletion of parietal and part of frontal cortex displayed an order memory deficit for all choice orders of the list.

Patients with an diagnosis of early Alzheimer's disease compared to healthy elderly subjects also had normal performance for the first, but impaired performance for the last choice orders of the list. This pattern of results is identical to what is seen in rats with small NBM lesions. Patients with diagnosis of late Alzheimer's disease, who can still perform the task, display an order memory deficit for all the choice orders of the list . This result is identical to what is seen in rats with large NBM lesions. These data suggest that perhaps early damage to NBM area in humans might be critical in producing specific memory deficits. Furthermore, these data provide a basis for a possible animal model of the mnemonic symptomatology of Alzheimer's disease.

283.6 RECALL AND CLUSTERING BY ALCOHOLIC KORSAKOFF PATIENTS. D. Kyaw*, R. H. Bauer and M.M. Kilbey. Dept. of Psychology, Middle Tennessee State University, Murfreesboro, TN 37132.

Alcoholic Korsakoff patients (KP) are severely impaired in remembering events in the immediate past (minutes) and have difficulty learning new information. Normal learners identify organization in verbal material and use this knowledge to increase recall. For example when presented with lists made up of words from several categories or random word lists, normal learners recall more category words and recall more words consecutively from the same category (clustering), even though the category words are presented at random. Recall of category lists is higher than random lists in both KP and alcoholic controls (AC), but recall of both list types is lower in KP than AC, even though clustering by KP and AC is not significantly different. Since recall of category lists and the level of clustering are positively related in normal learners, it is surprising that recall of category lists is lower in KP than AC, but clustering by KP and AC is no different. The major purpose of the present study was to further examine recall and clustering of category words and to extend this area of research by comparing recall and clustering of rhyming and associated words.

The subjects were KP, AC, and nonalcohlic controls (NAC) that were matched for age, sex, education, and IQ (n = 9 per group). Each subject was given 8 trials in which 9 words each were presented at the rate of one word per 2 sec. Each list was composed of 3 rhyming words, 3 associated words, and 3 category words. Immediately after the last word of each list, the subjects recalled the words in any order.

Statistical analyses showed that KP recalled significantly fewer rhyming, associated, and category words than the other two groups, but recall of each word type was comparable in AC and NAC. Both AC and NAC recalled significantly more associated and category words than rhyming words, but KP recalled a comparable number of rhyming, associated, and category words. There were no significant differences among the groups in clustering of the three word types and clustering of each word type was comparable in the three groups.

The finding that recall of category words is lower in KP than AC but clustering is no different is in accord with previous findings. The present study shows, in addition, that recall of rhyming and associated words by KP is lower than normal learners, but clustering of rhyming and associated words is not lower in KP than normal learners. These findings suggest that the lower recall of verbal material by KP is not due to inadequate organization of the material.

283.7 MEMORY AWARENESS (METAMEMORY) FOR PERFORMANCE IN A MEMORY TASK BY ALCOHOLIC KORSAKOFF PATIENTS. R.H. Bauer, D. Kyaw*, and M.M. Kilbey Department of Psychology, Middle Tennessee State Univ. Murfreesboro, TN 37132.

For the last century there has been a debate concerning the degree to which alcoholic Korsakoff patients (KP) are aware of their own learning and memory abilities and characteristics. Some researchers maintain that KP are aware of their memory problems but attempt to consciously conceal their deficits by fabricating tales to fill in memory gaps in order to spare themselves embarrassment, i.e. KP confabulate. Others have suggested that KP are unaware that they suffer from a severe memory disorder and are in no position to decide whether their replies are correct or incorrect. The major purpose of the present study was to provide information concerning awareness of KP's own memory abilities and strategies for a memory task they performed.

The subjects were KP, alcoholic controls (AC), and nonalcoholic controls (NAC) (n = 9 per group) that were matched for age, sex, education, and IQ. Each subject was given 8 trials in which lists of 9 words each were presented by a slide projector. The words were presented at the rate of one word per 2 sec, and immediately after the last word the subjects recalled the words in any order. Immediately prior to one half the trials the subjects were asked to estimate the number of words they thought they could recall on that trial. After being tested in the recall task, the subjects were asked questions concerning what they had been doing to recall the word lists. The first questions were open-ended or required examples, whereas later questions provide cues for a desirable response.

As compared to AC and NAC, KP recalled fewer words and over estimated the number of words they thought they could recall, suggesting that KP are less aware of their own learning and memory abilities. Since the degree of correspondence between open-ended questions which provide no cues for correct replies and questions providing cues for a desirable answer is no worse in KP than AC and NAC, it appears that KP were not intentionally hiding their poor learning strategies. Comparison of performance in the memory task and answers on the questionnaire indicated that KP were unaware of appropriate strategies to use in the memory task and that KP answered the questionnaire in a manner which corresponds to how they actually perform the memory task. In general, these findings indicate that although KP over estimate their memory abilities, they are aware of their learning and memory strategies, and do not attempt to conceal their poor strategies.

283.8 DBI, A PROCONFLICT NEUROPEPTIDE PURIFIED FROM RAT BRAIN IS FOUND IN HUMAN BRAIN. P. Ferrero*, A. Guidotti, B. Conti-Tronconi and E. Costa (SPON: S. H. Koslow). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032 and Div. Chemistry and Chemical Engineering, Cal. Inst. Technol., Pasadena, CA 91125.

DBI is a neuropeptide purified from rat brain homogenates which displaces beta-carbolines from specific brain binding sites. When injected intraventricularly in rats DBI has a pharmacological profile similar to that of anxiogenic beta-carbolines. Studies with tryptic DBI fragments suggest that the active portion of DBI molecule is contained in an octadecaneuropeptide (ODN) with the following amino acid sequence: Gln-Ala-Thr-Val-Gly-Asp-Val-Asn-Thr-Asp-Arg-Pro-Gly-Leu-Leu-Asp-Leu-Lys (Neuropharmacology 23: 1359, 1984). Working with post mortem human brain extracts, we have now purified a neuropeptide which appears to be similar to rat DBI with respect to molecular weight (approx. 11,000) amino acid composition and retention time on reverse phase HPLC. Similarly to rat DBI, the neuropeptide extracted from human brain elicits proconflict responses when injected intracerebroventricularly in thirsty rats.

Human DBI cross-reacted with an antibody raised against synthetic ODN with a potency similar to that of rat DBI. Moreover by sequencing various tryptic fragments of human DBI, we detected the ODN sequence found in rat DBI. However studying a number of antisera raised in rabbits against human and rat DBI, we found a poor cross reactivity (1/100) between the rat and human neuropeptides. Using a specific antibody raised against human DBI we have measured DBI content in few areas of post mortem human brain and found a regional distribution (amygdala > cerebellum > hippocampus > cortex > striatum) similar to that observed in rat. Moreover DBI-like immunoreactivity was found in spinal fluid of a small group of healthy volunteers. The data suggest that human and rat DBI though similar may not be identical, immunologically. However since similarly to rat DBI, human DBI causes a proconflict action in rats when injected intraventricularly and since they both contain the ODN sequence we believe that human and rat DBI are equivalent functionally. Moreover the presence of high concentrations of DBI in selected areas of human brain and in spinal fluid allows to infer that this neuropeptide may play an important role in the manifestation of anxiety and other symptoms of various neuropsychiatric disorders.

283.9 MEASURING DBI-LIKE IMMUNOREACTIVITY OF HUMAN CEREBRO-SPINAL FLUID. M.L. Barbaccia*, P. Ferrero*, A. Guidotti, D. Pickar*, S. Paul, F.K. Goodwin and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032 and Div.of Intramural Research Programs, NIMH, Bethesda, MD 20814

Human brain contains a neuropeptide (HDBI) (Ferrero et al., Neuroscience Abstracts 1985) very similar to the anxiogenic peptide extracted from rat brain (Science 277:934, 1985). The aim of the present investigation was to assess the reliability in measuring the content of DBI-like immunoreactivity of human cerebro-spinal fluid (CSF). These studies were carried out in a group of 28 normal volunteers age and sex matched with a group of 45 patients suffering from various neuropsychiatric disorders. An antiserum against purified HDBI was raised in rabbits; it detects selectively and with high sensitivity (10 fmole) HDBI in brain extracts and CSF. Only 100 µl of CSF are needed for a reliable quantitation of HDBI-like immunoreactivity. The specificity of this assay was determined by immunoblotting and HPLC. For routine assay CSF was acidified (1 N acetic acid) and 100 µl aliquots of the extract were tested for competition with $^{125}$I-Bolton-Hunter reagent-labeled HDBI. The displacement of $^{125}$I-HDBI by increasing concentrations of CSF extract shows a slope identical to that of authentic HDBI. The HDBI stability in CSF was tested by measuring HDBI like immunoreactivity in aliquots of the same sample after different treatments: 1) heating 15 minutes at 90°C; 2) acidification with 1 N acetic acid and heating; 3) acidification with 0.1 N and 1.0 N acetic acid; 4) freezing and thawing; 5) incubation for up to 24 hrs at room temperature. The highest content of HDBI-like immunoreactivity was found in acidified samples. Serial measurements of HDBI-like immunoreactivity in the same samples yielded virtually the same amounts. Moreover, when serially collected fractions of CSF from normal volunteers were assayed virtually no concentration gradient of HDBI-like immunoreactivity was found. Pooling together the 73 samples, the amount of HDBI-like immunoreactivity in CSF appears to change with age (aged > young) and sex (male > female). We have indications of modifications in CSF-HDBI content related to psychiatric symptoms, but at this time, we refrain to make any conclusion waiting for a greater number of cases to be analyzed.

283.10 HANDEDNESS AND VISUO-CONSTRUCTIVE PERFORMANCE IN HUMANS. P.J. Donovick[1], R.G. Burright[1*], M.E. Kovaleski[1*], D. Bronzino[1*], G.R. Ruhl[1*], and A. Yozawitz[2]. [1]Dept. Psychology, SUNY Binghamton, Binghamton, NY 13901, [2]Neuropsychology Laboratory, Hutchings Psychiatric Center, Syracuse, NY 13210.

The present investigation was designed to address how handedness, assessed with a common laterality scale, would interact with visuo-constructive performance. Right and left handed male and female college students were evaluated for style of visuo-constructive performance on a block design task, including individual preferences for hand manipulation and for starting position of the first block.

Analysis of block design performance revealed that task complexity influenced hand use. For 2x2 patterns, males and females frequently employed bimanual strategies for their constructions. When complexity increased to 3x3 patterns, one hand typically was used exclusively. Interestingly, there did not appear to be a consistent relationship between handedness and the hand employed in block placement. Moreover, there was no consistency across designs for preferred starting position of the first block.

These data indicated that the relationship between handedness and visuo-constructive performance was complex and did not exclusively interact with hand preference for executive-motor performance. Measures of grip strength, writing speed and fine motor coordination support this conclusion. To establish reliability for the assessment of pathological visuo-constructive performance, it is necessary to further explore the nature of this complex relationship with extensive sampling of a normal population.

283.11 EFFECTS OF BRAIN LESIONS ON CUED VISUAL BEHAVIOR IN MAN. David Lee Robinson, Steven E. Petersen*, and Jon Currie*, Laboratory of Sensorimotor Research and Section on Neuro-ophthalmology, National Eye Institute, Bethesda, Maryland 20205.

Reaction times to the onset of a visual target can be influenced by the appearance of prior visual stimuli. In normal control subjects, a light (cue) which correctly predicts the location of a subsequent target will be associated with faster reaction times than cues which incorrectly predict location. Also, weak illumination of the whole visual field (diffuse cue) is associated with slower reaction times. It is hypothesized that valid cues draw attention to the target location and speed reaction times; incorrect or diffuse cues move attention from the correct location and lead to slow reaction times.

Patients with many types of brain pathology have slower reaction times than normal control humans, even when age is not a factor. For patients with specific brain damage we have observed that:

1) Humans with lesions of parietal cortex show significantly slowed reaction times for targets in the contralateral visual field following diffuse and incorrect cues and even for targets in the ipsilateral field following diffuse cues.

2) Humans with damage to the frontal lobes do not show this same pattern of responses. These individuals are only slowed with diffuse cues prior to targets appearing in their affected visual fields.

3) People diagnosed as schizophrenics show slowed reaction times to diffusely cued targets that are in the right visual field.

4) Individuals with Alzheimer's disease generally show such a dramatic overall slowing that the effects of the cue are lost.

5) Humans with occipital lesions which cause a hemianopsia show no influence of the cue when it is presented to their "blind" field; their reaction times are identical to those on trials in which no cue is actually presented, suggesting that the attentional system is dependent on visual data arising from the occipital cortex.

Tests that measure specific capacities can help to understand how different brain areas deal with attentional situations and could also lead to diagnostic markers of brain pathology.

284.1 ONGOING CHANGES IN THE DENDRITIC ARBORS OF INDIVIDUAL SUPERIOR CERVICAL GANGLION NEURONS VISUALIZED IN LIVING MICE. R. D.Hadley and D. Purves. Dept. of Anatomy and Neurobiology, Washington Univ. Medical School, 660 S. Euclid, St. Louis, MO 63110.

A major obstacle to understanding mechanisms of long-term change in the vertebrate nervous system has been the inability to observe the same cell at different times during the life of an animal. We report here a means of making such observations in a relatively simple part of the nervous system. Using this technique we have asked whether the morphologies of dendrites are stable or continuously changing in the superior cervical ganglion of the adult mouse.

The dendritic morphology of single superior cervical ganglion neurons was determined at intervals of up to 3 months in vivo. The cell bodies of neurons at the surface of the ganglion were visualized by asymmetric illumination contrast, and their positions recorded photographically. Neurons were recognized as individuals by their unique shapes, neighbor relationships, and positions with respect to blood vessels. One neuron in each ganglion was arbitrarily chosen and injected with the dye 5(6)-carboxyfluorescein; the dye remains in the neuron for only a few hours. The morphology of the dendritic arbor was recorded with epifluorescence optics and low levels of illumination using a sensitive video camera. After an interval of 3-90 days, the same neuron was identified from the surface photographs and examined a second time by reinjecting it with the fluorescent dye. Approximately 60% of the neurons survived the initial experiment. Comparison of the morphology of the same cell over time showed that the dendrites of these neurons gradually change; little difference was observed at intervals of 1 week, whereas at longer intervals there were progressively more changes of dendritic geometry. The changes were greatest at intervals of 2-3 months. Alterations involved extension of some branches, the retraction or loss of others, and the de novo formation of still other branches.

The progressive nature of these dendritic changes argues that the results we describe are not due to injury; it is unlikely that damage at the time of the initial experiment could continue to stimulate changes many weeks later. Rather, our observations suggest that extension and retraction of dendrites is a normal occurrence in mouse superior cervical ganglion. Since the majority of synaptic contacts occur on the dendrites of these cells, it seems likely that there are corresponding changes in the terminal arborizations of the presynaptic neurons.

284.2 ALTERATIONS IN HYPOTHALAMIC PEPTIDERGIC NEURONS AND ANGIOARCHITECTURE FOLLOWING RETROCHIASMATIC KNIFE CUTS IN THE RAT. C.P. Phelps and S. Saporta. Dept. of Anatomy, Coll. of Med., U. So. Fla, Tampa, FL 33612

Retrochiasmatic knife cuts made in the frontal plane (FC) have a time dynamic regarding their effect on luteinizing hormone (LH) release function. In brains stained for LH-releasing hormone (LH-RH) using H-15 anti-LH-RH (I. Lengvari) 3 mos after FC, axons containing LH-RH immunoreactivity (ir) are present within and posterior to the FC glial scar in rats that show recovery of LH release after steroid priming. Here we report on the reorganization of peptide-containing neurons (PCN) and angioarchitecture of the mediobasal hypothalamus (MBH) during the first month after FC. PCN were studied using both H-15 anti-LH-RH and Gomori's aldehyde fuchsin (GAF) stain for peptides. Female rats received a right hemi-FC extending 1.5mm laterally and were then processed (Peroxidase anti-peroxidase) for study of LH-RHir 14d later. Immediately posterior to the hemi-FC the anterior median eminence was depleted of LH-RHir terminals and there was the expected accumulation of the peptide rostral to the cut. However, within the FC scar there were also novel LH-RHir positive axons extending dorsally and posteriorly across the cellular wound matrix. The appearance of $GAF^+$ axons in scar tissue 14-30d after FC was a mixture of tangled, beaded structures that appeared to have taken circuitous routes towards or parallel with blood vessels (bv) before forming presumptive terminals on small bv and capillaries. Similar alignments of LH-RHir axons and bv in scar tissue were also seen several months after FC. Studies of angioarchitecture after FC in the retrochiasmatic area (RCA) revealed a transition from a blood filled wound to a well developed microvascular bed in FC scar tissue. Rats were injected with India ink and 4% gelatin in saline through the left ventricle under anesthesia and the brain fixed by immersion in buffered formalin. During the first hours after FC there was poor filling of bv along the lesion border with some leakage of ink into the blood-filled wound. In rats killed 14-30d after FC there was evidence of extensive development of a capillary network and larger (30-40$\mu$) diameter vessels growing in the FC scar tissue. At 30d post-FC the ultrastructure of capillaries within the scar tissue was characterized by a continuous endothelium containing pinocytotic vesicles without fenestrations. In conclusion, FC of neural and vascular connections of the MBH produces a chronology of reorganization in peptidergic neurons and bv during a postoperative period of low pituitary LH release function. The extent of this re-organization was associated in a graded proportion with the degree of eventual recovery of LH release function in individual rats after knife cut lesions. (Supported by the Whitehall Foundation)

284.3 INJURED ADULT NADPH-DIAPHORASE NEURONS SPROUT FIBERS INTO FETAL FRONTAL CORTEX TRANSPLANTS. F.R. Sharp, M.F. Gonzalez, D.M. Ferriero*, and S.M. Sagar, Dept. Neurology, Univ. Calif. SF and VA Med Center, SF, CA 94121.

Data support the existence of transplant-host brain and host-transplanted brain connections particularly in the newborn mammal. Björklund and colleagues have shown that fetal aminergic transplants including dopamine and noradrenergic cells send fibers for some distances into adult host brains and may reverse behavioral deficits due to chemical deficiences in the adult host brain. There is little data to suggest that adult host brain might send connections into fetal transplants with the exception of growth of adult cholinergic fibers into fetal hippocampal transplants ( Kromer et al., Brain Res., 153-200, 1980, 1981). We now provide evidence for growth of adult host brain cell fibers into surviving fetal frontal cortex transplants.

Adult albino rats were anesthetized and the right motor cortex removed (Sharp and Gonzalez,Neurology,34:1305-1311,1984). After surviving one week, hosts were reanesthetized and frontal cortex from 17-19 day old embryos placed in the host cavity. Cavities were sealed and host rats allowed to survive one to three months. They were reanesthetized and perfused with phosphate buffered 3% paraformaldehyde. Brains were removed and 50$\mu$m thick sections cut on a vibratome and reacted for NADPH-diaphorase (Scherer-Singler et al., J. Neurosci. Meth., 9:229-234, 1983). The results revealed that many blue stained cells and their processes were always seen in normal adult neocortex. Two types of stained transplants were found. Some had NADPH-diaphorase stained cells and fibers throughout the transplant which was comparable to host neocortex. In others there were no stained cells in the transplant, but there were a few fibers at the transplant-host brain interface which could be traced from the host brain into the transplant for as much as a millimeter in some cases. NADPH-diaphorase stained sections of 17-19 day old fetal brain revealed few fibers and rare cells in the developing neocortex.

It has been suggested that NADPH-diaphorase may be a selective histochemical marker for neocortical and striatal neurons containing somatostatin and Neuropeptide Y (Vincent et al., J. Comp. Neurol., 217:252-263, 1983). This data and our results suggest that injured adult host brain neurons sprouted fibers into the fetal transplant, and that these NADPH-diaphorase staining fibers may be peptidergic.

284.4 Morphological Characteristics of Fetal Cortex Implants in Adult Rats Following Cortical Ablation. R. Labbe, E.J. Mufson, and D.G. Stein, (SPON: T.A. Schoenfeld) Clark University, Worcester, MA and Harvard Med. Sch. Boston, MA.

Previously, we found that implants of fetal cortical tissue partially correct the cognitive deficits resulting from damage to frontal cortex in adult rats and that these implants form neural connections with the host brain (Labbe et al. 1983). The present study is a more extensive analysis of the morphological characteristics of fetal frontal cortex implants.

Seven days after aspiration of the medial frontal cortex in 100 day old male C-D Sprague-Dawley rats, animals received implants of frontal cortex tissue (approximately 6 $mm^3$) from day 19 C-D rat fetuses. Approximately 100 days after implantation, the animals were perfused, the transplant tissue was reacted for the enzymes acetylcholinestrase (AChE), choline acetyltransferase (ChAT), cytochrome oxidase, and stained for myelinated fibers and with thionin.

Transplants either formed continuous bridges connecting injured hemispheres or formed separate grafts, each adhering to the host cortex. Thionin-stained sections revealed little internal order or laminar arrangement of neurons characteristic of intact frontal cortex.

Tissue processed for AChE histochemistry (Hedreen et al. 1985) revealed AChE positive fibers and cell bodies throughout the implants. The distribution of fibers was nonlaminar and some AChE positive fibers appeared to cross the host-transplant border. Other enzyme positive fibers, were seen coursing within neural bridges interconnecting portions of the transplant. AChE processed tissue counterstained with thionin showed non-AChE positive neurons intermixed with enzyme containing cell bodies. Sections processed with butrylthiocholine as a substrate revealed an extensive esterase positive vascular network. ChAT immunohistochemistry showed only a few ChAT positive fibers and perikarya in the transplant.

Implant tissue stained for the mitochondrial enzyme cytochrome oxidase revealed regional variations in activity levels within the implants. Sections stained for myelinated fibers showed long interconnecting tracts along the exterior surface as well as a reticularlike network of fibers within the transplant.

In conclusion, although frontal cortex implants fail to exhibit a distinct laminar architectonic profile, they share many of the intrinsic morphological characteristics of intact frontal cortex.

284.5 LAMININ STIMULATES NEURITE OUTGROWTH FROM RAT RETINAL EXPLANTS. T. S. Ford-Holevinski*, J. M. Hopkins, P. J. McCoy* and B. W. Agranoff (SPON: G. J. Siegel). Mental Health Research Institute and Department of Pathology, University of Michigan, Ann Arbor, MI 48109.

Recent experiments have suggested that the failure of the mammalian CNS to regenerate after injury is due to a deficient or hostile extraneuronal environment, since CNS neurons will grow axons through properly grafted PNS tissue. We here compare the teleost visual system, a model of successful CNS regeneration, and the adult rat visual system, in which regeneration fails, to elucidate the relative significance of intrinsic and extrinsic factors related to nerve regeneration. We previously demonstrated that retinal explants from goldfish with prior-lesioned optic nerves extend neurites onto a surface coated with the basal lamina component laminin at a much higher rate than is observed with other substrata (Hopkins et al., J. Neurosci., in press). In vivo, there was a generous laminin investment surrounding the goldfish optic nerve fascicles, presumably due to invaginations of the pial membrane. Furthermore, we observed a dramatic increase in laminin immunoreactivity within the fascicles after these nerves were lesioned or their retinas removed. Since it is also known that laminin is prominent in mammalian peripheral nerve, these findings were taken to suggest that laminin plays an important role in the ability of a nerve to regenerate following injury. We have now examined the optic nerve of the rat for the presence of laminin before and after axotomy. Unlike the goldfish, laminin immunoreactivity was restricted to the nerve sheath and vascular endothelium, and axotomy did not result in incremental laminin staining within the nerve. Explants of prior-lesioned retinas from adult rats were found to extend neurites in vitro, and the proportion of explants exhibiting neuritic growth was significantly enhanced by the presence of laminin in the substratum. Neurite outgrowth from explants of unlesioned rat retinas was minimal. Thus, retinal ganglion cells of both the goldfish and the adult rat possess the intrinsic ability to regrow their axons in primary tissue culture following a conditioning lesion if provided with a suitable substratum, optimally laminin. We suggest that the failure of the rat visual system to regenerate after axotomy in vivo may be due in part to the inability of supporting cells of the mammalian optic nerve to provide a laminin-containing matrix in response to injury. 284.6 GLIAL FIBERS IN ADULT CANARY BRAIN ARE THOUGHT TO ACT AS PATHWAYS FOR PUTATIVE MIGRATING NEUROBLASTS. F. Nottebohm, D.R. Buskirk, G.D. Burd and B. O'Loughlin*. Rockefeller University, New York, N.Y. 10021.

Monoclonal antibodies were prepared against the crude plasma membrane fraction of forebrain homogenate from adult male canaries and were screened in cryostat sections of adult canary brain using immunofluorescence. One antibody, an IgM designated III-40C-E3, stained perivascular astrocytes, fibrous astrocytes, brain surface astrocytes and tanycytes as well as Bergman glial fibers in the cerebellum and long processes that extend from ventricular zone cells that line the lateral ventricles of the forebrain.

The processes extending from the lateral ventricle are of special interest to us because we hypothesize that they may serve as pathways for young migrating neurons that are generated in the ventricular zone of adult canaries (Goldman and Nottebohm, PNAS 80:2390, 1983). To test our hypothesis, we pretreated adult male and female canaries with 3H-thymidine (2.5 μCi per g body wt, twice daily for 14 days) to label newly generated neurons and processed the tissues for immunocytochemistry using the unlabeled peroxidase method followed by autoradiography. Labeled neurons were observed in the forebrain 30 days after the first 3H-thymidine injection, and at this time had no particular association with processes immunoreactive with III-40C-E3. At short survival times (15 days after the first 3H-thymidine injection) small, elongated cells, located in the forebrain close to the ventricular zone, were labeled with 3H-thymidine and tightly apposed to long processes that were immunoreactive with III-40C-E3. These processes were extensions of cells that lined the lateral ventricle.

III-40C-E3 shows immunoreactivity in vitro with the cytoskeleton of vimentin-positive tissue culture cells. The immunocytochemical staining of astrocytes and Bergman glia fibers suggests that this antibody may also recognize glial fibrillary acidic protein.

We believe that at least some of the small elongated cells described above are generated in the ventricular zone and migrate along glial processes toward their final destination in the forebrain. This is similar to what is thought to occur in parts of the developing brain and is the first report of migration of putative neuroblasts along glial fibers in the adult brain.

284.7 SEPARATE CLASSES OF INTERNEURONS IN A SONG CONTROL NUCLEUS: THOSE SHOWING GABA IMMUNOREACTIVITY AND THOSE BORN IN ADULTHOOD. G.D. Burd, J.A. Paton, and Fernando Nottebohm. Rockefeller University, New York, NY 10021.

Neurons continue to be generated and incorporated into the forebrain of canaries during adulthood. (Goldman and Nottebohm, PNAS 80:2390, 1983). This addition of neurons is especially prominent in hyperstriatum ventralis, pars caudalis (HVc), a forebrain nucleus that is an essential part of the motor pathway controlling vocalization in song birds. New neurons located in this nucleus are predominately local interneurons (Paton, et al., J.Neurosci., in press). In this abstract, we report that cells containing GABA immunoreactivity have been found throughout the forebrain, including HVc, and that within HVc, these cells are also local interneurons, but are not new neurons.

The first set of experiments tested the hypothesis that the newly generated neurons contain GABA. In these experiments, adult canaries were pretreated with $^{3}$H-thymidine (2.5 μCi per g body wt, twice daily for 14 days). After 30-45 days, these canaries were perfused with 1% paraformaldehyde and 1.25% glutaraldehyde and tissue sections from the forebrain were processed for immunocytochemistry using GABA-BSA (ImmunoNuclear Corp.) or GABA-KLH (Hoskins, et al., Soc. Neurosci. Abstr., 1984) antisera and the unlabeled antibody peroxidase method; this was followed by autoradiography. While new neurons and neurons immunoreactive for GABA are numerous and widely distributed throughout the forebrain, only rare neurons were doubly labeled with $^{3}$H-thymidine and GABA immunoreactivity. No doubly labeled neurons were observed in HVc.

In a second set of experiments, we examined the potential axonal projections of HVc neurons that contain GABA immunoreactivity. In these experiments, projection neurons in HVc were labeled by retrograde transport of rhodamine-coupled latex beads (Katz, et al., Nature 310:498, 1984). The beads were injected into the two nuclei known to receive axonal projections from HVc neurons - robust nucleus of the archistriatum (RA) and area X. After 2-3 days, tissue sections from the forebrain of these canaries were processed for immunocytochemistry, as described above. No cells with GABA immunoreactivity were labeled with fluorescent beads. Thus, the GABA immunoreactive neurons in HVc are not projection neurons, and therefore are local interneurons.

We conclude that HVc contains two separate classes of local interneurons, those that contain GABA and those that are added during adulthood. This implies that the pool of new neurons is only a subset of the interneurons located in HVc.

284.8 ALTERATIONS IN NODE OF RANVIER STRUCTURE THAT ACCOMPANY ELECTROPHYSIOLOGICAL STIMULATION ARE EFFECTED BY PHARMACOLOGIC AGENTS. Charles C. Wurtz and Mark H. Ellisman. Lab. for Neurocytology, Dept. of Neurosciences, UCSD, La Jolla, Ca. 92093.

We recently reported on alterations in the ultrastructure of peripheral nodes of Ranvier that are associated with repetitive action potential propagation (Wurtz & Ellisman, Nsci. Abs. 10:865, 1984). Morphologic changes included the appearance of extracellular intramyelinic vacuoles and an alteration in the axonal matrix within the nodal region. These changes were easily induced by activation of frog dorsal roots in situ at 50 Hz for 15 min. This stimulation also results in slowed conduction velocity (CV) of the compound action potential (CAP) and a reduced amplitude indicative of fiber drop-out. Fibers recover from the stimulation associated paranodal disruption and axonal matrix alteration if incubated in Ringers for 30 minutes after stimulation is halted. To better understand the basis for the observed alteration and recovery, a series of experiments using pharmacologic agents to manipulate metabolic and ionic conditions were performed during the stimulation and recovery phases.

The observations that appear most interesting at present are from two different experiments using drugs that disturb the movement of ions across membranes. In one series, 4-aminopyridine (4-AP) was employed to block $K^+$ channels during stimulation, while in another series ouabain was included during the recovery to inhibit the $Na^+$+$K^+$ATPase. To block or reduce $K^+$ conductance 250μM 4-AP was included in the bathing media superfusing the excited portion of the nerve throughout 15 min. of stimulation at either 50 or 100 Hz. Morphologic data indicates that the paranodal vacuolization previously shown to occur at these activation frequencies is reduced in magnitude. This is accompanied by a slowing of the CAP and a broadening of its waveform, but not by a significant decrease in amplitude, suggesting that fiber drop-out is not pronounced under these conditions.

To investigate the dependence of recovery on active transport we added 1.5mM ouabain to the superfusate during the recovery phase. Morphologic recovery was substantially inhibited in ouabain treated fibers, which exhibited paranodal vacuolization even if fixed after 45 min. of recovery. The CAP of the ouabain treated preparations displayed both a substantial reduction in CV from the pre-stimulation state, and a smaller reduction from the CV measured at the end of the 15 min. of stimulation at 50 Hz. In other words recovery in ouabain further depresses CV. The amplitude of the CAP, however, recovered to a value 15-20% greater than the pre-stimulation value. These results may be interpreted to implicate the involvement of $K^+$ movements within the paranodal-nodal complex in modulating structural effects and, subsequently, characteristics of action potential propagation.

284.9 CALCIUM-DEPENDENT LONG-TERM ENHANCEMENT OF SYNAPTIC TRANSMISSION WITHOUT ACTION POTENTIALS IN AXONAL TERMINALS AT THE CRAYFISH NEUROMUSCULAR JUNCTION. J.M. Wojtowicz and H.L. Atwood, Dept. of Physiology, University of Toronto, Toronto, Ont. M5S 1A8.

The neuromuscular junction of the crayfish (Procambarus clarkii) opener muscle was studied in vitro using electrophysiological methods. One microelectrode was placed in the terminal region of the excitatory axon and another in the underlying muscle fiber. Excitatory postsynaptic potentials (EPSPs) were evoked in muscle fibers at a frequency of 5 Hz by remote stimulation of the axon. Tetanic stimulation at 20 Hz for 10 minutes resulted in a large, gradual enhancement (>15 fold) of the EPSPs which recovered to a level 50-100% above the baseline 30 min after the tetanus. The phenomenon is known as long-term facilitation (LTF). LTF can be accounted for by accumulation and subsequent decay of Na and Ca in the terminals (Wojtowicz and Atwood 1983, Neurosci. Abst Vol. 9 p. 169). However, a significant part of the enhancement remains for periods in excess of 30 minutes following the tetanus and its ionic mechanism has not been studied rigorously. The purpose of the present study was to investigate its mechanism using a new technique of local stimulation. Presynaptic action potentials were abolished by exposure to 30 nM TTX. Passive, depolarizing pulses 3-5 msec in duration were produced by intra-axonal current injections through the presynaptic electrode. The amplitude of the pulses was adjusted to obtain the same average amplitude (0.3-0.6mV) of EPSPs as measured during evoked activity prior to the TTX treatment. The resulting release of transmitter was synchronous, quantal in nature and mimicked the EPSPs. This mode of stimulation was localized to a few terminal branches and the possiblity of activating processes of any other axons was eliminated. In 15 preparations LTF was produced by such local stimulation at 20 Hz for 10 min. The component of LTF which is normally caused by influx of Na into the axon was absent in these TTX treated preparations. However, a long-term enhancement (50-100%) of transmitter release was present at 40 min following the tetanus. This effect was fully accounted for by the increase of quantal content of the EPSPs, but not of quantal size. Binomial analysis (Wojtowicz and Atwood 1984, Neurosci. Abst Vol. 10 p. 666) indicated an increase in the number of active, synaptic release sites. Furthermore, substitution of Ca with equimolar concentration of Mg (in the presence of 1mM EGTA) or with 6mM Mn for the duration of the tetanus blocked transmitter release during the tetanus as well as the long-term enchancement. We conclude that the long-lasting enhancement of synaptic transmission is a presynaptic effect confined to the terminal branches of the excitatory axon. The presence of calcium is necessary for the establishment of this phenomenon. Supported by MRC of Canada.

284.10 SYNDACTYLY RESULTS IN THE EMERGENCE OF DOUBLE-DIGIT RECEPTIVE FIELDS IN SOMATOSENSORY CORTEX IN ADULT OWL MONKEYS. T.T. Allard, S.A. Clark*, W.M. Jenkins, and M.M. Merzenich. Coleman Laboratory, Departments of Otolaryngology & Physiology, UCSF, San Francisco, CA 94143; and Department of Plastic & Reconstructive Surgery, Stanford University, Stanford, CA 94305.

Surgical syndactyly or cutaneous fusion of two adjacent digits in adult owl monkeys induced central reorganization in the representation of the two digits as observed in Area 3b of somatosensory cortex. Both the dorsal and glabrous surfaces of digits 3 and 4 were surgically joined from the proximal web space to the distal tips in 3 monkey hands. A single detailed cortical map of digits 3 and 4 was obtained in these three cases at 3, 5½, or 7½ months after surgical syndactyly. During the mapping procedure, receptive fields were defined for clusters of units in a series of microelectrode penetrations in a fine grid (mean interpenetration distances ranged from 112 to 172 microns). In all three cases, penetrations in about 30% of the cortical sector representing digits 3 and 4 had receptive fields that overlapped both fingers: Case 1 had 46 double-digit receptive fields; Case 2 had 49 double-digit fields; Case 3 had 32 double-digit fields. In contrast, double-digit fields were recorded infrequently in normal maps, and were observed in only a few instances at the D2-D3 and D4-D5 borders in these experimental monkeys. The double-digit fields of the syndactyly were equally distributed across the proximal, middle and distal phalanges. As in a normal map, glabrous fields outnumbered dorsal fields by approximately 3 to 1.

Immediately after two of these maps were completed, the syndactyly was released surgically and additional penetrations made at or near double-digit recording sites. In one case, 20 of 21 penetrations showed response to stimulation of each separate digit. Fifteen of these sites had cutaneous fields on both fingers. In the second case, 15 of 17 post-release penetrations revealed double-digit fields. These release data support the view that the double-digit representation reflects a central reorganization rather than cross-digit peripheral nerve regeneration in the hand. In 7 penetrations, physically discontinuous receptive fields were formed at the distal tips of D3 and D4, again suggesting that central rather than peripheral mechanisms underly the emergence of double-digit fields.

Results of this study are consistent with our operating hypothesis: cortical receptive fields are derived from extensive input repertoires through an input selection process based on the temporal correlations of specific inputs. They also demonstrate that the normal representational discontinuities between digits in Area 3b are established by use through the operation of intrinsic, central somatosensory system processes.

284.11 PLASTICITY OF SOMATOSENSORY MAPS IN THE ADULT MAMMALIAN SPINAL CORD

P.J. Snow* and P. Wilson* (SPON: J. Pettigrew), Department of Anatomy, University of Queensland, St. Lucia, Brisbane, Australia.

Previous attempts to demonstrate plasticity in the neural connections underlying the somatosensory maps in the dorsal horn have utilized the steep mediolateral gradients in somatotopic organization. There is currently considerable disagreement between workers on whether or not such changes do in fact occur (Devor, M. & Wall, P.D. Nature, 267: 75, 1978; Lisney, S.J.W. Brain Res., 259: 31, 1983; Brown, A.G. et al. J. Physiol., 354: 375, 1984). The demonstration that cutaneous primary afferents have projections to those somatotopically inappropriate regions of the spinal grey which are rostrally and caudally displaced from the appropriate region (Meyers, D.E.R. et al. Neurosci. Letts., 44: 179, 1984) suggested to us that reorganization along the rostrocaudal axis might be more easily demonstrable. Previous work in our laboratory has shown that in both the adult and neonatal cats the toes are precisely represented in a rostrocaudal order from toe 2 to toe 5. The present experiments were aimed at studying the effects of acute (same day) and chronic (30-70 days survival) denervation of toe 3 on dorsal horn somatotopy. Experiments were conducted on 2 cats in which all toes were ligated acutely, on 1 cat in which all toe 3 nerves were ligated chronically and 6 cats in which these nerves were ligated chronically on one side and actuely on the other. Animals were anaesthetized with α-chloralose (70 mg/kg), paralysed with gallamine and artificially respired. Recordings on both sides of the cord were made from a total of 235 antidromically identified spinocervical tract cells and 20 unidentified dorsal horn neurons using pontamine filled microelectrodes. After acute denervation no cutaneous receptive fields were found on toe 3. After chronic denervation cells in the toe 3 area responded to brisk hair movement on areas of skin surrounding the denervated toe. Dissection of the foot showed that no regeneration of the ligated nerves had occurred. We conclude that even though somatotopic organization is present in the neonatal kitten rostrocaudal reorganization does occur in somatotopic maps of adult cats following nerve section.

284.12 REPEATED AFFERENT STIMULATION AND EXERCISE RESTORE MOTOR FUNCTION IN HUMANS WITH CHRONIC SPINAL CORD INJURY.

J.Walker, K.K.Jain†, S.Ullal†, M.Cooney†, P. Fleming†, L.K.Akhanjee†, The Walker Institute, 1964 Westwood Blvd., Los Angeles, CA 90025.

The prognosis for humans with spinal cord injury is poor because effective regeneration is prevented by physical barriers such as scarring and glial proliferation (W.J.Freed et al., Science 227: 1544, 1985). On the other hand, neurophysiological evidence indicates a sparing of some spinal pathways even in apparently complete injuries (J.Walker, Science, 216: 203, 1982), and stimulation can alter spinal cord circuitry for prolonged periods of time (Mendell, Physiol. Rev., 64: 260, 1984). We therefore investigated the effects of repeated afferent stimulation, in the form of photostimulation with a low power helium-neon laser (J.Walker, Soc Neurosci Abst 14: 866, 1984) and exercise on neurological function in subjects with chronic traumatic spinal cord injuries ranging from 1-10 years duration.

Twenty nine healthy subjects (21 quadriplegics and 8 paraplegics) received a full day evaluation which included videotaped quantitative neurological assessment, cardiovascular evaluation, cortical somatosensory evoked potentials, and review of medical records including radiological studies. After acceptance, subjects were placed on a daily program that consisted of physical therapy (standing, passive range of motion, resistance exercise, aerobics, gait training) and eight 40 second exposures with a low power laser to skin overlying the peripheral nerves. Participation of each subject ranged from 3 months to 1 year. Videotaped quantitative neurological assessment and electrophysiological studies were repeated every six weeks.

All subjects demonstrated a 10-100% improvement in overall muscle strength, and 26/29 subjects exhibited a return of muscle function below the level of the lesion (range: 2-20 muscles). Eighteen of the 20 quadriplegics who had absent cortical SEP's to median nerve stimulation exhibited a return of the cortical SEP's ($F=12.1$ $df=47$ $p<.001$). Only two of the eight paraplegics exhibited an improvement in cortical SEP's to posterior tibial nerve stimulation. Eighteen untreated subjects showed no change in 6 months of observation.

Improvements in neurological function were accompanied by the return of the ability to ambulate in 10/21 quadriplegics and 8/8 paraplegics. The subjects use walkers or crutches as assistive devices and their range varies from 50 feet to 1.5 miles. The neurological basis of this surprising recovery is under investigation. These results suggest that exposure to such rehabilitation may optimize the results of future experimental interventions such as neural transplantation.

285.1 SOMATOSTATIN HAS AN EXCITATORY EFFECT ON SPINAL NOCICEPTIVE MECHANISMS: BEHAVIORAL AND ELECTROPHYSIOLOGICAL STUDIES. Z. Wiesenfeld-Hallin. Department of Clinical Neurophysiology, Huddinge University Hospital, S-141 86 Huddinge, Sweden.

Somatostatin (SOM) is present in the central terminals of some small diameter primary afferents, presumably nociceptors. Yet the role of SOM in spinal sensory mechanisms is unresolved. On the one hand, it has been reported that intrathecally (IT) applied SOM induces behaviors indicative of unpleasant sensations in conscious animals (Seybold et al, 1982, Peptides 3, 49). On the other hand, physiological studies (Randic and Miletic, 1978, Brain Res. 152, 196; Suzue et al, 1981, Neurosci. Lett. 26, 137; Yanagisawa et al, 1985, Europ. J. Pharmacol. 106, 231) have indicated that SOM has an inhibitory effect on the spinal cord. In this study both behavioral and electrophysiological experiments were carried out in rats using a wide dose range of SOM in order to resolve these inconsistencies.

In the behavioral experiments the rats were implanted with IT catheters and 100 ng - 25 µg SOM (Ferring) was injected onto the lumbar enlargement. The modulation of the hamstring flexion reflex to stimulation of nociceptive afferents by 10 ng - 10 µg SOM IT was studied in decerebrate, spinal, unanaesthetized rats. It has been found that this reflex can be facilitated by conditioning stimulation of C-afferents in peripheral nerve (Wall and Woolf, 1984, J. Physiol. 356, 443) and IT injection of substance P and calcitonin gene related peptide (Woolf and Wiesenfeld-Hallin, in press).

In the behaving animal 1 and 10 µg, but not 100 ng, SOM caused a dose-related scratching response lasting about 20 min directed toward the hind limbs and flanks, thus confirming previous results. The 25 µg dose caused paralysis of the hindlimbs. In the physiological experiments low doses of SOM facilitated the flexion reflex, whereas the highest dose blocked the response.

In conclusion, at low doses SOM had an excitatory effect on spinal nociceptive mechanisms and "inhibition" was a result of blockade due to application of excessively high doses. Furthermore, the doses causing excitatory responses were considerably lower in the physiological preparations than in conscious animals.

285.2 EFFECTS OF PHYSALAEMIN ON FUNCTIONALLY IDENTIFIED SPINAL DORSAL HORN NEURONES IN THE CAT. M.W. Salter and J.L. Henry, Depts. Physiol. & Anaes. Res., McGill Univ., Montreal, Que., H3G 1Y6.

Physalaemin is an agonist of the SP-P type of tachykinin receptor in peripheral tissues (Iversen,L.L., Br. Med. Bull. 38:277, 1982). Tachykinins endogenous to the mammalian dorsal horn include substance P, which has been implicated as a possible mediator of excitatory synaptic transmission in nociceptive pathways (Henry,J.L., Br. Res. 114:439, 1976). To further investigate the role of tachykinins in spinal sensory mechanisms an electrophysiological study was done on the effects of iontophoretic application of physalaemin on dorsal horn neurones.

Experiments were done on 26 cats: 12 were anaesthetized with alpha-chloralose (60 mg/kg, i.v.), 11 were anaesthetized with Na-pentobarbital (40 mg/kg, i.p.) and 3 were decerebrated at the intercollicular level. All cats were acutely spinalized at L1. Extracellular, single unit spikes were recorded in segments L5-L6 with one barrel of seven-barrelled micropipettes. Physalaemin (1mM in 165 mM NaCl,pH 5.5), substance P (0.8 mM in 165 mM NaCl, pH 5.5) and NaCl (165 mM,pH 5.5) were each contained in separate barrels for iontophoresis. Units were classified by responses to peripheral stimuli as wide dynamic range (WDR), non-nociceptive (NN), nociceptive specific (NS) or proprioceptive (PR).

Physalaemin (40-150 nA; 45-150 sec) excited 46 of 55 units. Excitation began 30-120 sec after the start of ejection, increased to a maximum about 1 min after the end of ejection and disappeared gradually over 2-5 min. Effects on the functional groups of neurones were:

| | WDR | NN | NS | PR |
|---|---|---|---|---|
| Excitation | 35 | 5 | 2 | 4 |
| No effect | 5 | 4 | 0 | 0 |

Twenty-four units were tested both with physalaemin and with substance P. Thirteen units were excited by both peptides, 7 were excited by physalaemin but not by substance P, one was excited by substance P but not by physalaemin and 3 were unaffected by both. Of non-nociceptive units 3 of 4 were excited by physalaemin while none was affected by substance P.

These results indicate that physalaemin not only excites nociceptive units, as might expected from earlier studies with substance P, but also excites non-nociceptive units. Thus, tachykinin receptors appear to be present on both nociceptive and non-nociceptive neurones. However, in view of the observation that non-nociceptive neurones are unaffected by substance P, tachykinin receptors on non-nociceptive neurones are probably different from those on nociceptive neurones.

285.3 BRADYKININ-ACTIVATED TRANSMEMBRANE SIGNALS ARE COUPLED VIA $N_i$ OR $N_o$ TO INOSITOL-1,4,5-TRISPHOSPHATE, A SECOND MESSENGER IN NG108-15 NEUROBLASTOMA X GLIOMA CELLS. Haruhiro Higashida*, Werner Klee, David Brown, and Marshall Nirenberg. NIH, Bethesda, MD., 20205.

The addition of bradykinin (BK) to NG108-15 cells results in a transient outward transmembrane current (hyperpolarization) followed by a prolonged inward current (depolarization). Concomittantly, BK also increases the rate of hydrolysis of phosphatidyl-inositol-4,5-bisphosphate (PI-$P_2$) yielding inositol-1,4,5-trisphosphate ($IP_3$) and diacylglycerol (DAG), presumably by activation of phosphatidyl-4,5-bisphosphate phosphodiesterase (PI-$P_2$ PDE), and increases the rate of secretion of acetylcholine from NG108-15 cells. (Yano et al. J. Biol. Chem. 259, 10201 (1984), and FEBS Letters 181, 403 (1985)). Injection of $IP_3$ or $Ca^{2+}$ into the cytoplasm of NG108-15 cells results in cell hyperpolarization followed by depolarization, similar to the effects elicited by extracellular BK. $IP_3$ stimulates the release of $Ca^{2+}$ ions from internal storage sites into the cytoplasm in NG108-15 cells (Ohsugi et al. personal commun.). Cell membrane permeability increases during the hyperpolarization phase, and the hyperpolarization reverses at approximately -75 to -80 mV. These results suggest that elevation of cytoplasmic $Ca^{2+}$ ions activate $Ca^{2+}$-dependent $K^+$ channels resulting in cell hyperpolarization. BK also stimulates uptake of extracellular $^{45}Ca^{2+}$ by cells. BK-dependent cell depolarization decreases to 20% of the control value when cells are incubated in medium without $Ca^{2+}$ or with $Co^{2+}$. Membrane resistance increases during the depolarizing phase of the cell response to BK, which suggests that the rate of $K^+$ efflux via M channels is reduced. In contrast, elevation of intracellular $IP_3$ decreases membrane resistance, but has no effect on M channel activity.

The mean amplitudes of the hyperpolarization and depolarization responses of NG108-15 cells to BK decrease approximately 50% (maximum inhibition) after cells are incubated with 200 ng pertussis toxin (PT)/ml for 15-20 hr. BK stimulates low $K_m$ GTPase activity in NG108-15 membrane preparations, but not in membranes prepared from NG108-15 cells treated with 10 ng of PT/ml for 18 hr. Incubation of NG108-15 membranes from PT treated cells with an approximately equimolar mixture of purified $N_i$ and $N_o$ (>95% pure) from bovine brain restores BK-dependent GTPase activity. BK also inhibits basal adenylate cyclase activity in NG108-15 homogenates. These results show that [BK·Receptor] complexes interact with $N_i$ and/or $N_o$ and suggest that $N_i$ and/or $N_o$ may couple BK activation of receptors with activation of low $K_m$ GTPase and PI-$P_2$ PDE and with inhibition of adenylate cyclase.

285.4 NEUROPEPTIDE Y REDUCES RAT HIPPOCAMPAL CA1 POPULATION SPIKE AND MONOSYNAPTIC EPSP BY PROBABLE PRESYNAPTIC ACTION. William F. Colmers, Ken Lukowiak* and Quentin J. Pittman. Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Neuropeptide Y (NPY) has been localized in cell bodies and fibers of the hippocampus and dentate gyrus. Because NPY has potent effects on the physiology of synaptic transmission in peripheral contractile tissues, we wished to examine its effects on synaptic transmission in the hippocampus.

Hippocampal slices from 75-100 g male Sprague-Dawley rats were incubated, submerged, at 32°C, and perfused at 2-3 ml/min with oxygenated artificial CSF. A bipolar stimulating electrode was placed on stratum radiatum to elicit orthodromic, and on alveus to elicit antidromic, population spikes (PS's), which were recorded with an extracellular microelectrode in the CA1 cell body layer. PS's were averaged and stored with a digital oscilloscope. Intracellular recordings were made with $K^+$ acetate electrodes.

Application of $10^{-6}$M NPY for 4 minutes caused a reduction of the PS to 14.01 ± 4.17% of control amplitude. Threshold for effect was $10^{-8}$M; $10^{-9}$ to $10^{-10}$M had no significant effects. Effects of NPY were completely reversible; $10^{-6}$M required 1-1.5 hours washout. There appeared to be no difference between NPY's effects on single pulse or paired pulse (ISI=30 msec) facilitated PS's. $10^{-6}$M NPY had no effect on PS's evoked by antidromic stimulation from alveus.

In another series of experiments, CA1 pyramidal neurons were impaled concurrently with the extracellular field potential recording. By varying the stimulus voltage, stimulus-response relationships could be constructed for both the PS and EPSP amplitudes. Application of $10^{-6}$M NPY to healthy (20-30mV action potential overshoot, > 30MΩ input resistance) CA1 cells reduced the amplitude of the evoked EPSP to 63.78 ± 6.55% of control when measured at the midpoint of the stimulus-response curve, and to 71.29 ± 6.77% of control at the maximum of the curve (n=8, $P < 0.05$). The resting potential, the number and amplitude of action potentials evoked by a current pulse of constant amplitude, and input resistance of the cells were not affected. NPY had a greater effect on the PS amplitude than on the EPSP. The lack of apparent effect of NPY on the passive membrane properties and action potentials of these cells, along with its action on afferent inputs to these cells, suggests strongly a presynaptic action of NPY.

285.5 EFFECT OF NEUROHYPOPHYSEAL HORMONES AND SOME OF THEIR FRAGMENTS ON SYNAPTICALLY EVOKED FIELD POTENTIAL IN LATERAL SEPTUM OF RATS. M.Joëls* and I.J.A.Urban* (SPON: European Neuroscience Association). Rudolf Magnus Institute for Pharmacology, State University of Utrecht, Vondellaan 6, 3521 GD Utrecht, The Netherlands.

Recent experiments showed that iontophoretically applied arginine$^8$ vasopressin (AVP) excites part (30%) of the neurons in the lateral septum (LS).Moreover, in the majority of the LS cells AVP induces a long-term increase in the cell responses to excitatory amino acids. Thus, in ca. 65% of the LSC cells responses to exogenously applied excitatory amino acids were markedly increased by AVP and remained elevated for at least 15 minutes after the peptide administration. The enhanced responsiveness to exogenously applied amino acids was accompanied by an increase in the LS cell responses to endogenously released amino acids: Single unit and field responses evoked in the LS by stimulation of the fimbria and fornix, which constitute an excitatory amino acid mediated projection to the LS, were increased after local application of AVP. In the present study we addressed two questions: (i) Is this facilitatory effect on amino acid transmission specific for AVP or can substances structurally related to AVP, e.g. oxytocin (OXT), desglycinamide AVP (DGAVP) or 1-deamino-D-AVP (dDAVP) exert similar actions; (ii) Is it possible that the facilitatory action evoked by AVP is the result of the action of one of the AVP-metabolites as was postulated with regard to the behavioral effects of AVP. To answer these questions we examined the effect of AVP, OXT and related fragments on the amplitude of the synaptically evoked field potential (FP) negativity, comprising excitatory postsynaptic potentials induced in LS cells by fimbria-fornix stimulation. The compounds were dissolved in artificial cerebrospinal fluid and perifused (0.2ml/min) on the septal surface at various concentrations. It appeared that AVP increased the FP negativity already at a concentration of $10^{-10}$M. Like AVP, $10^{-8}$M OXT enhanced the FP amplitude; with $10^{-10}$M OXT the effect was no longer significant. DGAVP also induced a significant increase in the FP negative wave but here at least $10^3$-fold higher concentrations than of AVP were needed. Increases induced by the antidiuretic agonist dDAVP ($10^{-7}$M) were not significant. A significant increase of the FP negativity was evoked by the AVP-metabolites [pGlu$^4$,Cyt$^6$]AVP(4-9) and [pGlu$^4$,Cyt$^6$]AVP(4-8) at $10^{-6}$M concentrations, whereas only a weak increase was observed with $10^{-7}$M.A small increase was observed with $10^{-6}$M of [Cyt$^6$]AVP(5-9). OXT-metabolites tested at $10^{-7}$M doses did not affect the amplitude of the FP. These results demonstrate that the facilitatory effect of OXT and some of the neurohypophyseal hormone-fragments on the excitatory amino acid mediated synaptic input to the LS is similar to the AVP-effect. Yet, the considerably lower effective dose of AVP in comparison to the dose of the other compounds indicates that (i) the facilitatory effect is to a great extent specific for AVP and (ii) the effect observed with AVP is not likely to be the result of the action of one of its metabolites.

285.6 CHOLECYSTOKININ ACTS AS AN EXCITATORY NEUROMODULATOR IN RAT AMYGDALA. R.B. Innis and G.K. Aghajanian. Dept. of Psychiatry, Yale University School of Medicine, New Haven, Connecticut 06508.

Cholecystokinin is a neuropeptide which is widely distributed in the CNS of many species. CCK has fulfilled most criteria for neurotransmitter status, including excitatory actions in many areas of rat CNS. The amygdala is enriched in fibers which stain for CCK-like immunoactivity and in binding sites for CCK radioligands. Therefore, we are studying the electrophysiologic actions of CCK iontophoretically applied in rat amygdala.

We have used the technique of single unit recording with a 5-barrel micropipette in transected rats (cerveaux isole preparation) with local anesthetic to pressure points. The naturally occurring sulfated form of cholecystokinin octapeptide (0.25 mg/ml CCK-8 in normal saline, pH 7) was ejected as a negative current. The position of the electrode was determined by passing a dye spot at the end of each experiment, and to date, we have studied cells in the nuclei centralis, corticalis, and basalis of the amygdala. Most amygdaloid neurons were not spontaneously active and were driven by low currents (-0.1 to -10 nA) of iontophoretically applied glutamate (10 mM in normal saline, pH 8).

Iontophoretically applied CCK-8 increased the firing rate of amygdaloid neurons tested. This uniform excitation is in marked contrast to hippocampal CA1 pyramidal neurons, which had only a 10-25% response rate and which frequently showed rapid desensitization to CCK-8. The enhanced firing rate induced by CCK-8 usually required the concurrent ejection of glutamate. For example, in the absence of ejected glutamate, CCK-8 at high ejection currents (to -40 nA) had no effect; but in the presence of glutamate which drove the otherwise silent neuron to fire, CCK-8 at low currents (-0.5 to -5.0 nA) markedly enhanced firing and could easily cause the cell to go into depolorization block. Furthermore, we have found that subthreshold currents of CCK-8 and glutamate (which by themselves had no effect on neuronal firing) significantly increased firing when both were applied together. In the nucleus centralis, the enhanced firing induced by CCK-8 could not be blocked by diazepam (1.2 mg/kg), or lorazepam (0.4 mg/kg), the putative CCK antagonist, proglumide (2.8 mg/kg), all given i.v. However, iontophoretically applied morphine sulfate markedly suppressed the enhancement of firing induced by CCK-8.

As CCK significantly enhanced the potency of concurrently administered glutamate, our results are most consistent with the role of CCK in the amygdala as a neuromodulator of the excitatory effect of glutamate.

285.7 HUMAN PANCREATIC GROWTH HORMONE-RELEASING FACTOR (hpGRF), RAT GRF(1-29)$NH_2$, AND RAT GRF(3-40)OH ALTER THE ACTIVITY OF NEURONS IN RAT AMYGDALA. Michael J. Twery and Robert L. Moss. Dept. Physiology, Univ. Texas Hlth. Sci. Ctr., Dallas, TX 75235.

Extrahypothalamic regulation of growth hormone secretion is postulated to include inhibitory pathways which originate in the amygdala (1). Since nerve fibers containing GRF-like immunoreactivity have recently been reported to be in the amygdala, the present electrophysiological investigation was undertaken to study the effects of iontophoretically applied hpGRF, rat GRF(1-29)$NH_2$, and rat GRF(3-40)OH on the activity of individual amygdala neurons and to determine the local distribution of neurons which possess membrane sensitivity to these peptides. Experiments were performed on 15 male, Long-Evans rats (275-450g) anesthetized with urethane (1.3 mg/kg, IP). A multibarrelled glass microelectrode was used for extracellular recording of single units (center barrel, 4M NaCl, 4-12 MΩ) and iontophoretic application of chemicals.

Iontophoretic application of hpGRF altered the firing rate of 16 out of 24 amygdala neurons tested. Inhibition was the predominant effect (15 of 16). HpGRF depressed the firing rate in 5 of 5 central, 1 of 1 cortical, 2 of 3 medial, and 5 of 7 basolateral amygdala neurons, but only 2 of 8 lateral amygdala neurons. One neuron in the medial amygdala was excited by hpGRF. The firing rate of the 8 remaining neurons was not affected by the iontophoretic application of hpGRF. Further testing of 11 amygdala neurons determined that the majority (7 of 11) responded to rat GRF(1-29)$NH_2$ in a manner which resembled their response to hpGRF. Four neurons were inhibited and 3 neurons unaffected by application of either peptide. Some neurons responded only to hpGRF (N=3) or rat GRF(1-29)$NH_2$ (N=1). In 10 amygdala neurons the effect of hpGRF on neuronal firing rate was compared to that of rat GRF(3-40)OH. Iontophoretic application of rat GRF(3-40)OH decreased the firing rate of 5 neurons whose activity had been inhibited by hpGRF and produced no effect on the firing rate of 2 neurons which were also not affected by hpGRF. Three neurons exhibited membrane sensitivity to either hpGRF (N=2) or rat GRF(3-40)OH (N=1) but not both peptides. These results confirm earlier reports from this laboratory that a subpopulation of neurons in the rat CNS possess membrane sensitivity to hpGRF. Importantly, the present findings indicate a possible role for GRF in regulating amygdala efferents which have an influence on the hypothalamic control of GH secretion. We thank Drs. W. Vale and J. Rivier (Salk Institute) for peptides used in this study. This work was supported by NIH grant NS10434 to R.L.M. M.J.T. is an NIH postdoctoral trainee (HD07062).

285.8 ESTROGEN PRIMING EFFECTS LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) SENSITIVITY BUT NOT β-ENDORPHIN (β-END) SENSITIVITY OF NEURONS IN THE MIDBRAIN CENTRAL GRAY (MCG). Mya C. Schiess*, Carol A. Dudley, and Robert L. Moss (SPON: W. Weinberg). Dept. Physiol., UT Health Sci. Ctr., Dallas, TX 75235.

The MCG is believed to modulate the lordosis response in the female rat by acting as an intermediate relay station between the descending input from the medial preoptic and ventromedial nucleus of the hypothalamus and its own output to the medullary reticular core. The present investigation determined the effect of exogenously administered estrogen (EB) and EB plus progesterone (P) on the membrane sensitivity of MCG neurons to LHRH and β-END. Experiments were completed on 26 female ovariectomized Sprague-Dawley rats (275-325 g) anesthetized with urethane (1.3 mg/kg, IP). All animals received 1 µg EB/week to maintain receptor integrity. Animals receiving this treatment only were classified as non-primed (n=6). EB-primed animals received 10 µg EB 48 hrs prior to recording (n=11) and EB-P animals received 10 µg EB at 0 hrs and 2.5 mg P at 48 hrs (n=9). Seven-barreled glass microelectrodes were used for single unit extracellular recording (center barrel, 4M NaCl, 6-10 MΩ) and iontophoresis of LHRH (1 mM, pH 7) and β-END (1 mM, pH 7.1). Cell localization was determined by ejecting pontamine sky blue and histologically reconstructing the electrode tracks.

Iontophoresis of LHRH increased the firing rate in 31 cells and decreased the firing rate in 33 cells from a total of 94 cells tested, while iontophoretic application of β-END excited only 22 and inhibited 40 of the same 94 cells. Application of LHRH and β-END elicited no change in the firing rate of 29 and 26 of the 94 cells respectively. In the non-primed rat, the majority of cells were inhibited by LHRH (14 of 23), while a smaller number were excited (6) or showed no response (7). In contrast, in animals primed with EB, the predominant effect of LHRH was excitation (17 of 34); 7 cells were inhibited and 10 showed no change. In EB-P animals, LHRH produced a response profile similar to that obtained in non-primed animals in that more cells were inhibited (12 of 33) than excited (8 of 33) by the decapeptide. The percent of cells responding to β-END with excitation, inhibition, or no response was not altered by hormonal priming paradigms. Additionally, a discrete area of the MCG at the level of the superior colliculi in a dorsal medial region consistently showed the greatest number of cells with membrane sensitivity to LHRH and β-END.

These results suggest that EB priming can alter the membrane sensitivity to LHRH of neurons in the MCG, and that these effects appear to be negated by the addition of P. Importantly, these findings suggest a possible MCG neurohumoral mechanism for modulating the lordosis reflex, whereby estrogen increases an LHRH induced excitation at the MCG which in turn may contribute to the facilitation of the lordosis response. Supported by NIH HD00615 and NS10434.

285.9 PRESENCE AND FUNCTIONAL SIGNIFICANCE OF CALCITONIN GENE RELATED PEPTIDE (CGRP) IN THE CEREBRAL CIRCULATION. T.A. Kingman*, L. Edvinsson*, R. Ekman*, R. Uddman* and J. McCulloch. Wellcome Surgical Institute, University of Glasgow, United Kingdom, and the University of Lund, Sweden.

The 37 amino acid peptide, calcitonin gene related peptide (CGRP) has recently been identified, in neuronal tissue, as an alternative expression product of the calcitonin gene. We have established the presence and origin of CGRP-immunoreactivity in nerve fibres around cerebral vessels and have characterised the vasomotor actions of the peptide upon cerebral vessels in vitro and in situ.

Dense plexuses of CGRP-immunoreactive nerve fibes invest the major cerebral arteries and the pial arterioles of the cortical surface. These nerve fibres are present in the adventitia and at the adventitial-medial border in the blood vessels. The CGRP-like immunoreactive material in feline cerebral blood vessels appears to be extremely similar, or identical to rat CGRP on HPLC. There are numerous CGRP-immunoreactive perikarya in the feline trigeminal ganglia. Unilateral surgical division of the trigeminal nerve under anaesthesia 14 days prior to sacrifice resulted in the loss of CGRP-like immunoreactivity from ipsilateral cerebral vessels. In the trigeminal ganglia and cerebrovascular nerve fibres, CGRP-like and substance P-like immunoreactivity are co-localised.

Rat CGRP is a potent dilator of cat middle cerebral arteries in vitro (max. relaxation: 10.5 $\pm$ 1.5 mN; $EC_{50}$ 9.6 $\pm$ 1.3 nM) and of the cortical arterioles of anaesthetised cats in situ (max. increase in calibre: 38 $\pm$ 5% at perivascular microapplication of CGRP $10^{-7}$M). The arteriolar dilatations produced by high concentrations of CGRP were markedly persistent, with arterioles remaining dilated for 5-10 minutes. Both in vitro and in situ, CGRP is the most potent cerebrovascular dilator neuropeptide yet tested.

The physiological significance of cerebrovascular trigeminal CGRP system was investigated after chronic (14 day) surgical lesions of the trigeminal nerve. The cortical arteriolar responses to subarachnoid microinjections of acidic (pH 6.8) and basic CSF (pH 7.6) were examined in anaesthetised cats with immunocytochemically verified lesions of the trigeminal nerve, and contrasted with their effects in sham-operated animals. The magnitude of the vasodilatory and vasoconstrictor responses to these agents was unaffected by trigeminal lesions. However, the duration of the vasoconstriction produced by basic CSF, but not the vasodilatation to acidic CSF, was markedly prolonged by trigeminal lesions (from 0.8 $\pm$ 0.1 to 2.2 $\pm$ 0.3 min, $p < 0.01$). The cerebrovascular trigeminal system, in which CGRP is the most potent vasoactive constituent, appears to be a neurogenic mechanism which provides protection to the brain against excessive vasoconstriction.

285.10 EFFECTS OF DAILY TRH ADMINISTRATION IN MURINE MOTOR NEURON DISEASE (Wobbler Mice) W. Kozachuk*, H. Mitsumoto, V. Salanga*, A. Boggs*, (Spon: R.J. Lederman)Department of Neurology, Cleveland Clinic, Cleveland, OH 44106 and J. Wilber, Endocrinology, L.S.U., New Orleans, LA

Although the neurobiological function of TRH found in axon terminals apposing spinal cord anterior horn cells has yet to be elucidated, the clinical use of TRH for the treatment of human motor neuron disease has been advocated (Engel et al, 1983). We tested the effects of TRH on neuromuscular functions in the wobbler mouse, the best natural disease model for the investigation of human motor neuron disease. Wobbler mice develop their disease at the age of 3-4 weeks with rapidly progressive paralysis, atrophy and contractures in the forelimb muscles. At the time of clinical detection, intraperitoneal injection of 50 mg/kg of TRH (the dosage producing compulsive sustained scratch behavior, jumping and jitteriness lasting 10-15 minutes after the injection) was given daily (6 days a week) for 9 weeks in 5 wobbler mice and 5 healthy littermates. Another group (5 pairs) received saline-placebo injections identical to the TRH group. Weekly assessments were performed by 2 examiners (VDS and HM) without knowledge of drug identification, including body weight, time running $2\frac{1}{2}$ feet (best of 3 trials), front paw grasping power (best of 3 trials by means of gram dynamometer), and semiquantitative grading for gait features, eye hygiene, grooming, and the degree of forepaw contractures. At the end of the treatment the brain and spinal cord were sampled for TRH and cyclo(His-Pro) determinations. Control animals with TRH did not develop deleterious effects on weight increase, or other neuromuscular functions. In wobbler mice all neuromuscular function steadily declined regardless of the type of treatment. Although TRH-treated wobbler mice appeared slightly better in running time and grasp power there was no statistical significance between the two groups. Semiquantitative tests also showed no differences. TRH levels in the spinal cord were found to be significantly increased ($p<0.01$) in placebo-treated wobbler mice (252.9 $\pm$ 23.9 pg/mg protein) as compared to controls (102.1 $\pm$ 17.7 pg/mg protein). However, there were no significant differences in TRH and cyclo(His-Pro) levels in TRH-treated animals. The lack of beneficial effects with TRH in wobbler mice may be due to the increased TRH levels in the wobbler spinal cord; hence further administration of TRH has no additional effect. The negative results from the TRH trials in murine motor neuron disease supports the negative results found in our TRH trials with patients with amyotrophic lateral sclerosis (Mitsumoto et al, 1984 and 1985). (The study was partly supported by the A.L.S. Society of America)

285.11 FAILURE OF SUBSTANCE P ANALOGUE, SPANTIDE, TO ANTAGONIZE GASTRIC EFFECTS OF BOMBESIN. Y. Tache, M. Gunion, D. Hamel*, T. Pappas* and H. Debas*. Center for Ulcer Research and Education, VA Wadsworth Med. Ctr., Dept. of Medicine, UCLA, Los Angeles, 90024.

Spantide [D-Arg1,D-Trp7,9,Leu11] substance P has been reported to be a specific and potent antagonist of the binding of bombesin peptides and substance P to exocrine pancreas and brain receptors (Yachnis et al., Life Sci. 35:1963-1969, 1984). The ability of spantide to antagonize bombesin induced changes in gastric secretion was investigated in rats and dogs. Rats fasted for 24 h were injected under ether anesthesia either intracisternally (ic) in 10 ul volume with spantide or saline and 15 min later with bombesin or intracerebroventricullarly (ivt) in 5 ul volume with bombesin alone or combined with spantide, then the pylorus was ligated. Rats regained consciousness within 5-10 min after the injection. The animals were decapitated 2 h after pylorus ligation and their gastric secretion collected. Bombesin given ic (6.2 pmol) or ivt (62 pmol) inhibited gastric secretion. Spantide (2.0 nmol ic, or 6.6 nmol ivt) did not modify bombesin action. The ic route of administration of spantide was associated with 100% mortality within 1-10 min at peptide dose of 3.3 nmol and 58% at 2.0 nmol dose. Injection of spantide icv (6.6 nmol) did not cause mortality but elicited severe barrel rolling in all rats. In conscious mongrel dogs with gastric fistula, intravenous infusion of bombesin (6.2 pmol/kg.h) stimulated gastric acid and gastrin secretions. Spantide infused intravenously (10 nmol/kg.h) starting 30 min prior to bobmesin and throughout the experiment did not alter either gastrin or gastric acid response to bombesin. No behavioral changes were observed. In summary 1) in rats, nmol doses of spantide injected into the cisterna magna are lethal; given ivt, the peptide elicited severe barrel rolling 2) spantide did not antagonize the central or peripheral actions of bombesin on gastric secretion. These data indicate that the use of spantide as bombesin antagonist in vivo is limited.

285.12 CHOLECYSTOKININ OCTAPEPTIDE (CCK-8) IS RELEASED FROM THE HYPOTHALAMUS IN RESPONSE TO AN INTRAGASTRIC MEAL IN ANESTHETIZED CATS. R.R. Schick*, T.L. Yaksh*, V.L.W. Go*. (SPON: J.D. Grabow) Gastroenterology Unit and Neurosurgical Research Unit, Mayo Foundation, Rochester, MN 55905.

CCK-8 suppresses feeding in several species after either peripheral or central administration and has therefore been considered as a putative satiety factor. The presence of CCK-8 in the hypothalamus, a brain area involved in feeding regulation, suggests a hypothalamic site of action.

Aim: The present study was designed to investigate the physiological significance of these findings by examining if hypothalamic extracellular levels of CCK-8 are influenced by a test meal.

Materials and Methods: In 5 halothane anesthetized cats (2.5-4 kg) push-pull perfusions of the lateral hypothalamus were carried out stereotaxically (AP 12.5/LAT 3.0/HV -1.0) as described previously (J Appl Physiol 37:428, 1974). Perfusion samples were collected in 30-min intervals. Peripheral venous blood samples were frequently drawn for gastrin measurements. After a 90-min baseline perfusion, a test meal consisting of 4 g carbohydrates and 4 g amino acids dissolved in 30 ml water was administered intragastrically. 2 hrs postprandially a 30-min perfusion with 40 mM KCl was performed additionally. In 3 cats intravenous (i.v.) infusions of synthetic CCK-8 at increasing rates of .05, .2, 2 and 20 µg/kg · h, each lasting 30 min, were carried out to assess the existence of a blood-brain barrier. Plasma gastrin and perfusate levels of CCK-like immunoreactivity (CCK-LI) were determined by radioimmunoassay. Identification of the molecular form of hypothalamic CCK-LI was performed with reverse phase high performance liquid chromatography (HPLC).

Results: Baseline CCK-LI in the hypothalamic push-pull perfusate was below assay sensitivity (< 7 pg/30 min). After the test meal, however, CCK-LI rose to 27$\pm$3 pg/30 min and 24$\pm$4 pg/30 min, respectively in the first two postprandial perfusion samples thereafter falling below assay sensitivity again. This rise in perfusate CCK-LI was accompanied by an increase of peripheral venous gastrin levels from a mean baseline of 233$\pm$24 pg/ml to a maximum of 320$\pm$43 pg/ml after 10 min. During potassium perfusion, perfusate CCK-LI rose again up to 27$\pm$11 pg/30 min. HPLC characterization demonstrated that the majority of CCK-LI coeluted with the synthetic CCK-8 standard. During i.v. infusion of synthetic CCK-8 peripheral venous plasma levels of CCK-LI were increasing from 94$\pm$37 pg/ml by 2 log units, but hypothalamic perfusate levels of CCK-LI did not change.

Conclusion: These data show that extracellular levels of CCK-8 are increasing in the lateral hypothalamus after administration of a meal and support the hypothesis that CCK-8 may play a physiological role in the central regulation of feeding and satiety.

285.13 CHARACTERIZATION OF THE NEURALLY-INDUCED INCREASE IN VASCULAR PERMEABILITY IN RAT TRACHEA. J.J. Brokaw and D.M. McDonald. Cardiovascular Research Institute and Department of Anatomy, Univ. of California School of Medicine, San Francisco, CA 94143

Electrical stimulation of the cervical vagus nerve is known to increase the permeability of blood vessels in the rat trachea. Current evidence is consistent with the hypothesis that this response is mediated by substance P released from unmyelinated vagal afferents in the airway mucosa. The aim of our study was to characterize the response by determining the rate of onset and duration of the change in vascular permeability and to assess the development of tachyphlaxis to subsequent stimuli.

In anesthetized rats treated with atropine (1 mg/kg, i.v.), the right vagus nerve was cut rostral to the superior laryngeal branch and then stimulated electrically coincident with the injection of Evans blue dye (30 mg/kg, i.v.). Five min later, the rats were perfused with 1% paraformaldehyde in citrate buffer (pH 3.5) and the tracheas removed. Tracheal dye-content was measured by spectrophotometry. The amount of dye extravasation was found to vary with the duration, frequency, and voltage of the stimulus. The conditions producing the maximal effect were found to consist of a 15 sec stimulus of 5 V at 20 Hz; these conditions were used in our other experiments.

To explore the kinetics of the response, intervals of time between the electrical stimulus, the dye injection, and the fixative perfusion were systematically varied in different groups of rats over the range of 0 - 10 min. The results indicate that the dye content of the trachea was half-maximal at 1 min and maximal by 5 min. The increase in vascular permeability had a half-life of 2 min. The time-course of tachyphylaxis was investigated by varying the interval between two stimuli 2 min to 4 hr apart. The results showed that within 10 min of the first stimulus, there was a diminished response to the second stimulus.The degree of tachyphylaxis was less after an initial stimulus of 15 sec duration than after one of 5 min. The subnormal response to the second stimulus persisted for 2 - 4 hr after the first stimulus.

In summary, the neurally-induced increase in vascular permeability in the rat trachea depends upon the duration, frequency, and amplitude of the stimulus. It has a rapid onset and a short duration, and is subject to a rapidly developing tachyphylaxis that is long lasting. This project was supported by NIH training grant HL-07185 and program project grant HL-24136.

## CHEMICAL SENSORY SYSTEMS I

286.1 ADEQUATE STIMULI FOR HYDROXY-PROLINE RECEPTORS IN THE OLFACTORY ORGAN OF THE AMERICAN LOBSTER. B.R. Johnson, C.L. Merrill* and J. Atema. Boston University Marine Program, Marine Biological Laboratory, Woods Hole, MA 02543.

The lateral antennule from the American lobster, Homarus americanus, functions as an olfactory organ; it is necessary for efficient orientation to a food odor source (Devine, D.V. and Atema, J., Biol. Bull., 163:144, 1982). A majority of the chemoreceptors surveyed from the lateral antennule of H. americanus are narrowly tuned to trans-4-hydroxy-L-proline (OH-Pro) (Johnson, B.R. and Atema, J., Neurosci. Letts. 41:145, 1983). This suggests that OH-Pro may act as a chemical feeding signal. However, OH-Pro is usually bound in connective tissue proteins of lobster prey and thus may be normally unavailable to stimulate chemoreceptors as a free amino acid. Here we examined the tuning of OH-Pro cells from lateral antennules with a variety of compounds to determine the adequate stimuli for this receptor population. We chose compounds suspected of possible social functions or associated with breakdown of connective tissue.

Single OH-Pro sensitive cells were identified through extracellular recordings from small bundles of the antennular nerve in ablated lateral antennules. Cells sensitive to $10^{-5}$M OH-Pro were then tested for their sensitivity to proline, kainate, octopamine, serotonin, hydroxy-lysine, cis-4-hydroxy-D-proline, and cis-4-hydroxy-L-proline, all at $10^{-5}$M; alpha and beta ecdysone at $2x10^{-6}$M and gelatin in a fully saturated and one-tenth diluted solution. Gelatin is denatured connective tissue which contains 14% bound OH-Pro. Most of the test compounds elicited little or no response. Cis-4-hydroxy-D-proline and cis-4- hydroxy-L-proline were not stimulatory, demonstrating the stereo-specificity of these chemoreceptor responses. Serotonin and particularly gelatin caused strong responses in some of the cells tested.

The responses to OH-Pro, gelatin and serotonin suggest that these or similar compounds may play a role in feeding and/or social behaviors of the lobster. The responses to gelatin may indicate that these receptors are tuned to collagen and its breakdown products. Studies are in progress to further characterize the OH-Pro receptor response to serotonin, collagen and collagen derivatives.

Supported by grants from the Whitehall Foundation and NSF (BNS-8411969) to J.A. and a Grant-in-Aid-of-Research from Sigma Xi, The Scientific Research Society to B.R.J.

286.2 AMILORIDE BLOCKS THE BEHAVIORAL FEEDING RESPONSE BUT NOT THE NERVE RESPONSE TO FEEDING STIMULI IN THE LEECH. E. J. Elliott. Dept. of Zoology, Univ. of Maryland, College Park, MD 20742.

Studies of chemoreception in the leech Hirudo medicinalis have shown that Hirudo can detect and will ingest artificial mixtures of chemicals found in blood. In particular, a mixture containing only NaCl (150 mM) and arginine (0.1 to 1 mM), but not NaCl alone or arginine alone, is recognized and ingested as readily as blood. This mixture also elicits a robust response in the cephalic nerves innervating the dorsal lip sensilla, chemosensory structures located near the mouth. The diuretic drug amiloride, which at micromolar concentrations inhibits passive $Na^+$ transport and at higher concentrations blocks $Na^+$-$H^+$ exchange in transport epithelial cells, has been shown in a variety of species also to inhibit chemosensory or taste responses to NaCl, by behavioral and/or electrophysiological criteria. Bathing a leech in amiloride reversibly blocked the feeding response (i.e., attraction, probing, attachment and ingestion) to the mixture of NaCl + arg, as well as to blood. $10^{-4}$M amiloride inhibited the response of 50% of the leeches tested, and $10^{-3}$M inhibited feeding in all leeches tested. These results suggest that, as proposed for other systems, amiloride blocks the chemosensory detection of NaCl by the leech. However, in an isolated lip preparation in which the outside surface of the lip was bathed in amiloride, the response recorded extracellularly from the cephalic nerves during stimulation of the lip sensilla with NaCl + arg remained unchanged. Possible explanations for the apparent discrepancy in these results are being explored. The nerve response to NaCl + arg is more complex than simply the sum of the response to NaCl and the response to arginine. Moreover, the behavioral inhibition by amiloride may be a non-specific effect unrelated to a block of $Na^+$ transport or NaCl sensing. Supported by NIH grant NS 20432.

286.3 ELECTRICAL PROPERTIES OF OLFACTORY CELLS ISOLATED FROM THE EPITHELIUM OF THE TIGER SALAMANDER. Stuart Firestein* and Frank Werblin* (SPON: P.A. Anderson). Graduate Group in Neurobiology, University of California, Berkeley, CA 94720.

Enzymatically dissociated olfactory epithelial cells were studied using the 'gigaseal' whole cell patch clamp technique. Cells identified morphologically as neurons had a resting potential of -45 mV and an input resistance between 2.5 and 5 gigohms. This value is more than an order of magnitude greater than that reported previously using intracellular microelectrodes.

Two unusual transient inward currents could be identified. The larger current, up to 1.0 nA in magnitude, was TTX insensitive but blocked by the addition of $Co^{2+}$ and is presumed to be carried by $Ca^{2+}$ ions. This current activates over a narrow potential range between -40 and -30 mV and inactivates within 20 msec. A second transient inward current was blocked by TTX; it is less than 0.5 nA and shares a similar time course and activation range with the transient $Ca^{2+}$ current. There was no sustained inward current.

Two outward currents, both carried by $K^+$, could be distinguished kinetically and pharmacologically. One was an inactivating current which was $Ca^{2+}$ dependent and closely followed the transient $Ca^{2+}$ current; the other was sustained and voltage dependent. Both currents could be blocked by replacing KCl with CsCl in the patch electrode.

The unusually high input resistance measured in these cells would allow even small transduction currents to polarize the membrane to within the activation range of the gated currents. Thus, these gated currents could be actively involved in forming the cell's response waveform.

286.4 A CELL FREE ASSAY FOR OLFACTORY REACTIVITY REVEALS PROPERTIES OF ODORANT RECEPTOR MOLECULES. Zehava Chen*, Michael Greenberg*, Umberto Pace* and Doron Lancet (Spon: J.M.Gershoni) Dept. of Membrane Research, The Weizmann Institute of Science,Rehovot,Israel

We have recently reported that isolated olfactory cilia exhibit odorant-stimulated, GTP-dependent cyclic AMP synthesis (Pace,U., Hanski,E., Salomon,Y. and Lancet D. Nature, in press; Lancet et al, this volume). This strongly suggests that olfaction is mediated by receptor-coupled cyclic nucleotide processing enzyme and a GTP-binding protein (G-protein), similar to visual, hormone and neurotransmitter reception. We utilize the measurement of cyclic AMP production as a novel cell-free assay for olfactory reactivity, useful in studying and possibly identifying olfactory receptor proteins. We find that both in-vivo electroolfactogram responses and the cell-free elevation of cyclic AMP synthesis induced by various odorants are specifically diminished in the presence of the lectin wheat germ agglutinin (WGA), or by the sulfhydryl-blocking reagent N-ethyl maleimide (NEM). Such correspondence between in-vivo and in-vitro results supports the notion that ciliary adenylate cyclase activity is related to physiological olfactory responses. In parallel, these findings provide new information on the putative olfactory receptor molecules. The only frog ciliary protein that reacts with WGA is gp95, a major glycoprotein that fulfills several criteria for being a membrane receptor molecule (Chen et al, PNAS 81, 1859 (1984)). The polypeptide gp95 is glycosylated, spans the membrane, is enriched in the sensory organelles and its abundance and molecular size correspond to those of ciliary freeze fracture intramembranous particles, as expected for olfactory receptor proteins. The WGA inhibition constitutes an additional important indication for the possible functional role of gp95. The effect of NEM on cell-free odorant-induced cyclic AMP synthesis is found to be mainly due to direct inhibition of adenylate cyclase: at an NEM concentration where 95% of the cyclic AMP production is lost, the relative stimulation by odorants remains virtually unchanged. Thus, it appears most plausible that NEM affects functionally important fulfhydryls in the transductory enzyme rather than in the receptor molecule itself. In view of results obtained in other systems, such a model would still be consistent with odorant protection against NEM inhibition - via an allosteric mechanism. Currently we are pursuing reconstitution experiments aimed at transferring odorant receptors from ciliary membranes to other membranes, where adenylate cyclase is odorant-insensitive. Such studies will provide a direct means for identification and eventual isolation of olfactory receptor proteins.

Supported by grants from the U.S.-Israel Binational Science Foundation and from the Minerva Foundation.

286.5 SIMPLE PATTERN RECOGNITION MODELS OF OLFACTORY DISCRIMINATION. T. J. Sejnowski, P. K. Kienker* & G. M. Shepherd. Biophysics Dept., Johns Hopkins Univ., Baltimore, MD 21218 & Sect. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510

In a previous $^{14}$C-2-deoxyglucose study of the rat olfactory bulb several different odors were presented over a range of concentrations and the patterns of labeling observed in the glomerular sheet where the receptor axons terminate (Stewart et al., J. Comp. Neur. 185:715, 1979). The patterns, though different, showed significant overlap for all three odors tested as well as the pure air control. We have generated several network models to see whether odors could be discriminated on the basis of these two-dimensional patterns of activity within the glomerular sheet of the bulb.

The activity pattern for each of the four odor conditions was approximated by contour plots on an 8x8 grid. The highest values represented the most sensitive regions for that odor. An olfactory "unit" was assigned to each of the 64 grid regions and for a particular "sniff" the input pattern was generated by taking each unit to be active or not with a probability proportional to its sensitivity and to the log concentration.

In the first network four additional units were chosen to represent the four odors each of which had a connection to all 64 olfactory units. Each unit summed the active units in a given sniff weighted by the synaptic strength, and if the total was above threshold the unit was considered active. Following each sniff the weights were changed according to the perceptron learning rule. After 2,000 sniffs the weights converged to a stable pattern. The overall performance of the network was 90% correct discrimination at high concentrations with a gradual falloff to chance level at low concentrations.

In a second model a layer of 12 additional units was interposed between the 64 olfactory units and the 4 odor units. The same training procedure was followed except that the Boltzmann learning rule was applied to all the weights between the layers of units (Ackley et al., Cog. Sci. 9:147, 1985). The weights in this network converged after 10,000 sniffs to a pattern in which all of the 12 "feature" units had excitatory and inhibitory connection to more than one odor unit. The performance was 97% at high concentrations and about 25% better than the previous model at low concentrations; the performance was also much less affected when random changes were made to the weights.

These simulations provide examples of networks that can discriminate between different odors using only the information in the spatial pattern of activity at the level of sensory input to the olfactory bulb despite the large overlaps between the patterns of different odors. Some odor discriminations could be acquired in this manner even though the initial connectivity may be innate.

286.6 THE PRIMARY OLFACTORY PROJECTION HAS TWO CHEMICALLY DISTINCT ZONES. J.E. Schwob and D.I. Gottlieb. Dept. Anatomy & Neurobiology, Washington University School of Medicine, St.Louis, MO 63110.

The receptor neurons of the olfactory epithelium are an anatomically uniform population which are differentially excited by odorants. We have discovered an unexpected chemical heterogeneity in this population. A newly discovered monoclonal antibody, designated RB-8, stains about 2/3's of the olfactory epithelial sheet and its projection onto the olfactory bulb. The remaining 1/3 is either unstained or stained at a much lower level.

RB-8 is an IgG derived from a fusion of SP-2/0 myeloma cells with splenocytes from a mouse immunized 4X with triturated homogenates of neonatal rat posterior piriform cortex. The RB-8 producing hybridoma was cloned twice and found to be a stable producer of antibody over a period of several months of continuous growth. Binding of unlabelled primary antibody to 8-12 µm thick cryostat sections of the rat primary olfactory projection was visualized with the Vectastain ABC reagents (Vector Laboratories).

In sections of decalcified muzzle from adult rats, RB-8 stains the receptor neurons of the ventral and lateral parts of the olfactory epithelium and densely labels fascicles of the olfactory nerve projecting from this RB-8 positive area. RB-8 labelling of the epithelium of the dorsal recess and medial tips of the dorsal turbinates is not detectable, and the fascicles from this RB-8 negative area are only very weakly stained. These RB-8 negative areas form a contiguous zone on flattened maps of the epithelial sheet. RB-8 staining of the glomeruli in the ventrolateral part of the bulb is correspondingly heavy, while that in the dorsomedial glomeruli is undetectable or weak. In RB-8 labelled glomeruli, the staining is precisely co-extensive with anti-olfactory marker protein staining. In addition, knife cut lesions of the olfactory nerves totally eliminate the RB-8 staining in the glomeruli where the destruction of the olfactory terminals is complete. We conclude that in the olfactory nerve and the glomeruli, RB-8 is staining the olfactory axons and their terminals. Survey of the CNS and peripheral tissues demonstrates that staining with RB-8 is nervous system specific; however, not all components of the CNS and PNS are stained.

In conclusion, these results demonstrate that the primary olfactory projection can be visualized as a sheet which is divided into two portions; one of these is stained with RB-8 and the other is not. These two portions may have distinguishable roles in early development and/or olfactory sensation. A similar result was recently reported for the rabbit (Fujita et al., Brain Res. 326:192-196, 1985).

286.7 MAPPING RECEPTOR POPULATIONS THAT PROJECT TO GLOMERULI IN THE MAIN OLFACTORY BULB. P. E. Pedersen, P. J. Jastreboff*, W. B. Stewart and G. M. Shepherd. Sec. of Neuroanatomy, Anatomy, and Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510.

Spatial patterns of activity in the glomeruli of the olfactory bulb in response to odor stimuli have suggested the hypothesis that there is a spatial organization of olfactory receptor neurons projecting to those glomeruli (Stewart et al., 1979). We have introduced the horseradish peroxidase (HRP) tracing technique to identify populations of olfactory receptor cells that project to specific groups of glomeruli (Jastreboff et al., 1984). The aim of the present study was to develop a method for mapping these HRP-labeled populations of receptor neurons within the nasal cavity of young rats.

Ionophoretic injections of wheat germ agglutinin HRP were made via stereotaxically placed glass micropipettes into the modified glomerular region of the MOB. Pups (N=21) were treated according to procedures reported previously (Jastreboff et al., 1984). Camera lucida drawings were made of the entire olfactory bulb and the nasal cavity of six experimental animals. In order to establish the relationship between the bulb and its receptor sheet, maps of the entire olfactory epithelium were constructed in 2 dimensions; within these maps, the distribution of labeled neurons was plotted, and compared with maps of the location of HRP injected into the olfactory bulbs.

HRP label was confined to a clearly identifiable localized region in the modified glomerular region of the MOB. Label included 2-9% of the glomerular sheet of the MOB, including the modified glomerular complex. HRP labeled receptor neurons within the olfactory epithelium ipsilateral to the injected side occurred within topographically defined regions. Anteriorly, labeled olfactory neurons were confined to a narrow strip in the dorsal recess, and, more posteriorly, this strip widened medially along the septal wall and laterally onto a limited area on the nasal turbinates. In very posterior regions most of the epithelium was occupied with labeled cells. The labeled olfactory neurons were confined to 9-32% of the total epithelial area; in addition, they comprised only a portion of the receptor population within a region. This suggests that the unlabeled neurons project to other glomerular regions of the MOB. The functional implications of these findings will be discussed as well as analysis of HRP label at the cellular level.

286.8 THE TOPOGRAPHY OF OLFACTORY EPITHELIUM TO OLFACTORY BULB PROJECTIONS IN THE RAT. William B. Stewart, Patricia E. Pedersen, Charles A. Greer and Gordon M. Shepherd. Sections of Anatomy, Neurosurgery, Neuroanatomy, Yale University School of Medicine, New Haven, CT. 06510.

We have shown previously, using the 2-deoxyglucose method, that specific regions of the olfactory bulb were metabolically active during exposure to odors. Furthermore, different regions were active with different odors. We have also shown, using the horseradish peroxidase (HRP) method, that one of the metabolically active regions in the posterior medial olfactory bulb receives projections from a defined region of the olfactory epithelium. The present experiments were designed to test the hypothesis that another metabolically active region in the lateral anterior olfactory bulb receives its input from a different region of the olfactory epithelium. Therefore, rats had HRP placed in restricted regions of the olfactory bulb by iontophoresis or by direct placement of HRP crystals. The distribution of HRP in the decalcified nose was examined following sacrifice and processing. Placement of HRP in the medial posterior bulb produced labelled receptor cells along the septal wall, posterior dorsal recess and medial turbinals. By contrast, placement of HRP in the anterior lateral bulb produced labelled receptors along the dorsal and lateral turbinals and the anterior dorsal recess, but not the septal wall. These results show that these two regions of the bulb receive input from distinct but overlapping populations of receptor neurons.

286.9 HISTOLOGICAL LOCALIZATION AND IMPROVED RESOLUTION OF 2-DEOXYGLUCOSE UPTAKE IN THE OLFACTORY BULB USING COMPUTERIZED IMAGE PROCESSING. J.S. Kauer. Depts. of Neurosurgery, Anatomy and Cell Biology, Tufts-N.E.M.C., Boston MA 02111

The 2-deoxyglucose (2DG) method has been widely used to map regional brain glucose metabolism under a variety of experimental conditions. In its usual format the method provides a view of glucose uptake related to neuronal activity throughout the brain with a practical resolution, dependent on a number of factors, of 50-100 μm. Autoradiographs are usually generated on X-ray film which is separated from the tissue sections at the time of film development. In order to analyze which anatomically defined brain structures show changes in glucose uptake, the densities on the autoradiographs must be compared to the original tissue sections. Several systems have been developed for this prupose (Gallistel et al., Neurosci. Biobehav. Rev. 6:409, 1982; Kauer et al., J. Neurosci. Meth. 11:143, 1984). Here we present a computerized image processing method for superimposing the image of the stained histological section on its companion autoradiograph allowing exact correlation of architectonic structure and glucose uptake densities. The method consists of storing a digitized 512 x 512 x 8 bit image of an autoradiograph, giving a possible range of 255 gray levels for each pixel in the computer memory and aligning with it, on the TV monitor, its histological counter-part. The image of the autoradiograph is then retained in memory in registry with the histology, but blanked from view, leaving only the histological image visible. Single density values on the hidden autoradiograph may then then be assigned a color which is superimposed onto the histological image. By looking at the sites of color-enhanced single gray levels, minute differences in glucose uptake may be observed that are directly related to the cellular architecture, thus providing higher practical resolution than other image processing methodologies.

Previous experiments in which glucose metabolism was examined in the olfactory bulb (Sharp et al., Br. Res. 107:663, 1975; Stewart et al., J. Comp. Neurol. 185:715, 1978) have shown increased 2DG uptake in glomerular layer foci in response to odor. Using the method described here, we have often found that highest 2DG uptake appears in the periglomerular regions coextensive with slightly lower uptake within the glomeruli, which together make up the dense foci seen in previous studies. These observations suggest that 2DG uptake is manifest in periglomerular cell bodies which are more active during odor stimulation than intraglomerular structures. Localized uptake has also been seen related to activity in mitral, tufted and granule cells as well as various regions of neuropil. Supported by NINCDS NS-20003.

286.10 TOPOGRAPHICAL PROJECTIONS OF SEPTAL ORGAN RECEPTOR NEURONS TO THE MAIN OLFACTORY BULB IN RATS. T.E. Benson, P.E. Pedersen, P.J. Jastreboff* and G.M. Shepherd. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510-8001.

The septal organ of Masera (SO) is an isolated patch of olfactory epithelium. Its relatively simple topology makes it suited to a study of the topography of olfactory receptor neuron projections into the olfactory bulb. As a component of our ongoing studies on receptor-bulb relations we have mapped the distribution of labeled receptor neurons in the SO following punctate injections of horseradish peroxidase (HRP) into the olfactory bulb. We have thus tested the hypotheses that SO receptor neurons project to the ipsilateral main olfactory bulb and that this projection is topographically organized.

Wheat germ agglutinin HRP was ionophoretically delivered into the dorso-caudo-medial olfactory bulb of 10 young rats and tissues processed as previously described (Jastreboff et al, PNAS 81: 5250, 1984). Injection sites comprised 2-8% of main olfactory bulb glomeruli. Camera lucida drawings were made of SO and nearby landmarks at 25x. Sagittal maps were generated for qualitative assessment of labeled receptor neuron distributions and quantitative analyses of distributions were performed.

In 5 animals SO receptor neurons ipsilateral to the injected olfactory bulb were retrogradely labeled. The labeled cells had a morphology similar to that of olfactory receptor neurons in the main olfactory epithelium labeled by retrograde transport of HRP from the olfactory bulb (Ibid). The epithelium of the SO was thinner than the main olfactory epithelium, especially in its dorsal part.

Correlation of bulbar injection sites with the distribution of labeled receptor neurons within the SO indicated a distinct topography in the projection of the SO into the olfactory bulb. Labeled receptor neurons were preferentially located in the caudal SO and were clustered about a plane dorsal to the plane bisecting the SO. Animals with injection sites confined to the accessory olfactory bulb had dense labeling of receptor neurons in the ipsilateral vomeronasal organ but no main olfactory epithelium or SO receptor neurons were labeled.

These results indicate that the projection of septal organ receptor neurons is ipsilateral and is most likely confined to the main olfactory bulb. They also indicate that the projection to the dorso-caudo-medial olfactory bulb does not arise randomly throughout the septal organ, rather there is clearly a degree of topographical organization in this projection. Because of the simple topology of the septal organ within the nasal cavity, the functional significance of this topographical organization invites further study.

286.11 NADPH-DIAPHORASE AND NPY LABELING OF RAT OLFACTORY BULB SHORT AXON CELLS AND GLOMERULI. John W. Scott, John K. McDonald and Janice L. Pemberton*, Department of Anatomy, Emory University School of Medicine, Atlanta, Georgia 30322.

Short axon cells of the olfactory bulb are found in all of the cell layers of that structure but they exist in several classes with restricted distributions. At present no function has been clearly ascribed to these cells but they have been studied with morphological and immunohistochemical procedures. We have seen two populations of short axon cells that are intensely stained for the presence of NADPH-diaphorase and neuropeptide Y (NPY) in 80 micrometer serial sections of the rat olfactory bulb. The superficial short axon cell population corresponded to that observed with Golgi impregnation. Their somata lay near the border of the periglomerular region with the external plexiform layer. The dendrites were distributed in the periglomerular region and were never seen to enter the glomeruli. Multiply branching NPY immunoreactive axons from these cells could occasionally be traced across the upper portion of the external plexiform layer. A second population of short axon cells stained by both procedures was seen in the depths of the granule cell layer and the deep white matter surrounding the ventricular layer. These deep cells might correspond to either the Golgi or Blanes cells (Schneider and Macrides, Brain Res. Bull. 3:73-82, 1978) but in contrast to the Golgi observations or Blanes cells, no spines were apparent in our material. The deep short axon cells we observed are similar in appearance and distribution to those labeled by somatostatin immunohistochemistry (Davis et al., JCN 204:377-383, 1982). However, peptide or transmitter histochemistry of the superficial short axons cells has not been previously reported. Some olfactory glomeruli and the entering olfactory nerves were intensely stained with the NADPH-diaphorase procedure. We found that, while the intense NADPH-diaphorase staining of short axons cells and other neurons of the forebrain was abolished by periodate in the fixative, there was no such effect on the NADPH-diaphorase staining of olfactory nerves and glomeruli. Glomerular and olfactory nerve axons were not labeled with NPY antiserum.

These observations are consistent with previous reports that NADPH-diaphorase and APP (NPY)-like immunoreactivity are localized in the same cell populations of cortex and striatum. The selective staining of glomeruli may be an important functional marker of either the locus or the developmental state of the olfactory receptor cells which innervate these glomeruli and thus could be useful in functional studies of the olfactory bulb.

286.12 SPECIES DIFFERENCES IN EXPRESSION OF SUBSTANCE P AND TYROSINE HYDROXYLASE IMMUNOREACTIVITY IN OLFACTORY BULB. H. Baker, Laboratory of Neurobiology, Cornell Univ. Med. Coll. New York, NY 10021.

Perikarya containing substance P-like (SP) immunoreactivity have been localized to the juxtaglomerular region of the hamster main olfactory bulb (Davis and Macrides, J. Comp. Neurol, 214:244, 1983). However, similar neurons have not been observed in either the mouse or rat main olfactory bulb. Utilizing a newly prepared high titer antibody to SP (Generously provided by Dr. R. Kream), the immunoreactive elements in rat, mouse and hamster olfactory bulb were investigated. In addition the distribution of SP immunoreactive cells and processes was compared with that of tyrosine hydroxylase (TH). The main olfactory bulb (MOB) of the hamster contained large numbers of both SP and TH positive juxtaglomerular neurons. TH, but not SP, containing neurons were also numerous within the external plexiform layer. For both antigens terminal arborizations were observed within the glomeruli and internal granule cell layer of the MOB. The hamster accessory olfactory bulb (AOB) also stained for SP with fibers and/or terminals within the mitral, internal plexiform and granule cell layers, and light processes within the glomerular layer. A few small, lightly-stained cells were localized to the granule cell layer. By contrast, SP staining in the rat MOB was limited to fine varicose fibers within the olfactory nerve and glomerular layers with no juxtaglomerular cell body staining. Numerous TH immunoreactive cells were predominant within the juxtaglomerular region and in comparison to the hamster few TH cells were found in the external plexiform layer. As opposed to the hamster AOB, where few SP cells were observed, the granule cell layer of the rat AOB contained numerous darkly stained SP positive cells. The fibers from these cells appeared to send axons through the inner plexiform layer to the mitral cell layer which contained numerous processes and the glomerular layer where only a few processes were found. The pattern of staining in mouse differed from both rat and hamster with no SP cell staining in either the MOB or AOB. Only fiber staining was observed. It was most prominent within the granule and mitral cell layers of the AOB. The TH staining resembled that observed in the rat with cells primarily in a juxtaglomerular position and processes filling the glomeruli. The mechanisms underlying the species differences in perikaryal staining for SP are not known. It is possible that the rat and mouse MOB juxtaglomerular neurons simply do not contain SP or that the peptide is present at levels below those detectable by the immunocytochemical procedures employed. Alternatively, SP may be present only in terminals of the rat and mouse MOB or the hamster and mouse AOB while the cell bodies contain a precursor which undergoes processing in terminals. These studies demonstrate that tyrosine hydroxylase is similarly expressed in different species while the expression of substance P is species dependent in neurons of the main and accessory olfactory bulb. (Supported by NSF grant BNS-8317552.)

## REGENERATION I

287.1 ENHANCEMENT OF ELECTRICAL COUPLING BETWEEN REGENERATING NEURONS BY STRESS. A.G.M. Bulloch. Dept. Physiol., Univ. Calgary, Alta., Canada T2N 4N1.

Adult neurons can exhibit sprouting in a number of situations not involving direct damage. The physiological consequences of such sprouting, however, are largely unknown. The identified neurons of the adult mollusc Helisoma have been utilized for studies of adult neuronal plasticity. For example, a new electrical synapse forms between the buccal neurons L5 and R5 when axonal regeneration is evoked by axotomy. Recently, specific forms of stress were found to evoke sprouting and retraction of neurites from neurons L5 and R5 in the intact nervous system. The present study examined the efficacy of the neuron 5-5 synapse in ganglia from previously stressed animals.

The experimental basis of this study was as follows. Animal were exposed to a stress (bleeding) known to cause sprouting of intact neurons 5. After 3 days, i.e., when the number of neurons 5 sprouted is maximal, ganglia were excised from both stressed and control animals and placed in organ culture in which axonal regeneration and neuron 5-5 electrical synapse formation occurs. Subsequent to physiological measurements each neuron was stained with Lucifer Yellow CH for assessment of sprouting.

The strength of the neuron 5-5 electrical synapse was substantially increased in ganglia from previously stressed animals. Specifically, the coupling coefficient between the neurons 5 after 2 days of culture was increased by 221% in experimental ganglia. This was due to a substantial reduction of coupling resistance (68%) and was in spite of a small decrease (26%) of non-junctional resistance.

A correlation between the degree of central sprouting and the strength of neuron 5-5 coupling has been observed in a number of previous studies. In this study, however, neurons sprouted to the same extent in both experimental and control animals. It is therefore possible that the increased electrical coupling could reflect more subtle metabolic changes such as increased synthesis of gap junction proteins.

It is concluded that stress can enhance the ability of neurons to form electrical synapses upon axonal regeneration. The modification of neuronal properties in stress could be important for a number of aspects of adult neuronal plasticity.

287.2 A STRUCTURAL AND FUNCTIONAL COMPARISON OF NERVE RECONNECTION. J. Kerns, J. Siuciak* and H. Weinrib* (SPON: R. Penn). Depts. of Anatomy and Microsurgery, Rush Medical College, Chicago, IL 60304.

In the evaluation of new techniques for nerve repair, it is important to consider both structural and functional parameters. Rats were prepared for (a) sciatic nerve crush injury, (b) transection and reconnection by the method of de Medinaceli (Exp. Neurol. 81:469, 1983), and (c) conventional anastomosis with two 10-0 sutures. We have developed four quantitative methods to compare the nerve regeneration for the above three groups. (1) The "SCIATIC FUNCTIONAL INDEX" or SFI during the recovery period is determined by behavioral track analysis (de Medinaceli et al., Exp. Neurol. 77:634, 1982). The deficit values at one month are -13%, -79% and -88% for the respective lesion groups. (2) TOE-TWITCH TENSION recordings give functional data from the motor units. The deficits of the amplitude/area on the experimental side are -6/17%, -39/25% and -79/75% respectively. (3) NERVE MORPHOMETRY from transverse light microscopic sections and Bioquant computerized image analysis gives an estimate of the size and number of regenerated nerve fibers in the distal nerve segment. The change in the nerve fiber number is zero, +18% and +24%, while the reduction in fiber diameter is -41%, -48% and -51% respectively. The fiber density is variable, but the g-ratio remains fairly constant. (4) HORSERADISH PEROXIDASE (HRP) data is obtained by the retrograde transport from the distal segment past the lesion to the cell bodies. The mean nubmer of labeled motoneurons on the transection side at two months postoperative equals -31% compared to the control side. The cell body size and label intensity is not significantly different. The results suggest that following nerve transection and conventional repair, it is the reduction in the number of the motoneurons by 1/3 and the size of the distal fibers by 1/2 which best explains the 75-88% loss of function. It is not yet clear what is the role of the increase in the number of distal fibers by 1/4. We have confirmed independently that the reconnection method of de Medinaceli gives functional improvement over the conventional method of repair, but not as good as following a crush lesion. The structural data suggest an intermediate result as well, but less conclusively. (Supported by Grant NS 19769)

287.3 FUNCTIONAL RECONNECTION OF LOCOMOTOR CIRCUITRY IN THE SPINAL TRANSECTED SEA LAMPREY. A. H. Cohen, S.A. Mackler* and M.E. Selzer. Section of Neuroscience and Behavior, Cornell U., Ithaca, N.Y. 14853 and Depts. Neurology and Anatomy, U. of Pa. Sch. Medicine, Phila., PA 19104.

Large larval sea lampreys recover behaviorally from spinal transection. Their spinal axons are known to regenerate (Yin and Selzer, J. Neurosci., 3:1135-1145, 1983) and to form physiologically functioning synapses with target neurons distal to the transection scar (Mackler and Selzer, this Meeting). In order to determine whether synaptic regeneration is responsible for behavioral recovery the isolated spinal cords of previously transected lamprey larvae (Petromyzon marinus) 4-5 years old were bathed in physiological solution with 1 mM D-glutamate to activate "fictive locomotion" (Cohen and Wallen, Exp. Brain Res., 41:11-18, 1980). The motor discharges were recorded simultaneously from ventral roots above and below the healed transection.

Two types of fictive locomotor patterns were observed in untransected control larvae: 1) slowly propagating waves with burst durations of 2.0-5.0 sec. and phase lags of approximately 3% of the cycle per spinal segment; 2) rapidly propagating waves with burst durations of 0.3-2.0 sec. and phase lags of less than 1% of the cycle per segment. All eight animals which had recovered at least two months from spinal transection at mid-body showed some degree of recovery of intersegmental coordination during fictive locomotion. Seven of 8 recovered coordination of fast swimming. Three animals recovered coordination of slow simming. Median values for phase lags between segments on opposite sides of the transection scar were in the normal range for all but one fast and one slow swimming pattern. Retransection eliminated the coupling so that phase lags between reseparated segments became randomly distributed. Therefore, synaptic regeneration in lamprey spinal cord includes components of the circuits for intersegmental coordination of locomotor pattern generation. Supported by NIH grants NS16803 and NS14837 and by the American Paralysis Association.

287.4 ELEMENTS OF SPECIFICITY IN SYNAPTIC REGENERATION BETWEEN LAMPREY SPINAL NEURONS. S.A. Mackler* and M.E. Selzer. Depts. of Anatomy and Neurology, U. of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Spinal axons of 4-5 year-old larval sea lampreys regenerate following spinal transection. We now report that neurons above and below the transection scar can reestablish monosynaptic connections with each other in a way which shows similarities with the original pattern of interconnections.

In control animals intracellular stimulation of giant interneurons (GIs) elicited composite electro-chemical EPSPs in 50% of other GIs located rostrally. These followed stimulation at 3-33 Hz with fixed latencies and persisted in 20 mM $Ca^{++}$ Ringer's. In animals recovered 6 weeks or more from spinal transection, stimulation of GIs located below the scar elicited EPSPs in 7 of 35 GIs (20%) located within 8 mm above the scar. Since it is probable that 50% of the GI axons regenerated (Yin and Selzer, J. Neurosci. 3:1135-1144, 1983), the proportion of regenerated axons which formed synapses with rostral GIs was approximately 40%. As in control GI-GI connections, the regenerated ones were monosynaptic composite electro-chemical EPSPs. However, the chemical components in regenerated synapses were significantly larger than those of controls (2.4 mV $\pm$ 0.6 SEM vs. 0.7 mV $\pm$ 0.1) and the electrical components were smaller (0.9 mV $\pm$ 0.1 vs 1.5 mV $\pm$ 0.2).

In control animals no dorsal cells (DCs) were monosynaptically linked to rostral GIs in 19 cases. In transected animals none of 42 DC-GI pairs were synaptically linked across the scar. Similarly none of 14 giant reticulospinal axons were synaptically linked to GIs below the scar, also in conformity to the normal pattern.

Finally, DCs (intraspinal primary sensory cells) normally receive no synaptic input. In animals recovered from spinal transection whole cord stimulation, either across the scar or on the same side, failed to elicit synaptic activity in any of 55 DCs.

We conclude that: 1) Regenerating axons of lamprey GIs can form functioning monosynaptic connections with other GIs distal to the scar. 2) The frequency and characteristics of such connections are similar to those in the normal spinal cord. 3) The axons of two types of cells which normally do not contact GIs fail to do so after regeneration and one type of cell which ordinarily receives no synaptic input remains so. (Supported by NIH grant NS14837 and by the American Paralysis Association).

287.5 EVIDENCE FOR REGENERATION OF SPECIFIC SYNAPTIC CONNECTIONS IN APLYSIA FOLLOWING CNS LESIONS. S.M. Fredman. School of Biological Sciences, University of Kentucky, Lexington, KY 40506

The mollusc Aplysia has been used to investigate the cellular mechanisms of behavioral plasticity. Behavioral, morphological and physiological evidence has now been obtained that demonstrates that Aplysia exhibits another form of plasticity: Regeneration and recovery of function.

An electric shock to the tail of Aplysia evoked a stereotyped escape locomotor sequence. This response was selectively abolished by crushing both cerebro-pleural (C-PL) connectives. The effects of the lesion were specific. Spontaneous and food-evoked locomotion was unimpaired. Prior to lesioning, the mean latency of the response was 13.6 $\pm$ 3.1 sec (5 subjects, 45 trials). Two days after lesioning, escape locomotion was absent (latency > 60 sec), although tail withdrawal and inking could still be evoked. Behavioral recovery was gradual. Partial responses at long latency were observed 7-14 days postlesion. By 24 days postlesion, recovery was complete; lesioned animals again exhibited the full escape locomotor response. The latency (16.5 $\pm$ 4.7 sec) was not significantly different (t-test, $p = 0.01$) from prelesion values.

Behavioral recovery was paralleled by both morphological and physiological changes in lesioned neurons. This was studied in the isolated nervous system. Intracellular injections of cerebral ganglion neurons with nickel-lysine (Fredman, in preparation) revealed the sprouting of new axon-like processes as well as smaller diameter neurites. Axon-like sprouting occured from or near the cell body not from the stump of the lesioned axon. By the time behavioral recovery was complete, it was possible to demonstrate that a neural correlate of the escape locomotor response triggered by tail shock also had recovered. Electrical stimulation of the posterior pedal nerves normally evokes IPSPs in cerebral B neurons which are mediated by pleural interneurons. Synaptic input evoked by posterior pedal nerve stimulation was absent both immediately after crushing the C-PL connectives and prior to the initial phase of behavioral recovery. This input returned 14-20 days postlesion. Finally, it was possible to demonstrate that specific excitatory and inhibitory chemical monosynaptic connections between cerebral B neurons and identified pleural neurons were re-established.

From this it is concluded that Aplysia is capable of axonal regeneration which can restore specific synaptic connections and behavioral function.

287.6 STRUCTURAL AND FUNCTIONAL ASSESSMENT OF THE REINNERVATION PATTERN OF CAT EXTRAOCULAR MUSCLE FOLLOWING CENTRAL CUT OF THE IIIrd, IVth AND VIth CRANIAL NERVES. R. Baker, C. Peck, R. F. Spencer, J. Delgado-Garcia* and J. Winterkorn. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, N.Y. 10016.

Within 2-3 weeks following peripheral cut of any extraocular nerve near its muscle insertion site, reinnervation occurs and normal oculomotor function returns. Delgado-Garcia et al. (1981) found subtle changes in motoneuronal properties, afferent organization and muscle fiber composition accompanying axotomy, but they were reversible upon reinnervation. We have studied eye movements, motoneuron physiology and morphology including organization of the extraocular nuclei and muscles in 8 cats 1-2 years following either mono- (3) or binocular (5) central cut of nerves III, IV and VI near the cavernous sinus at 4-6 weeks of age. Reinnervation occurred within 2-4 months as indicated largely by the return of retraction rather than rotational eye movements. Measurement with a magnetic coil system revealed that eye movements were not conjugate, of small amplitude (gains $\leq$0.1 of normal) and frequently in directions opposite to those expected in response to visual or vestibular stimuli. Resistance to mechanical displacement of the globe was high, yet dissection of the orbital contents revealed no adhesion or other abnormality underlying the stiffness. Reinnervated muscles appeared normal by light and electron microscopy. Since these data suggested that the pattern of motor reinnervation might be altered we injected HRP into either all (3 cats) or individual (3 cats) extraocular muscles. To our surprise we found the oculomotor nuclei subgroups degenerated in all 6 cats suggesting reinnervation of extraocular muscles by the quantitatively fewer (never more than 50%) motoneurons in the trochlear and abducens nucleus. Isolated injection of either medial or inferior rectus muscles confirmed innervation by motoneurons from both IV & VI. We conclude that the abnormal eye movements are in part explained by this ubiquitous IV & VI reinnervation scheme. The remarkably peculiar resiliency of some abducens motoneurons to degeneration was also used to examine Sperry's re-specification hypothesis. In two cats, we recorded from antidromically identified abducens motoneurons that largely reinnervated the medial rectus muscle as inferred by stimulation of the VIth nerve and eye movements. Direction, position and velocity sensitivity of the motoneurons were unchanged, leading to the conclusion that there was no central adaptive readjustment to re-specify oculomotor activity. In general, we surmise that the role for a particular motoneuron is specified early in ontogeny and is independent of the muscle innervated as well as being impervious to sensory reafference from inappropriate motor responses.

287.7 ALTERED PATTERN OF SKELETAL MUSCLE REGENERATION AFTER X-IRRADIATION. A.K. Gulati* (SPON: H.G. Goshgarian). *Department of Anatomy, Medical College of Georgia, Augusta, GA 30912.*

*Devascularization injury to adult skeletal muscle caused by experimental autotransplantation produces degeneration of majority of original myofibers. Upon revascularization, the surviving precursor myosatellite cells become activated, proliferate, and fuse to form new myotubes and myofibers. This study describes alterations in specific events involved in myofiber degeneration and regeneration due to X-irradiation. Rat extensor digitorum longus muscle was removed, irradiated to administer 2,000 or 10,000 Rads (Clinac 4 x-ray machine; 750 R/min), and transplanted back into the same animal. Muscle transplants from unirradiated controls and each irradiated group were analyzed between 4 and 28 days at light and electron microscopic level. Muscles in the control group underwent rapid degeneration and regeneration and by 14 days were filled with regenerated myotubes and myofibers. Muscles exposed to 2,000 Rads underwent similar degeneration and myosatellite cell activation; however, no fusion of cells to form myotubes was evident. In muscles exposed to 10,000 Rads, myofiber degeneration and myosatellite proliferation was not as rapid but was clearly evident. Again no fusion of myosatellite cells was seen. After 14 days muscle from both irradiated groups appeared similar and resembled dense connective tissue with many fibroblasts, macrophages and thick collagen bundles. Many isolated (un-fused) myoblasts were also present in these later grafts, they remained undifferentiated and did not express any myofilaments and lacked basal lamina. These results reveal that inital events involved in muscle regeneration such as revascularization, myofiber degeneration, myosatellite cell activation and proliferation appear not to be altered by irradiation. However, later events such as myoblast differentiation, their fusion to form myotubes, formation of contractile myofilaments and basement membrane are inhibited. The mechanism by which irradiation affects these processes is currently unknown, but it may be that irradiation, in part, produces alterations in the cell surface components important for myoblast differentiation, fusion and subsequent maturational events.*

287.8 SPECIFIC RESTORATION OF HIPPOCAMPAL NERVE CONNECTIONS BY DENTATE GRANULE CELLS TRANSPLANTED TO X-IRRADIATED RATS. J. Zimmer*, N. Sunde* and T. Sørensen* (SPON: I. Divac). Inst. of Anatomy B (Neurobiology), University of Aarhus, Aarhus, Denmark.

The rat dentate gyrus is a useful model for repair of specific nerve connections by intracerebral transplants: - 1) The major afferents, the two entorhinal perforant pathways (PP) and the hippocampal commissural-associational system, are segregated in laminae along the granule cell dendrites, and the efferents, the mossy fibers (MF), terminate in a well-defined layer along the hippocampal CA3 pyramidal cells. - 2) Most granule cells develop after birth. Their formation can therefore be stopped by neonatal X-irradiation, leaving the irradiated rats to grow up with only 10-20% of the granule cells, a corresponding small MF projection and aberrant PP projections to CA3 (Laurberg and Hjorth-Simonsen, *Nature, 269*: 158, 1980). The late development moreover makes the cells easily available as transplantable, well-surviving neurons.

Taking advantage of these features we attempted to replace the damaged granule cells by transplants of intact cells from newborn donors, either immediately after irradiation (600 rad bilaterally at birth) or with a delay of up to several months. The recipient brains were processed and examined six weeks or more after transplantation, using Timm staining for transplant MF and host PP connections, silver staining and electron microscopy for host commissural and PP connections and AChE staining for cholinergic host septohippocampal fibers.

Transplantation within 3 weeks after irradiation, i.e. within the normal developmental period of the recipients, revealed a remarkable capacity of the granule cells to exchange specific nerve connections with the host, provided the transplant was properly located. Host commissural and PP fibers thus terminated in appropriately sized and spaced laminae in the transplant dentate molecular layer, and transplant MF normalized the MF-zone in the host CA3 (Sunde et al., *Nature, 310*: 51, 1984). With further delay of transplantation the exchange of host-transplant connections decreased. Host commissural afferents to the transplants vanished, and host PP became confined to thin laminae superficial in the transplant molecular layer. Also the transplant MF projection to the host weakened. Only the AChE-stained, cholinergic host projection to the transplants appeared unaffected by the delay and increase in recipient age.

The present observations have interesting reparative implications, but we also want to emphasize the developmental aspects. The mutual changes of terminal territories in the transplant molecular layer seen with decreasing host PP ingrowth thus suggests that the laminar segregation of the afferents primarily is determined by interaxonal competition and not axodendritic specificity.

287.9 NEOCORTICAL TRANSPLANTS IN THE SI CORTEX OF ADULT MICE RECEIVE THALAMIC AFFERENTS FROM THE POSTEROMEDIAL (POm) BUT NOT THE VENTROBASAL (VB) NUCLEUS. D.T. Ross* and F.F. Ebner, Center for Neural Science, Brown University, Providence RI, 02912.

The primary somatosensory cortex (SI) of adult mice receives convergent input from several thalmic nuclei including the ventrobasal complex (VB) and posteromedial nucleus (POm). In the present study embryonic neocortical tissue was transplanted into the SI cortex of adult BALB/c mice and the ingrowth of thalamocortical axons from the VB and POm was examined using anterogradely transported HRP.

Neocortical tissue from embryos in their 12th to 19th gestational days was transplanted into the somatosensory cortex of adult BALB/c mice. Two to six months later HRP (0.05ul of 25% Sigma type VI) was injected at the coordinates of the VB or POm. 18-24 hours later the animals were sacrificed and their brains processed for the histochemical visualization of HRP using TMB as the chromagen (Adams, 1980).

No thalamic afferent ingrowth to the transplants was seen in any of the cases which received HRP injections restricted to the VB. Despite the presence of HRP terminal labeling in layer IV immediately adjacent to the transplant and the presence of retrogradely labeled pyramidal neurons in layer VI ventral to some transplants, axons labeled by injection of HRP into the VB were never found to cross the host brain/transplant interface. Injections of HRP into the POm did result in the labeling of a meager thalamic afferent projection to the transplants. Anterogradely labeled axons were found to enter the transplants from the host white matter and layer V and to arborize locally within the transplant parenchyma.

The differential ability of the two thalamic nuclei to innervate the transplants appears to reflect the differential sensitivity of VB and POm neurons to axotomy. Cortical lesions made by transplantation into the SI cortex produced retrograde degeneration in topographically corresponding regions of the VB, as seen in Nissl stained sections and sections reacted for GFAP immunohistochemistry. Neuronal degeneration and the accompanying reactive astrogliosis occur in the POm only following extensive ablation of the somatosensory motor cortex. Focal cortical lesions produced by transplantation into the SI cortex appear to extensively axotomize the VB neurons that project densely to narrow regions of SI but only partially axotomize the POm neurons that project widely and terminate diffusely over several cortical areas. The "sustaining" collaterals of the POm neurons in undamaged regions of the cortex may both protect the nonspecific thalamocortical neurons from retrograde degeneration and allow them to express a capacity for axonal regeneration. (Supported by NIH grant NS13031-09).

287.10 EPENDYMAL CELLS IN HOMOGRAFTS OF RAT E14 FETAL CORTEX TRANSPLANTED TO ADULT RAT SPINAL CORD INDICATE THE ORIGIN AND EPICENTERS OF TRANSPLANT GROWTH. J. J. Bernstein and Yipeng Tang* Lab. CNS Inj. and Regen., V.A. Med. Ctr., Wash., D.C. 20422 and Depts.of Neurosurg. and Physiol., George Washington. Sch. Med., Wash., D.C.

The dividing ventricular layer of fetal cortex and spinal cord differentiates into ependyma approximately at birth or shortly thereafter. Rat cortical ependyma are cuboidal or squamous in shape whereas spinal ependyma are columnar or psuedo-columnar. Cortical and spinal ependymal cells are ciliated and posses villi at the luminal surface. Thirty-eight Sprague Dawley male rats (350g) had E14 fetal rat cotex (0.5X1.0 mm,minced pieces) pressure injected (30g needle on 50ul Hamilton syringe) between the dorsal horn and dorsal column of the spinal cord under the T6 vertebra (N=5, at 7,14,21,30,45,60,90 DPO,and 3 normals). The tissue was prepared for light and electron microscopy. At 7 and 14 DPO there are actively dividing layers of cells. Up to 60 days after transplantation dividing cells differentiate into ependyma (based on cytoplasmic constituents) in the parenchyma of the transplant. By 21 DPO cysts are observed in the transplanted spinal cord which are lined by columnar and psuedocolumnar ependymal cells (derived from the host), cuboidal and squamous ependymal cells at the base of the cortical homograft (derived from the transplant) and neuroglia. Psuedomorphic reactive ependymal cells are also present with cilia and villi on one surface. Ependyma form cilia and villi lined channels or spaces in a myriad of combinations and are joined by tight junctions when contiguous. Within the body of the transplant rosettes are formed by dividing cells, ependymal and subependymal cells. These data show that although the cortical homograft is in spinal cord, which alters the phenotype, cortical ependyma differentiates, indicating the preservation of transplant genotype. In addition, there are multiple epicenters for growth in the transplant as indicated by the location and morphology of ependymal cells. Supported by the Veterans Administration. 287.11 AChE-POSITIVE AXONAL SPROUTING AND REGENERATION ACROSS SCAR TISSUE IN ADULT RAT BRAIN. J.S. Wendt* and K.A. Ayyad* (SPON:H. Feit). Dept. of Neurology, VA Medical Center and iv Unof Tex Health Science Center, Dallas TX 75216.

After hippocampal fimbria transection in the adult rat we have noted that acetylcholinesterase (AChE)-positive fibers (1) have a limited capacity for sprouting and growth over cellular substrata, (2) occasionally grow across a post-traumatic tissue bridge between the septum and caudate nucleus, and (3) can exhibit plexus-like growth in regions of marginal injury. To investigate further the regenerative potential of AChE-positive fibers, the following study was conducted: a 2mm-wide, 3mm-deep incision was made in the right sensorimotor cortex in the coronal plane 1.3mm posterior to the bregma suture line. After survival periods of 0,3 and 6 hours; 1,2,3,4 and 10 days; 2,3 and 4 weeks; and 2 months; the animals were sacrificed, and frozen horizontal brain sections were stained for either AChE (cresyl violet counterstain) or astrocytes by Cajal's gold chloride method.

At 0 hr the brain cytoarchitecture around the lesion was preserved. At 3 hr axonal swelling and a suggestion of growth cone formation was noted at the rostral margin of the lesion. Neurite extension from growth cones was seen at 6 hr. Over time there was further neurite outgrowth, accumulation of AChE stain at the rostral margin of the lesion, and retrograde extension of axonal swelling. By day 7 the rostral and caudal margins of the lesion were apposed, and extensive AChE-positive fiber growth was seen through the scar. Numerous fibers entered the scar rostrally, and many fibers extended from the scar into caudal brain tissue. Progressive reaccumulation of AChE-positive fibers caudal to the lesion occurred up to the 2-month endpoint. Astroglial reaction was evident at day 3, was maximally developed at 2-4 weeks, and was diminished by 2 months.

The results indicate that AChE-positive axons are capable of sprouting and regrowth through scar tissue after trauma in adult rat brain.

287.12 REGENERATED VISUOTECTAL PROJECTIONS OF HETEROTOPIC GRAFT CHIMERIC EYES OF XENOPUS LAEVIS. R. Tompkins, M. Miller*, B. Bartholomew*, B. Szaro and D. Reinschmidt*. Dept. of Biology, Tulane Univ., New Orleans, LA 70118.

Heterotopic grafts of portions of stage 32 eyebuds of Xenopus laevis embryos may develop visuotectal projections which reflect the embryologically determined tectal affinities of the graft. Such mosaic projections have tectal responses that are stimulated by two different areas of the visual field. However, identical grafts may instead develop normal visuotectal projections despite the continued presence of graft-derived retinal ganglion cells in the chimeric eyes. Such regulated projections have been explained in terms of signalling from the host retinal surround. The tectal affinities of retinal ganglion cells of mosaic and regulated chimerae were assessed by visuotectal mapping following intraorbital optic nerve crush and prolonged regeneration.

Pigment and ploidy marked ventral into dorsal heterotopic grafts were performed at stage 32 and the visuotectal maps of the chimeric eyes assessed 3-6 weeks after metamorphosis. Unoperated control eyes with normal visuotectal projections at that age required 3 to 6 months to regenerate normal projections. Therefore, mapping of regenerated visuotectal projections of chimeric eyes was done after 6 months of regeneration. Heterotopically grafted chimeric eyes with mosaic projections after metamorphosis regenerate mosaic projections. Those with initially regulated visuotectal projections yielded two visuotectal projection patterns following regeneration. Eleven of 16 animals regenerated mosaic maps. This result was correlated with the presence of graft-derived retinal ganglion cells in the chimeric eye. The duplicated visual fields occupied that portion of visual space viewed by the graft-derived cells and elicited responses in those portions of the tectum predicted by the position of origin of the grafts. Five of the 16 animals regenerated regulated projections but this result was correlated with the absence of retinal ganglion cells derived from the graft in these eyes. These results suggest that heterotopic grafts which develop normal visuotectal projections do not do so because of changes in the embryologically determined tectal affinities of the retinal ganglion cells. Rather, these results suggest that the dynamics of eye growth and fasciculation of the retinal ganglion cell axons can subvert the determination of the grafted cells. Signalling resulting in changes in positional information need not by invoked to explain regulated patterns. Indeed, such changes in determination are incompatible with the regeneration of mosaic projections from initially regulated projections.

## SPECIFICITY OF SYNAPTIC CONNECTIONS II

288.1 SPECIFIC REGENERATION OF DEVELOPING SPINAL MOTONEURONS IN THE ABSENCE OF PERIPHERAL SENSORY FIBERS. Paul B. Farel and Sibyl E. Bemelmans*. Dept. of Physiology, Univ. N. Carolina Sch. of Medicine, Chapel Hill, NC 27514.

Horseradish peroxidase (HRP) applied to circumscribed hindlimb regions of the bullfrog tadpole (Rana catesbeiana) retrogradely labels motoneurons located in particular regions of the lumbar lateral motor column (LMC). The localization of retrogradely labeled motoneurons has been used to assess the specificity of neuromuscular connectivity during early development (J. Comp. Neurol., in press) and after regeneration of motor axons following ventral-root transection (Soc. Neurosci. Abstr., 9:373, 1983).

At early stages of development, retrogradely labeled motoneurons are as localized along the dorsal-ventral and rostral-caudal axes of the LMC as they are in juvenile frogs. Following ventral rhizotomy before st. VI, retrogradely labeled motoneurons are as localized as in unoperated tadpoles. When ventral roots were transected between st. VI and VIII, localization following regeneration is present along the dorsal-ventral axis but is lost along the rostral-caudal axis. Localization of retrogradely labeled motoneurons is largely lost in tadpoles operated after st. IX. We are interested in the cues which guide regenerating axons to the appropriate limb regions at early developmental stages.

Sensory axons, particularly muscle afferents, could serve as a source of guidance information. For example, muscle spindle afferents, which normally make monosynaptic contact with the motoneurons supplying that muscle, may provide cues that can be read by motor axon along their regenerative course. To test this possibility, the dorsal and ventral roots were transected and the dorsal root ganglion removed in the three spinal segments that provide innervation to the hindlimb. Despite the fact that this operation left a 2-3 mm gap between the proximal stump of the ventral root and the distal stump of the spinal nerve, the hindlimb was usually reinnervated during the 6-8 week postoperative survival period. Following application of HRP to circumscribed regions of the hindlimb, retrogradely labeled motoneurons were as localized in the LMC as in tadpoles that had undergone ventral-root transection without damage to sensory fibers. At st. V, localization along both the dorsal-ventral and rostral-caudal axes of the LMC was found. Between st. V and VIII, localization was present along the dorsal-ventral axis, but was not evident along the rostral-caudal axis. Thus, neither peripheral nor central branches of sensory fibers appear to be necessary for motoneurons to regenerate to appropriate limb regions.

288.2 THE SOMITIC ORIGIN OF LIMB MUSCLES IN THE CHICK EMBRYO: A CORRELATION WITH MOTOR INNERVATION. C. Lance-Jones. Dept. of Anatomy and Cell Biology, Sch. of Med. and Ctr. for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15261.

There is good evidence in the chick embryo that limb innervating motoneurons show a considerable selectivity for paths or targets within the limb, yet the developmental basis for this selectivity is not known. Studies of the reinnervation of transplanted mammalian trunk muscles suggest that target selectivity may be based on a positional quality shared by neurons and their targets (Wigston, D.J. and Sanes, J.R., Nature, 299:464, 1982). As a first step in addressing this hypothesis in the chick limb system, I have examined the relationship between the somitic level of origin of myogenic cells within limb targets and their segmental innervation pattern. One to two identified lumbosacral (LS) somites were transplanted from stage 15-17 quail embryos to an equivalent position in similarly staged chick embryos. Some overlying ectoderm was frequently included in the transplant, however its presence or absence did not appear to affect results. Chimeras were sacrificed at stage 27-31. Serial sections were stained by the Feulgen method and examined for the presence of quail cells within individual limb muscles.

Myogenic cells arising from a specific quail somite or pair of somites populated a discrete subset of limb muscles. For example, following transplantation of anterior somites such as LS 1 or 2, quail cells were found only in anterior thigh and pelvic muscles; following transplantation of posterior segments such as LS 5 and 6, quail cells were present only in posterior thigh and shank muscles. The pattern of somitic contribution to an individual chick muscle appeared to relate to its known segmental innervation pattern. For example, the sartorius, a muscle normally innervated in the chick by spinal cord segments LS 1 and 2, contained quail cells only when somites LS 1 or 2 were transplanted. While the specific somitic origin of all limb muscles has yet to be determined, in all embryos examined (n=13) transplanted somites only contributed to muscles or muscle regions normally innervated by cord segments adjacent to the transplant region.

These data indicate a correlation between the axial level of origin of motoneurons and the myogenic cells of their target. Somite manipulations are presently being carried out to determine whether target or pathway choice might be based on these shared positional characteristics.

288.3 SELECTIVE REINNERVATION OF AXOLOTL LIMB MUSCLES. D. J. Wigston. Physiology Department, Emory University, Atlanta, GA 30322.

Mammalian intercostal muscles transplanted from different thoracic segments to the neck are selectively reinnervated by subsets of the autonomic preganglionic axons in the cervical sympathetic trunk that originate from appropriate rostro-caudal levels of the spinal cord (Wigston and Sanes, Nature 299:464, 1982; J. Neurosci. 5:1207, 1985). Previous work on the regeneration of motor nerves to mammalian limb muscles, however, indicated a lack of specific reinnervation. The difference between these results suggests two possibilities: 1) regenerating motor axons may lack the selectivity expressed by preganglionic axons, and 2) individual limb muscles, which each develop from several somites, may lack the unique recognition labels that segmented intercostal muscles seem to have. I am presently examining this further by studying the reinnervation of axolotl hindlimb muscles.

To test if limb muscles can be selectively reinnervated by motoneurons I transplanted individual muscles, whose segmental innervation I had determined in other experiments, to new positions in the limb and studied the segmental origin of the axons that reinnervated them. This approach provides a more direct test of the existence of target recognition cues than limb denervation or rotation experiments which require axons to regenerate over long distances to their original muscles. I removed two adjacent knee extensors, the anterior and posterior iliotibialis (ILT), which have distinct segmental innervation patterns, and exchanged them so that the original anterior ILT occupied the site normally inhabited by the posterior ILT, while the posterior ILT assumed the position vacated by the anterior ILT. Intracellular recording 6-13 weeks later showed that both muscles were reinnervated according to their initial rather than their new position. The innervation of transplanted anterior ILT muscles was consistently of more rostral origin than that of transplanted posterior ILT muscles, and closely resembled that of control anterior ILT muscles removed and reimplanted in their original position.

These results show that 1) regenerating motor axons, as well as preganglionic axons, are capable of selective synapse formation; and 2) different limb muscles, like intercostals, can be distinguished from one another by regenerating axons. The existence of a mechanism for selective synapse formation that can contribute significantly to the restoration of specific nerve-muscle connections suggests that the reason transected limb nerves fail to re-establish specific connections in adult mammals is that regenerating axons fail to reach the vicinity of their original muscle and therefore do not reveal their target preference. (Supported by NIH grant NS20965.)

288.4 THE EFFECT OF BLOCKING FUNCTIONAL ACTIVITY AND MOTONEURON CELL DEATH ON THE ACTIVATION PATTERNS OF CHICK LUMBOSACRAL MOTONEURONS. L. Landmesser, M. Szente*, and L. Dahm. Dept. of Physiology and Neurobiology. Univ. of CT, Storrs, CT 06268.

Chronically applied neuromuscular blocking agents have been shown to prevent normal motoneuron cell death during development of the chick lumbosacral spinal cord (Pittman & Oppenheim, J. Comp. Neurol. 187: 425). Since cell death has been implicated in refining neural circuits, we investigated the effect of daily in-ovo doses of dTC sufficient to block activity and cell death on the activation patterns of hindlimb motoneuron pools; these were assayed by EMG or muscle nerve recordings in isolated spinal cord-hindlimb preparations at st 36.

Chronically treated preparations, where motoneuron death was later shown to be completely blocked, were isolated and allowed to recover in Tyrodes. Although the neuromuscular junctions rapidly recovered and could be activated by direct spinal nerve stimulation, the cords were unable to produce the patterned bursts characteristic of control preparations for several hours. However, with sufficient washing (5-7 hrs) the cords recovered and were able to produce typical alternating sequences of flexor and extensor activity that differed only slightly from control cords. The blockade of patterned activity and the minor changes that persisted after washing appeared to be due to a direct effect of dTC on the spinal cord. This was confirmed by showing that similar effects were brought about by single in-ovo injections of dTC 10 hrs prior to sacrifice or by bath application of $1 \times 10^{-6}$ M dTC to isolated cords. We also found that bath-applied αBTX (3-4 μg/ml) in concentrations sufficient to block the neuromuscular junction also prevented patterned bursting in isolated cords.

We conclude that some cholinergic circuits within the cord that are necessary for patterned activation of motoneurons are blocked by in-ovo levels of dTC and αBTX required to block the neuromuscular junction. It is therefore possible that other similarly applied drugs may also have direct effects on the CNS. However, since cords which recovered from the drugs were able to produce normal activation patterns, we also conclude that neither motoneuron cell death nor the patterned activation of motoneurons is needed for the development of the basic neural circuits responsible for the normal alternating pattern of flexor and extensor motoneuron activation.

288.5 PHENOTYPE AND NEURAXIS POSITION OF FETAL MOUSE SPINAL CORD NEURONS DETERMINE THE AMOUNT OF CHOLINERGIC PROJECTIONS INTO CO-CULTURED SUPERIOR CERVICAL GANGLIA. A.Chalazonitis, S.M.Crain and J.A.Kessler#. Depts. of Neuroscience and Neurology#, Albert Einstein Coll. of Medicine, Yeshiva University, Bronx, N.Y. 10461

The specificity of CNS innervation of sympathetic ganglia was analyzed with organotypic explants of fetal mouse spinal cord (E13-14) and superior cervical ganglion (SCG;E17). Meninges-free cord from upper thoracic levels (C8-T4) was dissected in "open-book" orientation and cut longitudinally into dorsal (D), medial (M) and ventral (V) strips. To reduce surgical damage to the autonomic preganglionic neuron population in M cord, strips consisting of both M+D and M+V cord were prepared for comparison with isolated D and V strips. Unilateral strips were co-cultured with a single SCG; bilateral strips with a pair of SCGs.

Fascicles of neurites formed bridges across the gaps (0.5-1 mm) between the cord and SCG explants. After 4 wks of maturation in vitro, cholinergic projections into SCGs were quantitated by choline acetyltransferase (ChAT) assays of individual ganglia. ChAT activity (pmole product/ganglion/hr) was 98±12 (n=15) in SCGs co-cultured with MD cord, as compared to only 15±2 (n=24) in SCGs co-cultured with D cord and 10±1 (n=18) in SCGs grown alone. Similarly, SCGs co-cultured with MV cord contained higher ChAT activity (72±7; n=44) than those with V cord (35±5; n=18). Furthermore, co-culture of MV cord with an inappropriate target, lumbar dorsal root ganglion (DRG), elevated ChAT activity in this ganglion by < 18% of the value in similarly co-cultured SCGs.

Transverse sections of cord from different levels of the neuraxis were also co-cultured with pairs of SCGs. ChAT activity in SCGs co-cultured with T5 and T1/T2 cord was remarkably high: 317±87(n=6) and 176±18 (n=33), respectively, whereas SCGs with less appropriate levels of the cord, T9 and L2/L3, contained less enzyme activity:89±20 (n=10) and 18±4 (n=11). Electrophysiologic analyses and control tests are in progress to ascertain that the increased ChAT activity in co-cultured SCGs does, in fact, reflect innervation by specific cord neurites.

These data suggest: I) phenotypic preference for (a)'innervation' of SCGs by co-cultured cholinergic, presumably autonomic preganglionic, neurons located in medial cord, rather than by dorsal or ventral cord neurons; and (b) projections by cholinergic cord neurons into appropriate SCG targets rather than inappropriate DRG tissue; II) positional preference for 'innervation' of SCGs by appropriate cord neurons in upper thoracic levels. These conclusions are consistent with studies of specificity of sympathetic ganglion innervation by cord neurons in situ (Lichtman et al, J.Physiol.'80; Rando et al, J.Comp. Neurol.'81; Rubin, J.Neurosci.'85). Supported by NINCDS research grants 17572 (AC), 20778 & 20013 (JK).

288.6 SUBPOPULATIONS OF SYMPATHETIC NEURONES DIFFER IN THEIR REGENERATIVE CAPACITIES AND THEIR RESPONSES TO POSTNATAL REMOVAL OF NERVE GROWTH FACTOR. C.E. Hill*, I.A. Hendry*, M.C. Ngu* and D.F. van Helden*. (SPON: S.J. Redman). Dept. of Pharmacol., John Curtin Sch. of Med. Res., Canberra, A.C.T. Australia, 2601.

Rapid freezing of a mesenteric artery supplying the ileum of the rat leads to a sympathetic denervation of the artery distal to the point of freezing and of the enteric neurones within the segment of gut supplied by that artery (Furness, J.B., Histochemie, 21: 295, 1970). In the subsequent weeks after this operation, there is a more rapid return of sympathetic control of gut motility than of arterial contractility, the early regenerating fibres growing alongside the denervated artery to reach the enteric neurones. Since sympathetic denervation has been reported to result in an increase in nerve growth factor (NGF) in target tissues (Ebendal, T. et al., Nature, 286: 25, 1980), we have investigated whether the populations of sympathetic neurones innervating the mesenteric arteries and enteric neurones are differentially sensitive to NGF.

Neonatal rats were injected daily with antiserum to NGF (kindly supplied by Dr. R.A. Rush) or saline for the first postnatal week. Mesenteric arteries and segments of ileum were tested both physiologically and histochemically for the presence of a sympathetic innervation when the animals were 4 and 8 weeks old. At both ages, stimulation of the paravascular nerves in animals treated with anti-NGF led to a decrease in spontaneous gut motility, while a single perivascular stimulus failed to elicit the excitatory junction potential seen in control arterial preparations, nor did repetitive stimulation produce arterial constriction. Fluorescence histochemistry confirmed that the intramural ganglia were innervated by noradrenergic fibres in a manner similar to that of control animals while the mesenteric arteries of the same treated animals completely lacked a sympathetic innervation. Retrograde labelling of nerve cell bodies with the fluorescent dye, fast blue, in control and antiserum treated rats showed that the neurones innervating the intramural ganglia were situated in the prevertebral, coeliac and superior mesenteric ganglia and in ganglia along the greater splanchnic nerves (splanchnic ganglia). By inference from studies in control animals in which both populations of cells were labelled, the neurones supplying the mesenteric arteries were located in prevertebral and splanchnic ganglia and in the thoracic and lumbar paravertebral sympathetic chains.

We conclude that the sympathetic neurones innervating the mesenteric vasculature require NGF postnatally for their survival, while those innervating the enteric ganglia do not. The neurones comprising these two populations appear to overlap considerably in their distributions throughout the prevertebral and splanchnic ganglia although only neurones supplying the blood vessels are found in the paravertebral chains.

288.7 CLUSTERED SYNAPSE FORMATION BY EARLY REGENERATING RETINOTECTAL FIBERS PRECEDES THE SUBLAMINAR REDEPLOYMENT OF RETINAL CONNECTIONS. W.P. Hayes and R.L. Meyer. Developmental Biology Center, University of California, Irvine 92717.

After optic nerve crush in goldfish retinotopically appropriate tectal connections are regenerated in two phases. During the first 40 days gross retinotopography is reformed without impulse activity. The development of refined retinotopography over the next several months is activity-dependent(Meyer, 1983, Dev. Brain Res. 6:293). In this study the horseradish peroxidase(HRP) labeled retinotectal projection to the Optic Fiber(SO) and Superficial Fiber and Gray(SFGS) layers has been examined by electron microscopy. Successful labeling was carried out as early as two weeks after crush in fish maintained at 20 degrees Centigrade at which time numerous labeled synaptic contacts were seen and this represents the earliest demonstration of specifically labeled synapse formation in this system. Interestingly, many HRP-labeled retinal synapses are concentrated into large discrete clusters consisting of labeled unmyelinated axons, labeled vesicle-containing synaptic profiles and unlabeled post-synaptic processes. The density of HRP-labeled unmyelinated axon bundles and clusters containing HRP-labeled synaptic profiles increased dramatically in goldfish three and four weeks after optic nerve crush.

At 30 days after crush no sublaminar deployment of labeled retinal afferents is evident. In contrast, in normals, quantitative analysis of labeled retinal afferents from overlapping electron micrographs representing a column through the SO-SFGS shows that the primary innervation layer consists of six sublaminae of optic fibers and terminals. Preliminary electron microscopic results indicate that the normal laminar pattern of retinal afferents is discernible at 60 days after crush. Subsequently, six months after crush, the unmyelinated axon bundles have disappeared, large fascicles of labeled myelinated optic fibers are restricted mainly to the SO and the normal sublaminar pattern of labeled retinal synapses is restored.

These findings indicate that the laminar pattern of retinotectal connectivity arises from a reorganization of retinal synaptic clusters and that the laminar reorganization of retinotectal afferents in the SO-SFGS is temporally correlated with the transition from gross to refined retinotopography. The bundling and clustering of early regenerating retinal fibers and terminals implicates direct interactions between retinal fibers during the early phase of retinotectal regeneration.

In addition, we show that optic fibers regenerating under continuous tetrodotoxin blockade of nerve impulse activity form numerous synaptic contacts twelve weeks after crush and these HRP-labeled retinal afferents appear to be deployed in a sublaminar fashion. PHS Grants HD-07029 and NS-16319.

288.8 TECTAL INTERACTIONS INFLUENCE THE RECOVERY FROM INJURY OF GOLDFISH RETINAL GANGLION CELLS. D.W. Burmeister*[1], A.A. Dunn-Meynell*[2] and B. Grafstein[1]. [1]Dept. of Physiology, Cornell University Medical College, New York, NY 10021, and [2]Dept. of Ophthalmology, New York Medical College, Valhalla, NY 10595.

Following axonal injury the retinal ganglion cells (RGCs) of the goldfish exhibit an increase in size, uptake of amino acids, and amount and velocity of axonal transport, reaching a peak when the regenerating optic axons contact the appropriate (contralateral) lobe of the optic tectum, then returning to near normal levels by 12W after injury. Removal of the tectum greatly extends the time required for RGC recovery (Burmeister and Grafstein, 1985, Brain Res 327:45).

When the normal target site for the RGC axons is removed, the regenerating fibers form synapses at alternative sites. For example, when half of an optic tectal lobe is ablated there is a synaptic rearrangement leading to compression of the entire visual field onto the remaining tectal remnant (Gaze and Sharma, 1970, Exp Brain Res 10:171; Murray et al. 1982, J Comp Neurol 209:374).

We examined the RGC changes following either removal of the caudal portion of the optic tectum or after a mid-lobe transverse transection. The resident fibers of the remaining rostral tectum were then either left intact or made to relinquish their tectal termination sites by a crush of the optic nerve. --Following a tectal transection without nerve crush, only the RGCs normally projecting to the caudal tectum (those in the nasal retina) increased in size, reaching a maximum at 2W after injury and then declining to near normal size by 6W. --Following a tectal transection and nerve crush, RGCs in temporal as well as nasal retina initially increased in size and by 12W had declined from peak levels to values 20% larger than normal. --Following caudal tectal ablation without nerve crush, nasal cells alone increased in size initially, and remained 45-50% larger than normal after 12W. --After a caudal tectal ablation and nerve crush, all the RGCs in the retina increased in size. But at 12W after the injury cells in the nasal retina remained 50% larger than normal while cells in the temporal retina were 20% larger than normal.

These results show that the increased competition for synaptic targets in a reduced tectal field led to a prolongation of the regenerative state only among the "foreign" nasal RGCs. Temporal cells recovered from injury equally well in the presence or absence of the caudal tectum and the invading nasal fibers.

288.9 SYNAPTIC ORGANIZATION OF ANOMALOUS RETINAL TERMINALS WITHIN SOMATOSENSORY THALAMUS AFTER NEONATAL BRAIN LESIONS IN HAMSTERS. G. Campbell* and D.O. Frost. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510,

If the superior colliculus and dorsal lateral geniculate nucleus (LGd) are ablated and the ventrobasal nucleus (VB) is partially deafferented in the Syrian hamster on the day of birth, the normally transient neonatal retino-VB projection (Frost, J. Comp. Neurol., 230:576, 1984) becomes permanently stabilized and sprouts (Frost, J. Comp. Neurol., 203:227, 1981). This study was undertaken to determine whether the anomalous, permanent retino-VB axons form synapses with VB neurons. In 8 neonatally operated, adult hamsters the anomalous projections were labeled by intravitreal injections of horseradish peroxidase; VB sections were then reacted with modified Hanker-Yates and tetramethyl benzidine protocols and processed for electron microscopy. VB and LGd material from unoperated adult animals with and without eye injections was also examined. Reaction product was clearly visible in retino-VB axons and their terminals. Labeled terminals were of variable size and shape and contained round synaptic vesicles and pale mitochondria. In these respects they were similar to retinal terminals in normal LGd (So et al., Anat. Embryol., 171:223, 1985). Labelled retino-VB terminals were almost exclusively located in well-differentiated glomeruli where they formed Gray type 1 synapses with invaginating spines arising from the proximal dendrites of presumptive thalamocortical relay cells. They also established filamentous and adherens contacts with relay cell dendritic shafts. Some labeled terminals appeared larger and were presynaptic to more invaginating dendritic spines than retinal terminals in normal LGd. In these respects they closely resembled presumptive somatosensory lemniscal terminals in normal VB, although they lacked the dark mitochondria of lemniscal terminals. Boutons containing flattened synaptic vesicles and resembling the likely inhibitory F-boutons of normal rodent thalamus made Gray type 2 synapses adjacent to, or opposite, labeled terminals on the same dendritic shaft. This arrangement is rarely found in normal LGd glomeruli which have presynaptic dendritic appendages as their probable inhibitory component. However, F-boutons are characteristic of normal VB glomeruli which lack presynaptic dendrites. These results demonstrate that in neonatally operated hamsters, anomalous retino-VB axons form well-differentiated synapses with thalamocortical relay cells. Although some anomalous retino-VB terminals resemble retinal terminals within normal LGd, others have synaptic relationships more similar to those of somatosensory lemniscal terminals. This suggests that the differentiation of some retinal terminals is influenced by their targets. Supported by NIH Grant EY03465, March of Dimes Grant 5-417, and a Burroughs-Wellcome Bridging Grant.

288.10 THE ROLE OF THE TARGET IN THE FORMATION OF THE OLFACTORY GLOMERULUS. J.A. Heckroth*, E.E. Morrison, P.P.C. Graziadei and G.A. Monti Graziadei. Department of Biological Science, Florida State University. Tallahassee, FL 32306

The glomerulus in the intact olfactory bulb of mammals is composed of three fundamental elements: a) the input fibres, i.e. the olfactory sensory axons, b) the target, i.e. the dendritic branches of the mitral cells, c) the interconnecting element, i.e. the periglomerular cells. At the LM level the glomerulus can be recognized as a globose structure, some 100 microns in diameter with boundaries well defined from the surrounding brain parenchyma. Previous observations in our laboratory have shown that the glomeruli do not necessarily need the mitral cells or periglomerular cells profiles for their formation. In partial bulbectomies we have observed glomerular structures in the granular layer of the bulb. In total bulbectomy experiments glomeruli have been observed in several regions of the telencephalic cortex. However, while axons originated from the entire sensory sheet of the nasal cavity invariably form glomeruli in several regions of the brain, fragments of the olfactory epithelium transplanted in those regions fail to do so. We have postulated that glomeruli are formed by mutual recognition between complementary sets of sensory axons, originating from different areas of the sensory sheet, even independently of any specific target.

To investigate this hypothesis we have transplanted discrete areas of rat olfactory epithelium or the entire olfactory anlage in four selected regions of rat hosts: 1) the anterior chamber of the eye, 2) the lateral cerebral ventricle, 3) the parietal cortex, 4) the olfactory bulb. Fibre bundles from fragments of the neuroepithelium never formed glomeruli, while fibre bundles comparable in size from the entire nasal anlage were consistently able to form glomeruli. These glomerular formations were different from common neuromataor from axon curls at both LM and TEM levels. At the ultrastructural level they were composed of sensory axon terminals arranged in tangles and showing spurious synaptic contacts between sensory fibres or between the latter and glial profiles. Thus, we can redefine glomeruli as a tangle of sensory axon terminals provided with vesicles and arranged in a discrete, globose formation. It appears that recognition between sensory fibres, even in the absence of any other target, is a prerequisite and sufficient condition for the formation of glomerular structures, so far as complementary populations of sensory axons can intermingle. The mechanisms by which sensory axons specifically recognize mitral cells in normal development seems to be secondary to the primary reciprocal recognition between subsets of primary sensory axons.

288.11 GAP JUNCTIONS IN THE BRAINSTEM RETICULAR FORMATION: A GOLGI-EM STUDY. J. Quattrochi* (SPON: M. Marin-Padilla). Departments of Neuroscience, Children's Hospital and Neuropathology, Harvard Medical School, Boston, MA 02115.

Five isodendritic magnocellular neurons in the nucleus gigantocellularis of the mouse medullary reticular formation were examined with combined rapid Golgi-EM after fixation with buffered 5% glutaraldehyde and 4% paraformaldehyde. The multipolar somata of these five cells measured approximately 22x34 um with 3-5 dendrites extending from the cell body. Selected cells were cut initially into 2 um serial sections transverse to the longitudinal axis of the brainstem, re-embedded, and selected sections from the series were serially sectioned at 60 nm. Ultrastructural profiles of these de-impregnated cells were identified by the gold particles in their cytoplasm. Each individually gold-toned neuron was examined with particular attention to dendritic synaptic profiles. In addition to synaptic boutons forming symmetric and asymmetric synapses, 9 gap junctions were seen between gold-toned and unimpregnated dendrites. Gap junctions were located 80-200 um from the cell soma. They were found in 4 animals between the ages of 5 and 20 postnatal days. Each demonstrated characteristic ultrastructure and measured 0.2-0.5 um in diameter. All gap junctions were seen along primary dendrites: 6 located distal and 3 proximal to an initial dendritic branch point. One gap junction was seen between two de-impregnated dendrites in linear parallel apposition to each other. Computer reconstruction of 26 serial 60 nm sections of this particular junction site revealed a dendritic contact measuring 1.6 um in length with a single gap junction of approximately 0.3 um in diameter. Ultrastructural evidence of gap junctions hitherto unrecognized on neurons within the brainstem reticular formation is presented. Supported by NIH grants NS20822, NS07264, NS20820.

288.12 USE OF CELL SURFACE-DIRECTED MONOCLONAL ANTIBODIES TO ISOLATE AND STUDY CULTURED NEURONAL SUBPOPULATIONS FROM THE DEVELOPING MOUSE CNS. U. di Porzio, G. Rougon*, J. Mazzetta*, W. Kell* and J.L. Barker. Laboratory of Neurophysiology, NINCDS and Laboratory of Cell Biology, NIMH, NIH, Bethesda, Md. 20205; Institute of Molecular Embryology, CNR, Naples, Italy

Primary cultures of central and peripheral neurons have been extensively used in recent years to study development of functional connections during neurogenesis. For example, we have shown in previous work that target neurons from the striatum and/or cerebellum specifically stimulate uptake and synthesis of catecholamines in the presynaptic dopaminergic or noradrenergic neurons (di Porzio et al., Nature, 288:370, 1980; Dev. Brain Res., 16:147, 1984). A major limitation of primary culture systems is that many cell types survive in vitro with consequent high heterogeneity in the cultures; in many instances the class of neurons under study accounts for a relatively minor proportion of the total cell population. Therefore the isolation and subsequent enrichment in culture of neurons with specific neurotransmitter phenotypes is an important goal in developmental study of the nervous system.

We have used several monoclonal antibodies (MAb) raised in rats immunized against weaver mouse cerebellar membranes that recognize surface glycoproteins differentially expressed in neuronal subpopulations (Rougon et al.,Neurosci., 10:511, 1983; J. Neuroimmunol., 6:411, 1984). The MAbs NSP4 and NSP5 have been used first to identify subpopulations of neurons in cell cultures from the embryonic mouse mesencephalon and brain stem. In these cultures about 15% of the neuronal population appeared to be NSP4+ at early (2 days) and late (10 d) stages in vitro whereas NSP5 recognizes a subpopulation of neurons only in 10 d cultures thus indicating a developmental regulation of the surface antigens recognized by the two MAbs. Flow cytometric analysis with a FACS 440 showed that about 20% of cells freshly dissociated from mouse E13 mesencephalon and E15 basal ganglia were NSP4+. The NSP4+ population sorted by FACS and plated over different substrata showed optimum attachment to a feeder layer of brain astrocytes. Under these conditions the majority of the sorted cells exhibited neuronal morphologies after 2-3 days in culture and exenteded neurites as shown by immunohistochemistry with MAb anti neurofilament. We conclude that NSP4 can be used to separate subpopulations of neurons at various stages of embryonic development. Further studies will establish whether MAbs NSP4 and NSP5 can be used to isolate homogeneous subsets of neurons according to their neurotransmitter phenotype and/or stages of neuronal differentiation.

## ACETYLCHOLINE II

289.1 EFFECT OF PIPERIDINE ANALOGS OF HEMICHOLINIUM-3 ON HIGH AFFINITY UPTAKE OF CHOLINE. J.P. Long*, T.K. Chatterjee*, J.G. Cannon*, and R.K. Bhatnagar, (SPON: W.J. Steele). Department of Pharmacology, University of Iowa, College of Medicine, Iowa City, Iowa 52242

We have reported that quaternary and tertiary analogs of 4-methyl piperidine derivatives of hemicholinium-3 (HC-3) are potent inhibitors of rabbit neuromuscular transmission (Fed. Proceed. 43: 342, 1984). In this study we evaluated the effect of 4-methyl as well as 4-hydroxy derivatives of HC-3 on $Na^+$ dependent high affinity choline uptake (HACU) in rat caudate synaptosomal preparations. At low concentrations (2-4 nM) HC-3 facilitated HACU by 10-15% while at higher concentrations it inhibited HACU with an $IC_{50}$ value of 20 nM. The tertiary analog of HC-3, 4-methyl piperidine derivative ($A_4$), produced a similar biphasic response, an initial uptake facilitation (20-40%) at concentrations between 2 and 8 nM and inhibition at higher concentrations with an $IC_{50}$ value of 40 nM. The quaternary analog of HC-3, N-methyl 4-methyl piperidine derivative ($A_5$), however, did not elicit a biphasic response but potently inhibited HACU with an $IC_{50}$ value of 2.4 nM, a concentration at which both HC-3 and $A_4$ stimulated this uptake. The kinetic characteristics of HACU inhibition by HC-3 and $A_5$ were different also. While HC-3 inhibited HACU competitively, $A_5$ inhibition was noncompetitive with the following apparent $K_m$ and $V_{max}$ values:

| | $K_m$(μM) | $V_{max}$ (pmole/4 min/mg protein) |
|---|---|---|
| Control (n=3) | 1.4 ± 0.06 | 107 ± 12 |
| HC-3-10nM (n=3) | 2.5 ± 0.20* | 112 ± 8 |
| $A_5$-1 nM (n=3) | 1.4 ± 0.09 | 87 ± 7* |

(* Significantly different from control, $P < 0.05$)

The effects of both $A_5$ and HC-3 on HACU inhibition were reversible since washing of the drug-treated synaptosomes with drug-free buffer restored normal HACU. Quaternary and tertiary analogs of 4-hydroxy piperidine derivatives of HC-3, in contrast to 4-methyl derivatives discussed above, were inactive either in affecting rabbit neuromuscular transmission or HACU.

These results indicate that, unlike 4-hydroxy piperidine derivatives, both tertiary ($A_4$) and quaternary ($A_5$) 4-methyl piperidine derivatives of HC-3 are potent inhibitors of $Na^+$ dependent high affinity uptake of choline. Furthermore, $A_5$ may inhibit this choline uptake by a mechanism different from that of HC-3 and $A_4$, and may be useful in further characterizing the mechanism for high affinity uptake of choline in the biosynthesis of acetylcholine. This work supported in part by the U.S. Army Medical Research and Development Command under Contract DAMD-17-83-C-3010.

289.2 CHARACTERISTICS OF [$^3$H]HEMICHOLINIUM-3 BINDING IN RAT BRAIN CAUDATE MEMBRANE PREPARATIONS: EQUILIBRIUM, KINETIC AND COMPETITIVE BINDING STUDIES. T.K. Chatterjee*, J.G. Cannon*, J.P. Long*, and R.K. Bhatnagar. Department of Pharmacology, University of Iowa, College of Medicine, Iowa City, Iowa 52242

Cholinergic nerve terminals have the unique ability to accumulate choline inside nerve terminals via a sodium dependent high affinity uptake system. Hemicholinium-3 (HC-3), a competitive inhibitor of this uptake process, appears to be a sensitive probe to label and characterize this carrier site in vitro. In this study we examined the equilibrium, kinetic and competitive binding characteristics of [$^3$H]HC-3 in twice-washed homogenate of rat brain caudate tissue at 25°C in 50mM $Na^+/K^+$ phosphate buffer, pH 7.4, containing 150mM NaCl. Nonspecific binding was estimated in the presence of 1μM unlabeled HC-3.

Scatchard analysis of equilibrium binding data indicates at least two binding sites for [$^3$H]HC-3, one with high affinity ($K_d$ 1.5nM) and low capacity ($B_{max}$ 80 fmol/mg protein) and other with low affinity ($K_d$ 30nM) and high capacity ($B_{max}$ 400 fmol/mg protein). The dissociation of [$^3$H]HC-3 from its binding sites, induced by infinite dilution with buffer, proceeded in a multi-exponential manner with a fast and a slow dissociating component and the dissociation rate was accelerated when unlabeled HC-3 was included in the diluting buffer. The association of varying concentrations of [$^3$H]HC-3 with its binding sites was also non-linear. The displacement studies demonstrated that HC-3 and choline displace [$^3$H]HC-3 with a Hill coefficient (nH) of less than unity. At 12nM concentration of [$^3$H]HC-3 the $IC_{50}$ values for HC-3 and choline for displacement were 30 nM and 0.6 μM respectively, while at 1 nM [$^3$H]HC-3, these values were 8 nM and 0.15 μM, respectively.

These results suggest the presence of at least two binding sites for HC-3. The accelerated dissociation of [$^3$H]HC-3 by competitive displacement and nH of < 1 for [$^3$H]HC-3 displacement by HC-3 and choline suggest the possibility of a ligand induced occupancy dependent conversion of the high affinity binding state to low affinity one. Since the affinities of HC-3 and choline for the low affinity site correspond to their affinities in affecting choline uptake process, the low affinity state, induced by ligand occupancy, may represent the active choline carrier site. This work supported in part by the U.S. Army Medical Research and Development Command under Contract DAMD-17-83-C-3010.

289.3 RAPID REGULATION OF $^3$H-HEMICHOLINIUM-3 ($^3$H-HCh3) BINDING SITES IN THE RAT CEREBRAL CORTEX AND STRIATUM. P.R. Lowenstein, B. O'Hara* and J.T. Coyle. Dept. of Neuroscience. Johns Hopkins University School of Medicine, Balto., MD 21205.

The velocity of the sodium-dependent high affinity choline uptake (SDHACU) is regulated by the antecedent activity of cholinergic neurons, consistent with SDHACU being the rate-limiting step in the synthesis of acetylcholine (ACh). The mechanisms responsible for the rapid changes in SDHACU velocity have not yet been elucidated. Recent studies indicate that [$^3$H]HCh-3, a potent inhibitor of SDHACU, labels the choline carrier in brain homogenates. In order to characterize the mechanisms involved in SDHACU regulation, we studied the acute effects of drugs known to affect cholinergic neuronal activity on [$^3$H]HCh-3 binding in the cerebral cortex and corpus striatum of the rat. The drugs were administered by IP injection and the rats were sacrificed 30 min later. Extensively washed membranes were prepared from the cortex and the striatum for specific binding of [$^3$H]HCh-3 (10uM). Results are mean + SEM of 4 or more rats. Atropine (20mg/kg) and scopolamine (5mg/kg), two cholinergic antagonists which increase ACh turnover and SDHACU, elicited an 85+11% and 63+4% increase respectively in [$^3$H]HCh-3 binding in the cortex. In the striatum, atropine increased the binding by 66+5%, while oxotremorine (2mg/kg), a cholinergic agonist which decreases cholinergic nerve activity and SDHACU, decreased the binding by 43+18% in the cortex and 32+9% in the striatum. Cholinergic neurons in the striatum, but not in the cortex, are under inhibitory dopaminergic control. Treatment of rats with haloperidol (4mg/kg, 1hr), a dopaminergic antagonist which increases striatal ACh turnover and SDHACU, increased total binding in the striatum by 23+5%. Pentobarbital (65mg/kg), a general anesthetic agent, decreased total binding by 38+18% in the cortex and 30+8% in the striatum, while pentylenetetrazole (75mg/kg), a convulsant agent, increased total binding in both the cortex (17+4%) and striatum (26+3%) by the time of convulsion's onset. Scatchard analysis of saturation isotherms for [$^3$H]HCh-3 under different treatment conditions revealed that alterations in binding resulted from changes in the total number of binding sites ($B_{max}$) and not the $K_D$, which remained constant ($K_D$=4uM). These results show that different types of drugs, known to affect cholinergic function in specific (e.g., atropine) or nonspecific (e.g., pentobarbital) ways are able to affect the density of high affinity [$^3$H]HCh-3 binding sites in accordance with their overall effects on cholinergic nerve activity. Thus, not only SDHACU but also [$^3$H]HCh-3 binding sites might represent a reliable index of cholinergic neuronal activity in vivo. In addition, a rapid up or down regulation of the total number of choline carrier sites on the cholinergic nerve terminals appears to account for the changes in SDHACU activity.

289.4 AGE RELATED RE-APPEARANCE OF PARTIAL BASAL FOREBRAIN CHOLINERGIC DEFICITS. M. Brown*, C.F. Hohmann, P.R. Lowenstein, W. Meck, G.L. Wenk and J.T. Coyle. Johns Hopkins Univ., Balto., MD 21205 and Dept. of Psychol., Brown Univ., Prov., R.I. 02912 (SPON: L.Tune).

Lesions of basal forebrain cholinergic nuclei have recently received attention as a potential animal model for selected pathological aspects of Alzheimer's Disease (AD). Loss of cholinergic cells in the ventral globus pallidus correlates with a significant decrease in cortical cholinergic markers, such as choline acetyltransferase (ChAT) and levels of high affinity choline uptake (HACU). The specific activity of ChAT is assumed to correlate with the density of cholinergic innervation to a brain region. HACU and the specific binding of [$^3$H]Hemicholinium-3 (HCh-3) to the choline carrier are under dynamic controls that reflect the recent history of cholinergic neuronal firing. In rats that receive unilateral lesions in the basal forebrain cholinergic system, levels of ChAT activity and HACU gradually recover.

The present study shows that the post-lesion recovery of cortical ChAT activity is temporary. ChAT activity and the specific binding of [$^3$H]HCh-3 were measured in neocortex 4 months and 14 months after unilateral basal forebrain injections of the perikaryal specific neurotoxin, ibotenic acid. By 4 months after the ibotenate lesion, the activity of ChAT on the lesioned side had recovered to that of the contralateral unlesioned cortex (89 + 4 S.E.M. vs 86 + 2 S.E.M. nmoles/mg/hr, N=4). However, animals lesioned 14 months prior to enzyme measurements showed a 30% decrease of ChAT activity in the cortical hemisphere ipsilateral to the ibotenic acid injection ($p < 0.001$, N=4). The specific binding of [$^3$H]HCh-3 did not differ significantly between cortical hemispheres at either time post-lesion. Since the re-appearance of ChAT losses seemed to coincide with aging in the lesioned animal, we examined how aging in this rat strain may affect cholinergic marker levels. ChAT activity, QNB binding, HACU and [$^3$H]HCh-3 binding were monitored in cortex of animals aged 3 to 30 months. The specific activity of ChAT did not change with age. Both HACU and specific binding of [$^3$H]HCh-3 increased with age and QNB binding showed a slight concomitant decrease. It thus appears that cholinergic activity in cortex increases with aging while the number of cholinergic elements in cortex remains constant. We hypothesize that the re-appearance of post-lesion ChAT losses in aging animals is a consequence of cholinergic neuron overactivity. Initial recovery of ChAT levels in unilaterally lesioned animals appears to be a consequence of sprouting. But, as the lesioned rats age, fewer neurons must maintain increased firing levels in a more extended axonal territory. Some neuronal processes may not be able to sustain these levels of activity and degenerate. The present finding may have important implications for the time of disease onset in AD or Down's syndrome.

289.5 QUANTITATIVE HISTOCHEMISTRY OF BRAIN ACETYLCHOLINESTERASE IN HUMANS AND AGED RATS. A. Biegon, M. Wolff*, V. Greenberger* and M. Segal*. Isotope Department, The Weizmann Institute of Science, 76100 Rehovot, Israel.

Acetylcholinesterase (AChE) is an important marker of the cholinergic system. Selective decreases in AChE activity are observed in the brains of patients who died of Alzheimer's disease. In the rat, it was not clear whether aging is accompanied by changes in AChE activity, mainly, we believe, because highly localized changes in small nuclei (such as the medial septal nucleus) were technically hard to determine using available methodologies. To facilitate quantitative and reproducible measurements of AChE in discrete brain regions, we have adapted a AChE histochemical procedure for quantitative use. Mashed rat cerebelli were mixed with known quantities of a purified AChE preparation, frozen and thin sectioned on a cryostat at -20°C. Experimental brains were frozen and cut under the same conditions. The brain sections and standards underwent histochemical staining simultaneously and a computerized image analysis system was used to construct a standard curve and analyze the densities of staining in experimental tissue. The distribution of AChE in coronal sections of human brains collected post mortem was quantified. In a group of six normal middle aged subjects, inter individual variation was small. In a single case of suicide by parathion ingestion (an AChE inhibitor) a large but anatomically heterogeneous decrease in AChE staining was observed. Using this technique, we have measured AChE in the rat brain nuclei containing cholinergic neurons (medial septal nucleus and ventral pallidum) and several terminal areas. Eight aged (31 months old) and eight young (4 months old) rats were compared. We observed a substantial (10% to 70%, mean 33%, $p<0.003$) decrease in AChE activity in the ventral pallidum. Significant decreases were also found in the medial septal nucleus, anterior cingulate cortex and the dentate gyrus of the hippocampus. No changes were observed in the CA fields of the hippocampus, caudate nucleus and olfactory tubercule. The AChE levels in individual rats showed a significant positive correlation with performance in a water maze, indicating the heterogeneity of spatial memory deficits in aged rats and the involvement of the cholinergic system in cognitive processes. Quantitative histochemistry is currently being applied to a detailed analysis of AChE content in brains of Alzheimer's disease patients post mortem.

289.6 CHOLINERGIC CORTICAL INNERVATION: A CORRELATIVE STUDY OF CHOLINE ACETYLTRANSFERASE-IMMUNOREACTIVE VERSUS ACETYLCHOLINESTERASE-POSITIVE FIBER DISTRIBUTION. A. Lysakowski[1], B.H. Wainer[1], D.B. Rye[1], G. Bruce[2], and L.B. Hersh[2]. [1]Dept. Pharmacological and Physiological Sciences, The University of Chicago, Chicago, IL 60637; [2]Dept. Biochemistry, University of Texas Health Sciences Center, Dallas, TX 75235.

Cholinergic innervation of cerebral cortex contributes to cognitive function, yet little is known concerning the precise anatomical organization of this system. Previous studies have utilized acetylcholinesterase (AChE) histochemistry to visualize putative cholinergic cortical fibers. In the present study, a recently developed polyclonal antiserum against the specific cholinergic marker, choline acetyltransferase (ChAT), was employed to localize ChAT-immunoreactive (ChAT-IR) fibers in different areas of rat cerebral cortex. In adjacent sections, acetylcholinesterase-positive (AChE+) fibers were visualized histochemically (Hedreen et al., J. Histochem. Cytochem., 33:134-140, 1985).

In 16 cytoarchitectonic areas examined, several unique laminar patterns of ChAT-IR fibers were observed. In some of these areas, distinct differences were noted when compared with the distribution of AChE+ fibers. Most neocortical areas exhibit tangentially-oriented bands of both fiber types in layer I. Primary sensory cortices also exhibit bands of ChAT-IR and AChE+ fibers in layer IV. However, in the barrel field, ChAT-IR fibers form "septa," leaving ChAT-poor "hollows" within the barrels, while AChE+ fibers ramify within the "hollows," leaving the "septa" relatively clear. Motor cortex exhibits a homogeneous pattern of ChAT fibers in layers II-VI. In medial areas, cingulate cortex contains thick ChAT-IR and AChE+ tangential fibers in layers I and VI, while marked differences are noted in retrosplenial cortex. ChAT-IR fibers are dense in layers I and IV-VI and scarce in layers II-III. The latter two layers are primarily populated by small, densely-packed cells and contain significant numbers of ChAT-IR cell bodies. In contrast, AChE+ fibers are very dense in layers II-III and much less dense in other layers. In hippocampus, ChAT-IR fibers are prominent as narrow bands immediately above and below the granule and pyramidal cell layers. AChE+ fibers are also dense adjacent to the cell layers, but show additional banding within the fiber layers.

In summary, regional and laminar variations in cortical cholinergic fibers may represent different functional circuitries. In addition, AChE varies from ChAT in its fiber distribution and may not be a reliable marker for cortical cholinergic innervation.

289.7 IDENTIFICATION OF CHOLINERGIC NEURONS IN RAT RETINA. C.T. Lin, Y.-F. Xu*, J. W. Liu*, H.S. Lin*, S. Wei*, J.-Y. Wu. Department of Physiology, College of Medicine, The Penn State University, Hershey, PA 17033

Choline acetyltransferase (ChAT) was purified from rat brain to homogeneity. The purified ChAT preparations were used for the production of polyclonal antibodies as well as monoclonal antibody. Both polyclonal and monoclonal antibodies were characterized by enzyme inhibition test and by Western blot transfer method and used to localize ChAT in the rat retina by indirect immunoelectron microscopy. Rats were perfused with 4% paraformaldehyde and 0.1% glutaraldehyde mixture. Each eye ball was dissected and retina isolated. The retina was further fixed in the same fixative for another 2 h and immersed in 4% paraformaldehyde overnight. Fifty micrometer sections were obtained from a vibratome. Sections were incubated with antibodies against ChAT, followed by peroxidase labeled second antibody, and finally with peroxidase substrate. At light microscopic level, reaction product (RP) was seen mainly in the inner plexiform layer (IPL), some in the inner nuclear layer (INL) and the outer plexiform layer (OPL), and occasionally in the outer nuclear layer (ONL). In the INL, some horizontal cells, amacrine cells and possible bipolar cells were stained. At electron microscopic level, in the IPL, electron dense RP was seen in some amacrine terminals and bipolar terminals. The stained amacrine terminals were seen to make synapse with other stained and unstained amacrine and bipolar terminals. Similarly, the stained bipolar terminals also made synaptic contact with some stained and unstained amacrine and bioplar terminals. In the OPL, some rod spherules and cone pedicles also contained RP. In both IPL and OPL, RP was seen to be associated with presynaptic vesicles and presynaptic membrane. RP in the stained cell bodies in ONL and INL was seen to be associated with free polysomes and other cellular organelles. These findings suggest that some rod and cone cells in the ONL, some horizontal cells, bipolar cells and amacrine cells in the INL may use acetylcholine as neurotransmitter. (Supported by EY-05397, NS-20978 and NS-20922).

289.8 **FREQUENCY DEPENDENT POTENTIATION OF A PRESUMPTIVELY CHOLINERGIC FOREBRAIN INPUT TO THE RAT OLFACTORY BULB.** W.T. Nickell and M.T. Shipley. Department of Anatomy and Cell Biology, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267

Anatomical studies have demonstrated an extensive, largely cholinergic projection from the nucleus of the horizontal limb of the diagonal band (DB) to the olfactory bulb (OB) in the rat. Very little is known, however, about the functional characteristics of this or any other basal telencephalic cholinergic projection system. The DB→OB projection terminates in a highly specific laminar pattern which greatly facilitates the analysis of pre-and post-synaptic events. We have stimulated the region of the diagonal band using bipolar electrodes while recording from OB of anaesthetized rats (chloral hydrate) with micropipettes. In some cases mitral cells were stimulated antidromically by electrodes placed in the lateral olfactory tract (LOT) to test for interaction with DB potentials.

Single DB shocks produce a biphasic (positive-negative) potential in the internal plexiform layer (IPL). This potential develops immediately after the recording electrode passes the mitral cell layer (MCL). A potential of opposite sign is present in the external plexiform layer. At low stimulation frequency these potentials show no detectable facilitation or depression. Single shocks have no influence on potentials resulting from LOT stimulation.

However, when the DB is stimulated for >10 seconds at 10 Hz or greater, dramatic changes are produced in OB. After a few seconds of DB stimulation, there is a period of inhibition of the potential lasting 1-3 seconds. Then, abruptly, the amplitude of the DB potential increases to an extraordinary degree. Although both phases of the potential are increased, the negative phase increases so much in magnitude and time-course as to suggest the initiation of a new process. If stimulation continues for several seconds after onset of the potentiation, the bulb is sometimes left in an oscillatory state in which potentials resembling the negative phase of the DB potential occur spontaneously. This potentiated state persists for 5-10 seconds and can be maintained for long periods by stimulation at low frequency (1-2HZ). Stimulation of LOT during the potentiated state causes the appearance of a long-latency negative going potential not present in the unpotentiated record. This potential has similar latency and time course to the negative phase of the DB potential during potentiation.

The features of this potentiation are consistent with those of muscarinic synapses. If the cholinergic nature of the effect is confirmed, the DB→OB pathway will be an important model for cholinergic influence on cortical structures.

289.9 EFFECT OF INTRA-CORTICAL INJECTION OF DFP ON CHOLINERGIC NEUROCHEMISTRY AND PASSIVE AVOIDANCE BEHAVIOR IN THE RAT. S.E. Robinson, H. Muller-Kahle* and M.A. Rice*. Department of Pharmacology and Toxicology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0001.

Peripheral administration of the irreversible cholinesterase inhibitor DFP has been reported to enhance retention of passive avoidance behavior in conjunction with reduced muscarinic receptor binding in the cerebral cortex (Lerer et al., Pharmacol. Biochem. Behav. 21:467, 1984). In order to determine if DFP can enhance memory by action in the cerebral cortex, we have investigated the effect of intra-cortical injection of DFP into the parietal cortex on passive avoidance behavior. Male Sprague-Dawley rats (150-250 g) were implanted bilaterally with guide cannulas in the parietal cortex (AP interaural + 9.7 to 8.7 and L ± 5.5). One week later, 122 nmol of DFP in a total volume of 0.75 µl or 0.75 µl of artificial CSF:emulphor (9:1) vehicle was injected in the following way. An internal cannula was lowered through the guide cannula to a depth of 6.5 mm from the skull surface, half the volume infused over a period of 1 min and then the internal cannula was raised 3 mm and the remainder of the dose infused over 1 min. Thus, maximal inhibition of cholinesterase activity in the cortex with minimal inhibition of enzyme activity outside of the cortex was achieved. Cholinesterase activity, as measured by the method of Ellman et al. (Biochem. Pharmacol. 7:88, 1961), in the cortex was 42%, 43% and 51% of control at 20 min, 1 hr and 24 hr following DFP administration, whereas cholinesterase activity was not inhibited by more than 38% in any other brain area examined (striatum, medulla/pons, hypothalamus, hippocampus, amygdala). A separate group of animals were tested in a passive avoidance paradigm in a two-compartment shuttle-box. Animals were allowed a 30 sec period in which to explore the illuminated compartment of the shuttle box, after which the animals were allowed access to the dark compartment. Animals received a brief 1 mA inescapable shock when they crossed to the dark side. A maximum crossover latency of 300 sec was allowed. A total of 10 trials was performed and rats were allowed 180 sec in their home cage between trials. Twenty min after intracerebral injection there was no significant difference between the DFP and vehicle-treated rats in acquiring the passive avoidance behavior or in the initial crossover latency. Atropine (total dose 30 nmol, injected as described for DFP above) also does not appear to affect acquisition of passive avoidance behavior or initial crossover latency 20 min after injection into the parietal cortex. Behavioral studies are also being performed 1 hr and 24 hr following DFP administration. (Supported by contract number DAMD 17-83-C-3183).

289.10 AGING AND ACETYLCHOLINE-RELEASE FROM RAT CORTICAL SYNAPTOSOMES AND ATRIAL MINCES. E.M. Meyer, S.P. Baker, F.T. Crews, and K. Larsen* Dept. of Pharmacology and Therapeutics, U. Florida, Gainesville.

Aging consistently reduces the depolarization-induced, calcium-dependent release of newly synthesized ACh but not that of other transmitters from rat brains. In order to ascertain whether this reduction in transmitter release reflects changes in voltage-dependent calcium influx or to a step distal to calcium uptake, we studied the effects of several secretagogues on calcium-dependent ACh release from rat cortical synaptosomes derived from 6 or 24 month old male Sprague-Dawley albino rats. $K^+$-depolarization increased the release of newly synthesized ACh from synaptosomes in both groups of animal but released significantly more transmitter in the younger tissues. A23187, the calcium ionophore that bypasses voltage-dependent calcium uptake, increased ACh-release to a greater extent in the younger group at submaximal concentrations (up to 10 ug/ml), but the maximal release induced by 20 ug/ml of the drug was identical in both groups of animals. No age-related difference in the $^{45}Ca^{2+}$ uptake induced by any concentration of A232187 was observed. Ouabain, which acts by mobilizing intracellular calcium ions in the absence of extracellular calcium, increased ACh release to a similar extent in both age-groups. 4-Aminopyridine, which blocks potassium channels and protracts depolarization-induced release of ACh, increased ACh release to a greater extent in the older animals than in the younger ones. None of these age-related differences in the release of ACh were due to changes in the synthesis or levels of the transmitter. Further, no age-related difference in the muscarinic inhibition of ACh release was observed. Taken together, these results suggest that during aging, brain ACh release is attentuated by a reduction in the potency but not efficacy of calcium ions at intracellular release-triggering sites, that larger stores of intracellular calcium ions may be available for mobilization in the older tissues, and that 4-aminopyridine may be useful for selectively increasing ACh release in senescent brains.

Atrial presynaptic cholinergic activity was affected differently by aging than the brain activity was. The 24-month old atria had significantly lower rates of high affinity choline transport activity, synthesized less ACh, and released less of the transmitter in response to 50 mM $K^+$ depolarization than the 6 month old tissues did. The ability of oxotremorine (100 uM) to inhibit ACh release via presynaptic receptors in this tissue was also significantly attenuated by aging in this tissue. These results are consistent with an age-induced reduction in presynaptic cholinergic function in the parasympathetic innervation of the heart, as opposed to the more selective reduction in the potency of calcium ions at intracellular release-triggering sites in brain cholinergic neurons.

290.1 BIOPHYSICAL ALTERATIONS OF RABBIT HIPPOCAMPAL NEURONS STUDIED IN VITRO AFTER CONDITIONING. J.F. Disterhoft, D.A. Coulter* and D.L. Alkon, Laboratory of Biophysics, NINCDS, Marine Biological Laboratory, Woods Hole, MA 02543.

Young adult male albino rabbits were trained in the nictitating membrane/eyeball retraction conditioning paradigm using white noise CS and periorbital shock US in a short-delay paradigm. The conditioned group was well trained (three 80 trial sessions). The pseudoconditioned group received three sessions of explicitly unpaired, randomized CSs and USs.

Intracellular recordings were made from hippocampal CA1 pyramidal neurons within brain slices prepared one day following the last training session. Surface slices were prepared and maintained using standard techniques. All neurons included (19 conditioned, 19 pseudoconditioned, and 22 naive) had stable penetration, at least 60 mV impulse amplitudes and 20MΩ input resistances. A marked reduction in the afterhyperpolarization (AHP) following an impulse was apparent for conditioned (X=1.0 mV) as compared to the pseudoconditioned (X=1.8 mV; p<.001) and naive (X=1.9 mV; p<.001) neurons. The AHP has previously been attributed to activation of a $Ca^{++}$dependent outward $K^+$ current, $I_C$. This conditioning-specific difference could not be accounted for by differences of input resistance and resting membrane potential also observed. The distribution of AHP amplitudes for the conditioned group included a new lower range of values for which there was no overlap with the other groups. The percentage of conditioned cells in this new group, ~55%, was comparable to that previously observed in vivo to show increased excitability (in response to conditioned stimulus presentations) as measured with extracellular recordings (Berger, T.W. et al., J. Neurophysiol., 50: 1197, 1983. The conditioning-specific reduction of AHP may be due to reduction of $I_C$ as previously shown for neurons from conditioned Hermissenda (Alkon, Science, 226: 1037, 1984).

The amount of sag in the voltage response after injection of large hyperpolarizing pulses was also reduced. The magnitude of sag was significantly less for the conditioned (X=1.7 mV) as compared to the pseudoconditioned (X=3.1 mV; p<.01) and the naive (X=5.4 mV ; p<.001 neurons). The pseudoconditioned group was reduced from the naive (p<.001) so the sag effect was not conditioning-specific.

Our experiments demonstrate that ionic alterations, intrinsic to the hippocampus and not dependent upon other brain regions for their expression, are stored in CA1 pyramidal neurons after conditioning. These alterations are present even in in vitro brain slices separated from the rest of the brain circuitry.

This research was partially supported by NSF BNS-8302488 and by a NINCDS IPA Fellowship to J.F.D.

290.2 CONDITIONING-SPECIFIC REDUCTION OF CA1 AFTERHYPERPOLARIZATION AMPLITUDE AND DURATION IN RABBIT HIPPOCAMPAL SLICES. D.A.Coulter*, M.Kubota*, J.W.Mooret, J.F.Disterhoft§, and D.L.Alkon. Lab. Biophysics, NINCDS-NIH, MBL, Woods Hole, MA 02543; †Dept. Psychol., Univ. Massachusetts, Amherst, MA 01003; and §Dept. Cell Biol. & Anat., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Hippocampal slices were prepared from rabbits one day after training with the nictitating membrane conditioning paradigm for 3 days, 80 trials/day. The CS was a binaural 400 msec tone, coterminating with the UCS, a 100 msec, 1-2 mA periorbital shock train. Pseudoconditioned animals received an equal number of randomized explicitly unpaired stimuli. Intracellular recordings from CA1 pyramidal cells of submerged 500 μm slices (as opposed to fluid interface slices of the companion study, Disterhoft et al., 1985) were included here if impulse amplitudes were $\geq$ 70 mV and if the resting membrane potential was constant during the entire protocol (20-45 min). Among all cells included (N=75) there were no significant differences in membrane potential or input resistance between groups. The afterhyperpolarization (AHP) following a positive current pulse, previously shown to be due in part to activation of a $Ca^{2+}$-dependent $K^+$ current, was greatly reduced by $Co^{2+}$ and $Cd^{2+}$ (N=5, 10 respectively) and by carbachol (N=14). The AHP following a 100 msec positive pulse was significantly lower for conditioned as compared to pseudoconditioned and naive animals when the pulse elicited 4 impulses (cond. $\bar{X}$=-3.43 mV, pseud. $\bar{X}$=-4.9 mV, p<.01; naive $\bar{X}$=-4.52, p<.025, one-tailed t-test), when the pulse elicited 3 impulses (cond. $\bar{X}$=-2.71, pseud. $\bar{X}$=-3.88, p<.01; naive $\bar{X}$=-3.48, p<.025) and, to a lesser degree, when the pulse elicited 2 impulses (cond. $\bar{X}$=-2.16, pseud. $\bar{X}$=-2.90, p<.025; naive $\bar{X}$=-2.51, N.S.). This trend continued but was not significant for pulses eliciting 1 impulse. No significant differences occurred between pseudoconditioned and naive cells for any of the positive pulses used. These findings were consistent with a significantly different distribution for the conditioned cells (vs. pseudoconditioned and naive) in both the AHP amplitude (p<.025, df=4, Chi-square) and duration (p<.02, df=4). Conditioned cells (as compared to pseudoconditioned and naive cells) had many more AHP amplitudes $\geq$-3.0 mV and much fewer $\leq$-6.0 mV and many more AHP durations < 2.0 sec and much fewer $\geq$ 3.5 sec. A clear relationship was found between AHP amplitude (and duration) and the ability of a cell to sustain impulse responses to repetitive activation (by positive 100 msec pulses) of varying frequencies, suggesting the functional importance of these conditioning-specific AHP reductions. In summary, conditioning-specific reduction of a $Ca^{2+}$-dependent $K^+$ current, $I_C$, can contribute to long-term storage of a learned association in the rabbit as was previously shown for $I_C$ (as well as an early current, $I_A$) in the mollusc Hermissenda (cf. Alkon, Science 226, 1037, 1984).

290.3 REVERSIBLE INACTIVATION OF THE HIPPOCAMPUS: EFFECTS FOLLOWING MEMORY REACTIVATION. Douglas C. Smith and James Talman*, Developmental Biopsychology Program and School of Medicine, Southern Illinois University--Carbondale, IL 62901

Lidocaine is a local anesthetic which, when injected directly into the brain, completely and reversibly inactivates all neural activity in the area affected. We have previously presented evidence that bilateral inactivation of the hippocampus (HC) immediately following one-trial inhibitory avoidance training results in deficits, but not complete amnesia, when retention is tested either 60 sec. or 24 hr. later (Smith et al., Soc. Neuroscience Abst., 1983). An even more robust effect is obtained when the HC is inactivated immediately prior to a 24-hr retention test. With this paradigm, rats demonstrate a complete retrieval failure, crossing over into the dark with latencies comparable to those found prior to training (Smith and Talman, Soc. Neuroscience Abst., 1984).

We now report the effects of HC inactivation following memory reactivation. In a one-trial inhibitory avoidance task, 20 Long Evans rats received 1.5 ma, 1.0 sec shock immediately upon entering the dark side from the lighted side of a two-compartment alley. In one group (pre-retrieval), 1 ul of lidocaine was delivered bilaterally to the HC immediately prior to the 24 hr retrieval trial and median latency to enter the dark was 8.3 sec. The other group (reactivation) was placed in the lighted side of the alley 24 hrs after training and demonstrated perfect retention (median latency, 300 sec = ceiling). These animals were then removed from the apparatus, bilaterally injected with lidocaine into the HC and returned for another retention test, and again demonstrated perfect retention (median latency = 300 sec.).

Several conclusions are possible from these results. First, the finding that the subjects in the reactivation group remained in the lighted side of the alley following lidocaine injections into the HC indicates that these injections do not have their effects via some nonspecific motor affect. Thus, the failure of the pre-retrieval group to demonstrate memory for the task must be due to a retrieval failure, and not to any motor activation or failure to be able to inhibit a response. Further, these results suggest that once a memory has been retrieved, the hippocampus is no longer necessary for the continued expression of the memory.

290.4 THE CLASSICALLY CONDITIONED RABBIT NICTITATING MEMBRANE RESPONSE: EXCITATORY AND INHIBITORY CONDITIONED ACTIVITY FROM SINGLE UNITS IN THE BRAIN STEM. J.E. Desmond and J.W. Moore, Dept. of Psychology, Univ. of Massachusetts, Amherst, Mass. 01003

The classically conditioned rabbit nictitating membrane (NM) response is a widely adopted model system for studying the physiology of learning and memory. New Zealand albino rabbits were trained to partially discriminate between a reinforced conditioned stimulus (CS+) and a nonreinforced CS- (tones of 1200 or 600 Hz,75 dB SPL). The unconditioned stimulus was electrostimulation to the periorbital region. Rabbits were anesthetized and prepared for subsequent electrophysiological recording. A stimulating electrode was implanted into the right accessory abducens nucleus (AAN), the principal nucleus mediating the NM reflex. A recording chamber was cemented in place over a small hole on the right side of the skull.

Following recovery, single units in the brain stem were recorded extracellularly in the awake restrained animal during CS+ and CS- presentations. Incomplete discrimination resulted in conditioned response (CR) and non-CR trial types for each CS. Units were tested for antidromic response to stimulation of the AAN electrode.

Statistical tools were developed to investigate CR vs. non-CR unit activity. A binomial method suggested by Dorrscheidt (Brain Res., 220: 397, 1981) was used to compare rates of firing for CR and non-CR trials during identical time periods. Cross correlations of unit activity with the CR, or CR first derivative, were useful in determining lead/lag relationships of unit activity and behavior. CR onset-dependent unit activity was examined via response histograms, which use the CR onset time for each trial as the reference point. Spikes are accumulated in bins around this reference. Multiple regression was also used to assess trial by trial spike/CR relationships. Variables of interest were CR onset latency, CR magnitude, number of spikes during CS period, mean spike time during CS period, and standard deviation of spike time.

Units displaying both CR-related excitation and CR-related inhibition were found. Excitatory units with activity leading the behavior were located in proximity to the motor trigeminal nucleus, including the supratrigeminal region (see Desmond et al., Brain Res. Bull., 10: 747, 1983) or dorsomedial to the brachium conjunctivum. Lead times were sufficiently long for causal involvement, typically ranging from 30-100 ms. Inhibitory units leading the CR were predominately located in dorsal and dorsomedial aspects of nucleus reticularis pontis oralis (RPO). One case of antidromic activation was observed in an excitatory cell in dorsolateral RPO. However this cell probably fired concurrently with the CR.

290.5 CLASSICAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE USING STIMULATION OF THE DORSOLATERAL PONS AS A CS. D.G. Lavond, J.E. Steinmetz, D.J. Rosen*, G.J. Beekman & R.F. Thompson. Dept of Psychology, Stanford University, Stanford, CA 94305.

A number of theories have suggested a role for the cerebellum in learning and memory (Albus, Marr, Ito, Eccles). Recent studies have demonstrated an essential role of the cerebellum in classical conditioning. Lesion of the interpositus nucleus prevents or abolishes learning (conditioned responses) without affecting the unconditioned response. Lesion of the inferior olive (climbing fibers) prevents learning and causes extinction in well trained animals, agreeing with the suggestion that the IO provides "reinforcing" input to the cerebellum concerning the unconditioned stimulus. If the cerebellum is the site of neuronal plasticity responsible for learning and memory --the "engram"-- then information concerning the CS and UCS must converge and integrate there into a coherent response (i.e., CR). The present study asks whether stimulation of the mossy fiber afferent from the dorsolateral pontinue nucleus (DLPN) can act as an effective CS when paired with corneal airpuff UCS.

Adult male New Zealand White rabbits were anesthetized and implanted with bipolar stimulating electrodes in the DLPN or mossy fibers. Training consisted of 108 trials per day in which stimulation near the DLPN (CS, 200 Hz, 350 msec, 60 uA) was paired with coterminating corneal airpuff as the UCS (2.1 $N/cm^2$, 100 msec). Group one (N=5) was given paired CS/UCS training to criterion (8 CRs out of 9 consecutive trials) and overtrained. They were then given 4 days of CS-alone extinction followed by 2 days of unpaired CS and UCS trials. Finally, they were retested with paired conditioning. Group two (N=4) was given CS-alone and unpaired experience before paired conditioning. Finally, lesions were made of the cerebellar interpositus nucleus, the rabbits given a few days of recovery, and were then retested for 4 days.

Both groups learned in an average of about 100 trials. Extinction and spontaneous recovery were observed in Group one over days. There was no evidence of nonassociative effects such as sensitization during CS-alone and unpaired training. Lesions of the interpositus nucleus abolished the CRs with no signs of recovery of CRs in 4 days of retraining.

The present study demonstrates that stimulation of DLPN or of mossy fibers can be an effective CS for training an eyeblink response. Furthermore, the CR pathway must involve the cerebellum because lesions there abolish the response. We suggest that the cerebellum is the site of plasticity.

Supported by NIMH fellowship MH08994 to JES, and by ONR contract N00014-83-K-0238, NSF grant BNS-81-17115, and a Sloan Foundation grant to RFT.

290.6 CLASSICAL CONDITIONING OF SKELETAL MUSCLE RESPONSES WITH MOSSY FIBER STIMULATION CS AND CLIMBING FIBER STIMULATION US. J. E. Steinmetz, D. G. Lavond, and R. F. Thompson. Dept. of Psychology, Stanford University, Stanford, CA, 94305.

Recent studies have demonstrated that the rabbit eyelid can be classically conditioned when a mossy fiber stimulation CS is paired with an airpuff US (Steinmetz et al., Bull. Psychon. Soc., 1985) and when a tone CS is paired with a climbing fiber stimulation US (Mauk & Thompson, Neurosci. Abst., 1984). The present experiment was an attempt to classically condition skeletal muscle responses with a mossy fiber stimulation CS and a climbing fiber stimulation US.

Stimulating electrodes were implanted into the right dorsolateral pontine nucleus (DLPN) and the right dorsal accessory olive (DAO) of six anesthetized rabbits. The stimulating electrodes were guided into position by recording potentials from cerebellar cortex evoked by single pulse stimulation of the DLPN and DAO. After 1 wk, classical conditioning was begun. Training involved pairing a 350 msec train of DLPN stimulation (60-90 uA, .1 msec, 200 Hz) with a coterminating 100 msec train of DAO stimulation (200-400 uA, .1 msec, 100-400 Hz). The DLPN-CS initially produced no discernable movements while the DAO-US produced a discrete eye blink in 3 animals and a discrete head turn in 3 animals. Rabbits were trained to a criterion with daily sessions of 108 trials, overtrained with an additional session, then given CS-alone or explicitly unpaired extinction training. Paired presentations of the DLPN-CS and DAO-US produced fairly rapid acquisition of the conditioned eyelid or head turn response. Subsequent extinction training abolished the conditioned response with unpaired CS-US presentations producing more rapid extinction than CS-alone presentations. Histological examination of the stimulation sites revealed that US electrodes were positioned in rostromedial portions of the DAO in eye blink animals and in slightly more rostrolateral portions of the DAO in head turn animals. CS electrodes were located in the DLPN or at its border with the middle cerebellar peduncle. Rabbits with US electrodes in the reticular formation or in more caudal portions of the inferior olive that evoked behavioral responses (n=5) failed to condition.

Demonstration of classical conditioning of skeletal muscle responses with direct stimulation of mossy fibers (CS) and climbing fibers (US) provides strong evidence that the cerebellum is critically involved in the acquisition of simple learned motor responses. In addition, the present data support previous theories of cerebellar function (e.g., Albus, Math. Biosci., 1971; Eccles, Brain Res., 1977; Ito, Int. J. Neurol., 1968; Marr, J. Physiol., 1969) which have suggested that motor learning involves interaction of mossy and climbing fiber inputs to the cerebellum.

Supported by NIMH fellowship MH08994 (JES) and ONR contract N00014-83-K-0238, NSF grant BNS-81-17115, and the Sloan Foundation (RFT).

290.7 DEGRADATIVE OPIOID ENZYME ACTIVITY IN PLASMA IS HIGHLY CORRELATED WITH AVOIDANCE PERFORMANCE IN RATS. Joe L. Martinez, Jr., Susan B. Weinberger*, Sandra Morrow*, and Richard C. Dana. Psychology Department, University of California, Berkeley, CA 94720.

We previously reported (Neurosci Abs., 1984, 10, 176) that methylnaloxonium and an antiserum to leu-enkephalin (LE) enhanced acquisition of an active avoidance response, and that LE impaired acquisition of the same response, indicating that peripheral endogenous opioid systems may be involved in the normal machinery of learning. The present study extends these findings by examining the dynamic relationship between opioid metabolism and behavior.

Male (300-450 g) Sprague-Dawley rats were anesthetized (Nembutal) and cannulated in the femoral artery. Two days later the rats were trained in a one way active avoidance task (600 uA footshock). The rats had 10 s to avoid the onset of shock, and 30 s to escape; a total of 8 trials were given. Blood (.5 ml) was withdrawn before the first trial. Enzyme activity was measured by incubating $^3$H-LE in plasma for 1, 2, or 15 min at 37 deg C, followed by the addition of 0.1% TFA in methanol to stop the reaction. Unmetabolized LE was separated from its metabolites by thin layer chromatography using reverse phase KC-18 plates. Metabolism rates were determined with a liquid scintillation counter by comparing the amount of unmetabolized LE to that of its combined metabolites, at each time point. Enzyme activity was found to be correlated with age; there was no correlation between age and latency to escape.

The correlation between the latency to escape on the first trial and the amount of LE metabolism, as corrected for age, was $r(17) = 0.82$, $p = .00001$. The kinetics of LE degradation measured in this study are consistent with those reported by Hambrook et al. (1976; Nature, 262, 782).

The findings demonstrate a strong and direct relationship between a measure of opioid degradation and behavior on the first avoidance trial. These data support the suggestion that endogenous peripheral opioids function to influence complex behavior, and indicate that this relationship can only be revealed by examining a dynamic measure of opioid function. (Supported by ONR N00014-83-K-0408).

290.8 ERROR SIGNALS IN LIMBIC CORTEX (AREA 24) OF MONKEYS DURING MOTOR LEARNING. V.B. Brooks, H. Gemba* and K. Sasaki*. Dept. of Physiology, Univ. of Western Ontario, London, Canada, N6A 5C1; and Inst. for Brain Res., Fac. of Med., Kyoto Univ., Kyoto 606, Japan.

Monkeys learn to perform simple motor tasks in two successive main phases. Progress increases abruptly in transition from the first to the second. During the first phase the subjects gain insight about behavioral task requirements and form stimulus-response associations. During the second, insightful, phase subjects improve skill of motor performance in proportion to their degree of insight, reflected by correct task behavior. Motor skill is improved by rapidly increasing use of 'continuous' movements, distinguished by single-peaked velocity profiles, which are predictively programmed by the cerebro-cerebellar circuit (1,3).

The sequence of two major phases in motor learning has been shown for monkeys reacting to visual cues in order to make horizontal elbow flexions and extensions to turn a handle in a step-tracking task (1,3) and for wrist dorsiflexions to lift a lever (2,4). Behavioral insight follows maximal growth of evoked potentials in prestriate, prefrontal and premotor cortex, preceding correct task performance (2,4). The subsequent sudden increase of insightful learning is accompanied by shortening of reaction times and by growing cerebello-cerebral projection potentials in motor cortex (2,4).

Rostral cingulate cortex (area 24) does not exhibit task-related evoked potentials preceding behaviorally correct movements (5), but we now report that they follow incorrect lever lifts made without reference to the visual task-cues (i.e., after the 900 msec presentation of the visual cues that were repeated on average about every 4 sec). The limbic error signals have been observed during the period of insightful learning ipsi- or contralaterally to the operant arm in two monkeys (M. fuscata). The potentials usually follow incorrect lever lifts within 50 msec. The surface-positive, depth-negative potentials were recorded with electrodes implanted at the cortical surface and at 3 mm depth. Dipole analysis (2,4) suggests their origin to be from cortico-cortical fibers or from thalamo-cortical fibers terminating in deep layers of the cortex. Evoked "error" potentials may represent activation of cingulate "error-recognition" units (6).

290.9 LEARNING-MEMORY IMPAIRMENTS IN RATS AFTER UNILATERAL KAINATE LESIONS OF THE MEYNERT'S NUCLEUS. A.C.Rossi M.A.Cervini* and M.Buonamici*. Biological R.& D., Farmitalia C. Erba, 20014 Nerviano, Italy.

Some tests aimed at measuring the nociceptive thresholds are also useful tools for the study of learning-memory processes in rats (e.g. "threshold conditioned escape response": Giurgea C., et al., 11th C.I.N.P. Congress, Vienna, Abstracts, 248, 1978). The present experiments were carried out on male Sprague-Dawley rats weighing 250-275 g. 10 animals were normal controls (C) and other two groups of 10 each were respectively sham-lesioned (S) or unilaterally lesioned (L) with kainic acid in the Meynert's nucleus (Johnston M.V. et al. Exp. Brain Res., 43:159, 1981). From the 3rd day after treatments all the animals randomly underwent to repeated measurement of their nociceptive thresholds by 4 different tests: hot plate, 56°C (HP), tail pinch (TP), tail flick (TF) and paw pressure (RS). No significant differences among the three experimental groups did appear in nociceptive thresholds in three (TP, TF and RS) of the tests used from the 3rd up to the 100th day after treatments. In the context of the HP test, repeated every day, mean nociceptive thresholds of L animals remained almost constant in time, whereas thresholds of S and C animals were progressively reduced. The correct "learning" by S and C animals was further demonstrated placing them on the HP apparatus without heathing the plate: S and C animals showed "retention" jumping away for several days. In the same situation, L animals did not respond at all, showing no "retention", i.e. impairment of learning and memory, in the absence of detectable motor defects as assessed by the rotarod test. It is concluded that this kind of lesion of the Meynert's nucleus in rats does not affect nociceptive thresholds but does impair learning-memory processes as measured by "threshold conditioned escape response" methods.

290.10 REDUCED AFTERHYPERPOLARIZATION AND RAPID ACTIVATION OF CORTICAL CELLS PRODUCED BY ELECTRICAL STIMULATION OF HYPOTHALAMUS IN MONKEY AND CAT. S. Aou*, C.D. Woody, C.D. Chapman*, Y. Oomura and H. Nishino* (SPON: B. Swartz). Depts. of Anatomy and Psychiatry, UCLA Med. Ctr., Los Angeles, CA 90024 and National Inst. Physiol. Sci., Okazaki 444, JAPAN.

Previous studies have shown that short latency activation (<20 ms) of cells of the motor cortex can be elicited by electrical stimulation of the lateral hypothalamus. Such stimulation can help accelerate rates of conditioning in cats and can be used as an operant reinforcer in cats and monkeys (Woody, C.D. et al. J. Neurophysiol., 49: 780, 1983; Aou S. et al. Soc. Neurosci. Abstr. 10: 312, 1984). The present study shows that lateral hypothalamic stimulation can also elicit very short latency (<1 ms) unit activity as well as a reduction of afterhyperpolarization (AHP) in cortical cells of both species.

Lateral hypothalamic stimulation (A: 18-20, L: 2-4, H: 1-3) evoked action potentials with latencies <1 ms in 38 of 125 motor cortex neurons in monkeys (macaca fuscata). Comparably short latencies of activation were found in a smaller proportion of motor cortex cells in cats. Some responses followed stimulation at 300 Hz with fixed latency and met collision tests. A direct cortico-hypothalamic projection has been reported in the monkey (Nauta, W.H.J., Acta Neurobiol. Exp. 32: 125, 1972).

Following electrical stimulation of the lateral hypothalamus with a 4 or 5 pulse train (100-500 μs, 50 Hz, 0.5-1.5 mA, bipolar), 14 of 23 cells in monkeys showed a reduction in both amplitude and duration of the AHP with little or no accompanying change in levels of spontaneous resting potential. The effect began 15 to 70 ms after stimulation and persisted for 50 to 300 ms after stimulation. Sometimes, a decrease in the threshold level for spike generation accompanied the AHP reduction. This phenomenon could also be observed in neurons of the motor cortex of awake cats together with increases in input resistance.

These studies provide evidence in two different mammalian species for shared commonalities in hypothalamo-cortical interactions which are of potential significance to development of learned behavior. (Supported in part by AFOSR and NICHHD.)

290.11 THE ACOUSTIC PINNA REFLEX : A MODEL SYSTEM FOR THE BEHAVIORAL AND ELECTROPHYSIOLOGICAL ANALYSIS OF DRUG EFFECTS, HABITUATION, PREPULSE INHIBITION, AND FEAR CONDITIONING IN RATS. J.V.Cassella and M.Davis. Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06508.

A reliable component of the acoustic startle response in animals is a flexion of the ears, the pinna reflex. One goal of the present investigation was to develop a preparation and apparatus suitable for analyzing the pinna reflex in the awake rat. The second goal was to examine the pinna reflex under behavioral and pharmacological conditions known to affect other response systems like the whole-body startle reflex and determine if the pinna response is a valid model for analyzing behavioral plasticity. The third goal was to assess the viability of conducting single-unit analysis of mechanisms mediating plasticity of the acoustically-elicited pinna response in these awake rats.

For behavioral testing, male albino rats were first spinally transected under halothane anesthesia and then implanted with a stainless steel bolt which was attached to the skull. In other cases, the spinal transection procedure was replaced by epidural anesthesia of the spinal cord via chronically implanted PE-10 tubing in the epidural space at T-2. Infusion of 10% procaine produces a reversible mid- and hind-body paralysis thus allowing for pinna measurement and unit recording in awake, restrained animals. Awake animals were subsequently mounted in a modified Kopf stereotaxic instrument using the implanted bolt. Acoustically-elicited pinna movement was measured with a photocell device. At rest the pinna interrupted a light beam. However, movement of the pinna in response to an acoustic stimulus activated a phototransistor which produced a graded output proportional to the magnitude of pinna movement.

The amplitude of the pinna reflex was directly related to stimulus intensity, exhibited short-term habituation, pre-pulse inhibition, and enhancement by prior fear conditioning. Pinna response amplitude was increased following systemic administration of strychnine and decreased following clonidine. It is concluded that this preparation and response system are valid for studying various forms of behavioral modification.

Other investigators using anatomical tracing techniques have indicated that pinna muscles are innervated by the medial subdivision of the facial motor nucleus (FMN). Electrophysiological investigation of the FMN in the present study revealed that cells in the medial division are accessible to single-unit analysis in this awake preparation and respond with a latency of less than 6 msec to an acoustic startle stimulus. Currently we are analyzing single-unit activity of the FMN during changes in the pinna response in the awake, spinally anesthetized rat.

290.12 ASSESSING THE INHIBITORY LONG-TERM HABITUATION MECHANISM USING THE TIME COURSE OF THE BEHAVIORAL ACOUSTIC STARTLE RESPONSE IN THE RAT. Wesley P. Jordan, Psychology, St. Mary's College of Maryland.

Auditory stimuli to a rat of sufficient intensity to provoke a startle reflex produces two independent types of response habituation. A transient, short-term habituation is mediated by neural mechanisms within the stimulus-response (S-R) pathway for the reflex in the caudal brainstem. Superimposed upon this short-term mechanism is a relatively permanent, long-term habituation. Long-term habituation requires inhibitory neural mechanisms extrinsic to the S-R pathway of the response. Lesions to either the midbrain reticular formation (MRF) or to the vermis of the cerebellum severely attenutes or abolishes habituation over days without altering short-term habituation. This long-term habituation mechanism actively inhibits the S-R pathway on each stimulus presentation.

The extra synapses necessary for the extrinsic habituation mechanism requires that the influence of these elements on the response occurs shortly after the stimulus has elicited the reflex. By sampling rapidly with a microcomputer the activity of the stabilimeter used to measure the startle response, it is possible to chart the time course of the response.

On the initial stimulus presentation, the amplitude of the response peaked within the first 100ms from stimulus onset and then declined to baseline within approximately 300ms. With habituation, the amplitude of the peak of the startle response declined and the slope of the response curve from the peak back to baseline became more negative (i.e., became steeper). There was no systematic change in the latency of the peak response during habituation. Of particular interest was a suggestion that the steep slope of the response from peak to baseline was due to the arrival of the inhibitory influence from the extrinsic mechanism. This was suggested by two observations. First, the responsiveness approximately 200ms after stimulus onset was below the baseline of activity seen several hundred milliseconds later and occured only after habituation. Second, animals with lesions in the MRF failed to show this change in slope.

These results must be interpreted with caution until the dynamics of the test apparatus's response can be evaluated fully. A more direct approach that measures the EMG response is in progress.

290.13 DENDRITIC SPINES AND ASSOCIATIVE SYNAPTIC PLASTICITY.
D. H. Perkel. Theoretical Neurobiology Facility, Department of Psychobiology, University of California, Irvine 92717.

Previous theoretical studies (Perkel and Perkel, 1985; Miller et al., 1985) have shown that active membrane in spine heads can lead to amplification of the postsynaptic potential in the dendrite, as compared with synaptic placement on a passive spine head or on the dendritic shaft. Other studies (Shepherd et al., 1985) have shown that, in a population of spines having active membrane, stimulation of a sufficient number of synapses produces a cooperative effect, in which large-amplitude depolarizations are produced in groups of neighboring spines, which in turn can propagate nearly non-decrementally along the dendrite, for as long as there is a sufficient density of active spines.

A class of theories on the cellular basis of plasticity (G. S. Lynch et al., 1985) proposes that as a consequence of repeated stimulation of synapses on dendritic spines, the synaptic efficacy is enhanced; in the particular case of long-term potentiation (LTP), the mechanism is thought to be an increase in the number of effective receptors for neurotransmitter, the increase being mediated through calcium-ion accumulation in the spine head. LTP is increased heterosynaptically, i.e., when several synapses are activated concurrently. However, if the cooperative effect of active spines were operative, the large depolarizations in a widespread population of spine heads would be expected to result in high levels of calcium ion in most such spine heads, and the consequent enhancement of synaptic efficacy would be too widespread and nonspecific to serve as a plausible learning mechanism.

Accordingly, we have explored the effects of transmitter-actuated, voltage-dependent calcium-ion channels, alone and in combination with the usual voltage-dependent channels. When the degree of voltage dependence in transmitter-actuated channels is sufficient, both signal amplification and cooperative effects are produced; however, the required degree of voltage dependence is higher than is usually attributed to depolarizing synaptic conductances.

With more modest degrees of voltage dependence in these channels, suffient amplification is provided through additional inward-current channels (not activated by transmitter). Cooperative effects may then be effectively limited to those spines under concurrent synaptic activation. As a result, calcium-mediated subsynaptic modification is confined to those synapses that are repeatedly and simultaneously activated; neither the large depolarizations nor the synaptic enhancement spread beyond the appropriate synapses. Such combinations of channels are suggested as possible substrates for LTP and associative learning in such systems as the hippocampus.

## FUNCTIONS OF GLIA III

291.1 ASTROCYTIC CELL CLONES FROM MOUSE CEREBELLA : EFFECTS ON SURVIVAL AND DIFFERENTIATION OF EMBRYONIC NEURONES.
B. PESSAC* and F. ALLIOT* (SPON : G. Barbin). INSERM U178, Hôpital Broussais, 75674 Paris Cedex 14, France.

To investigate the role of astrocytes on the survival and differentiation of neurones, we have used astrocytic clonal cell lines which we have derived from 8 day post-natal mouse cerebellum and might be the in vitro counterparts of the fibrous and velamentous astrocytes and of the Golgi epithelial cells (Alliot, F. and Pessac, B., *Brain Res.*, 306:283, 1984). Single cell suspensions from cerebellum of 15 day embryonic mice were seeded upon confluent monolayers of each of the astrocytic cell clones. About 80 % of the embryonic neurones, identified by tetanus toxin binding, adhered within 3 hours. The astrocytic clones had distinct effects on the survival of these neurones. On the Golgi epithelial cells and the velamentous astrocytes, the number of neurones remained constant or increased ; in contrast, only 10-20% of the neurones that had adhered to the fibrous astrocytes were present after 5 days of coculture. This "toxic" effect could be mimicked by conditioned media of fibrous astrocytes.

The differentiation pattern of the neurones varied markedly between the cocultures with the 3 types of astrocytic cell clones. After 48 hours, the majority of neurones cultured on Golgi epithelial astrocytes appeared highly branched often with a spiderweb morphology, while many neurones extended a network of recurrent processes on the velamentous astrocytes. Most neurones present on the fibrous astrocytes had few long unbranched processes. These differences in neuronal morphology were more pronounced in cocultures maintained up to 12 days. In addition these morphologically differentiated neurones acquired distinctive markers ; specific anti-GABA antisera (given by A. Towbie and M. Geffard) labeled 50% and 25% of the neurones maintained respectively on the velamentous or on the Golgi astrocytes and monoclonal antibodies specific for cerebellar neurones bound with a distinct pattern to the embryonic neurones cocultured with the astrocytic clones.

Taken together these data indicate that each astrocytic type has a distinct effect on the survival of neurones and induces a distinct differentiation pattern in embryonic cerebellum neurones.

291.2 NEURON-GLIAL CONTACTS INDUCE ASTROGLIAL DIFFERENTIATION.
M.E. Hatten, M. Woods*, J. Sanchez*, C.A. Mason and R.K.H. Liem. Dept. Pharmacology, NYU Sch. of Med., New York, NY 10016.

In vitro studies on purified mouse cerebellar granule neurons and astroglia have revealed that neurons induce the expression of complex astroglial shapes needed for neuronal migration and regulate the rate of glial proliferation. Here, we have used the technique of recombining purified cerebellar granule neurons and astroglia in vitro to measure the time course of the effects of neurons on astroglia and analyze the importance of cell-cell contacts for astroglial differentiation.

The time course of the effects of neurons on glial form and cell division is rapid. Neurons bind to glia within minutes and $^{3}$H-thymidine incorporation drops several thousand-fold within 3-6h. This result depends on the number of neurons added, with a threshold at one neuron per astroglial cell. Also within 3-6h of neuronal binding to the glia, the amount of glial filament protein, measured by immunocytochemistry, increases dramatically, the glial cytoskeleton reorganizes and glial form changes from an undifferentiated, flat shape into highly elongated shapes. Over the next 36h, the astroglia transit through a series of forms from simple, elongated shapes to the complex shapes commonly seen in microcultures of postnatal cerebellar cells.

To analyze whether the effects of neurons on astroglial morphology and differentiation are mediated by trophic factors or contact interactions, we tested conditioned medium, fixed neurons and neuronal membranes. Medium conditioned by neurons alone or by both neurons and astroglia does not induce astroglial differentiation. Similarly, the co-culture of neurons and astroglia in separate wells with co-mingled medium does not effect glial growth or shape.

The effects of fixed neurons and neuronal membranes are similar to results seen with intact, viable granule neurons. Adding fixed neurons (0.5 percent paraformaldehyde) or neuronal membranes to purified glia inhibits astroglial $^{3}$H-thymidine incorporation and induces glial morphological differentiation. The major difference between intact cells and fixed cells is the duration of the effect. Intact neurons regulate glial proliferation and shape for periods as long as a week, fixed cells for 24-48h only.

These experiments suggest that cell-cell contacts between neurons and astroglia regulate astroglial cell division and differentiation. Supported by NIH grants NS 15429 and NS 21097 (MEH) NS 16951 (RKHL) and NS 15182 (CAM), The Alfred P. Sloan Foundation and the Irma T. Hirschl Trust.

291.3 ASTROCYTES IN THE DORSAL COLUMNS OF THE DEVELOPING SPINAL CORD. T. J. Sims,[1] S. A. Gilmore,[1] J. S. Kenney*[2] and S. G. Waxman[2]
[1]Univ. of Arkansas for Med. Science, Little Rock, AR 72205.
*Inst. of Biolological Science, Syntex Research. Palo Alto, CA 94304.
[2] Stanford Univ. Sch. of Med. and V. A. Med. Ctr. Palo Alto, CA 94304.

Astrocytes and their related cells, the radial glia, have been implicated in the guidance of axons during normal development. This issue, however, remains to be settled. In this study astrocytes in the midline of the dorsal spinal cord in normal and irradiated rats were examined postnataly to assess their involvement with developing axons of the dorsal columns. For the irradiation procedures a beam of x-rays (4000R) was localized to a 5 mm segment of lumbosacral spinal cord in 3-day-old rats. Normal and irradiated lumbosacral spinal cords were examined by immunocytochemical staining against GFAP and by electron microscopy. Two antibodies directed against GFAP were used; one was a polyclonal anti-GFAP ( source L. Eng ) and the other a monoclonal against both GFAP and vimentin ( source J. Kenney and T.Sims ). At 7 days postnatal the first cells to exhibit immunoreactivity in the dorsal columns had radial processes in the midline oriented toward the surface of the cord. At 14 days many positively stained astrocytes were observed in the dorsal half of the columns and were contrasted by the lack of staining in the cells of the dorsal funiculus adjacent to the dorsal columns. Ultrastructural identification of 9 nm filament-containing cells in the midline at 7 days confirmed that these cells were radial glia. In the normal and irradiated spinal cord the processes of the radial glia terminate at the cord surface, where they form, in part, the glia limitans. At 7 and to a greater degree at 14 days, radial glia project finger-like processes around bundles of axons. In the irradiated cord at 14 days, ectopic axons were seen on the dorsal surface of the glia limitans outside the confinement of the cord. In this situation radial glia extend finger-like projections to contact or surround these ectopic axons. At 25 days, ectopic axons were no longer seen on the surface of the cord. These findings strongly suggest that GFAP positive radial glia play an active (and a corrective) role in the maintenance of spinal cord architecture. Supported by NIH NS-04761 and NS-15320.

291.4 OUTGROWTH OF ASTROGLIAL PROCESSES IN DISSOCIATED CEREBELLAR CULTURES. C.A. Mason and M.E. Hatten. Dept. Pharmacology, N.Y.U. School of Medicine, New York, NY 10016.

Little is known about the induction and elongation of the processes of astroglia. With the in vitro model system developed in this laboratory, we have asked how neurons associate with glia during outgrowth and compared glial process outgrowth to neuronal process outgrowth. Cultures of dissociated mouse cerebellum at postnatal day 4-7 were observed 1, 3, 5, 8, and 24 hrs after plating, with a combination of immunocytochemistry with antisera to glial filament protein, electron microscopy, and video time-lapse microscopy. The forms, activity, and corresponding cytology of glial processes, particularly the stellate astroglial forms, and the cell-cell contacts of neurons with glia during the various phases of outgrowth were studied. Three phases of glial process outgrowth and neuron association occur: 1). 1 hr - rounded neurons and glia fall to the surface of the dish. Astroglia contain scattered glial filaments in their soma, their cell surface is highly ruffled, and extension and withdrawal of short filopodia take place. 2). 3-8 hrs - rapid extension of glial processes. As glial processes originate on the soma, filopodial extension ceases on that aspect of the soma. The growing glial processes end in a growth cone that generally has the motile behavior and appendages of neuritic growth cones (lamellopodia, filopodia). In contrast to neurites, however, the glial growth cone is the leading edge of a thick paddle of cytoplasm, rather than a thin neurite, and glial filaments extend from the process well into the growth cone. The thick glial arms do not branch extensively, and they reach their final length of 50-70 μm during this period. 3). 5-24 hrs - increasing association of neurons with glia. When first plated, neurons and glia are randomly arranged. By 5 hrs, neurons begin to preferentially associate with glia, and veil-like structures and filopodia extend from glial arms near the soma to encompass groups of neurons. By 24 hrs, at low power, islands of cells with neurons positioned on glia are well-formed. These experiments suggest tht glial process outgrowth results in specific glial forms and that neurons might play a role in this process. (Supported by NIH Grant NS 15182, and The Alfred P. Sloan and Irma T. Hirschl foundations).

291.5 ASTROCYTES OF THE CENTRAL NERVOUS SYSTEM (CNS) AND NON-MYELINATING GLIA OF THE PERIPHERAL NERVOUS SYSTEM (PNS) ARE ASSOCIATED WITH APOLIPOPROTEIN E. J.K. Boyles*, R.E. Pitas* and R.W. Mahley* (SPON: R.M. Nitkin). Gladstone Foundation Laboratories, University of California, San Francisco, CA 94140.

The plasma protein apolipoprotein E (apo-E) ($M_r$ = 35,000) is an important determinant of lipid transport and lipoprotein metabolism in mammals. Although a major source of apo-E production is the liver, recent work has identified apo-E mRNA in high concentration within the brains of rats, marmosets, and man (Elshourbagy et al., **PNAS**, 82:203, 1985). In the present study, apo-E has been identified with specific cells of the CNS and PNS by light and electron microscopic immunocytochemistry using cryostat sections of formaldehyde-fixed tissue.

All astrocytes from each of the major subdivisions of the CNS, including specialized astrocytic cells — Bergmann glia, tanycytes, pituicytes, and Müller cells — contained significant concentrations of apo-E. Neurons, oligodendroglia, microglia, ependymal cells, and choroidal cells did not. In dual labeling experiments, apo-E was expressed with equal intensity by all astrocytic glia, whereas GFAP was variable in its expression. Apolipoprotein E was present not only in the perinuclear region of astrocytic cells, but also in those cell processes ending on basement membranes at either the pial surface or along blood vessels. Extracellular apo-E was present along many of these same surfaces, suggesting that apo-E is secreted by astrocytic cells. This impression was confirmed by electron microscopic immunocytochemical studies: apo-E could be identified in the Golgi apparatus, which is a secretory organelle. In culture, astrocytes continued to secrete apo-E. The apo-E extracted from rat brain was similar to that secreted by astrocytes in culture but differed from plasma apo-E. Brain apo-E had a slightly higher apparent molecular weight ($M_r$ = 36,000) and was composed of more acidic isoforms.

In the PNS, apo-E was found by light level immunocytochemistry to be present within the perinuclear region of those glia that surround neurons (satellite cells of the cervical dorsal root ganglia and superior cervical sympathetic ganglion as well as the enteric glia of the intestinal ganglia). Apolipoprotein E was also present, but to a lesser extent, within the non-myelinating Schwann cells but not within the myelinating Schwann cells of peripheral nerves (cervical sympathetic trunk, brachial plexus, sciatic nerve, and cervical spinal nerves).

The secretion of apo-E by support cells of both the CNS and PNS suggests that apo-E has an important, previously unsuspected role in the physiology of nervous tissue. In addition, apo-E secretion promises to be a valuable marker for cells of astrocytic lineage in the CNS and perhaps of non-myelinating glia in the PNS.

291.6 MODULATION OF ASTROCYTE RESPONSES BY EPIDERMAL GROWTH FACTOR, FIBROBLAST GROWTH FACTOR, AND PLATELET-DERIVED GROWTH FACTOR. K. R. Huff* and W. Schreier*. (SPON:L.Erinoff) Neurology Research Lab, Children's Hosp. L.A., Univ.Southern Calif. Sch.of Med., Los Angeles, CA 90054.

There must be controlling signals for the proliferation of astrocytes in the developing brain and in the reactive gliosis response. Epidermal Growth Factor (EGF), Fibroblast Growth Factor (FGF), and Platelet-Derived Growth Factor (PDGF) are found in the nervous system but much remains to be known about the nature of the astrocyte response to these signals. For example it is not known whether these growth factors may modulate each other's effect on astrocyte behavior.

Primary astrocyte cultures have been purified from the cerebral cortex of 1 day rat pups and maintained for several months in media containing fetal calf serum (FCS) or several weeks in serum free media. The cells have a flat polyhedral undifferentiated morphology but contain bundles of cytoplasmic filaments which stain intensely for glial fibrillary acidic protein. EGF stimulated a maximal increase in cell number at 10 ng/ml and an increase in thymidine incorporation for DNA synthesis at 2 ng/ml at 24 hours. FGF also mildly stimulated thymidine incorporation. The rate of leucine incorporation into protein was not stimulated by EGF, although it did not decline and the cell total protein increased with higher EGF concentration. The mitogenic effects and increase in protein by EGF treatment was not as great as with addition of FCS however. EGF produced an absolute increase in ornithine decarboxylase (ODC) activity, a marker for cell trophic responses, at 2 and 4 hours.

Pretreatment of the cells by FGF 50 ng/ml for 18 hours reduced both the EGF-induced increase in cell number and thymidine incorporation rate into DNA. PDGF pretreatment 0.5 unit/ml for 18 hours also reduced the EGF-induced increase in thymidine incorporation at lower EGF concentrations of 0.5-1.0 ng/ml but not higher. Dibutyryl cyclic AMP (dBcAMP) 1mM pretreatment did not have this effect. The pretreatments did not effect EGF-induced leucine incorporation. Although the growth factors increased the protein content of the cultures slightly, pretreatments with FGF and PDGF but not dBcAMP consistently reduced the thymidine incorporation stimulation produced by FCS treatment.

These data support the conclusion that EGF has a definite mitogenic influence on astrocytes which is dose and time dependent. It may have a maintainence influence on protein catabolism and stimulate an ODC mediated trophic response. Although FGF was mitogenic to a lesser extent, pretreatments by both FGF and PDGF reduced the mitogenic effect of both EGF and serum. Possibly this pretreatment effect is through heterologous down regulation of EGF receptors. These findings point to a modulation or turning off effect through growth factor interaction of proliferative signals to the astrocyte.

291.7 **ANTEROGRADE SPREAD OF SCHWANN-CELL MITOSIS IN WALLERIAN DEGENERATION** A. L. Oaklander and P. S. Spencer. Institute of Neurotoxicology and Departments of Neuroscience and Pathology, Albert Einstein College of Medicine, Bronx, N.Y. 10461

Neuron-glia communication is required for events such as nerve development, myelination, degeneration and regeneration, but little is known about how it occurs. We are studying axon-Schwann cell relations during Wallerian degeneration (W.D.) in the peripheral nervous system. Transection of a peripheral nerve triggers a series of phenotypic alterations in Schwann cells distal to the injury, of which mitosis is one of the earliest and best characterized events. This study examines the spatio-temporal spread of premitotic DNA synthesis along transected peripheral nerves.

Sciatic nerves of anesthetized adult cats were transected at the notch. Animals were housed at stable temperature for 2.5, 3, 3.25, 3.5, or 4 days following surgery. Three cats (6 sciatic nerves) were used at each timepoint. Operated animals were reanesthetized and distal stumps excised from the transection site to the level of the ankle. Nerves were sliced into 2-mm segments, desheathed, and incubated for 2 h at 37°C in tissue culture medium M199 containing $^{3}$H-thymidine (85-90 Ci/mmol). Following incubation, nerve pieces were rinsed in saline, then homogenized and washed 3 times in 10% trichloroacetic acid containing 0.1% thymidine. Remaining insoluble material was dissolved in 1N sodium hydroxide. Incorporation of $^{3}$H-thymidine was measured by scintillation counting, protein by the Lowry method, and results expressed as femtomoles $^{3}$H-thymidine incorporated/microgram protein.

At 2.5 and 3 days post-transection, $^{3}$H-thymidine incorporation was enhanced only in the most proximal portion of distal stumps. In contrast, by 4 days, incorporation was elevated along the entire length (14-18 cm) of excised nerve. Previous autoradiographic studies have shown that Schwann cells comprise approximately 80% of $^{3}$H-thymidine-labelled nuclei in 4-day distal stumps. At 3.25 days, the elevation in $^{3}$H-thymidine incorporation had advanced to approximately 11 cm distal to the transection site, and at 3.5 days the front had progressed virtually to the end of the nerves studied. Sham-operated nerves exhibited extremely low baseline levels of incorporation of $^{3}$H-thymidine.

These data suggest that Schwann cells close to the site of nerve injury enter premitotic S-phase prior to those located more distally. Following a lag of approximately 3 days, distal Schwann cells enter S-phase within approximately 12 h. S-phase appears to be initiated in a proximo-distal sweep whose rate is comparable to that of fast axonal transport.

Supported by Shell Companies Foundation and NIH grant OH00851.

291.8 SERUM ASCORBIC ACID REGULATES MYELIN FORMATION AND BASAL LAMINA ASSEMBLY BY SCHWANN CELLS IN VITRO. C.F. Eldridge*, M.B. Bunge, and R.P. Bunge. Dept. of Anat. and Neurobiol., Washington Univ. Sch. Med., St. Louis, MO, 63110.

Rat Schwann cells co-cultured with sensory neurons in serum-free (N2) medium are viable for many months in vitro but fail to ensheathe or myelinate axons and do not form a basal lamina. Supplementation of N2 medium with either human placental serum plus chick embryo extract (EE) or fetuin plus ascorbic acid has been reported to stimulate Schwann cell myelination and basal lamina assembly (JCB 97:369a,1983; JCB 99:404a,1984). We have made counts of myelin segments in whole mount cultures to study the relative efficacy of these supplements in promoting myelination and have made parallel observations of the deposition of basal lamina components using immunocytochemistry. In agreement with previous reports we found that cultures grown in N2 medium alone lacked both myelin and extracellular basal lamina components (collagen type IV, heparan sulfate proteoglycan) except for a sparse punctate distribution of laminin on the Schwann cell surface. Whereas the addition of fetuin plus ascorbic acid to N2 medium promoted myelin formation (mean number of myelin segments/sq.mm=65, SEM=31, n=5 cultures), the effect was less pronounced and more variable than after the addition of serum plus EE (mean=290, SEM=12, n=5). The serum used could be divided into two categories according to whether or not EE was required for myelin formation. Some lots of serum promoted myelination in the absence of EE; dialysis of such serum abolished its ability to stimulate myelination, and the addition of ascorbic acid to the dialyzed serum restored the ability. Other lots of serum did not promote myelination unless EE was present; the addition of ascorbic acid to such serum (either whole or dialyzed) was sufficient to promote myelination equal to or greater than that achieved after the addition of EE. Myelin formation in N2 medium supplemented with ascorbic acid alone was minimal, indicating a requirement for a non-dialyzable serum component. There was a strict correlation between myelin formation and the deposition of basal lamina components by Schwann cells under all conditions tested. The role played by serum is not understood; ascorbic acid is known to promote the formation of triple-helical collagen molecules, which are not detectable in cultures fed N2 medium alone. Although a direct effect of ascorbic acid on the process of myelination itself has not been ruled out, we believe that an important role of ascorbic acid is to indirectly promote myelin formation by enabling the Schwann cell to surround itself with a basal lamina stabilized by triple-helical collagen.

(Supported by NIH grant NS09923)

291.9 NEURONAL REGULATION OF BASAL LAMINA FORMATION BY SCHWANN CELLS. M.B. Clark*, C.F. Eldridge*, and M.B. Bunge. Dept. Anat. & Neurobiol., Washington Univ. St. Louis, MO 63110.

Earlier studies from this laboratory demonstrated that the presence of nerve cells is required for the formation of a basal lamina on the Schwann cell (SC) surface in tissue culture (Bunge et al., 1982). In these cultures SCs and neurons (Ns) were in contact with each other. The present study investigated whether direct contact between Ns and SCs is required for the generation of basal lamina. SCs on 10 mm coverslips were co-cultured on 37 mm bed cultures of SCs, Ns, or SCs + Ns according to one of four conditions: 1) as SCs in contact with Ns (SCs+Ns) on coverslips placed on beds of SCs in contact with Ns (SCs+Ns/SCs+Ns), 2) as isolated SCs on beds of SCs in contact with Ns (SCs/SCs+Ns), 3) as isolated SCs on beds of Ns (SCs/Ns), and 4) as isolated SCs on beds of SCs (SCs/SCs). Coverslip cells and surrounding bed cells were not in contact. Co-cultures were maintained for 3-4 weeks in medium known to induce myelination (Eldridge et al., this volume). Accumulation of basal lamina components, such as type IV collagen and heparan sulfate proteoglycan, was assessed by light microscopic immunocytochemistry; formation of basal lamina was assessed by electron microscopy.

Our results indicated that contact between Ns and SCs was necessary for the formation of a linear immunostaining pattern typical of well-differentiated basal lamina and for the formation of an organized continuous basal lamina fine structure. Nevertheless, isolated SCs on beds of SCs + Ns (SCs/SCs+Ns), Ns (SCs/Ns) or SCs (SCs/SCs) exhibited some positive staining for basal lamina constituents, although the pattern of this staining was not linear around the isolated coverslip SCs. This indicated that uncontacted SCs could synthesize and secrete at least some basal lamina components. Electron microscopy of these isolated SCs demonstrated that organization into a continuous basal lamina had not occurred. In aggregates of isolated SCs (SCs/Ns, SCs/SCs, or SCs/SCs+Ns), however, basal lamina-like material had accumulated between the clustered SCs, and discontinuous segments of basal lamina sometimes appeared on SC surfaces. Accumulations of basal lamina-like material noted electron microscopically among clustered SCs corresponded to patches of immunostaining at the light microscopic level.

In summary, these studies demonstrate that direct contact between SCs and Ns is not essential for SCs to synthesize and accumulate at least some basal lamina constituents, but contact is required for the development of a well-organized, continuous basal lamina. (Supported by NIH grant NS 09223.)

291.10 MONOCLONAL ANTIBODY RAT-401 IDENTIFIES DEVELOPING SCHWANN CELLS. B. Friedman and S.J. Hockfield. Cold Spring Harbor Laboratory, Cold Spring Harbor, NY 11724

Previous work in this laboratory, generated a monoclonal antibody, Rat-401, that stains embryonic nonneuronal cells in the rat peripheral and central nervous system. The stained nonneuronal cells in the central nervous system become the radial glial cells, as shown by their morphology and by the close temporal correlation of their appearance and disappearance with the period of neuronal cell migration. The fate of the Rat-401 nonneuronal cells in the peripheral nervous system is the focus of the present study, which presents evidence that these cells survive and become differentiated Schwann cells.

Immunoreactivity of Rat-401 with nonneuronal cells was examined in adult and developing peripheral nerve and in mixed Schwann cell-fibroblast cultures prepared from peripheral nerve from rats at postnatal day 2. Rats were transcardially perfused with 4% paraformaldehyde and fixed peripheral nerve was dissected and stored in fixative. Nerve was sectioned at 100 $\mu$m and reacted with Rat-401, followed by antimouse IgG antibody conjugated to horseradish-peroxidase (HRP). The HRP was visualized with diaminobenzidine and the sections were subsequently dehydrated, embedded in plastic and sectioned for light and electron microscopy. Schwann cells and fibroblasts grown on glass coverslips in tissue culture were tested for Rat-401 immunoreactivity after removal of the media and fixation with 4% paraformaldehyde. Immunostained cultures were dehydrated and mounted on glass slides with permount.

Rat-401 recognizes Schwann cells that have ensheathed axons in early postnatal peripheral nerve. At the light microscopic level, the staining appears to be distributed throughout the cell cytoplasm. Rat-401 recognizes morphologically differentiated Schwann cells in mature nerve. At the electron microscopic level, the Schwann cell cytoplasm is immunoreactive but the subjacent myelin sheath is unstained. Peripheral nerve endoneurium is also not stained, an indication that fibroblasts are not recognized by Rat-401. This has been corroborated by Rat-401 immunostaining of nonneuronal cell cultures. Schwann cells, identified by their spindle shapes, are intensely immunostained while fibroblasts, identified by their irregular flattened profiles, fail to be recognized by Rat-401.

These results indicate that Rat-401 stains Schwann cell cytoplasm in differentiating and mature Schwann cells as well as Schwann cells deprived of axonal contact in cell culture. This suggests that the embryonic nonneuronal cells present in peripheral nerve prior to axon outgrowth (Hockfield and McKay, 1985) are early Schwann cells and may play a role in the support of growing axons.

291.11 HIGH MOLECULAR WEIGHT GLYCOPROTEINS RELATED TO MAG ARE FOUND IN ACTIVELY MYELINATING OLIGODENDROCYTES BUT NOT IN MYELIN.
J.R. Gulcher,* L.S. Marton,* and K. Stefansson* (SPON: B.G.Arnason) Dept. of Neurology, U. of Chicago, Chicago, IL 60637

Myelin-associated glycoprotein (MAG) is a minor constituent of CNS myelin. Previous work on developing human CNS has demonstrated the existence of several high molecular weight glycoproteins (130 to 250kd) that share at least three epitopes with MAG (Marton and Stefansson, JCB, 1984, 99, 1642).

These glycoproteins appear before MAG and are undetectable in the mature adult. More specifically, these proteins seem to be present only in areas of the CNS undergoing active myelination.

We have isolated one of these polypeptides (130kd) in the following manner:

1) Centrifugation (90,000g) of human fetal brain homogenate in Tris-saline buffer.
2) The supernatant was brought up to 30% Ammonium sulfate at pH 7.0.
3) After centrifugation (10,000g) the supernatant was brought up to 40% AS.
4) The pellet (10,000g) was resuspended and put over a MonoQ anion exchange column (Pharmacia).

The 130kd polypeptide is 15-20% carbohydrate based on deglycosylation with Endoglycosidase F.

Affinity purified polyclonal antibodies specific for the 130kd protein that do not bind to MAG were used for immunohistochemical staining of adult and fetal (30 weeks) spinal cord. We found:

1) No staining of myelin in either the adult or fetus.
2) No staining of cells in adult.
3) Strong staining of cells that appear to be actively myelinating oligodendrocytes in the fetus.

These preliminary results indicate to us that this glycoprotein may have an important but as yet, unknown role in myelination.

291.12 THE DEVELOPMENT OF TRANSFERRIN-POSITIVE CELLS IN THE RAT CNS
J.R. Connor and R.E. Fine* Lab. of CNS Injury and Regeneration, Veterans Administration Medical Center, Washington DC. 20422, Dept of Physiology, George Washington University School of Medicine, Washington DC and Dept. of Biochemistry, Boston University School of Medicine, Boston MA, 02118

Transferrin is a plasma protein whose major function is iron transport and mobilization. In an earlier study we demonstrated that Tf is present in oligodendrocytes and endothelial cells in the adult rat brain. The purpose of this experiment is to describe the development of Tf positive cells in the rat CNS.

Rat pups were perfused with 4% paraformaldehyde and the tissue to be studied was removed at cut on a cyrostat at 16-32 um thickness. Thus far, animals at 7(n=2),8(n=1), 20(n=2), 23(n=1) and 30(n=2) post natal days have been examined. Antiserum to rat Tf prepared in rabbits was utilized and the reaction sites visualized using either PAP or ABC. In either case, 3'3' diaminobenzidine was the chromogen.The adult pattern of Tf-immunoreactivity is seen in the cerebral cortex, corpus callosum, corpus striatum and spinal cord at 30 days of age. Oligodendrocytes are Tf positive and the reaction product is confined to the soma in a "cap-like" fashion. Very few processes of oligodendrocytes are Tf-positive except for those in the corpus striatum and the white matter of the spinal cord.

At 20 days after birth, many Tf positive oligodendrocytes are observed throughout the CNS areas studied and the density and distribution pattern are similar to that observed at 30 days. However, in addition to oligodendrocytes in the spinal cord some anterior motor horn neurons are Tf-positive in the 20 postnatal day group.

In the 7 or 8 day old CNS tissue, very little Tf-immunoreactivity is observed. The greatest density of Tf positive cells in this age group is in the corpus striatum.

The function of Tf in the CNS is still speculative. The development pattern suggests: 1) The storage of Tf in oligodendrocytes occurs or increases to detectable levels after formation of the blood-brain-barrier. The formation of the blood-brain-barrier apparently initiates the requirement for Tf storage because Tf is no longer immediately accessible to the CNS. 2) Tf-Positive cells increase in number at the beginning of myelinogenesis, 3) Tf-immunoreactivity follows the pattern described for carbonic anhydrase labelling of oligodendrocytes.The bicarbonate ion is necessary for Tf to bind iron. No data on the development of iron in the CNS are available. Our findings suggest that Tf is important in myelination and is stored in the mature nervous system.

## MORPHOGENESIS AND PATTERN FORMATION II

292.1 AN ATLAS OF THE DEVELOPING MOUSE BRAIN.
P.A. Simmons. Southern California College of Optometry, 2001 Associated Road, Fullerton, CA 92631.

This study describes the histological features of the mouse brain during development from embryonic day 10 through adulthood. The atlas will allow identification of both the location and size of particular structures and also the timing of specific developmental events.

Timed matings (within 12 hours) were made between normal C57Bl/6J mice (Jackson), and embryos were removed at daily intervals from the 10th embryonic day through birth (generally at day 19) and for postnatal days 0 (day of birth) through 21, as well as for adults. Embryonic brains were fixed by immersion; older postnatal and adult brains were fixed by cardiac perfusion. 4% paraformaldehyde or 4% paraformaldehyde with 0.5-1.0% glutaraldehyde in a phosphate buffer was used as the fixative. Following dehydration and paraffin embedding, serial sections were made of specimens from each day in both coronal and sagittal planes. Adjacent sections in each series were stained for cell bodies or for fibers so that the growth of nuclei and fiber tracts could be followed.

This study will provide the basis for quantitative morphological investigations on the growth rates of various brain structures. In addition, the atlas will provide valuable information to cellular neurobiologists who wish to determine the optimum locations and time periods to remove portions of the brain for study of cell-cell interactions in vitro.

292.2 PRENATAL TELENCEPHALIC DEVELOPMENT IN THE PRECOCIAL MOUSE, ACOMYS CAHIRINUS.
Peter C. Brunjes, Dept. of Psychology. University of Virginia, Charlottesville, VA 22901

Acomys cahirinus (the "spiny mouse") is born after a 38 day gestation period fully furred, with ears and eyes open and with sophisticated locomotor capabilities. Acomys is a member of the same subfamily (muridae) as the laboratory rat and mouse, which are both born in a very immature state. This fortuitous circumstance has allowed us to pursue an in-depth comparison of rates and patterns of brain growth between closely-related altricial and precocial species. In studies of the postnatal development the olfactory bulb (Dev Brain Res 8,1983,335), hippocampal formation (Brain Behav Evol 24,1984,58) and area 17 of visual cortex (Dev Brain Res in press) we have reported that 1) each of the three regions undergoes a different time course of postnatal growth, suggesting regional control of maturation and 2) two out of the three regions show quite different patterns of postnatal brain development when Acomys is compared to mice or rats of the same post-conception age, suggesting that regional patterns of brain development vary between species and that Acomys is not merely a mouse or rat born late. The present research is an examination of prenatal development in order to have a fuller picture of brain growth in Acomys. Fetuses were obtained every other day throughout the last two-thirds of gestation, brains embedded in either GMA or paraffin and coronal and sagittal sections stained with H&E or toluidine blue. A similar set of sections from rats were also prepared for comparison. At the earliest times examined, (day E 14) the two species seemed to be in a rather similar ontogenetic state. However, by the time of birth in the rat (E 22-23) Acomys was approximately 4 days less mature. For example, the E 22 Acomys olfactory bulb contains a widely patent ventricle, and the only visible layer is that of the mitral cells. The same-aged rat or mouse has developed at least the rudiments of all bulb layers. The neocortex of the E 22-24 Acomys exhibits a dense cortical plate with the first layers barely differentiated at the ventral margin, a situation much less mature than that found in the altricial species. The lag between the species appears to increase, with Acomys approximately a week less mature than the rat by E 25-27. A prenatal growth spurt occurs in Acomys near the end of the fourth week and continues into the postnatal period. The results indicate 1) the notion that precocial species have long gestation periods so that they can be mature at birth is in error, Acomys "wastes" considerable time in its prenatal development when compared to the mouse or rat, and 2) the protracted mid-gestation of Acomys may allow increased resolution into processes of brain growth.

292.3 DEVELOPMENTAL PATTERN OF THE CELLS OF ORIGIN OF THE CORTICOSPINAL TRACT OF THE RAT. D. J. Schreyer and E. G. Jones. Dept. Anatomy, University of California at Irvine, Irvine, CA 92717.

We have used the retrograde transport of the fluorescent dye Fast Blue injected specifically at cervical or lumbar segments of the spinal cord to label cortical cells projecting axons to these levels of the cord during the first three weeks of life and during adulthood in the rat. The cortical projection to cervical segments is first established during the first few postnatal days by a circumscribed group of layer V pyramidal cells in the dorsal parietal cortex. The set of cortical cells projecting axons at least as far as the cervical cord then expands widely to include layer V cells occupying frontal, parietal and cingulate cortex in a continuous sheet by the end of the first postnatal week. During the second and third postnatal weeks the set of cells contributing axons to the cervical cord and beyond diminishes such that unlabeled areas appear in lateral frontal and lateral parietal cortex, dorsally at the border of frontal and parietal cortex, and medially in medial frontal and cingulate cortex, according to a complex schedule. At the end of the third postnatal week, the adult pattern of cortical cells projecting to cervical levels and beyond is attained. Major concentrations of corticospinal cells occupy frontal, dorsal parietal and ventrolateral parietal cortex including, but not limited to MI, SI and SII, exclusive of the facial representation.

The cortical projection to lumbar segments is first established at the end of the first postnatal week by a circumscribed group of layer V pyramidal cells in dorsal parietal cortex. In contrast to the projection to cervical segments, the projection to lumbar segments undergoes only modest expansion during the subsequent week. The dorsal parietal cell group then maintains the projection to lumbar segments without diminution throughout the developmental period and into adulthood. The dorsal parietal area containing the projection to lumbar segments is the same area that contains the cells initially projecting to cervical segments and includes the hindlimb representation of SI in the adult.

We conclude that the first cortical axons to advance down the spinal cord are those that will innervate the lumbar segments in the adult. Later addition of axons projecting only as far as cervical levels includes those which will establish a persistent connection from frontal and ventrolateral parietal cortex and others that will shortly be eliminated from lateral and medial frontal, lateral parietal and cingulate cortex. At no stage do we observe a substantial projection to the spinal cord from occipital cortex. Supported by NIH Grant NS 10570.

292.4 EARLY HISTOGENESIS IN THE BASAL FOREBRAIN OF THE RAT EMBRYO: THE BASAL FOREBRAIN CELL COLUMN AND ITS ADULT DERIVATIVES. R. Marchand and C. Blanchet*, Laboratoire de Neurobiologie, Hôpital de l'Enfant-Jésus, Québec Canada G1J 1Z4.

Autoradiographic $^{3}$H-thymidine studies dealing with the timing of genesis of the neurons of both the diencephalon and the telencephalon have shown that several of the most early generated neurons of the forebrain are found in the following cell groups: the bed nucleus of the stria terminalis, the lateral preoptic area, the central, medial and anterior cortical nuclei of the amygdaloid complex, the entopeduncular nucleus, the lateral hypothalamic area, the retrochiasmatic nucleus, the dorsal hypothalamic area and the most medial area of the zona incerta.

To study the histogenesis of these early generated cell groups, a series of 13 precisely dated gestating rats were given a pulse of tritiated thymidine at day 11 and 15 hours of gestation. On each subsequent day, the embryos of one gestating animal were killed and prepared for autoradiography. One rat gave birth and its pups were also killed on different days of postnatal life.

As we progress to younger stages of development, the different cell groups so typically organized in the adult forebrain become less clearly circumscribed. It is the radioactive labeling that allows recognition of the early generated neurons identified in adult forebrain. On day 15 of gestation, the heavily labeled neurons of the lateral hypothalamus, of the bed nucleus of the stria terminalis, of the lateral preoptic area and of the amygdala become organized along the longitudinally oriented fibers of the basal forebrain bundle. The longitudinal slab of heavily labeled neurons thus formed in the mantle of the early forebrain was called the basal forebrain cell column. In day 14 embryos, all the heavily labeled neurons of the forebrain form an unbroken cell column extending caudorostrally from the tuberculum posterius to the optic stalk where it divides in two limbs. The heavily labeled neurons of the ventral limb of both sides of the brain merge on the midline in close relationship with the chiasmatic plate primordium. In later stages of development these neurons form the retrochiasmatic nucleus. The neurons of the dorsal limb extends rostrally as far as the ventricular elevation in the floor of the foramen of Monro.

This study discloses that many early isochronically generated cell groups of the forebrain of the rat originate from an ependymal matrix closely asssociated with the ventral diencephalic sulcus and migrate to the early forebrain mantle to constitute the basal forebrain cell column. In later stages of development, the neurons derived from the basal forebrain cell column begin to break up into a series of more definite nuclei. [Supported by the MRC of Canada and the FRSQ].

292.5 MODULAR ARRANGEMENTS OF NEURONAL PROCESSES IN HUMAN CINGULATE CORTEX. F.M. Benes, C.A. Marotta, R. Majocha* and E.D. Bird. Departments of Psychiatry and Neurology, Harvard Medical School and McLean Hospital, Belmont, MA 02178.

The cerebral cortex is known to have unique cytoarchitectural features that are believed to play an important role in its function as a central integrator. Our basic understanding of cortical cytoarchitecture may continue to expand as a result of recent immunocytochemical techniques which can produce widespread staining of neuron-specific markers such as peptides, transmitters and components of the axonal and dendritic cytoskeleton. Recently, it has been found that robust neuron-specific immunostaining in human post-mortem specimens of anterior cingulate cortex is possible using an antibody raised against the neurofilament 200K subunit (NFP-200). Widespread staining, presumed to occur primarily in axonal cytoskeleton, was observed throughout the cortical matrix of 7 control specimens. This neuron-specific staining appeared to occur preferentially in medium and large calibre axons, since stained processes in the sub-cortical white matter were noted to be continuous with fiber bundles in the overlying cortical matrix. Some bundles travelled in a horizontal direction and followed the natural radial curvature of the gyrus, while others were vertical and projected radially toward the molecular layer in a highly ordered arrangement. The distance between neighboring bundles appeared to be uniform for both the horizontal and vertical arrays and produced the net effect of 25-30 μm box-like compartments or modules throughout layers IIIB through VI. These modules, therefore, produced a columnar appearance in both the vertical and horizontal planes. The space lying between adjacent vertical bundles, where there was an absence of NFP-200 immunostaining, may conceivably correspond to the putative minicolumn, since both have a similar width. The fact that modular columns also occurred in the horizontal axis further suggests that cortical processing, which is generally believed to occur predominantly in the vertical plane, may be two-dimensional. Thus, the module may be important as the smallest unit for integration of horizontal with vertical information. Further studies will seek to determine whether other cortical areas, particularly those in sub-human species, show this modular arrangement of NFP-200 immunostained fibers and whether a dementing illness like Alzheimer's disease may involve a disruption of this orderly arrangement of neuronal processes. Supported by RSDA MH 00423, MH 31154, MH/NS 31862, AG 02126, AG 00084, and a McKnight Foundation Award.

292.6 IMMUNOCYTOCHEMISTRY OF NEUROEPITHELIAL BASAL LAMINA ALTERATIONS IN RAT EMBRYOS WITH GENETIC HYDROCEPHALUS. K.S. O'Shea, C.J. D'Amato, and S.P. Hicks. Dept. of Anatomy & Cell Biology and Dept. of Pathology, Univ. of Michigan Medical School, Ann Arbor, MI 48109.

The neuroepithelial basal lamina (BL) appears to play a crucial role in controlling cell-cell interactions during early CNS development, particularly between neuroepithelium (NE) and underlying mesenchyme. In the current study, the distribution of BL components, laminin and collagen IV, were examined in developing control embryos, and embryos homozygous for a gene which produces prenatal hydrocephalus.

Embryos were removed from pregnant rats on the afternoon of days 12-14 days development (1st day = sperm +), immersion fixed for 1 h at room temperature in 4% paraformaldehyde, 0.2% glutaraldehyde in 0.1 M phosphate buffer. Embryos were then cryoprotected in 20% sucrose, and 8 um frozen sections cut through the cephalic region. Sections were incubated in rabbit anti-laminin antibody (1:50) or rabbit anti-collagen IV antibody (1:100) for 2 hours, followed by goat anti-rabbit IgG-FITC (1:50) for 30 minutes. Additional controls were not exposed to the primary antibody. Sections were then viewed and photographed in a Leitz Orthoplan photomicroscope.

Except in regions of active neural crest cell migration, distribution of laminin and collagen IV immunoreactivity appeared very similar in control embryos; following the smooth uninterrupted contour of the BL. However, in hydrocephalic embryos there were numerous interruptions in BL staining for these components. Collagen IV distribution was especially patchy and unlike controls, there was little collagen IV present in the BL of hydrocephalic embryos on the 12th day, but by the 14th day considerable immunoreactivity was observed. These results suggest a delay in synthesis or deposition of this structural element in the neuroepithelial basal lamina of hydrocephalic embryos.

Current investigations are in progress to extend these observations to the ultrastructural level. Supported by NIH grants NS-19825 and NS-21108.

292.7 ASYMMETRIC DEVELOPMENT OF THE HIPPOCAMPAL REGION IN THE SHAKER SHORT-TAIL (sst) MUTANT MOUSE. R.S. Nowakowski and D. Wahlsten. Dept. of Anat., U. Miss. Med. Ctr., Jackson, MS 39216 and Dept. of Psych., Univ. of Waterloo, Waterloo, Ont., Canada N2L 3G1.

Shaker short-tail (sst) is an autosomal recessive mutation that produces abnormalities in a variety of CNS structures including the hippocampus and the dentate gyrus (Wahlsten et al., '83, J. Hered. 74:421-425; Nowakowski and Wahlsten, '85, Anat. Rec. 211: 140A). The mutation sst is particularly interesting because it has differential penetrance (i.e., the sst/sst genotype does not always produce the same phenotype), and a variety of abnormalities have been observed. These abnormalities include complete or partial absence of the granule cell layer of the dentate gyrus, the presence of ectopic pyramidal and granule cells in the stratum oriens, variations in pyramidal cell number in area CA3, and reductions in the thickness and apparent cell density in the entorhinal cortex. The occurrence of these abnormalities varies not only from mouse to mouse but also from one side of the brain to the other. Thus, any one of the abnormalities listed above may be present on one side of the brain, whereas the other side of the brain may appear virtually normal. At present we do not have sufficient numbers of animals to determine if the abnormalities in different portions of the hippocampal region occur independently or if there are any right-left preferences.

Tritiated thymidine experiments show that in the case of the reductions in thickness and cell density in the entorhinal cortex the side with the reduced number of cells lacks the late-generated cells that would normally occupy the most superficial strata, whereas the side with the apparently normal number of cells in the entorhinal cortex has the late-generated cells. This observation suggests that the influence of the sst/sst genotype in the entorhinal cortex is on cell proliferation, although the role of differential cell death has not yet been explored.

Previously, we have reported that the abnormalities in the hippocampus and dentate gyrus are also the result of developmental deficits in both neuronal proliferation and neuronal migration (Nowakowski and Wahlsten, '85). Thus, taken together, these data suggest that the asymmetric development of the hippocampal region occurs relatively early in the developmental process. It seems likely that the asymmetry produced by the sst/sst genotype is not a normal feature of the hippocampal region, although it is also possible that it is acting by amplifying asymmetries that are normally present but masked by other features of the mature structure. In either case the availability of a mutation in which clear asymmetries are present may be a useful tool for analyzing the normal development of asymmetries in the CNS.

Supported by grants from the NSF (BNS-8120050), NIH (NS-21922) and the Vaughan Stroke Fund to RSN and from NSERC (A4748) to DW.

292.8 THE WEAVER MUTATION: REGIONAL VARIATIONS IN CEREBELLAR DEVELOPMENT AND PROPOSED EARLY TIME OF GENE ACTION. K. Herrup and E. Trenkner. Dept. Human Genetics, Yale Med. School, New Haven and Dept. Pharmacology, NYU Medical Ctr., New York City.

Weaver (wv) is an autosomal mutation of mice. Homozygotes express a characteristic ataxia first noticeable in the second postnatal week. The most obvious structural corollary to the behavioral defect is the abnormal development of the cerebellum. The major pathological deficiencies reported to date are 1) an abnormal development of the Bergmann gial cell; 2) a defective postnatal migration of the granule cell neurons from their site of genesis in the external granular layer (EGL) to their final adult position in the internal granular layer (IGL); 3) the postnatal degeneration of most granule cells; and 4) the misalignment of the cerebellar Purkinje cells accompanied by a deficit in their numbers.

In our study of the weaver abnormalities, we have focussed on the developmental interaction of the Purkinje and granule cell, and have uncovered several previously undescribed anomalies. First, viewed from its dorsal aspect the patterns of cerebellar foliation appear haphazard (although bilaterally symmetric) with a distinct sulcus marking the midline. Second, although in midline sagittal sections the foliation resembles the wild type pattern, in sagittal sections from the hemispheres, the folia are chaotic in appearance due, in part, to a dorsal overgrowth of cerebellar tissue. This finger like extension of one hemispheric folium tends to run predominantly anterior-posterior with many medial extensions. The ectopic growth appears as if it compresses the more regular cerebellar tissue beneath it. Third, as late as postnatal day 35, the lateral cerebellum, particularly the flocculus/paraflocculus, has a modest population of granule cells in a semblance of an IGL. Fourth, the regional variation suggested by these observations is further emphasized by the density of Purkinje and Golgi II cells. Cell counts reveal that, while the number of cells per section is down by half at the midline, the value in the hemispheres is nearly normal. Overall we observe a 40% decrease in number.

We believe the data point to a mechanism of gene action that involves the Purkinje as well as the granule and Bergmann glial cell. The spectrum of defects suggests that the mutation interferes with the normal migration of both neuronal types beginning at early times in cerebellar development.

Supported by the March of Dimes and NS-20591 (KH) and NS-20073 (ET).

292.9 STAGGERER MUTANT SHOWS DEMINISHED EXPRESSION OF TWO PURKINJE CELL-SPECIFIC PEPTIDES. J.R. Slemmon*, J.I. Morgan* and Dan Goldowitz. (SPON: R.E. Wimer) Div. Neurosci., Beckman Rsch. Inst., Duarte, CA, 91010; Phys. Chem. & Pharm., Roche Inst. Mol. Biol., Nutley, NJ, 07110 and Dept. Anat., Jefferson Med. Coll., Philadelphia, PA, 19107.

Two Purkinje cell-specific peptides (cerebellin and des-ser$^1$-cerebellin) were previously isolated and sequenced from rat and mouse (PNAS USA 1984,81; 6866-6870). Both chemical and immunocytochemical studies demonstrated that the expression of these peptides was developmentally regulated in the cerebellum. Chemical analyses of the cerebellins in Purkinje cell mutants (PCD, nervous) demonstrated only moderate losses of peptide expression, while in other cerebellar mutants (Weaver, Reeler), where primary gene action is believed to be extrinsic to Purkinje cells, there was a precipitous loss of peptide expression. Immunocytochemical localization of the cerebellins in Weaver and Reeler confirmed the chemical analyses. The Purkinje cells in these animals showed restricted peptide localization that was largely confined to regions with dense clusters of granule cells in Reeler and in the flocculo-nodular lobe in Weaver and Reeler.

These earlier studies suggested that cerebellin expression was at least partially dependent on granule cells and that the mechanism may involve synaptic contact. To examine this possibility, Staggerer (15, 30 and 90 days old) was employed since the genetic lesion in this animal results in an altered dendritic spine that interrupts the establishment of these synaptic contacts. Immunocytochemical localization in the control mice showed a typical expression profile for the cerebellins. In contrast, the Staggerer contained no cerebellin-positive Purkinje cells in any of the different aged animals examined. These results were unexpected in the 15-day-old mutant since a large number of granule cells were still present, and the majority of these had successfully migrated toward the internal granule cell region.

The results from this investigation suggests that synapse formation between granule cell and Purkinje cell neurons is therefore required for the normal expression of the cerebellins. The mechanism by which cerebellin levels are maintained does not appear to involve environmental conditioning, but rather a localized process that requires the establishment of synaptic contacts.

292.10 EARLY CORTICAL LESIONS ALTER CEREBRAL MORPHOGENESIS AND CONNECTIVITY IN THE RAT. B. Kolb and D. van der Kooy, Dept. of Psychology, Univ. Lethbridge, Lethbridge, AB., Canada, T1K 3M4.

Rats with neonatal removal of the frontal, motor, or parietal cortex are behaviorally different from rats with similar lesions in adulthood. Although they show spared functions on some learning tasks, the animals show severe impairments at most species-typical behaviors and complex spatial learning tasks. A possible reason for these data is that the early lesions produce changes in the development of the remaining brain. This study examined the gross morphology and cytoarchitectonics of the cortex, as well as some of its connections following neonatal cortical ablations. Rats were given bilateral lesions of the frontal or parietal cortex or complete hemidecortication at 1, 5, 10, or 100 days of age. The retrograde tracers true blue, propridium iodide, or nuclear yellow (.1 µl) were injected into the neocortex, striatum, or hippocampus of different animals in adulthood.

There were striking changes in both the morphology and connectivity in the neonatal operates, the effects being largest in the youngest operates. First, the earlier the lesion, the smaller the adult brain. Second, in the bilateral lesion groups, the earlier the lesion, the thinner the residual cortex. In contrast, for the hemidecorticates, the earlier the lesion the thicker the cortex, Third, acetylcholinesterase staining showed the normal patchy striatal organization was still present, even in the complete absence of cortical afferents in the hemidecorticate group. Fourth, details of the cortical cytoarchitecture were altered in both Nissl and myelin preparations. Fifth, early lesions altered the structure and connectivity of the thalamus, the earliest lesions having the greatest effect. Sixth, there were changes in thalamocortical organization, the most striking change being the presence of many labeled cells in the lateral geniculate nucleus following injections into the sensorimotor cortex of rats with frontal lesions. Seventh, there was an abnormal projection from the substantia nigra (compacta) to the sensorimotor cortex just posterior to the lesion boundary in the 1-day, but not older, frontal operates. Lucine injected into the nigra of 1-day frontal lesion rats also produced anomolous labeling in the parietal cortex. Finally, there were anomolous projections from the striatum ipsilateral to the early hemidecortication to the contralateral prefrontal cortex. In addition, the nigrostriatal projection was organized differently on the side ipsilateral to the lesion. These anatomical abnormalities may account both for why early cortical lesions may have different effects than adult lesions and why 1-day lesions have far more severe effects upon behavior than do later lesions.

292.11 LECTIN BINDING SITES IN THE POSTNATAL MOUSE CEREBRAL CORTEX: EPHEMERAL APPEARANCE OF THE BARREL FIELD. N.G.F. Cooper* and D.A. Steindler. (SPON: B.J. McLaughlin). Dept. Anat., Univ. Tenn. Ctr. Health Sciences, Memphis, TN 38163

Plant lectins bind to sugar residues of oligosaccharides, and enzyme linked lectins can therefore be used to histochemically localize cellular glycoproteins. We have shown that lectin affinity changes occur globally within the cerebrum and cerebellum during postnatal development (Cooper and Steindler, Neurosci. Abs., 10:43, 1984). The objectives of the present study were to define developmentally regulated changes in lectin affinities within a specific region of the cortex, namely, the primary somatosensory cortical barrel field. The somatotopic representation of the contralateral whisker pad in this region has been extensively studied, and it is recognized as a useful model for studying CNS pattern formation and plasticity. Parasagittal and flattened tangential vibratome sections from aldehyde-fixed cortex were treated with peroxidase-conjugated lectins. Following peroxidase histochemistry, the sections were processed for light and electron microscopy (LM and EM). At the LM level, we observed lectin binding in the barrel field of postnatal days 3 through 6 animals. The lectins bind with greater affinity to the presumptive sides rather than the centers of the individual barrels at a time when cells are evenly distributed throughout this region as judged by cresyl violet staining. The absence of a lectin delineated barrel field in postnatal days 1 and 2 suggests that this region develops its unique topography later than other areas of the cerebrum, described previously, and the cerebellum (Steindler and Cooper, Neurosci.Abs., 11, 1985) where discrete lectin bound laminae are present on day 1. While the barrel field is readily demonstrated with cresyl violet staining in the adult cortex, we were unable to demonstrate its presence with lectins in the adult. The ephemeral appearance of the barrel field suggests a critical period in development with respect to the synthesis of glycoconjugates recognized by these lectins. This period may be correlated with the development of a topographic pattern of innervation. Preliminary EM analysis demonstrates that lectin binding is predominantly related to the neuropil, being present on and between membrane surfaces of growing axons and dendrites. Supported by USPHS grants EY 02708 (N.G.F.C) and NS 20856 (D.A.S.).

292.12 LECTIN AND CHOLERA TOXIN BINDING SITES IN THE POSTNATAL MOUSE CEREBELLUM. D.A. Steindler and N.G.F. Cooper*. Div.Neurosci. Dept. Anat. Univ. Tenn. Ctr. Health Sciences, Memphis, TN 38163

Neuronal and glial cell surface glycoconjugates, and possibly extracellular glycosoaminoglycans, are presumed to play a role in the development of pattern formation in the CNS. We have used the binding properties of lectins and cholera toxin to determine if their binding to glycoproteins and gangliosides labels prospective cytoarchitectonic features in the early postnatal mouse cerebellum. Vibratome sections of postnatatal day (P) 1, 3 and 7, and adult mouse brains were incubated in peroxidase-labeled wheat germ agglutinin (WGA), peanut agglutinin (PNA), concanavalin A (Con-A), cholera toxin (CT), and radiolabeled WGA([N-acetyl-3H]). Control sections were incubated with lectins in the presence of various sugar haptens (e.g. N-acetylglucosamine, chitotriose, N-acetylgalactosamine, a-methyl mannoside, mannan) at different concentrations. Competition experiments were also performed by way of incubating sections with both peroxidase-labeled or unlabeled lectins (or CT) and WGA, N-[acetyl-3H]. Tissue sections were processed for histochemistry and/or autoradiography and examined under the light and electron microscopes.

The labeling patterns of the P1-P7 cerebellar cortex appear similar with all three lectins and CT, in contrast to that seen in the adult where different lectins and CT label different cellular layers. Most striking is the presence of an intense band of lectin and CT binding in the developing molecular layer. Electron microscopy reveals a pronounced labeling of young parallel fibers in this region. CT binding within the internal granule cell layer is patch-like beginning between P3-P7, and in the adult such labeling is similar to that seen in other studies using antibodies to gangliosides such as GD3 (Graus et al., Brain Res.324:190,'84). Negative staining of such patches with lectins such as Con-A indicates differences in ganglioside versus glycoprotein synthesis and distribution. Double labeling studies using peroxidase-labeled and radiolabeled lectins reveal the development of complementary labeling patterns within cortical layers as well as the deep cerebellar nuclei- e.g. in the adult, WGA and CT binding produces heavy labeling of the molecular layer; Con-A labels Purkinje and deep nuclear cells, whereas WGA binding in the deep nuclei is distinctively punctate and mostly perisomatic.

These results indicate that lectins and toxins recognize the development of distinct cytoarchitectural features in the cerebellum. The presence of variation in intensity between folial crowns and fissures of a lectin and CT positive band within the developing molecular layer, for example, adds credence to a notion of lectin and toxin recognition of glycoconjugates involved in neuronal migration, alignment, and synaptogenesis. Supported by USPHS grants NS-20856 (DAS) and EY 02708 (NGFC).

292.13 LECTINS AS MARKERS OF DEVELOPMENT IN THE RAT BRAIN T.J. DeGrauw* and B.H. Liwnicz. Division of Pediatric Neurology, Children's Hospital Medical Center and Department of Pathology, University of Cincinnati Medical Center, Cincinnati, Ohio 45229.

Biochemical studies have shown qualitative and quantitative changes of central nervous system (CNS) carbohydrate moieties during brain development (Margolis) et al, Brain Research, 112:363, 1976). Raedler and Raedler (Anat. Embryol, 162:21, 1981) have demonstrated an alteration in lectin affinity during the fetal development of rat brain. This study lacked later stages of brain development. We evaluated the binding of four lectins to rat brain at several fetal and postnatal stages of development. Rat brains at gestational days 13 (G13), 16(G16), 22(G22) and at newborn days 5 (N5) and 11(N11) were fixed in buffered formalin, slices were embedded in paraffin and 5 um sections were stained with concanavalin A (ConA), Ulex Europaeus Agglutinin I(UEAI), Wheat germ Agglutinin(WGA) and Peanut Lectin(PNL). Immuno-cytochemical staining was performed using biotinylated lectins in an Avidin-Biotin Complex(ABC) with and without neuraminidase digestion. At G13 the ventricular layer stained positively with all lectins. WGA stained bloodvessels and Con A bound diffusely to all brain structures. The ventricular layer at G16 showed the same staining pattern. In addition we found that UEAI bound to the majority of cells and cell processes and PNL stained scattered cells. Neuraminidase treatment did not alter the staining pattern. A clear change was seen at G22. PNL did no longer bind to the ventricular layer, positive staining was however evoked after digestion with neuraminidase. The number of cells, labeled by UEAI decreased progressively at G22 and N5. At this stage the pyramidal layer of the hippocampus did no longer stain. The pattern of WGA and Con A did not differ from earlier stages, but PNL stain started to diminish. However, pretreatment with neuraminidase increased PNL binding. The weakening of PNL staining continued at the next stage of development and at N11 a remarkable enhancement was seen after neuraminidase digestion. Other changes at this age included the absence of UEAI binding and a patchy distribution of Con A and WGA in cortex and other gray matter.

Lectins showed differential binding to rat brain at different stages of development. It appears that they can be useful in following structural changes of the developing CNS.

292.14 SYNAPSIN I IMMUNOHISTOCHEMISTRY DEMONSTRATES SYNAPTIC DEVELOPMENT IN THE RAT SUPRACHIASMATIC NUCLEUS. M.F. Bernstein and R.Y. Moore, Depts. of Neurology and Neurobiology, SUNY at Stony Brook, N.Y. 11794.

Synapsin I is a neuron-specific phospho-protein that is an endogenous substrate for cyclic AMP-specific and Ca/calmodulin-dependent protein kinases. Synapsin I is concentrated in nerve terminals in both the central and peripheral nervous system where it is associated with small synaptic vesicles (Navone et al. 1984).

The suprachiasmatic nucleus (SCN) is a late forming hypothalamic nucleus; perikaryal birth occurs between embryonic day 13 (E13) and E17 (Altman and Bayer 1978). Circadian rhythmicity in 2-deoxyglucose uptake appears in the SCN at E19, an age when ultrastructural analysis indicates that few synapses are present in the nucleus. The maternal circadian system entrains the fetal clock but the mechanism by which maternal influences are mediated is unknown (Reppert and Schwartz 1984).

In order to better understand the relations between the development of circadian rhythmicity and synaptogenesis in the SCN, synapsin I immunoreactivity was studied in coronal sections of the SCN from E19 through P10. Results from this study were compared with a previous electron microscopic (EM) study (Bernstein and Moore 1982) in which two counts were made from the SCN, total synaptic counts from micrographs scattered evenly throughout each coronal section and area counts from subdivisions of the nucleus. There are few immunoreactive elements in the E19-P2 SCN and this is corroborated by the EM total counts of synaptic terminals. At P4 synapses appear along the SCN-optic chiasm interface both in EM material and in the immunohistochemical material. The numbers of synapses increases until P8 when an essentially adult pattern is achieved. The virtual identity between the development of synapses in the EM material and the synapsin immunolabeled material indicates the power of the immunohistochemical method for the demonstration of synapse formation.

In other areas of the brain, for example, paraventricular nucleus, neostriatum, cortex and hippocampus, there is a distinctive pattern of development of synapsin immunoreactivity that differs from that in SCN. In those areas there is early staining of perikarya followed by development of densely stained terminal fields. These observations suggest that, as synaptogenesis is initiated, synapsin I is produced in perikarya and transported to axon terminals as synapsin is formed.

In conclusion, this study indicates that synapsin I immunohistochemistry provides an effective method for studying synaptogenesis.

We are grateful to Drs. Paul Greengard and Charles Ouimet for providing the synapsin I antibody. This study was supported by NIH grant NS-17600.

292.15 THE POSTNATAL DEVELOPMENT OF ANTIGENIC SAGITTAL BANDS IN THE CEREBELLAR CORTEX BY SELECTIVE REPRESSION OF IMMUNOREACTIVITY R. Hawkes* and N. Leclerc* (SPON: L. Poirier). Lab. of Neurobiology and Dept. Biochemistry, Laval University, Quebec, Canada G1K 7P4.

Monoclonal antibody mabQ113 recognizes a single polypeptide, apparent molecular weight 120 Kdaltons. In the rat cerebellum, immunoreactivity is confined exclusively to the Purkinje cells. Deposits of reaction product are found throughout the cytoplasm including the dendrites and dendritic spines, the cell body, the axons and the recurrent axon collaterals. No other cell types in the cerebellum are immunoreactive. Monoclonal antibody mabQ113 can distinguish between two classes of Purkinje cells. The mabQ113$^+$ cells are arranged in parasagittal bands which run throughout the cortex interdigitated by bands of mabQ113$^-$cells. Serial reconstructions reveal 15 bands of mabQ113$^+$ cells, one which straddles the midline and seven disposed symmetrically to either side.

We have now studied the postnatal development of mabQ113-bands. In the newborn rat (PO) there is no mabQ113-immunoreactivity. Staining first begins at around P7 and mabQ113$^+$ cells are first seen in the vermis. By P12 immunoreactivity is found throughout the cerebellar cortex. At P12 all the Purkinje cells are mabQ113$^+$. Parasagittal bands of staining emerge between P12 and P18 by the selective repression of immunoreactivity in the cells destined to become the mabQ113$^-$ bands. The adult display of bands is achieved at around P30.

292.16 ABNORMAL CEREBELLAR FOLIATION FOLLOWING NEONATAL ADMINISTRATION OF METHYLAZOXYMETHANOL ACETATE: ANALYSIS OF PARALLEL FIBER ORIENTATION. D. E. Hillman and S. Chen. Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016

A single 20 mg/kg injection of methylazoxymethanol acetate (MAM) within 24 hours of birth has been reported to produce ataxia and tremor in rats similar to the agranular cerebellum in genetic mutants or that induced by x-irradiation, virus or other chemical agents. However, our application of the procedure resulted in a large variability in the size of the cerebellum without noticeable behavioral abnormality except a slight tremor. Most unusual was a marked abnormality of the foliation persisting into adulthood regardless of the size of the cerebellum. The characteristic of this foliation was a cauliflower appearance formed by small blebs that could not be followed easily on the surface in any direction.

The cerebella were weighed and treated for Golgi impregnation and routine light microscopy. Serial-section reconstruction was used to determine the continuity in the lamination. We divided the cerebella into 3 groups as based on their weight: severe, moderate, and normal to mild. These size groups paralleled the reduction in number of granule cells. The most severely affected cerebella were reduced to half the size of controls and consisted of primitive lobules with a pebbly surface. Many folia lacked granule cells and consistently had a dispersion of Purkinje cells. The moderate group revealed a thinning of the molecular layer containing many ectopic granule cells. Many Purkinje cell somas were located in the internal granule layer. The mild group had a near normal lamination with only a few ectopic Purkinje cells. The folial pattern was the most complex in this group. The cortical layer was traced as a continuous sheet in serial sections.

The orientation of the parallel fibers seen in Golgi preparations and electron microscopy was variable in direction but primarily remained in parallel bundles following the prominent axis of the blebs. At the interception point between bundles, the parallel fibers crisscrossed or turned to merge with the larger bundle.

The mal-alignment of folia and parallel fibers was associated with perturbations in the proliferation of precursors in the external granular layer (EGL) and did not affect fiber direction once the parallel fibers began to form. This early effect on the EGL is a patchy survival of these precursors and is seen at postnatal days 5-7. A differential alignment of granule cell precursors in the patches may be responsible. Other mechanisms may involve the granule cells themselves or Bergmann glia. [Research supported by USPHS grant NS-13742 from NINCDS].

292.17 EARLY ABLATION OF THE SUPERIOR COLLICULUS DECREASES THE SIZE BUT NOT THE NUMBER OF LAYER V VISUAL CORTICAL CELLS. S. L. Pallas, K. C. Wikler and B. L. Finlay, Section of Neurobiology and Behavior and Department of Psychology, Cornell University, Ithaca, NY 14853.

Target availability is an important factor in the regulation of cell survival in the nervous system. For example, the amount of motoneuron survival in the vertebrate spinal cord parallels increases (Hollyday & Hamburger, J. Comp. Neurol., 1976) or decreases in target availability (Hamburger & Levi-Montalcini, J. Exp. Zool., 1949). The situation may be different for neurons lying completely within the central nervous system, however, because an individual neuron is both a target and a source of afference, and because central nervous system neurons often have collaterals projecting to more than one target. Mechanisms other than target control of cell survival are thus likely to operate in the central nervous system. In order to address this question, we have studied the response of pyramidal cells in layer V of visual cortex to removal of one of their principal targets, the ipsilateral superior colliculus, in the hamster. The hamster is particularly useful for this study because cortical cell death occurs postnatally.

Unilateral tectal lesions were made in neonate hamsters within 12 hours after birth. Lesioned animals were then killed on each of postnatal days 4-10, the major period of cell death in the cortex. The brains were fixed in formalin-alcohol, embedded in paraffin, and cut at 10μm. Serial sections were collected and stained with cresylecht violet. Lesions were 60-100% in extent, as verified by reconstruction. Sections through visual cortex (defined by reference to the adult) were examined and counts were made of degenerating cells, cells in layer V, and total cell number for both the lesioned and intact sides of the brain. We did not detect any differences in the normally low cell death rate between the lesioned and intact side (9.49 death index, lesion side vs. 11.16, intact side). Similarly, number of cells in layer V (748.7 cells/mm ± 164.0 (s.e.) lesion side vs. 675.4 cells/mm ± 133.5 intact side) and total cell number (3260 cells/mm ± 820.4 lesion side vs. 2840 cells/mm ± 466.8 intact) in the lesioned animals did not differ. However, we did observe a relative decrease in size of layer V pyramidal cells. The average diameter of pyramidal cells on the lesion side was 10% less than the diameter of cells on the intact side (14.6μm ± .22 lesion side vs. 16.3μm ± .25 intact side, n = 310).

Our results demonstrate that cells in lamina V of the visual cortex respond to loss of one of their principal targets not by an increase in cell death, but by a shrinkage in soma size. Death may be prevented by retention of collaterals projecting to other targets. This hypothesis will be tested with horseradish peroxidase injections into the pons following the period of synaptogenesis.

292.18 EARLY THALAMIC LESIONS INCREASE NEONATAL CELL DEATH AND ALTER ADULT CYTOARCHITECTURE IN THE NEOCORTEX M. S. Windrem* and B. L. Finlay, Department of Psychology, Cornell University, Ithaca, NY 14853

Mammalian neocortex varies regionally both in number and in relative proportions of pyramidal and non-pyramidal cells in a unit cortical column. We have hypothesized that these regional differences in adult neocortical cytoarchitecture could be produced in part by differential cell death during development (Finlay and Slattery, Sci., 219, 1983). The factors that control neocortical cell death are thus of interest. In this study we assess the roles of afference and target availability on early cell death and adult cell number and type in hamster neocortex.

Electrolytic lesions were made in thalamic nuclei on the day of birth, prior to the establishment of thalamocortical connectivity and laminar differentiation in the neocortex. The cortical projection areas of the lesioned nuclei were assessed for cell death rates in neonates and for cell number and laminar distribution in a cortical column in adults. Cell numbers and cell death rates were assessed before (postnatal days 4 and 5) and at the peak (postnatal day 7) of the normal cell death period, and cell number and type were assessed at adulthood. In a second experiment to trace the fate of neurons destined for layer 4 after thalamic lesions, pregnant hamsters were injected with $^3$H thymidine on embryonic day 14 when the cells of cortical layers 2, 3 and 4 are generated.

Total cortical area is decreased ipsilateral to the lesion in both neonates and adults, and in the adult, total neuron number per unit cortical column is reduced in variable amounts (10 to 40%) depending on lesion size. The superficial layers, 2-4 combined, were reduced by one third; particularly, layer 4, the principal thalamic input area, was barely discernible. In an adult with a small lesion, layer 6 was normal; while in an adult with a large lesion, the number of cells in layer 6 was reduced by half. The number of cells in a column remained constant only in layer 5, which is neither afferent nor target for the thalamus.

The amount of cell death in the neocortical areas investigated here is normally quite low. Cell death increase was seen at all postnatal days, including the earliest postnatal day in which normal cell death has not yet begun (P4 and P5, when normal rates are close to 0, 12.5 times higher on the ipsilateral side than the contralateral side; P7, 3.3 times higher on the ipsilateral side). In the autoradiography experiment, by P7, the numbers of labeled live cells were still unchanged, though the numbers of labeled dead cells more than doubled in the ipsilateral cortex.

These results indicate that early loss of thalamic input and target availability profoundly alter adult neocortical cytoarchitecture. Part of this alteration must occur through differential cell death. Whether the apparent disappearance of layer 4 is entirely due to increased cell death, or also to changed cell morphology is presently under investigation.

293.1 MPTP TREATMENT DECREASES NIGRAL LEVELS OF REDUCED GLUTATHIONE. T.N. Ferraro, G.T. Golden, R.G. Fariello, and T.A. Hare. Depts. Pharmacology and Neurology, Thomas Jefferson Univ., Phila., PA 19107 and Neurology Service, VA Medical Center, Coatesville, PA 19320.

Administration of the synthetic compound 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) has been documented to produce a parkinsonian syndrome in both humans and animal models. To elucidate the mechanism underlying the selective toxic effect of MPTP on substantia nigra (SN) neurons, an ultrasensitive HPLC method was used to study over 30 amino acids and related compounds (AA) in SN and caudate/putamen (C/P) from control and MPTP-treated Long-Evans rats. Animals were given one daily injection of MPTP (25 mg/kg ip) for 15 days, and sacrificed 24 hr after the last dose. Brains were removed in < 1 min, dissected on ice and discrete anatomical regions frozen immediately; SN and C/P death-to-freezing intervals were < 3 min. Tissues were homogenized in 0.4M PCA, centrifuged and supernatant fluids filtered prior to AA analysis. Baseline studies in untreated rats documented characteristic AA profiles in SN and C/P. MPTP-treated rats exhibited significantly lower levels of Asp and reduced glutathione (GSH) in SN and significantly higher levels of Tyr, Phe, Trp, Lys and ethanolamine in C/P compared to controls. An interaction of MPTP with GSH may be related to its selective action on SN neurons since it has been documented that for toxicity to develop, MPTP must be enzymatically converted to $MPP^+$, a reactive electrophile suspected of setting up a powerful oxidation center in the brain. Compared to other brain regions, normal SN is characterized by low levels of GSH, rendering this region particularly vulnerable to insult.

293.2 ARGYROPHILIC DEGENERATION OF SUBSTANTIA NIGRA NEURONS IN C57 MICE DUE TO 1-METHYL-4-PHENYL-1,2,5,6 TETRAHYDROPYRIDINE (MPTP). R.C. Switzer, III. R.H. Cole Neuroscience Lab., Depts. Pathology and Medical Biology, University of Tennessee Memorial Research Center and Hospital, Knoxville, TN 37920

Intake of MPTP by humans causes Parkinson's disease (PD)-like symptoms which are treatable with standard L-dopa therapy. Primates and some rodents given MPTP display cerebral biochemical and pathological changes, including loss of the dopaminergic (DA) neurons of the pars compacta of the substantia nigra (pcSN), similar to PD, thereby suggesting that MPTP may be useful as an animal model for PD. However, adequate neuroanatomical evidence is lacking to show that the affected DA neurons in pcSN are the only DA neurons affected.

To determine what areas of the brain show neuronal cell death after treatment with MPTP, brain sections from 9-month-old male C57 mice were stained with the degeneration-sensitive cupric-silver stain of de Olmos. The mice were given MPTP-hydrochloride i.p. 30 mg/kg on a schedule similar to that described in an earlier biochemical study (*Science* 224:1451, 1984). The mice were grouped to receive 1,2,5, or 10 daily injections and allowed to survive either 3 or 10 days after the last injection. Groups of 6-12 brains from treated mice were embedded in the same gelatin blocks, along with one untreated control brain, for freeze-sectioning. In cupric-silver stained sections, degeneration, represented by characteristic argyrophilic neuron cell bodies, was found in the pcSN but not in the reticular part of SN. The degeneration of neuron cell bodies was most prominent in mice that survived 3 days after receiving either 1 or 2 injections. In striatum, the argyrophilic grain pattern typical of degenerating axon terminals, apparently representing the degenerating terminals of the nigra-striatal projection, was also best seen in the 3 day survival group. In those mice surviving 10 days, little or no argyrophilic debris was found, as was also true of all mice receiving 5 or 10 doses. No degenerating neurons were observed in the median eminence where other dopaminergic neurons reside.

These findings indicate three important points: 1) in MPTP-treated C57 mice, the only neurons destroyed are those of the pcSN, thereby providing some degree of validation of the MPTP-treated mouse as an animal model of PD; 2) the neuronal loss due to treatment with MPTP can occur early with only one injection, as indicated by the appearance of argyrophilic neuron cell bodies, a finding consistent with decreased dopamine in the striatum (ibid); and 3) the cupric-silver staining method is useful in the early detection of neurotoxic effects that are lethal to neurons, as well as providing a means to efficiently survey the brain for affected sites. This study was supported by the Robert H. Cole Neuroscience Foundation.

293.3 ASCORBIC ACID ATTENUATES THE NEUROTOXIC EFFECTS OF METHAMPHETAMINE, 6-HYDROXYDOPAMINE (6HDA) AND 1-METHYL-4-PHENYL-1,2,5,6-TETRAHYDROPYRIDINE (MPTP). R.M. Carelli*, M.F. Jarvis and G.C. Wagner. Dept. of Psychology, Rutgers University, New Brunswick, NJ 08903

Methamphetamine, 6-HDA and MPTP are potent central nervous system toxins causing; 1) depletion of monoaminergic neurotransmitters; 2) a decrease in dopamine uptake pumps; 3) a decrease in tyrosine hydroxylase activity; and 4) neuronal degeneration. It has been speculated that the mechanism through which each of these agents destroys neurons is the generation of hydroxyl radicals which, in turn, cause lipid peroxidation leading to membrane disruption and cell death. The formation of hydroxyl radicals can be limited by antioxidants such as ascorbic acid. Accordingly, the following study was conducted to determine if treatment with ascorbic acid attenuates the toxic actions of these compounds.

Subjects were 72 adult male Long-Evans rats housed individually with free access to food and water. They were randomly divided into nine groups of eight rats each. All rats received unilateral lesions of methamphetamine (40 ug), 6-HDA (20 ug) or 1-methyl-4-phenyl pyridine ion $MPP^+$ (20 ug). The toxin was stereotaxically delivered in a 5 ul saline vehicle to the caudate nucleus under pentobarbital anesthesia. The unlesioned side served as control. Three of the groups received ascorbic acid (100 mg/kg) IP 20 min before and then 20, 60 and 120 min after delivery of the toxin. Three of the groups received ascorbic acid (1000 mg/kg) in an otherwise similar regimen. Finally, the last three groups received only the toxin. All rats were allowed to survive one week and were then sacrificed, brains removed and caudate nucleus dissected. Brain parts were stored in liquid nitrogen until assayed by HPLC with electrochemical detection.

Methamphetamine depleted dopamine (DA) to 63% of control. Ascorbic acid (100 or 1000 mg/kg) attenuated the methamphetamine-induced DA depletion (to 84% and 90% of control, respectively). 6-HDA depleted caudate DA to 30% of control. Ascorbic acid (100 or 1000 mg/kg) attenuated the 6-HDA-induced DA depletion (to 49% and 51% of control, respectively). Finally, $MPP^+$ depleted DA to 12% of control. Ascorbic acid (100 or 1000 mg/kg) attenuated the $MPP^+$-induced DA depletion (to 34% and 57% of control, respectively). Serotonin levels were not altered by any of the treatments.

These observations indicate that ascorbic acid loading reduces the neurotoxic actions of methamphetamine, 6-HDA and $MPP^+$. Besides other neurotoxins, the generation of hydroxyl radicals is thought to be responsible for the loss of neurons associated with aging. It is conceivable that ascorbic acid could be effective in these situations as well. However, based upon the facts that ascorbic acid did not completely protect the rats, and that only one antioxidant was used, caution must be exercised in the interpretation of these results.

293.4 EVALUATION OF THE RODENT MODEL OF PARKINSON'S DISEASE USING MPTP M.F. Jarvis, J.G. Rubin* and G.C. Wagner. Dept of Psychology Rutgers University, New Brunswick, NJ 08903

The systemic administration of 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) causes destruction of nigro-striatal neurons. The toxic effects of MPTP are dependent upon its oxidation to the 1-methyl-4-phenyl pyridine ion ($MPP^+$) by MAO B. In humans and rhesus monkeys this neurotoxicity is accompanied by a behavioral symptomology similar to Parkinson's disease including resting tremor, rigidity, and akinesia. These behavioral symptoms as well as the depletion of striatal dopamine caused by MPTP are reversed by l-dopa administration. In rodents, neurochemical and histological evidence indicates that MPTP also causes nigro-striatal toxicity. However, MPTP is less potent in producing this effect in the rodent and, furthermore, the behavioral symptoms following MPTP are less severe in rodents. These latter observations have led some to question the utility of the MPTP/rodent model of Parkinson's disease. The following studies were conducted in order to evaluate the effects of $MPP^+$ on the shuttle box performance of mice. The shuttle box was chosen because, traditionally, this procedure has proven to be a sensitive screen to both dopaminergic toxicity and for neuroleptic actions.

Adult, male Rockland-Swiss mice served as subjects. Shuttle box training consisted of the following: mice were trained to respond (i.e. cross to the opposite side of the chamber) during a 20 sec buzzer (70 dB, 2500 Hz); in the absence of an avoidance response a scrambled 1.0 mA footshock was delivered until the animal either made an escape response or until 20 sec had elapsed (response failure); a 20 sec intertrial interval seperated each trial and mice received 20 trials/day.

All mice were trained to an 90% correct avoidance responding criterion/day for three days. Under these baseline conditions mice made an average of 19.6 $\pm$ 0.2 avoidance responses, 0.4 $\pm$ 0.2 escape responses, no response failures, and 19.2 $\pm$ 3.1 spontaneous crossings (during the ITI). Mice then received bilateral intra-caudate injections of 10 ug of $MPP^+$ delivered stereotaxically in a 3 ul saline vehicle. Following $MPP^+$ treatment, performance was significantly disrupted. Mice made 3.6 $\pm$ 1.4 avoidance responses, 7.2 $\pm$ 1.8 escape responses, 9.1 $\pm$ 2.6 response failures, and 2.3 $\pm$0.7 spontaneous crossings. L-dopa (400 mg/kg) reinstated shuttle box performance (9.2 $\pm$ 2.7 avoidance responses, 9.9 $\pm$ 2.5 escape responses, 0.8 $\pm$ 0.6 response failures, and 17.8 $\pm$ 8.5 spontaneous crossings). Finally, four seperate groups of mice received bilateral intra-caudate $MPP^+$ (0.0 or 10 ug/side). $MPP^+$ caused significant dopamine depletions (to 30% of control) and l-dopa (400 mg/kg, 30 min pretreatment) reversed this depletion to 127% of control. These observations substantiate the use of the rodent-MPTP model of Parkinson's disease.

293.5 EFFECT OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (1-MPTP) ON NIGRAL SUBSTANCE P-LIKE IMMUNOREACTIVITY (SPLI).
L.A. Matsuda*, P.K. Sonsalla*, J.W. Gibb and G.R. Hanson. Dept. Biochem. Pharmacol. & Toxicol., Univ. of Utah, Salt Lake City, UT 84112.

1-MPTP has been reported to have neurotoxic actions on the catecholaminergic transmitter systems of several different animal species. Most notably, 1-MPTP selectively decreases dopamine concentrations and tyrosine hydroxylase (TH) activity in the same neuronal systems that are destroyed in patients suffering from Parkinson's disease and its use in laboratory animals has been proposed as a model for this neurological disorder. In addition to the significantly reduced dopamine concentrations found in the basal ganglia of parkinsonians, the concentrations of the neuropeptide, substance P (SP) in the globus pallidus and the substantia nigra also are significantly diminished (Mauborgne et al., Brain Res., 268:167, 1983). This decrease is thought to be a compensatory reaction to the loss of nigrostriatal dopamine neurons in these patients and likely reflects increased release of SP. In order to assess the validity of the MPTP animal model for parkinsonism, we examined the effect of this neurotoxin on the nigral concentrations of SP in both rats and mice.

In male C57Bl mice, 1-MPTP treatment (15 mg/kg, q 6 h; 4 doses) reduced nigral SP concentrations to 66% of control three days after treatment. This decrease appeared to be only transient, however, since at seven days after treatment the decrease of SPLI was not significantly different from control. Similarly, in male Sprague-Dawley rats whose striatal dopamine concentrations were decreased to 51% of control by constant infusion of 1-MPTP (42 mg/24 hr; 7 days after treatment), nigral SPLI was 76% of control ($p<0.05$).

We previously reported that coadministration of the dopamine receptor antagonist, haloperidol (HALO) enhances the effect of 1-MPTP-induced reductions of striatal dopamine concentrations and TH activity (Matsuda et al., Soc. Neurosci., 10:882, 1984). However, in both mice and rats the concurrent administration of HALO (2 mg/kg, q 6 h; 4 doses) with 1-MPTP prevented the 1-MPTP-induced decrease of nigral SPLI concentrations.

These data suggest that 1-MPTP treatment modifies the transmission of the striatonigral SP system in a manner similar to that seen in patients with idiopathic Parkinson's disease. However, it is unclear why the MPTP-induced responses of the DA and SP systems are contrarily affected by the concurrent administration of HALO.

293.6 CLONIDINE PROTECTION FROM THE TOXICITY OF PERIPHERALLY AND CENTRALLY ACTIVE ACETYLCHOLINESTERASE INHIBITORS. R.S Aronstam and J.J. Buccafusco. Department of Pharmacology & Toxicology, Medical College of Georgia, Augusta, GA 30912 and Veterans Administration Medical Center, Augusta, GA 30910.

Echothiophate and soman are potent cholinesterase inhibitors whose toxic effects involve several systems. Soman affects both central and peripheral nervous systems, although it is not clear whether the primary site for acute lethality is central or peripheral. Echothiophate, on the other hand, does not cross the blood-brain barrier. The purpose of this study was to compare the symptoms of echothiophate and soman poisoning and to examine the protective effect of clonidine, a centrally-active alpha$_2$-adrenergic agonist, against each of these agents.

Echothiophate and soman were dissolved in saline and injected by a subcutaneous route into outbred, ICR mice (25-34 g) in a volume of 5 ul/g body weight. Lethal dose (LD)-response curves were constructed using 5 doses of inhibitor (8-12 animals/point). LD50 values were obtained by linear regression analysis of log dose vs probit of % lethality plots (the correlation coefficient was greater than 0.9 in all cases). Behavioral measures taken were: time to onset of whole body tremors (OTT), time to onset of loss of righting reflex (LRR), and the occurrence of Straub tail (ST), salivation (SAL), and muscle fasiculations (MF).

The LD50s for soman and echothiophate were 156 and 141 ug/kg, respectively. Tremor (OTT=3.52 min at LD90), ST (92% at LD90) and SAL (83% at LD90) were observed in soman-treated mice, but MF were never seen. Although acute respiratory paralysis was evident with both agents, no tremors were observed in echothiophate-treated mice and the occurrence of ST was low (6.3% at LD90). MF and SAL, however, occurred in all mice receiving an LD50 dose of echothiophate. Therefore, as expected, symptoms of peripheral toxicity (MF and SAL) predominated in echothiophate toxicity. With soman, central symptoms (ST and tremor) predominated and SAL was the only consistent peripheral symptom.

Pretreatment (20 min) with clonidine (300 ug/kg) reduced the toxic manifestations of an LD90 dose of soman. Lethality was reduced to 44%, OTT and LRR were increased 4 fold, and the occurrence of ST and SAL were reduced to 56 and 44%, respectively. In contrast, clonidine did not alter lethality or the occurrence of MF, ST and SAL caused by an LD90 dose of echothiophate. LRR, however, was increased (from 12.9 to 18.4 min).

These findings indicate a predominantly central site of action for the acute toxicity of soman in mice, and confirm our earlier finding that clonidine affords a selective protection against the central and peripheral muscarinic, but not peripheral nicotinic, toxic effects of cholinesterase inhibitors.

293.7 ORGANOPHOSPHATES INCREASE DIHYDROPYRIDINE RECEPTOR SITES IN RAT BRAIN. N. Monis*, J. Valdes and D.H. Ross. (SPON. J.C. Flynn) Div. Molecular Pharmacology, Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284.

Voltage-dependent ion channels have been studied as sites of action for a wide variety of neurotoxins. Some of these neurotoxins specifically alter $Ca^{++}$ fluxes across neuronal membranes, which contribute to their pharmacological effects. One such toxin, maitotoxin, derived from a dinoflagellate (Gambierdiscus toxicus) is believed to activate $Ca^{++}$ channels leading to enhanced release of neurotransmitters (Takahashi et al, JBC 258:20944-10949, 1983). Recently, the dihydropyridine $Ca^{++}$ agonist BAY K 8644 has been reported to produce profound behavioral responses when administered in vivo (Bolger et al, Arch. Pharmacol. 328:373-377, 1985). These include limb clonus, tonus, arched back, Straub tail and increased sensitivity to auditory stimulation. Since $Ca^{++}$ content in nerve terminals is believed to increase during electroshock-induced convulsions, we suspected that organophosphates may alter $Ca^{++}$ movement in conjunction with their behavioral effects. We have monitored dihydropyridine receptor sites in rat brain following in vitro and in vivo administration. $Ca^{++}$ channel receptor sites were measured as nifedipine (1 μM), displaceable [$^3$H]nitrendipine binding in cortex synaptic membranes (1 hr) following a single injection of Soman or Sarin (50 μg/kg) and 24 hrs after a single injection. Control dihydropyridine receptor binding of 112 fmol/mg protein was increased (37.5%) to 154 fmol/mg protein 1 hr after Soman administration. 24 Hrs later, treated rats still exhibited an increased dihydropyridine receptor binding activity at 133 fmol/mg protein. Membranes from Soman- or Sarin-treated rats were treated with EGTA/EDTA to remove $Ca^{++}$ and $Mg^{++}$ ions and dihydropyridine binding was repeated. In stripped membranes without $Ca^{++}$ or $Mg^{++}$, dihydropyridine receptor binding was still increased following in vivo Soman (15%), while 1.5 mM $Ca^{++}$ and $Mg^{++}$ addition further increased receptor binding to 40% over control levels. In vitro dichlorvos (50 μM) or Sarin (10 μM) increased dihydropyridine receptor binding 40% and 25% over control. These results demonstrate that organophosphates increase $Ca^{++}$ antagonist receptor sites in rat brain. These findings suggest that organophosphates may produce some of their pharmacological effects by interaction with the dihydropyridine binding site influencing $Ca^{++}$ transport.

293.8 BRIEF MALATHION EXPOSURE DURING THE LATE BRAIN GROWTH SPURT AND THE LONG-TERM EFFECTS ON MUSCARINIC AND HISTAMINERGIC RECEPTOR BINDING IN RAT BRAIN. K.E. Light, Colleges of Pharmacy and Medicine, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205

Exposure to organophosphate insecticides in the environment is becoming an increasingly common experience. Although much of the acute toxicity of these compounds is known, the chronic toxicity and particularly the effects of these compounds on developing central nervous system (CNS) receptor dynamics has infrequently been the subject of investigation.

The post-natal period of the rat presents an opportunity to investigate the effects of controlled drug exposure on the potentially vulnerable developing structures of the CNS. We decided, therefore, to expand our recent investigations concerning the effects of drug exposure during development to include malathion. CD-derived rat pups were exposed to malathion (50 mg/kg/day and 150 mg/kg/day) by sub-cutaneous injection (PN4-PN8) in a corn oil vehicle. Control animals received vehicle injections only. The pups were kept with lactating dams throughout the total postnatal period and were sacrificed on PN20. The brains were removed and dissected into the following regions: cortex, striatum, medulla-pons, cerebellum and diencephalon. $H_1$-histamine receptor binding was measured in the cerebellum by saturation analysis using ($^3$H)-pyrilamine with excess triprolidine to determine non-specific binding. The results show a dose dependent decrease (51%) in receptor site density with no significant alteration of receptor affinity.

In the striatum and cortex, muscarinic receptor binding was determined by saturation analysis using ($^3$H)-quinuclidinyl benzilate with excess atropine to determine non-specific binding. In both sections, malathion exposure did not produce significant long-term alterations of receptor binding. We conclude that malathion exposure during brain development can produce significant long-lasting alterations of selected receptor systems dependent upon the regional stage of brain development and the duration of exposure. (Supported by the UAMS Foundation Fund and NSF Grant ISP 801147)

293.9 PRODUCTION OF CONVULSIONS AND BRAIN DAMAGE BY MICROINJECTIONS OF ORGANOPHOSPHATES INTO RAT BRAIN. J.H. McDonough, M.T. Nipwoda*, M. Smith*, and C.G. McLeod*. U.S. Army Medical Research Institute of Chemical Defense, APG-EA, MD 21010-5425.

Systemic administration of certain organophosphates can produce convulsions and a disseminated pattern of brain damage. The present studies investigated the effects of direct microinjections of soman (GD) or VX, into discrete areas of the rat brain to possibly localize structures which may mediate these effects. Direct injections were performed using a stereotaxically guided microsyringe (MS) while rats were maintained under halothane/oxygen anesthesia or in conscious animals using chronically implanted cannula (CA).

Bilateral MS injections up to 11 nmol GD into the basolateral amygdala (BA) failed to evoke either proconvulsive or convulsive reactions (N=6). If rats were pretreated with lithium (LiCl 3.0 meq/kg/da, sc), similar injections of 11 nmol GD into BA evoked repetitive clonic convulsions and brain damage (N=3), varying degrees of proconvulsive behaviors (wet dog shakes, repetitive mouth movements, facial clonus) with no brain damage (N=6), or no effect (N=2). When a cholinergic agonist, carbachol (5.0 nmol), was coadministered with a dose of GD (5.5 nmol) which was ineffective by itself, both convulsive behavior and brain damage were evoked with either bilateral or unilateral MS injections into BA in animals which received no lithium pretreatments. Similar combined MS injections of GD and carbachol into the medial septum, dorsal hippocampus or nucleus basalis of Meynart did not evoke convulsive behavior nor produce brain damage.

Unilateral injections of VX (3.37 nmol) into BA using either the MS or CA technique were highly effective in eliciting convulsive reactions and brain damage. MS injections in four animals resulted in two developing convulsions, one demonstrating proconvulsive behaviors and one showing no reaction. The same dose of VX resulted in strong convulsions in five of seven CA subjects and proconvulsive behaviors in one other. All animals which convulsed had extensive bilateral pyriform cortex damage.

Brain damage was only observed in animals which developed sustained limbic convulsions after central injections of these compounds. The degree and extent of the damage in a given animal was positively related to the severity of the convulsion. These compounds do not appear to be directly neurotoxic since damage was not evident in animals which did not develop convulsions even though they received amounts of drug equivalent to those animals which did convulse and had damage. In addition, in the convulsing animals, areas in close proximity to the injection site (caudate, putamen, globus pallidus) were consistently spared damage while there was extensive destruction to distal structures (pyriform cortex, hippocampus) synaptically connected to the target area. The BA, a cholinoceptive area, is probably a critical structure for either initiating or sustaining limbic convulsions evoked by these anticholinesterase compounds.

293.10 TARGET SIZE OF NEUROTOXIC ESTERASE AS DETERMINED BY RADIATION INACTIVATION. C. D. Carrington*, D. J. Fluke*, and M.B. Abou-Donia. Duke University, Durham, North Carolina 27710.

The target size of neurotoxic esterase (NTE), the putative target site for the initiation of organophosphorus compound-induced delayed neurotoxicity, was examined by determining the rate at which the esterase activity was destroyed by irradiation. Samples of hen brain were prepared by slowly drying a microsomal preparation under vacuum. The dried samples were then irradiated with electrons from a 1 MeV Van Der Graff generator. The doses ranged from 0 to 24 Mrads. The radiation doses were calibrated by the rate of inactivation of T1 phage activity (MW=560K). Following the irradiation procedure, the samples were resuspended in buffer and enzymatic activity was measured. In eight experiments with NTE, the target size was determined to be 148±13 kilodaltons, or 138K if all the data were pooled. In three experiments with acetylcholinesterase (AChE), the target size was found to be 56±13K or 58K if all the data were pooled. There is evidence that the molecular weight of the catalytic subunit of AChE is about 70K. If AChE inactivation is used to calibrate the radiation dose, the target size of NTE is calculated to be 167K, which is very close to the apparent molecular weight (155-160K), as determined by SDS-gel electrophoresis, of the major diisopropylphosphoroflouridate binding protein with a sensitivity to organophosphorous inhibitors similar to that of NTE. The target size of NTE was found to be similar in two experiments with rat brain and one with cat brain. This study was supported in part by NIEHS grant ES0-2717 and NIOSH grant OH0 2003.

293.11 FINE STRUCTURE OF RAT HIPPOCAMPAL SLICES AND SOMAN INDUCED ACTIVITY F.J. Lebeda, K.C. Sikora-VanMeter, R.C. Wierwille and W.G. VanMeter. Dept. Neurology, Baylor Coll. Med., Houston, TX; Dept. Pharmacol. Exptl. Therap., School Med., Univ. Maryland, Baltimore, MD 21201; USAMRICD, APG, MD 21010; Dept. Vet. Physiol. and Pharmacol., Iowa State Univ., Ames, IA 50011.

Fine structure of rat hippocampal slice preparations were examined in male and female 100 gram Sprague-Dawley rats after SOMAN induced epileptiform activity. The rats were decapitated, the brains quickly removed, placed in chilled saline, and hippocampal slices prepared with a tissue chopper. The slices were transfered to a modified Haas chamber, and continuously superfused in oxygenated saline at 33 to 35 degrees C. Two sets of slices were prepared: (a) slices used for electrophysiological studies followed by fixation as described below and (b) slices used for morphology only. Control recordings by conventional methods were made from CA1 prior to 100 nM SOMAN exposure. Following SOMAN exposure of 10,30,60,120, or 180 min, epileptiform events of ca. 0.2 Hz in CA3 occur within 10 minutes of bath application. However, this activity decreases markedly with duration of exposure. For comparative analysis of fine structure, control slices were incubated in saline up to 5h followed by fixation in cacodylate buffered 5% glutaraldehyde. All slices were postfixed in OsO4, dehydrated, embedded in a Polybed812/Araldite mixture, and thin sections made from CA3. After 5h of incubation in control saline the slices show 2 layers: (i) an outer layer which mainly contains deteriorating cells and profiles and (ii) an inner layer with the majority of the neurons and neuropil intact in the presence of degenerated neurons and glial cells. Pyramidal neurons of all SOMAN exposed slices either show indentation or invagination of their nuclei, often coupled with the appearance of multiple nucleoli. Large lipid inclusions are seen within the soma of the CA3 neurons in slices preexposed to SOMAN for 5h before washout of the agents and reexposure. Furthermore, lamellar bodies, an early sign of degeneration, are present in the neuronal as well as glial elements of these slices. More degenerated neurons and glia are present in SOMAN exposed than in control slices. Moreover, the degree and frequency of degenerating profiles is also dependent upon the duration of the total exposure time. (See also NS. Abst., Sikora-VanMeter et al, this meeting)

293.12 CHANGES IN COMPOSITION OF PROTEINS OF FAST AXONAL TRANSPORT IN RATS WITH ACRYLAMIDE NEUROPATHY. M.A. Bisby and J.D. Redshaw*. Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.

Changes in the ultrastructure of spinal ganglion neurons following acrylamide administration superficially resemble those induced by axotomy (Jones, H.B. and Cavanagh, J.B., Neuropath. Appl. Neurobiol. 10: 101, 1984). Since axotomy of these neurons produces characteristic changes in the composition of fast-transported proteins (Redshaw and Bisby, Exp. Neurol. (in press), 1985) we examined the composition of fast-transported proteins in sensory and motor axons of the rat sciatic nerve following acrylamide administration.

Acrylamide (Fisher) was injected i.p. daily (50 mg/kg in 1 ml sterile saline/kg), with an equal concentration of bis-acrylamide used as a control. The development of neuropathy was assessed using the extent of hind limb splaying on landing from a 30 cm drop (Edwards, P.M. and Parker, V.H., Toxicol. Appl. Pharmacol. 40: 589, 1977). At various time intervals after beginning acrylamide treatment, fast-transported proteins were labelled by injecting L[$^{35}$S] methionine into either lumbosacral cord or dorsal root ganglia of the anesthetized rats. Transported proteins were collected proximal to a sciatic nerve crush and characterized by 1- and 2-dimensional PAGE, followed by fluorography. In addition, other rats received a distal sciatic nerve crush 7 days before L[$^{35}$S] methionine injection so that changes following acrylamide intoxication could be compared with those following axotomy.

As shown by behavioural testing, the neuropathy began around day 4 of acrylamide treatment and increased until day 10. In 10-day animals, changes were observed in the composition of transported protein in both motor and sensory axons. Our analysis of these changes concentrated on the 20-30 K dalton range where we had previously observed the most significant and reproductive changes following axotomy. We found that changes after acrylamide were both quantitatively less and qualitatively different from those following axotomy. In sensory axons no significant changes in composition were observed at 2, 4 or 7 days of acrylamide treatment, showing that the detectable changes in fast-transported proteins do not precede the development of the behavioural features of the neuropathy.

We suggest that the changes in composition of transported protein are a consequence of the neuropathy, rather than a cause. The earliest effect of acrylamide administration is a reduction in retrograde transport of NGF (Miller, M.S. et al., Toxicol. Appl. Pharmacol. 69: 96, 1983), so we propose that the changes we observed are part of the cell body reaction to loss of target-derived trophic factors.

293.13 GAPDH, PFK AND ATP IN MOUSE SCIATIC NERVE AFTER SINGLE DOSES OF ACRYLAMIDE SUFFICIENT TO SLOW RETROGRADE AXONAL TRANSPORT. Stephen M. Ross and Peter S. Spencer, Institute of Neurotoxicology, Departments of Neuroscience and Pathology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Impairment of retrograde axonal transport following single doses of acrylamide comprises the earliest detectable change in nerve-fiber integrity and precedes, by several days, the well-documented morphological alterations associated with repeated exposure to this neurotoxin. This study attempts to establish whether comparable single doses of acrylamide disrupt energy systems supporting retrograde transport in peripheral nerve. Single doses (100-300 mg/kg) of acrylamide or N,N'-methylene-bisacrylamide, a reportedly non-neurotoxic analog of acrylamide, failed to produce dose- and time-dependent alterations in the glycolytic enzymes, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), phosphofructokinase (PFK) and of the ATP levels in whole and desheathed mouse sciatic nerve. Only at the highest dose (300 mg/kg, 5 h, 30% mortality) were deficits in the enzyme activity of GAPDH and PFK recorded in desheathed nerve from acrylamide- and bisacrylamide-treated mice. At this dose and time interval, ATP concentration in whole nerve was non-significantly decreased by 22% and 32% by acrylamide and bisacrylamide, respectively, with no evidence of inhibition of GAPDH and PFK in whole-nerve post-nuclear supernatants.

These observations indicate that single doses of acrylamide, sufficient to inhibit retrograde axonal transport (100 mg/kg), fail to lower whole and desheathed nerve GAPDH, PFK and ATP levels. The interpretation of these results is hampered by the unknown contribution of axon and Schwann cell compartments to the values obtained for nerve. However, if axons contribute a small component of the total pool, then a significant change in axonal glycolytic function may be readily missed. If, on the other hand, axons make a major contribution to the total values, these data suggest that disruption of glycolysis does not appear to underly deficits of retrograde axonal transport produced by single doses of this neurotoxin.

293.14 ACRYLAMIDE ALTERS THE FUNCTION OF THE PRIMARY AFFERENT TERMINAL. Teresa DeRojas* and Barry Goldstein. Dept. of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA 30912.

Acrylamide (ACR) is a neurotoxic chemical affecting both the peripheral and central nervous systems. Previous studies have shown that the sensory nerves are more susceptible to the neurotoxic actions of ACR than motor nerves. Studies in this laboratory on the monosynaptic reflex suggest that ACR exerts its effect on the primary afferent terminal. These studies were carried out to determine the effect ACR has on presynaptic inhibition.

Eight untreated and eight ACR-treated cats were used (30 mg/kg/day for 10 days). On day 11 the animal was anesthetized with ether, respired, the spinal cord transected at C1, and the ether removed. A dorsal laminectomy was performed from L3-S2, the dura opened, and dorsal roots L6 and L7 isolated. L6 was cut distal to where it enters the cord. The sural nerve was exposed on the ipsilateral hindlimb. A stimulating electrode was placed on the sural nerve and recording electrodes were placed on the intact L7 and cut L6 dorsal roots. Input-output relationships were compared in the ACR and control groups by recording the compound action potential across L7 as the input and recording the dorsal root reflex (DRR) evoked in L6 as the output. The relative input necessary to produce a liminal DRR response was defined as the critical input. The voltage required to produce a liminal response on the input was also recorded. Following these studies, the L7 dorsal root was cut distally and split into two rootlets. One rootlet was stimulated at group I strength and the dorsal root potential (DRP) was recorded in the other.

We found that approximately 25-35% of the input was necessary to produce a liminal DRR in control animals. No DRR could be evoked in the ACR-treated cats even with greater than C-fiber stimulation of the sural nerve. The stimulus voltage necessary to produce a liminal input response in the sural nerve was increased at least 10 fold in the ACR-treated animals. The threshold DRP in control animals could be elicited with as little as 0.27±0.054 volts applied to the L7 rootlet. In the ACR-treated animals, the DRP could not be evoked even with the stimulation voltage in excess of 60 volts.

The inability to evoke either a dorsal root reflex or potential suggests that sensory processing in the dorsal horn of the spinal cord, in particular pre-synaptic inhibition is greatly impaired following the administration of acrylamide. Supported by NIH grant NS 18664-02.

293.15 DECREASED SUBSTANCE P (SP) LEVELS FOLLOWING A NOCICEPTIVE STIMULUS IN THE DORSAL HORN OF RATS EXPOSED TO ACRYLAMIDE (ACR). Barry Goldstein, Margaret Kirby, and Norman Holland*. Depts. of Pharmacology and Toxicology and Anatomy, Medical College of Georgia, Augusta, GA 30912.

ACR produces a central-peripheral distal axonopathy. Classically, it is believed that the largest diameter fibers are the most susceptible to the actions of ACR. However, some studies suggest that small diameter fibers are also affected very early in the time course of the axonopathy (Post and Mcleod, 1977; Miller, et. al., 1984).

SP is believed to be involved in the transmission of nociceptive information from small diameter primary afferent fibers. We have previously quantitated normal SP levels and those evoked by an acute nociceptive stimulus by immunohistochemistry in the dorsal horn of the rat (Kantner, et. al., 1985). The purpose of this study was to determine whether chronic administration of ACR would alter resting levels of SP in the spinal cord dorsal horn and those evoked by an acute nociceptive stimulus.

Female rats (225-250 gm) were administered 50 mg/kg ACR for 10 days. On day 11, the animals were anesthetized with urethane and the right hindpaw injected with 0.4 ml of 5% formalin or saline. Sixty minutes after injection with formalin or saline, the rats were killed by perfusion with ice-cold 4% paraformaldehyde in phosphate buffer. The spinal cord was isolated and L5 was removed, postfixed for 90-120 min., frozen in liquid $N_2$, and stored at -70°C until immunohistochemical processing. Immunostaining was done according to a modification of the peroxidase anti-peroxidase (PAP) method of Sternberger. Ten to twelve microdensitometeric readings (1.25 mm aperture, 16x objective) were made of the upper two laminae of the dorsal horn in a minimum of three sections. Gelatin matrices containing known concentrations of SP were sectioned and processed through the PAP procedure so that a standard curve could be generated. Conversions were then made of microdensitometric readings to concentration of SP.

The resting SP levels, i.e. without formalin stimulus, in control and ACR-treated rats were 0.43±0.01 umoles and 0.4±0.02 umoles ($\bar{X}$±SEM), respectively. The SP levels following the nociceptive stimulus were 1.24±0.12 umoles in control and 0.83±0.21 umoles in the ACR-treated group. This represents a 3-fold increase in the SP levels in control rats while the ACR-treated rats only increased 2-fold.

In summary, SP levels appear to be the same in both control and ACR-treated rats prior to a nociceptive stimulus. However, the increase in SP following the formalin injection was partially blocked by ACR treatment. Supported by NS-18664.

294.1 BLOCKADE OF THE AMYGDALOID NUCLEI PARTIALLY REVERSES DOCA-SALT HYPERTENSION. J.E. Szilagyi and J.E. Skinner. Neurophysiology Section, Neurology Department, Baylor College of Medicine, Houston, TX 77030.

Cryoblockade has previously been employed in our laboratory to demonstrate that neuronal activity in projections of the frontocortical-brainstem pathway is a modulator in the maintainance of elevated arterial pressure in DOCA-salt hypertensive rats (Fed Proc 43: 443, 1984; 44: 629, 1985) as well as in the initiation of lethal arrhythmias in the ischemic heart of the psychologically stressed pig (Amer J Physiol 240: H156, 1981). Cryoblockade of the amygdaloid nuclei, which project through the hypothalamus to the brainstem, also prevents stress related arrhythmogenesis (Neurosci Abst 9:1057, 1983). We now report that cryoblockade in the amygdala sufficient to halt synaptic but not axonal activity partially reverses hypertension in the DOCA-salt experimental model. Further cooling results in an additional reduction in arterial blood pressure, possibly due to expansion of the cooling gradient to include more neurons. Heart rate at each cryoblockade temperature was also significantly reduced. These data provide evidence that multiple cerebral systems influence hypertension. These same systems also are known to reduce arrhythmogenesis when blocked and thus provide a neurological explanation for why hypertension and stress are risk factors in arrhythmogenesis.

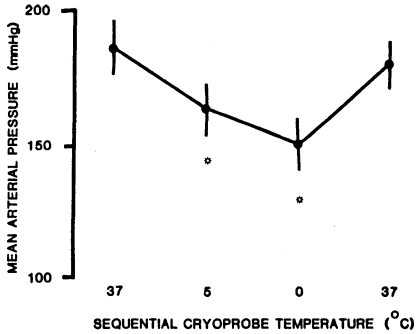

Figure 1: Reduction in mean arterial pressure during sequential cooling and rewarming of the bilateral amygdala cryoprobes. All values are mean ± SEM. * p<0.01.

294.2 HYPOTHALAMIC KNIFE CUTS ATTENUATE VASOPRESSIN-MEDIATED RECOVERY OF BLOOD PRESSURE FOLLOWING HEMORRHAGE. S.L. Bealer. Dept. of Physiology, Univ. Tenn. Ctr. Hlth. Sci., Memphis, TN 38163.

Hemorrhage results in neural and endocrine responses designed to restore blood pressure to normal. Vasopressin secretion is enhanced following hemorrhage, and the pressor effects of vasopressin are critical for recovery of blood pressure. However, the precise neural pathways which mediate this response are not completely understood. The effects of knife cuts posterior to the paraventricular nucleus alone (PVN-cut), or to both the paraventricular and supraoptic nuclei (PVN/SON-cut), on vasopressin dependent recovery of blood pressure following hemorrhage were tested in the rat. Animals received knife cuts or control surgery and were implanted with femoral artery and jugular vein catheters 2-3 weeks later.

The conscious, unrestrained rats were hemorrhaged a volume of blood equivalent to 1.8% body weight from the femoral artery. Blood pressure was continuously monitored through the arterial catheter for 30 min with no treatment. Rats then received an intravenous injection of a specific antagonist to the pressor action of vasopressin, and blood pressure was monitored for an additional 30 min. At this time, an intravenous infusion of the competitive antagonist for angiotensin II, saralasin, was initiated and continued for 15 min. Similar treatments were conducted in knife-cut and control-operated animals which were not hemorrhaged.

Prehemorrhage blood pressure was similar in all groups of rats (Cont, 100 ± 4 mm Hg; PVN-cut, 111 ± 4 mmHg; PVN/SON-cut, 102 ± 3 mmHg). In addition, the immediate post-hemorrhage decrease in blood pressure and the initial restoration of blood pressure 5 min following hemorrhage was not different between both groups of knife-cut rats and control-operated animals. However, 10 min after hemorrhage, blood pressure in control-operated and PVN-cut animals was not significantly different than pre-hemorrhage levels, while blood pressure in PVN/SON-cut animals remained significantly depressed. This relationship continued throughout the observation period. Injection of the specific antagonist of the pressor effects of vasopressin produced equivalent decreases in blood pressure 30 min following injection in control-operated (-16 ± 3 mmHg) and PVN-cut rats (-15 ± 2 mmHg), but did not alter blood pressure in PVN/SON rats (-1 ± 4 mmHg). Infusion of saralasin resulted in equivalent decreases in blood pressure in all groups of animals. These data show that in rats with knife cuts confined to the area posterior to the paraventricular nuclei, vasopressin contributed to the restoration of blood pressure following hemorrhage. However, when knife cuts extended into the ventral hypothalamus, the contribution of vasopressin was eliminated.
(Supported by USPHS Grant HL-25877, and USPHS RCDA HL-01237.)

294.3 ALTERED NORADRENERGIC ACTIVITY IN SPECIFIC HYPOTHALAMIC AREAS OF DAHL SALT-SENSITIVE RATS. K.P. Patel*, J.D. Peuler*, C.A. Whiteis*, B.J. Pardini, D.D. Lund and P.G. Schmid. V. A. Med. center., Cardiovascular center., and Dept. Int. Med., Univ. of Iowa, Iowa City, IA. 52240.

Central neurogenic mechanisms have been implicated in Dahl hypertensive rats. Lesions of anteromedial hypothalamus, paraventricular nuclei, or anteroventral third ventricle (AV3V) region have been shown to normalize arterial pressure in Dahl salt-sensitive rats. In the present study we examined the noradrenergic activity in various discrete hypothalamic areas postulated to be involved in the control of arterial pressure of 10-week old, female, Dahl salt-sensitive rats fed low (0.13%) or high (8.0%) salt (NaCl) diets (SL, SH respectively) for six weeks postweaning. The Dahl salt-resistant rats on similar regimen of low and high salt diets (RL, RH respectively) were used as controls. Blood pressure was elevated in SH group compared to RL, RH and SL groups (P<0.05). An index of norepinephrine (NE) turnover was determined by measuring the decline in tissue NE concentration 8 hours after administration of alpha-methyl-p-tyrosine (300 mg/kg, Q4hr, i.p.) in a group of animals from each of the four groups: RL, RH, SL and SH (n=5-8 per group). The data are expressed as a percent of mean initial value obtained from animals killed at zero time in each group (n=6-9 per group) (mean±S.E.) . A greater percent of NE remaining after inhibition of synthesis indicates a decreased turnover of NE in that particular tissue.

| | MPO | PO | PVN | SON | AH | PH |
|---|---|---|---|---|---|---|
| RL | 81±14 | 85±15 | 119±27 | 102±15 | 86±20 * | 49±7 * |
| RH | 69±10 | 82±11 | 78±10 | 71±14 | 82±9 * | 65±5 * |
| SL | 109±31 | 63±12 | 88±22 | 64±12 | 128±26 | 80±27 |
| SH | 59±21 | 55±12 | 79±17 | 51±18 | 152±26 | 123±19 |
| Strain diff. | | R>S | | R>S | S>R | S>R |

MPO = median preoptic area, PO = preoptic area, PVN = paraventricular nucleus, SON = supraoptic nucleus, AH = anterior hypothalamus, PH = posterior hypothalamus. * = p<0.05 vs SH.

There was increased turnover of NE in the preoptic area and supraoptic nucleus of salt-sensitive strain compared to salt-resistant strain. In contrast, NE turnover was decreased in anterior and posterior hypothalamus of the salt-sensitive strain compared to the resistant-strain. Generally SH rats had significantly different turnover of NE compared to the R-strain. These results indicate that there are genetic differences in the noradrenergic activity of hypothalamic areas in Dahl rats, which may be related to the increased arterial pressure observed in the SH group. Supported by Veterans Administration, HL-20768 and HL14388.

294.4 OPIOID μ-RECEPTORS AND CARDIOVASCULAR CONTROL: EFFECTS ON CARDIAC OUXPUT AND REGIONAL BLOOD FLOW. A.L. Siren and G. Feuerstein. Dept. of Neurology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

We have previously shown that centrally administered D-ALA$^2$-MePhe$^4$-Gly$^5$-ol-enkephalin (DAGO), a selective μ-opiate receptor agonist, induces changes in blood pressure and heart rate in conscious rats. The aim of the present study was to investigate the effects of DAGO, microinjected into the medial preoptic nucleus of hypothalamus (POM), on cardiac output and regional blood flow in the conscious rat (n=6-11). The animals were chronically instrumented for cardiac index (CI, thermodilution, Cardiomax) or blood flow (BF, directional pulsed Doppler technique) measurements. BF in hindquarters (HQ), mesenteric (M) and renal (R) arteries and the blood pressure and heart rate were continuously recorded. Microinjections of DAGO (1 or 10 nmol/rat) into the POM increased the mean arterial pressure (MAP) and pulse pressure (PP) in a dose-related manner to a maximum of +17±3 mmHg (p<0.001), respectively by the higher dose of DAGO. Central injections of DAGO induced a biphasic heart rate response: after an initial bradycardic effect (-74±17 bpm, p<0.001) the heart rate increased up to +106±13 bpm (p<0.001) 2 h after the drug administration. Concomitantly with the pressor and bradycardic responses, DAGO (10 nmol/rat) elicited a long-lasting rise of CI (max +18±5%, p<0.01) but had no significant effect on the calculated total peripheral resistance index (TPRI). Microinjections of DAGO into the POM increased the HQ BF and decreased the BF in M and R. The maximum increase in HQ BF after the 10 nmol/rat dose was +20±5% (p<0.001). The BF in M initially sharply decreased reaching its maximum (-30±4%, p<0.001) at about 3 min after the drug injection and remained impaired during the whole observation period of 2 h. The BF in R gradually decreased with the maximum drop (-22±5%, p<0.05) becoming apparent about 30 min after the injection. The calculated vascular resistance (VR) briefly decreased in HQ and dose-dependently increased in M and R. The maximum changes in VR after the 10 nmol dose of DAGO were: -10±3% (p<0.001) in HQ, +67±7% (p<0.001) in M and +51±12% (p<0.001) in R. The results indicate that the pressor response to centrally injected DAGO is due to its action on the CI. Since the increase in CI was accompanied by bradycardia, a positive inotropic effect seems to underly the increase in CI produced by DAGO. The lack of effect of DAGO on TPRI, may reflect the opposite action of DAGO on HQ and M BF and VR. This pattern of the DAGO-induced changes in organ BF suggests an involvement of the sympathetic nervous system in the cardiovascular effects of opioids, and a role of μ-receptors in the POM in redistribution of BF in peripheral organs.

294.5 ROLE OF CENTRAL OPIOID RECEPTORS IN BAROREFLEX CONTROL OF SYMPATHETIC AND CARDIOVASCULAR FUNCTION. F.J. Gordon* (SPON: R.F. Kibler) Dept. Pharm., Emory Univ. Sch. of Med., Atlanta, GA 30322.

These studies examined the influence of central opioid receptor activation on baroreflex regulation of mean arterial pressure (MAP), heart rate (HR), and sympathetic nerve activity (SNA). Rats were anesthetized with urethane, paralyzed, and artificially ventilated. The femoral artery and vein were catheterized for measurement of MAP and HR, and peripheral drug injection. SNA was recorded from the lumbar sympathetic chain. Arterial baroreceptor reflexes were provoked by electrical stimulation (5V, 2 msec) of the aortic nerve (AN) at graded frequencies (1.25 - 20 Hz) after all other arterial baroreceptor afferents had been destroyed. Baroreflex response curves were constructed following intracisternal (IC) administration of saline vehicle (5 µl), after IC injection of the relatively selective mu and delta opioid receptor agonists D-Ala$^2$, MePhe$^4$, Gly-ol$^5$ enkephalin (DAGO) or D-Ala$^2$, D-Leu$^5$ enkephalin (DADLE), and again after i.v. naloxone (0.1 and 0.5 mg/kg). Six groups of rats (n=6-7) were studied. Separate groups received IC DAGO (0.01, 0.1, 1.0 nmole), IC DADLE (1.0 nmole), i.v. DAGO (1.0 nmole), or i.v. naloxone (0.1 and 1.0 mg/kg). Graded reductions in MAP (15-60 mmHg), HR (20-130 bpm), and SNA (15-65%) produced by AN stimulation were not significantly different between the 6 groups after IC saline. IC injection of opioid peptides did not elicit any consistent pattern of cardiovascular or SNA change. Intravenous naloxone alone was also without effect. Reflex reductions in MAP, HR, and SNA elicited by AN stimulation were attenuated in a dose-dependent fashion following IC DAGO. The largest impairment (60-80%) was observed at low frequencies of AN stimulation (1.25-5.0 Hz), and became progressively less marked as the frequency of AN stimulation was increased. At 10-20 Hz only a 10-30% attenuation of baroreflex responses was observed. The inhibitory action of IC opioids was completely reversed by i.v. naloxone. Neither i.v. naloxone alone or i.v. DAGO alone had any effect on baroreflex responses. IC injection of the delta receptor agonist DADLE also attenuated baroreflex responses. The potency of this peptide was 10-100-fold less than that of DAGO, and baroreflex inhibition was completely reversed by the lowest dose of i.v. naloxone (0.1 mg/kg). These results indicate that: 1) stimulation of central mu receptors with DAGO significantly impairs arterial baroreflex control of sympathetic and cardiovascular function, 2) these effects are most marked at low levels of baroreceptor activation, 3) baroreflex impairment produced by IC DADLE was probably mediated by mu rather than delta opioid receptors. No evidence was obtained to suggest a role for endogenous opioid modulation of arterial baroreceptor reflexes since i.v. naloxone was without effect. (Supported by NIH-HL30537 and a PMA Foundation Research Starter Grant)

294.6 PREVENTION OF THE DEVELOPMENT OF ADULT ESSENTIAL HYPERTENSION BY SELECTIVE TOXICITY OF GLUTAMATE-SENSITIVE CARDIOVASCULAR CIRCUITRY AT CIRCUMVENTRICULAR ORGANS OF THE ADOLESCENT SPONTANEOUSLY HYPERTENSIVE RAT. D.K. Hartle and P.V. Krishnamurti*. Dept. of Pharmacology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

The pattern of neural toxicity produced by peripheral administration of large doses of monosodium glutamate (MSG) is limited to glutamate-sensitive soma and dendrites within the circumventricular organs (CVOs). Other regions of the brain are protected by the blood-brain barrier. Four CVOs have been implicated in blood pressure regulation. We recently reported that MSG toxicity reverses essential hypertension in the adult Spontaneously Hypertensive Rat (SHR), but the same treatment produces no hypotension in the adult Wistar Kyoto (normotensive) Rat (WKY). The present studies were done to determine if MSG toxicity in either the neonatal or adolescent period could prevent the development of essential hypertension in the SHR. SHR pups were treated with 4 mg/g MSG or isotonic saline s.c. at 4 days of age (n=8, each group). When the rats were 14 weeks of age, direct blood pressures were recorded by arterial catheter while the animals were conscious and unrestrained. Blood pressure of the MSG-treated animals were not significantly different from the control group. Because hypertension is not expressed in the SHR until the adolescent period, a second experiment was conducted to determine if MSG toxicity in the very early phase of hypertension (5-7 weeks) would prevent the development of adult essential hypertension. Eleven SHRs were treated with 8 mg/g MSG s.c. at 5 weeks and again at 7 weeks of age. A group of eight SHRs were injected with saline at these ages and served as the control group. At 14 weeks of age, direct arterial pressures were recorded in the conscious and unrestrained rats. In contrast to neonatal treatment, MSG treatment during adolescence produced no growth impairment in the SHR. Mean arterial blood pressure was significantly lower in the MSG-treatment group, 120 + 5 mmHg vs 190 + 6 mmHg in the saline treatment group ($p < .001$). The mean blood pressure of the group treated with MSG during adolescence was not significantly different at 14 weeks from those of either 14 week old WKY rats or SHR rats whose hypertension was reversed by MSG treatment at 14 weeks of age. These data suggest that the development of essential hypertension in the SHR is dependent upon the integrity of glutamate-sensitive elements of CVOs. The fact that MSG toxicity in the neonatal period is without effect on the development of hypertension suggests that the specific glutamate-sensitive CVO cardiovascular circuitry involved in the pathogenesis of SHR hypertension is not present in the neonate, but appears later in development. 294.7 ROLE OF THE SYMPATHETIC NERVOUS SYSTEM IN HIGH SODIUM RENAL HYPERTENSION DURING CHRONIC VASCULAR VASOPRESSIN RECEPTOR BLOCKADE. C. Hinojosa* and J.R. Haywood. Dept. of Pharmacology, Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX 78284.

The sympathetic nervous system (SNS) and arginine-vasopressin (AVP) have been shown to contribute to the development of several models of sodium dependent hypertension. Our previous studies demonstrated that the SNS and AVP maintain the elevated blood pressure (BP) in high sodium fed one kidney, figure-8 wrap hypertensive rats. The purpose of this study was to determine if the pressor effect of AVP was necessary for the development of the hypertension by chronic subcutaneous administration of a vascular AVP antagonist, d($CH_2$)$_5$Tyr(Me)AVP, (AA) via an osmotic minipump. In addition, the contribution of the SNS to BP was determined in these animals. One group of high sodium fed rats was treated with AA and the other group received vehicle (V). Two days later, the animals underwent unilateral nephrectomy combined with renal figure-8 wrap (W) or sham (S) surgery which was unilateral nephrectomy only. BP and heart rate were monitored one day before and 5 days after renal surgery. In addition, AVP receptor blockade was confirmed periodically by a 80% reduction of the pressor response to a bolus injection of 10 mU/kg AVP. Baseline BPs are shown below.

| | CONTROL | DAY 1 | DAY 3 | DAY 5 |
|---|---|---|---|---|
| V + S | 124 ± 4 | 119 ± 4 | 117 ± 4 | 123 ± 4 |
| AA + S | 120 ± 3 | 115 ± 3 | 114 ± 3 | 118 ± 3 |
| V + W | 119 ± 1 | 132 ± 6 | 138 ± 5 | 138 ± 6 |
| AA + W | 121 ± 3 | 141 ± 3 | 140 ± 4 | 147 ± 4 |

On day 5 after renal surgery all animals were given an i.v. injection of 25 mg/kg hexmethonium and 0.2 mg/kg atropine to produce ganglionic blockade (GB). In V + S and V + W rats, GB decreased BP by 38 ± 2 and 38 ± 3 mmHg, respectively. However, a subsequent bolus injection of AA caused a greater fall in BP in V + W rats (-30 ± 4 mmHg) than in V + S rats (-13 ± 4 mmHg), such that the final BPs were equalized to 75 ± 4 and 71 ± 3 mmHg, respectively. In AA treated S and W rats, GB also caused similar depressor effects of -52 ± 3 and -60 ± 7 mmHg, respectively. An additional bolus injection of AA had no effect on BP in either group, such that the final BP in AA + W rats (90 ± 6 mmHg) was greater than in AA + S rats (62 ± 3 mmHg). The difference in BP was not angiotensin II-dependent since captopril caused similar depressor effects in both groups. These results indicate that AA treatment did not affect baseline BP in S rats and did not prevent or attenuate the development of the hypertension in W rats. However, the mechanism of the elevated BP is not through an activation of the SNS or other neurohumoral mechanisms indicating that volume or other factors may be involved.

294.8 ANGIOTENSIN II NEURONAL PERIKARYA IN HUMAN CIRCUMVENTRICULAR ORGANS, S. Landas*, R.L. Schelper*, L.D. Wilkin, L.D. Mitchell, A.K. Johnson. Univ. of Iowa Coll. of Medicine and Cardiovascular Center, Iowa City, IA 52242.

An important role for the central nervous system in animal models of hypertension is widely accepted. Brain angiotensin II (AII) is a major component of many central hypertensive theories. In rats, AII systems have been shown to be involved in control of blood volume as well as the generation of certain types of pressor reflexes. Chronic administration of AII antogonists has been shown to ameliorate the development of hypertension in spontaneously hypertensive rats (Phillips et al., Physiologist, 18:350, 1975). Some of these AII systems have been localized to forebrain circumventricular organs (CVO) and shown to project to nuclei in the anterior hypothalamus (Lind et al., Brain Res., 321:209, 1984; Mitchell et al., Neurosci. Abstr., 10:480, 1984). In a preceding study, human Golgi-stained cells and rat AII containing neurons were compared and found to have similar dimensions and morphology (Mitchell et al., Fed Proc, 44:1199, 1985). However, AII neuronal systems have not yet been demonstrated in humans. It is crucial to show homology between human and animal systems if information derived from animal models of hypertension is to be applied to the human disease state.

In the present study, we examined AII immunoreactivity in human brain collected at autopsy using the unlabeled antibody-peroxidase technique. Previous observations of AII neuronal processes or fibers in human brain were confirmed. Additionally, AII immunoreactive perikarya were found within the subfornical organ, the median preoptic nucleus, and the lamina supraoptica (organum vasculosum of the lamina terminalis). These cells had a "primitive" appearance with ovoid to nearly spherical somata 10-15 um in diameter, one or two short dendritic processes, and a long axon. These AII neurons were frequently located in close proximity to blood vessels in the subfornical organ and the lamina supraoptica. AII immunoreactivity was also found within some magnocellular neurons of the paraventricular nucleus of the hypothalamus. These findings stand as important observations in the correlation of animal AII data with human physiology and disease. (Supported in part by NIH grant HL32192 to L.D.W.)

294.9 SALT APPETITE IN RATS AFTER PERIPHERAL PHYSIOLOGICAL DOSES OF ANGIOTENSIN. A.D. Dalhouse, O. Brooks*, A. Cook*. Dept. Psy., Jackson State University, Jackson, MS 39217. H.G. Langford* Dept. Med., Univ. of Miss. Med. Ctr., Jackson, MS 39216.

Sodium (Na) deprived mammals develop increased Na appetite and increased renal secretion of renin which causes the cleavage of angiotensin I (A I) from its parent protein. A I in the presence of converting enzyme is transformed into angiotensin II (A II) and A II increases the adrenal NA retaining steroid, aldosterone (aldo). Increasing doses of desoxycorticosterone acetate (DOCA) to adrenalectomized rats produce a V-shaped NA intake curve with decreasing Na consumption until a nadir is reached, then increasing consumption (Fregly & Waters, Physiol. Behav., 1, 65, 1966). These data are compatible with the assumption that both A II and aldo can increase Na consumption. The untreated rats would have had high A II levels which should stimulate Na appetite. With increasing amounts of aldo Na retention should occur, renin secretion should decrease, and Na appetite decrease. With increasing amounts of aldo, the increasing Na appetite can be attributed to the mineralocorticoid alone, for renin secretion should be well suppressed. The experiments reported here were designed on the assumption that an experimental design which started with A II fully suppressed would be optimum to test the effects of A II on Na appetite. It was felt desirable to use the minimum amount of mineralocorticoid compatible with full renin suppression to avoid confusion with mineralocorticoid elicited Na appetite.

Two experiments were conducted in which adrenalectomized male Sprague-Dawley rats (200g) were maintained ad libitum on distilled water, 3% saline (cafateria style) and Na free food. In Experiment I, 45 rats were given 100, 200, 400, 800, or 1000 ug/kg/day im. DOCA for 5 days to determine the dose that would produce the lowest voluntary Na intake, and 800 ug/kg/day was found to produce the nadir in Na intake ($p < 0.05$). In Experiment II, 40 rats were placed ad libitum on distilled water, saline and Na free food as described above, maintained on 800 ug/kg/day DOCA, and infused with 5, 25, 100 ug/kg/day A II or 0.9% saline for 5 days. The three A II groups showed significant percent changes in their Na intake above pre-A II levels and the saline group ($p < 0.02$), but no differences between each other ($p > 0.05$). These results were interpreted to demonstrate the production of Na appetite in rats by peripheral administration of physiological doses of A II.

Supported by NIH/MBRS 5-S06-RR08047-11 and NIH RO1-HL24369.

294.10 THE ROLE OF THE RENIN-ANGIOTENSIN SYSTEM IN THE MAINTENANCE OF ARTERIAL PRESSURE IN RATS WITH LESIONS OF THE LATERAL PARABRACHIAL AND KÖLLIKER-FUSE NUCLEI. J.W. Hubbard, R.A. Buchholz, T.K. Keeton*, and M.A. Nathan. University of Texas Health Science Center, San Antonio, Texas 78284.

Previous studies have shown that the parabrachial nuclei of the dorsolateral pons project to and receive projections from structures in the central nervous system which regulate fluid-electrolyte balance and arterial pressure (Fuleviler and Saper, Brain Res. Rev. 7:229-259, 1984). However, the role of these nuclei in the neurohumoral regulation of arterial pressure is unknown. Therefore, we examined the effects of bilateral electrolytic lesions of the lateral parabrachial and Kölliker-Fuse nuclei (LPB-KF) on plasma renin activity (PRA), plasma norepinephrine (NE) and epinephrine (E) concentrations, mean arterial pressure (MAP) and heart rate (HR) in conscious rats.

Male Long Evans rats were anesthetized with sodium pentobarbital (50 mg/kg, i.v.) and bilateral electrolytic lesions were made in the LBP-KF by passing a DC anodal current (0.8 mA) through a Teflon-coated tungsten electrode (0.18 mm, o.d. with a 0.2 mm tip exposure) for 15 seconds. Sham-lesioned (control) animals received similar treatment except that no lesions were made in LPB-KF. Cannulas were implanted in the left femoral artery and vein for the measurement of arterial pressure and the administration of drugs, respectively. Cardiovascular and neuroendocrine measurements were then made 3-7 days following the lesions.

We found that lesions of the LPB-KF did not alter baseline MAP, HR, or plasma NE and E concentrations compared to the control rats. However, the basal PRA in rats with LPB-KF lesions were 6.5 times higher than the basal PRA in sham-lesioned control rats. This increase in PRA was associated with normal plasma sodium and potassium concentrations and slightly elevated plasma osmolality.

| *$p < 0.05$ | | MAP (mm Hg) | HR (bpm) | PRA (ng AI/ml/hr) | NE (pg/ml) | E (pg/ml) |
|---|---|---|---|---|---|---|
| LPB-KF | (4) | 122±4 | 384±6 | 43.3±11.1* | 180±22 | 88±35 |
| Control | (4) | 116±5 | 355±9 | 6.7±1.9 | 143±32 | 63±28 |

$\beta_1$-Adrenoceptor blockade with atenolol (1 mg/kg, i.v.) normalized PRA in the LPB-KF rats. Sequential blockade with captopril (10 mg/kg, i.v.), vasopressin antagonist $d(CH_2)_5Tyr(Me)AVP$ (15 µg/kg, i.v.), and chlorisondamine ( 3 mg/kg, i.v.) revealed that the renin-angiotensin system plays in important role in the maintenance of resting MAP in rats with LPB-KF lesions. Supported by NIH grant HL33635 and AHA, Tx. Affil.

294.11 DIFFERENTIAL EFFECTS OF STIMULATION OF NUCLEUS AMBIGUUS ON ATRIAL AND VENTRICULAR RATES. M.E. Thompson*, G. Felsten, J. Yavorsky*, and B.H. Natelson. VA Med. Ctr. and New Jersey Med. School, East Orange, N.J. 07019.

The vagus is the primary efferent pathway for a variety of reflexes affecting heart rate and rhythmicity. The origin of vagal preganglionic neurons in the area of nucleus ambiguus (NA) has been recently established by neuroanatomical tracing methods. However, it is unclear which of these cells affect the SA node and which affect the AV node. Electrical and chemical stimulation in this area has been shown to produce bradycardia. Whether this represents both chronotropic (CE) and dromotropic (DE) effects is unclear. Therefore, the present study sought to determine whether stimulation at different sites within NA would produce differential effects on atrial (AR) and ventricular (VR) rates. Acute experiments were performed on open-chested male mongrel dogs which were anesthetized (pentothal), and respired. A pacing electrode was placed on the left atrial appendage and catheters were placed in the carotid artery and jugular vein. This latter catheter provided an atrial lead for the ECG. An average of 10 penetrations per side was used to explore the rostral-caudal organization of the NA and the area ventrolateral to it in .5-1.0 mm steps. Electrical stimulation with 50 pps, .1 ms square wave pulses varying in intensity from 100-300 uA was delivered in 5 second trains as the electrode was lowered in .2-.5 mm steps. Pacing was performed on some trials to clarify the occurrance of AV block. When pacing was used, the rate was adjusted to be as close to the unpaced rate as possible while maintaining control.

Stimulation in the area of the NA and lateral to it produced bradycardia and bradyarrhythmias without altering blood pressure more than 15 mmHg. Stimulation of either the left or right NA produced slowing of both VR and AR. However, slowing of the AR (i.e.,CE) was greatest with right NA stimulation (AR=36; VR=24; paced VR=144) while slowing of the VR (i.e.,DE) was predominant with left side stimulation (AR=72; VR=24; paced VR=60). The presence of AV block was evident from dropped QRS complexes with and without pacing. Futhermore, there was a rostral-caudal organization of AV dissociation with posterior sites producing greater AV block than anterior sites. From this evidence we conclude that the vagal preganglionic neurons controlling SA and AV nodes arise from different areas within NA. Control of AV conduction seems to predominate in the left and posterior areas of NA while the anterior and right side is predominantly chronotropic.
(Supported by HL 24498)

294.12 NEURONS IN NUCLEUS AMBIGUUS RESPOND TO CHANGES IN BLOOD PRESSURE. G. Felsten, M.E. Thompson*, J.A. Cook* & B.H. Natelson. VA Med. Ctr. & New Jersey Medical School, East Orange, N.J. 07019.

Because recent work suggests that the vagal preganglionic neurons mediating the baroreflex in cat and dog are located in or near nucleus ambiguus (NA), and not in the dorsal motor nucleus of the vagus, as previously thought, we investigated the responses of neurons in the region of NA, while manipulating arterial blood pressure (BP) nonpharmacologically. Sodium pentothal anesthetized dogs, were thoracotomized to permit the placement of inflatable silastic occlusion cuffs around the descending aorta (DA) and inferior vena cava (IVC), to increase and decrease arterial blood pressure, respectively. BP increases averaged 80 mm Hg, while BP decreases averaged 60 mm Hg. The dogs remained open-chested and were artificially respired. Stereotaxically placed stainless steel electrodes were used to record single or multiple unit activity from cells in or near nucleus ambiguus. For each unit or small group of neurons isolated, we recorded ECG, BP and neural activity with no manipulation of BP, and with BP increased and decreased 4 times in semi-random order.

Most neurons had spontaneous activity rates of less than 5 spikes/sec and some were completely quiet until blood pressure was manipulated. Brainstem neurons sensitive to changes in BP could be divided into 2 subgroups. 77% of these neurons (Group 1) responded with increased firing as BP increased during inflation of the DA cuff. Heart rate decreased from 5% to 40% following the increase in neural activity. The firing rate of these cells did not change as BP decreased due to inflation of the IVC cuff, but increased as BP increased when the IVC cuff was deflated. The other 23% of BP sensitive neurons (Group 2) had clear respiratory rhythms with spontaneous rates cycling from as low as 0 to as high as 50 spikes/sec. The activity of Group 2 neurons was suppressed during increases in BP and enhanced during BP decreases. These two groups differed not only in regard to respiratory properties, but also in that Group 2 neurons responded to BP increases and decreases, while Group 1 neurons responded only to BP increases. These differences may be due to input from different populations of BP receptors, with Group 1 neurons affected by stimulation of arterial and left ventricular receptors, and Group 2 neurons affected by stimulation of any combination of arterial, left ventricular, atrial or pulmonary receptors.

Our data indicate that the firing rates of some neurons in the area of nucleus ambiguus in the dog are altered by changes in BP, and that these neural response changes precede changes in heart rate. In conjunction with anatomical and physiological work indicating that NA is the site of origin of vagal preganglionic fibers to the heart, we conclude that these neurons participate in mediating the baroreceptor reflex. (Supported by HL 24498).

294.13 NEUROGENIC REGULATION OF ARTERIAL PRESSURE LABILITY IN RATS FOLLOWING SINO-AORTIC DEAFFERENTATION (SAD). R.H. Alper and M.J. Brody. Dept. of Pharmacology and CV Center, University of Iowa, Iowa City, IA 52242.

Aortic and carotid baroreceptors are involved in minute-to-minute regulation of arterial pressure. Baroreceptor deafferentation causes only relatively acute hypertension, but arterial pressure lability is increased chronically. Increased sympathetic tone accounts for the acute hypertensive phase, but mechanisms generating lability are unclear. These studies were to investigate neurogenic regulation of arterial pressure lability in rats following chronic SAD.

SAD or sham surgery was performed on male rats 10-14 days prior to experiments. Catheters were placed in the femoral artery and vein for pressure measurement and drug administration, respectively, in conscious, unrestrained rats. Animals showing impaired baroreflex function (<20% of control bradycardia in response to phenylephrine) were considered as SAD. Mean arterial pressure (MAP) and labiltiy (the standard deviation of the MAP) were determined for a 1 hr control period. Drugs were then injected and MAP was recorded for an additional 1 hr. In all experiments, MAP was the same in intact and SAD rats prior to drug treatment. Labiltiy, on the other hand, was always greater in rats following chronic SAD.

Ganglionic blockade by chlorisondamine (2.5 mg/kg) caused equivalent, sustained hypotension in all rats. Lability was increased in intact and decreased in SAD rats to values between those observed in untreated intact and SAD rats.

Yohimbine (2 mg/kg) did not alter MAP or lability in any rats. This dose was not selective for $\alpha_2$-adrenergic receptors as it partially attenuated the pressor response to phenylephrine.

The selective $\alpha_1$-adrenergic receptor antagonist prazosin (0.1 mg/kg) blocked the pressor response to phenylephrine and slightly decreased both MAP and lability in all rats. Lability was still greater in SAD than intact animals.

The simultaneous administration of prazosin and yohimbine (in the same doses used above) caused marked hypotension for 30 minutes. Arterial pressure rose during the next 30 minutes, but did not return to control values. Combined $\alpha$-receptor blockade increased lability in intact rats but decreased lability in SAD rats, similar to what was observed after chlorisondamine.

These data suggest that arterial pressure lability in rats following chronic SAD is not generated through selective activation of $\alpha_1$- or $\alpha_2$-adrenergic receptors. Neurogenic mechanisms appear to contribute to, but may not totally account for, fluctuations in arterial pressure characteristic of baroreflex deficient rats. (Supported by HLB-14338).

294.14 THE DEVELOPMENT OF THE RENAL $\alpha_2$-ADRENERGIC RECEPTOR IN THE RAT. B. Sripanidkulchai, R. Dawson and J.M. Wyss. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, AL 35294.

The renal $\alpha_2$-adrenergic receptor in the rat has two affinity binding sites. In the present study the development of these two sites was investigated using agonist [($^3$H)-para-amino clonidine, PAC] binding to crude membrane preparation in Sprague-Dawley rats from day of birth through adulthood.

Scatchard analysis of ($^3$H)-PAC binding to renal $\alpha_2$-adrenergic receptors on the day of birth reveals a single binding site with a KD of 0.9 nM and Bmax of 15 fmoles/mg protein. In contrast, analysis of kidneys from day 3 rats indicates that 2 sites exist at this stage, one with a KD of 0.9 nM and Bmax of 16 fmoles/mg protein (the high affinity site) and the other with a KD of 8 nM and Bmax of 55 fmoles/mg protein (the low affinity site). The absolute number of both sites increases during the next several days with the Bmax nearing adult levels around day 7 for the high affinity site (32 fmoles/mg protein) and day 30 (132 fmoles/mg protein) for the low affinity site. The KD of each site remains stable throughout this period. This suggests that the development of the high affinity $\alpha_2$-adrenergic receptor site predates that of the low affinity site, but the affinity of the sites remain unchanged throughout development.

To determine the possible interaction between development of the sympathetic nervous system and the $\alpha_2$-adrenergic receptor in the kidney, the time course of the renal sympathetic innervation has been characterized by both HPLC biochemical determination of renal norepinephrine content and morphological analysis of tyrosine hydroxylase (TH) positive axons. The results indicate that renal norepinephrine is present at the day of birth (2.42 ng/kidney) and the level increases gradually to adulthood. TH positive fibers are present on the day of birth and increase throughout development. These results indicate that the renal sympathetic innervation is present at birth and therefore could provide the biological signal which induces the appearance of the low affinity renal $\alpha_2$-adrenergic receptor.

294.15 ONTOGENY OF RENAL ADRENERGIC RECEPTOR SITES IN INBRED DAHL HYPERTENSION-SENSITIVE (DS/JR) AND -RESISTANT (DR/JR) RATS. J.A. McCaughran, Jr., C.J. Juno*, and E. O'Malley*. Dept. Psychiatry and Behavioral Science, SUNY at Stony Brook, New York, 11794.

The DS/JR rat develops severe elevations in BP when exposed to hypertensinogenic stimuli. The DR/JR rat remains normotensive when exposed to the same stimuli. Although the mechanisms responsible for the development and maintenance of hypertension have not been determined, there is compelling evidence to suggest that renal sympathetic factors participate. The renal proximal and distal convoluted tubules possess a high density of $\alpha_2$-adrenoceptors. The activation of these has been shown to influence sodium reabsorption and renin release. In the mature rat, studies have found that the density of $\alpha_2$-adrenoceptors is greater in the DS/JR than the DR/JR strain, regardless of the blood pressure. These differences have been related to alterations in natriuresis and renin release, both of which distinguish the DS/JR from DR/JR strain. The ontogeny of these distinguishing characteristics has not been examined. In this study, the $\alpha_2$ antagonist $^3$H-rauwolscine was used to assess the density of renal $\alpha_2$-adrenoceptors in the DS/JR and DR/JR strain at 5, 15, 25, and 50 days of age. In contrast to the adult, the density of adrenoceptors was lower in the DS/JR strain than the DR/JR strain at 5 days of age. The density of adrenoceptors was approximately 10-15% of adult values in the DS/JR strain and 20-25% of adult values in the DR/JR strain. The dissociation constants (Kds) were similar between the strains but lower than adults in both strains. At 15 days of age, the density in the DS/JR and DR/JR strains was approximately 30-35% and 48-53% of adult values, respectively. The Kds approached adult values (i.e., approximately 2.00 nM) and were similar between the strains. By 25 days of age, the density of adrenoceptors was greater in the DS/JR strain than the DR/JR strain. Although the density in the DR/JR strain was similar to adult values at this age, the density of adrenoceptors in the DS/JR strain continued to increase until 50 days of age. The results of this study indicate that the rate of development of $\alpha_2$-adrenoceptors differs between the DS/JR and DR/JR strains. The fact that the density of sites continues to increase to 50 days of age in the DS/JR strain suggests that the density of sites observed in the mature DS/JR rat may in part be due to secondary factors and not solely to the genetic predisposition to hypertension.

294.16 RENAL DENERVATION CAN PREVENT STRESS-INDUCED HYPERTENSION IN THE BORDERLINE HYPERTENSIVE RAT (BHR). J.E. Lawler, R.H. Cox, B.J. Sanders,* V.P. Mitchell,* and P.G. Baer.* University of Tennessee, Knoxville, 37996, and UTCHS, Memphis.

The F1 cross between the spontaneously hypertensive rat and the Wistar-Kyoto rat develops spontaneous borderline hypertension, and is called the BHR. This animal develops permanent and severe hypertension when exposed to conflict schedules lasting 15 weeks. The purpose of this study was to determine if renal denervation done at two different time periods after exposure to chronic stress could prevent stress-induced hypertension. Thirty-two male BHR were exposed to an uncontrollable cutaneous electric shock schedule for either 5 or 11 weeks. Half of the animals in each group received sham surgery, while the other half received bilateral renal nerve denervation. Tail cuff arterial blood pressures were recorded weekly in all animals. After 5 wks of stress, the systolic blood pressure of BHR was 169 mm Hg. Renal denervation prevented any further rise in blood pressure, since after 10 additional weeks of stress, the blood pressure of denervated BHR was still under 170 mm Hg (164±5 mm Hg), while in sham animals it was over 180 mm Hg (183±6 mm Hg). After 11 wks of stress, the systolic blood pressure of BHR was 179±7 mm Hg. Although denervation temporarily lowered the blood pressure of this group to approximately 160±4 mm Hg, it soon recovered to levels of the sham animals. These data are consistent with the hypothesis that the renal nerves are a necessary component to the development of stress-induced hypertension, since elimination of these nerves during a critical period prevents further development of hypertension. Once stress-induced hypertension has developed, renal denervation has no permanent protective effect on blood pressure. (Supported by HL-19680 and by HL-01395)

294.17 FURTHER ANALYSIS OF THE EFFECT OF DORSAL RHIZOTOMY ON GOLDBLATT HYPERTENSION. N. Aboukarsh, W. Sripairojthikoon and J.M. Wyss, Department of Cell Biology and Anatomy, University of Alabama at Birmingham, AL 352 94.

In past studies it has been demonstrated that renal denervation partially prevents or alleviates hypertension in one kidney, one clip (1K/1C) rats. Last year it was reported that cutting the $T_8$-$L_2$ dorsal root nerves (the nerves through which the renal afferents pass) similarily reduces the hypertensive effect in this model. In the present study, two further controls experiments have been carried out, to clarify the interpretation of that finding. The first experiment assessed the possibility that lesion of the $T_8$-$L_2$ dorsal root nerves ipsilateral to the remaining kidney, would reduce blood pressure in non clipped, normotensive rats. Four groups of rats were employed: sham (1K/1C), denervated (1K/1C in which the $T_8$-$L_2$ dorsal root nerves were transected ipsilateral to the remaining kidney); control (1K), and denervated control (1K, with ipsilateral lesion as above). The results demonstrated that the lesion had no effect on blood pressure. Final systolic blood pressures five weeks after clipping were: Sham = 179±5mm Hg, denervated = 148±4mm Hg, denervated control = 131±3mmHg and control = 127±5mm Hg.

The second experiment examined the possible antihypertensive effect of the loss of non-renal afferents that are cut along with the renal afferents in the $T_8$-$L_2$ dorsal root nerves. Four groups of rats were included: Sham, denervated, contralateral denervated (1K/1C with lesion of the $T_8$-$L_2$ dorsal root nerves contralateral to the remaining kidney) and control. The results indicate that the non-renal afferents in the $T_8$-$L_2$ dorsal root nerves do not play an important role in the antihypertensive effect. From 4-8 1/2 weeks after clipping, systolic blood pressures of the contralateral denervated and sham groups were indistinguishable from each other and each was significantly higher than the denervated group. Mean systolic blood pressures at week 8 were: Sham = 209±4mm Hg; contralateral denervated = 202±4mm Hg, denervated = 171±3mm Hg, control = 143±5mm Hg. It should be noted that the renal afferent lesion eliminates approximately 50% of the hypertensive effect in the 1K/1C rats. These results demonstrate that the antihypertensive effect of $T_8$-$L_2$ dorsal rhiztomy is not dependent upon the lesion of non-renal afferents. Further, it should be noted that 1) direct arterial blood pressures taken at week 8 1/2 were in close agreement with the indirect tail cuff measures taken at week 8 in experiment 2, 2) there were no differences in mean body weights of the three groups of clipped animals in experiment 2, 3) the dorsal rhizotomies in the denervated group, do not alter sodium handling by the kidney, and therefore the antihypertensive effect does not appear to be dependent upon a renal efferent nerve alterations.

294.18 GUANABENZ-PROMOTED ANTIHYPERTENSION IN THE RAT: ROLE OF NUCLEUS RETICULARIS GIGANTOCELLULARIS AND VAGAL MECHANISM. H.C. Lim* and Samuel H.H. Chan. National University of Singapore, Faculty of Medicine, Kent Ridge, Singapore, and Washington State University, College of Veterinary Medicine, Pullman, WA 99164-6520.

The antihypertensive agents guanabenz and clonidine may share common mechanisms in their cardiovascular effects because they have similar pharmacologic profiles and exhibit mutual interactive actions on the circulatory system (Ong and Chan, Exp. Neurol. 86: 105, 1984). Although guanabenz-promoted cardiovascular suppression has been attributed to its activation of $\alpha$-adrenoceptors located at the bulbar level, a gap still exists in our knowledge as to the specific brainstem locus(i) involved. Since the nucleus reticularis gigantocellularis (NRGC) and vagal mechanism were shown to be critically engaged in clonidine-induced hypotension and bradycardia, the present study was undertaken to evaluate the role of these two mechanisms in similar guanabenz actions, using pentobarbital anesthetized male Sprague-Dawley rats.

Intravenous injection of guanabenz (10 µg/kg) produced an initial, though transient hypertension, accompanied by an increase in cardiac contractility. These were followed by a significant and sustained hypotension, together with a decrease in force and rate of heart contraction. The same administration, delivered to rats that received bilateral electrolytic lesions (1.5 mA, 10 s, d.c.) of the NRGC, however, resulted in only the transient vasopression. The subsequent reduction in arterial pressure, cardiac contractility and heart rate, on the other hand, was sufficiently, though not completely, retarded.

Microinjection of guanabenz directly into the NRGC, at an ineffective systemic concentration (500 ng in 500 nl over 4-5 min), produced significant and prolonged hypotension as well as negative inotropic and chronotropic effects, without the initial hypertension. There was also topographic sensitivity to guanabenz in this reticular nucleus, with the lateral portion of NRGC being significantly less effective in eliciting cardiovascular suppression than its ventro-medial counterpart.

Bilateral cervical vagotomy, performed after significant reduction in arterial pressure, cardiac contraction force and rate was effected following microinjection of guanabenz (500 ng) into the NRGC, appreciably reversed, but did not abolish, the established circulatory depression.

It is concluded that the NRGC is at least one of the central sites involved in guanabenz-promoted cardiovascular suppression. This antihypertensive agent may activate neurons in the ventromedial NRGC, which in turn produces hypotension as well as negative inotropic and chronotropic effects via the vagal outflows to the circulatory effectors.

294.19 EVIDENCE FOR A ROLE OF CARDIAC ATRIOPEPTINS IN REDUCED RENAL MASS PERINEPHRITIC HYPERTENSION IN THE RAT. R.M. Chinn and D.K. Hartle. Dept. of Pharmacology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

Perinephritic hypertension was produced in 200-300 g male Sprague-Dawley rats by loosely wrapping the left kidney with plastic and removing the contralateral kidney. Control rats were subjected to right nephrectomy only. Blood pressure was significantly elevated in the perinephritic rats within 3 weeks after surgery. Rats were anesthetized with pentobarbital and diuresis was induced by continuous infusion of an electrolyte solution (Plasma-Lyte, pH 7.4) at a rate of 0.181 ml/min.Urine was collected in consecutive 10 min. periods. The diuretic, natriuretic, blood pressure and heart rate responses of the perinephritic and control rats were recorded before and after administration of a pharmacological dose of Atriopeptin III (AP III) (10 µg/0.1 ml of infusate, via the jugular vein). AP III was obtained from Peninsula Labs. The responsiveness of the rats to Lasix and Diuril was also tested. Perinephritic rats were unresponsive to the diuretic and natriuretic effects of AP III, but responded well to Lasix and Diuril. These diuretic and natriuretic deficits to AP III were not observed in two other hypertensive reduced renal mass models, Grollman wrap and DOCA/Salt. Blood pressure was lowered significantly more in perinephritic rats than in the controls. In addition, the depressor event was markedly prolonged in the perinephritic rats. AP III increased the rate of diuresis 800% and the rate of natriuresis 1300% in the one-kidney control group. Studies in conscious rats indicated that hypertension in the perinephritic rats is supported by a combination of endocrine (angiotensin and vasopressin) and neural factors. Bioassay of the heart atrial content of diuretic and natriuretic activity indicated that perinephritic rats appeared to have a normal heart content. In summary, anesthetized perinephritic rats appear to be hyperresponsive to the depressor effects of AP III but are unresponsive to the natriuretic and diuretic activities of the peptide. The inability of the perinephritic kidney to respond to AP III is probably due to altered hemodynamic mechanisms associated with AP III action since the kidney was capable of brisk diuresis/natriuresis in response to tubular diuretics (Lasix, Diuril). Because AP III has been shown to lower blood pressure by decreasing cardiac output, the sensitivity of the perinephritic rats to the depressor effects of the peptide indicates that increased cardiac output may be contributing significantly to the support of hypertension in these rats. The impaired perinephritic renal response to AP III may contribute to the process of hypertension, by enhancing sodium retention and increased extracellular fluid load in this reduced renal mass model. Supported in part by AHA, Georgia Affiliate, and PHS#T35-HL30706-06A1.

294.20 SEROTONIN-GABA INTERACTIONS IN DOCA/NaCl HYPERTENSION R. Dawson, S. Nagahama and S. Oparil. CVRTC, Univ. Alabama in Birmingham,Birmingham, AL 35294

The sympathetic nervous system (SNS) is thought to be involved in the genesis and/or maintenance of deoxycorticosterone (DOCA)/NaCl hypertension. The neural mechanisms that augment sympathetic tone in DOCA/NaCl hypertension are poorly understood. Electrical stimulation of the midbrain raphe nuclei or activation of postsynaptic serotonin (5-HT) receptors in the CNS results in increased sympathetic outflow. Conversely, stimulation of the CNS GABA receptors reduces the activity of the SNS. The present study examined the role of central serotonergic mechanisms in DOCA/NaCl hypertension and the effects of a centrally administered GABA agonist on 5-HT metabolism.

Sprague-Dawley rats that had received 4 weeks of DOCA/NaCl treatment were killed by decapitation and monoamine and metabolite levels were determined in brain regions by high performance liquid chromatography and electrochemical detection. DOCA/NaCl hypertensive and control rats were administered 1 µg of muscimol or saline vehicle intracerebroventricularly (icv) and killed 15 or 60 min. later (N=10-15/group).

DOCA/NaCl treated rats had significantly higher basal blood pressure than controls and the dose of muscimol used had previously been shown to produce a significantly greater depressor response in DOCA/NaCl rats than controls. Fifteen min. after icv saline infusion there were no significant differences in 5-hydroxyindoleacetic acid (5-HIAA) levels between DOCA/NaCl rats and controls in any brain region examined. Muscimol (15 min.) produced significant ($p<0.05$) elevations in 5-HIAA and 5-HT levels in the hypothalamus, medulla and pons of DOCA/NaCl rats, however, 5-HIAA and 5-HT levels were not affected in controls. Sixty min. after icv saline infusion, 5-HIAA levels were significantly ($p<0.05$) greater in DOCA/NaCl rats than controls in the spinal cord, medulla, pons, midbrain and hypothalmus. 5-HIAA levels were significantly ($p<0.05$) elevated in control rats 60 min. after muscimol infusion in all brain regions examined. DOCA/NaCl rats exhibited only a slight increase in 5-HIAA levels 60 min. after muscimol.

The results suggest that DOCA/NaCl treatment alters 5-HT metabolism in the CNS and that activation of CNS GABA receptors exacerbates the abnormality in 5-HT metabolism present in DOCA/NaCl hypertensive rats. Thus alterations in CNS GABA and/or 5-HT neurotranmission may contribute to the increased sympathetic tone present in DOCA/NaCl hypertensive rats.

294.21 GABA STRUCTURAL ANALOGUES: RECEPTOR BINDING AND CARDIOVASCULAR EFFECTS IN THE CAT. G. K. Matheson, E. Freed* and G. Tunnicliff*. Indiana University School of Medicine, Evansville, IN 47714.

Several classes of drugs are available for the treatment of hypertension. None, however, is free of side effects, some of which can be serious. A potential new class of drugs to treat high blood pressure is one that enhances gamma-aminobutyric acid(GABA) function in the central nervous system. Evidence existsthat activation of certain central GABA receptors can leadtoa fall in arterial pressure and a decrease in heart rate. On the other hand, antagonism of these same receptors can give rise to an increase in both blood pressure and heart rate.

For this study we measured the ability of over one hundred previously untested structural analogues of GABA to inhibit $GABA_A$ receptor binding in cortical membranes. Compounds found to have an effect on binding were morpholinopropanesulfonic acid (MOPS; $IC_{50}$ = 1.6 μM), 5-phenylpyrrolepropionic acid (5PPP; $IC_{50}$ = 15 μM), aminoethanethiosulfonic acid (AETS, $IC_{50}$ = 22 μM), DL-3-amino-3-phenylpropionic acid (3APP; $IC_{50}$ = 34 μM), m-aminobenzoic acid (MABA; $IC_{50}$ = 58 μM), and urocanic acid (UCA; $IC_{50}$ = 353 μM). To date four of these compounds, along with GABA, 3-aminopropanesulfonic acid and imidazoleacetic acid, have been infused at various concentrations into the fourth ventricle of the alpha-chloralose anesthetized cat, and blood pressure and heart rate were monitored. For blood pressure the $ED_{50}$ values ($1 \times 10^{-8}$ M/Kg) were calculated and are as follows: GABA = 1.95; 3-APS = 1.93; 3APP = 2.79; MABA = 3.36; 5PPP = 4.06; and MOPS = 4.39. We have demonstrated that GABA structural analogues that are capable of inhibiting $GABA_A$ receptor binding are also able to modulate blood pressure in the intact cat and that the two sets of data exhibit a positive correlation.

294.22 POSSIBLE INTERACTION OF SYMPATHETIC REACTIVITY, PAIN AND EMOTIONAL DISTRESS IN ACUTE POSTOPERATIVE HYPERTENSION. E.A. Anderson, Anesthesia Dept., Univ. of Iowa, Iowa City, IA 52242.

Coronary artery bypass graft (CABG) surgery patients have a uniquely high incidence ( 50%) of sympathetically mediated, acute postoperative hypertension (APH) occurring as patients awaken 1-4 hr. after surgery. Prior research suggests that APH patients may be sympathetically hyperreactive. This hypothesis was tested by comparing BP and HR responses of APH and non-APH patients to the intraoperative stimulus of tracheal intubation (TI; which elicits a sympathetic response). It has also been noted that emotional distress may contribute to sympathetic activity after surgery. This hypothesis was tested by comparing the incidence of APH in patients receiving extensive psychological preparation for surgery with those receiving routine preparation. Finally, there is evidence that the cardiovascular system and pain regulatory systems interact: pain increases BP and elevated BP can reduce perceptions of pain. It is possible that APH patients are more sensitive to pain and that increased BP after surgery may functionally reduce pain. The hypothesis of greater pain sensitivity was tested by comparing APH and non-APH patients' requests for analgesics during recovery (postoperative days 2-7; after BP has returned to normal).

60 male CABG patients were randomly assigned to one of two groups receiving extensive psychological preparation for surgery (which successfully reduced pre and postoperative anxiety) or to a control group receiving routine preparation (a short visit by a nurse; N=20/gp). Operative anesthetic was fentanyl-$O_2$. BP and HR were recorded immediately prior to TI and 1 min post TI. Postoperatively, diagnosis of APH was made if a patient was treated with a vasodilator for SBP$\geq$150 mm Hg.

Patients later developing APH (N = 32), had significantly greater SBP (16.5±2.2 vs 6.7±1.6 mm Hg; $p<.001$) and HR 4.1±1.8 vs 0.7±1.6 bpm; $p<.01$) responses to TI than non-APH patients. Second, the incidence of APH was significantly less in the two groups of patients (N=40) extensively prepared for surgery compared to the 20 patients receiving routine preparation (42.5% vs 75%; $p<.02$). Psychological preparation for surgery did not lower BP and HR responses to TI, suggesting that psychological stress and sympathetic reactivity are independent factors interacting in APH. Finally, APH patients requested more analgesics during recovery than non-APH patients (72.4±5.5 vs 54.9±4.0 mg morphine; $p<.04$), a difference not attributable to staff policy.

The results suggest that APH patients are sympathetically more reactive and may have lower pain thresholds than non-APH patients. Finally, reducing patients' anxiety by psychological preparation for surgery can reduce the incidence of APH.

294.23 FUNCTIONAL CHARACTERISTICS OF RAT AORTAE FOLLOWING PARATHYROID-THYROIDECTOMY AND DOCA HYPERTENSION. G.L. Pullen*, T.R. Hansen*, S.P. Singh*, S. Goldman* and J. Cheng*. (SPON: P.C. Tang). Endocrine Research Lab., VA Medical Center, and Univ.Health Sci./ Chicago Med. School, North Chicago, IL 60064.

The purpose of this study was to determine what functional changes occur in the smooth muscle of the rat aorta following 3 different time intervals between parathyroid-thyroidectomy (PXTX) and desoxycorticosterone acetate (DOCA) induced hypertension. Male PXTX Sprague-Dawley rats were purchased from Johnson Labs (Bridgeview, IL) and were subjected to the following protocol:

1. PXTX followed by DOCA treatment after 5 days.
2. PXTX followed by DOCA after 9 days, followed by DL-Thyroxine ($T_4$) supplement after an additional 42 days.
3. PXTX followed by DOCA after 30 days, followed by $T_4$ supplement after an additional 21 days.

Blood pressure in the rats delayed 5 days exhibited the normal increase observed following DOCA treatment without requiring $T_4$ supplement. On the other hand, with a 9 or 30 day delay between PXTX and DOCA, pressure did not increase above normal levels until $T_4$ was administered (10 μg, 3X a week). Following $T_4$ supplementation, the 9 day rats showed a rapid rise in blood pressure (within 48 hrs.) to hypertensive levels (above 150 mmHg) while the 30 day animals showed a gradual rise to hypertensive levels following 4 to 5 weeks of $T_4$ treatment.

The functional characteristics of aortic strips from these groups were studied in a muscle bath. Rats delayed 9 and 30 days between PXTX and DOCA were each split into 2 groups: with or without $T_4$ supplementation. Considering the aortic strip response to norepinephrine in rats with a 30 day delay, those rats which received $T_4$ supplements demonstrated significantly less maximum active stress than those which did not receive $T_4$ ($2.23 \pm 0.61$ vs $3.67 \pm 0.78$ $N/M^2 \times 10^4$). In rats delayed only 9 days, the difference between $T_4$ supplemented and non-supplemented was not statistically significant although the same tendency was noted ($2.65 \pm 0.51$ vs $3.27 \pm 1.34$ $N/M^2 \times 10^4$). There was no significant difference in aortic response between these same groups when barium was used as the agonist. These results confirm earlier findings that $T_4$ deficiency prevents the development of DOCA hypertension while replenishing $T_4$ allows blood pressure to increase (Fed. Proc. 43:443, 1984). In addition, current results are suggestive of an effect of $T_4$ on vascular smooth muscle, perhaps receptor mediated, which is produced either directly on the aorta or indirectly through central mechanisms which increase blood pressure.

Supported by the Veterans Administration

294.24 VENTRICULAR DILATION IN THE SPONTANEOUSLY HYPERTENSIVE RAT (SHR). S. Ritter and T.T. Dinh*. College of Veterinary Medicine. Washington State University. Pullman, WA 99164

In the course of our studies of the SHR we observed that the cerebral ventricles of these rats appeared to be dilated in comparison to age-matched Wistar Kyoto (WKY) and Sprague Dawley (SD) rats. Because ventricular pathology could have important implications for the pathophysiology of hypertension, we measured ventricular area in 14-wk-old male SHR and WKY rats (n = 7 per group) obtained from Taconic Farms. Rats were given a lethal dose of pentobarbital and perfused through the heart with a 4% paraformaldehyde solution from a reservoir of fixed height, elevated so that gravity flow would approximate normal arterial pressure. Ventricular area was measured from mounted brain sections using computer assisted image analysis. The ventricular space was measured at three levels: at the level of the anterior commissure, at the level of the subfornical organ and at the level of the posterior commissure. Sections from SHRs and WKYs were chosen carefully so that equivalent levels were analyzed for each group. All ventricular space in a given section was summed. Our results show that the ventricular space of SHRs is greatly expanded at all three levels analyzed compared to WKYs. At the level of the anterior commissure, ventricular space occupied 5.09 ± 0.56 sq mm in WKYs and 12.10 ± 0.86 sq mm in SHRs. At the level of the subfornical organ and posterior commissure, ventricular space occupied 8.82 ± 0.74 and 14.69 ± 0.92 sq mm, respectively in WKYs and 15.81 ± 1.10 and 23.33 ± 2.36 sq mm, respectively in SHRs. Thus, at these 3 levels, ventricular space of SHRs was 238%, 179% and 159% of the ventricular space in the equivalent sections from WKYs. Tissue surrounding the ventricles in the SHRs showed a parallel attrition in some loci, such as the temporal cortex.

In order to determine whether the apparent hydrocephalus in SHRs is related to their hypertension or is the result of an unrelated genetic defect, we analyzed ventricular size in SHR, WKY and SD rats of different ages: 1 day, 13 days, and 4, 8, 12, and 16 weeks of age. WKYs and SDs did not differ at any age. In SHRs, ventricular dilation was not apparent at 1 day, 13 days or 4 wks of age, when compared to controls. However, 1 out of 3 SHRs thus far examined at 8 wks was hydrocephalic and all rats 12 wks and over were hydrocephalic. The ventricular dilation appeared to be progressive between 12 and 16 wks of age. Thus, the ventricular dilation appears to develop over time and therefore may be related to the hypertensive condition. Experiments are underway to determine whether this condition exists in other forms of experimental hypertension or in other hypertensive rat strains.

294.25 EFFECTS OF SODIUM LOADING UPON CARDIOVASCULAR REGULATORY MECHANISMS. A.F. Tramposch*, K.B. Brosnihan and C.M. Ferrario. Research Division, Cleveland Clinic Foundation, Cleveland, OH 44106.

Previous experiments have shown that in dogs a positive sodium balance causes a marked potentiation of the cardiovascular pressor response due to acute carotid sinus hypotension (Tramposch et al.: The Physiologist 27: 4, 1984). Since the disturbance in baroreceptor function was observed after 14 days of exposure to high sodium ($Na^+$) intake it is possible that a longitudinal characterization of the hemodynamic and neurohormonal events associated with an increase in the concentration of $Na^+$ in the extracellular fluid may provide an insight into the mechanism(s) responsible for the alteration in the baroreflex control of the circulation. Accordingly, 6 male mongrel dogs were instrumented with arterial and venous catheters and an electromagnetic flow probe around the ascending aorta. Following convalescence, their mean arterial pressure (MAP), heart rate (HR), stroke volume (SV), cardiac output (CO) and total peripheral resistance (TPR) were recorded for 5 days before and 14 days during a continuous intravenous (IV) infusion of a 3 molar (M) sodium chloride (NaCl) solution (sodium-loaded (SL) group) or a 0.15 M solution of NaCl (normal (N) sham-group); in all cases the rate of infusion was 4 ml/hr. At frequent intervals throughout the experiment samples of arterial blood were collected for the assay of plasma renin activity (PRA), angiotensin II immunoreactivity (Ang II-ir) and plasma arginine vasopressin (AVP). Plasma norepinephrine (NE), epinephrine (EPI) and $Na^+$ concentrations were also determined. A 14 day IV infusion of 3M NaCl did not produce any consistent changes in either MAP (90 ± 1 in SL vs 93 ± 1 mmHg in N dogs), HR (82 ± 3 in SL vs 85 ± 3 beats/min in N group), SV (37 ± 1 in SL vs 34 ± 1 ml in N group), CO (2931 ± 97 in SL group vs 2848 ± 53 ml/min in N group) and TPR (3.4 ± 0.3 in SL group vs 3.3 ± 1 U in N group of dogs). On the other hand, serum $Na^+$ was increased in the SL group compared to the N group (152.3 ± 0.9 vs 146.5 ± 0.4 mEq/l respectively, $p < 0.05$). The hypernatremia was associated with a 52% decrease in PRA whereas plasma Ang II-ir fell to 0.4 ± 0.1 compared to 12.6 ± 0.1 pg/ml in the N group ($p < 0.05$). Although plasma volume did not change, there was a sustained elevation in plasma AVP concentrations (8 ± 0.4 in SL group vs 2 ± 0.3 pg/ml in N group, $p < 0.05$). Measurements of plasma NE and EPI concentrations revealed an increase in the levels of both NE and EPI in the SL group compared to the N group (406 ± 51 vs 279 ± 30 pg/ml and 239 ± 23 vs 172 ± 24 pg/ml respectively).

These data indicate that chronic $Na^+$ loading is associated with "an adaptive" response of the mechanism involved in the maintenance of base line MAP throughout the infusion period since sustained elevations of plasma markers of two recognized pressor systems (sympathetic and vasopressin) had no hemodynamic effect.

294.PO CATECHOLAMINE - CONTAINING INTRARENAL NERVE ENLARGEMENTS. D.S. Knight* (Spon: K.W. Barron). Dept. of Anatomy, L.S.U. Sch. of Med., Shreveport, LA 71130.

The electron microscope was used to study catecholamine-containing nerve enlargements that are associated with the renal arterial trees of male Wistar and Sprague-Dawley rats. Animals were perfused with 500 milliliters of 4% paraformaldehyde and 1% glutaraldehyde in 0.1 M Millonig's phosphate buffer. The Kidneys were then immersed in this fixative for three hours. Two hundred micrometer thick sections of the kidneys were examined with a fluorescence microscope, and specifically fluorescent structures were excised, embedded in Maraglas, thin sectioned and examined. Perivascular neural structures that contain clusters of vesicles and catecholamine have an identical ultrastructure in male Wistar and Sprague-Dawley rat kidneys. Each such structure consists of a small predominantly unmyelinated nerve bundle with two enlarged segments. Between the two enlargements, the nerve forms a thin band that contacts the outer medial surface of an arteriole. The two enlargements differ ultrastructurally. One enlargement consists of Schwann cells and axonal swellings each of which contains a central large cluster or several smaller clusters of agranular and dense-core vesicles 50 to 70 nanometers in diameter. Axonal swellings that comprise the other type of nerve enlargement are packed with microtubules, bundles of neurofilaments and small mitochondria. These swellings are more elongate than those containing vesicle clusters and are only partially covered by Schwann cell processes. There are myelinated axons of predominantly microtubular or neurofilamentous content in the nerve enlargements. Some axons lose the myelin sheath and may terminate in the nerve enlargements composed of vesicle-filled axonal swellings.

## PHARMACOLOGY OF SYNAPTIC TRANSMISSION III

295.1 INHIBITION BY NIMODIPINE OF BAY K 8644 AND KCl-STIMULATED CALCIUM ENTRY INTO AND ENDOGENOUS DOPAMINE RELEASE FROM STRIATAL SYNAPTOSOMES. John J. Woodward* and Steven W. Leslie. Division of Pharmacology, College of Pharmacy, Univ. Texas at Austin, Austin, TX 78712.

Recent studies have demonstrated the existence of high affinity $^3$H-nimodipine binding sites in brain. These studies, reporting $k_d$ values in brain similar to those obtained in cardiovascular tissue, suggest the existence of dihydropyridine-sensitive calcium channels in brain. However, other recent reports have shown that calcium channels in brain are insensitive to blockade by calcium entry blockers. Thus, there is a question as to whether or not dihydropyridine-sensitive calcium channels exist in brain. To pursue this question, the effects of nimodipine on voltage-dependent calcium entry into and endogenous dopamine release from striatal synaptosomes have been studied in response to KCl-stimulation and KCl plus the agonist BAY K 8644. Synaptosomes ($P_2$ pellets) were isolated from striata of male, Sprague-Dawley rats (approximately 300g) and preincubated at 30°C for 14 minutes (Leslie et al. Brain Res. 325, 99, 1985), in the presence or absence of nimodipine, BAY K 8644 or nimodipine plus BAY K 8644. $^{45}Ca^{++}$ entry and endogenous dopamine release under resting conditions (5mM KCl) or in response to depolarization (KCl, 15 or 30mM) were determined over a 3 second time period as previously described (Leslie et al. Brain Res. 325, 99, 1985). Nimodipine, 0.1nM to 10.0μM, did not alter resting calcium accumulation or dopamine release. Nimodipine, 0.1nM - 10.0μM, had no effect on 30mM KCl-stimulated calcium entry or dopamine release except for a slight stimulation of release with 0.1nM nimodipine and a slight reduction in release with 10.0μM nimodipine. These findings agree with previous reports suggesting a lack of effect of calcium entry blockers under these conditions. BAY K 8644, 0.1nM - 100nM, did not alter resting calcium entry or dopamine release but significantly enhanced 30mM KCl-stimulated calcium entry. A similar (but not significant) tendency for increased dopamine release by BAY K 8644 in response to 30mM KCl was observed. The combination of BAY K 8644, 1nM, plus KCl, 15mM, resulted in a significant 26.5 percent increment in calcium entry and 11 percent increment in dopamine release above that observed with 15mM KCl-depolarization alone. The BAY K 8644 increment in calcium entry and dopamine release was inhibited by nimodipine, 10nM. These studies show that the addition of 1mM BAY K 8644 to partially depolarized synaptosomes (15mM KCl) results in an incremental increase in calcium uptake and dopamine release that is sensitive to blockade by the calcium entry blocker nimodipine. The combination of BAY K 8644 and partial KCl-depolarization may unmask dihydropyridine sensitive calcium channels.

295.2 SLOW HYPERPOLARIZING POTENTIALS IN RAT SPINAL DORSAL HORN NEURONS. S. Jeftinija, L. Urbán* and M. Randić. Depts. of Vet. Anat. and Physiol. and Pharmacol., Iowa State Univ., Ames, IA 50011.

High intensity repetitive stimulation of a dorsal root elicits slow hyperpolarizing potentials in a portion of rat spinal dorsal horn neurons studied in vitro (Urbán and Randić, Brain Res., 290:336, 1984). The present experiments were designed to test the hypothesis that slow hyperpolarization is a synaptic event and to obtain information about possible mediators responsible for its generation. Norepinephrine and enkephalins are considered as inhibitory neurotransmitter candidates since they hyperpolarize rat spinal dorsal horn neurons (Murase et al., Brain Res., 234:170, 1982; North and Yoshimura, J. Physiol., 349:43, 1984).

Rats 10-30 days old were used. After lumbosacral laminectomy 300-400 μm thick horizontal or transverse spinal cord slices were made. Intracellular recordings from dorsal horn neurons were performed with micropipettes filled with 3 M K-acetate or 2 M KCl. Tested compounds were dissolved in Ringer solution and applied in known concentrations to the slices by perfusion.

High intensity repetitive stimulation of a dorsal root (10-25 V pulses of 0.2-0.5 ms duration applied at 10-20 Hz for 2-5 s) elicited two types of potential changes in dorsal horn neurons located in laminae I-V. In 17 cells a triphasic potential change was observed; the initial fast excitatory synaptic potentials were followed by a hyperpolarization which was in turn succeeded by a slow depolarization. When recorded at resting membrane potentials of -60 to -75 mV, the mean duration of the hyperpolarization was 24±11 s (mean±S.D.) and the amplitude 8±3 mV. In addition, in substantia gelatinosa cells and some of lamina V cells a biphasic potential change was observed; the initial fast excitatory synaptic potentials were followed by a slow hyperpolarization of 55±24 s with the mean amplitude of 9±6 mV (n=19). A low $Ca^{2+}$/high $Mg^{2+}$ solution or tetrodotoxin ($10^{-6}$M, n=3) reversibly abolished both types of hyperpolarizations. The two hyperpolarizing potentials were associated with a decrease in neuronal input resistance. Bath application of (D-$Ala^2$, $Met^5$)- or (D-$Ala^2$, $Leu^5$)- enkephalinamide (5 x $10^{-6}$M, CRB) and norepinephrine (NE, $10^{-7}$ to $10^{-6}$M, Regis) reversibly hyperpolarized the same neurons having slow hyperpolarizing potentials. Naloxone ($10^{-6}$M, n=7) and the yohimbine ($10^{-7}$ to $10^{-6}$M, n=3) reduced both types of the slow hyperpolarizations. The two hyperpolarizing potentials were enhanced, rather than depressed, by bicuculline ($10^{-5}$M, n=4).

The present findings demonstrate the presence of two types of slow hyperpolarizing potentials in dorsal horn neurons. In addition, the data suggest that NE and/or enkephalins may serve as inhibitory neurotransmitters.

295.3 EFFECTS OF POLYCLONAL AND MONOCLONAL ANTIBODIES TO SUBSTANCE P ON SLOW EXCITATORY TRANSMISSION IN RAT DORSAL HORN. M. Randić, L. Urban,* P. D. Ryu,* and R. Chin.* Dept. of Vet. Physiol. and Pharmacol., Iowa State Univ., Ames, IA 50011 and Dept. of Anatomy, Univ. Medical School, Debrecen H 4012, Hungary.

We have demonstrated that high intensity repetitive stimulation of a dorsal root elicits a slow depolarization in dorsal horn neurons that may be mediated by a substance P (SP) or a SP-like peptide (Urban and Randić, Brain Research, 290:336, 1984). In an attempt to provide a further support for the neurotransmitter role of SP, effects of bath perfusion of polyclonal and monoclonal antibodies to SP on slow excitatory transmission in rat dorsal horn neurons have been investigated by intracellular recording in the immature rat (13-24 days old) spinal cord slice preparation.

Both polyclonal (diluted to 1:50 or 1:100; n=25) and monoclonal (1:12.5 to 1:50; n=6) SP antisera produced a substantial decrease in the level and duration of the slow depolarization generated in dorsal horn neurons by dorsal root stimulation or exogenous SP application. In those cells where the slow depolarization was accompanied by an increase in fast synaptic activity and firing of action potentials, the SP antisera markedly suppressed the synaptic activity and firing. The effect on the dorsal root-elicited slow depolarization appeared within 10-40 min following the onset of perfusion, and after the removal of SP antisera, the response only partially recovered with a relatively slow time course. The effect of endogenous SP released during dorsal root stimulation appears likely since bath perfusion of a slice with a normal rabbit serum, or affinity chromatography adsorbed SP antiserum, or non-specific IgG, had no similar depressant effect.

The effects of SP antisera, if taken together with other experimental evidence, suggest that SP or a SP-like peptide, is in some way involved in generation of the dorsal root elicited slow depolarizing response. In addition, a novel approach is presented for using polyclonal and monoclonal antibodies to SP as pharmacological antagonists in vitro.

(For generous donation of SP antisera, we are most grateful to Dr. T. M. Jessell, Harvard Medical School. Supported by NIH grant NS 17297, National Science Foundation grant BNS 8418042, and the United States Department of Agriculture.)

295.4 EFFECTS OF 4-AMINOPYRIDINE ON SYNAPTIC CURRENTS IN CA3 HIPPOCAMPAL NEURONS. P.A. Rutecki*, F.J. Lebeda, and D. Johnston. Dept. of Neurol. & Neurosci. Prog., Baylor Col. of Med., Houston, TX 77030.

4-aminopyridine (4-AP) is a potent convulsant that produces synaptically mediated epileptiform activity in the hippocampal slice. The paroxysmal depolarizing shift (PDS) produced by 1-10 μM 4-AP is a complex waveform compared to the PDS produced by GABA antagonists. Several lines of evidence suggest that the convulsant properties of 4-AP are not due to a decrease in GABA-mediated synaptic inhibition. In order to test this hypothesis further, we have begun to study the effects of 4-AP on synaptic responses in CA3 pyramidal neurons under voltage clamp.

Rat hippocampal slices were prepared in a conventional manner. Intracellular recordings were made from CA3 pyramidal neurons using low resistance microelectrodes and a single-electrode current- and voltage-clamp system. Synaptic currents were evoked at 0.2 Hz by stimulating dentate granule cells with a bipolar stimulating electrode.

In control saline, the evoked synaptic currents at potentials near rest consisted of an initial inward current followed by an outward current. Measurements of the currents at different holding potentials were made at 15 ms following the stimulus. Previous studies have shown that the current at this delay from the stimulus results primarily from recurrent and/or feedforward inhibition (Brown and Johnston J. Neurophysiol. 50:487). In 10 neurons the measured synaptic current at this 15 ms time point had a mean conductance of 74.6 ± 7.9 nS and a mean reversal potential of -66.7 ± 1.3 mV. Measurements of the evoked synaptic currents were obtained before and at various times after adding 1-5 μM 4-AP to the bathing solution. In half the neurons studied there was an increase (>30%) in the 15 msec conductance measurement. In the other half there was either no change or a small decrease in conductance. Experiments are being conducted adding picrotoxin to the bath to evaluate the effects of 4-AP on pure excitatory synaptic currents.

These results support the hypothesis that the convulsant properties of 4-AP are not due to disinhibition and may even be accompanied by an increase in inhibition. We suggest that epileptiform activity can be observed in hippocampal slices in the presence of normal (and even increased) synaptic inhibition. 295.5 L-2-AMINO-4-PHOSPHONOBUTYRATE ACTS PRESYNAPTICALLY TO BLOCK NEUROTRANSMISSION IN THE HIPPOCAMPUS. Alan H. Ganong, Martin N. Perkins*, John A. Flatman*, and Carl W. Cotman. Department of Psychobiology, University of California, Irvine, California 92717.

The majority of excitatory synapses in the mammalian CNS probably use L-glutamate or a closely related amino acid as a transmitter. The L-glutamate analogue L-2-amino-4-phosphonobutyrate (L-AP4) is a potent and selective antagonist at several CNS excitatory pathways, but its mechanism of action is unknown. We have analyzed the effects of L-AP4 and several other synaptic antagonists on evoked and spontaneous EPSPs at the L-AP4—sensitive mossy fiber—CA3 pyramidal cell synapse in guinea pig hippocampal slices.

Intracellularly recorded stimulus-evoked mossy fiber EPSPs were strongly antagonized by 50 μM L-AP4 (89±2% inhibition, n=10), but were not affected by 50 μM D-AP4. The L-AP4 analogue L-serine-O-phosphate (L-SOP) applied at 200 μM also antagonized evoked EPSPs (67±2% inhibition, n=4). The presumed postsynaptic antagonists kynurenate (400 μM) and N-(p-bromobenzoyl)piperazine-2,3-dicarboxylate (200 μM, pBB-PzDA) also blocked evoked mossy fiber EPSPs by 64±5% (n=8) and 68±2% (n=6).

The effects of these synaptic antagonists on spontaneous mossy fiber miniature EPSPs (mEPSPs) fell into two groups. L-AP4 and L-SOP, applied at concentrations that blocked evoked EPSPs, did not affect amplitude distributions of spontaneous mossy fiber mEPSPs. In the presence of 50 μM L-AP4, spontaneous mEPSPs were recorded that ranged in amplitude similar to the amplitudes of events in control medium; the amplitude distributions of spontaneous mEPSPs were not affected by L-AP4 (8 of 9 cells, $p > .2$, Kolmogorov-Smirnov statistic). Spontaneous mossy fiber mEPSPs were also not affected by 200 μM L-SOP in 3 of 4 CA3 pyramidal neurons ($p > .2$). In one cell to which L-SOP was applied, there was an increase in mEPSP amplitude that persisted in the wash.

In contrast to the actions of L-AP4 and L-SOP, kynurenate and pBB-PzDA consistently reduced the amplitude distributions of spontaneous mossy fiber mEPSPs. Kynurenate (400 μM) reduced the amplitude of spontaneous mEPSPs in 4 of 4 neurons ($p < .01$). pBB-PzDA (200 μM) also reduced the amplitude of mossy fiber mEPSPs in 4 of 4 cells ($p < .01$).

The lack of effect of L-AP4 on the amplitude distribution of spontaneous mEPSPs at a concentration that virtually abolishes stimulus-evoked EPSPs, together with previous demonstrations of the weak action of L-AP4 as an antagonist of amino acid-induced excitations, demonstrates that L-AP4 (and L-SOP) act by way of a presynaptic receptor. The ability of kynurenate and pBB-PzDA to antagonize both stimulus-evoked and spontaneous EPSPs indicates that these compounds act at postsynaptic receptors. The ability to selectively manipulate pre- and post-synaptic components of synaptic transmission at the guinea pig mossy fiber and other L-AP4—sensitive synapses should lead to new insights into the mechanisms of excitatory amino acid neurotransmission in the CNS. (Supported by DAMD 17-83-C-3189).

295.6 PEROXIDATIVE DAMAGE IN CA1 HIPPOCAMPAL PYRAMIDAL CELLS OF THE GUINEA PIG. T. C. Pellmar. Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

Free radicals and active oxygen are thought to increase in concentration in the brain following ischemia and reperfusion. The electrophysiological consequences of active oxygen damage were investigated in a hippocampal brain slice preparation. Hydrogen peroxide (0.01%) and $FeSO_4$ (100 uM) ($H_2O_2$/Fe) were added to the Ringers' solution to generate hydroxyl free radicals. Extracellular recordings were obtained from the somatic and dendritic layers of CA1 region. Bipolar electrodes were positioned in the alveus for stimulation of the antidromic pathway and in the stratum radiatum for orthodromic stimulation.

$H_2O_2$/Fe had no effect on the antidromic population spike but greatly reduced the orthodromically elicited population spike. $H_2O_2$/Fe also decreased the dendritic response (pop PSP). Analysis of input-output curves revealed that the decrease in the pop PSP was insufficient to produce the observed change in the population spike. The results suggest that $H_2O_2$/Fe casues both a decrease in synaptic efficacy and impairment of action potential generation. Control experiments showed that 100 uM $FeSO_4$ alone was without effect on the orthodromic response. Peroxide alone (0.01%) produced similar results to $H_2O_2$/Fe but with a slower time course.

Intracellular recordings from CA1 pyramidal cells substantiated the extracellular findings. $H_2O_2$/Fe caused no change in resting membrane potential or membrane resistance. However, the orthodromically elicited EPSP was reduced. In addition, exposure to $H_2O_2$/Fe decreased the number and the firing frequency of action potentials evoked by a depolarizing current step.

These results suggest that free radicals can cause neuronal damage reflected in alteration of electrophysiological properties.

295.7 BIPHASIC EFFECT OF AMINOGLYCOSIDES ON TRANSMITTER RELEASE IN THE POTASSIUM-STIMULATED FROG NEUROMUSCULAR JUNCTION. P.A. Talbot and H.L. Peterson. Department of Pharmacology, Xavier University College of Pharmacy, New Orleans, LA 70125.

Miniature endplate potential (MEPP) frequency is dependent on $Ca^{2+}$ inside the presynaptic nerve terminal. High $K^+$ and other membrane depolarizing factors cause an increase in $Ca^{2+}$ influx into the nerve terminal with a consequent increase in MEPP frequency; an effect which is competitively antagonized by $Mg^{2+}$.

Using intracellular microelectrodes, aminoglycosides were investigated electrophysiologically in tetrodotoxin-blocked sciatic nerve-sartorius muscles. The preparation was superfused continuously with control Ringer's followed by Ringer's containing drug then by control Ringer's again. In 10mM $K^+$-Ringer's (no $Mg^{2+}$) sisomicin sulfate (used at 20ug/ml) consistently caused an immediate increase in MEPP frequency to 123% of control ($p < .01$) which lasted for 1 min and was subsequently followed by a maximal decrease to 24% of control ($p < .02$) at 10 min that remained unchanged in the presence of drug (for 20 min). Similarly, in 10mM $K^+$, amikacin (80ug/ml), tobramycin (80ug/ml), and the sulfate salts of gentamicin (20ug/ml), netilmicin (20ug/ml), kanamycin (80ug/ml), streptomycin (80ug/ml) and neomycin (5ug/ml) produced an initial increase which was followed by a depression to 28% ($p < .05$), 14% ($p < .05$), 24% ($p < .01$), 20% ($p < .05$), 13% ($p < .01$), 40% ($p < .01$) and 20% ($p < .05$) of control, respectively. In 5mM $K^+$-Ringer's, the magnitude of the initial increase caused by sisomicin was not significantly changed; this effect, however, was followed by a decrease that was not significantly different from the control baseline in the presence of drug. When 5mM $Mg^{2+}$ was present in 10mM $K^+$-Ringer's, sisomicin did not cause an effect on MEPP frequency that was significantly different from control.

In conclusion, the aminoglycosides caused a marked depression of $K^+$-stimulated transmitter release consistent with an action of these drugs to block $Ca^{2+}$ influx into the nerve terminal. These drugs also caused, however, an immediate increase in transmitter release that was not dependent on $K^+$ but was susceptible to $Mg^{2+}$ blockade suggesting an additional action of these drugs to depolarize the presynaptic membrane.

(supported by a grant from NIH)

295.8 LINDANE EXERTS BOTH PRE- AND POSTSYNAPTIC ACTIONS AT FROG NEUROMUSCULAR JUNCTION. S. M. Vogel*, R. M. Joy and T. Narahashi, Dept. Pharmacology, Northwestern University School of Medicine, Chicago, IL 60611.

Lindane (gamma-hexachlorocyclohexane) has previously been shown to increase miniature end plate potential (MEPP) frequency and decrease MEPP amplitude at frog neuromuscular junction. In this study we investigated whether the reduction in MEPP amplitude was pre- or postsynaptically mediated.

Cutaneous pectoris muscles were removed from frogs, and conventional microelectrodes filled with 3M KCl were used to record membrane potentials. For iontophoresis a second microelelectrode was filled with 1M ACh which was released by depolarizing pulses of 5-10 msec at a current intensity causing reproducible responses of 3-5 mV.

Perfusion with lindane produced a time and concentration dependent effect on MEPPs. At 50 uM MEPP frequencies were typically increased by 100-500%. MEPP amplitudes were progressively decreased, often becoming undetectable. Effects developed within 10-20 minutes, and full recovery usually occurred within 30-60 minutes.

To test whether the reduction in MEPP amplitude was mediated postsynaptically ACh was applied to the end-plate by iontophoresis. The amplitude of ACh-evoked depolarizations declined with a time course nearly identical to the decline of MEPP amplitude. This indicates that lindane causes a postsynaptic block at the end-plate which can account for the observed decrease in MEPP amplitude. It is unlikely that lindane reduces the quantal size because of the similarity in time course for depression of spontaneously released and iontophoretically applied ACh.

In solutions containing high $Mg^{++}$, evoked EPPs were increased or unchanged in amplitude at the time when MEPP amplitudes were severely depressed. This is interpreted to indicate that lindane also enhances evoked transmitter release. The magnitude of this effect is obscured because of the simultaneous postsynaptic block. These results indicate that lindane produces both presynaptic and postsynaptic actions at frog neuromuscular junction. Presynaptically it increases transmitter release. Postsynaptically it reduces the responsiveness of the end-plate to ACh.

Supported by NIH grant NS 14143.

295.9 ACTIONS OF BARIUM ON FROG SPINAL CORD. J.C. Hackman, G.P. Ryan, G.J. Wohlberg, and R.A. Davidoff. Neurophysiology Laboratory, VA Medical Center, and Depts. of Neurology and Pharmacology, Univ. of Miami School of Medicine, Miami,Fl. 33101.

The divalent cation barium ($Ba^{++}$) has several different effects on excitable tissue. $Ba^{++}$ can replace $Ca^{++}$ to maintain transmitter release at some synaptic junctions, but not at others, and can pass through $Ca^{++}$ channels in non-synaptic membrane. Other data indicate that $Ba^{++}$ interferes with the function of several types of $K^+$ channels. In contrast to $Ca^{++}$ and $Mg^{++}$, $Ba^{++}$ has potent excitatory effects on vertebrate central neurons. The present experiments investigated the effects of the cation on the frog spinal cord.

Sucrose gap recordings were made from the dorsal (DR) and ventral (VR) roots of the isolated,hemisected cord superfused with $HCO_3^-$-buffered Ringer's solution (15°C). $K^+$-sensitive microelectrodes measured changes in extracellular $K^+$ concentrations in the dorsal horn and intermediate gray matter.

Addition of $Ba^{++}$ (25uM-5mM) depolarized both DRs and VRs in a concentration-dependent and reversible manner. Much of this effect appeared to be indirect since $Mg^{++}$ (10mM) and TTX (0.625uM) substantially reduced the $Ba^{++}$-induced depolarization. $Ba^{++}$ (25-500uM) markedly increased the frequency and duration of spontaneous DR and VR potentials. Evoked DR and VR potentials were greatly prolonged in duration and frequently increased in amplitude at the same concentrations. At higher concentrations (1-5mM) both the spontaneous and evoked potentials were reduced in amplitude. However, the duration of the responses remained prolonged.

The increased excitability did not appear to result from increased postsynaptic responses to putative excitatory amino acid transmitters or to $K^+$ since the addition of $Ba^{++}$ reduced motoneuron depolarizations elicited by the application of L-glutamate, L-aspartate (1mM) or $K^+$ (15mM). However,a reduction in pre- and post- synaptic inhibition may be a factor because GABA-induced depolarization of afferent terminals and GABA- and glycine-induced hyperpolarizations of motoneurons were reduced by $Ba^{++}$.

Both the baseline levels and the evoked release of $K^+$ were increased by $Ba^{++}$. At higher concentrations of $Ba^{++}$ (>500uM) the evoked release of $K^+$ was reduced,but still remained above baseline levels.

In sum, low concentrations of $Ba^{++}$ are highly excitatory when applied to the spinal cord. A block of inhibitory amino acid transmitter action and enhanced release of $K^+$ by afferent stimuli appear to contribute to this increased excitation. 295.10 THE SUCROSE GAP RECORDING TECHNIQUE APPLIED TO THE RAT SUPERIOR CERVICAL GANGLION. D.G. McKenna*, C.A. Briggs, D.M. Barnes and D.A. McAfee. Beckman Research Institute of the City of Hope, Duarte CA 91010.

The sucrose gap technique provides a convenient method for obtaining a direct measure of transmembrane potentials. It can be used to record from a variety of excitable tissues provided that the preparation is large enough to span the gap. We describe here the fabrication of a sucrose gap apparatus for an unusually small preparation - the rat superior cervical ganglion.

Ganglia from young adult rats are fusiform shaped, about 4mm long by 0.8 mm maximum diameter, and have a wet weight of 1 mg. The actual gap is composed of a piece of polyethylene tubing (PE 10) through which isotonic sucrose flows by gravity feed. The internal carotid (postganglionic) nerve is threaded across the stream of sucrose through a 100 um hole pierced transversely in the tubing. The tubing is sealed between two chambers that are electrically isolated from each other and contain Locke's solution flowing at 0.1 ml/min.

The body of the ganglion is in one chamber while the end of the internal carotid nerve is in the other. Calomel electrodes in contact with the two chambers are used to differentially record the voltage across the gap. This voltage will reflect changes in the membrane potentials of the postganglionic axons which span the gap. In addition, potentials will be conducted to the gap from distant somata and dendrites with an estimated electrotonic decrement of 63%/220 um (McAfee, 1982 in Progress in Cholinergic Biology, Hanin and Goldberg eds., Raven press).

The preganglionic nerve is threaded into a third chamber containing Ag bipolar stimulating electrodes. Preganglionic stimulation produces a compound action potential (15 mV) and the following sequence of synaptic potentials: fast-EPSP, slow-IPSP, slow-EPSP, and late slow-EPSP. Brief periods of repetitive preganglionic stimulation produce both posttetanic and long-term potentiation. Increases in extracellular $K^+$ on the ganglion side of the gap depolarize as an exponential function of concentration (12 mV/decade). Nicotinic cholinergic agonists added to the Locke's solution cause depolarization (1 mV at 10 uM). This preparation is especially suitable for the quantitative study of receptor pharmacology. Current studies include receptor mediated activation of cyclic nucleotide and phosphatidylinositol second messenger mechanisms.

295.11 MEMBRANE AND SYNAPTIC PROPERTIES OF PROOPIOMELANOCORTIN-CONTAINING CELLS. Q.J. Pittman and B.A. MacVicar, Dept. of Medical Physiology The University of Calgary, Calgary, Alberta T2N 4N1, Canada.

The rat pars intermedia (PI) consists wholely of cells of the proopiomelanocortin family whose major secretory products include α-melanocyte stimulating hormone and endorphins. Hormone output from these cells is thought to be inhibited by GABAergic and dopaminergic inputs and stimulated by β-adrenergic agents. We have carried out intracellular recordings in isolated rat PI to examine the membrane properties of these cells and to characterize their synaptic inputs. Pituitaries were placed in a warmed (33° C) recording chamber and superfused with artificial CSF. Afferent fibres were activated with a bipolar electrode placed on the stalk and PI cells were impaled with microelectrodes filled with 2 M K acetate. Some cells were also filled with Lucifer yellow and subsequently these small (10 x 15 μm) rectangular cells were localized to the PI.

Pi cells (N=50) have low resting potentials (-30 to -65 mV) and high input resistance (200-1000 mΩ). Depolarizing current elicited over-shooting action potentials. This was followed by a pronounced after-hyperpolarization which displayed increased conductance and reversal at approximately -80 mV. Action potentials were blocked by TTX (1 μm). In high calcium (10 mM) or barium (10 mM) a calcium spike could be evoked which could be blocked with cadmium (1mM). Stalk stimulation evoked an IPSP which reversed at -60 mV or following intracellular chloride injection (KCl electrode). The IPSP was associated with increased conductance, was of variable duration (0.2-2 s) and decremented with repeated stimulation. Superfusion with $10^{-5}$ M bicuculline, a GABA antagonist, blocked this response. The GABA IPSP was often followed by a slow hyperpolarization which could last up to 12 s. It was associated with a slight (12%) decrease in conductance, was enhanced when the cells were hyperpolarized with negative current and was not readily reversible. This response summated upon repetitive stimulation. It was consistently blocked with the dopamine antagonists, chlorpromazine (50 μm) or domperidone (1 μm).

These results indicate that PI cells are under an interesting form of control wherein membrane potential can be altered for short periods of time by GABAergic inputs and over a much longer time course via a dopaminergic input. The monosynaptic nature of these inputs provides an ideal opportunity for further characterization of actions of identified synaptic transmitters.

295.12 Ia AFFERENT EXCITATION OF MOTONEURONS IN THE NEWBORN RAT SPINAL CORD IS SELECTIVELY ANTAGONIZED BY KYNURENATE. C.E. Jahr and K. Yoshioka*. Dept. Neurobiol., Harvard Med. Sch.,Boston, MA 02115.

Intracellular recordings from motoneurons of in vitro preparations of newborn rat spinal cord were used to study the sensitivity of the Ia excitatory postsynaptic potential (epsp) to antagonists of excitatory amino acids in order to test whether group Ia primary afferents release L-glutamate, or a similar compound, as a neurotransmitter. The Ia epsp was isolated from afferent evoked polysynaptic input to motoneurons by low intensity stimulation of individual muscle nerves and by the addition of high concentrations of divalent cations to the superfusate which suppressed polysynaptic circuits. The pattern of convergence of group Ia afferents from homonymous, heteronymous and antagonist muscle nerves onto motoneurons in the newborn rat was similar to that reported in the adult cat spinal cord. Homonymous muscle nerve stimulation evoked the largest amplitude Ia epsp while heteronymous muscle nerve stimulation elicited smaller epsps or had no effect. Stimulation of antagonist muscle nerves resulted in inhibitory postsynaptic potentials (ipsps). Superfusion of the specific N-methyl-D-aspartate (NMDA) receptor antagonist, 2-amino-phosphonovalerate, did not inhibit the Ia epsp but did suppress later, polysynaptic components of the dorsal root evoked response. Kynurenate was a potent inhibitor of the Ia epsp. The site of action of kynurenate was examined by observing its effect on synaptic depression and was found to be consistent with a postsynaptic mechanism. Kynurenate selectively blocked the depolarization of motoneurons elicited by L-glutamate and had no effect on the recurrent ipsp evoked by ventral root stimulation with its effect on the Ia epsp. The recurrent ipsp was antagonized by strychnine and dihydro-beta-erythroidine while kynurenate, at a concentration which greatly reduced the Ia epsp, had no effect. These results suggest that stimulation of group Ia primary afferents evoked the release of L-glutamate, or a similar compound, which activated non-NMDA excitatory amino acid receptors on motoneurons which, in turn, mediated the Ia epsp.

## SENSORY SYSTEMS: SUBCORTICAL VISUAL PATHWAYS III

296.1 LONG AND SHORT TERM EFFECTS OF AN AUDITORY STIMULUS ON VISUAL RESPONSES OF THE SUPERIOR COLLICULUS. S. Molotchnikoff, E. Sicard*, C. Casanova* and P. Lachapelle*. Dépt. de Biologie, Université de Montréal, Qué., Canada, H3C 3J7.

The convergence of visual, auditory and somatic inputs to the superior colliculus represents one of the most interesting aspects of collicular physiology. Evidence has been presented that there are interactions between these three modalities, but the characteristics of these interactions are far from being elucidated. Hence, the scope of the present investigations is to shed more light on the influences of auditory stimuli on light responses.

In anesthetized and paralyzed rabbits single units recordings were taken from superficial layers of the superior colliculus in a standard manner. Each neuron was stimulated with a circumscribed dark or light bar sweeping across its receptive field in the horizontal or vertical direction. An auditory pure tone (duration: 300 ms, 10 $KH_Z$, was added at various delays prior to the light-evoked discharges. One important methodological aspect must be underlined. Since the collicular cells tend to habituate to repetitive stimulus applications, very low frequencies were applied (up to 1 stimulus per 20 sec), when necessary. In addition the sequence between control and test trials was run randomly in blocks of 4 consecutive presentations. Results (N = 199) revealed that the auditory pulses are capable of increasing (N = 50) and decreasing (N = 53) light responses. Two patterns of interactions were noticed: a) a short term effect whose peak time is 50 to 100 ms, and b) a long term effect which may last several seconds. Computations to establish a correlation between the receptive field coordinates of the collicular cell and the magnitude of the influence of the auditory pulse revealed a lack of tight relations between these two variables. In addition, the distance separating the speaker and the collicular receptive field is not related to the amplitude of the alterations of the light responses. These results suggest that the collicular cells work according to a "functional gradient model" (McIlwain, J. Neurophy. 1982: 47) rather than a more rigid point-by-point activation which assumes fixed topographic representations. Finally, a survey of data obtained so far suggests that units influenced by auditory pulses are grouped together because once a neuron is isolated neighbouring cells had a high probability of yielding similar interactions. These latter results further suggest a modular organization of the collicular network in rabbits.

296.2 INFLUENCE OF THE CRYOBLOCKADE OF THE VISUAL CORTEX UPON LIGHT RESPONSES OF SUPERIOR COLLICULUS CELLS IN RABBITS. L. Lamothe*, S. Molotchnikoff, A. Cérat* and E. Sicard*. (Spon: F. Lepore) Dept. Biologie, Université de Montréal, Montréal, Qué. Canada, H3C 3J7.

It has been demonstrated in cats that collicular responsiveness to visual stimuli depends upon the cortical input. Particularly, movement sensitivity and directional selectivity are depressed with the interruption of cortico-collicular impulses. One of the peculiarities of the rabbit's visual system is that the movement sensitivity is already present at the retinal level. It is therefore justified to study the cortico-collicular influences in this species.

In anesthetized paralyzed rabbits single units recordings are carried out with a NaCl-filled glass micropipette. Each cell was tested for movement and directional sensitivity with appropriate images (bars, slats, etc...) sweeping across its receptive field. The cellular activity was obtained in PSTH form prior to, during and after cortical blockade. Field potentials recorded from the cortex permitted us to assess the cortical disfunction. Of 48 fully tested cells a fairly large proportion (85%, N = 41) were influenced by cortical depression. Thirty-one of these affected cells exhibited a robust decline in their responses. In some cases cells' responses to light were completely eliminated when cortical activity was also abolished. Only a small proportion (10%) of collicular cells reacted with an increase of their excitation concurrent to cortical blockade. Although in most instances, the responses to various trigger features (on-off stimuli, direction of the moving images) declined with the same magnitude, in a few cells the discharge to one particular trigger feature was more affected than it was to others. Finally, a trend seemed to emerge: cells which reacted by a facilitation to cortical blockade appeared to be located more dorsally than units with a depressing influence. These preliminary results indicate that the cortico-collicular influence is relatively homogeneous but in a few neurons the cortical impact exerts a more subtle and specific role. These findings stand in sharp contrast with cortico-geniculate influences. Indeed corticofugal axons which contact the lateral geniculate cells have a very specific action since they influence the center-surround equilibrium in concentric units, to the detriment of the surround in most cases. Thus, the global modulations of the collicular responsiveness by the cortex may be associated with the role attributed to the superior colliculus in alerting and preparing the oculomotor neuronal network to readjust the gaze of the animal and unlock (or lock) the fixation of the eyes.

296.3 IMMUNOCYTOCHEMICAL LOCALIZATION OF GAMMA-AMINOBUTYRIC ACID (GABA) IN THE CAT SUPERIOR COLLICULUS. R.R. Mize and L.H. Horner*, Div. of Neuroscience, Dept. of Anatomy, University of Tennessee Center for Health Sciences, Memphis, TN 38163.

Two cell types - horizontal I and granule I cells - accumulate tritiated GABA injected into the cat superior colliculus (SC) (Mize, et al., J. Comp. Neurol., 206:180, 1982). We now report the pattern of SC labeling using an antiserum to GABA visualized by light and electron microscope immunocytochemistry. Fifty um sections were cut through the SC of 9 cats. Each section was incubated in varying dilutions of GABA antiserum (Immuno Nuclear) and reacted using the avidin-biotin (ABC) technique. At the LM level, neuropil labeling was most dense within the zonal and superficial gray layers, but labeling was also observed deeper where large, densely stained fibers coursed through the intermediate and deep gray layers and the colliculus commissure. Apparent labeled terminals surrounded large cells in the deep strata. There was a marked variability in staining intensity in different cells. Most intensely labeled cells were located in the zonal and superficial gray layers, but some were also found in the deep layers. Most but not all intensely labeled cells were small (mean aver. diameter = 13 um) and had a variety of shapes.

With the electron microscope we observed several types of labeled cell. The most common type was small with a round or ovoid cell body and cytoplasm clumped at one end. Another type had a horizontal, fusiform cell body with thin cytoplasm surrounding a prominent, invaginated nucleus. Occasionally, labeled cells with morphologies distinct from these two were also seen. We found no clearly labeled glia.

Four distinct varieties of labeled process were observed. Myelinated axons were commonly seen. Conventional dendrites with parallel arrays of labeled microtubules were also seen frequently. Some of these had a horizontal orientation. One labeled dendrite gave rise to an unlabeled spine which contained a cluster of flattened vesicles and synapsed onto another process. Two other varieties of vesicle-containing profile were labeled. One had loose accumulations of pleomorphic vesicles which were small and usually round or ovoid in shape. These often received input from retinal terminals and formed symmetric synaptic contacts with other processes. The other variety had densely packed pleomorphic vesicles, some of which were flattened. These profiles were always presynaptic to other profiles and also formed symmetric synapses.

Our results largely confirm those using uptake of tritiated GABA. However, the GABA antiserum reveals a richer variety of cells, some of which are located in the deep as well as the superficial subdivision of cat SC (Supported by EY-02973).

296.4 TIME COURSE OF ELECTROPHYSIOLOGICAL CHANGES IN THE SUPERIOR COLLICULUS OF ADULT LONG-EVANS RATS FOLLOWING MONOCULAR ENUCLEATION. W.K. Boyes and B. Veronesi. Neurotoxicology Division, U.S.E.P.A., Research Triangle Park, NC, 27711.

Previous electrophysiological studies (Fukuda et al., Jap. J. Physiol. 28, 347, 1978;) report that in the rat visual system, the faster conducting/larger caliber fibers of the optic tract terminate in the lower portion of the stratum griseum superficiale (SGS) of the superior colliculus (SC), whereas slower conducting/smaller caliber fibers terminate in the stratum zonale and the upper portions of the SGS. Degeneration studies (Lund et al., Brain Res. 116, 83, 1976) in contrast, based on the premise that small diameter fibers degenerate before large diameter fibers, conclude that larger diameter fibers innervate upper portions of the SGS, and smaller fibers the lower portion of the SGS.

To address this discrepancy, the present study examined the electrophysiological changes in the SC in response to monocular enucleation. Long-Evans, male, 60-day-old rats were implanted surgically with a chronic bipolar stimulating electrode located in the optic chiasm and bilateral monopolar recording electrodes located just below the SGS and referenced to a skull screw electrode. One week after surgery, baseline recordings were performed in awake rats. In rats with satisfactory electrode placements (n=17), peaks which corresponded to presynaptic activity of fast conducting fibers (Pre), postsynaptic activity of fast conducting fibers (N1), and postsynaptic activity of slow conducting fibers (P3), were identified based on peak latency, polarity, stimulation threshold and resistance to 100 Hz stimulation (Fukuda et al., Jap. J. Physiol. 28, 347, 1978; Wilson et al., Soc. Neurosci. Abs., 460, 1984). Two days after enucleation, the contralateral Pre and N1 peaks were almost undetectable, whereas P3 was still prominent. The P3 peak was reduced by 4 days, and undetectable by 7 days after enucleation. Enucleation produced no obvious ipsilateral changes. Morphological analysis of parallel-treated rats is in progress. The preliminary electrophysiological results suggest that following enucleation in adult rats, fast conducting optic tract fibers degenerate before slow conducting fibers. This finding could account for the discrepant conclusions of previous degeneration and physiological studies.

296.5 CORRELATIONS BETWEEN STRUCTURE AND FUNCTION FOR SINGLE VISUAL CELLS IN THE SUPERFICIAL LAYERS OF THE HAMSTER'S SUPERIOR COLLICULUS. R.W. Rhoades, B.G. Klein and R.D. Mooney. Dept. of Anatomy, UMDNJ-School of Osteopathic Medicine and Rutgers Medical School, Piscataway, NJ 08854.

Intracellular recording, receptive field mapping and HRP injection techniques were used to determine the structural and functional characterisitics of 59 cells in the superficial laminae (the stratum griseum superficiale-SGS and stratum opticum-SO) of the hamster's superior colliculus. Of these, 8 were marginal cells, 14 had stellate morphology, 10 were narrow field vertical cells, 12 were widefield vertical cells and 8 were horizontal cells. Seven had somadendritic morphologies which did not fall into any of these groups.

There were strong correlations between the structural and physiological characteristics of the recovered neurons. Sixty-four % of the stellate cells and 75% of the marginal cells were directionally selective. Only 17% of the other cell types exhibited this response property. In addition, only 36% of the stellate and 25% of the marginal cells were discharged by stationary flashed spots. Eighty-one % of the other cell types gave reliable responses to such stimuli. Only 29% of the stellate and 13% of the marginal cells responded to stimulus speeds in excess of 20°/sec. Seventy % of the other cells were reliably discharged by speeds >20°/sec. None of the receptive field properties which we evaluated functionally differentiated narrow field vertical, widefield vertical and horizontal cells.

Reconstruction of the axonal arborizations of the recovered neurons demonstrated further that some marginal, narrow field vertical and widefield vertical cells had axon collaterals which terminated in the deep collicular laminae. While most of these innervated the stratum griseum intermediale, those of several cells extended as far as the stratum griseum profundum.

Our results thus demonstrate that marginal and stellate neurons in the SGS and SO can be functionally distinguished from other morphologically defined cell types in these layers and further that some visual cells in the superficial layers innervate the deep tectal laminae.

296.6 SELECTIVE SUPPRESSION FROM VISUAL STIMULI OUTSIDE THE CLASSICAL RECEPTIVE FIELD OF NEURONS IN MONKEY SUPERIOR COLLICULUS. R.M. Davidson* and D.B. Bender* (SPON: M. Titmus). Div. Neurobiology, Dept. Physiology, Sch. of Med., Univ. at Buffalo, Buffalo, NY 14226.

In monkey extrastriate cortex, visual stimuli presented well outside the classically defined receptive field can radically influence the response to stimuli presented inside the receptive field. This "surround" influence can be suppressive and stimulus specific: maximum suppression occurs when the surround stimulus matches the stimulus in the classical receptive field (CRF) along some particular stimulus dimension, such as direction of movement. Neurons making these local-global comparisons may contribute to the segregation of figure from ground.

To determine whether neurons in the monkey superior colliculus also make such local-global comparisons, we examined the effect of moving surround stimuli on colliculus receptive field properties. Cells in both superficial and intermediate layers were studied in anesthetized, immobilized Macaca fascicularis. We first plotted the CRF using small spots of light, both moving and stationary. Almost all cells were non-directional, giving strong responses for all directions of movement. We then paired movement of a small spot across the CRF with movement of a very large "background" stimulus in the surround. The background stimulus was an annular array of 1 deg spots extending well into the peripheral visual field; the inner border of the annulus was no closer than 2 receptive field diameters to the CRF. The background spots always moved coherently. Four to 8 directions of background movement, spaced 45-90 deg apart, were paired with each direction of CRF stimulus movement. The background stimulus presented alone did not affect discharge rate.

All cells more than 300 microns below the tectal surface were powerfully influenced by movement of the background stimulus. When background and CRF stimuli moved in the same direction at the same speed, the cell's response was suppressed more than 60% below that evoked by the CRF stimulus paired with a stationary background. When the directions of target and background movement differed by 45 deg or more, there was little or no suppression. This pronounced and sharply tuned sensitivity to the relative directions of target and background movement held for every direction of target movement tested. The surround influence was less pronounced for cells in the superficial layers: for about a third of these cells, the response to the CRF stimulus was virtually unaffected by background movement.

Thus monkey colliculus neurons appear to make local-global comparisons based on differential movement, a process well-suited to the segregation of target from background.

(Supported by NIH grants EY02254 and DE00145.)

296.7 INTERMEDIATE GRAY OF MOUSE SUPERIOR COLLICULUS: CYTOCHROME OXIDASE RESOLVES LAMINAR BORDERS, PATCHES AND A FLANK WITH NO SUPERFICIAL GRAY LAYER. S.I. Wiener and P.H. Hartline. Eye Research Institute of the Retina Foundation, 20 Staniford St., Boston, MA 02114.

In order to identify anatomically the laminar architecture of the mouse superior colliculus (SC), the cytochrome oxidase (CO), acetylcholinesterase (AChE), myelin and Nissl stained sections were compared. In some cases, anatomical findings were supplemented by electrophysiological data; recording sites were identified by electrolytic lesions.

The CO and myelin stains resolve the SC laminae more clearly than does the Nissl stain. Myelinated fiber bundles, which define laminar borders explicitly, are recognizable in CO-stained sections by virtue of their weak staining. A prominent layer of large, rostrocaudally oriented fiber bundles occurs in a layer above the dorsalmost of the large multipolar cell bodies. This fiber layer has been identified in mouse and rat atlases as the intermediate white layer. But this seems to conflict with the accepted nomenclature for the cat SC and we suggest that this fiber layer be considered, instead, a subdivision of the intermediate gray layer. Such a change in nomenclature seems further warranted by the fact that the cat's intermediate white layer contains mediolaterally, not rostrocaudally, oriented fibers. Moreover, in the mouse, we find that AChE patches span both sides of the layer of rostrocaudally oriented fibers. In the cat SC, such patches occur only in the intermediate gray layer, whereas the earlier rodent nomenclature places them in both the intermediate and deep gray layers.

Patches of CO activity measuring 60-100 μm wide are found in the intermediate gray layer. In horizontal sections, the CO patches are seen to connect and form a meshwork. The patches extend dorsal and ventral to the layer of rostrocaudally oriented fibers, but are more intensely stained ventrally. Intensely CO-active neurons with large somata (5-20 μm diameter) aggregate into clusters which lie exclusively in the ventral aspects of the CO patches. There appears to be no systematic correspondence between these patches and those in the AChE stain as judged by a careful comparison of serially adjacent sections. The CO patches extend further dorsal and ventral and are thicker than the AChE patches.

The CO, myelin and AChE stains and electrophysiological recordings all indicate that the intermediate gray layer extends considerably further laterally than does the superficial gray. Single and multiple unit recordings in this lateral 'flank' region of the intermediate gray indicate that it receives peri-oral, and to a lesser degree, limb and trunk somatosensory as well as auditory inputs. These somatosensory inputs are continuous with the somatotopic map previously described for the more medial parts of the intermediate gray layer. Since the body regions represented in the flank are not in the visual field, the lack of overlying visual projections is in accord with spatial register.

296.8 SUPERNORMALITY OF RETINOTECTAL FUNCTION IN 2,5-HEXANEDIONE (2,5-HD) DISTAL AXONOPATHY OF THE SUPERIOR COLLICULUS BRACHIUM (BSC) IN THE HOODED RAT. D. Impelman*, R.D. Wilson* and D.A. Fox. (SPON: L.P. Felpel). College of Optometry, University of Houston, Houston, TX 77004 and USDA, College Station, TX 77801.

The 2,5-HD axonopathy of the BSC (Neuropath. Appl. Neurobiol. 8: 289, 1982) preferentially affects the functional properties of the $t_2$ (middle) conduction group in the optic tract (OT) (Neurosci. Abs. 10: 460, 1984). Field potential recordings were obtained simultaneously from presynaptic $t_2$ axons in BSC and postsynpatic $c_2$ cells in stratum griseum of the anterior SC (the SC dipole field response in rat). They show that the axonopathy produces supernormality (> 100% recovery) with a subsequent loss of postsynaptic inhibition in $c_2$ recovery functions and, in some animals, prolonged supernormality in $t_2$ functions. The distal-proximal gradient of supernormality in $t_2/c_2$ recovery functions suggests that (1) a functional gradient of supernormality in $t_2$ axons develops with the distal-proximal progression of morphological changes which characterize the axonopathy (i.e., neurofilament accumulation, axonal swelling and paranodal demyelination) and (2) the supernormality of $c_2$ and its loss of postsynaptic inhibition is attributable to hyperexcitability of OT preterminals in the SC of 2,5-HD animals. We measured the distal-proximal gradient of $t_2/c_2$ excitability by recording $t_2$ recovery functions in BSC and 5mm anterior in OT, and $c_2$ recovery functions in SC. Axons at the BSC recording sites were examined to correlate stages of axonal pathology with $t_2$ supernormality. The recordings showed a gradient of supernormality ranging from 107% in $t_2$ axons in BSC to 129% in $c_2$ responses in SC. However, OT $t_2$ axons recovered to 94%. The most notable difference between axonal populations at BSC recording sites of $t_2$ supernormality was the almost complete absence of medium diameter ($t_2$) axons with a concomitant increase in the number and heterogeneity of swollen axons. No signs of neuronal degeneration were observed. The effects of $t_2$ supernormality on intracollicular inhibition which normally depresses the recovery of $c_2$ responses 52-65% was studied by generating supernormality in $t_2$ recovery functions and simultaneously recording $t_2/c_2$ responses in control animals. Both functions show supernormal periods in good temporal correlation with approx. 15% more excitability in $c_2$ than in $t_2$ which is similar to responses in 2,5-HD rats. Intracollicular inhibition in these animals was depressed approx. 20% as compared to approx. 40% in 2,5-HD animals. Thus $t_2$ supernormality can produce $c_2$ supernormal periods in 2,5-HD animals. The larger subsequent loss of postsynpatic inhibition may involve transsynaptic effects of 2,5-HD as well as preterminal hyperexcitability.

296.9 SUPERIOR COLLICULAR CORRELATES OF PARTIAL OPTIC TRACT LESIONS IN ADULT RATS. A.P. Foerster. Dept. of Neurosciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

The right superior colliculus (SC) of Long Evans rats (pentobarbital-anaesthetized) was mapped in 500 μm steps by transcortical penetrations, with tungsten-in-glass microelectrodes, to the depth at which the multiunit responses to a visual stimulus were optimal, and the "chug", a pentobarbital-related retina-dependent rhythmic bursting (15-20/s) was also maximal. At each SC site the location in the visual field, and the approximate size of the receptive field, of the multiunits were determined from the motion of a black card against the lighted background of a transparent hemisphere, r=34 cm, centered on the left eye. A dorso-ventral cut extending to the floor of the skull was then made by lowering a rectangular razor-ended blade, 1-2 mm wide, through the brain to cut the optic tract (OT) as it begins its ascent towards the lateral geniculate bodies; the blade was then withdrawn and the SC sites retested. When the SC was partially silenced the unresponsive sites (even to the motion of a very bright light in darkness) occupied a discrete area in which the chug was also absent. Intraocular HRP, and a sensitive glucose oxidase/TMB technique which demonstrates abundant reaction product with little crystalline artefact, revealed that the OT had been partially cut and that the terminal projections of the spared axons occupied the still-responsive region of the SC; they also extended into about 1 mm of the silenced area. Recordings made 3 hours - 3 days after such partial OT cuts occasionally revealed a return of response at a few sites within this innervated boundary zone, suggesting a recovery of conduction within a few initially conduction-blocked OT axons. Studies of retinas backfilled by injections of tracers into the SC support the anterograde and physiological findings.

Conclusions are: 1) The OT in the rat is retinotopically organized (cf. Bunt & Lund (1982). Soc. Neurosci. Abs. 8:451); 2) Conduction block, and subsequent recovery, of spared optic axons is a minor consequence of this lesioning technique; 3) Whether the silent fringe of optic innervation adjacent to a responsive region represents (i) a subthreshold excitatory input, (ii) a region of responses too small and/or sparse to be detected, or (iii) an inhibitory input, remains to be determined; 4) Since remaining multiunit receptive fields have normal sizes, sprouting or unmasking seem not to have occurred for at least 3 days; 5) This preparation is of potential value in analysing recoveries from OT injury, and in particular the question of whether these could be attributable to the regeneration of severed OT axons.

296.10 DUAL TECTAL EFFERENT SYSTEMS FOR THREAT AVOIDANCE IN FROGS CORRESPOND TO TWO DISTINCT STIMULUS CONDITIONS. D.J. Ingle, Eye Research Institute, 20 Staniford St., Boston, MA 02114

A simple model of the frog's tectal efferent system is that turning towards prey is mediated by the crossed projection to brainstem and spinal cord, while turning away from threat depends only upon the uncrossed tectal output to the ipsilateral brainstem. Although these predictions have been confirmed by transecting either the tectal efferent decussation of the tegmentum or the ipsilateral efferents via a post-tectal hemisection, an unpredicted result of the second lesion is that frogs now respond to looming black disks in the contralateral field by jumping towards them! These "misdirected" avoidance responses were abolished by adding a tegmental split to the hemisections.

What could be the adaptive purpose of a crossed pathway, contributing to wrong-way avoidance jumps? Further cine analysis revealed two different avoidance strategies in normal frogs: (a) the familiar tendency to jump away from off-center threat on a collision course by turning into the contralateral field, and (b) a newly discovered ipsilateral field route elicited by stimuli about to cross the rostral midline a few inches in front of the animal. Reconstruction of the sequence via single-frame analysis showed that the ipsilateral jumps were determined by the stimulus trajectory rather than its radial position just prior to a given response. The same behaviors are observed in monocular or unitectal frogs. Thus a single eye-tectum system can program jumps in either direction depending on the direction of stimulus motion.

296.11 THE TRANSNEURONAL TRANSPORT OF HORSERADISH PEROXIDASE IN THE VISUAL SYSTEM OF THE FROG, RANA PIPIENS. Thomas E. Hughes* and William C. Hall (SPON: M. Gruenthal). Dept. of Anatomy, Duke University, Durham, N.C. 27710

During the course of experiments designed to study the synaptic relationships between the terminals of retinal axons and the various cell populations in the optic tectum of the frog, Rana pipiens, we have found that neurons in many of the retinorecipient nuclei, including the tectum, are transneuronally labeled following injections of horseradish peroxidase (Sigma, type VI) into the optic nerve. These neurons are well labeled; both the dendrites and the somas are filled with reaction product. However, unlike normal retrograde transport, the labeling is often heaviest in the dendrites that extend into the retinal recipient neuropil while the cell somas are only faintly labeled. Transneuronal transport is seen consistently when we use an imidazole enhanced diaminobenzidine reaction (Straus, J. Histochem. Cytochem. '82), and a 4 to 9 day survival period.

One of our most interesting findings is that particular cell groups in the tectum are well-labeled while other cell types, which on the basis of the location of their somas or dendrites seem equally likely to receive direct retinal projections, remain free of label. Electron microscopic investigation of the optic tectum reveals that the label is confined to pre- and postsynaptic processes. These results suggest that transneuronal transport in this system depends on a transfer of label from presynaptic terminals to postsynaptic cells rather than on a widespread diffusion of label through the neuropil followed by a selective uptake by particular cell groups. Further, the results suggest either that only some of the tectal cell groups which receive direct retinal projections are transneuronally labeled, or that only a few of the cell types in the tectum are directly contacted by retinal axons.

Although not all retinorecipient neurons may be labeled in this process, the transneuronal transport of horseradish peroxidase is useful since it reveals the morphology as well as the location of at least some of the retinorecipient cells. (Supported by N.I.H. grant EY-04060 and N.S.F. grant BNS-8109794 to W. C. Hall).

296.12 LOSS OF VISUALLY-GUIDED BEHAVIORS FOLLOWING ABLATION OF NUCLEUS ISTHMI IN THE FROG RANA PIPIENS. H.S. Caine* and E.R. Gruberg. Dept. of Biology, Temple University, Philadelphia, PA 19122.

Nucleus isthmi receives input from ipsilateral optic tectum and projects bilaterally to the optic tectum. Electrolytic ablation of the frog's nucleus isthmi results in a visual scotoma contralateral to the lesion. The extent of the scotoma has been determined by analysis of videotaped behavioral responses to visually presented stimuli. Within the scotoma, animals do no respond to visually-presented prey (live crickets tethered on a thread) or threats (a large black square suspended on a 1m rod). The size of the scotoma is related to the amount of n. isthmi ablated. The more extensive the lesion, the larger the scotoma. With complete unilateral ablation, a frog displays no visually elicited prey-catching or threat-avoidance behaviors in the entire monocular field. This specific visual loss is stable over time with the longest period of testing having lasted 8 months. Frogs with extensive bilateral electrolytic lesions exhibit scotomas with the same specific visual deficits as unilaterally lesioned frogs. These scotomas extend over the entire visual field. After 3-5 weeks there is some recovery of function within the binocular field, but no recovery is seen in the monocular fields.

The frog's posture and ability to move in any direction are uncompromised by n. isthmi ablation. Therefore, the behavioral deficit caused by n. isthmi ablation appears to be "visual" and not "motor". The scotoma that follows n. isthmi ablation appears to be identical to the behavioral effect induced by unilateral tectal lobe ablation (Ingle, D., Science, 181:1053, 1973). Unilateral transection of the forebrain at the diencephalon-telencephalon border contralateral to a n. isthmi lesion does not alter the scotoma induced by the n. isthmi lesion. Outside the scotoma, prey-catching and threat-avoidance are normal. Other visual functions including barrier-avoidance, scototaxis and optokinetic nystagmus are normal throughout the entire visual field. Supported by NIH Grant EY 04366.

296.13 GABAergic NEURONS COMPRISE A MAJOR CELL TYPE IN RODENT VISUAL RELAY NUCLEI. R.A. Giolli, G.M. Peterson, C.E. Ribak, M.H. McDonald, R.H.I. Blanks and J.H. Fallon. Depts. of Anatomy & Surgery, Univ. of Calif. Coll. Med., Irvine, CA 92717.

The enzyme glutamic acid decarboxylase (GAD) has been localized in sections of rodent brains (gerbil, rat) using conventional immunocytochemical techniques. The findings show that large numbers of GAD-positive neurons and axon terminals (puncta) are present in the visual relay nuclei of the pretectum and the accessory optic system. The areas of highest density of these neurons are the nucleus of the optic tract (NOT) of the pretectum, the dorsal and lateral terminal accessory optic nuclei (DTN, LTN), the ventral and dorsal subdivisions of the medial terminal accessory optic nucleus (MTNv, MTNd), and the interstitial nucleus of the posterior fibers of the superior fasciculus (inSFp).

The findings indicate that 27% of the NOT neurons are GAD-positive and that these neurons are distributed over all of the NOT except the most superficial portion of the NOT caudally. The GAD-positive neurons of the NOT are statistically smaller (65.9 $um^2$) than the total population of neurons of the NOT (84.3 $um^2$) but are otherwise indistinguishable in shape from the GAD-negative neurons. The other visual relay nuclei that have been analyzed (DTN, LTN, MTNv, MTNd, inSFp) are similar in that from 21% to 31% of their neurons are GAD-positive; however, these neurons are smaller in diameter and are statistically more spherical than the total population of neurons. This study further shows that a large proportion of the neurons in these visual relay nuclei are contacted by GAD-positive axon terminals. Although it is not possible to determine the exact number of all of these "GAD-recipient neurons", it is estimated that about one-half of the neurons of the NOT and the terminal accessory optic nuclei are opposed by seven or more GAD-positive puncta. Further, the morphology of the GAD-positive neurons combined with their similar distribution to the GAD-recipient neurons suggests that many of these neurons are acting as GABAergic, local circuit neurons. On the other hand, the large number of GAD-positive neurons in the NOT and MTN (20-30%) in relation to estimates of projection neurons ( 75%) presents the possibility that some may in fact be projection neurons. The overall findings provide morphological evidence which supports the general conclusion that GABAergic neurons play a significant role in modulating the output of the visually related NOT and terminal accessory optic nuclei. (Supported by USPHS grants EY03642, NS15669, NS20228, EY03018 and NS15321).

296.14 ON/OFF ORGANIZATION OF PATHWAYS SUBSERVING THE PUPILLARY LIGHT REFLEX. Andrew G. Knapp* and Peter H. Schiller. Department of Psychology, M.I.T., Cambridge MA 02139.

In mammals, the neural substrate of the pupillary light reflex includes both cortical and subcortical pathways. Evidence for cortical involvement comes mainly from studies in which electrical stimulation of occipital cortex (both within and outside of striate cortex) has been shown to elicit pupillary constriction. Anatomical and physiological evidence implicates the pretectal olivary nucleus (PO) in the subcortical pathway. PO receives a direct retinal projection and projects to the Edinger-Westphal nucleus, the site of preganglionic pupilloconstrictor neurons. Trejo and Cicerone (*Brain Res.* 300: 49, 1984) have demonstrated that electrical stimulation of PO in the rat evokes constriction of the contralateral pupil at low threshold, and that PO in this animal is made up largely of neurons that respond to retinal illumination with a sustained increase in firing rate (tonic ON cells).

As part of an effort to characterize the ON/OFF organization of the mammalian visual system, we have examined the direct pupillary light reflex of macaque monkeys and of rabbits following administration to the retina of 2-amino-4-phosphonobutyrate (APB), a drug that eliminates light responsiveness in ON bipolar cells and that has been shown to silence ON retinal ganglion cells in several species. Monkeys were maintained on light barbiturate anesthesia and were paralyzed to eliminate eye movements. Alert rabbits were restrained throughout the experiments and briefly anesthetized with halothane to receive intravitreal injections of APB (50-75 $\mu$l of a 10-20 mM solution). These injections were successful in eliminating retinal ON activity as inferred from complete abolition of the b-wave of the electroretinogram (Knapp and Schiller, *Vision Res.*, 24: 1841, 1984). Retinal illumination was provided though a fiber-optic light guide and pupillary reactions measured using a television pupillometer (kindly provided by Dr. Robert Kenyon).

We have studied both normal monkeys, normal rabbits, and rabbits which had received large unilateral ablations of the occipital cortex 2-10 days previously. In monkeys, APB had no discernible effect on the pupillary light reflex. In normal rabbits, APB raised the threshold for pupillary constriction by 0.5 log unit and reduced by 20% the maximal constriction elicited by suprathreshold stimuli. Both these effects were larger (1.0 log unit, 40%) in animals with cortical lesions. Moreover, in rabbits with lesions, but not in normal animals, APB altered the temporal course of the light reflex, making it markedly more transient. Prior to administration of APB, pupillary constriction lasted the length of the stimulus and recovery to the initial pupil diameter commonly took 10 seconds or more. Afterwards, constriction lasted no longer than 5 seconds regardless of the length or intensity of the stimulus. In agreement with previous physiological investigations, these results suggest that ON-channel input to the subcortical reflex pathway is tonic in nature. However, retinal OFF cells are apparently capable of mediating sustained pupillary constriction, provided the occipital cortex is intact. The pathways subserving the residual transient light reflex in rabbits with cortical lesions following APB administration remain to be determined. Supported by EY00676.

296.15 A GOLGI STUDY OF THE VISUAL TEGMENTAL RELAY ZONE IN THE RAT AND RABBIT. K.M. Gregory, Y. Torigoe*, R.A. Giolli and R.H.I. Blanks. Depts. of Anatomy and Physiology, CSU Long Beach, CA 90840 and Depts. of Anatomy and Surgery, Calif. Coll. of Med., Univ. of Calif. Irvine, Irvine, CA 92717.

A portion of the ventral tegmental area of Tsai (VTA) termed the visual tegmental relay zone (VTRZ) is known to have projections and some physiological response properties similar to the adjacent medial accessory optic terminal nucleus (MTN). Although the VTRZ is a part of the visual pathways related to the accessory optic and oculomotor systems, the morphology of the neurons in this region is poorly described. Accordingly, the present analysis examines the form of neurons in the VTRZ in Golgi-Cox and Golgi-Kopsch impregnated tissue.

The neurons forming the VTRZ have a distinctive dendritic architecture. Three types of neurons are identified within the VTRZ: (1) bipolar neurons with long (400-500 um) primary and secondary dendrites oriented in the mediolateral plane of the VTRZ; (2) small-to-medium sized multipolar neurons with primary dendrites also oriented in the mediolateral plane of the VTRZ; (3) large multipolar neurons with long (300-400 um) primary dendrites and a few secondary dendrites. These large multipolar neurons are located in the more dorsal region of the VTRZ and have dendrites extending either dorsally into the parvocellular subdivision of the red nucleus or ventrally into the nucleus parabrachialis pigmentosus of the VTA. Dendritic spines are scarce proximally, but increase in numbers on the more distal dendrites. Overall, the staining character, somal size and shape, dendritic diameters and dendritic spine density of the VTRZ neurons resemble more closely the features of the neurons of the parvocellular subdivision of the red nucleus than nuclei of the ventral tegmental area. The most laterally placed neurons of the VTRZ appear to be continuous with the neurons forming the dorsal division of the MTN. In fact, the dendritic extensions of the VTRZ neurons into the MTN form the morphological basis for the binocularity of the VTRZ neurons. The distinctive morphology of the neurons comprising the VTRZ suggests that this population should be identified as a separate nuclear subdivision of the VTA, a finding which is consistent with the connectional and functional subdivision of this cell population as a visual relay group. (Supported by USPHS grants EY03642 to RAG and EY03018 to RHIB. YT is a recipient of NASA Research Associate Award #MAGW-70.)

296.16 DIRECTION SELECTIVE CELLS IN THE NUCLEUS OF THE OPTIC TRACT IN THE SQUIRREL MONKEY. K.P. Hoffmann, Abt. Vergl. Neurobiologie, Universität Ulm, Postfach 4066, D-7900 Ulm, GFR.

In a number of mammals (rat, rabbit, cat) direction selective cells in the nucleus of the optic tract (NOT) have been shown to encode retinal slip and to be involved in the control of optokinetic nystagmus. In all mammals studied so far, these neurons project to the dorsal cap of the inferior olive. We now have been able to show that the same pathway exists in a primate.

In 2 squirrel monkeys 100 nl of horseradish peroxidase (HRP) were stereotaxically injected into the inferior olive under ketamine anaesthesia 2 days before the recording session. On the day of recording the animals were reanaesthetised with ketamine, fixed in a stereotaxic frame, artificially respired with $N_2O/O_2$ (2 : 1) and paralysed. The pretectum was approached stereotaxically directly from above. Recording sites were marked by microlesion. At the end of the recording session animals were deeply anaesthetised with nembutal and perfused transcardially for HRP-histochemistry.

The neurophysiological properties of NOT neurons in the squirrel monkey resemble very much those in the cat. Neurons had huge receptive fields (40° x 40°) including the fovea. Large area random dot patterns were optimal stimuli although single spots were also effective. All 8 neurons recorded in the left NOT preferred movements from right to left and were inhibited by movements in the opposite direction. All were binocular and showed the same properties through both eyes. Velocities from 0.1°/s to more than 300°/s were effective to modulate the activity of NOT cells direction specifically. Optimal velocities were 60 - 80°/s.

The recording sites of these neurons were found in the same part of the mesencephalon where the cells, retrogradely labelled from the inferior olive were located. These cells were dispersed in the NOT and in the fibers of the brachium of the superior colliculus. Our results clearly show that in primates as in other mammals the NOT cells relay information about retinal slip to the inferior olive.

296.17 RECEPTIVE FIELDS OF NEURONS IN THE PRINCIPAL OPTIC NUCLEUS OF THE PIGEON. K.H. Britten* and D.H. Cohen (SPON: A.D. Carlson). Dept. of Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, NY 11794

The principal optic nucleus (OPT) is the avian homologue of the mammalian dorsal lateral geniculate nucleus. Using a variety of stimuli, we have studied the visual receptive fields (RF) of these neurons to determine if they segregate into functional classes and how these classes might relate to those of mammalian LGN. The stimuli included: 1) a grid of stationary, flashed spots for describing center response type and RF size and geometry; 2) moving spots for exploring directional selectivity; 3) counterphased sinusoidal intensity gratings presented at eight spatial phases for investigating linearity of spatial and temporal summation; 4) drifting gratings for determining spatial and temporal frequency-response tuning functions; 5) whole-field illumination for measuring visual response latencies and for generating intensity-response functions; and 6) optic nerve stimulation for measuring response latencies. Animals were anesthetized with $N_2O$ and local anesthetic.

A preliminary sample of over 100 neurons showed large, homogeneous RFs with a mean area of 145 square degrees. Most (72%) had on-centers, with the remainder having on-off- (23%) or off-center (5%) responses. Antagonistic surround responses were never elicited by either spot or annular stimuli. RFs tended to be located forward of the optic axis, and the larger RFs were located outside the region of binocular overlap. Retinotopy is at best crude, since there was no apparent relationship between electrode and RF locations. All cells responded best to spatial frequencies below .45 cycles/degree, with some showing a response roll-off at the lowest spatial frequencies. Responses to counterphased gratings were quite nonlinear, showing rectification at low spatial frequencies and harmonic distortion at high spatial frequencies. Most neurons showed broad temporal-frequency tuning, and the distribution of preferred frequencies had a mode at 4 Hz.

The distributions of most response properties appeared continuous and unimodal. The exception was response duration which was bimodally distributed; some cells showed distinctly transient responses, while others had sustained responses. However, these two types of cells did not differ in other respects. Also, two-dimensional scatter plots and contingency tables revealed no relationships between response measures.

Given these results, we favor the hypothesis that OPT neurons represent a single, rather heterogeneous group which does not obviously resemble either the X- or Y-cells of the mammalian LGN. In many respects they resemble mammalian W-cells.(Supported by NSF Grant BNS-8016396.)

296.18 IDENTIFICATION OF THE RETINAL GANGLION CELLS PROJECTING TO A PRETECTAL NUCLEUS, THE LENTIFORM NUCLEUS OF THE MESENCEPHALON (LM) IN CHICKEN. Stefan R. Bodnarenko, Olivia C. McKenna and Shulamith Levi*. Dept. of Biology, City College of CUNY, New York, N.Y. 10031

In birds, the LM, which is considered homologous to the mammalian nucleus of the optic tract, is known to respond to retinal slip, i.e., whole-field visual motion, and is responsible for mediating horizontal optokinetic nystagmus (OKN). We have examined in chickens the retinal ganglion cells (RGC's) that project to the LM, the topography of this projection within the LM and the distribution of these RGC's across the retina using the retrograde HRP tract tracing technique.

After iontophoretic injection of 30% HRP into the LM of seven 5-6 week old chickens, retrogradely labeled RGC's were found only in the contralateral eye and almost exclusively within the retinal ganglion cell layer. The cells, which appeared round or oblong, ranged in size from 5 x 8 μm to 12 x 30 μm, with most cells measuring 10 to 15 μm along their long axes; separate classes of cells could not be distinuished. The location of labeled cells in the retina after HRP injections into limited areas of the LM strongly suggested that the LM projection is retinotopically organized: the inferior temporal retina projects to the rostral LM, the central retina to the middle of the LM along its rostro-caudal and dorso-ventral axes, and the superior nasal retina to the caudal LM. This retinotopy is consistent with that reported by Ehrlich and Mark (JCN 223 1984). Three HRP injections which included almost all of the LM resulted in labeled RGC's that lay in an oblique band extending from the inferior temporal retina to the superior nasal retina. After any of these injections few labeled cells were found in the two other retinal quadrants, the superior temporal and inferior nasal.

The RGC's projecting to the LM share several characteristics with a separate population of RGC's that project to another avian visual nucleus, the nucleus of the basal optic root (nBOR) which, like the LM, receives retinal slip signals and mediates OKN. In both cases the RGC's project in a topographical manner onto their recipient nuclei and their RGC's are located principally in areas of the retina where high concnetrations of other RGC's are not found. This location of cells projecting to the LM and nBOR in portions of the retina where visual acuity is low is consistent with the findings that both nuclei respond to whole-field visual motion.

297.1 IDENTIFICATION OF LOCAL NEURONAL CIRCUITS IN THE VISUAL CORTEX OF THE CAT. J.P.Landolt, S.Reinis and D.S.Weiss*, DCIEM, Toronto, and Dept. of Psychology, Univ. of Waterloo, Waterloo, Ont., Canada, N2L 3G1.

Local neuronal circuits in Brodmann's area 18** were analyzed following the recording of population neuronal activity by a single tungsten microelectrode. The receptive field areas, directional preferences, peristimulus time histograms, and spontaneous activity were identified both in the cell with the recorded spike having the largest amplitude ("leading cell"), and in the cell population surrounding the microelectrode. The spikes were divided into five classes according to their amplitudes. The correlation of the activities of individual classes of neurons (or even individual neurons) was then computed in the following way:

First, the auto- and cross-correlation histograms between and within individual amplitude classes of the spikes were computed. These histograms summarize the length and the frequency of all interspike intervals within the multiple cell record. Then, the most common interspike intervals were selected from each histogram. These latter intervals were attributed to the real pairs of spikes in the original records. All such pairs of spikes were listed in a separate file. Each pair was described by the position of the first and second spikes in the original record expressed in milliseconds from the beginning of the record; by the amplitude of the first and second spikes expressed in relative units; and by the interval between them. Using these data, a continuous system of neuronal spikes was constructed that was interconnected by the preselected intervals. In control calculations, records were constructed in which the numbers of the spikes were preserved, but their positions were randomized. No continuous systems could be constructed from the randomized data. In another set of calculations, the time-dependent distribution of spikes was collapsed, and the number of cells involved in the system of interactions was estimated.

The responses of the neuronal systems in the vicinity of the recording microelectrode were compared to the light bar moving in eight different directions across the receptive field of the leading cell. Although many cells in the recorded area responded to the visual stimulation, a change of the angle of the light bar altered their interactions. When the visual pathway was not activated by any defined visual stimulus, the activity of the neuronal systems was still present, and it was sustained by nerve impulses circulating in large reverberating circuits.

Funded under DCIEM Research Contract 97711-0-5951/8SE82-00100.

**All experiments conform to guidelines approved by the Canadian Council of Animal Care.

297.2 DISCONTINUITY-ANALYSIS IN THE CAT'S AREA 19. H. Saito, K. Tanaka, Y. Fukada* and H. Oyamada*. NHK Science and Technical Research Labs., Setagaya-ku, Tokyo, Japan 157.

We studied receptive field properties of cells in the cat's area 19 using four animals anesthetized with gas mixture of $N_2O$ and $O_2$ (70:30-80:20) and paralyzed with gallamine triethiodide (7 mg $\cdot$ $kg^{-1} \cdot hr^{-1}$).

One of the most remarkable features of this area, found in this study, was that orientation selective cells which responded best to an elongated bar or edge of a particular orientation were in the minority (26/81, 32%). The majority (55/81, 68%) showed a good response to a non-oriented small stimulus moving in any direction. The minor group included cells which preferred long bars (longer than $32^o$) and cells whose responses were suppressed when the length of the bar exceeded a distance across the discharge center in both directions. The latter cells correspond to lower-order hypercomplex cells described by Hubel and Wiesel (J. Neurophysiol., 28:229, 1965).

For two-thirds of the major group of cells which showed the non-oriented responses, an elongation of the stimulus along an axis orthogonal to the direction of movement resulted in the suppression of responses. This suppression was observed for any direction of movement. These same cells, however, responded to a long bar if an end of the bar, i.e., a tongue was pushed into the discharge center from any direction. The response was again suppressed when the width of the tongue was increased.

To our surprise, a considerable number of cells which did not respond to a long bar moving across the receptive field in the direction orthogonal to its long axis, were activated by the same bar when just the discharge center was masked from the stimulation. Thus, the trigger feature for them is not only the presence of a small object, but also that of a discontinuous part of contours at a particular position in the visual field. This property cannot be explained by a simple model of the receptive field that the discharge center is surrounded by a pure inhibitory field. Instead, there may be some kind of nonlinearity in the inhibitory mechanism and/or a particular spatial arrangement of on- and off-structures in the organization of the receptive field of these area 19 cells.

The role of the area 19 contrasts with that of the area 17 which seems to decompose the visual world into oriented contours. The area 19 analyzes the visual pattern in its various aspects including detection of discontinuity, orientation and length of contours.

297.3 A REASSESSMENT OF THE VISUAL CORTICAL AREAS OF THE CAT'S SUPRASYLVIAN SULCUS. H. Sherk. Department of Biological Structure, U. of Washington, Seattle WA 98195.

A clue to the functions of the multiple visual cortical areas found in the cat may come from an understanding of how information is routed among them; the initial aim of this study was therefore to determine the connectivity of the 9 visual cortical areas reported by Tusa et al. (Cortical Sensory Org. vol. 2, 1981) to lie in the vicinity of the suprasylvian sulcus. However, these experiments showed an unexpected discrepancy between the visual areas identified by Tusa et al., and those defined in terms of their connections. A visual cortical area is often defined as a region containing a partial or complete hemifield represenation, but one can instead consider it to be a region whose parts are all connected to the same sets of cortical and thalamic regions, with the magnitudes of such connections being similar throughout. When this definition was applied to the visual suprasylvian cortex, I found that some of Tusa et al.'s areas could be combined, while 3 of them were subdivided because different regions within them showed quite different patterns of connectivity.

Inputs to sites in the vicinity of the suprasylvian sulcus were examined by making small injections of wheatgerm agglutinin conjugated to horseradish peroxidase at physiologically identified locations. Retrogradely labeled cells were counted in each identifiable area of cortex, and in thalamic nuclei; the resulting data were assessed statistically using cluster analysis. Segments of some borders between cortical areas were identified autoradiographically by labeling their inputs from contralateral area 19's area centralis representation with 3H-amino acid.

Both cortical and thalamic patterns of cell labeling indicated that a single cortical area occupies most of the medial bank of the suprasylvian sulcus, much of its posterior bank, and a small fraction of its lateral bank. The Clare-Bishop area, as I call it, takes in portions of between 4 and 6 of the visual areas described by Tusa et al.: their areas PMLS, 21a, VLS, DLS, and possibly PLLS and 21b. Its extent was confirmed by examining anterograde transport from 33 physiologically-identified injection sites in area 17, since the latter was found to lack any significant input to areas adjoining the Clare-Bishop area.

Tusa et al.'s area 21a was found, on the basis of its connections, to be split between Clare-Bishop and a distinct area lying medial and posterior (area 21). Area DLS was likewise found to be divided between Clare-Bishop and a visual region on the lateral bank of the suprasylvian sulcus. Finally, area PMLS was split between the Clare-Bishop area and a visual region lying anterior and medial to it. In summary, a simpler scheme resulted in which the visual cortex of the suprasylvian sulcus was divided into only 5 discrete areas.

Supported by EY04805, EY04847, and the Alfred Sloan Foundation.

297.4 THE UPPER VISUAL FIELD MAP IN THE CLARE-BISHOP AREA OF THE CAT. M. Ombrellaro* and H. Sherk (SPON: A. Hendrickson). Department of Biological Structure, U. of Washington, Seattle WA 98195.

In the cat, the medial and posterior banks of the suprasylvian sulcus can be considered to comprise a single visual cortical area because tracer injections anywhere in this region show the same pattern of extrinsic connections (see accompanying abstract). The Clare-Bishop area, as we call it, includes the lower visual field representation of area PMLS of Palmer et al. (JCN 177: 237-256, '78). Its upper field representation, if any, is not well understood, and the aim of this study was thus to determine the location and organization of this representation.

To do so, we made small anterograde tracer injections into physiologically identified sites in area 17's retinotopic map, and examined the resulting patches of label in the Clare-Bishop area. Two distinguishable tracers (3H-amino acid and wheatgerm agglutinin conjugated to horseradish peroxidase) were injected at different sites in each cat to allow visualization of the relative positions of two visual field loci. We also mapped the posterior Clare-Bishop area physiologically, and in the same cats injected the area centralis (AC) of area 17 with tracer to obtain both physiological and anatomical data in single experiments.

The upper visual field representation of the Clare-Bishop area was found to differ from those in areas 17, 18, and 19 in two obvious ways. First, the map was coarser: a given patch of visual field occupied a relatively larger fraction of Clare-Bishop. Second, this area contained redundant representations of a significant portion of the visual field. At the boundary between the upper and lower visual quadrants, the map contained two distinct AC representations, one on the lateral and the other on the medial margin of the Clare-Bishop area; they were separated by a short segment of horizontal meridian (HM). The vertical meridian (VM) bounded the Clare-Bishop area posteriorly. In the depths of the posterior suprasylvian sulcus, the area was bounded by the HM, which extended laterally from the lateral AC out to the far periphery's representation. The map was complicated by a forking of the VM: its central segment (from $0^o$ to about $+10^o$) had a duplicate representation that ran dorsoventrally down the face of the posterior suprasylvian sulcal bank to terminate at the lateral AC. Because this VC representation was embedded within the Clare-Bishop area, roughly the central $10^o$ of visual field must be represented at least twice, once on either side of the VM. The data suggest that in fact there may be three representations of this segment of visual field, with the most anterior one being quite compressed. We would conclude that, although its connectivity indicates that the Clare-Bishop area is indeed a single entity, within this area there are redundant representations of a portion of the upper visual field.

Supported by EY04805, EY04847, and the Alfred P. Sloan Foundation.

297.5 BINOCULAR ACTIVATION OF ANTERIOR ECTOSYLVIAN VISUAL AREA (EVA) NEURONS IN SPLIT-CHIASM CATS. M.Ptito, G.Tassinari* and A.Antonini*. Groupe de Recherche en Neuropsychologie, Univ. du Quebec,CP 500, Trois-Rivières, PQ, CAN G9A 5H7 and Istituto di Fisiologia Umana, Strada Le Grazie, Verona, Italia 37121.

In the present experiment we have evaluated electrophysiologically the contribution of the corpus callosum (CC) to the receptive field properties of EVA neurons in split-chiasm (SC) preparations. Ten SC cats were used; in 6 of them the posterior half of the CC was sectioned during the actual recording in EVA ("acute") whereas in the remaining 4 the same portion of CC was cut 2 weeks prior to the physiological experiment ("chronic"). Single units responses were obtained with tungsten microelectrodes in anaesthetized, curarized preparations. The following stereotaxic coordinates were used to reach EVA: AP 11 to 14mm and L 12 to 14mm. Receptive field properties for each eye were studied before and after callosotomy using moving slits of light or shadows projected onto a screen 57 cm away from the animal's eyes.

Our results have shown that:

1) a very high proportion of EVA neurons (79%) in SC cats were driven by stimuli presented to either eye;

2) both receptive fields of each binocular neuron in SC cats abutted or were very close to the vertical meridian;

3) the receptive field size of EVA neurons was generally large (X=27°) thus providing for a wide representation of the ipsilateral visual field;

4) the majority of units (80%) encountered in EVA were bimodal (visuo-tactile) and the somatic receptive fields were often bilateral;

5) after the "acute" or "chronic" callosal section all neurons became monocularly driven whereas the bilateral somatic responses were unaffected.

These results led to the conclusion that EVA is a high order visual area whose neuronal properties are similar to those of the Lateral Medial Suprasylvian Area (PMLS) with which it has the richest anatomical connections. More importantly, our data indicate that the posterior part of the corpus callosum is an important contributor to the physiological organization of EVA neurons. This interhemispheric influence is likely to be mediated by a polysynaptic loop involving PMLS on both sides of the brain.

297.6 CORTICAL CONNECTIONS OF AREA 18 IN SQUIRREL MONKEYS. J. H. Kaas and C. G. Cusick. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Cortical connections in squirrel monkeys were investigated after single or multiple injections into area 18 of the anatomical tracer, wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP). In order to better visualize the areal patterns of connections, visual cortex was flattened and cut parallel to the surface. Brain sections were treated with tetramethyl benzidine for revealing WGA-HRP, or stained for cytochrome oxidase or myelin. All injections were placed in the portion of area 18 on the dorsolateral surface of the brain.

Single injections revealed punctate intrinsic connections in cortex immediately surrounding the injection site, and punctate foci of intrinsic connections spaced mediolaterally over 5 mm from the injection site. Interconnections were apparent in area 17, in cortex just rostral to area 18, and in the middle temporal visual area (MT). Additional features of these connections were revealed by a mediolateral row of injections that fused to form a 2 x 12 mm bandlike injection zone in caudal area 18. Such an injection band revealed short .2-.5 mm semiperiodic rostral extensions of intrinsic connections in medial area 18 devoted to the lower visual quadrant, and a more extensive 2 mm zone of rostral intrinsic connections in lateral area 18 representing central vision. In different experiments, dense connections in area 17 varied from forming a continuous lattice in upper layer III with the holes matching the locations of cytochrome oxidase dense blobs on adjacent sections, to punctate foci matching the location of of the blobs. A region of cortex rostral to area 18 was labeled with closely-spaced patches of label in a 2-3 mm x 6 mm strip of cortex that merged laterally with the intrinsic label in rostral area 18 and extended medially to curve rostrally away from the area 17-18 border. A 3-4 mm extent of unlabeled cortex separated the rostral extent of this strip from MT. The label in MT was sparse and patchlike. Callosal connections in caudal area 18 formed meshlike extensions into rostral area 18, and crossed the width of area 18 laterally. Patchlike callosal connections were present in cortex rostral to area 18. One of the implications of the results is that there are at least two visual areas between VII and MT.

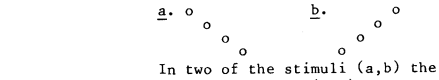
297.7 EVENT-RELATED CORTICAL FIELD POTENTIALS IN MONKEYS DISCRIMINATING PATTERN CATEGORIES THAT HAVE NO LOCAL FEATURE DISTINCTIONS. R.K. Nakamura, J. Johannesen* and R. Coppola, Laboratory of Psychology and Psychopathology, NIMH, Bethesda, MD 20205.

We have been recording event-related potentials (ERPs) via cortical surface-to-depth bipolar electrodes, in monkeys trained to perform a visual go/no-go discrimination task with reversals (Nakamura et al., Neurosci. Abs., 1984). To minimize artifacts related to eye movements or eye position, we have developed a new stimulus set that consists of four stimuli of four dots each:



In two of the stimuli (a,b) the four dots form diagonal lines, and in the other two (c,d) the four dots form diamonds with the same dominant angle as the diagonals. The objective for our monkeys is to respond in one way to the diagonals (e.g., go) and another to the diamonds (e.g., no-go). Brightness, contour, and distance of dots from any fixation point are inherently controlled and no single dot can be used to distinguish between the stimulus categories. The animals must base their responses on the spatial relationship of the dots. In addition, the stimuli are symmetrical so that there is no stimulus-generated inclination to move the eyes from the center of the stimulus presentation screen. With this stimulus set in our task it is possible to evaluate stimulus, stimulus category, motor response, and cortical area differences in the ERPs.

To date we have analyzed the task-related ERPs generated by this stimulus set from 32 electrodes in the cortical convexity of two monkeys. ERPs from all electrodes displayed additivity in that the early sensory components generated by the diagonal stimuli (averaged together) were identical to those generated by the diamond stimuli (averaged together) even though the individual stimuli produced highly differentiable results in some cortical areas. All electrodes in modality specific visual areas showed clear stimulus-related differences beginning at about 80 ms in striate cortex. The differences seen in striate and prestriate cortex could be related to the locations of the dots within the individual stimuli. Unlike striate and prestriate placements, two inferior temporal electrodes showed ERP differences between 160 and 200 ms that predicted the animal's motor response though time-locked to the stimulus, and preceded it by 140-180 ms. Contrary to prior reports, none of the visual system ERPs showed differences that were time-locked to the motor response.

Electrodes outside of the modality-specific visual areas showed only motor response-related differences, not stimulus-related differences. In prefrontal and parietal areas these differences appeared only after the motor response had begun.

297.8 DIRECTIONAL SENSITIVITY OF PARIETAL VISUAL NEURONS TO MOVING STIMULI DEPENDS UPON THE EXTENT OF THE FIELD TRAVERSED BY THE MOVING STIMULI.

B. C. Motter, M. A. Steinmetz, & V. B. Mountcastle, Bard Laboratories of Neurophysiology, Dept of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Parietal visual neurons display a lack of specificity for many physical properties of visual stimuli (e.g., orientation, color, speed of motion), but they are often quite sensitive to the direction of motion along any given meridian. We have investigated whether the directional sensitivity observed for simple bar stimuli during long traverses of the visual field is produced by local mechanisms encountered in each succeeding region of the visual field.

Monkeys (M. mulatta) were trained on a fixation/detection task during which visual stimuli irrelevant to the behavioral task were used to determine visual response properties. The sequential and cumulative aspects of directional sensitivity were examined in several different stimulus presentation paradigms, including: (a) decomposition of long stimulus movements into a series of shorter movements; (b) conditioning and test (C&T) paradigms designed to separate spatial and temporal sequencing effects; and, (c) simultaneous presentations of two stimuli in different areas of the visual field.

We found that for the majority of comparisons the directional response elicited from a local region (10 deg) of the visual field by stimuli restricted to that region could not account for the directional responses elicited from that same small region by stimuli passing through it while on much longer (90 deg) trajectories. Nevertheless, the C&T paradigms revealed that the directional sensitivity observed for the long movements required that stimulus passage be spatially continuous through regions adjacent to the test location, although the temporal C&T separation could be as large as 600 msec.

The studies with dual stimuli presented simultaneously revealed that responses to complex stimuli could not be derived by any linear combination of the responses to individual stimuli, although in some cases the response to the combined stimuli appeared to be predicted by the best response to a single stimulus. Often, stimuli that when presented alone evoked no response could alter the responses to other stimuli when presented simultaneously, with either facilitation or suppression. This indicated an effective convergence from very large regions of the visual field. Indeed, it may be that under certain stimulus conditions some parietal visual neurons may be influenced by stimuli throughout the entire visual field. (Research supported by USPHS, EY03167)

297.9 ATTENTIVE FIXATION INFLUENCES DIFFERENTIALLY THE RESPONSES OF VISUAL NEURONS OF PRESTRIATE AND PARIETAL AREAS OF THE CEREBRAL CORTEX.

M. A. Steinmetz, B. C. Motter, & V. B. Mountcastle, Bard Laboratories of Neurophysiology, Dept of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, Md 21205

The responses of parietal visual neurons are strongly facilitated during a state of attentive fixation of a small foveal target, when compared to the responses to identical stimuli delivered in an alert state without target fixation (Mountcastle, et al., J. Neuroscience, 1981). We have now compared the effect of attentive fixation upon neurons of the prestriate (V4) and parietal (PG) cortical areas, in the same animals and under the same behavioral and stimulus conditions.

Male monkeys (M. mulatta) were trained to achieve and maintain fixation of a small target light for 2-5 sec, and to detect its dimming for reward. During the fixation period visual stimuli were used to determine the functional properties of prestriate neurons, and to map their receptive fields. Optimal stimuli were then delivered, and the responses evoked by them were compared with those evoked by physically and retinotopically identical stimuli deliveredin the intertrial interval, during eye pauses made as the animal viewed - without attentive fixation - his visual environment, awaiting the next appearance of the target light. The strong facilitation (3x) of the responses of parietal visual neurons was regularly observed. By contrast, the responses of the population of prestriate neurons did not differ significantly in the two behavioral states.

Thus the effect of directed attention upon cortical neuronal excitability can be quite different in two closely related cortical visual areas. The resultimplies that the neuronal systems mediating the facilitatory effect of directed attention can do so in a rapidly varying and highly differential manner as regards different cortical areas. The present results on the prestriate cortex were obtained in theexposed portion of the prelunate gyrus, and do not preclude the possibility that directed attention may affect the excitability and response properties of neurons in other prestriate areas. (Research supported by USPHS, EY03167)

297.10 THE FUNCTIONAL AND ANATOMICAL SUBDIVISION OF THE INFERIOR PARIETAL LOBULE. R.M. Siegel, R.A. Andersen, G.K. Essick and C. Asanuma. The Salk Institute, La Jolla, CA 92037.

The identification of functional subdivisions within the inferior parietal lobule is a necessary step in determining its processing role in spatial perception, spatial orientation, and attention. In these experiments we have identified four cortical areas in the inferior parietal lobule and adjoining dorsal aspect of the prelunate gyrus of macaque monkeys on the basis of different functional properties and cortico-cortical connections: areas 7a, 7b, the lateral intraparietal area (LIP), and the dorsal prelunate area (DP).

Area 7a contains neurons responsive to visual stimuli and to eye position. The receptive fields are large and generally bilateral. The responsiveness of the retinal receptive fields of many of these neurons is influenced by eye position and this modulation produces an eye-position-dependent tuning for the location of visual stimuli in head-centered coordinates. Although there is no obvious retinotopic order of receptive fields in 7a, a crude topography for head-centered coordinate space was found in two hemispheres with upward positions represented more dorsally than downward positions.

Area 7b, located rostral to 7a on the convexity of the inferior parietal lobule, contains cells that are predominantly selective for somatosensory stimuli.

The lateral intraparietal area (LIP) is located on the caudal aspect of the lateral bank of the intraparietal sulcus (caudal half of area POa). It contains neurons sensitive to visual stimuli and eye position and has many more cells that respond to saccadic eye movements than does area 7a.

The dorsal prelunate area (DP) is located on the convexity of the dorsalmost aspect of the prelunate gyrus abutting area 7a rostrally and V4 ventrally. It provides a major visual projection to LIP and 7a. Its receptive fields are smaller than those found in 7a and LIP and are generally located in the contralateral inferior visual field.

Small injections of anterograde and retrograde tracers in these areas reveal that they have different patterns of reciprocal cortico-cortical connections; their only common connection is with area MST. Notable differences are that LIP, which contains a majority of the saccade-related neurons, projects to the superior colliculus and strongly to frontal eye fields, whereas area 7a has only weak connections with the frontal eye fields and is much more strongly connected to area 46 of Walker in the frontal lobe. Area 7b has connections with somatosensory areas (area 5 and insular cortex) and area DP has connections with extrastriate visual area V3A.

By comparing the laminar organization of the terminations and sources of the cortico-cortical projections it was possible to construct a hierarchy for the transmission of visual information from V1 to area 7a (which is at the top of the hierarchy). Several parallel paths exist for this flow to 7a, but all require relays through at least two other extrastriate visual areas.

297.11 ORGANIZATION AND NEURONAL PROPERTIES OF VISUAL AREA TEO. S.B. Fenstemaker*, T.D. Albright and C.G. Gross (SPON: B. Campbell). Dept. of Psychology, Princeton Univ., Princeton, NJ 08544.

In the macaque, the cortical region anterior to visual area V4 and posterior to inferior temporal cortex (IT) has been termed TEO. It is reciprocally connected with both V4 and IT and the laminar distribution of these connections suggests that TEO follows V4 and precedes IT in the hierarchy of visual cortical areas that begins in V1 (Fenstemaker et al., ARVO 25, 1984). Unlike in IT, receptive fields of TEO neurons are always unilateral, and unlike in V4 they are within a few degrees of the center of the visual field (Desimone and Gross, Brain Res. 178, 1979). In order to clarify further its organization, properties and extent, we recorded from single and multi-units in TEO and surrounding cortex in immobilized animals anesthetized with nitrous oxide.

We found a representation of the center of gaze immediately anterior to the ascending tip of the inferior occipital sulcus (IOS). This representation is contiguous with that in V4 and forms the posterior border of TEO. Moving anteriorly within TEO, there is a representation of the central 10° of the inferior quadrant of the contralateral visual field located between the lower lip of the superior temporal sulcus and the lateral lip of the occipito-temporal sulcus. This representation is not well organized topographically. That is, on some penetrations the receptive fields were in approximately the same location in the visual field, while on other penetrations, the receptive fields were widely scattered. In contrast, we found the representation of the visual field in V4 to be more clearly topographic. Furthermore, within TEO, the neurons are less selective for orientation and more selective for complex stimuli, such as textures, than are those in V4.

The border of TEO with IT cortex lies 6-8 mm anterior to the ascending tip of IOS. Approaching this border, receptive fields become larger and their centers approach the horizontal meridian. Crossing into IT cortex, the neurons have more complex stimulus selectivity and still larger receptive fields which usually extend into both the inferior and superior visual fields and across the midline into the ipsilateral visual field. Previously we reported that dorsal V4 projects more strongly to TEO than to TE (ARVO, 1984). The border between TEO and IT as defined by these projections coincides with that defined here by receptive field size, and location and stimulus selectivity.

297.12 MULTIPLE VISUAL AREAS IN THE CAUDAL SUPERIOR TEMPORAL SULCUS OF THE MACAQUE. L.G. Ungerleider and R. Desimone. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205.

Anatomical studies have shown that area MT projects to much of the cortex surrounding it within the caudal STS. Yet, the boundaries, visuotopic organization, and neural properties of areas outside of MT remain unclear, and there are even conflicting data on the boundaries of MT itself. To examine these issues, we recorded from neurons throughout this region in three monkeys and then injected anterograde or retrograde tracers into MT to identify its projection fields.

Several visual areas were distinguished on the basis of visual topography, neural properties, receptive field (RF) size, myeloarchitecture, and pattern of connections with MT. MT, defined as the heavily myelinated portion of the V1 projection zone in STS, contained a systematic representation of only about the central 30°-40° of the contralateral field. The far peripheral field was represented medial to MT in a zone we term MTp, which receives projections from far peripheral V1 and V2. Like MT, MTp contained a high proportion of directionally selective cells, and RF size in MTp was the size expected of MT fields if MT fields were to extend into the periphery.

Areas MST and PP were found medial to MT and MTp. Both MST and PP had a high proportion of directionally selective cells, but only MST received a direct projection from MT. MST had larger RFs than MT or MTp but nonetheless had a crude visual topography. RFs in PP were even larger, some including the entire contralateral visual field. Furthermore, unlike cells in MST, some in PP responded to auditory or somesthetic stimuli in addition to visual.

Area FST, which has a distinctive myeloarchitecture, was found in the fundus of STS anterior to MT. FST received a direct projection from MT, but only about 1/3 of its cells were directionally selective. RFs in FST were large, often included the center of gaze, and were often bilateral.

Area V4t and a portion of V4 were found lateral to MT within STS, and both received direct projections from MT. V4t has a distinctive, light myelination. Both areas had a low incidence of directionally selective cells, and both contained coarse representations of the lower visual field.

These results combined with those of other studies suggest that MT, MTp, MST, and PP, together with area STP, constitute a cortical system for motion analysis. As one moves through this system, neurons appear to integrate motion information over an increasingly large portion of the retina, respond selectively to more complex types of motion, respond to inputs from additional sensory modalities, and may become more directly involved in oculomotor control.

297.13 INFERIOR TEMPORAL NEURONS DO NOT SEEM TO CODE SHAPE BY THE METHOD OF FOURIER DESCRIPTORS. T.D. Albright, R.A. Charles*, and C.G. Gross. Dept. of Psychology, Princeton Univ., Princeton, NJ 08544.

Inferior temporal (IT) cortex is necessary for normal shape discrimination learning and many IT neurons are selective for shape. Any shape may be described by a set of Fourier Descriptors (FD's). This method of shape description is used in computer pattern recognition (Zahn and Roskies, I.E.E.E. Trans. Comput. 21, 269). Previously we suggested that IT cortex might code shape by this method. The FD method depends, first, on determining the boundary orientation function for the shape, i.e., the orientation (tangent angle) of the shape's boundary measured at regular intervals around the perimeter. Then, this function is expanded in a Fourier series. Each term in the expansion is associated with a particular frequency, amplitude and phase and is known as an FD.

If IT cells acted as filters or detectors for FD's, the activity of an ensemble of such cells could code any shape. To test this possibility, we studied the responses of IT neurons to stimuli that were produced by the inverse transforms of single FD's. This process uniquely determines a shape which has a specific number of lobes (corresponding to frequency), lobe indentation (amplitude), and orientation (phase) and is known as an FD stimulus. Previously, we showed that many IT cells were selective for the frequency and amplitude of FD stimuli and maintained this selectivity over changes in the size, contrast and retinal location (P.N.A.S. 80, 5776). In the present study, we further examined the possibility that IT cells might act as filters or detectors for FD's. After determining the selectivity of each IT cell for the frequency of FD's, we presented stimuli produced by combining two FD frequencies. If IT cells act as filters for FD's, then the responses to the combined stimuli should be predictable from the responses to the component FD stimuli. Of 135 visually responsive IT cells, 49% were selective for particular FD stimuli. However, for none of these did we find a consistent relationship between the responses to the combined and component stimuli. These results suggest that the selectivity of IT cells for shape is not based on the analysis of boundary curvature into its component Fourier Descriptors.

297.14 NEURAL PATHWAYS MEDIATING DISTANCE ESTIMATION IN THE GERBIL. C. G. Ellard* and M. A. Goodale. Dept. of Psychology, Univ. Western Ontario, London, Ontario, Canada, N6A 5C2.

In previous experiments (Ellard, C. G., Goodale, M. A., and Timney, B., Behav. Brain Res., 14: 29, 1984), we have shown that Mongolian gerbils (Meriones unguiculatus) executed a series of vertical movements of the head prior to jumping over a gap that varied in size from trial to trial. Quantitative analysis of the size and frequency of these head movements suggested that their purpose was to generate motion parallax cues that were useful in judging distance. These cues appeared to be especially important at long distances (20 cm or greater), suggesting that other cues, such as loom and stereopsis, were more useful at short distances.

In the present experiment, we trained gerbils on the same jumping task and then subjected them to either aspiration lesions of visual cortex (areas 17, 18a, and 18b), radiofrequency lesions of the superior colliculus, ibotenic acid lesions of the pretectum, or sham operations. Preoperatively, all the animals showed the same relationship between gap distance and the frequency and amplitude of vertical head movements. After surgery, however, the pattern of head movements and the accuracy of the jumps changed dramatically in two of the operated groups. While the pretectal animals appeared to show little change in their behaviour, the animals with lesions of visual cortex or superior colliculus showed a significant decrease in the accuracy of their jumps compared both to their preoperative performance and to the sham-operated control group. Animals with cortical lesions were less accurate than animals with lesions of the superior colliculus. The frequency of head movements increased in both these groups, but visual cortical animals made many head movements at all distances while collicular animals, like the sham operates, made more head movements at long distances than at short distances. The mean latency to jump was significantly correlated with gap distance in both the collicular group and the cortical group, indicating some sparing of the ability to discriminate distance. These results suggest that while lesions of any one of the major retinofugal targets leave some residual depth discrimination intact, the severity of the deficit in visuomotor performance in the jumping task may vary depending upon the site of the lesion. The results further suggest that the ability to utilize motion parallax cues may depend to a large extent upon neural processing carried out within cortical areas 17, 18a, and/or 18b.

This research was supported by Grant No. A6313 from the Natural Sciences and Engineering Research Council of Canada to M. A. Goodale.

297.15 SIZE-THRESHOLD CHANGES AFTER LESIONS OF THE VISUAL TELENCEPHALON IN PIGEONS. W. Hodos, S. R. B. Weiss* and B. B. Bessette*. Dept. of Psychology, Univ. of Maryland, College park, MD 20742.

Pigeons were tested in a psychophysical procedure that determined the limits of their ability to detect differences in the sizes of circular stimuli. On average, normal pigeons were able reliably to discriminate an annulus with a 3.0-mm diameter from one with a diameter of 3.9 mm.

In the first experiment, pigeons with lesions of the ectostriatum that spared its medial 15% were unimpaired in their size-discrimination ability. In contrast, those cases in which the lesions involved both the medial and lateral regions of ectostriatum had elevated size-difference thresholds. A second experiment, which was a replication of the first, yielded the same results and provided the additional observation that destruction of the medial 15% of ectostriatum with little or no damage to the lateral regions had no measurable effect on size-difference thresholds.

The medial region of ectostriatum is part of the termination field of a second tectofugal pathway to the telencephalon. This pathway passes from the optic tectum to nucleus dorsolateralis posterior thalami (DLP) and then to the medial neostriatum and the medial ectostriatum (C. A. Kitt & S. E. Brauth, Neurosci.,7:2735, 1982). Single-unit recordings have indicated a role for DLP in the transmission of visual information to the telencephalon (P. D. R. Gamlin & D. H. Cohen, Soc. Neurosci. Abstr., Vol 8, p. 206, 1982).

A comparison of the present data with those of previous psychophysical studies of ectostriatum suggests that its medial region may play a role for the processing of information about the low spatial-frequency components of visual stimuli.

297.16 ORGANIZATION OF CORTICOGENICULATE PROJECTIONS IN THE TURTLE, PSEUDEMYS SCRIPTA ELEGANS. P.S. Ulinski, Dept. Anatomy and Committee on Neurobiology, Univ. Chicago, Chicago IL 60637.

Turtles have a dorsal lateral geniculate complex that receives a bilateral, retinotopically organized projection from the retina and projects to a visual area on the ipsilateral cerebral hemisphere. This area includes the region known as the pallial thickening and the lateral part of the dorsal cortex or D2. It has been known for some time that the visual cortex projects back to the geniculate complex, but the organization of these projections had not been studied.

Cortical cells giving rise to the corticogeniculate projections were identified using the retrograde transport of horseradish peroxidase (HRP) following injections in the geniculate complex. Both D2 and the pallial thickening are trilaminar structures. Layer 1 consists of a few scattered neurons, none of which were retrogradely labeled by geniculate injections. Layer 2 consists of many densely packed oval somata. Labeled somata were scattered in layer 2 throughout the areal extent of the pallial thickening and D2. Layer 3 is a thin layer that contains a small number of fusiform somata with their long axes oriented parallel to the ventricle. Many of these were labeled. Thus, morphologically distinct cells in layers 2 and 3 contribute to the corticogeniculate projection.

The trajectory of corticogeniculate axons was studied using the orthograde transport of HRP following cortical injections. These axons course laterally between the lateral cortex and anterior dorsal ventricular ridge. They pass through the striatum bearing very few varicosities, enter the lateral forebrain bundle and turn caudally to run in the ventral peduncle of the lateral forebrain bundle. Individual axons turn dorsally as they pass beneath the geniculate complex and enter the complex from its medial face, running from ventral to dorsal through the geniculate cell plate. Each axon bears varicosities and terminaux en passant at irregular intervals, but never forms traditional axonal arbors.

Earlier work from this laboratory has shown that the geniculocortical projections are not topologically organized, having a point-to-line organization instead. This study shows the corticogeniculate projection has a similar point-to-line organization such that a given cortical neuron can contact geniculate neurons that lie along a vertical meridian of the retinal representation in the geniculate complex. Supported by PHS Grant NS 12158.

297.17 AN INTACT VERTEBRATE VISUAL SYSTEM IN VITRO: VISUALLY EVOKED PYRAMIDAL CELL RESPONSES IN TURTLE CORTEX. A.R. Kriegstein, (SPON: J. Wine). Dept. of Neurology, Stanford University School of Medicine, Stanford, CA 94305.

Young specimens (3-4 cm shells) of red-eared turtles, (Pseudemys scripta) were cooled to 0°C, decapitated, and the brains were surgically removed with eyes and optic nerves attached and submerged in 22°C saline in a recording chamber. Incisions were made along the medial walls of the cerebral hemispheres, and each dorsal cortex was unfolded and pinned back to expose the ependymal surface. The dorsal cortex contains the primary visual cortex of turtles, and in this preparation the retino-geniculo-cortical pathways were preserved. Light flashes were provided by a photo stimulator (Grass Model PS2) and directed to the contralateral eye by a fiberoptic conduit. Experiments were performed on turtles because they have a unique ability to function normally under conditions of prolonged hypoxia. Stable intracellular recordings were obtained from pyramidal neurons and responses to visual stimuli could be observed for up to 6 hours in vitro.

The pyramidal cell response to a brief (10 μsec) flash of light consisted of early excitation (50-100 msec) composed of EPSPs that often triggered one or more action potentials (APs). A subsequent inhibitory phase (250-400 msec) consisted of discrete synaptic events associated with net hyperpolarization and an increase in input conductance. Averaging 3-5 responses obtained at each of a series of potentials between -50 and -90 mV allowed calculation of reversal values for the early and late responses of -50 and -70 mV respectively. This suggested that the excitatory response may be shunted by concurrent inhibition and that the hyperpolarizing response may be composed of summated $Cl^-$ dependent IPSPs. This hypothesis was tested by recording from cortical neurons with KCl-filled microelectrodes. During intracellular $Cl^-$ injection the light-evoked response gradually inverted to a depolarizing event that lasted 200-400 msec and fired a barrage of APs. The hyperpolarizing component of the flash response therefore consists of prolonged activation of $Cl^-$ dependent IPSPs. A similar response sequence consisting of early excitation and long lasting GABA-mediated inhibition has been observed in the isolated cortical slab in response to electrical shock of thalamocortical fibers.

These results correspond well with anatomical, histochemical, and physiological data suggesting that geniculo-cortical afferents contact dendrites on both pyramidal cells and GABAergic interneurons, and that the interneurons in turn mediate feed-forward inhibition onto pyramidal cells. The in vitro turtle visual system will therefore allow detailed cellular analysis of light-evoked cortical responses.

Supported by a Klingenstein Fellowship in the Neurosciences and NIH Grants NS00887-01 and NS21223-01.

## *DEVELOPMENT AND PLASTICITY: VISUAL SYSTEM PLASTICITY*

298.1 LOSS OF VISUAL RECEPTOR CELLS DURING EARLY POSTNATAL DEVELOPMENT: EFFECTS ON VISUAL BEHAVIOR IN THE RAT. Jane D. Shepherd and Lawrence A. Rothblat. Department of Psychology, The George Washington University, Washington, D.C., 20052

We have been investigating the effects of light-induced photoreceptor degeneration on visual behavior to determine whether the types of visual impairments resulting from receptor cell loss are dependent on the time period in the life of the animal when the damage occurs. In the present study atropine sulfate (1% ophthalmic solution) was used in conjunction with high intensity continuous illumination (400 ft-c) to produce retinal damage in pigmented rats either early (15-28 days of age) or later (49-51 day of age) in development. For both groups the thickness of the outer nuclear layer was reduced by 50%. Control groups included (1) rats reared in a normal lighting environment without atropine (C1); (2) rats exposed to high intensity continuous light without atropine (C2); and (3) rats which were atropine treated but reared in a normal lighting environment (C3). Changes in retinal morphology were not evident in any of the control animals. The effects of the treatments were assessed by the performance of the rats tested as adults on both complex and simple visual discrimination tasks. For the complex task the animals were required to discriminate between columns and rows of 5mm squares. For the simple tasks the animals were required to discriminate between solid black-white striations (6,2,1mm in width) and a solid grey field of equal luminance.

Rats which had experienced retinal damage during early development were profoundly impaired on the complex discrimination when tested as adults; all animals failed to reach criterion within 1800 trials. In addition, these animals demonstrated small, but significant impairments on the simple discriminations in comparison to both control animals and rats suffering retinal damage as adults. The complex discrimination task was learned by all rats which had experienced damage as adults, although they were significantly impaired ($\bar{X}$ trials to criterion=594) compared to control animals (C1=336; C2=345; C3=344). On the simple discriminations, the performance of rats with retinal damage produced in adulthood was not significantly different from that of controls.

The results of the present study show that visual deficits which follow photoreceptor loss are related to the age at which the damage occurs, as well as the complexity of the behavioral task used for assessment.

Supported by NEI grant EY03304 and NIH Biomedical Support Funds from The George Washington University.

298.2 FUNCTIONAL PARCELLATION OF ACCESSORY OPTIC SYSTEM REQUIRES VISUAL EXPERIENCE. Ximena Rojas*, Olivia C. McKenna and Josh Wallman, Dept. of Biology, City College of CUNY, New York, NY 10031

In chicks the principal nucleus of the accessory optic system, the nucleus of the basal optic root (nBOR) and nBOR dorsalis are functionally divided into two parts, one responsive to upward visual motion and the other to downward visual motion. Several lines of evidence argue that these subdivisions provide the visual input for optokinetic eye movements in these directions. In previous studies we have shown that this functional parcellation develops to a large degree postnatally, as shown by (1) differences in the regions labelled when 2-deoxyglucose (2DG) is injected during the viewing of upward and downward visual motion (here called localization), (2) differences in the direction of highest OKN gain, and (3) differences in the location and properties of directionally selective single units. The first two of these effects have been shown to be affected by deprivation of visual experience.

To study whether visual experience during a critical period is essential for the development of this functional parcellation, we have studied, in the same individuals, OKN in a variety of directions and 2DG uptake during vertical visual motion, both in normal and visually deprived chicks. By 7 to 10 days in normal chicks, there is differential localization of 2DG uptake within nBOR. Birds deprived of form vision for the first 3 weeks of life showed no 2DG localization in the nBOR and had poor non-horizontal OKN with an abnormal direction of highest gain. Birds with the same period of visual deprivation, but then allowed 3 weeks of normal vision, showed the same effects, although the overall OKN gain was normal.

We infer from these results that visual experience seems necessary for the functional parcellation of nBOR, rather than simply accelerating it, since after six weeks, three of them with visual experience, there is no localization, although normally it appears after 7-10 days. These same results also suggest the existence of a critical period for the influence of visual experience, since 3 weeks of vision is ineffective if delayed by 3 weeks. The effect of visual deprivation noted here seems specific to the AOS, rather than being a generalized visual or oculomotor dysfunction, since horizontal OKN, which uses other visual pathways, appears to be normal. Finally, preliminary results indicate that birds with 1 week of visual experience beginning at hatching and then deprived for 2 weeks showed the same pattern of no localization and abnormal non-horizontal OKN, suggesting that localization, once attained, may not be permanent, but may require continued form vision for its maintenance. (Supported by NIH EY03613 and EY02937).

298.3 VISUAL SPATIAL DISCRIMINATION IN GOLDFISH FOLLOWING OPTIC TECTUM ABLATION. R. E. Davis, B. E. Schlumpf and P. D. Klinger*. Mental Health Research Institute, Univ. of Michigan, Ann Arbor, MI 48109.

Goldfish optic axons project sparsely to various diencephalic and pretectal nuclei and massively to the optic tectum. Bilateral tectum ablation results in greatly decreased sensitivity to classically conditioned visual stimuli and blockade of whole body orientation responses to dorsal light, food objects and optomotor stimuli (Yager et al. Brain Res., 137, 267-275, 1977; Schlumpf and Davis, Neurosci. Abstr., 10, 1158, 1984; Springer et al. Brain Res., 128, 393-404, 1977) suggesting that in part the tectum is necessary for discrimination of images in space. We examined whether nontectal optic pathways can mediate a conditioned spatial discrimination by ablating the optic tectum in previously conditioned fish. Discrimination was measured with a classically conditioned branchial suppression response.

The visual conditioned stimulus (CS) consisted of a spot of red diode illumination (1600 cd/$m^2$) that was presented for 5 sec. The positive CS was reinforced with an electric shock (US). Intact fish were trained to a nasal x temporal ($N^+ \times T^-$) or right X left ($R^+ \times L^-$) discrimination in lighted tanks. The nasal lamp was at 30° and the temporal lamp at 90° to the longitudinal axis of the fish and near the horizontal optic meridian. The lamp subtended < 1° at an apparent viewing distance of 34 cm. Following discrimination training the fish received bilateral optic tectum ablation and weekly sessions of discrimination test trials in darkness as illumination over 0.2 cd/$m^2$ blocked responding. The fish were dark adapted for 2 hr prior to each postoperative session.

Nine of nine R x L fish responded from the initial postoperative session and the mean response in R and L trials showed strong discrimination. The N x T fish initially responded to both stimuli and did not discriminate between them. Discrimination was restored after the second postoperative week. Whether the N x T discrimination is strictly monocular is unclear. When both stimuli were conditioned to the shock, during the fourth postoperative week, the responses to N and T or to R and L were similar indicating that all could be perceived. The average 50% threshold of response was 7.1 and 6.7 cd/$m^2$ to N and T and 3.2 and 3.4 cd/$m^2$ to R and L, respectively. Transection of the optic nerves blocked responding.

These results indicate that nontectal optic pathways can mediate discrimination of right from left eye stimulation and of nasal from temporal field stimulation. The implication is that the optic tectum is unnecessary for learning or memory of a simple visual spatial discrimination.

298.4 EFFECTS OF ABLATION OF VISUAL CORTEX IN NEONATAL RABBITS ON RETINOFUGAL PROJECTIONS. E.H. Murphy, A.M. Grigonis, T. Hayden*, D. Tashayyod* and M. Wilkes*. Dept. of Anatomy, Medical College of Pennsylvania, Philadelphia, PA 19129.

Visual pattern discrimination is severely disrupted in most mammals by ablation of visual areas receiving projections from the dorsal lateral geniculate nucleus (LGd). If a visual cortex lesion is performed in the neonate, some sparing of visual discrimination occurs in the cat but not in the rabbit. We have been comparing the morphological consequences of this lesion in cats and rabbits in order to elucidate the re-organization of subcortical visual projections which might underly the sparing observed in cats and the absence of sparing in rabbits. In infant operated (IO) cats we have reported significant expansion of the retino-pulvinar projection, sparing of large neurons in the LGd and significant transneuronal degeneration of medium sized retinal ganglion cells. In rabbits we have reported no transneuronal degeneration of retinal ganglion cells. In the present study we have analyzed cell survival in the LGd, and modification of retinofugal projections in IO rabbits. Unlike cats, there is no significant sparing of any population of neurons in the LGd in rabbits. However, there is a significant expansion of projections of retinal ganglion cells to the lateral posterior nucleus and to the pretectal nuclei. The results indicate that surviving LGd cells may play a role in behavioral sparing. However, expanded retinofugal projections to alternate termination sites and survival of retinal ganglion cells do not necessarily promote behavioral sparing in this preparation.

298.5 EFFECT OF REMOVAL OF RETINAL INPUT ON THE DEVELOPMENT OF THE COLLICULOGENICULATE PROJECTION. J. K. Sutton* and J. K. Brunso-Bechtold. Dept. of Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27103

The dorsal lateral geniculate nucleus (dLGN) of the tree shrew (Tupaia belangeri) contains six cytologically-distinct layers separated by interlaminar spaces. Each layer receives a dense retinogeniculate projection and each interlaminar space receives a dense corticogeniculate projection. Layers 3 and 6, which contain small cells with similar connections, receive a dense colliculogeniculate projection as does the interlaminar space between layers 4 and 5. Prior studies have shown that following bilateral enucleation at birth, cytological characteristics of the layers remain yet interlaminar spaces fail to form and corticogeniculate fibers project diffusely across the nucleus instead of to the laminar borders as might be expected. Since colliculogeniculate fibers project to two dLGN layers as well as to one interlaminar space, it is possible to determine whether the absence of retinogeniculate fibers affects the development of laminar and interlaminar projections similarly. Based on the corticogeniculate projection in bilaterally enucleated animals, the interlaminar projection of the colliculogeniculate fibers is unlikely to terminate at the border between layers 4 and 5; however, it is of interest to know whether the colliculogeniculate projection to layers 3 and 6 remains denser than to the other layers. We therefore injected horseradish peroxidase into the superior colliculi of adult tree shrews which had been bilaterally enucleated at birth when colliculogeniculate fibers project diffusely across the nucleus in a topographic band, but do not reach the medial border. We then studied the pattern of anterograde transport to the dLGN to determine the effect of bilateral enucleation on the maturation of the colliculogeniculate projection pattern. In experimental animals, colliculogeniculate fibers terminate as densely in the region of dLGN layers 4 and 5 as they do in the region of layers 3 and 6; however, as in normal adults, the projection avoids the region of layers 1 and 2. The colliculogeniculate projection pattern reveals some specificity of termination since the projection is restricted to the lateral portion of the dLGN even in the absence of the retinogeniculate fibers which normally terminate in the medial layers. Nevertheless, competition between colliculogeniculate and retinogeniculate fibers must also play a role in the development of the normal colliculogeniculate projection pattern, since the projection in bilaterally enucleated animals is not limited to the small cell layers as is the case in normal animals.

298.6 PHYSIOLOGICALLY IDENTIFIED RETINOGENICULATE AXONS DEVELOP NORMALLY IN DARK-REARED CATS. P.E. Garraghty, D.O. Frost and M. Sur. Sect. of Neuroanatomy, Yale Medical School, New Haven, CT 06510.

The normal postnatal development of X- and Y-cell retinogeniculate axons in cats (Sur et al., Nature, 310:246, 1984) can be dramatically altered by manipulation of visual input, such as monocular lid suture (MLS, Sur et al., Nature, 300:183, 1982). These observations, in aggregate, have led to the hypothesis that X- and Y-cell retinogeniculate axons compete during development for synaptic sites in the lateral geniculate nucleus (LGN).

In the present experiment, we attempted to expand our understanding of the process of X- and Y-cell development by examining the terminations of single retinal axons in the LGN of cats reared from birth in the dark. When these cats were at least 12 weeks of age, optic tract axons were recorded, classified as X- or Y-cell, and then impaled and intracellularly injected with HRP. In 5 dark-reared (DR) cats, we have recovered 10 X- and 12 Y-cell axons which were sufficiently filled to permit the complete reconstruction of their terminal arbors in the LGN.

Dark-rearing has no effect on the terminal morphologies of either X- or Y-cell axons. As in normal cats, X-cell axons project to lamina A or A1, ipsilateral Y-cell axons project to lamina A1 and contralateral Y-cell axons to laminae A and C. Furthermore, X- and Y-cell axons are normal both in their numbers of boutons and the volumes of their terminal arbors.

We find this result surprising because dark-rearing reportedly leads to a loss of physiologically defined LGN Y-cells, albeit without a change in LGN cell sizes (Kratz et al., Science, 203:1353, 1979). Monocular lid suture, which also leads to a loss of Y-cells recorded in the LGN, causes a reduction of retinal Y-cell arbors from the deprived eye in the A laminae of the LGN. In particular, in MLS cats, contralaterally projecting Y-cell axons often lack lamina A terminations. Yet Y-cell axons (both contralaterally and ipsilaterally projecting) in the DR cats develop normally. We considered the possibility that we simply failed to recover any affected Y-cell axons in dark-reared cats, but this possibility seems unlikely ($\chi^2$, $p<.02$; based on a comparison of whether contralaterally projecting Y-cell axons in DR and MLS cats retained their lamina A terminations). We are left with the possibility that dark-rearing and monocular lid suture have profoundly different effects on the development of retinogeniculate axons, such that development proceeds normally in the complete absence of light but is severely affected by the diffuse light stimulation present with lid suture. Finally, these results raise the question of how the retinogeniculate physiological relay can be so disrupted in the Y-cell pathway that retinal ganglion cell terminations are apparently normal while relay cells are irretrievably lost.

298.7 ASYMMETRY OF BILATERAL VISUAL CORTEX LESIONS EFFECT AMPHETAMINE'S ABILITY TO PRODUCE RECOVERY OF DEPTH PERCEPTION. David A. Hovda, Richard L. Sutton and Dennis M. Feeney, Ment. Ret. Res. Ctr., UCLA, Los Angeles, CA and Dept. of Psychology and Physiology, UNM, Albuquerque, N.M.

We have reported that amphetamine (AMP) and visual experience can restore binocular depth perception after bilateral ablation of areas 17 and 18 in the adult cat (Feeney & Hovda, Brain Research, In Press). We now report that adult cats with complete removal of areas 17 and 18 (including the lateral suprasylvian gyrus) are able to perceive depth at presurgical thresholds after administration of AMP provided the bilateral lesions are symmetrical. Depth perception threshold was defined as the distance between the shelves at which the cat achieved 7 successes in 12 trials. The shallow side was randomly determined for each trial to control for side preference. Beginning at the greatest displacement, 12 trials were conducted and if the animal scored 8 or more successes the shelves were advanced 2 cm closer and tested another 12 trails. This was continued until the animal scored fewer than 8 successes. The shelves were then separated at 0.6 cm increments until the animal scored more than 7 successes. After 3 baseline testing sessions the striate and extrastriate cortex were aspirated bilaterally under standard aseptic conditions in 17 adult cats (male or female, 1.8-4.0 kg). Beginning on day 4 postsurgery the cats were tested every other day out to 30 days postsurgery. At day 10 postsurgery the cats were randomly divided into two groups. An AMP group received single d-AMP (5 mg/kg, i.p.) injections on days 10, 14, 18, and 22 postsurgery. The remaining animals served as saline (SAL) controls. On injection days animals were tested on the visual cliff 3 hours after AMP or SAL administration. After surgery all cats were unable to solve the simplest visual cliff. The SAL cats showed no improvement in depth perception throughout the experiment. Only the AMP cats showed recovery of depth perception as measured on the visual cliff. However, cats that did not show signs of AMP intoxication were like SAL treated animals in that they showed no recovery of depth perception. Furthermove, AMP treated cats with asymmetrical lesions (more of one hemisphere damaged than the other) showed only mild, drug dependent recovery with the depth perception deficit returning after discontinuation of AMP treatment. Finally, AMP-treated animals that had symmetrical lesions recovered to baseline levels and this complete recovery endured throughout the experiment. We therefore conclude that for AMP to produce a complete and total recovery of binocular depth perception after bilateral visual cortex ablation, AMP intoxication must be obtained and the bilateral lesions must be symmetrical.

298.8 EFFECT OF $GM_1$ GANGLIOSIDE TREATMENT ON CORTICAL RECOVERY FOLLOWING MONOCULAR DEPRIVATION IN KITTENS. G. Carmignoto*, R. Canella* and S. Bisti*° (SPON: G. Toffano). Fidia Neurobiological Research Laboratories, Abano Terme, Italy and °Institute of Neurophysiology, CNR, Pisa, Italy

Previous reports from our laboratory have described that $GM_1$ ganglioside treatment in kittens subjected to monocular deprivation is capable of partially preventing the ocular dominance shift of striate cortex neurons (Carmignoto, G., et al., J. Neurosci. Res., 12:477-483, 1984). We now report the results obtained following reverse-suturing experiments in which the initially deprived eye was reopened and the other eye occluded. The treatment with the internal ester of $GM_1$ (30 mg/kg/i.p. every 2 days) was performed only during the period of reverse-suturing. Ocular dominance distribution of area 17 neurons was assessed by conventional single unit recordings. A total of 519 cells in 6 control and 6 $GM_1$-treated kittens were studied. Results obtained indicate that in kittens treated with $GM_1$ the recovery of the initially deprived eye is less prominent than in control animals. Altough such data could appear contradictory with that previously obtained in monocularly deprived kittens, the shift of ocular dominance which occurs after reverse-suturing involves not only the recovery of inputs from the initially deprived eye but also the concurrent suppression of inputs from the newly deprived eye. As such, the diminished recovery of the originally deprived eye input observed with $GM_1$ treatment during the period of reverse-suturing may be due to enhanced maintenance of the newly deprived eye input. Therefore reverse-suturing data strengthen the hypothesis that $GM_1$ counteracts the effects of visual deprivation by supporting the maintenance of the connections from the deprived eye. Although the molecular mechanisms involved are still unknown, these findings are consistent with the hypothesis that gangliosides play a role in central nervous system (CNS) plasticity perhaps by regulating neuronotrophic interactions involved in the development and maintenance of CNS neuronal connections.

298.9 FACTORS INVOLVED IN AMBLYOPIA DEVELOPMENT IN EXPERIMENTALLY STRABISMIC MONKEYS. L.Kiorpes* M.Carlson*and R.Boothe. University of Washington, Seattle, Washington, 98195.

Two groups of monkeys (Macaca nemestrina) were made esotropic at ages ranging from 1 to 15 postnatal weeks. For one group, the esotropia was induced surgically. For the other group, the esotropia was induced by injection of Botulinum A neurotoxin into an extraocular muscle. The time course for the development of grating acuity was measured for each eye of each monkey.

Within both experimental groups, the monkeys could be divided into two subgroups: those who developed amblyopia (defined as an interocular acuity difference of greater than one octave) and those who did not. The two subgroups could be separated on the basis of fixation pattern. Basically, those who developed amblyopia chose to fixate primarily with the non-deviated eye, whereas those who did not develop amblyopia tended to alternate fixation. Such factors as size of deviation, refractive error, and age of intervention (esotropia induction) did not discriminate the two subgroups. One exception, however, was the animal whose esotropia was induced at 15 weeks. He showed primarily a monocular fixation pattern but never developed amblyopia.

Within the subgroup of surgically esotropic monkeys who developed amblyopia, there were consistent relationships between the extent of resultant amblyopia and both the age of intervention and the initial size of the esotropia. On the basis of data from the subgroup of neurotoxin induced strabismic monkeys with intervention ages of 4 weeks or less, the extent of amblyopia in this group depends on other factors.

298.10 EFFECT OF NEONATAL TRANSECTION OF THE THALAMIC RADIATIONS UPON THE DISTRIBUTION OF VISUAL CALLOSAL PROJECTION NEURONS IN THE GOLDEN HAMSTER. S.E. Fish, N.L. Chiaia and R.W. Rhoades. Neurobiology Program, Northeastern Ohio College of Medicine, Rootstown, OH 44272, and U.M.D.N.J.-S.O.M., Piscataway, NJ 08854.

Previous experiments (Cusick, C.G. and Lund, R.D., J. Comp. Neur., 212:385, 1982) have shown that thalamotomy in neonatal rodents alters the pattern of callosal terminals in visual cortex ipsilateral to the damaged diencephalon. However, the effect of disconnection of the cortex from thalamus upon the distribution of callosal projection neurons has never been examined. We have transected the thalamic radiations in newborn (<12 hrs. old) hamsters and used retrograde transport of horseradish peroxidase (HRP) to examine the distributions of visual callosal neurons ipsilateral and contralateral to the neonatal lesion when the animals reached at least 30 days of age.

The thalamic radiation lesions were incomplete in most animals, but they all resulted in extensive retrograde degeneration in the ipsilateral thalamus. In most cases, the dorsal lateral geniculate and lateral posterior nuclei were almost completely absent. The neonatal lesions also resulted in a consistent change in the distribution of callosal projection neurons in the cortex of the damaged hemisphere. On this side, HRP labelled cells were distributed in a nearly continuous band in layer VI and the lowermost part of lamina V across the entire mediolateral extent of areas 17 and 18a. The number of labelled neurons in the supragranular layers in the lateral part of area 17 and the medial portion of area 18a was, on the other hand, sharply reduced, relative to that observed in normal hamsters with similar HRP injections. In some neonatally brain damaged animals, no HRP labelled supragranular neurons at all were visible in this region. The effect of the neonatal lesion in this cortex thus appeared quite specific: A pronounced reduction in the number of supragranular, and virtually no effect upon infragranular callosal neurons.

The effect of the neonatal lesion in the intact hemisphere was much different. On this side, the number of labelled cells appeared abnormally low in most cases, but the tangential and laminar distribution of these neurons was not significantly different from that observed in normal hamsters.

299.1 QUANTITATIVE DATA ON THE REGIONAL DISTRIBUTION OF THE DOPAMINE INNERVATION IN ADULT RAT CEREBRAL CORTEX. B. Lemay*, G. Doucet and L. Descarries (SPON: H.H. Jasper). Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal, Qué., Canada H3C 3J7.

The topographic distribution of the dopamine (DA) innervation in rat cerebral cortex has been well documented by earlier biochemical, fluorescence- and immuno-histochemical studies. However, there is still only semi-quantitative information as to the number of these axon terminals (varicosities) within the various cortical areas. To obtain such data, we used an *in vitro* radioautographic approach based on the uptake of [$^3$H]DA in fresh, transversal, 200 µm-thick slices of the whole cerebral hemisphere (Doucet, G. and Descarries, L., *Soc. Neurosci. Abstr. 10*, 422, 1984). The slices were incubated for 15 min at 35°C with $10^{-6}$M [$^3$H]DA and 5 x $10^{-6}$M desipramine in the presence of $10^{-4}$M pargyline, and radioautographed as large 4 µm-thick Epon sections exposed for 15 days. With the aid of a camera lucida, the labeled axonal varicosities were mapped at 4 transverse levels representative of the major cytoarchitectonic divisions of adult rat cortex. The highest density of DA innervation (number of labeled varicosities per unit of surface) was that of the supragenual cingulate areas, where the labeled terminals predominated in layers II and III. Slightly lesser overall densities of DA innervation were found in the antero-median cingulate cortex, suprarhinal and perirhinal claustrocortex and prepiriform area, with terminals mostly located within the deep layers of these regions. The entorhinal cortex showed a DA innervation of medium density spreading into all its layers except layer I. In the precentral, parietal and temporal areas, there was a DA innervation of low density which was restricted to layer VI. The occipital cortex showed exceedingly scarce DA terminals again confined to layer VI. Counts done on serial semi-thin (0.5 µm) sections exposed for various periods of time (7-30 days) indicated that, after 15 days, a plateau had been reached in the number of detected labeled varicosities. Besides, similar examination of serial sections cut at different thicknesses (0.5 - 4 µm) indicated that, beyond a section depth of 1 µm, an increasing number of labeled terminals failed to record their image into the emulsion. A factor was therefore calculated from these latter counts in order to correct the values obtained in 4 µm-thick sections. Lastly, the average diameter of the labeled endings was measured in electron microscope radioautographs from the same material. Under such conditions of specific labeling and optimal visualization, simple stereological extrapolation of the data will provide truly quantitative estimates of the areal and laminar densities of cortical DA innervation expressed as number of axon terminals per mm$^3$ of tissue. (Supported by grant MT-3544 from the MRC of Canada).

299.2 RADIOAUTOGRAPHIC QUANTIFICATION OF THE DOPAMINE INNERVATION IN ADULT RAT NEOSTRIATUM. G. Doucet, S. Garcia* and L. Descarries. Centre de recherche en sciences neurologiques (Dép. de physiologie), Université de Montréal, Montréal, Qué., Canada H3C 3J7.

In the rat, the total number of dopamine (DA) varicosities in one entire neostriatum has been approximated to $10^9$ by means of the Falck and Hillarp histofluorescence method (Andén, N.-E. et al., *Acta Physiol. Scand. 67*, 306, 1966). Since then, various studies have suggested that the intrastriatal distribution of these nerve endings is heterogenous, with patches of higher density, the so-called subcallosal streak and DA islands, as well as a slight decreasing rostro-caudal gradient. To evaluate the actual number of DA axon terminals in the various parts of adult rat neostriatum, 200 µm-thick slices of whole cerebral hemisphere were incubated for 15 to 60 min at 35°C with $10^{-6}$M [$^3$H]DA and 5 x $10^{-6}$M desipramine in the presence of $10^{-4}$M pargyline, and processed for light microscope radioautography as large 4 µm-thick Epon sections exposed for 7-30 days. However, in these conditions which lead to integral labeling of DA terminals in areas of relatively low DA innervation, [$^3$H]DA failed to label the varicosities in the core of the striatal portions of the slices. In contrast, following injection of 6-hydroxydopamine into the substantia nigra, residual striatal DA varicosities could be labeled throughout the full thickness of the slices. To acquire data in normal rat, the slices were therefore incubated at lower temperature (15°C) so as to diminish the efficiency of the reuptake mechanism and thus allow the tracer to overcome the "barrier" raised by the multitude of neostriatal DA varicosities. At this temperature, all DA varicosities could indeed be labeled throughout the full thickness of the slices. Yet, within certain areas of neostriatum, the extremely high density of DA innervation now precluded their direct counting in 4 µm-thick sections. Radioautographs had to be prepared from thinner section (0.5 µm) and to be exposed for shorter periods of time, when only a fraction of the labeled terminals were detected. A correction factor was then determined from counts carried out after various exposure times in less densely innervated portions of the striatum. A preliminary estimate of the mean density of DA innervation at one transverse level (A-8500 µm in König and Klippel's atlas) gave a figure in the order of $10^7$ per mm$^3$ of tissue. This value is consistent with the estimate of Andén et al. when extrapolated to the entire volume of the striatum. At the same level, the dorsolateral DA islands and the subcallosal streak reached a density of 9 x $10^7$ per mm$^3$ compared to 5 x $10^7$ outside these patches. Such quantitated data should be particularly useful for the study of various experimental models of growth or reinnervation and for correlations with other measurable parameters of DA function in the striatum. (Supported by grant MT-3544 from the MRC of Canada).

299.3 SEROTONIN INNERVATION OF RAT NEOSTRIATUM: IMMUNOHISTOCHEMICAL AND RADIOAUTOGRAPHIC STUDY. J.J. Soghomonian, L. Descarries and G. Doucet. Centre de recherche en sciences neurologiques (Dép. de physiologie), Université de Montréal, Qué., Canada H3C 3J7.

There is only fragmentary data regarding the distributional and fine structural features of the serotonin (5-HT) innervation in adult rat neostriatum. To obtain further information, three morpho-chemical approaches were used: immunohistochemistry with an antibody against 5-HT (IMMUNO); light microscope radioautography of tissue slices incubated with [$^3$H]5-HT (RAG *in vitro*); electron microscope radioautography after intraventricular administration of [$^3$H]5-HT (RAG *in vivo*). IMMUNO on histological sections taken at regular intervals across the striatum stains a relatively loose, ramified axonal network spread throughout but unevenly distributed within the nucleus. In addition to a slight caudo-rostral decrease, the 5-HT arborizations are less tightly intermingled in the dorsal and latero-dorsal than in the ventral sectors of neostriatum (and subjacent "ventral striatum"). Moreover, they appear somewhat crowded around the traversing myelinated fascicles of the internal capsule, as if they had been pushed into this location during development. RAG following the uptake of [$^3$H]5-HT *in vitro* or *in vivo* visualizes mainly axonal varicosities (terminals) rather than intervaricose segments. After incubation of whole hemisphere slices with $10^{-6}$M [$^3$H]5-HT and $10^{-5}$M non-radioactive noradrenaline in the presence of $10^{-4}$M pargyline, all but only 5-HT varicosities can be detected (Doucet, G. and Descarries, L., *Soc. Neurosci. Abstr. 10*, 422, 1984). In the striatum, the topographic distribution of the [$^3$H]5-HT-labeled endings is roughly proportional to that of the 5-HT-immunoreactive fibers. For instance, the actual number of 5-HT varicosities is at least twice higher in the medio-ventral (1.5 x $10^6$ varicosities per mm$^3$ on a first approximation) than in the latero-dorsal neostriatum (0.6 x $10^6$). In electron microscope radioautographs, the neostriatal terminals labeled *in vivo* with [$^3$H]5-HT are mostly of small caliber (0.2 - 0.5 µm in diameter), often barely larger than the thin unmyelinated fibers bearing them. In single thin sections, a very low proportion (less than 10%) exhibit membranous synaptic differentiations. The few observed junctions are made on dendritic spines and they are generally asymmetrical. These preliminary results illustrate the respective and complementary value of each approach in revealing various aspects of the 5-HT innervation within a given brain region. IMMUNO visualizes the full extent of the axonal network, allowing analysis of its intra-regional distribution. RAG *in vitro* is uniquely suitable for quantifying the innervation density as number of axonal varicosities per mm$^3$ of tissue. RAG *in vivo* remains the method of choice to characterize the intrinsic and relational features of these terminals. (Supported by grant MT-3544 from the MRC of Canada).

299.4 DISTRIBUTION OF MONOAMINES IN MONKEY HIPPOCAMPUS. C. A. Kitt, L. C. Walker, R. G. Struble, D. L. Price, T. H. Joh§, B. H. Wainer†, D. T. O'Connor*†† and M. E. Molliver. The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205; §Cornell Univ. Med. Col., New York, NY 10021; †Univ. Chicago, Chicago, IL 60637; ††Univ. Calif., San Diego Sch. Med., San Diego, CA 92093

The pattern of monoaminergic (MA) innervation of monkey hippocampus was investigated using polyclonal antibodies directed against tyrosine hydroxylase (TH), dopamine ß-hydroxylase (DBH), serotonin (5HT), and a monoclonal anti-choline acetyltransferase (ChAT) antibody. Staining patterns of TH and DBH were compared to each other and to 5HT and ChAT in order to determine contributions of dopaminergic, noradrenergic, serotonergic, and cholinergic systems to the MA innervation of monkey hippocampus. MA fibers appear to enter the hippocampus through four main routes: the perforant pathway; alvear fiber bundle; association (axial) pathway; and fimbria/fornix. DBH-immunostained fibers course primarily along the alvear path, while few DBH-positive processes are seen in other fiber tracts. TH-positive fibers course through both the alvear and perforant pathways; however, many TH-immunostained fibers are also seen in the axial path and within the fornix. The majority of 5HT-immunostained fibers were seen in the alvear and perforant paths; however, a dense collection of 5HT-positive fibers was present in the portion of the axial path located within CA1. ChAT-immunostained fibers enter the hippocampus primarily through the fimbria/fornix. Few fibers were seen in the alvear, perforant, and axial paths. Differences in MA fiber densities were observed in CA1-4 regions. Fibers of all four monoamines are present in the dentate gyrus with axons scattered throughout the molecular layer of the dentate gyrus; the granule cell layer receives only sparse MA input -- most fibers appear to pass through the granule cell layer en route to polymorphic cells of the hilus. A thin band of ChAT-positive fibers were seen in the infra- and supragranular layers of the dentate gyrus. In CA3, the stratum oriens contains the most ChAT-positive fibers; few ChAT-positive fibers terminate in the pyramidal and molecular cell layers. The pyramidal cell layer and stratum moleculare of CA3, however, receives a particularly dense series of DBH, TH, and 5HT inputs. Stratum oriens and radiatum of CA3 receive sparse DBH, TH, and 5HT inputs. CA1 contains an intricate pattern of MA innervation; DBH, TH, 5HT, and ChAT-immunostained fibers are present in all layers, with a predominance of MA input to pyramidal neurons. A dense cluster of 5HT fibers are seen in the strata lacunosum and moleculare of CA1, perhaps terminating on the apical dendrites of pyramidal neurons. Clearly, monkey hippocampus receives a very rich MA innervation with an overlap in distribution, suggesting that MA inputs may converge onto individual hippocampal sectors and/or neurons.

299.5 SEROTONIN- AND SUBSTANCE P-LIKE IMMUNOREACTIVITY IN THE INTERPEDUNCULAR NUCLEUS: POSTNATAL DEVELOPMENT AND EFFECTS OF NEONATAL FASCICULUS RETROFLEXUS LESIONS. G. A. Barr*, T. C. Eckenrode* and M. Murray. (SPON: M.E. Goldberger). Biopsychology Program, Hunter College, City University of New York and Dept. Anatomy, Medical College of Pennsylvania, Philadelphia, Pa. 19129.

The interpeduncular nucleus (IPN) is a midline nucleus with cytoarchitectonically distinct subnuclei (Hamill & Lenn, *J. Comp. Neurol.*, **222**: 396, 1984). The IPN contains a number of putative neurotransmitters that arise both from extrinsic and intrinsic sources. Important afferents are the fasciculi retroflexi (FR) which contain major substance P (SP) and acetylcholine projections to the IPN. Furthermore, SP and specified types of synapses show degeneration and reinnervation following FR lesions (Artymyshyn & Murray, *J. Comp. Neurol.*, **231**: 78, 1985; Lenn et al., *Neurosci.*, **9**: 383, 1983; Murray et al., *J. Comp. Neurol.*, **187**: 447, 1979). Because lesions in young animals often produce effects that are different from those of lesions in adult animals, we studied the effects of FR lesions in neonates on the immunohistochemical distribution of SP, which projects to the IPN via the FR, and on the distribution of serotonin (5-HT) which arises from other sources.

The distribution of the putative transmitters was examined using the unlabeled antibody (PAP) technique of Sternberger. The normal development of each was defined in Sprague-Dawley pups sacrificed at regular intervals from birth to 3 months of age. Pups were anesthesized and perfused intracardially with saline followed by 4% paraformaldehyde. FR lesions were performed stereotaxically in 3 day old pups using the Heller adaptor for infant rats. Lesioned pups and unlesioned controls were assayed at 19 -21 days of age and 40 - 42 days of age.

SP-like immunoreactivity developed in stages (Eckenrode et al., *Neurosci. Abst.*, **9**: 987, 1983). The SP projection to the lateral subnucleus was present at birth, but staining was absent from the other subnuclei. Adult distribution of immunoreactivity was seen at 17 days of age, with staining present in the rostral, central and dorsal subnuclei. In contrast, the distribution of 5-HT - like immunoreactivity in the infant was similar to that of the adult although with lower density. Staining was evident in the dorsal and rostral subnuclei and the caudal aspects of the lateral subnuclei.

At the shorter survival time following unilateral lesions, ipsilateral loss of SP was seen in the lateral aspects of the lateral subnuclei. The loss from the infant lesions was similar to that described for the adult. There was no noticeable change in the other subnuclei. The distribution of serotonin was similar to that seen in normal infants and adults.

Thus, the 5-HT system in the IPN is an early developing system. SP develops more slowly, appearing in the lateral subnuclei prior to the rostral, central or dorsal subnuclei. Lesions of the FR in infants produced a loss of SP similar to that seen following FR lesions in adults. There was no evidence of heterotypic sprouting by serotonin, at least at the short survival times used here. Supported by NIH NS16556.

299.6 MAO A IN CATECHOLAMINERGIC AND MAO B IN SEROTONERGIC REGIONS: IMMUNOCYTOCHEMICAL LOCALIZATION IN HUMAN BRAIN. K.N. Westlund, R.M. Denney*, R.M. Rose, and C.W. Abell.* Depts. of Human Biol. Chem. & Genetics and Psychiatry & Behav. Sciences. University of Texas Medical Branch, Galveston, TX 77550.

In human autopsy brain, two distinct populations of MAO-positive neurons which corresponded to known monoaminergic cell groups were identified with two highly specific monoclonal antibodies (MAO A-7E10 and MAO B-1C2) elicited to human placental MAO A and human platelet MAO B. One cm thick slabs of human brain were immerse-fixed in 10% buffered formalin for 5-30 days prior to overnight equilibration in 20% buffered sucrose. Frozen 30-40 μm sections were cut on a sliding microtome, and the tissues collected and rinsed in phosphate buffer. Overnight incubation in 1:1,000 dilution of ascites fluid preceded localization by standard PAP immunocytochemistry. Immunocytochemical controls included omission of one or more of the reagents in the PAP protocol, dilution of the antibody, competition of the antibody with antigen, and incubations with ascites fluid from mice injected with vehicle only. Specific staining was not seen in control stains or when the antibody was preadsorbed with antigen (10 μg/ml).

MAO A was localized in regions containing catecholamine neurons designated cell groups A1-A14 by Dahlström and Fuxe (1964), including known noradrenergic cell groups such as the nucleus locus coeruleus and cells scattered in the commissural and solitary nuclei, and known dopaminergic cell groups such as the substantia nigra and the periventricular nucleus of the hypothalamus. Under the conditions used, the number of cells containing detectable levels of stain for MAO A in the substantia nigra did not represent all dopaminergic cells normally observed in this region in other species. MAO B was localized in regions containing serotonergic neurons designated cell groups B1-B9, including the raphe complex and the nucleus centralis superior. Furthermore, MAO A and MAO B staining were observed in the scattered magnocellular components of the hypothalamus, in varicose terminations, and in some astrocytes throughout the neuraxis. Both forms of the enzyme were localized in distinct but intermingled populations of neurons in the hypothalamus. Similar or identical localization of MAO A and B has been observed in monkey brain, using similar methods. The clear segregation of MAO A in catecholamine regions and MAO B in serotonergic regions suggests that these enzymes perform different physiological roles. 299.7 MORPHOLOGY AND SYNAPTIC RELATIONSHIPS OF NORMAL AND SEROTONERGIC PROCESSES IN CAT RAPHE DORSALIS: A FINE STRUCTURAL SERIAL ANALYSIS. G. Chazal* and H.J. Ralston III. (SPON: C. Morgan) Dept. Anatomy, Univ. California School of Medicine, San Francisco, CA 94143.

Most of our present knowledge of the ultrastructure of serotonergic (5-HT) neurons in the nucleus raphe dorsalis (RD) is derived from autoradiographic studies using radiolabeled 5-HT on rats. There have been relatively few studies in the cat and none has given a detailed morphological description of the 5-HT intrinsic innervation. It is to this purpose that we undertook a study using an antibody to 5-HT to describe the serotonergic profiles in cat RD and to determine, by analysis of serial thin sections, their synaptic relationships. In addition, a comparison with the ultrastructural features of RD profiles in conventional, aldehyde-fixed material, was conducted to clarify the nature of the structure, i.e. dendrite or axon terminals, of some 5-HT processes.

For immunocytochemical (ICC) procedures, adult cats were anaesthetized and then perfused with 4% paraformaldehyde-0.1% glutaraldehyde. The brain stem was removed and sectioned on a vibratome at a thickness of 30 or 50 um. Tissue sections were incubated for 12 hrs in 5-HT antisera (1/400-1/800 dilution) and then processed by the PAP method. Following osmication, dehydration and epon embedding, sections from the RD were cut in serial 4 um sections and areas were subsequently selected, for serial ultrathin sectioning. Brain stem tissue from other cats was prepared following perfusion fixation with 2% paraformaldehyde-2% glutaraldehyde and subsequent osmication, embedding and staining.

In the tissue processed using the ICC method, we observed different types of 5-HT profiles. Large dendritic shafts (>1.5μm diameter) which contained PAP reaction product comprised the dominant population. In addition, several immunoreactive axonal varicosities were also present and easily distinguished by the presence of electron-dense PAP reaction product that coated the outer membranes of vesicles. Some of these varicosities were observed to participate in synaptic junctions. Another type of process appeared to be dendritic by the usual criteria of content but also exhibited groups of vesicles. In raphe dorsalis sections prepared for conventional EM, we frequently observed dendritic profiles containing vesicles, some of which established synaptic contacts with other dendrites and thus could be interpreted as presynaptic dendrites (PSD). Others presented clusters of vesicles accompanied by unusual dense structures larger than the vesicles themselves. These results suggest that some 5-HT profiles containing vesicles are dendrites. These data are consistent with the hypothesis that a local serotonergic system, including dendritic release of 5-HT, regulates the activity of raphe dorsalis neurons.

299.8 IMMUNOHISTOCHEMICAL LOCALIZATION OF SEROTONIN NEURONS IN AUTONOMIC REGIONS OF RAT SPINAL CORD. B.W. Newton & R.W. Hamill, Department of Neurology, University of Rochester/Monroe Community Hospital, Rochester, New York 14603

5HT is one of the neurotransmitters implicated in the control of autonomic functions, e.g. blood pressure and sympathoadrenal function. Spinal 5HT is thought to originate from descending projections from brainstem raphe neurons synapsing in spinal preganglionic areas. Although 5HT spinal neurons have been described in other species (monkey, stingray), previous studies have not revealed these neurons in rat. This is the first known report of 5HT neurons in the rat spinal cord, and describes the existence of 5HT neurons in spinal autonomic regions.

In order to study the distribution of serotonin-like immunoreactive (5HT-LI) neurons in rat spinal cord, 21 adult female rats were examined with the PAP method. Ten or 30 days prior to perfusion spinal cords of 4 rats were transected at the T4-T5 junction. One hr before perfusion 8 rats were pretreated with L-tryptophan and a MAO inhibitor, either pargyline or tranylcypromine. Rats were perfused with Zamboni's fixative and the spinal cords were serially sectioned at 40um on a vibratome. Sections were incubated for 48 hrs in antiserum generated against 5HT (R21M) coupled to bovine serum albumin (BSA; technique of Maley & Elde, Neurosci., 7:2469, 1982) diluted 1:5000. All antibodies were diluted in phosphate buffered saline/3% normal sheep serum with 0.3% Triton X-100. Absorption controls (5HT, BSA, tryptophan, tryptamine, epinephrine, norepinephrine, dopamine) demonstrated R21M specificity towards 5HT.

5HT-LI soma were observed in normal rats, although a greater number of 5HT-LI neurons were found in pretreated rats. 5HT-LI neurons were found in spinal cord regions known to contain preganglionic autonomic neurons. The majority of these 5HT-LI neurons were located in the dorsal commissural nucleus and just lateral to the central canal. The most rostral and caudal 5HT-LI neurons were at T3 and S4, but the greatest number occurred between levels T7-T10. Most 5HT-LI neurons appeared as bipolar fusiform cells oriented longitudinally to the long axis of the cord. However, multipolar cells were observed. 5HT-LI neurons were found among a network of 5HT-LI fibers resembling previously described enkephalinergic patterns. In rats with spinal cord transections 80-90% of the 5HT-LI fibers disappeared below transection, but 5HT-LI soma were still observed. These 5HT-LI neurons are the probable source of the remaining 5HT-LI fibers below the transection and may also explain the origin of intrinsic 5HT, eluciated biochemically, below spinal cord transections. 5HT spinal neurons may serve as interneurons participating in the serotoninergic control of preganglionic autonomic neurons. 299.9 ULTRASTRUCTURAL HISTOCHEMISTRY OF BIOGENIC AMINE LOCALIZATION IN INTERNEURONS OF THE CARDIAC GANGLION IN NECTURUS MACULOSUS. R.M. Kriebel, A. Angel*, D.S. Neel*, and R.L. Parsons. Dept. of Anatomy & Neurobiology, University of Vermont College of Medicine, Burlington, VT 05405.

The parasympathetic cardiac ganglion in the mudpuppy, N. maculosus, contains postganglionic principal cells and interneurons. Several bioactive substances have been localized in the interneurons which may have integrative effects at synapses within the ganglion. Ganglionic interneurons can be identified electron microscopically by the presence of numerous cytoplasmic granules 80 - 120 nm in diameter. Throughout the ganglion there are bundles of unmyelinated fibers some of which are filled with granular and agranular vesicles and axosomatic terminals with similar vesicles synapsing on principal cells. Structural features alone are not sufficient to determine the chemical basis of synaptic circuitry within a system. Therefore, to understand the aminergic contribution to ganglionic synaptic circuitry the chromaffin reaction was used. Ganglia were immersion fixed in 2% para- and 2% glutaraldehyde in sodium chromate/potassium dichromate buffer (pH 7.2) for 30 min at 4°C, incubated in chromate buffer at pH 6.0 for 18 h, osmicated, dehydrated, and embedded in epon. Thin sections were stained with lead citrate to visualize the chromaffin reaction product and studied in a JEOL 100CX II STEM. In these preparations, interneurons were readily identified by their characteristic intracellular granule population. All interneurons identified showed granules which were positively labelled by the chromaffin reaction. In each interneuron, there appears to be an electron dense heterogeneity of reaction product in the granules. Many granules are intensely electron dense while others cannot be differentiated from background tissue density. This heterogeneous appearance may reflect different levels of amine content or the presence of granules which contain other substances. Granules within unmyelinated fibers were also labelled. Dense cored granules in synaptic terminals on principal cells were also labelled indicating an aminergic synaptic innervation to these cells. In confirmation of previous studies, the interneuron cell bodies, ensheathed with supportive glial-like cellular processes, rarely receive synapses. Elemental microanalysis was used to verify the chromium content of the reaction product within the dense cored granules. Studies are in progress to further define the interaction of interneuronal synapses with other interneurons and the principal cells of the cardiac ganglion.

299.10 NEW HISTOCHEMICAL STAIN FOR HISTAMINE. A. Li* and R.J.Dinerstein University of Chicago, Dept. Pharmacol. & Physiol. Sci., Chicago, IL 60637 and Merrell Dow Research Institute, Indianapolis, IN 46268-0470.

Histamine (HA) is a putative neurotransmitter in the mammalian brain and is known to be a neurotransmitter in Aplysia. We have developed a simple fluorescent technique that is specific for histamine.

Histamine is known to undergo a condensation reaction with vitamin B6 under physiological conditions to form a tetrahydroimidazopyridine (TIP). The reaction product formed between HA and vitamin B6 is different from the normal Schiff product formed between other amines and vitamin B6. Based on this observation, a number of vitamin B6 analogues were examined and salicyladehyde (SA) was found to form a similar derivative with HA in MeOH/$H_2O$ at pH10. In a polyvinylpyrrolidone (PVP) matrix, the TIP derivative of HA exhibits a green fluorescence (ex max: 375 nm; em max: 495 nm) that increases in intensity and changes to a yellow fluorescence (ex max: 420 nm; em max 530 nm) after exposure to UV light. The chemical basis for this change is a photochemical singlet oxygen reaction. This fluorescence is distinctly different from that seen for other similarly treated biogenic amines and amino acids. Rat mast cells isolated from peritoneal washes were treated with SA at pH 11. The resulting cellular fluorescence was found by microspectrofluometry to be identical to that for the TIP derivative of HA. In stretch preparation of rat peritoneum, alkaline SA produced the same fluorescence in mast cells. Furthermore the intensity of the background mesentary fluorescence was less than 15% of the mast cell fluorescence. Using mast cells as a model we have developed a specific histochemical method for histamine which could be used in studying histamine in neurons. This research supported by Mental Health Training Grant 1 T32 MH 14274-09 and NIH GM-22220, Brain Research Foundation, University of Chicago.

299.11 WHEATGERM AGGLUTININ APO-HRP-GOLD: A NEW TRACER FOR LIGHT AND ELECTRON MICROSCOPY. Basbaum, A. I. and Menetrey, D*. Dept. of Anatomy, University of California San Francisco, CA 94143 and INSERM U-161, 75014 Paris, France.

There is great interest in the development of anatomical techniques for the study of axon collateralization in the CNS. The introduction of transportable dyes has significantly simplified such studies. For EM analysis, however, electron dense markers are required. To this end, Menetrey and Lee ('85) have recently described a technique that couples colloidal gold to a wheatgerm agglutinin (WGA)-HRP conjugate. The resultant molecule is a very sensitive tracer that can be used for retrograde transport studies at both the LM and EM level. Double labelling studies with immunocytochemistry are also possible, however, in that case, the HRP in the gold complex must first be inactivated so that there is no interference with detection of, for example, the PAP molecule. Unfortunately, this latter treatment is harsh and thus the preservation of the tissue for EM analysis is reduced.

To overcome the problem, we have adapted the approach of Hayes and Rustioni ('79) and in collaboration with Sigma have conjugated WGA to the enzymatically inactive apoprotein (Apo-HRP). Although the gold coupling properties of the WGA-Apo-HRP conjugate differ somewhat from that of WGA-HRP, LM studies established that WGA-Apo-HRP-gold is also a very sensitive retrograde tracer. Somatic and dendritic labelling of retrogradely labelled neurons is readily detected after silver enhancement of the gold particles. We have also sucessfully used the new complex in combined immunocytochemical studies. We are presently evaluating its properties at the EM level, (both with and without silver enhancement), in combination with immunocytochemistry as well as with the anterograde and/or retrograde transport of enzymatically detected, active WGA-HRP. The possible use of WGA-Apo-HRP-gold in anterograde studies is also being assessed.

By coupling different size gold particles to the new complex, we believe that multiple retrograde tracers can be generated. Finally, the complex should prove of value in studies of the cell biological mechanisms underlying axonal transport.

299.12 BENZIDINE DIHYDROCHLORIDE (BDHC) AS A CHROMOGEN FOR LIGHT AND ELECTRON MICROSCOPIC IMMUNOCYTOCHEMISTRY. S. Lakos* and A. I. Basbaum. (SPON. J. LaVail) Dept. of Anatomy, University of California San Francisco, CA 94143

Despite the fact that there are very sensitive chromogens available for the localization of horseradish peroxidase (HRP), these have rarely been used to detect the PAP molecule in immunocytochemical studies. Often this is because the reaction product is soluble and thus difficult to preserve for EM analysis. Peschanski and Ralston ('85), however, recently adapted the chromogen, BDHC, for anterograde and retrograde studies. In this report, we describe its use for immunocytochemistry.

The protocol is similar to that typically used with tetramethylbenzidine (Mesulam, '78), with several modifications. Although the greatest sensitivity is produced at low pH (e.g. 3.5, like TMB), to preserve ultrastructural quality, the BDHC reaction is run at pH 6.5. This results in a reaction that is still considerably more sensitive than DAB. There is not only much more reaction product, (at higher dilutions of primary antisera, e.g. against 5HT), but perfusion fixatives can also contain up to 1% glutaraldehyde. The increased sensitivity is also reflected in the background staining, however, treatment of sections in low glutaraldehyde after the PAP step can differentially increase signal. The BDHC reaction product is particulate and has a blue-green color that is very different from the reddish-brown DAB reaction product. We have used these color differences for LM double labelling studies.

To preserve the BDHC product for EM analysis, osmication must be carried out in an s-collidine buffer at 45°C. Dehydration and embedding are standard. At the EM level, the BDHC reaction product consists of discrete, electron dense crystals that contain parallel cross bridges. Since the crystals are readily distinguished from the flocculent DAB reaction product, EM double labelling studies are possible. To this end, we have detected retrogradely transported WGA-HRP with DAB and combined this with the EM immunocytochemical localization of 5HT in the medullary raphe.

300.1 THE MODELING OF HIPPOCAMPAL CONVULSANT ACTIVITY USING AMPLITUDE AND FREQUENCY DAMPED SINE WAVES. L.W. Jennings* and H.J. Doller*. (SPON: G. Drust) Depts. of Internal Medicine and Neurology, UTHSCD and Epilepsy Center, VAMC, Dallas, TX.

The rhythmic discharges recorded from the in vitro hippocampal slice exposed to picrotoxin are fit to one or more amplitude and frequency damped sine waves. Such analysis allows the response to be described by as few as 5 parameters: delay to start of response (T), amplitude (A), amplitude decay (B), frequency, and frequency decay (g(t)). The general formula is:

$$y(t) = a + bt + A \exp[-Bt] \sin[\, g(t)\,(t-T)] + e(t)$$

where a+bt is a linear base line, g(t) is a function of time chosen to describe the change in frequency observed with time, and e(t) is the residual error term.

Rat hippocampi were quickly removed, sliced (450 uM), and placed in a trough-like chamber. Stimulating electrodes were placed in the perforant pathway and a glass recording electrode (1 to 2 M ohms) in the CA1 cell body layer. After a recovery period, single stimuli evoked a field containing a single population spike (Doller & Weight, Brain Res. 237:1, 1982). When picrotoxin (0.1 mM) was added to the superfusate, multiple population spikes (3 to 7) were evoked by a single stimulus.

The data were fit to an amplitude and frequency damped sine wave using the following strategy. Ordinary least squares techniques were used to estimate the linear trend, a+bt. Using the residuals, z=y-(a+bt), the remaining parameters were estimated using the Marquardt method for nonlinear regression by least squares. Initial estimates for A and B were obtained by fitting ln(z)=ln(A)+Bt to the absolute values of the extremes of the curve. The form and initial estimates for g(t) were obtained by analyzing the frequency estimates f=1/Δt, where the t's are the locations of the extremes.

This damped sine wave model may be useful in quantifying seizure activity and the actions of convulsant and anticonvulsant drugs. In addition Fredman (Ann. Rev. Biophys. Bioeng. 1:225, 1972) suggested that in the olfactory cortex cells the normal rate of neuronal firing resembles an amplitude damped sinusoid. O'Connor (EEG, 59:497, 1984) has recently used a summation of amplitude damped sine waves to model clinically evoked visual potentials. The hypothesis is that the general neuronal circuitry pattern of feed back excitation and inhibition leads to the production of damped sine wave potentials. Evoked potentials are the summation of different waves produced by specific groups of neurons. Changes in a parameter of such a model may be related to a specific change in a group of neurons. The current investigation suggests that the more general model for fitting evoked potentials may be the summation of amplitude and frequency damped sine waves.

300.2 MULTINEURON ANALYSIS REVEALS COMPLEX PATTERNS OF INTERACTION AMONG NEURONS IN FOREBRAIN NETWORKS AND CARDIORESPIRATORY PARAMETERS DURING SLEEP-WAKING STATES. R.D. Frostig, Z. Frostig*, R.C. Frysinger, V.L. Schechtman, and R.M. Harper. Neuroscience Program, Brain Research Institute, and Department of Anatomy, UCLA, Los Angeles, CA 90024.

Several studies demonstrate the existence of forebrain areas participating in the control of the cardiovascular and respiratory systems. Part of this evidence derives from cross-correlation studies between forebrain units and cardiorespiratory parameters. Each cross correlation, however, can detect interactions between only a single neuron and a single cardiorespiratory parameter. The study of simultaneous interactions among neurons and cardiorespiratory parameters may reveal the existence of unique interactions that would not be detected by examining only pairs of interactions.

We studied local networks of four or five simultaneously recorded single units in forebrain areas that participate in cardiovascular and respiratory control, the central nucleus of the amygdala and the medial frontal cortex. Neuronal and cardiorespiratory measures were recorded in freely moving, drug-free cats during different sleep-waking states, so that an experimental manipulation (sleep states) could induce potential alterations in their interactions.

We used the joint multicorrelation procedure (Frostig, R.D., et al., Soc. Neurosci. Abs., 10: 756, 1984) to analyze interactions among neurons in these networks and cardiorespiratory parameters that could be represented as point processes (e.g., the QRS peak in the ECG, the onset of respiration). Analysis of these neuronal and cardiorespiratory processes (up to seven simultaneously) revealed the existence of complex recurring patterns of interaction among neuronal discharges and among neuronal discharges and cardiorespiratory activity. These patterns consisted of repetitions of spike discharge from different spike and cardiorespiratory trains (e.g., AB interval of 4 ms, followed by BC interval of 9 ms, followed by CD interval of 10 ms, etc.). The pattern's recurrence was statistically significant and involved up to five simultaneous processes appearing with no, or minimal, variation in their timings (1- and 5-ms bins, respectively). Many patterns could appear at the same recording session, and changes in sleep-waking state produced different patterns.

These findings suggest the presence of complex coding properties involving many neurons in networks within forebrain areas and cardiorespiratory parameters. These interrelations are altered by changes in sleep and waking state.

300.3 DOES GLYCINE INHIBITION MEDIATE AIRSTEPPING AND PAW-SHAKE RESPONSES IN SPINAL CATS? C.A. Giuliani, S.H. Chandler, G. Caneta*, and J.L. Smith. Dept. of Kinesiology, UCLA, CA, 90024.

Rhythmical hindlimb movements, including airstepping (ASTP) and paw-shake response (PSR), are thought to be centrally generated by the lumbosacral spinal cord. However, neural mechanisms of the central pattern generator (CPG) controlling these rhythmical behaviors is unknown. Recent evidence suggests that glycine may mediate the inhibitory coupling that controls alternating segmental activity during lamprey swimming (Grillner and Wallen, Acta Physiol Scand. 110:103, 1980; Cohen and Harris-Warrick, Brain Res. 293:164, 1984). The purpose of this study was to investigate the role of glycine inhibiton mediating intra- and interlimb control during ASTP and PSR in cats spinalized at T-12.

Bipolar electrode wires were implanted in selected flexor and extensor muscles of the hindlimbs. A cannula (PE 10) was implanted in the subarachnoid space at the $L_4$ vertebral level and affixed to the skull (adapted from Yaksh and Rudy, Physiol Behav., 17:1031, 1976). The effects of strychnine (a glycine antagonist) on the intralimb synergies of ASTP and PSR and the interlimb coordination of ASTP were assessed by EMG and videotape records before and after injection of strychnine and control injections of the vehicle solution (saline).

High doses of strychnine (>50 ug/200 ul) produced seizure-like movements, characterized by cocontraction of all muscles recorded for 2-10 minutes following injection. During this period no ASTP was observed, however, PSRs were easily elicited. Recovery to control behavior returned within an hour. During recovery or following intermediate range doses of strychnine, interlimb coordination of ASTP was severely affected. Variability in the phase relationships between limbs occurred frequently. Additionally, independent hindlimb activity was noted when one hindlimb airstepped and the other was silent or exhibited cocontraction of antagonists. Neither the average cycle period, nor the intralimb synergy of ASTP appeared affected; however, the integrated EMG doubled. Intermediate doses of strychnine tended to increase the cycle period of the PSR, but did not disrupt the characteristic intralimb synergy. Low doses of strychnine (<10 ug/200ul) had no apparent affect on ASTP or PSR.

Our data suggest that glycine inhibition may be more important in mediating interlimb than intralimb coordination of ASTP in the spinal cat. Furthermore, our results indicate that while glycine mediated synapses may be important in the production of ASTP, they do not appear to be as important for the production of the PSR. Supported by NIH grant NS 19846.

300.4 PHARMACOLOGICAL ACTIVATION OF LOCOMOTOR ACTIVITY IN THE DEVELOPING SPINAL CORD OF THE CHICK EMBRYO. M. Barry* and M.J. O'Donovan. (Spon: I. Bruce) Dept. of Physiology and Biophysics, Univ. of Iowa, Iowa City, IA 52242.

The purpose of this study was to analyze the role of excitatory amino acids in the initiation of embryonic motor activity. Locomotor activity was recorded from antagonistic hindlimb muscles or muscle nerves in St.32-36 chick embryos using a superfused isolated spinal cord preparation (Landmesser and O'Donovan 1984; J. Physiol., 347:189, 1984). We found that bath applied NMA (N-methyl-DL-aspartate was effective in influencing motor activity over a narrow range of concentrations (3-30μM). Low doses of NMA initiated spontaneous burst activity in quiescent preparations and increased the frequency of otherwise normal burst episodes in spontaneously active embryos. Higher concentrations (30μM) of NMA activated continuous bursting in which the pattern of muscle activity was similar to that observed during spontaneous activity (see Fig. 1). At concentrations >50μM flexor and extensor motoneurons were tonically activated and rhythmic activity was abolished. In younger embryos (St.32), in which the pattern of antagonist alternation was not yet mature, NMA increased the frequency of burst episodes but did not result in the appearance of alternating activity. Application of the NMA antagonist 2-amino-5-phosphonovalerate (2-APV) did not block spontaneous motor activity suggesting that non-NMDA amino acid receptors may be involved in the generation of spontaneous motor activity in the chick embryo.

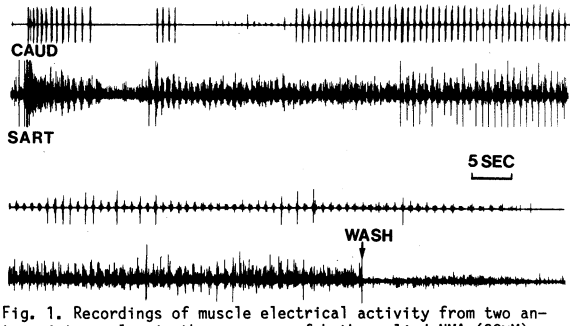

Fig. 1. Recordings of muscle electrical activity from two antagonist muscles in the presence of bath applied NMA (30μM). Lower set of records is after 45 mins of continuous activity. (Supported by NSF BNS-02838).

300.5 SEGMENTAL PROPERTIES OF THREE FORMS OF SCRATCH REFLEX IN THE SPINAL TURTLE: LOCALIZATION OF INPUT DERMATOMES AND CENTRAL PATTERN GENERATING ELEMENTS. L.I. Mortin and P.S.G. Stein, Biology Dept., Washington Univ., St. Louis, MO 63130.

The spinal turtle, immobilized via neuromuscular blockade, produces three distinct forms of the scratch reflex (J. Neurophysiol. 53:1533, 1985). We have investigated the organization of 1) the afferent inflow which initiates each scratch form, and 2) the localization of central pattern generator (CPG) elements within various spinal cord segments. The spinal cord of Pseudemys scripta elegans consists of the following segments: 8 cervical segments; 10 dorsal segments (D1-D10, equivalent to the mammalian thoracic and lumbar segments); 2 sacral segments (S1-S2); and about 16 caudal segments (Ca1-Ca16). All turtles are spinalized between D2 and D3, just posterior to the forelimb enlargement. The hindlimb enlargement consists of D8-D10, S1 and S2.

The rostral scratch receptive field is innervated by afferents entering D3-D6; the pocket scratch receptive field is innervated by D6-D8; the caudal scratch receptive field is innervated by Ca1, other caudal segments, and sometimes S2. There is a striking discontinuity in the innervation of the anterior part of the anal shield, ventral to the hip: spinal segments D8 and Ca1 innervate adjacent and overlapping regions of the shell and skin. Segments D8-S2 innervate the hindlimb skin.

The motor pattern for each scratch form consists of at least three phases of activity per cycle. Each scratch form can be produced if the five segments of the hindlimb enlargement are connected with a segment whose dermatome innervates some of the receptive field for that scratch. Removal of additional segments may affect parts of each scratch form's CPG. A rostral scratch is produced with D8-D10 connected to segments innervating the rostral receptive field; the posterior 40% of the enlargement is not needed for rostral scratch production. After removal of D10, leaving D8-D9 connected to more anterior segments, rostral scratches are produced with little or no hip retractor phase, but otherwise normal motor patterns. A pocket scratch motor pattern is produced with D7-D9 or D8-D10. D8-D9 alone produces a pocket rhythmicity with missing elements. These results imply that the pocket scratch CPG is distributed over the four segments D7-D10. A largely normal caudal scratch can be generated by the enlargement connected to more caudal segments. Removal of D8 reduces or eliminates the hip protractor phase of the caudal scratch motor pattern; further experiments will clarify the contributions of different segments to the caudal scratch. The entire enlargement is not necessary for the production of every scratch form. As few as 3 spinal cord segments can produce a normal scratch pattern. From these experiments we will determine the segmental localization of shared and unique elements of the CPG circuitry for each scratch form.

300.6 MOTOR PATTERNS EVOKED BY STIMULATION OF THE OPTIC TECTUM IN TWO SPECIES OF WEAKLY ELECTRIC FISH. J. Yuthas* (SPON:H. D. Christensen). Dept of Zoology, University of Oklahoma, Norman, OK 73019.

Previous studies have shown that electrical stimulation of the optic tectum results in orientation, escape or avoidance behaviors in toads (reviewed in Ewert, Burghagen and Schurg-Pfeiffer, Advances in Neuroethology 56A) and iguanas (Stein and Gaither, J. Comp. Neurol. 202:69).

Both the glass knife (Eigenmannia virescens) and the brown ghost (Apteronotus leptorhynchus) have relatively simple locomotor patterns. They propel themselves by generating sinusoidal waves along their anal fin. The direction of wave propagation can be from head to tail (forward swimming) or from tail to head (backward swimming). To quantify the swimming responses to tectal stimulation I glued the exposed skulls of anesthetized fish to a two-axis strain gauge. Responses to stimulation were also recorded on videotape. Fish responded to 0.5 sec trains of stimulus pulses at rates of 20 to 100Hz and amplitudes of 25-100uA with anal fin reversals or accelerations, body flexions and pectoral fin movements. No eye movements were observed. Stimulation in the rostral tectum caused backward swimming (reversal, negative forces). Stimulation in the caudal tectum caused an acceleration of forward swimming (positive forces). Constant intensity stimulations at several points along the caudal to rostral axis (the caudal-most point of the tectum was designated '0' the rostral-most was '100') showed that the response of the anal fin to stimulation changes from acceleration to reversal at 60 in Apteronotus and 66 in Eigenmannia. The largest positive forces (>0.7grams/gram fish) were found between 20 and 40. The largest negative forces (-0.5grams/gram fish) were found at about 70 in Apteronotus and at 85 in Eigenmannia.

In Apteronotus stimulation in the left tectum generally caused a body flexion that brought the tip of the fish's tail to the left of its longitudinal body axis. This response seemed to be independent of body position at the start of stimulation. As the stimulation site progressed from rostral to caudal the final position of the tip of the tail moved further anterior due to a decreasing radius of curvature of the bend. A mid-body flexion to the right often complicated the leftward tail flexion. Stimulation in the rostro-lateral tectum caused rigid braking movements of the pectoral fins. The pectoral fins can respond independently of each other and at more caudal stimulation sites complex rhythmic movements were evoked. The responses evoked by stimulation are site specific and appear to be avoidance responses. Supported by NIH grant #NS12337 to J. Bastian.

300.7 A MODEL OF PATTERN GENERATION OF INSECT WALKING RECONSIDERED. S.N. Zill, Dept. Anatomy, Univ. Colo. Med. Sch., Denver, CO 80262

Cockroaches that have been decapitated or that have cut thoracic connectives can show rhythmic bursting in motoneurons to intrinsic leg muscles. These preparations have been studied as models of walking (Pearson, Sci. Am., 235:72, 1976) and to evaluate the functions of leg proprioceptive sense organs. Several subsequent studies have, however, raised doubts as to whether motoneuron bursting in headless cockroaches actually reflects attempts at walking or other behaviors such as righting responses (Reingold and Camhi, J. Insect Physiol. 23:1407,1977) when an animal on it's back tries to turn upright. The present study was undertaken to 1) examine which behavior is associated with bursting in these preparations and 2) to determine the usefulness of this preparation in evaluating the functions of sensory inputs in walking.

Myographic recordings were taken conventionally from four muscles, the extensors and flexors of the trochanter and tibia, in the hindlegs of freely moving cockroaches. Animals were first released into an arena and motor activity in walking was recorded. To record righting responses animals were either picked up and placed on their backs or tripped while running. The same behaviors were re-examined after decapitation and cutting of thoracic connectives.

Intact cockroaches showed rhythmic activity in leg motoneurons during both walking and righting. However, the phase relations of bursting in synergist muscles of the two joints differed in each of these behaviors. In walking, bursting was tightly coupled in synergist muscles while phase relations were more variable in righting.

After decapitation or cutting of thoracic connectives, cockroaches walked extremely poorly and slowly (mean rate, 2.5 cm/hr + 1.4 SD) with severe discoordination of motoneuron bursting and extensive co-contraction of antagonist muscles. All animals, however, showed rhythmic bursting when placed on their backs, which resembled righting responses of intact preparations in phase relations of synergist muscles. Rhythmic activity was completely inhibited when animals were subsequently turned upright and had sensory inputs normally occurring in posture and locomotion.

It is therefore concluded that motoneuron bursting in these preparations does not represent attempts at walking but righting responses. Headless cockroaches may still be useful preparations for studying the motor mechanisms underlying both these behaviors but are not of value in testing the functions of leg sense organs.

300.8 HOMOLOGOUS PYLORIC MUSCLES ARE INNERVATED BY DIFFERENT MOTOR NEURONS THAT USE DIFFERENT NEUROTRANSMITTERS IN PANULIRUS AND CANCER. M.B. O'Neil*, S.L. Hooper, R.J. Wagner*, & E. Marder. Biol., Brandeis Univ., Waltham, MA 02254.

The motorneurons of the pyloric system of the stomatogastric ganglion of decapod crustaceans function both to excite the muscles of the animal's stomach and to participate in the generation of the foregut motor patterns. These neurons were named and identified on the basis of which muscles they innervate (Maynard & Dando, Phil Trans Roy Soc Lond B, 1974). In Panulirus interruptus there are two PD neurons that innervate two sets of extrinsic muscles (one attachment on an ossicle of the stomach; the other on the hyperdermis). Although the pyloric rhythm in the crab, Cancer borealis, is almost indistinguishable from that of Panulirus, there are four neurons in the crab that fire together and were called PD neurons (Hermann, J. Comp. Physiol., 1979). We now find that these 4 PD neurons fall into two classes that innervate different muscles. Two of these PD neurons ($PD_{in}$) innervate intrinsic muscles p.4, p.7, and p.10 (both attachment points on ossicles of the pyloris) of the pyloric region that are innervated by PY neurons in Panulirus. Two PD neurons ($PD_{ex}$) are homologous to the PD neurons in Panulirus and innervate extrinsic muscles .

The data that support these conclusions are: a) action potentials arising in any Cancer PD neuron can be recorded extracellularly only in either the nerve innervating the $PD_{in}$ or that innervating the $PD_{ex}$ muscles, b) suction electrode stimulation of the lvn in which all four PD neurons send their axons while recording intracellularly from $PD_{in}$ and $PD_{ex}$ muscles results in four different threshold voltages for the production of excitatory junctional potentials (EJPs), two which evoke EJPs only in the $PD_{in}$ muscles and two which evoke EJPs only in the $PD_{ex}$ muscles, and c) hyperpolarization of any one PD neuron only removes EJPs in either the $PD_{in}$ or $PD_{ex}$ muscles.

Since in Panulirus the PY neurons are glutamatergic and the PD neurons are cholinergic, the transmitter used by the two Cancer $PD_{in}$ neurons was determined. Bath application of $10^{-4}$M carbachol produced a large depolarization and conductance increase in $PD_{in}$ muscles. The amplitude of EJPs recorded in $PD_{in}$ muscles evoked by suction electrode stimulation of the $PD_{in}$ axons was reversibly decreased 60-80% by bath application of $10^{-4}$M tubocurare.

We conclude that these anatomically homologous muscles are innervated by different types of neurons (and thus contract at different times in the motor pattern) in Cancer and Panulirus, and that a switch in neurotransmitter receptivity has occurred in these muscles. Research supported by NS-17813 to E.M.

300.9 MOTONEURONAL AND MUSCULAR CONDITIONAL OSCILLATORS COOPERATE TO ORGANIZE CRUSTACEAN RHYTHMIC PYLORIC DILATIONS. P. Meyrand* and M. Moulins. Lab. de Neurobiologie et Physiologie Comparées, place Peyneau, F-33120 Arcachon, France.

In Crustacea, rhythmic movements of the pyloric chamber are driven by an oscillatory network which consists almost entirely of motoneurons. Among these the 2 PD motoneurons, which innervate the pyloric dilator muscles (cpv), are conditional endogenous bursters (Moulins, M. & Cournil, I. J. Neurobiol., 13:447, 1982); Miller, J. & Selverston, A.I. J. Neurophysiol., 48:1378, 1982) i.e. they express their endogenous oscillatory activity only under extrinsic neuromodulatory influences. We show here that the cpv muscles themselves are conditional endogenous oscillators which can be entrained by the rhythmic output of the PD motoneurons.

After denervation, the cpv muscles of shrimps (Palaemon serratus) and rock lobsters (Homarus gammarus) can show two different states : one where they are quiescent and one in which they continue to contract rhythmically. It is always possibe to switch from the quiescent state to the oscillatory state by bath application of $10^{-6}$M dopamine. In the oscillatory state (occuring spontaneously or pharmacologically induced) each contraction is associated with a slow membrane potential oscillation on which fast spikes are superimposed.

This oscillatory behavior seems to be an intrinsic property of the muscle itself since : (1) the frequency of the oscillations is voltage-dependant ; (2) a brief depolarization of a muscle fibre provokes a full, large and long duration oscillation and (3) the ongoing spontaneous oscillatory behavior can be reset by a brief electrical stimulation of the muscle. Furthermore this oscillatory behavior appears to be conditional in that total isolation by bath application of $10^{-5}$M tetrodotoxin abolishes the oscillations which are restored however by addition of dopamine.

When the cpv muscle is in the oscillatory state its rhythmic activity can be entrained either experimentally by phasic stimulation of the appropriate motor nerve or spontaneously by the endogenous burst activity of the PD motoneurons. It has been shown previously that the PD neurons are themselves entrained by higher order oscillatory interneurons (CP) (Moulins, M. & Nagy, F. J. Physiol. Paris, 78:755, 1983). Our results suggest that the final rhythmic dilatory behavior of the pyloric chamber is organized by a cascade of three endogenous oscillators (a premotor oscillator, a motoneuronal oscillator, and a muscular oscillator) at least two of which are conditional oscillators.

300.10 CHOLINERGIC INPUTS REDUCE A STEADY OUTWARD K+ CURRENT ALLOWING ACTIVATION OF A CA2+ CONDUCTANCE WHICH UNDERLIES THE BURST-GENERATING OSCILLATIONS IN LOBSTER PYLORIC NEURONS. F. Nagy, J.A. Benson and M. Moulins Lab. de Neurobiologie et Physiologie Comparées, place Peyneau F-33120 Arcachon, France.

The rhythmic activity of the pyloric neuronal network of the Cape lobster (Jasus lalandii) is due to the ability of the neurons to produce slow, regenerative oscillations which underly their bursting discharge. This ability depends on neuromodulatory inputs from premotor centers. One of these inputs (APM, the Anterior Pyloric Modulator neuron) is cholinergic and involves muscarinic receptors (Nagy, F. and Dickinson, P.S., J.exp.Biol., 105:33, 1983). It was shown previously that the capacity to produce rhythmic slow oscillations results from the activation of voltage-dependent Ca2+ channels (Nagy, F., Benson, J.A. and Moulins, M., Soc. Neurosci. Abs., 10:148, 1984). We now present evidence that this activation is indirect and depends on the reduction by cholinergic inputs of a steady outward current. After deafferentation of the stomatogastric ganglion (which contains the pyloric network) by bath application of $10^{-7}$M tetrodotoxin (TTX) the slow regenerative rhythmic oscillations of the pyloric neurons disappear. Superfusion with oxotremorine, a muscarinic agonist, induces a steady depolarization and subsequently restores the slow regenerative oscillations. In the presence of Ca2+ channel blockers (Mn2+ and Cd2+), oxotremorine does not provoke the regenerative events but still causes the same amount of steady depolarization. Since this depolarization is insensitive to TTX and Ca2+ channel blockers, the possibility of a reduction in a steady outward K+ current by the muscarinic agonist was investigated. In earlier experiments we injected TEA, a K+ channel blocker, into one of the pyloric pacemaker (PD) but this treatment does not mimic the effects of oxotremorine i.e. does not evoke the slow regenerative oscillations. However, the PD neuron is one of a group of three strongly electrically coupled pacemakers : it is thus possible that the membrane of the single TEA-injected neuron was held at a constant potential (subthreshold for oscillation) by the two non-injected neurons. TEA was therefore injected into all three neurons simultaneously. In the presence of TTX the injected neurons then exhibited regular oscillations. Thus blockade of the K+ channels of the neurons (by intracellular injection of TEA) mimics the action of oxotremorine. The oscillations induced by TEA are still blocked by Mn2+. However the three neurons are depolarized and addition of oxotremorine does not depolarize the neurons further. This suggests that induction of oscillations by either TEA injection or oxotremorine exposure occurs via the same mechanism, namely a reduction in a steady K+ conductance. From these observations, we propose that activation of muscarinic receptors of the pyloric neurons reduces a substhreshold outward K+ current allowing activation of a voltage-dependent Ca2+ current which causes the production of burst-generating oscillations.

300.11 GABAERGIC INACTIVATION OF BURST GENERATING OSCILLATIONS IN LOBSTER PYLORIC NEURONS. J.R. Cazalets*, I. Cournil* and M. Moulins (SPON: F. Nagy). Lab. de Neurobiologie et Physiologie Comparées, place Peyneau F-33120 Arcachon, France.

Rhythmic motor output of the rock lobster pyloric network of the stomatogastric ganglion (STG) results from the ability of the neurons to produce slow regenerative oscillations which underly their firing in periodic bursts. However these properties, although endogenous, are expressed only under the influence of neuromodulatory inputs descending from premotor centers. Until now all such modulatory influences described cause activation of the oscillatory behavior of the pyloric neurons (see Nagy, F. et al., Abstract this meeting). Here we show that inactivation of the oscillatory behavior can be produced by GABAergic inputs to the STG.

Bath application of $10^{-4}$M GABA to the STG suppresses burst generating oscillations in all the pyloric neurons, i.e. the pyloric dilator neurons no longer produce oscillations while the pyloric constrictor neurons are no longer able to generate plateau potentials. The same effects can be obtained by bath application of $10^{-5}$M muscimol, a GABA agonist. Conversely prior application of GABA antagonists (bicuculine, picrotoxin) protects the pyloric neurons against GABA exposure. All these pharmacological effects are reversible. Moreover GABA seems to act directly on the pyloric neurons themselves. After isolation of the STG neurons by bath application of $10^{-6}$M tetrodotoxin and subsequent induction of oscillations in the pyloric neurons by bath application of a muscarinic agonist ($5.10^{-6}$M oxotremorin, see Nagy, F. and Dickinson, P.S. J. exp. Biol. 105:33, 1983) GABA superfusion of the STG still causes suppression of oscillation.

Parallel to this pharmacological study we have obtained evidence which shows that the STG receives GABAergic inputs. Firstly, an immunohistochemical study using an antibody against GABA reveals immunoreactive fibres in the single input nerve to the STG and profuse ramification of axon terminals in the STG neuropile. Moreover no cell body in the STG appears to be GABA immunoreactive. Secondly, a radio-enzimatic assay demonstrates a strong glutamate decarboxylase activity in the STG (10 times higher than in the remainder of the nervous system) further suggesting that GABA is synthesised in the STG.

These results suggest that GABAergic inputs to the STG are able to inactivate the burst generating oscillations of the pyloric neurons. Thus the pyloric neurons appear to be exposed to two different neuromodulatory influences : inductive inputs which are able to unmask their oscillatory behavior and suppressive inputs which are able to mask their oscillatory behavior.

300.12 OPERATION OF THE STOMATOGASTRIC NERVOUS SYSTEM IN SITU: MODULATION AND FUNCTION OF PYLORIC MOTOR PATTERNS. B.C. LaMon and J.P. Miller. Zoology Dept., University of California, Berkeley, 94720.

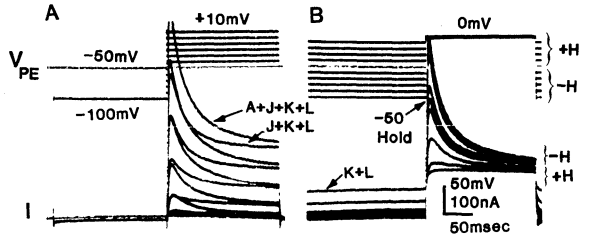
The stomatogastric nervous system of the spiny lobster, Panulirus interuptus, has received intensive investigation as a model system for the study of pattern generation. The stomatogastri ganglion(STG) is located in the lumen of the anterior aorta and contains the cell bodies of two central pattern generators(CPGs) that control the activities of the gastric mill and pylorus regions of the foregut. Studies utilizing isolated ganglion preparations have recently characterized the network connectivity and intrinsic cellular properties of the stomatogastric CPGs. We have now developed an in situ preparation from which we can record the motor patterns of the pyloric CPG with all sensory, CNS and neuromuscular connections intact. In order to maintain a viable preparation it is necessary to cannulate and perfuse the anterior aorta with fresh saline solution. By appropriate selection of multiple recording sites, the activity of the motorneurons innervating each of the muscles involved in pyloric function can be separately identified. Comparison of in situ and isolated ganglion motor patterns shows that the patterns are qualitatively similar with respect to the sequence of neuromuscular activity. However, in situ preparations reveal a far greater repertoire of motor patterns involving substantial variation in cycle frequency, burst parameters(phases,durations, spike frequencies) and the number of cell types participating in the rhythm. We will describe a previously unreported modulation of the pyloric pattern which occurs during midgut peristalsis as well as pattern alterations produced by stimulation of sensory nerves. Systematic changes in perfusion rate, temperature and oxygenation were also found to have substantial pattern effects, indicating that experimental control of these variables is important for physiological studies of the pyloric CPG. Diagrams presenting the anatomy and mechanics of the pylorus will describe the function of pyloric movements. The expression of different motor patterns by the pyloric CPG will be evaluated with respect to the physiological mechanisms proposed to account for pattern generation in this system. (Supported by grants NIH-NRSA NS-06979 and NSF BNS-8202416.)

300.13 VOLTAGE CLAMP STUDIES OF ISOLATED SOMATA FROM IDENTIFIED PATTERN GENERATOR NEURONS IN THE LOBSTER STOMATOGASTRIC GANGLION.
D.K. Hartline, J.Y. Palacio* and D.V. Gassie*, Bekesy Lab, Univ. of Hawaii, Honolulu, HI 96822

We extended the study of Graubard and Hartline (Soc. Neurosci. Abstr. 10:1073, 1984) to ligatured pyloric somata using a 2-microelectrode voltage clamp. Somata had rest potentials more negative than intact neurons, and input resistances up to 25 Mohms (3-6 Mohms more usual). They were devoid of obvious inward current but exhibited at least 3 outward currents: 1) $I_J$: $Ca^{++}$ dependent inactivating current elicited from a standard hold of -50(mV) by test steps above -25; magnitude up to 500 nA at 0 mV; inactivation increased for holds from -45 to 0 (+H, Fig. B); 2) $I_A$: $K^+$ dependent inactivating current activated by steps above -45 from hold levels or 200 msec conditioning pulses below -50; magnitude up to 600 nA at 0 mV; inactivation increased with holds from -90 to -50 (-H, Fig. B) 3) $I_K$: inactivation-resistant current activating slowly above -25 mV and persisting when $I_J$ is eliminated; magnitude up to 100 nA at 0 mV. Fig. A shows activation, B inactivation of these currents.

$I_J$ was very susceptible to elimination or permanent inactivation in damaged somata. Decreases in $I_J$ by blockers or inactivation were frequently associated with increases in $I_A$. Two time-constants of inactivation of $I_A$ (ca 30 and 300 msec) and at least 2 for $I_J$ (ca 30 and 3000 msec) were observed. $I_A$ was particularly prominent in PD and some PL somata; it was small in IC, VD, and some LP somata. The slowly-inactivating component of $I_J$ was prominent in PD; the rapidly-inactivating component in "followers" (LP, PL, PE, IC, VD). The residual $I_K$ was more prominent in LP than in PD. Differences in prominence of $I_A$ may contribute to differences in phase relations in the patterned output. $I_J$ may control depolarization during plateaus.

Supported by NIH NS15314.



300.14 INTRACELLULAR ANALYSIS OF UROPOD STRETCH RECEPTOR INPUT IN THE TERMINAL GANGLION OF THE CRAB EMERITA ANALOGA.
D. H. Paul. Biology Department, University of Victoria, BC V8W 2Y2

Extracellular recordings from roots of the 6th abdominal ganglion of Emerita revealed complex motor reflexes elicited by tension applied to the uropod stretch receptors, of which 4 non-spiking sensory receptors (NSSR) constitute the principle component. Injection of long current pulses intracellularly into individual NSSRs produced qualitatively similar motor reflexes (Paul, Science 176: 680-682). This observation suggests that input from all 4 NSSRs converges on the same set of premotor interneurons that orchestrate the reflexes. Furthermore, one interpretation of results of other experiments, in which electromyograms associated with uropod beating were compared before and after bilateral receptor ablations, is that those neurons coordinating the reflexes are themselves part of the central pattern generator (Paul, J. exp. Biol.65: 243-258; J. Neurobiol.10: 273-289). In order to test this hypothesis I have begun to trace the afferent signals through the ganglion by recording intracellularly from and injecting dye into neurons whose activity is affected by stretch applied to the uropod receptors. These include motoneurons (MN) and local interneurons (IN). Simultaneous intracellular recordings from an NSSR and certain MNs reveal that polarization of the MNs' membranes is very sensitive to the amount of tension on the receptor strand. Some, including the power-stroke excitor and return-stroke peripheral inhibitor, depolarize, whereas others, including one of the return-stroke excitors, hyperpolarize in parallel with depolarization of the recorded NSSR, there being no apparent threshold for these responses. Whether any of the MN depolarizations are mediated monosynaptically is not yet known. Among the INs, one spiking bilateral neuron has a particularly provocative behavior. It receives tonic IPSPs from an unidentified source that appear to be modulated in frequency by NSSR input; however, the neuron also undergoes apparently smooth hyperpolarizations during stretch of the receptor ipsilateral to its soma. Following release from hyperpolarization, caused either by the afferent input or by current injection, this IN generates trains of bursts (3 to >30 bursts/hyperpolarization, N=7; periods/train of 0.3±0.1s to 2±1s, N=87). This post-hyperpolarization bursting does not elicit motor output, but it could provide phasic reafference to the pattern generator during uropod beating. It might also contribute to generation of the rhythmic motor pattern in isolated nerve cords if the frequency of the IPSPs the neuron receives were modulated during this activity; and if this were the case, the neuron's structure would suit it for a role in bilateral synchronization of motor output.

300.15 DUAL ACTION OF SEROTONIN ON SWIMMING IN TRITONIA.
P.A. Getting, A.D. McClellan and M. Li*. Department of Physiology & Biophysics, University of Iowa, Iowa City, IA 52242.

To assess the potential involvement of various neurotransmitter substances in the generation and modulation of escape swimming in Tritonia, we tested the effects of 12 pharmacological agents. Substances were injected into the hemocoele of whole animals or were bath applied to isolated brain preparations. Swimming was elicited in the whole animal by application of 1 ml of 3M NaCl to the dorsal epithelium or, in the isolated brain, by electrical stimulation of a peripheral nerve. For the behavioral experiments, swimming was quantified by counting the number of ventral flexions. In isolated brain preparations, intracellular recording from flexion neurons was used to assess swim activity. Four agents (glycine, histamine, proctolin, and FMRFamide) had no effect on swimming at concentrations up to $10^{-3}$M. Swimming was inhibited by 7 other agents (dopamine, octopamine, aspartate, glutamate, carbacol, pilocarpine, and $SCP_B$).

Serotonin (5-HT) had a dual effect on swimming. At concentrations above $10^{-3}$M, 5-HT application elicited a swim within two minutes in the absence of peripheral stimulation. This initial swim bout was followed by a prolonged period of inhibition lasting up to 24 hrs. The extent of the inhibition was dose dependent with a threshold of $5 \times 10^{-6}$M and a maximal effect at $10^{-3}$M. At the higher concentrations, swim activity was completely blocked. The 5-HT antagonist, methysergide (10ug/ml), caused a significant reduction in the number of cycles per swim and in the extent of the dorsal flexions. Injection of 5,7-dihydroxy-tryptamine at doses of 22-220 ug/gm body weight also caused a marked reduction in both the number of cycles and the magnitude of the dorsal flexions. These data suggest that the activation of 5-HT receptors was sufficient and necessary for the expression of the normal swim pattern.

Potential serotonergic neurons were localized using an antibody to 5-HT (Immuno Nuclear Corp)(rhodamine labelled IgG). Five neurons in the region of the swim pattern generator interneurons were stained by this antibody. Intracellular injection of identified neurons with Lucifer yellow prior to antibody staining indicated that 3 of the 5 neurons were dorsal swim interneurons (DSI). These interneurons form a necessary part of the central pattern generator network for swimming (Getting, P.A. et al., J. Neurophysiol., 44, 151-164, 1980) and appear to use 5-HT as a transmitter. Supported by NIH research grant NS17328.

300.16 INHIBITORY MOTOR NEURONS ARE PART OF THE NETWORK WHICH GENERATES LEECH (HIRUDO) SWIMMING ACTIVITY.
W. O. Friesen. Department of Biology, University of Virginia, Charlottesville, VA 22901.

Three essential properties characterize all elements of neuronal network oscillators: 1) membrane potential oscillations are present, 2) intracellular current injection acts to shift the activity phase of the other elements in the circuit and 3) connections occur with other neurons of the oscillator circuit. Leech oscillatory interneurons described previously exhibit all three properties and are therefore considered to be members of the network generating the swimming rhythm (Friesen, Poon and Stent, J. Exp. Biol. 75, 1978; Weeks, J. Comp. Physiol. 148, 1982; Friesen, J. Comp. Physiol. 156, 1985). A motor neuron, cell 1 (a Dorsal Inhibitor 'DI'), which exhibits the first two properties was not considered previously to be a member of this network. Recent experiments show that cell 1 also exhibits the third property; namely, cell 1 (and a second DI, cell 102) displays synaptic interactions with cell 115, a recently discovered oscillatory neuron of the swim network.

Cell 115 is a paired intersegmental interneuron found on the dorsal aspect of most (perhaps all) segmental ganglia. It exhibits all three properties of oscillator elements. 1) Its soma potential undergoes 10 mV oscillations which are phase-locked ($0^o$ phase) to oscillations in the swim network. 2) Injection of depolarizing current into cell 115 shifts the phase of the swimming rhythm. 3) Cell 115 exhibits strong (probably monosynaptic) inhibitory interactions with cell 28 and receives strong (probably monosynaptic) excitatory input from cell 208, both of which are neurons in the swim network. Cell 115 also receives monosynaptic excitatory input from swim-initiating neurons (cells 204/205).

The two DI motor neurons are linked to cell 115 via strong reciprocal inhibition, thus forming a subcircuit which could contribute to oscillation generation. The inhibitory connections of DI neurons to cell 115 also provide a pathway by which depolarization of these cells can act to shift the phase of the swimming rhythm. Because of these new results, the DI motor neurons must be considered elements of the network which generates the swimming rhythm of the leech. Therefore this oscillator network includes both interneurons and inhibitory motor neurons. Supported by NSF grant BNS81-10243.

301.1 SIZES AND INTRANUCLEAR DISTRIBUTION OF RUBROSPINAL NEURONS IN THE RAT. D. Bulyalert* and D.R. Humphrey (SPON: D.J. Reed). Lab. of Neurophysiology, Emory Sch. of Med., Atlanta, GA 30322.

On the basis of relative cell sizes, the red nucleus of the monkey, the cat and the rat can be divided into a rostral parvocellular and a caudal magnocellular division. In the monkey, rubrospinal fibers originate exclusively from medium and large sized neurons in the magnocellular division (Smith & Courville, Neurosci. Abstr., 2: 551), whereas in the cat, rubrospinal fibers originate also from small and medium sized neurons in the parvocellular division (Pompeiano & Brodal, J. Comp. Neurol., 108: 225). In the rat, rubrospinal fibers are known to originate from all portions of the nucleus (Shieh et al, J. Comp. Neurol., 214: 79), but the relative contribution from neurons of different sizes and their intranuclear distribution have not been studied in detail. It is the purpose of this presentation to provide such data.

Injections of 1% WGA-HRP were made into the cervical (C4, N=2) or lumbar (L3, N=2) spinal cords of adult, Long-Evans rats. After survival periods of 48 hr, the animals were perfused transcardially with saline, followed by 2.5 % glutaraldehyde in phosphate buffer. The tissue was processed with a modification of the TMB method developed by Mesulam (Gibson et al, Brain Res., 298:235), and all sections were counterstained with thionin. Cell sizes were measured only in labeled neurons with visible processes and nuclei. Our major findings were as follows. (1) As reported for other species, cells projecting to cervical levels were found dorsomedially within the nucleus, whereas those projecting to lumbar levels were found ventrolaterally. (2) Projections to both the cervical and to the lumbar level originate, however, from the entire rostrocaudal extent of the nucleus, with an increasing density of projection neurons in the rostral-to-caudal direction. (3) Cells of all sizes are found throughout the nucleus, but small (soma dia. $<20\mu$) to medium (20-25$\mu$) cells predominate in the rostral one-third, medium-sized cells in the middle one-third, and large (26-40$\mu$) to giant-sized ($>40\mu$) cells in the caudal one-third of the nucleus. (4) At any rostrocaudal level within the red nucleus, the size distribution of labeled rubrospinal neurons was similar to that for all nuclear cells found at that level; i.e., projections originate from cells of particular sizes in proportion to their numerical density at that rostrocaudal level. (5) At any rostrocaudal level, however, the average or median size of neurons projecting to lumbar levels is slightly greater than that of neurons projecting to cervical levels. (Supported by NIH Grant NS 10183).

301.2 IDENTIFICATION OF SENSORY AFFERENTS TO RED NUCLEUS AND THEIR SPINAL PATHWAY, IN THE CAT. D. Bourbonnais* and Y. Padel. Lab. of General Neurophysiology, CNRS, INP, B.P. 71, 13402 Marseille Cedex 9, France.

In mammals, the caudal red nucleus (RN) receives converging influences from both the contralateral nucleus interpositus of the cerebellum and from the ipsilateral motor cortex. It has been shown that the RN receives a third input from the periphery via fibres or collaterals of fibres running in the dorsal columns of the spinal cord (Padel Y. & Jeneskog T., Neurosci. Lett., 21:177-182, 1981). The present experiments were designed to identify the types of primary afferents responsible for the sensory responses in red nucleus cells and to locate the spinal pathway relaying the dorsal column fibres.

Cats were anaesthetized with chloralose (60 mg/kg I.V.), decorticated and the brachium conjunctivum was cut stereotaxically in order to remove cerebral and cerebellar inputs to red nucleus. The rubrospinal neurones were intracellularly recorded with glass micropipettes filled with saturated solution of $Na^+$ citrate.

When graded stimulation was applied to cutaneous nerves, the responses of RN cells started with low current (1.5 T) and their amplitudes increased with currents reaching 10 T. This indicates that different types of cutaneous receptors contribute to the red nucleus response. When muscular nerves were stimulated, currents over 2.5 T were necessary to obtain responses. This seems to exclude any participation of group I afferents.

Large transversal lesions of the dorsal part of the spinal cord at cervical level did not prevent the sensory responses in red nucleus cells. Moreover, systematic mappings with microstimulation of the spinal cord and brain stem showed that the sensory pathway runs ventromedially in the spinal cord and that its fibres are intermingled with lemniscal fibres in the brain stem. However, repeated spinal stimulation induced a progressive decrease of the amplitude of the responses, although brain stem stimulation gave short latency monosynaptic EPSPs. This indicates that at least some of the spinal afferents are not projecting directly to the red nucleus. They are relaying in the upper spinal cord or in the caudal brain stem at synapses subjected to inhibitory influences.

301.3 LOCALIZATION OF SEROTONERGIC MEDULLARY RAPHE NEURONS PROJECTING TO THE LUMBAR SPINAL CORD IN THE CAT. S.J. Fung, V.K. Reddy,* R.M. Bowker and C.D. Barnes. Dept. of VCAPP, College of Veterinary Medicine, Washington State Univ., Pullman, WA 99164

Serotonin-immunoreactive (5-HT) neurons have been localized in the medullary raphe nuclei of the cat (Jacobs et al., 1984) and so also the projections of the medullary raphe neurons to the spinal cord have been demonstrated by retrograde labeling with horseradish peroxidase (Martin et al., 1978). However, 5-HT neurons of the medullary raphe nuclei of the cat that project to the lumbar spinal cord have not been localized. These neurons were observed using a retrograde transport method combined with immunocytochemical techniques.

Laminectomy was performed in anesthetized cats at vertebra L5 and a 25-50% solution of HRP was injected bilaterally into the $L_7$ segment of the spinal cord. Following a 3-day survival period, the animals were reanesthetized and perfused with physiological saline followed by 3.8% paraformaldehyde in 0.1M phosphate buffer. 30% buffered sucrose solution was infused after fixation to prepare the brain stem for sectioning. The brain stem was sectioned on a freezing microtome followed by reacting the sections in 3,3' diaminobenzidine hydrochloride and $H_2O_2$ after preincubating them in 0.5% $CoCl_2$. The sections were then incubated in serotonin antiserum (1:3,000 dilution) and were further processed by immunoperoxidase method.

In the cats, 5-HT neurons projecting to the lumbar spinal cord contained homogenous brown staining cytoplasm and the HRP reaction was seen as black punctate granules distributed throughout the soma and the proximal parts of the dendrites. These double labeled cells (5-HT and HRP) were small to medium sized neurons and were either fusiform or multipolar in shape. They were observed in all three medullary raphe nuclei-nucleus raphe obscurus, nucleus raphe pallidus and nucleus raphe magnus. A few multipolar neurons exhibited HPR reaction product but did not stain for serotonin. In representative sections, the numbers of spinally projecting neurons in the raphe nuclei were counted. These preliminary counts suggest that 69.0% (96 of 139 neurons counted) of the HRP filled neurons also stained for serotonin immunoreactivity. These observations correlate well with similar findings in monkey and rat (Bowker et al., 1982; 1983).

301.4 CYTOARCHITECTONIC/CYTOCHEMICAL FEATURES OF THE NUCLEUS TEGMENTI PEDUNCULO-PONTINUS (NTPP) IN THE RAT ARE DISTINCT FROM 'EXTRAPYRAMIDAL' PROJECTIONS TO THE MESOPONTINE TEGMENTUM. D.B. Rye, C.B. Saper, and B.H. Wainer. Dept. Pharm. and Phys. Sciences, Univ. of Chicago, Chicago IL, 60637.

A cytoarchitectonic delineation of the NTPP has been established only in the primate brainstem. Terminal labeling of nigral and other 'extrapyramidal' efferents to the tegmentum has been associated with the NTPP in the feline and rodent. A correlation between the area of the tegmentum in receipt of these projections and any recognizeable cell group(s) (i.e. the NTPP) has not been established. Since previous delineation of the nuclear pattern of the mesopontine tegmentum has engendered considerable inconsistency and confusion, the cytoarchitecture and cytochemistry of the NTPP was investigated employing coronal, horizontal and sagittal sections of the rat brainstem stained for Nissl substance alone, and in combination with choline-acetyltransferase (ChAT) and/or tyrosine-hydroxylase immunohistochemistry. Cytoarchitectonic criteria, the presence of large, multipolar cholinergic neurons, and other cytochemical features distinguish the NTPP from the substantia nigra (SN)/A9 and retrorubral field (RRF)/A8 rostrally, cells embedded within the decussation of the brachium conjuctivum (DBC) medially, lateral lemniscal nuclei laterally, the nucleus cuneiformis dorsally, the pontine oralis ventrally, and the parabrachial nucleus caudally. Nigral and pallidal efferents were then labeled employing autoradiographic tracing or WGA-HRP in combination with ChAT immunocytochemistry, in order to establish their relationship to the NTPP. In both cases, labeled fibers exit the SN laterally and immediately assume a position in the RRF/A8, dorsomedial to NTPP. Fibers continue through the DBC medial to the middle third of the NTPP, and encounter only a medial portion of the NTPP in its caudal third. Labeled fibers were conspicuously absent within a caudal, dorsolateral compact portion of the NTPP. In summary, the NTPP is a readily demarcated nucleus within the rat brainstem comprising a population of cholinergic neurons that is not completely delimited by nigral or pallidal efferents. Supported by The McKnight Foundation and USPHS 5T32-GM07281, HD-0453,NS-17661,NS-00631,and NS-18669.

301.5 ORGANIZATION OF CORTICORETICULAR PROJECTIONS IN THE RAT. D.B. Newman*, Department of Anatomy, Uniformed Services University, Bethesda, Maryland 20814-4799.

A mounting body of evidence suggests that the mammalian brain stem reticular formation exhibits an organization which is far more complex than previously thought. Recent studies by this investigator suggest, for example, that at least twenty-six brain stem reticular nuclei or subnuclei of the rat send fibers to the spinal cord. These nuclei can be distinguished on the basis of several criteria, particularly cytoarchitectonics and dendroarchitectonics. The variegated dendritic ramification patterns observed when comparing one reticular nucleus with another suggests that these reticular nuclei may receive distinct or characteristic sources of afferent inputs. To test this hypothesis, one class of reticular afferent systems, namely, corticoreticular fibers, were examined in detail. Small volumes (900 nl) of 1% horseradish peroxidase-wheat germ agglutinin (HRP-WGA) conjugate were stereotaxically injected into various cortical regions of anesthetized adult albino or hooded rats. The animals were allowed to survive two to three days, and then were anesthetized and perfused with aldehyde fixatives. The tissue was reacted with tetramethylbenzidene histochemistry and examined with polarized light microscopy for the presence of HRP-WGA-filled corticoreticular terminals. The data to date suggest that corticoreticular fiber systems exhibit a high degree of specificity, i.e., certain reticular nuclei or subnuclei receive a much heavier corticoreticular input than others. Furthermore, the various corticoreticular fiber systems tend to respect the reticular nuclear or subnuclear boundaries delineated previously by this author on the basis of cytoarchitectonic or dendroarchitectonic criteria. Finally, the pattern of corticoreticular labeling varies when comparing one cortical injection site, e.g., motor cortex, with another, e.g., somatosensory cortex. Taken together, these data lend credence to the hypothesis that the mammalian brain stem reticular formation is a heterogeneous, highly complex assemblage of discrete nuclei, each with its own particular cytoarchitectonics, hodology and function. (Supported by USUHS Grant R07059.)

301.6 CONTROL OF ATONIA ELICITED BY STIMULATION OF THE MEDIAL MEDULLA. Y. Y. Lai and J. M. Siegel. Neurobiol. Res., VAMC Sepulveda, CA 91343 and Dept. of Psychiatry, UCLA School of Medicine, Los Angeles CA 90024.

Stimulation of the medial medullary reticular formation (MMRF) produces atonia of the antigravity muscles in decerebrate animals. Activation of this area is believed to be responsible for muscle atonia during REM sleep. We have found that MMRF-induced muscle atonia can be inhibited or reversed by administration of sodium nitroprusside, which decreases systemic blood pressure. The present experiment was aimed at further investigating the mechanisms controlling the MMRF-induced muscle atonia.

The experiment was performed on decerebrated, unanesthetized cats of either sex, weighing 2.5-4.0 kg. The animals were decerebrated at the precollicular level under halothane-oxygen anesthesia. Balloon tipped catheters were inserted into the descending aorta and inferior vena cava for nonpharmacological manipulation of blood pressure. Bipolar electrodes were implanted into the splenius, occipitoscapularis, and triceps brachii muscles bilaterally. A stainless steel monopolar microelectrode or concentric bipolar electrode was placed in the medial medulla at P 8.0 to 13.0, L 1.0, and D -6.5 to -9.0. The stimulation frequency and intensity was varied from 20 to 150 Hz and 10 to 800 uA, respectively. A 300 msec train of 0.2 msec rectangular pulses was delivered to MMRF. Electromyograms were recorded by a Grass polygraph and digitized for computer analysis. Pulse triggered averaging was used to analyze the effect of MMRF stimulation on neck muscle activity.

The results showed: 1) there is an optimal stimulation intensity at each frequency for the MMRF-induced muscle atonia. Optimal current levels ranged from 30 to 100 uA. 2) the inhibitory effect of MMRF stimulation on muscle activity is more prominent in the contralateral side than in the ipsilateral side ($p < 0.01$, sign test). 3) Decreasing the blood pressure by inflation of a balloon in the inferior vena cava induced the reversal of response of muscle tone to the MMRF stimulation, while increasing the blood pressure by occlusion of the descending aorta had no effect. Therefore, the reversal response can be induced by blood pressure reduction, and does not require any other pharmacological action of sodium nitroprusside.

These results lead us to hypothesize that two intermixed populations of neurons, having inhibitory or facilitatory effects on muscle tone, are present in the MMRF. These cell groups have different sensitivity to electrical stimulation and have opposite response to blood pressure change.

301.7 HETEROGENEITY OF RETICULAR FORMATION PROJECTIONS FROM THE MEDULLA TO THE DIENCEPHALON. R. Waltzer* and G.F. Martin (SPON: E. Michal). Department of Anatomy, The Ohio State University, Columbus, Ohio 43210.

The study reported here was designed to determine whether connectional heterogeneity is characteristic of the projections from the medullary reticular formation (RF) to the diencephalon of the North American opossum. Three experimental paradigms were used to address this question. In the first, large injections of horseradish peroxidase (HRP) were made into the diencephalon of anesthetized opossums. Such injections labeled neurons in all nuclei of the medullary RF and raphe except for the raphe pallidus. These results provided a framework for the second paradigm in which we examined autoradiographic cases with injections of 3H-leucine in many of these medullary nuclei. Similarities and differences were noted in the location and density of diencephalic labeling. In all cases orthograde labeling was present within the pretectum (PrT), the parafascicular (PF) and central nuclei of the thalamus as well as the lateral hypothalamic area (HyL) and zona incerta. Labeling in the PrT was dense after injections in the nucleus reticularis gigantocellularis (RGc) and the adjacent nucleus reticularis gigantocellularis-pars ventralis (RGcv), but sparse after injections of the nucleus reticularis lateralis (RL). In contrast, injections of the RL produced the heaviest labeling within medial hypothalamic areas. When the injection included the RL or raphe magnus, autoradiographic labeling was also found in the ventrobasal nucleus of the thalamus. Data derived from these studies provided the basis for the third group of experiments in which injections of HRP or lectins conjugated to HRP were confined to specific diencephalic areas labeled in the autoradiographic cases. Injections which included the HyL or PF resulted in retrograde cell labeling in most nuclei of the medullary RF. In contrast, injections of other diencephalic nuclei often produced more restricted RF labeling. For example, only the RL, RGc, and RGcv were labeled after a PrT injection. Our results suggest that some RF nuclei of the medulla project to widespread areas of the diencephalon but that certain of these projections are more dense in some cases than in others. The connectional heterogeneity observed in these studies may subserve the functional diversity of the RF reported by others (Siegel, Brain RS. Rev. 1:69 '79). It is our intent to utilize opossums, because of their unique embryology, to determine whether the heterogeneity referred to above is present initially in development or is carved out of a more uniform, widespread connectional pattern. Supported by BNS-8309245.

301.8 BRAINSTEM PROJECTIONS OF MOTOR AND SENSORY COMPONENTS OF THE VAGUS NERVE IN THE SQUIRREL MONKEY. M. Kalia and G. Kane-Wanger *. Dept. of Pharmacology, Thomas Jefferson Univ. Sch. of Med., Philadelphia, PA 19107.

The motor and sensory projections of the cervical vagus nerve have been traced in the brainstem of five adult squirrel monkeys using the retrograde and transganglionic transport of horseradish peroxidase (HRP) (Type VI Sigma). Tetramethyl benzidine (TMB) was used as the substrate for HRP histochemistry. Retrogradely labeled neurons were found in the dorsal motor nucleus of the vagus (dmnX), the nucleus ambiguus (nA), nucleus retroambigualis (nRA), the nucleus dorso-medialis (ndm), and the spinal nucleus of the accessory nerve (nspA) (levels 1.5 to -1.6 mm with reference to the obex). In addition, retrogradely labeled neurons were found in the nucleus retrofacialis (nRF) in the rostral medulla (level 1.7 mm) and in the nucleus parabrachialis medialis (nPBM) of the pons (level 3 mm). The existence of these populations of vagal preganglionic motoneurons in the pons have not been described previously in any other species. Transganglionically transported HRP to vagal sensory nerve terminals was identified in various subnuclei of the nucleus of the tractus solitarius (nTS) and the area postrema (ap). In addition a significant number of sensory nerve terminals were found in the nPBM, the nucleus parabrachialis lateralis (nPBL) and the Kolliker-Fuse (KF) nucleus. This is the first anatomical demonstration of vagal afferents terminating in the pons. Previous studies in the cat and the rat have not demonstrated these pontine motor and sensory vagal projections. Examination of serial sections in this study indicates that these medullary and pontine vagal projections form a continuous column through the brain stem. In the squirrel monkey, vagal rootlets enter the brain stem at the ponto-medullary junction which considerably more rostral than in the cat and the rat.

301.9 **BRAINSTEM DISTRIBUTION OF HORSERADISH PEROXIDASE AFTER INJECTION OF THE CANINE NODOSE GANGLION.**
**N.L. STROMINGER, A.P. KNOX*, D.O. CARPENTER AND D.B. BRIGGS*. DEPT. OF ANATOMY, ALBANY MEDICAL COLLEGE, ALBANY, NY 12208 AND NEW YORK STATE DEPARTMENT OF HEALTH, ALBANY, NY 12201.**

**Horseradish peroxidase conjugated to wheat germ agglutinin (120 ul,5%) was injected unilaterally into the nodose ganglion in a series of dogs. After 48-72 hours, animals were anesthetized and perfused transcardially with heparinized phoshate buffered saline followed by 4-8% gluteraldehyde. Brainstems and cervical spinal cords, blocked transversely, were sectioned at 50 um. Material was reacted with tetramethyl benzidine and stained with neutral red.**

**Dense label ipsilateral to the injection filled the afferent vagal fibers entering the brainstem. This was most distinct near the oral end of the vagal input. The solitary fasciculus contained copious label at all levels. The region immediately surrounding the solitary fasciculus was intensely labeled. This included the areas of the lateral, ventral, dorsal and medial solitary nuclei extending into the region immediately oral to the area postrema (AP) which we designate the pre-area postrema (PAP). Label could be followed almost but not right to the ependymal surface. It is possible that finer terminal ramifications were unlabeled. Label approached the junctional zone of the AP and a few fibers could be followed into it. A small number of labeled fibers were present in corresponding locations contralaterally.**

**Labeled perikarya were entirely ipsilateral to the injection, and were not as numerous as might be expected considering the large number of fibers with chromagen. Label was present in the dorsal motor nucleus of the vagus and in the nucleus ambiguus. Labeled cells also occurred in the PAP as shown previously. In contrast to studies of the origins of vagal efferents (Strominger et al., Neurosci. Abst., 10:331, 1984), the solitary nuclei, especially the ventrolateral subnucleus, contained a good number of filled cells. These tended to be the larger perikarya; reaction product varied from a few scattered particles to intense. In addition, a small cluster of labeled cells were located within the interstices of the spinal trigeminal tract along the course of the entering roots.**

301.10 AFFERENT CONNECTIONS OF THE MAGNOCELLULAR PONTINE RETICULAR FORMATION: A HORSERADISH PEROXIDASE STUDY IN THE RAT. S.J. Shammah-Lagnado*, N. Negrão*, B.A. Silva*, J.A. Silva* and J.A. Ricardo* (SPON: L.R.G. Britto). Dept. of Physiology and Biophysics, Institute of Biomedical Sciences of the University of São Paulo, 01000 São Paulo, SP, Brazil.

As part of a series of studies (Shammah-Lagnado, S.J. et al., Neuroscience, 9:391, 1983, and Neuroscience, 1985, in press) of the fiber connections of the reticular formation, a systematic examination of the nuclei reticularis pontis oralis (RPO) and caudalis (RPC) afferents was undertaken in the rat by the aid of the horseradish peroxidase (HRP) tracer technique. The retrograde markers, either free HRP or HRP conjugated with wheat germ agglutinin (WGA-HRP), were microelectrophoretically ejected and the tissue sections processed according to the tetramethylbenzidine method.

A similar distribution of retrogradely labeled neurons was observed in HRP and WGA-HRP experiments. The RPO appears to receive its main input from the zona incerta and fields of Forel, the superior colliculus, the central gray substance, and the mesencephalic and magnocellular pontomedullary reticular formation. Many other structures seem to constitute only modest sources of RPO afferents; these structures include extensive cortical territories, the nucleus basalis, hypothalamic districts, the anterior pretectal nucleus, the substantia nigra, the accessory oculomotor and the deep cerebellar nuclei, trigeminal, parabrachial and vestibular sensory cell groups, the nuclei raphe dorsalis and magnus, the locus coeruleus, the dorsolateral tegmental nucleus, and the spinal cord. While the afferentation of the rostral portion of the RPC appears to conform to the general pattern outlined above, some striking differences emerge when the innervation of the caudal district of the RPC is considered; thus, for instance, both spinal and fastigial inputs distribute much more heavily to this specific district than to the remaining magnocellular pontine reticular formation.

The present results may contribute to the elucidation of the anatomical substrate of the functionally demonstrated involvement of the RPO and RPC in several domains that include the regulation of the electrocorticographic activity of the neo- and archicortices, somatic motor mechanisms, autonomic phenomena, and processing of nociceptive as well as other kinds of sensory information. (Supported by FAPESP grant 04-76/1375 and FINEP grant B-43/83/0757.)

301.11 RHOMBENCEPHALIC CELLS THAT PROJECT TO THE INTRALAMINAR THALAMUS IN THE RAT. G.A. Kevetter and A.R. Parrott*. Dept. of Otolaryng. and Anat., Univ TX Med. Branch, Galveston, TX 77550

Cells in the rhombencephalon that project to the intralaminar thalamus were investigated in order to determine the input to the portions of the thalamus associated with affective and motor responses to sensory input. Horseradish peroxidase (HRP; 30% Miles in 0.05 M Tris 0.5 M KCl) was injected ionophoretically (5 μA positive current; 50% duty cycle for 7 minutes) into the intralaminar thalamus and surrounding areas of the diencephalon of albino rats. Injections were centered on the parafascicular-centre median complex. After a 48 hour survival time, the animals were perfused with mixed aldehydes and 50 μm frozen sections were cut. Alternate sections were reacted with tetramethylbenzidine. Cells labeled with HRP were identified using both brightfield and darkfield light microscopy. After injections centered on the parafascicular-centre median complex, labeled cells were concentrated in three major areas in the caudal rhombencephalic reticular formation. These areas were the N. paragigantocellularis lateralis (PGCL), the N. gigantocellularis (NGc) and adjacent N. raphe magnus, and the dorsal N. reticularis pontis caudalis (NPc) especially adjacent to the genu of the facial nerve. Although labeled cells were located bilaterally, more were concentrated on the side contralateral to the injection in PGCL and NPc. Labeled cells were also located in the vestibular nuclear complex and the adjacent N. prepositus hypoglossi and N. supragenicularis. Sensory nuclei, such as the dorsal column and trigeminal nuclei contained few labeled cells after injections of the intralaminar complex. By contrast, after control injection into ventrobasal complex, these areas were heavily labeled. Labeled cells were also observed in the deep cerebellar nuclei and the central N. of the medulla. We calculated the cell areas of cells labeled in the three regions of the reticular formation. NGc contained the largest cells ($\bar{X} \pm SD$ = 346.36 ± 172.32, n = 31), of the three areas. However, these projection neurons are not the largest cells in the nucleus. The cells labeled in PGCL ($\bar{X} \pm SD$ = 226.12 ± 67.16, n = 38) and NPc ($\bar{X} \pm SD$ = 211.25 ± 87.14, n = 50) had similar areas. As NGc receives a spinal input, these studies indicate that the NGc may be one component in a spinoreticulothalamic system involved in affective and motor responses to sensory input, such as nociceptive stimuli. The NPc may provide important input to the intralaminar nuclei for its involvement in eye movement control. (Supported by BRSG SO7-RR5427.)

301.12 **LESIONING OF THE INFERIOR OLIVARY NUCLEUS FACILITATES STRYCHNINE SEIZURE IN THE RAT,** M. Anderson*, E. Chung and M.H. Van Woert (Spon: G.M. Lehrer), Graduate Program in Neurobiology, Departments of Neurology and Pharmacology, Mount Sinai School of Medicine, New York, N.Y. 10029

Systemic administration of the nicotinamide analog 3-acetyl-pyridine (3AP) has been shown histologically to result in complete degeneration of the inferior olivary nucleus (ION)[1], specifically all climbing fiber afferents to the cerebellum,[2] in addition to partial ablation of the nucleus ambiguus. Acute toxicity marked by partial aphagia and stridulous breathing is observed 1-2 days post 3AP injection. Pending survival of the initial insult (survival rates ranged from 34-66%) rats display a generalized ataxia. Earlier work done in this laboratory has implicated intact olivo-cerebellar fibers in a protective capacity for pp-DDT induced myoclonus.[3] Here we examined the effect of 3AP treatment and electrolytic lesions of the ION on tonic-clonic seizures produced by the glycinergic antagonist strychnine.

Male Sprague-Dawley rats weighing 125-150 gm were given a single i.p. dose of 80 mg/kg 3AP 18 days prior to strychnine challenge. Bilateral electrolytic lesions of the ION were made using Konig-Klippel coordinates:AP=+4.0 mm, L=±0.7 mm, V= -10.2 mm and by applying a 120 mV for 10 seconds. Lesions were confirmed histologically. Animals were scored for symptoms of ataxia and abnormal movement (reeling, tremor, spasticity), weight loss and signs of general autonomic impairment using an ataxia rating scale devised for this purpose. Seizures were induced by administration of 1.5 mg/kg strychnine i.p.

| | Average No of seizures | Incidence of seizures | Average Seizure Coefficient[a] | Average Onset Latency[b] |
|---|---|---|---|---|
| Control | .06±.07*** | 1/16 | .2[c]** | 7:25[c] |
| 3AP Lesion | 10.62±2.35 | 12/16 | 3.9±1.0 | 5:15±:40 |
| Control | .46±.24*** | 4/13 | 1.8±0.85* | 5:42±1:46 |
| ION Lesion | 2.15±.68 | 11/13 | 9.5±3.6 | 7:55±1:14 |

a:seizure coefficient = total time in seizure state x seizure intensity, units are I-min.
b:Latency values reflect only animals exhibiting seizure.
c:Only one animal exhibited seizure
*P < .05,**P < .001, *** P < .0005.

Animals were not noise sensitive. There was no difference in $^3H$ strychnine binding in the medulla or $^3H$-GABA binding in the deep cerebellar nuclei in 3AP treated rats. These data indicate that destruction of the olivo-cerebellar pathway lowers threshhold to seizures induced by strychnine.

1: Brain Research 77 (1974) 349-364; 2:Brain Research 77 (1974) 365-384, 3:Neuroscience Letters 24 (1981) 103-108.

301.13 SPONTANEOUS INTRINSIC OSCILLATORY BEHAVIOR IN INFERIOR OLIVE CELLS FROM GUINEA PIG: ITS ORIGIN AND MODULATION. L.S. Benardo and R.E. Foster. Neurological Inst, Columbia-Presbyterian Medical Center, New York, NY 10032 and Neurotoxicology Branch, US Army Med Rsch Inst of Cml Defense, Aberdeen Proving Ground, MD 21010-5425.

The source of oscillatory firing behavior of mammalian inferior olive (I.O.) neurons has been the subject of study for many years. Most recently Llinas and Yarom (J. Physiol. 315:549-584, 1981) studied these cells in vitro and identified two kinds of calcium conductance: 1) a high threshold type present in dendrites and 2) a low threshold type of somatic origin. They proposed that interactions between these two conductances were the basis for the olivary rhythmic potentials seen in vivo, though this type of prolonged, self-sustaining activity was not observed in their studies. In the experiments presented here, we now report on recordings of I.O. cells in vitro demonstrating spontaneous oscillations of the membrane potential. Parasagittal or coronal brainstem slices (350-400 um) were cut by Vibratome (brainstems submerged in oxygenated artificial CSF at 4-6°C during cutting) and immediately transferred to the brain slice recording chamber (Schwartzkroin, Br Res. 128:53-68, 1975). We have recorded from over 100 oscillating cells and they are routinely present in all anatomical subdivisions of the I.O. The frequency of oscillation was 4-13 Hz and the amplitude ranged up to 20 mV, peak-to-peak, at rest potential. In some cells the oscillation was of constant amplitude while in others there was a superimposed rhythmicity consisting of cyclic variability in oscillation amplitude having a period of about 0.5 - 1 Hz. The oscillations responded to intracellularly applied current such that there was attenuation with depolarization and amplification with hyperpolarization. Lucifer Yellow CH injection into such cells revealed their morphology to be typical of I.O. cells and multiple cell labeling from a single injection (i.e. dye coupling) was observed in 50% of cases. The oscillatory behavior could be damped for up to 4 sec or longer by stimulation of the neuropil dorsal to the I.O. Oscillations were blocked when slices were exposed to calcium-free medium containing 2mM $Mn^{2+}$. Oscillations could be synchronous within local aggregates of neurons, as revealed by simultaneous intracellular recordings, but such behavior became out of phase with increasing distance between pairs of neurons. The evidence suggests an intrinsic somatic origin for the oscillatory behavior. Our findings are consistent with, and more fully explain, the I.O. physiology seen in vivo. This study offers support for an intrinsically generated oscillatory mechanism which may be operative endogenously, can be locally synchronous within a neuronal aggregate and may be modulated extrinsically by afferent and/or efferent sources.

301.14 IMMUNOHISTOCHEMICAL LOCALIZATION OF ADENOSINE DEAMINASE IN PREGANGLIONIC PARASYMPATHETIC NEURONS IN THE RAT. E. Senba[1], P.E. Daddona[2*] and J.I. Nagy[1]. (SPON: K.W. CHENG) Dept. of Physiology, Univ. of Manitoba, Winnipeg, Manitoba, R3E OW3, Canada and Dept.of Internal Medicine, Univ. of Michigan Med. Sch., Ann Arbor, MI., 48109.

The enzyme adenosine deaminase (ADA) converts the biologically active compound adenosine to its inactive metabolite inosine. We have previously found that ADA could be detected immunohistochemically in only a limited number of discrete neural systems in rat brain and spinal sensory ganglia (Nagy et al., Science 224 166-168, 1984; Neurosci. lett. 48 133-138, 1984). It was suggested that a relationship may exist between high neuronal levels of ADA and the putative neuromodulatory role of adenosine in the CNS. However, some of the best evidence available for such a role of adenosine is with respect to peripheral autonomic systems (Akasu et al., Nature 311 62-65, 1984; Portter et al., Fed. Proc. 42 1623-1632, 1983). We therefore examined whether brain stem and spinal parasympathetic systems or superior cervical ganglia (SCG) exhibit ADA-immunoreactivity.

In the brain stem an ADA-containing cell group was detected dorsolateral to the rostral part of the facial motor nucleus. ADA-immunostained fibers emerging from these neurons could be followed dorsally and laterally to enter main fiber bundles which emerged from the brainstem just caudal to the facial nerve. It has previously been shown (Contreras et al., J. Comp. Neurol., 190 373-394, 1980 that neurons at this location project to sphenopalatine ganglia which supply parasympathetic fibers to various tissues including the lacrimal glands and nasal mucosa. We found that the ADA-immunoreactive brainstem neurons when stained by the immunofluorescence method were simultaneously labelled with fast blue after injection of this retrograde fluorescent tracer into the sphenopalatine ganglion, thus confirming their parasympathetic nature. No ADA-immunostaining was seen in parasympathetic neurons of the inferior or superior salivatory nuclei. In the spinal cord ADA-immunoreactive cells were observed in the intermediolateral region of the 6th lumbar to 4th sacral segments corresponding to the location of preganglionic parasympathetic neurons. To date, we have been unable to detect ADA-immunostaining in neurons of SCG.

The presence of ADA in at least certain populations of preganglionic parasympathetic neurons is consistent with a possible neuroregulatory action of adenosine in these neurons and with the notion that ADA may reflect such an action.

301.15 THE INTERACTION BETWEEN GABA/BZP AND THE OPIOID SYSTEM IN SPINAL CORD. T. Shibuya*[1,3], Y. Watanabe*[1], T. Matsumiya*[2] and B. Salafsky*[3] (SPON: T. Marczynski). 1. Dept. of Pharmacol., Tokyo Med. Col., Tokyo 160, Japan, 2. Dept. of Pharmacol., Tokai Univ., Sch. of Med., Isehara 259-11, Japan, 3. Dept. of Biomed. Sci., Univ. of Ill. Col. of Med. at Rockford, Rockford, Ill. 61107-1897.

The interaction between GABA/BZP's and the opioid system in the central nervous system may relate to certain physiologic functions (e.g. feeding, convulsion, stress, etc.). Our previous paper (Europ. J. Pharmacol., 96:141, 1983) supported the existence of such a mechanism in the CNS. However, it is not known whether these relationships exist in the spinal cord. More recently, we had reported (Europ. J. Pharmacol., 109:307, 1985) that the proportion and development of BZP receptor subtypes in the spinal cord are quite different from those of other brain regions. In the present study we examined the interaction between the GABA/BZP and the opioid system on c-fiber reflex, the heat evoked discharge and the pinprick discharge. In addition we further investigated the characteristics of "peripheral" BZP receptors in the spinal cord. Electrophysiologic experiments were conducted in spinal and intact cats utilizing previous methodology (Life Sci., 29:1507, 1981) while the details of biochemical studies have been published elsewhere (Japan J. Pharmacol., 36:15, 1984). The administration of diazepam to spinal cats suppressed the c-fiber reflex in a dose-dependent fashion while similar treatment in the intact animal showed attenuation of these reflexes. In the spinal cat, naloxone antagonized the suppressed effects of diazepam on the c-fiber reflex. Additionally, the inhibitory effects of diazepam on the heat evoked discharge of the spinal cat were blocked by small doses of naloxone. Biochemically we have noted that the number of "central" BZP receptors was approximately three times less than that of "peripheral" BZP receptors in rat spinal cord. The effects of Ro-5-4864, a "peripheral" BZP antagonist on neuronal activities in the spinal cord was also studied. Preliminary indications suggest that "peripheral" BZP receptors are involved in interrelationships between GABA/BZP and opioid systems in the spinal cord.

301.16 INVOLVEMENT OF NON-GLYCINE INHIBITION IN SPONTANEOUS, COORDINATED RHYTHMS IN CULTURED NEURONAL NETWORKS Michael H. Droge & Guenter W. Gross, Texas Woman's University, Denton, TX.

Monolayer cultures of dissociated mouse spinal tissue develop spontaneous, persistent rhythmic bursting activity that is coordinated among multiple recording sites (Droge & Gross, 1984,1985). Strychnine ($10^{-6}$ M) typically increases firing frequencies to the point of disrupting pre-test bursting indicating that glycine transmission does participate in the observed rhythms. However, we have also observed that $10^{-6}$ M strychnine can suddenly block activity at one recording site while increasing activity at other simultaneous recordings sites.

Since low dose strychnine specifically blocks glycine synapses, the enhancement of activity is considered a disinhibition of excitatory synapses. Similar results in other systems have been used to support the hypothesis that networks capable of generating rhythm involve recurrent inhibition. The differential effect of strychnine presented here indicates that glycine transmission is not the only inhibitory transmitter involved in pattern generation. Rather, the loss of activity following strychnine administration may represent a disinhibition via glycine that increases activity in other types of inhibitory connections. The nature of this connectivity has yet to be determined since much more detailed information is needed at the level of the individual cells to identify the pattern generating network.

302.1 DORSAL ROOT REFLEX DURING LOCOMOTION IN NORMAL AND DECEREBRATE CATS. S.H. Duenas*, G.E. Loeb and W.B. Marks. Lab. of Neural Control, NINCDS, NIH. Bethesda, MD 20205

During fictive locomotion, homonymous monosynaptic reflexes (MSR) produced by triceps surae group Ia afferent fibers are reduced in amplitude during the flexion (F) phase of the step cycle, at which time these group Ia afferents are more excitable by stimulation in spinal cord (Eidelberg et al., adjacent poster). MSR transmission could be modulated by the locomotor pattern generator at presynaptic or postsynaptic levels. The present study was designed to determine whether a similar modulation occurs during normal and decerebrate locomotion and to further assess the importance of presynaptic mechanisms. Presynaptic inhibition can be caused by the depolarizing effects of synapses ending on the terminal arborizations of primary afferents (so-called PAD). In addition to reducing the threshold to microstimulation, such PAD, if large enough, can itself give rise to antidromic spikes known as the dorsal root reflex (DRR). We used chronically implanted nerve cuff and EMG electrodes to stimulate and record MSR and DRR responses in normal walking cats that were subsequently decerebrated at precollicular level (sparing the thalamus) and allowed to walk spontaneously on a moving treadmill belt.

In both preparations the amplitude of the MSR evoked by stimulation of lateral gastrocnemius (LG) nerve and recorded in medial gastrocnemius (MG) nerve (or vice-versa) increased during extensor (E) phase of the step cycle and decreased during flexor (F) phase. In decerebrate cats the MSR in MG nerve was also evoked by stimulation in sciatic nerve. A similar waxing and waning in the amplitude of MSR occurred.

In both normal and decerebrate cats, a DRR was recorded in MG nerve (but not in MG or LG muscle) following the stimulation of LG nerve as well as posterior biceps-semitendinosus nerve. This reflex had a latency of 3-4 msec and occurred in correlation with F phase of the step cycle. In contrast, the MSR was recorded in the homonymous and heteronymous muscles. Its latency was 4-5 msec and its amplitude peaked during E phase. In decerebrate cats DRR could be produced by stimulating LG, sciatic and posterior tibial nerves. These findings suggest that the locomotor program includes substantial phasic depolarization in ankle extensor group I fibers during F-phase of the step cycle. Thus presynaptic inhibition appears to play a significant role in gating transmission in the ankle extensor Ia-motoneuron pathway.

302.2 EXCITABILITY CHANGES IN ANKLE EXTENSOR GROUP Ia AND Ib AFFERENTS DURING SPONTANEOUS FICTIVE LOCOMOTION E. Eidelberg, S.H. Duenas* and P. Rudomin. (SPON: M. Bak) Division of Neurosurgery VAH, San Antonio, Texas 78284; Dept. of Physiology, Biophysics and Neurosciences, CINVESTAV del IPN 07000 Mexico, D.F.

Spontaneous fictive locomotion in immobilized cats is a good model to investigate the action of the central pattern generator on afferent input since there are no phasic changes in the patterns of peripheral sensory inflow. One possible mechanism for regulating the efficacy of group I input is the modulation of afferent fiber membrane potential. Experiments were designed to study the excitability of gastrocnemius-soleus (GS) group Ia and Ib fibers by measuring changes in threshold to microstimulation of the intermediate nucleus in high decerebrate, paralyzed cats. In addition, we studied the amplitude of the GS monosynaptic reflex (MSR) and the excitability of group Ia afferent fibers in the motor nucleus.

The excitability of both types of fibers increased during fictive locomotion and decreased following episodes of locomotion. Excitability changes were cycle- and gait-dependent. An increase in excitability usually occurred during the flexion (F) phase of the step cycle for both types of fibers. During spontaneous fictive locomotion, extracellular potentials (ECPs) were recorded in the intermediate nucleus. Spontaneous ECPs were phasically modulated in correlation to the F-phase of the step cycle. This modulation was superimposed on a more tonic modulation with a time course of tens of seconds.

The amplitude of the MSR evoked by stimulation in lateral gastrocnemius and recorded in medial gastrocnemius increased during the extension phase of the step cycle and after periods of locomotion; MSR amplitude decreased during the F-phase of step cycle. The excitability of Ia afferent fibers in the GS motor nucleus, measured by Wall's method on whole nerve, was similar in both phases of the step cycle. However, there was an increase in excitability during the F-phase in individual Ia afferents.

The present experiments support the idea of a tonic primary afferent depolarization (PAD) of extensor group Ia and Ib fibers during spontaneous fictive locomotion. In addition, phasic PAD seems to occur in relation to different fictive gaits. The ECPs suggest the possibility that this PAD may be potassium-mediated.

302.3 LONG TERM DISCHARGE PATTERN OF MOTOR UNITS. B. Bigland-Ritchie, E. Cafarelli and R. Johansson . John B. Pierce Foundation and Quinnipiac College, New Haven, Ct. 06519.

Action potentials were monitored for periods of 5 to 30 min from single muscle fibers of the extensor digitorum communis, rectus femoris and vastus lateralis muscles using tungsten micro-electrodes. In some records the potentials from up to four different low threshold units could be distinguished by differences in their amplitudes and waveforms. These were then followed simultaneously.

During constant low force contractions firing rates declined with time. They were usually higher when first recruited during ramp force contractions than during subsequent force maintainance. After variable intervals (2-5 min) many units ceased firing but they could be re - recruited if the force was increased slightly. Plots were constructed for each unit of changes in threshold as a function of time. The drop-outs were not due to electrode movement because, in most cases, other units recorded simultaneously continued firing without changes of amplitude or waveform. Some units recommenced firing after drop out even though the force remained unchanged and others fired for only short periods(1-5 min) at various times during the contraction, while still others fired continuously.

After 20-30 min of low force activity the maximum voluntary contraction (MVC) had declined by 30-50%. The mean firing rates between drop outs remained relatively unchanged at about 10-12Hz despite several increments in force. During this time the relative force increased from 10 to 50% of the current MVC.

These results support the early concept of motor unit rotation during long term activity; a concept largely discarded in recent times (Stuart and Enoka, 1984, Clinical Neurosciences (5): 471-518). During fatigue muscle contractile failure in previously active units may be minimized by periods of inactivity. But, as contractile failure develops, this may be compensated by recruitment of new units rather than by rate coding in those units already active. The drop out of motor unit activity may be associated with decreased motor neuron excitability rather than changes in synaptic input. This is suggested by the return of unit activity following a period in which the input drive presumably remained unchanged.

302.4 INTERACTION BETWEEN STRETCH REFLEX AND 8-12 HZ COMPONENT OF PHYSIOLOGIC TREMOR. R.J. Elble, J.Adelman*, and C. Higgins*. Dept. of Medicine, Southern Illinois U. Sch. Med., Springfield, IL 62708.

Physiologic tremor has two distinct rhythmic components. The most prominent component results from underdamped properties of limb mechanics and controlling stretch reflex and has a frequency that is largely determined by limb inertia, mechanical-reflex stiffness, and reflex loop time. A second component of physiologic tremor has a frequency of 8-12 Hz regardless of limb mechanics and loading, and the origin of this tremor remains a source of continuing controversy. We have measured wrist tremor and forearm EMG in 30 adult controls, ages 18-74, during the maintenance of steady posture against gravity. Only 30% exhibited a prominent 8-12 Hz component whereas all controls exhibited a mechanical-reflex tremor. Five control subjects with and without prominent 8-12 Hz components were then studied using a computer-controlled torque motor and manipulandum. Fifty millisecond torque pulses were applied randomly to the wrist to determine 1) the amplitude and latency of the stretch reflex response and 2) the ability to reset the mechanical-reflex and 8-12 Hz tremors. Spring and inertial loads were used to separate the mechanical-reflex and 8-12 Hz oscillations which were otherwise fused into a single hybrid oscillation. The stretch reflex responses did not differ between the two groups of controls. As expected, the mechanical-reflex tremor was readily reset and augmented by the torque pulses. The 8-12 Hz tremor, by contrast, was disrupted rather than reset by the perturbations. Furthermore, the 8-12 Hz tremor behaved in a manner identical to that of mild essential tremor in 7 patients. We conclude that 1) the 8-12 Hz component of physiologic tremor exhibits marked intersubject variability that is not obviously related to stretch reflex gain; 2) this 8-12 Hz tremor may be a forme fruste of essential tremor, and 3) the 8-12 Hz tremor is distinct from mechanical-reflex oscillations produced by external perturbations.

302.5 ACTIVITY OF INDIVIDUAL CAT LATERAL GASTROCNEMIUS AND SOLEUS MOTOR UNITS DURING PAW SHAKES. A.W. English, Emory Univ., Atlanta, GA 30322

Paw shaking is a rhythmic movement which involves rapid alternate flexions and extensions of the foot and is produced by selective recruitment of fast-twitch units in lateral gastrocnemius (LG), without activity of slow twitch motor units in soleus (SOL) (Smith et al, J. Neurophysiol. 43:612-620, 1980). Since some of the compartments of LG contain significant proportions of slow twitch motor units, this study sought to determine whether they are also inactivated during shaking. The activity of single motor units in LG and SOL was recorded using miniature "hatpin" microelectrodes which were implanted into the lateral gastrocnemius-soleus nerve (English, Soc. Neurosci. Abstr. 9:360, 1983). Recordings were made as the cats walked on a treadmill with a piece of cellophane taped to the plantar surface of the foot. Shaking was elicited at irregular intervals during the swing phase of the step cycle. All LG units were activated according to one of two walking task groups: early in the EMG burst, or in a sustained pattern during both muscle lengthening and shortening. None of the SOL units studied displayed the sustained pattern during walking, but units in the early task group were noted. During shakes, all LG units fired very briskly. Discharges were very highly correlated to changes in LG length (Fig. 1). Most SOL units were inactive during shakes, but for those which were active, their firing rates were not impressive, and synchronization to LG length changes was poor. The activity of these SOL units is probably related more to the maintenance of limb position during shaking than to the movements. Since, based on axonal conduction velocity and compartmental location, some of the LG units sampled were slow twitch, they are clearly activated differently than SOL units during shakes but not during walking. Thus motor units of similar physiological type in different synergist muscles are not necessarily strict synergists. Different motor units may belong to similar locomotor task groups but they may be used quite differently during different behaviors.

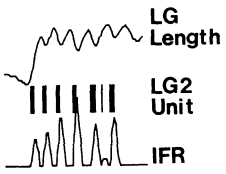

FIGURE 1

302.6 **COMPARISON OF FIRING RATE PATTERNS OF DIFFERENT TYPES OF MOTOR UNITS AT THE SAME RELATIVE TENSION OUTPUT.** B.R.Botterman and T.C. Cope. Dept. of Cell Biology and Anatomy, Univ. Texas Hlth. Sci. Ctr., Dallas, TX 75235.

**Evidence from a variety of experimental approaches suggests that the recruitment and usage of motor units is generally ordered according to their tension output and fatigue resistance. Most studies concerned with the relative fatigue resistance of motor units have been based on one stimulation rate, in which the separation of unit types was stressed. One approach to the study of motor unit fatigue (and potentiation) is to examine the response of different types of units when their tension output is maintained at various levels of maximum tetanic tension (e.g., 15%). In this way, the firing behavior of different units can be compared at the same relative tension output level. Under constant-tension conditions, the firing rate of the motor axon must be adjusted to accommodate the ongoing changes in the tension output of its muscle unit due to the opposing processes of fatigue and potentiation.**

**In 5 cats, motor axons to either the FCR (n=15) or MG (n=24) muscles were isolated from ventral root filaments. Units were classified as type F or S based on the presence or absence of a "sag" profile. A LSI-11/23 computer system was used to maintain a constant-tension output from a unit by changes in its activation rate. This was accomplished via a closed-loop feedback system, in which small deviations in "target" tension resulted in a proportional adjustment of the activation rate of the unit's motor axon.**

**From this approach, it is clear that at low percentages of maximum tetanic tension (<25%) activation rates of type F units dramatically decrease during the contraction, sometimes as much as 50%. Therefore, for many type F units it appears that post-activation potentiation delays the onset of "motor" fatigue. At 15% of maximum tension, two groups of type F units could be tentatively identified. One group could maintain the target tension between 700-2,000 activations, while the other group could do so for >3,500. In addition, it is clear that for many units, particularly type S, constant tension could be maintained for tens of thousands of activations, encompassing a wide range of target tensions (15-75%). It is anticipated that this approach will be helpful in interpreting various recruitment and usage schemes for the three motor-unit types found in most mammalian muscles. 302.7 ELECTROMYOGRAPHIC ACTIVITY OF SELECTED CAT HINDLIMB MUSCLES DURING UNRESTRAINED LOCOMOTION AT VARYING SPEEDS AND GRADES. M.Kuehl*, R.R.Roy, R.J. Gregor and V.R.Edgerton. Brain Research Institute and Kinesiology Dept, UCLA, L.A., CA. 90024.

The duration of electromyographic (EMG) activity of flexors and extensors during unrestrained locomotion is asymmetrical, particularly at slow speeds. To study the asymmetry in more detail, EMG was recorded using chronically implanted intramuscular electrodes from the soleus (SOL), medial gastrocnemius (MG), gluteus medius (GM) and tibialis anterior (TA) muscles of seven adult cats during treadmill locomotion at speeds ranging from .23 to 3.74 m/sec and at grades of 0, 10 and 20°. From the rectified EMG the average cycle period (CP), burst duration (BD) and integral per burst (IA) were determined over a series of 10-20 consecutive steps. Subsequently, mean EMG was calculated as IA/BD, IA per min as step rate*IA per step and 'on-time' per min as step rate per min*BD. The EMG activity to varying speeds and grades was similar in all cats. CP decreased in a hyperbolic fashion with increasing speed for all muscles at any given grade. The BD of the SOL and MG decreased exponentially whereas the BD in the TA remained essentially unchanged or was slightly reduced as a function of speed. The BD of the GM followed the pattern of the SOL and MG at slow speeds, but was longer at speeds greater than 1.17 m/sec. The trends associated with increasing speeds were similar at all grades. Across speeds the IA was relatively constant in the MG, GM and TA, whereas it decreased progressively in the SOL. The IA was elevated at higher grades but at each grade the relationship to velocity was similar. SOL mean EMG did not change at slow speeds but decreased slightly at speeds faster than 2.11m/sec. This finding was most obvious at 10 and 20° incline. In contrast, the mean EMG was elevated in the MG, GM and TA, with the MG showing the largest increase. IA per min was always highest for the SOL followed by the MG and was always the least for the TA. The SOL IA per min decreased at speeds faster than 2.11m/sec. Ankle extensor 'on-time' per min was reduced with increasing speeds as a result of the progressive reduction in BD. In contrast, the TA 'on-time' increased by 150% at the higher speeds. The GM showed a decrease in 'on-time' at the lower speeds, but an increase at speeds faster than 1.17 m/sec. This reflects the slightly longer BD of the GM in comparison to the SOL and MG at the higher speeds. These data are consistent with the hypothesis that as speed increases the level of activity of the motor pools (number of motor units active and/or frequency of excitation) of the MG and GM are increased markedly while the activation levels of the TA and SOL change only slightly.

302.8 Force-Velocity Potentiation in Cat Soleus Muscle During Treadmill Locomotion R.J.Gregor, W.C. Whiting, R.R. Roy, J. Hodgson, R.G. Lovely and V.R. Edgerton. Brain Research Institute and Kinesiology Department, UCLA, Los Angeles, CA 90024

Isometric and isotonic contractions monitored in situ provide selected information on the mechanical properties of a skeletal muscle. Contractions under such controlled conditions however, rarely occur in natural movements and may not directly apply to our understanding of muscle mechanics during locomotion. We have therefore, made direct measurements of soleus muscle force, length and EMG during locomotion and from these measurements examined the force-velocity relationship of the muscle during treadmill locomotion.

Sixty-five step cycles in four cats were analyzed at speeds ranging from 0.8-2.2m/s. Force transducers were surgically implanted on the soleus tendon and bipolar EMG electrodes implanted into the muscle belly. Direct linear transformation techniques were employed using high speed cinematography to estimate muscle length changes in 3D (J. Biomech. 17:685-94, 1984). Data were subsequently smoothed using digital filtering techniques and velocities calculated using finite differences. Terminal experiments provided direct comparison of in situ isometric and isotonic properties with in vivo observations made during locomotion.

Peak force remained relatively constant and time to peak force occurred consistently at 13% of the step cycle at all treadmill speeds. While the magnitude of the stretch fell slightly as speed increased, peak lengthening velocities increased from -46mm/s at 0.8m/s to -77mm/s at 2.2m/s. Peak shortening velocities also increased from 52mm/s at 0.8m/s to 144mm/s at 2.2m/s. Isotonic $V_{max}$ averaged 190mm/s in these animals. At the speeds employed in this study the in vivo force-velocity curve displayed consistently higher forces than those recorded at similar shortening velocities in situ. These higher forces may be due to the stretch imposed on the active muscle in early stance ($E_2$). Preliminary studies on rat soleus, in situ, showed similarly higher forces when the active muscle was lengthened and allowed to shorten. The data suggest that skeletal muscle may be capable of developing considerably more power than that predicted from isotonic force-velocity properties recorded during shortening contractions.

302.9 KINEMATICS AND DYNAMICS OF THE CAT HINDLIMB DURING LOCOMOTION. G.E. Loeb, W.B. Marks, A.J. Rindos, Jiping He*, W.M. Roberts*, and W.S. Levine*. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205 and Dept. of Electrical Engineering, University of Maryland, College Park, MD 20747

We are developing an analytical model of the cat hindlimb musculoskeletal system. The model presently consists of five two-dimensional segments: toes, foot, shank, thigh, and pelvis. The gross anatomy of 33 muscles with significant action in the sagittal plane has been modeled, including ranges of origin and insertion and radii of pulleys and tethers constraining their tendons. Skeletal motion was derived from digitally smoothed (10 msec time constant) stick figure reconstructions of video stills recorded at 60 fields/s by a high resolution camera with stroboscopic illumination. Ground reaction forces were recorded by a multiaxis force plate: vertical and longitudinal forces and center-of-force of the foot. In the results described below, the skeletal motion was obtained from fast, steady walking on the treadmill and the ground forces were obtained from a similar gait in a nonmoving runway.

The lengths and velocities of each muscle were calculated, including the partial effects attributable to motion at each joint spanned by multiarticular muscles. From the Newtonian equations of motion, an inverse dynamic solution was obtained for the net torque at each joint attributable to muscle tension.

During stance, extensor torque in hip, knee, and ankle peaked together in E2 (40% of stance phase duration), when active extensor muscles were lengthening. Toe extensor torque peaked later in E3, when toe extensor muscles were lengthening, and was associated with a propulsive ground force that cancelled the negative longitudinal ground forces that occurred in the first half of stance.

Swing phase motion involved complex, large angular accelerations and decelerations at all joints, some of which presented real or apparent paradoxes when compared with net joint torques and EMG patterns. Flexion was initiated by synchronous flexor torques at all joints. The transition from flexion to extension in the knee occurred without net muscle torque, being the product of a whipping motion initiated by translational deceleration of the pelvis (during decelerating phase of stance in the contralateral limb). Similarly, the deceleration of hip flexion was attributable to translational acceleration of the pelvis rather than extensor muscle torque. The further angular acceleration of the hip in the extensor direction just before footfall was actually accompanied by net flexion muscle torque, and appeared to be caused by a kickback from the large knee flexion torque applied via the hamstrings to stop knee extension. Whip motion also produced ankle extension, apparently partly opposed by extensor digitorum longus. Deceleration of ankle extension just before footfall occurred despite net extensor muscle torque, suggesting translational accelerations not yet fully understood.

302.10 INHIBITORY PROCESSES POSSIBLY INVOLVED IN MOTONEURON SLOWING DURING SUSTAINED MAXIMUM ISOMETRIC CONTRACTIONS IN MAN. C.G.Kukulka, M.A.Moore* and A.G.Russell. Physical Therapy Research Labs, University of Iowa College of Medicine, Iowa City, IA 52242.

Fatigue of human soleus muscle, induced by sustained maximum isometric contractions, has an associated decline in motor unit firing rates (Neuro.Abs. 10:638,1985). Possible factors responsible for this slowing include peripheral feedback, descending influences recurrent inhibition via Renshaw cell activation, and summation of motoneuron afterhyperpolarizations (AHP). Under nonfatiguing conditions, an H-reflex conditioning technique has been used to indirectly evaluate recurrent inhibition (J.Physiol.269:319,1977). The purpose of this study was to adapt the conditioning technique for use during fatiguing contractions.

Subjects were positioned prone, hip extended, knee flexed 60°, ankle neutral, and foot secured to a torque measuring plate. During initial brief, 2 sec maximum efforts, conditioned (Htest) and unconditioned (Href) H reflexes were obtained. Htest was elicited by a subthreshold motor stimulus followed 15 msec later by a supramaximal stimulus. Single shocks were adjusted to produce Href, of amplitude equal to that of Htest. Both reflexes should be influenced by similar segmental and descending influences. Htest was influenced additionally by the conditioning stimulus. Changes in Htest relative to Href were used to infer the combined effects of recurrent inhibition and summations of motoneuron AHP during sustained efforts.

Subjects performed sustained, 60 sec maximum isometric contractions of triceps surae during which time repeated samplings of Htest and Href were made. Tests were repeated on at least 4 separate days for each subject and changes in Htest and Href were submitted to regression analysis and comparisons made. On average, Htest displayed a depression during the first 30 sec of effort and was highly variable for the remaining 30 sec of effort. Href, on average, displayed an increase in amplitude within the first 30 sec of effort, and was highly variable therafter. The diverging of the two reflexes within the first 30 sec of effort suggests that recurrent inhibition/AHP effects are augmented during this period. These findings provide a possible explanation for the initial slowing of motoneuron firing reported earlier.

This work was supported in part by a grant from the Muscular Dystrophy Association of America

302.11 FUNCTIONAL ROLE OF THE HAMSTER PYRAMIDAL TRACT DURING LOCOMOTION. J. Keifer and K. Kalil. Neurosciences Training Program and Dept. of Anatomy, University of Wisconsin, Madison, WI 53706.

The pyramidal tract (PT) of the hamster projects from the sensorimotor cortex to all contralateral spinal cord segments where it terminates in the medial aspect of lamina V and VI of the dorsal horn. Previous studies on the role of the PT in motor behavior have emphasized the fine movements of the forepaw and digits. We have chosen to examine the function of the PT in locomotion for several reasons. First, locomotion is a centrally programmed, stereotyped behavior in which the coordination of the joints of the limbs can be quantified. Second, locomotion requires accurate placement of the limbs. Finally, defects in this behavior after a lesion of the PT can be accurately measured. Normal freely locomoting hamsters and those with a unilateral section of the medullary pyramid were filmed on two types of terrain: smooth terrain, where sensory feedback is relatively less important for accurate limb placement, and rough terrain, where sensory feedback is more important.

A frame-by-frame movement analysis was conducted by projecting the film onto a screen, tracing the position of the limbs, and measuring the following joint angles: the scapula, shoulder and elbow angle for the forelimb, and the hip, knee and ankle for the hindlimb. When these angles are plotted against time, the coordination of the joints for each limb are revealed. The results show that during normal locomotion, as the forelimb lifts off the ground to initiate swing phase, the scapula and elbow flex, while the shoulder extends. This is followed by a phase of elbow extension midway through swing. When the limb is placed on the ground in stance, the scapula extends and the shoulder flexes. Following a yield in the elbow, a second phase of elbow extension occurs in late stance. Similarly, as the hindlimb lifts off the ground, the hip, knee and ankle flex. Knee and ankle extension occur midway through swing. In stance, the hip extends while the knee and ankle show a second phase of extension. In the lesioned animals, both the first phases of elbow and knee extension in the swing phase drop out so that activation of the elbow and shoulder are completely out of phase, while the hip and knee are in phase. The movement of the joints for a given limb are activated as a unit either in-phase or out-of-phase such that no independent phases of movement can be initiated. In addition, lesioned animals show a deficit in the ability to accurately place the limb while locomoting over the rough terrain. Thus, the results suggest that the pyramidal tract plays an important role in the fractionation of movement and accurate placement of the limbs, both of which are required for normal locomotion.

302.12 PICROTOXIN AND GLUTAMATE ACTIVATION OF NEURONS IN THE PREOPTIC BASAL FOREBRAIN INITATES LOCOMOTION IN THE ANESTHETIZED RAT. H. M. Sinnamon and M. Kaplan*. Neuropsych. Lab., Wesleyan Univ., Middletown, CT 06457

Locomotion by the anesthetized rat produced by electrical stimulation of the lateral hypothalamus requires projections to the midbrain. Preoptic neurons project axons through the lateral hypothalamus and this study attempted to initiate locomotion by pharmacologically activating their cell bodies.

Male rats were anesthetized with Nembutal and held in a stereotaxic apparatus such that their limbs contacted a wheel which rotated when stepping occurred. A 30-gauge stainless steel canula insulated except for the tip was lowered into the basal forebrain. Cathodal stimulation (0.5-msec pulses, 50-Hz frequency, 10-sec train, <100 uA) was used to test for locomotor effects. Glutamate (20mM or 2M) or picrotoxin (100 or 200 ng) were injected in volumes of 0.2 or 0.1 ul of saline at a rate of 1ul/5min.

Electrical stimulation elicited locomotion in a total of 31 sites which included the lateral (LPO) and medial (MPO) preoptic areas, and the bed nucleus of the stria terminalis (BST). Stimulation in another 23 sites, most in the BST and septal area, failed to produce locomotion. As with stimulation in the lateral hypothalamus and midbrain, the hindlimbs were principally involved in the locomotion.

Stepping was elicited by glutamate in 15 sites; at all of these sites electrical stimulation also produced stepping. Glutamate failed to elicit locomotion at 21 sites. At 6 of these sites electrical stimulation produced stepping, and at 16 it did not. Glutamate locomotor sites were found in the LPO, the MPO and the BST. Longer bouts of locomotion were produced by 2M than by 20nM glutamate.

Picrotoxin injected in 15 sites elicited stepping. At 12 of these sites electrical stimulation was also positive. Picrotoxin was negative in 12 sites, 7 of which were positive for electrical stimulation. The picrotoxin-positive sites were distributed similarly to the glutamate sites but the intensity and duration of the locomotor effects were greater with picrotoxin. The median duration was 10 min and the longest was 30 min.

These results indicate that activity of neurons in the preoptic region can cause locomotor initiation.

302.13 CHANGE IN SPONTANEOUS MOTOR ACTIVITY (SMA) OF RATS TREATED WITH 3-ACETYLPYRIDINE (3-AP), HARMALINE (HLM), AND NICOTINAMIDE (NAA). E. Toyoshima[1], K. Adachi*[2], M. Mukoyama*[2], T. Kihira*[3], K. Ando*[2], and R.F. Mayer[1]. [1]V.A. Med. Ctr. & Dept. of Neurol., Univ. of Maryland Sch. of Med., Baltimore, MD 21201. [2]Natl. Ctr. for Nerv., Ment. & Musc. Dis., Tokyo, JAPAN. [3]Dept. of Neurol., Wakayama Med. Univ., Wakayama, JAPAN.

In this study we compared the open-field SMA of rats treated with 3-AP, HLM, and NAA with 3-AP alone. In group A of 10 rats (8 weeks of age), 75mg/Kg of 3-AP, 15mg/Kg of HLM, and 300mg/Kg of NAA were injected (i.p.) in temporal sequence according to Llinás (1975). In group B of 10 rats, the same dose of 3-AP was injected. 18 rats injected with normal saline were the controls. SMA and locomotion loci were measured and recorded by Animex 2G (LKB-Farad Ltf., Sweden) for 5 min at the same time in a plastic cage (420x 250x400 mm in size). Although only 2 rats in group B survived over 2 weeks, 7 rats in A survived in spite of severe posture and gait disturbances. All rats in A showed wide-base posture and 'mud-walking' within 12 hr, but most rats in B did not show these abnormalities. 1 day after, they showed basically similar signs, and in some long term rats intention-tremor-like movements were observed. SMA (in m, less than 210 mm reflected locomotion) of rats in A, B, and control were as follows (M±SE(No.), *P < 0.01): Before; 13.4± 0.7(5), 13.8±0.8(5), 9.6±1.1(13), 1 day after; 4.8±1.3*(5), 2.4± 0.7*(5), 9.5±1.0(13), 15 days after; 13.2±1.8(7), 8.8±1.0*(2x3), 9.0±1.2(13), 29 days after; 10.4±2.0(5), 13.3±0.7(1x5), 8.8±1.2 (13). Both groups showed significant reduction in SMA of large size (reflected rearing) even after 29 days. Loci of locomotion were similar in both groups. Histological examination showed dark staining neurones without astrocytosis focally in str. pyramidale in the hippocampus in both groups. 2 days after, many degenerated and fewer nuclei with astrocytosis of the inferior olive were observed in both groups. There were also wide-spread degenerated nuclei in the brain-stem in group B. Atrophied and decreased numbers of Purkinje cells with astrocytosis in both vermis and hemisphere were observed in the cerebellum 16 days after in both groups, and this was more prominent later. There were no obvious abnormalities in the rest of CNS and PNS. This study confirmed the observations of Llinás, who suggested that animals treated with these drugs were a good model of chronically degenerated olivo-cerebellar system. Both reduction of SMA and abnormalities in the locomotor loci in the rats treated with 3-AP, HLM, and NAA might occur from destruction of the olivo-cerebellar system rather than the hippocampus. (Supported in part by a grant from the Institute of Health and Welfare, JAPAN and the Veterans Administration, U.S.A.)

302.14 CHANGES IN GLUCOSE METABOLISM IN THE CNS OF THE WALKING CAT. R.J. Schwartzman, E. Eidelberg, and G.M. Alexander*. Department of Neurology, Jefferson Medical College, Philadelphia, PA 19107

The local metabolic rate for glucose (lMRg) was studied in the motor areas of the central nervous system of cats utilizing the quantitative 2-deoxyglucose (2DG) method (Sokoloff, L., J. Neurochem. , 28:897, 1977). Four animals were used as controls and four cats were made to walk on a treadmill (.72 ft/sec). The animals walked for 5 minutes prior to 2DG injection (75 micro Ci/Kg) and during the 45 minute experiment. The lMRg (micromoles/100g/min) was measured in the putative locomotor regions of the midbrain, thalamus, and brainstem. It was also measured in all spinal cord rexed layers, motor cortex, basal ganglia, motor thalamus, cerebellar nuclei, lateral vestibular nucleus, red nucleus, subthalamic nucleus and substantia nigra. The lMRg of all rexed layers in the cervical cord was significantly ($P<0.05$) increased over control values. There was no significant increase in lMRg in the thoracic spinal cord. All layers of the lumbar cord demonstrated greater lMRg compared to control but only rexed layers 1 and 7 were significantly ($P<0.05$) increased. A generalized increase of 10-20% in lMRg was noted in all locomotor regions. The motor cortex demonstrated a 40-70% increase over control values. The caudate, putamen and globus pallidus deomonstrated a 10-20% increase over controls. There was no significant increase in lMRg of the substantia nigra and subthalamic nucleus. The motor thalamus and red nucleus demonstrated a 40-60% increase in lMRg. This technique permits an integrated view of CNS fuction during a specific motor paradigm.

302.15 EXTRACELLULAR RECORDINGS FROM VENTRAL AND DORSAL SPINOCEREBELLAR TRACT NEURONS IN THE SPINAL CORD OF AWAKE, FREELY MOVING CATS. Corey L. Cleland and J.A. Hoffer, Department of Clinical Neurosciences, University of Calgary, Alberta, Canada T2N 4N1.

The dorsal (DSCT) and ventral (VSCT) spinocerebellar tracts are the cerebellum's only monosynaptic sources of information about the hindlimb. Since both tracts, especially the VSCT, receive extensive convergence from descending, interneuronal and sensory pathways, it is difficult to infer their function from experiments in anesthetized or decerebrated cats. Recording the activity of single neurons in the spinal cord of awake, freely moving animals, however, has been impossible because of spinal cord movement. We have solved this problem by using floating microelectrodes to obtain stable extracellular records from VSCT and DSCT axons.

Cats were chronically implanted with: 6-12 microelectrodes in the dorso- and ventrolateral funiculi (L3-T12), bipolar cuffs on the hamstring, sciatic and femoral nerves, stimulating/recording spinal cord electrodes (T2), ankle, knee, and hip angle gauges, and bipolar emg electrodes in 6 hindlimb muscles. Leads converged onto an external 40-pin connector anchored to lumbar vertebrae. Over the next several weeks, signals were recorded and stimuli were delivered via a flexible cable while the cat performed a variety of motor tasks.

VSCT axons were identified by contralateral, short latency group I muscle afferent excitation and an ascending projection. Group I input was evoked by electrical stimulation through the nerve cuffs. The ascending projection was demonstrated by either antidromic activation after spinal cord stimulation or spike-triggered averaging of the spinal cord neurogram. DSCT axons were identified by ipsilateral, short-latency group I afferent excitation and an ascending projection. These criteria excluded other characterized ascending, but not propriospinal, pathways.

We recorded the activity of 90 neurons in four cats. Stability was often sufficient to record from the same axon for 2-12 consecutive days. Thirteen neurons were identified as VSCT (7) or DSCT (6) neurons. During locomotion, five VSCT neurons were active during stance and one was active during swing. The other VSCT axon was most active during light cutaneous stimulation of the anterior hindlimb. The activity of DSCT neurons mirrored the expected activity of muscle receptors in ankle extensor, ankle flexor, toe dorsiflexor and toe plantarflexor muscles.

Our results demonstrate the feasibility of recording the activity of identified neurons in the spinal cord of awake cats during unrestrained movements. In these initial experiments we have begun to characterize the natural activity patterns of spinocerebellar tract neurons in search of their functional roles. (Funded by the Alberta Heritage Foundation for Medical Research)

302.16 LOCALLY INJECTED SUCCINYLCHOLINE ACTIONS ON CAT MULTIJOINT FORELIMB TRAJECTORIES AND THALAMIC NEURONS. V. E. Amassian and L. Eberle*. Dept. of Physiology, SUNY, Downstate Med. Ctr., Brklyn, NY 11203.

The ability of an awake cat to generate a specific multijoint forelimb trajectory, e.g., the initial vertical trajectory of contact placing (CP), raises many questions, including: 1) What are the relative contributions to the trajectory of active (muscle) versus passive forces, e.g., pressure of the dorsum of the paw against the contacted surface, gravity and inertia? 2) Which receptors aid in trajectory regulation? A technique (J. Physiol., 358, 39P, 1985) for injecting succinylcholine (Sch; 30-90 mg/kg) or gallamine (90-300 mg/kg) distally into the brachial artery via an implanted catheter, results in temporary paralysis (or marked paresis) of ipsilateral forearm muscles, as shown by atonia and loss of direct EMG responses to median nerve stimulation via implanted electrodes. The awake cat was not distressed by the injections. Joint angles at shoulder, elbow and wrist-digits were measured at 60 Hz with a TV-computer system. The forelimb trajectory was least affected by gallamine, wrist ventroflexion occurring passively mainly through contact pressure on the paw. By contrast, some CPs by normal cats show increasing wrist ventroflexion when paw pressure is markedly reducing, consistent with activation of forearm flexors as previously shown with EMG recording. Sch effects differed in that transiently, e.g., for 1-2 minutes, angular velocities of posterior flexion at the shoulder and elbow flexion were reduced, while that of wrist ventroflexion increased relatively. At the end of the lifting phase of CP, anterior flexion at the shoulder increased disproportionately to elbow extension, the effect persisting for many minutes. Sch has an additional action of driving strongly Ia spindle afferents (Dutia, M.B., J. Physiol., 304: 315-330, 1980). We tested local Sch on 105 thalamic neurons in or bordering N. VPL contralateral to the injection; they were stereotaxically recorded with tungsten microelectrodes in cats under residual pentobarbital anesthesia supplemented by repeated injections of ketamine(I.M.). Sch activated 36% of neurons, which usually were located anteriorly at the VPL dorsal border and were driven by bending joints or probing muscle below the elbow. Sch inhibited 23%, such neurons usually being driven by , e.g., forelimb skin input or by bending proximal joints.

We conclude that passive forces contribute significantly to ventroflexion of wrist-digits in normal CP; in some CPs, a forearm flexor contribution to the trajectory is readily identifiable. The special effects of Sch probably result from intense Ia driving, e.g.,in the lengthening forearm extensors, which is interpreted ( incorrectly) by the motor control system as an excessive wrist ventroflexion, resulting in reduced central drive to the posterior flexors of the shoulder, which results in high contact pressure on the paw and therefore a marked ventroflexion of the wrist.

302.17 PARADOXICAL SLEEP WITHOUT ATONIA AND CONTROLLED LOCOMOTION: EVIDENCE FOR INVOLVEMENT OF THE SAME SYSTEMS. A.R. Morrison, G. L. Mann,* T. Mitchell,* and G. Cotsarelis.* Sch. of Veterinary Medicine, University of PA, Philadelphia, PA 19104 U.S.A.

Bilateral dorsolateral pontine tegmental lesions eliminate postural atonia and release elaborate behaviors during paradoxical sleep (PS), such as headlifting, righting, "orienting," standing, walking and attack, depending on the exact sites of the lesions (Hendricks, J.C., et al., Brain Res., 239:81-105, 1982). Because cats that walk quadrupedally during PS without atonia have larger, more ventral and more caudal lesions than those that do not, we have suggested that more than one inhibitory system may be damaged by our lesions and that multiple inhibitory systems may be engaged in normal PS. We have now examined whether a region in the dorsal midline of the pons that, when stimulated electrically, inhibits controlled treadmill locomotion induced in acutely decerebrated cats by stimulation of a lateral locomotor strip (Mori, S., et al., J. Neurophysiol., 41:1508-1591, 1978) has a role in PS without atonia.

Surgery for electrode implantations and lesions in 11 cats was performed aseptically under general inhalant anesthesia. Midline electrolytic lesions were aimed for P3-P6 and V -3.5 to -6.0 in cats already displaying PS without atonia as a consequence of bilateral dorsolateral pontine electrolytic lesions placed at least 3 weeks earlier. Waking locomotion was assessed in five 10-minute daily sessions before and after each lesion in a standard open-field chamber. It was significantly increased ($p<0.005$-$0.05$) after the midline lesion in the 5 cats studied. To determine if an additional release from inhibition occurred during PS without atonia after the midline lesion, increases in limb movements (excluding abrupt jerks) made in the first 3 minutes of at least 7 PS without atonia episodes were determined from videotapes. One cat became insomniac and could not be adequately studied in PS. Videotapes of 4 of 7 cats examined in sleep were suitable. They had a statistically significant increase ($p<0.005$-$0.05$) in limb movements during PS without atonia. Two walked in PS after the midline lesion; and 2 already walking increased it significantly. A midline kainic acid injection duplicated the effect of electrolytic lesions in both wakefulness and sleep, but additional chemical lesions with histological analyses are needed to determine with certainty whether cellular or fiber destruction is responsible for the observed behavioral changes.

Thus, the motor inhibition of PS depends on complex brainstem processes and is not solely the province of a circumscribed group of cells in the dorsal pons as has been suggested (Sakai, K., et al., Brain Res., 176:233-254, 1979). We propose that the lateral locomotor strip contributes to locomotor drive in PS without atonia.

302.18 PERINATAL EXPOSURE TO MORPHINE DISRUPTS POSTURAL SUPPORT IN POST-WEANLING RATS: POSSIBLE FACILITATION OF THE 'IMMOBILITY REFLEX.' Rebecca M. Chesire. Psychology Dept., Univ. Hawaii at Manoa, Honolulu, HI, 96822.*

In some animals, stress or experimentally-induced shock produce akinesia, loss of postural support and loss of righting reflexes; responses that have adaptive value in death feining (Carli, Psy. Rec. 27:Suppl., 1977; Carli et al., Behav. Brain Res. 2, 1981). This form of 'immobility reflex' is believed to be regulated in part by endogenous opiates, and morphine-induced catalepsy resembles the natural defensive state (De Ryck & Teitelbaum, Behav. Neurosci. 98, 1984).

Morphine is a known teratogen that produces persistent (Sonderegger et al., Neurobeh. Toxicol. 1, 1979) and usually deleterious effects in rats. However, this report describes preliminary evidence of a possible facilitation of a component of the immobility reflex in rats exposed in infancy to morphine.

Eighty male and female rats (Long-Evans hooded or Charles River CD albinos) were implanted in the flank on postnatal days 5, 8, or 11 with 75 mg slow release morphine (n=30), lactose placebo (n=30), or no pellets (n=20). On postnatal days 28-30 (5-7 days after weaning), each animal was given one 3 min. trial per day in the open field (a stressful situation).

Rats treated perinatally with morphine showed a significant tendency to lose postural support intermittently during bouts of forward locomotion (other movement differences will be reported elsewhere). The loss of support took three basic forms: (1) complete - no fore- or hindlimb support and the ventrum in contact with the floor, (2) hindlimb - loss of hindlimb support with normal positioning of the forelimbs and (3) mixed - loss of hindlimb support without normal positioning of the forelimbs (e.g., forelimbs splayed beyond the width of the shoulder girdle, forelimbs crossed over one another, or forelimbs leaning markedly to one side). Placebo-implanted and untreated control rats rarely showed a complete loss of postural support, and never lost only hindlimb support or displayed mixed losses. Such support deficits are also absent in rats exposed in infancy to heat, cold or shock stress, or rats injected in infancy with large doses of haloperidol (Chesire, in preparation).

The results suggest that perinatal exposure to morphine may facilitate the development of at least one component that mimics a presumably adaptive death feining response: the loss of complete or partial postural support during stressful stimulation.

302.19 INFLUENCE OF B-VITAMINS ON THE CONTROL OF FINE MOTORIC MOVEMENTS. D. Bonke and B. Nickel, Messrs. E. Merck, Darmstadt, and Hess. Verband für modernen Fünfkampf, Darmstadt.

The functional role of vitamins of the B-Group in the metabolism of the nervous system is well known by deficiency experiments in animals and volunteers. In case of an avitaminosis the pathologic mechanisms can be described as a blockade of encymatic controlled metabolic steps, in which these vitamins act as coencymes, embedded in the energy-, transmitter- and structural metabolism of nerve cells and also of accompanying cells.

The relevance of functional deficit within the nervous system even due to subclinical deficiency states has been shown in studies by proving cognitive functions or personality structure (J.S. Goodwin et al., JAMA 249:2917, 1983; Chomé et al., Ernährungs-Umschau 91:12, 1984).

It has been stated elsewhere that various transmitter producing encymes (GAD, 5-HTP-D, Dopa-D) are not fully saturated by their cofactor pyridoxal phosphate under normal conditions. The activity of these encymes also seems to be stimulated differentially by pyridoxalphosphate (T.P. Porter and D.L. Martin, J. of Neurochemistry 43:1464, 1984; A.R. Green and D.G. Grahame-Smith, Handbook of Psychopharmacology 3:169, 1975) Thus the question rises, if addition of various vitamin cofactors in dosages above quantities provided by nutritional sources may lead to an improvement of functional nervous system properties.

Because of possible effects as well in sensory as motory pathways the model should involve a performance task in which both aspects may contribute to a performance improvement. The model, by which these conditions are fulfilled, was found in shooting.

The results of two studies (1. open, controlled; 2. double blind versus placebo) with healthy normal marksmen (pentathlon), treated over a period of 8 weeks by a vitamin combination of $B_1$, $B_6$ and $B_{12}$* show that firing accuracy (measured by their succeeded points out of 20 shots and by the deviation of the hits to the centre point of the target disk) improves continuously up to 10 % (1. study $p < 0.05$; 2. study $p < 0.001$). A psychological self-rating test (state trait anxiety inventory) also shows a statistical significant stabilisation of the rating values, which may be interpreted as an increased capability of compensating stress factors, e.g. in competitions, which has been involved in the study.

303.1 EFFECT OF BICUCULLINE ON SACCADIC EYE MOVEMENT ELICITED BY MICROSTIMULATION OF THE PRE- AND POSTSYNAPTIC COMPONENTS OF FASTIGIAL NEURONS. H. Noda, S. Murakami* and T. Aso*. Visual Sci. Dept., Sch. of Opt., Indiana Univ. Bloomington, IN 47405

Microstimulation of the posterior vermis (lobuli 6 and 7) with electrical currents less than 10 μA elicits a saccadic eye movement in the direction of the stimulation side in the monkey. Similar oculomotor responses can be seen also when the white matter immediately above the fastigial nucleus is stimulated. When the stimulus electrode enters the fastigial nucleus, the direction of eye movements changes from ipsilateral to contralateral side of stimulation. As the synaptic action of Purkinje cells is inhibitory, it is possible that the eye movements in the ipsi- and contralateral directions were caused by stimulation of the pre- and postsynaptic components of fastigial neurons, respectively.

In the present study, oculomotor responses were compared before and after bicuculline injections by using a magnetic search coil technique in three macaque monkeys. The depth of the reversal point of response directions was identified in each track by testing the responses systematically at 100 μm steps. Then, bicuculline (0.2-1 μg) was injected in five loci along the track (1 and 0.5 mm above, 0.5 and 1 mm below, and at the reversal point). Positive effects of bicuculline were observed in 7 out of 8 tracks tested, and the reversal points were histologically identified by iron deposits near the upper border of the fastigial nucleus. Following the injections, the ipsilateral responses from the white matter were almost completely suppressed, while the contralateral responses from the fastigial nucleus were either unchanged or enhanced. The effects continued for several hours but the ipsilateral responses returned to preoperative sizes in less than 10 hours. The negative track was found in the white matter anterior to the fastigial nucleus, suggesting that bicuculline did not reach oculomotor fastigial neurons. It is concluded that the eye movements in the direction of the stimulation side were evoked by activation of the presynaptic component (axons of Purkinje cells from the posterior vermis), while those in the opposite direction resulted from the excitation of the postsynaptic component of the oculomotor fastigial neurons. (Supported by NIH Grant EY-04063).

303.2 ADAPTIVE INTERFERENCE OF OPTOKINETIC EYE MOVEMENT RESPONSE (OKR) WITH VESTIBULO-OCULAR REFLEX (VOR) AND RELATED NEURONAL EVENTS IN THE RABBIT FLOCCULUS. S. Nagao*(SPON:M. Ito). Dept. of Physiol., Fac. of Med., Univ. of Tokyo, Tokyo, 113, Japan

The OKR and VOR operate synergistically to stabilize retinal images of the visual environment during head movement, and have been assumed to linearly interact with each other. However, analyses of the changes induced in OKR under sustained visual-vestibular interaction in cats and monkeys suggest an interaction to take place between adaptive mechanisms of the VOR and those of OKR. In this study on pigmented rabbits, the author found that prolonged optokinetic stimulation, without any vestibular stimulation, induced not only adaptive changes of OKR but also changes in VOR. To locate the source of this adaptive interference of OKR to VOR, effects of floccular lesions and single unit activities of floccular Purkinje cells were investigated. Adaptive changes of OKR were induced in alert pigmented rabbits chronically prepared for fixation on turntable, by sustained sinusoidal rotation (5°, 7.5° or 10° peak-peak; 0.1 or 0.2Hz) of the striped screen. VOR was measured every one hour by rotating the turntable sinusoidally (5° peak-peak; 0.1 or 0.2 Hz) in darkness. During the sustained screen rotation for 4 hours the gain of OKR increased by 0.12-0.26, and at the same time the VOR gain also increased by 0.12-0.22. The VOR gain increased maximally when the screen was rotated by 7.5° peak-peak at 0.1Hz. Slight advancement of the phase (7°-11°) occured in the VOR. In bilaterally floccular lesioned rabbits with local injection of 0.01% kainate, sustained screen rotation no longer produced any noticeable changes in OKR gain, VOR gain or VOR phase. To estimate optokinetic and vestibular responsiveness of floccular Purkinje cells, amplitudes of frequency modulation of simple spike discharges were measured during sinusoidal screen rotation (7.5° peak-peak, 0.1 Hz), and during sinusoidal turntable rotation (5° peak-peak, 0.1 Hz) in darkness, respectively. After the end of recording, brief trains of pulse currents were applied through the microelectrode (tip negative). The floccular areas where the microstimulation induced abduction in the ipsilateral eye were specified as H-zone which was presumed to be involved in the control of horizontal VOR. It was found that sustained screen rotation (7.5° peak-peak, 0.1 Hz) induced significant changes of the optokinetic responsiveness in 75%, and also of the vestibular responsiveness in 57% of the H-zone Purkinje cells tested. The direction of these changes were consistent with the view that these were causal to the changes in the OKR and VOR. Only very minor changes of responsiveness, either optokinetic or vestibular, occured in Purkinje cells recorded from other floccular areas. These observations suggest that OKR and VOR adaptively interfere with each other through their common neuronal circuitry in the flocculus.

303.3 VISUALLY RESPONSIVE NEURONS IN THE FASTIGIAL NUCLEUS OF THE CAT AND ITS MEDIATING PATHWAY. M.Kase*, K.Kawamura, M.Ohno*, T.Hashikawa*, and M.Kato*. Department of Physiology, Hokkaido University, Sapporo 060, Japan (M.K., M.O., M.K.) and Department of Anatomy, Iwate Medical University, Morioka 020, Japan (K.K., T.H.).

It has been said that cerebellar vermis-fastigial nucleus system plays an important role in the control system of pursuit eye movements and optokinetic nystagmus as well as saccades. It remains unsettled, however, whether the fastigial nucleus (FN) receives inputs from the visual system.

Using 11 cats, immobilized by gallamine under urethane anesthesia, 111 FN neurons were extracellularly recorded that responded to electrical stimulation (bipolar: 0.5-0.75 mA 100 μsec) at the optic chiasm. Their responses to the stimulus were classified into three classes: fifty-five FN neurons (type 1) showed a burst, following a transient suppression of discharges. Thirty-seven units (type 2) exhibited a long suppression after a transient burst. Eighteen units (type 3) showed a long suppression associated with the stimulus. In some of our experiments, eight units also responded to a flash of light given to both eyes. Three, four, and one units showed type 1, type 2, and type 3 response patterns, respectively. These classes of units were intermingly located at the dorsal part of the caudal FN where axons of Purkinje cells from the mid-vermal part (lobules VI and VII) of the cerebellum terminate predominantly.

In an attempt to determine the pathways through which the visual information may propagate to FN, HRP was injected iontophoretically into the area of FN where responsive neurons were recorded. In this experiment , a large number of retrogradely labeled cells were found bilaterally in the medial (M) and descending (D) nuclei of the vestibular complex (VN). An injection of HRP in the M and D resulted in the labeling of many cells in the dorsal part of the nucleus reticularis gigantocellularis (Rgc). In another HRP experiment, the nucleus of optic tract (NOT) and the interstitial nucleus of Cajal were shown to give off fibers ipsilaterally to this part of the Rgc.

The present results suggest that the caudal part of FN receives visual information through a channel of the NOT-Rgc-M and D of VN as well as through lobules VI and VII of the vermis where the pontine nuclei send potentially visual information, indicating that the vermis-FN system may participate in the control of optokinetic nystagmus.

303.4 PURKINJE CELL ACTIVITY IN THE FLOCCULUS OF THE ALERT RABBIT DURING NATURAL VISUAL AND VESTIBULAR STIMULATION. PART 2. C. S. Leonard and J.I. Simpson, Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

The simple spike discharge rate of rabbit floccular Purkinje cells (P-cells) was recorded extracellularly during several combinations of vestibular and visual stimulation consisting of velocity step rotations (.1 Hz, ± 2 deg/sec) about the earth vertical axis. As we reported last year, none of the P-cells had the temporal response characteristics of an unprocessed vestibular nerve signal during vestibular stimulation in the dark (VD). Furthermore, one group of cells resembled the 'eye movement only' class of P-cells found in the monkey (c.f. Miles et al., 1980) and, therefore, exhibited virtually no modulation during visual-vestibular conflict (VS) when eye movements were suppressed. We have correlated the discharge rates of these cells with parameters related to both the sensory stimuli and motor responses and here focus on the correlation with eye position. An eye position sensitivity (EPS) was estimated during VD, optokinetic stimulation (OK) and vestibular stimulation with a staircase function. In the rabbit, this latter stimulus moves the eye to different steady positions in the orbit and thereby allows a measure of the steady-state EPS. The mean steady-state EPS was 5.4 spikes/sec/deg (n=4). An apparent EPS was computed during VD and OK stimulation by choosing portions of the stimulus cycle where eye velocity and retinal image velocity were nearly constant and independent of the changing eye position. This apparent EPS was often dependent on the direction of the eye velocity. In the VD condition, the mean apparent EPS was 4.6 spikes/sec/deg for eye velocities ipsilateral to the recording site (the on-direction for all cells) and 2.8 spikes/sec/deg for contralateral eye velocities (n=6). During OK stimulation, this asymmetry was preserved, but the magnitudes were doubled to a mean apparent EPS of 10.8 spikes/sec/deg for ipsilateral eye velocities and 6.1 spikes/sec/deg for contralateral eye velocities (n=6). In summary, the mean steady-state EPS for the rabbit is much larger than that reported for the monkey flocculus (0.7 spikes/sec/deg for 'eye movement only' P-cells; Miles et al., 1980). In addition, the fact that the apparent EPS in the OK condition was roughly twice that in the VD condition suggests that retinal image velocity, which is the adequate stimulus for optokinetic eye movements, manifests itself, in part, as an enhanced eye position sensitivity of floccular P-cells. [Supported by USPHS Grant NS-13742 from NINCDS].

303.5 VISUAL RESPONSES IN "GAZE VELOCITY" PURKINJE CELLS IN THE PRIMATE CEREBELLAR FLOCCULUS. L.S. Stone and S.G. Lisberger, Neurobiology Div., Physiology Dept., UCSF, San Francisco, CA, 94143.

Previous investigators have used sinusoidal stimuli to show that many Purkinje cells in the monkey flocculus have simple spike modulation during visually evoked smooth eye movements. These cells receive vestibular inputs encoding head velocity and oculomotor inputs signalling smooth eye velocity. The vestibular and oculomotor signals sum to produce a firing rate proportional to gaze velocity (eye velocity in the world). There is both anatomical and electrophysiological evidence that the flocculus also receives visual mossy fiber inputs but their influence on gaze velocity Purkinje cells (GVP-cells) is as yet unclear.

We have used a transient visual stimulus to reveal visually driven simple spike responses in GVP-cells related to horizontal eye movement. Cells were identified as GVP-cells according to previous criteria and were then studied while the monkey pursued a step-ramp target movement. This visual stimulus produced 100 msec of 30 deg/sec retinal image motion followed by saccade-free pursuit. For target motion in the ipsilateral direction, the majority of our sample of GVP-cells (21 of 38 cells in 2 monkeys) emitted a clear pulse of simple spikes that was 2 to 8 times larger than could be accounted for by the cell's sensitivity to eye velocity alone. The pulse followed the onset of target motion by about 100 msec, lasted from 75 to 300 msec and coincided with the large eye acceleration during the initiation of pursuit. It was not, however, seen in the responses of eye movement mossy fibers to the same stimuli.

To determine whether the pulse was related to the visual stimulus (retinal slip) or the motor response (eye acceleration), we examined the same cells using a rapid change in head velocity. This vestibular stimulus produced a change in eye velocity comparable to that during step-ramp pursuit but without the preceding visual stimulus. None of the GVP-cells showed a pulse during the rapid eye acceleration evoked by vestibular stimulation, ruling out any significant eye acceleration sensitivity. In addition, GVP-cells with particularly large pulses showed, at the appropriate latency for visual signals (about 100 msec), a difference in their response depending on whether the rapid change in head velocity was imposed in the dark or during fixation of a stationary target. This is caused by the short-lived low velocity image motion at the onset of the rapid change, due to the VOR latency.

We conclude that a large fraction of the GVP-cells in the primate flocculus receive visual mossy fiber input. The strong correlation between the pulse of simple spikes and the eye acceleration suggests that the visual mossy fiber pathways through the flocculus form an important part of the neural command for the initiation of pursuit. (Supported by NSF grant #BNS 8444605).

303.6 DIRECTION OF SACCADIC EYE MOVEMENTS ELICITED BY MICROSTIMULATION OF THE PRE- AND POSTSYNAPTIC COMPONENTS OF FASTIGIAL NEURONS. S. Murakami*, H. Noda, T. Warabi* and T. Aso*. (SPON: A. Strickholm). Visual Sci. Dept., Sch. of Opt., Indiana Univ. Bloomington, IN 47405.

With currents of less than 10 μA, microstimulation of the fastigial nucleus and of the white matter surrounding it elicits a saccadic eye movement. The direction of the eye movement varies depending on whether the presynaptic (vermal Purkinje cell axons) or postsynaptic component (fastigial neurons) is activated. Stimulation of the presynaptic component causes an ipsilateral eye movement, while that of the fastigial neurons causes a contralateral response.

In the present study of three macaque monkeys, the changes in the direction of evoked eye movement in relation to the position of the stimulating electrode were systematically studied, testing at 100 μm steps. Eye movements were recorded with a magnetic search coil technique and analyzed with a PDP-11 computer. When the white matter immediately above the fastigial nucleus was stimulated, the eyes moved to the side of stimulation regardless of the eye position prior to stimulation. However, when the electrode entered the fastigial nucleus, the eyes tended to move toward a point (goal) in the ipsilateral hemifield. Thus, the direction was dependent on the initial eye position. As the electrode was advanced in the fastigial nucleus, the goal gradually moved into the central field and the evoked eye movements were typically "goal-directed". A larger eye movement was elicited when the eyes were far from the goal, and a smaller response was associated with an initial eye position closer to it. Interestingly, the goal moved across the midline into the contralateral hemifield as the electrode passed by the fastigial oculomotor neurons and then moved away to the contralateral periphery. Then, the direction of eye movement was always contralateral. The fastigial loci showing such a goal-shift in the central $30^{o}$ of the field were usually confined to less than 1 mm along a single track. There were, however, variations in the trails of the goal-shift. The goal shifted in some tracks along a straight horizontal line across the primary eye position, while in the other tracks it detoured. In spite of the variations, there was a systematic trend in the type of the goal-shift depending upon the location of electrode tracks in the fastigial nucleus. In 63 out of 85 tracks tested, the goal moved into the central $30^{o}$ of the primary eye position. (Supported by NIH Grant EY-04063).

303.7 ANATOMY AND PHYSIOLOGY OF CEREBELLAR EFFERENTS TO THE VESTIBULAR COMPLEX AND NUCLEUS PREPOSITUS HYPOGLOSSI OF THE SQUIRREL MONKEY. D. B. Belknap and R. A. McCrea. Department of Pharmacological and Physiological Sciences, Univ. of Chicago, Chicago, IL 60637.

The regions of the cerebellar cortex which project to the medial vestibular nucleus (MVN), ventral lateral vestibular nucleus (VLVN) and nucleus prepositus hypoglossi (PPH) were delineated by retrograde transport of WGA-HRP as a part of the physiological and anatomical investigation of floccular efferents which code parameters of horizontal gaze. WGA-HRP was injected iontophoretically and alternate sections were reacted with TMB and left unstained, or with DAB and counterstained with cresyl violet. All retrograde labeling in the cerebellar cortex was ipsilateral to the injection sites. Injection of the central rostral MVN in three monkeys resulted in labeling of a central band of Purkinje cells, extending rostrocaudally through all folia of the ipsilateral flocculus. Labeling of a parasagittal strip of Purkinje cells in the nodulus was also present with MVN injections. A large injection including both the VLVN and MVN resulted in labeling of cells within a broader central floccular band, and scattered labeling in the paraflocculus; the ipsilateral vermis was also labeled in this animal. In two cases in which the injection site included only the lateral portion of the PPH and the adjacent medial MVN, a small region within Crus I was labeled. Labeling of the folium of the paraflocculus adjacent to the flocculus occurred when the lateral PPH was injected. Injections restricted to the medial two-thirds of the PPH resulted in no retrograde labeling of the cerebellar cortex.

In order to determine the orientation of the parallel fibers in the flocculus, particularly relative to the strip of floccular Purkinje cells projecting to the MVN, the parallel fibers were impregnated with silver and their orientation was examined in transverse sections, which were then used to construct a two-dimensional representation of parallel fiber orientation within the floccular cortex. This map was compared with similar maps of the MVN-efferent strip. This analysis demonstrated that the MVN-efferent strip was oriented orthogonally to the parallel fibers.

In order to investigate the physiological properties of the floccular output relating to the control of the horizontal VOR, Purkinje cells coding horizontal gaze are being studied by extracellular recording in alert squirrel monkeys and by injection of an anterograde tracer, Phaseolus vulgaris leucoagglutinin. The preliminary results of this physiological study suggest that Purkinje cells responding to parameters of horizontal gaze may occur in restricted regions of the flocculus.

303.8 CHANGES IN SIMPLE SPIKE ACTIVITY ACCOMPANYING EVOKED CLIMBING FIBER INPUT IN LOCOMOTING CATS. J.H. Kim, J.J. Wang*, and T.J. Ebner. Departments of Neurosurgery and Physiology, Univ. of MN, Mpls., MN 55455

In an accompanying abstract climbing fiber afferent activity was shown to be preferentially associated with a treadmill perturbation which arrested the step cycle. Increases in climbing fiber discharge occurred at the onset of the perturbation and at the resumption of locomotion. This study was designed to examine whether the evoked climbing fiber input was associated with alterations in the simple spike modulation. The presence of concomitant changes in the forelimb muscle activity and displacement was also evaluated. The experimental procedures and recording techniques are described in the accompanying abstract (Wang, et al, Soc. Neurosci. Abstr. 1985). To evaluate the changes in simple spike activity as well as locomotor behavior associated with complex spike occurrence the trials were divided into two groups based on the presence or absence of a complex spike within a time window determined by visual inspection of the complex spike post-stimulus time histogram. The first group consisted of those trials in which a complex spike was evoked within the time window (climbing fiber trials) and the second group those trials in which no complex spike (non-climbing fiber trials) was evoked. From each group of trials a set of histograms (simple spike, complex spike, biceps, triceps, displacement) normalized to the number of trials was constructed. In an additional set of histograms constructed from the climbing fiber trials, the simple spike activity was realigned setting the time of the complex spike occurrence to the first bin in the time window. The biceps and triceps EMG activity as well as limb position were shifted accordingly. Simple spike activity in the climbing fiber trials was quite different from that of non-climbing fiber trials. In the majority of Purkinje cells (16/22) the simple spike modulation increased following the climbing fiber input. In some cells (4/22) the increased simple spike discharge was followed by a reduction in simple spike activity. In two cells the simple spike activity was reduced in the climbing fiber trials. In some cells the increased simple spike discharge was associated with increased triceps activity, and in a few cells the alterations were correlated with the biceps activity. Changes in the step cycle in the climbing fiber trials were also observed. In a walking cat climbing fiber afferent input is associated with changes in the simple spike modulation. These observations are consistent with the hypothesis that the climbing fiber afferent system alters the responsiveness of Purkinje cells to mossy fiber inputs. Supported by NIH grant NS 18338 and NSF grant BNS-8318885.

303.9 CEREBELLAR CLIMBING FIBER AFFERENT ACTIVITY DURING NORMAL AND PERTURBED TREADMILL LOCOMOTION IN THE DECEREBRATE CAT. J.J. Wang*, J.H. Kim, M. Partington* and T.J. Ebner (Spon: F. Torres). Departments of Neurosurgery and Physiology, Univ. of MN, Mpls., MN 55455.

The relationship and contribution of climbing fiber afferent input to volitional or non-volitional motor behavior remains unclear. To begin to answer these questions climbing fiber discharge was evaluated during treadmill locomotion in the cat. A precollicular-premamillary decerebrate cat preparation was chosen because of the spontaneous, treadmill walking these animals exhibit. In these experiments the simple and complex spike discharges of Purkinje cells were examined during spontaneous treadmill walking in which the step cycle could be systematically interrupted. Conventional electrophysiological techniques were used to record and discriminate the simple and complex spike discharge of Purkinje cells in the anterior lobe. Biceps and triceps EMG activity, right forelimb displacement, and treadmill speed were also recorded. Treadmill braking which arrested the cat's locomotion could be timed to occur at specific phases of the step cycle. Peristimulus time histograms of each cell's simple and complex spike discharge, rectified and integrated forelimb EMG, forelimb displacement and treadmill velocity in relation to the step cycle were constructed. In 140 of the Purkinje cells studied the neuron was held for a sufficient length of time to permit averaging its discharge throughout a minimum of 50 step cycles. For 52 cells examined during unperturbed locomotion simple spike discharge was almost always modulated (46/52 cells, 88.4%), usually increasing during the swing phase (23/46). During unperturbed locomotion approximately one third of the cells exhibited complex spike modulation with the step cycle (18/52). Treadmill braking evoked alterations in climbing fiber afferent discharge in 61% of the cells examined (75/122). Different patterns of complex spike discharge were evoked in different cells including increases at the onset of treadmill braking, increases during the period of arrested locomotion and increases at the resumption of locomotion. Reduction in climbing fiber discharge during the period of arrested locomotion was also observed. The most prevalent pattern was an increase in climbing fiber discharge at the resumption of the step cycle (34/75, 48%) following the perturbation period. Complex spike modulation during the unperturbed step cycle suggests this afferent system is active throughout this type of motor activity. The strong association of the climbing fiber afferent discharge to the perturbation suggests a role for this afferent system during changes in motor behavior. Supported by NIH grants NS 18338 and NSF grant BNS-8318885.

303.10 EVOKED PERIODICITY IN CEREBELLAR CLIMBING FIBER AFFERENT DISCHARGE: RELATIONSHIP TO SIMPLE SPIKE ACTIVITY AND RESETTING CHARACTERISTICS. T.J. Ebner and J.H. Kim. Departments of Neurosurgery and Physiology, Univ. of MN, Mpls., MN 55455

Recently the tendency of climbing fiber afferents and inferior olivary neurons to discharge rhythmically and some of the properties of this rhythmic behavior have been described (Bloedel and Ebner, J. Physiol. 352, 1984; Llinas and Yarom, J.Physiol. 315, 1981). In this study additional characteristics of this periodicity and its relationship to simple spike activity were evaluated. Whether the rhythmic discharge was present in a motor behavior was also determined. In the initial part of this study the simple and complex spike discharge of Purkinje cells was recorded in the decerebrate, unanesthetized cat. An ipsilateral forepaw flexion-extension displacement was used to evoke rhythmic complex spike discharge. The resetting characteristics of the evoked oscillation were determined by calculation of the "winding number", a measure of how the evoked rhythmicity interacts with the spontaneous climbing fiber afferent discharge. In most Purkinje cells the complex spike discharge exhibited a winding number of 0 suggesting that the forepaw stimulus completely resets the oscillation. Autocorrelations of the simple spike activity showed that in only a few Purkinje cells was there associated periodicity in the simple spike discharge. Whether the rhythmic climbing fiber afferent discharge occurred in a motor behavior was evaluated in treadmill walking precollicular-premamillary cats. Rhythmicity was evaluated by examining the autocorrelation of the complex spike histogram for specified time periods in the step cycle. Comparable time periods in the triceps and biceps EMG, simple spike discharge and forelimb displacement were evaluated for associated periodicity. Rhythmic discharge of 5-10 Hz was present in the climbing fiber afferent discharge in some Purkinje cells, preferentially in association with an increase in complex spike activity evoked by treadmill braking. Analysis of the forelimb EMG and forelimb displacement revealed little associated rhythmicity . These observations suggest that the forepaw stimulus resets the inferior olivary oscillation which has implications for the underlying mechanisms. Furthermore this rhythmic discharge was observed in a motor activity. In both preparations the rhythmicity was not generally associated with a comparable periodicity in the simple spike activity and in the locomoting animal there was no periodicity in the EMG activity or forelimb displacement, suggesting this oscillation may have a function that is not reflected as a periodicity in the output of the cerebellar cortex. Supported by NIH grant NS 18338 and NSF grant BNS-8318885.

303.11 CROSS-INTERVAL CORRELATION OF FIRING PATTERNS OF SIMULTANEOUSLY RECORDED NEIGHBORING CEREBELLAR PURKINJE CELLS. D.C. Tam, C.K. Knox, and T.J. Ebner. Departments of Neurosurgery and Physiology, Univ. of MN, Mpls., MN 55455

Recently there is renewed interest in simultaneous recording from multiple Purkinje cells. However, analytical techniques to evaluate multi-unit data are limited, relying primarily on cross-correlation analysis. New methods need elucidation. In the present experiments the simultaneous firing patterns of neighboring cerebellar Purkinje cells were examined. Two new analytical techniques are presented for analysis of simultaneously recorded spike trains. These techniques emphasized the temporal relationships among the discharge of the adjacent neurons. Simultaneous extracellular recordings were done on closely spaced Purkinje cells in decerebrate, unanesthetized cats. Poisson distributed pulse trains were used to electrically stimulate forearm nerves and/or parallel fibers to elicit Purkinje cell simple spike modulation without introducing stimulus periodicity. Periodic stimuli were also used at times for comparison. In addition to conventional cross-correlation techniques and post-stimulus time histograms, two new techniques were introduced to analyze the temporal relationship between the simple spike discharge of two neurons. First, the cross-interval histogram was used to assess the relationship between the intervals of the preceding spike of the adjacent cell and the reference cell, and the subsequent intervals between the reference and adjacent cell. In the second technique a cross-interspike interval histogram was used to assess the relationship between the intervals of the preceding spike of the adjacent cell and the subsequent interspike intervals of the reference cell. Both techniques produced a two-dimensional histogram that delineates the effects of a preceding spike of a neighboring cell on the likelihood of subsequent firing intervals. The spike trains were also shuffled, cross-interval correlated, and subtracted from the unshuffled cross-interval histogram to produce the appropriate difference histogram. These techniques permit examination of the conditional probability of the interspike intervals or waiting-time intervals given that a spike occurred in a neighboring cell. The difference cross-interval histograms revealed coupled peaks and valleys present at precise intervals. These preferred intervals of spike occurrence and non-occurrence were not present in conventional one-dimensional correlation techniques. The coupled peaks and valleys profile of these histograms may suggest a temporal surround inhibitory relationship between neighboring Purkinje cells. Supported by NIH grant NS 18338.

303.12 THE RESPONSES OF SIMULTANEOUSLY RECORDED PURKINJE CELLS TO PERTURBATIONS OF THE STEP CYCLE AND THEIR RELATIONSHIP TO THE CLIMBING FIBER INPUT. J.R. Bloedel and J. Lou*. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Experiments were performed in decerebrate ferrets capable of maintained locomotion on a treadmill to examine the responses of Purkinje cells located in various sagittal zones of the cerebellar cortex to perturbations of the locomotor step cycle. The perturbations were produced either by intermittent breaking of the treadmill or the interposition of a rod in the footpath of the forelimb. Up to 6 Purkinje cells were recorded simultaneously in the surface layer of lobules V or VI using an array of 5 tungsten electrodes aligned sagittally and separated by approximately 200 microns. The responses of 37 sets were analyzed using a new analytical procedure, the real time postsynaptic response (RTPR). This method enables a sweep-by-sweep analysis of the combined action of all recorded neurons by calculating a simulated response of a cerebellar nuclear neuron based on the assumption that all the recorded cells terminate on the same postsynaptic cell. The output of a low friction potentiometer attached to the right forelimb was used to trigger the construction of the RTPR and to apply the perturbation at specific and repeatable phases of the step cycle. Each cell's simple and complex spikes were discriminated, and the simple spikes were converted to simulated IPSPs using an alpha function with the appropriate time course. These were then summed linearly to generate the RTPR. The modulation of the RTPR was compared during step cycles in which a perturbation either was or was not applied. Purkinje cells located at one site approximately 1 mm lateral to the paravermal vein characteristically were poorly modulated during the step cycle but responded to the perturbation. These responses were quantified by integrating the RTPR over a specified epoch and comparing this integral in perturbed and unperturbed trials. Across all sets of neurons, the perturbation evoked a 46.59% increase in the modulation of the RTPR as well as a 100% increase in the occurrence of a complex spike in at least 50% of the cells in the set. These data show that sagittally oriented, neighboring Purkinje cells in this cerebellar cortical region respond to the perturbations much more dramatically than to the normal step cycle, and that their responses are associated with the synchronous activation of climbing fiber inputs by the same perturbation. These data are consistent with the hypothesis that perturbations of motor behavior elicit a synchronous discharge of climbing fiber inputs in Purkinje cells located in specific sagittal zones, and that these climbing fibers act to increase the responsiveness of these neurons to mossy fiber inputs activated by the same perturbation. This research was supported by NIH grant #NS-09447.

303.13 THE REAL TIME POSTSYNAPTIC RESPONSE (RTPR): A NEW APPROACH FOR ANALYZING THE RESPONSES OF SEVERAL SIMULTANEOUSLY RECORDED NEURONS AND ITS APPLICATION TO THE CORTICONUCLEAR SYSTEM OF THE CEREBELLUM. J. Lou* and J.R. Bloedel. (SPON: A. Shetter) Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Because of the evolving interest in characterizing the response properties of a neuronal population, a method was developed for describing the synaptic action of a simultaneously recorded pool of neurons which have a common site of termination. This method has been applied initially to the corticonuclear system of the cerebellum. Previous methods employed to examine the responses of simultaneously recorded neurons have required either comparison of poststimulus time histograms or various types of cross-correlation techniques. This new approach provides a description of the population's output in terms of its action on a postsynaptic neuron. The first step in the application of this technique requires the conversion of each cell's action potentials to postsynaptic potentials with a specified amplitude and time course. In these initial studies based on the corticonuclear projection, an alpha function was chosen which simulates an IPSP with a time constant of 5 msec. The amplitudes of these potentials were constant and were not corrected for membrane potential. The simulated PSPs were then summed linearly to obtain an analog signal representing the fluctuation in the membrane potential produced by the convergent activity of the recorded nerve cells. One of the most important attributes of this method is that it permits a real time analysis of the action of the recorded neurons without averaging, the construction of histograms, or the calculation of some analytical relationship between the spike trains of the recorded neurons. The spike trains of 3-5 neighboring Purkinje cells are sufficient to generate a RTPR which is sensitive enough to visualize a reproducible response or modulation. The responses can be further quantified by determining the integral of the simulated postsynaptic response for specified epochs related to a stimulus or behavior. One of the most valuable features of this type of analysis is that the effects of the impulse activity of the recorded neurons can be examined on models of postsynaptic neurons with varying complexities. Consequently, the response properties of the postsynaptic neuron can be compared under various hypothetical conditions including various distributions of afferent terminals and variations in the membrane properties. Even under the simplified assumptions used to date, this method has provided a way to characterize the response of a neuronal population based on its action on postsynaptic targets rather than on a comparison between the discharge properties of the presynaptic neurons themselves. This work was supported by NIH research grant #NS-09447.

303.14 LOCATION AND TONIC DISCHARGE PATTERNS OF PHYSIOLOGICALLY-IDENTIFIED PALLIDAL-RECEIVING AND CEREBELLAR-RECEIVING THALAMIC NEURONS IN THE AWAKE MONKEY. R.S. Turner* and M.E. Anderson, Depts. of Physiol. and Biophys. and Rehab. Med. and Regional Primate Research Center, University of Washington SJ-40, Seattle, WA 98195.

Information reaches the cerebral cortex from the globus pallidus and cerebellum via thalamic neurons that seldom receive convergent input from the two sources. Furthermore, it has been proposed from a comparison of anatomical studies that thalamic neurons projecting to the supplementary motor area (SMA) receive input from the pallidum, those projecting to postarcuate area 6 receive input from the posterior cerebellum, and those projecting to primary motor cortex receive input from the anterior cerebellum (Schell and Strick, 1984).

In experiments designed to compare movement-related activity in pallidal-receiving (PR) and cerebellar-receiving (CR) thalamic neurons, stimulating electrodes were positioned in the lateral portion of the ipsilateral internal pallidal segment and in the contralateral brachium conjunctivum (BC). PR-thalamic neurons were inhibited by pallidal stimulation, and CR-thalamic neurons were excited by BC stimulation. The steady-state activity patterns of identified PR and CR thalamic neurons and other nearby cells was determined during a variable 1-3 sec preparatory hold period prior to the visual trigger in a reaction time task. PR neurons had a rather regular tonic discharge pattern, with mean interspike intervals less than 55 msec. CR neurons, however, had lower frequency, irregular discharge patterns with mean intervals greater than 55 msec unless the neuron exhibited particularly high frequency bursts. Recording tracks were run through the entire rostro-caudal extent of VA, VLo, and VPLo, although the pallidal stimulating electrode was not in place during most of the caudal tracks. The recording locations were determined later by reference to electrolytic lesions made in several recording tracks.

Seventy-two hours prior to euthanasia, HRP was injected into the SMA at an A-P position the same as the tip of the arcuate sulcus. Comparison of the location of HRP-labeled neurons and physiologically-identified PR and CR neurons showed that PR neurons were identified in rostral portions of the thalamus, at A-P planes of VA and VLo where HRP-labeled neurons were located. No CR neurons were found in VA or rostral VLo; they were primarily in VPLo, lateral, and at caudal levels, ventral to neurons labeled retrogradely with HRP injected into SMA.

These data are consistent with those of Schell and Strick and indicate that some of the PR thalamic neurons whose activity we have studied probably projected to SMA, whereas the CR thalamic cells sampled physiologically probably projected to the primary motor cortex.

Supported by NS15017 PR 00166, GM17108 and NIHR Goo8300076.

303.15 PARVOCELLULAR RED NUCLEUS IS IMPORTANT DURING COMPENSATION FOR RUBROSPINAL TRACT LESIONS IN OPERANTLY CONDITIONED RATS. P. R. Kennedy, D. Newby,* M. Wallert,* and D. R. Humphrey. Lab of Neurophysiology, Emory Univ. School of Medicine, Atlanta, GA 30322.

Recordings of histologically verified single parvocellular red nucleus (pRN) neurons in monkeys showed relative unresponsiveness during motor or sensory testing (Kennedy et al., Soc. Neurosci. Abstr. 10[1]:537, 1984). Fiber-damaging electrolytic lesions of the red nucleus in monkeys (Carpenter et al., J. Comp. Neurol. 105:195-249, 1956) failed to ascribe a specific function other than hypokinesia. To determine pRN function, fiber-sparing chemical lesions were made in behaving rats. Since pRN cells partly intermingle with magnocellular red nucleus (mRN) neurons (which project as the rubrospinal tract [RST]), it is impossible to avoid lesioning both pRN and mRN when lesioning the red nucleus. To control for this, bilateral RST lesions were made before nuclear lesions; thus the RST lesions in effect were mRN lesions, and the subsequent nuclear lesions were in effect pRN lesions. Note that RST fibers run in the dorsolateral funiculus and corticospinal fibers run in the dorsal columns, allowing separate lesioning of these systems in the rat.

Long Evans rats (275-450 g) were trained to walk on a 2 cm diameter bar rotating at 9 times per min, 70 cms above a cushioned surface. Rats were averse to falling and so could be operantly conditioned to walk daily for 10 trials, 300 s each trial, with 1 min rest between trials. Naive rats were trained to criterion (250 s average daily trial time) in 3-5 days. Bilateral RST lesions were made in 7 trained rats under Nembutal anesthesia by using needles and fine scissors to sever the dorsolateral funiculus at C3-4. Recovery from quadraparesis occurred in 6-24 h and retraining to criterion in about 1 week (2-10 days). Then 2% Quinolinic acid (Sigma; Schwartz et al., Science 219:316-18, 1983) lesions of each pRN were made about 1 week apart (bilateral same-day lesions were fatal in 2 rats), using corrected stereotaxic coordinates and 1.25-1.50 mm diameter lesions. After unilateral pRN lesions in 3 rats, retraining to criterion occurred in 1-4 days. After subsequent lesioning of the opposite pRN retraining to criterion occurred in 1 day in 1 rat with 98% complete lesions, and was close to criterion in 2 rats before they became ill on day 2 (one had 50% lesions and hydrocephalus; the other is still alive). This suggests that pRN lesions have no effect on rotating bar performance in rats that have already compensated for RST lesions.

To see if pRN has a role to play during compensation for RST lesions, both lesions were performed at the same time by ablating the nucleus with 2% Quinolinic acid (thus destroying pRN plus mRN neurons that give rise to RST). After unilateral lesions in 6 rats, retraining to criterion occurred in a few days. It was possible in 2 rats to lesion subsequently the opposite side. In these rats a prolonged performance deficit occurred. One rat performed at only 20% of criterion for 9 weeks, at which time almost complete lesions were histologically verified (caudal sparing on left). A second rat (with a verified 100% left lesion and rostral 33% right lesion) took over 3 weeks to return to criterion.

These early results suggest that while pRN may not play a role in the control of finely coordinated movement in the already compensated rat performing on the rotating bar, it has an important role to play during compensation for RST lesions. (Supported by NIH grant NS10183.)

303.16 THE ACCESSORY OPTIC SYSTEM IN THE GOLDFISH (CARASSIUS AURATUS): PHYSIOLOGICAL AND ANATOMICAL ASPECTS. J.F. McGurk and W. Graf. The Rockefeller University, New York, NY 10021.

Visual and vestibular responses in the goldfish cerebellum and the pathways mediating them were studied in order to describe the physiological and anatomical context of cerebellar control of eye movements. Field potentials and single unit activity were recorded in the cerebellum following stimulation of the optic nerve and the ampullae of the horizontal semicircular canals. Visually evoked potentials were recorded in a large area of the corpus contralateral to the stimulated eye and in a small region of the ipsilateral corpus along its rostral border. Vestibular potentials were recorded in the center region of the corpus as well as in several portions of the lobus caudalis. Visually evoked field potentials appeared as a positivity on the cerebellar surface and reversed to a negativity at a depth of 1500 μm (maximum amplitude 350-400 μV, latency 15-20 ms). Vestibular field potentials in the corpus exhibited an initial positivity followed by a prolonged negativity. The latency of the positivity was 15-20 ms, the latency of the negativity 40-50 ms. One region in the central one-third of the corpus exhibited activity following stimulation of the contralateral eye and both labyrinths. Into this region of the corpus, horseradish peroxidase (HRP) was injected iontophoretically, after the location had been verified by recording visually-evoked field potentials through the HRP electrode. Large injections of the enzyme into this location produced bilateral retrograde labelling in four pretectal nuclei including the two reported to be the nuclei of the accessory optic system (P1 and P2). In addition, the nucleus lateralis valvulae, the descending and magnocellular octavolateralis nuclei, nuclei in the reticular formation and the inferior olive were labeled bilaterally, as has been described previously. Focal injections into the same cerebellar area, however, produced labelling ipsilaterally only in the pretectal nuclei P1 and P2 of the accessory optic system, in the contralateral inferior olive, and bilaterally in the nucleus lateralis valvulae and the descending and magnocellular octavolateralis nuclei. Intraocular injection of lectin conjugated HRP (WGA-HRP) produced anterograde transsynaptic labelling in both contralateral pretectal nuclei of the accessory optic system (P1 and P2) as well as in cells in the hypothalmus, the dorsomedial optic nucleus and the optic tectum. These physiological and anatomical data indicate that afferents from two sensory systems converge in one area of the cerebellum. This study provides a framework for examining cerebellar control of compensatory and optokinetically evoked eye movements.

303.17 **EFFECT OF PURKINJE CELL LOSS ON COMPLEX MOTOR BEHAVIOR.** R. Wetts, T. Moran, M. Oster-Granite, and J. Gearhart*. Departments of Pediatrics, Psychiatry, Neuroscience, Cell Biology and Anatomy, and Gynecology and Obstetrics, Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205

The final number of neurons in the mammalian CNS can be reduced by chromosomal aneuploidy, prenatal environmental insults, or genetic mutations. Heterozygous Lurcher (Lc/+) mice lose cerebellar Purkinje cells (PCs) (100%), granule cells (GCs) (90%), and inferior olivary neurons (IONs) (75%) postnatally, but deep cerebellar nuclear cells (DCNs) are spared. In Lc <-> normal aggregation chimeras, all PCs derived from the Lc embryo (10-90%) are lost selectively. All remaining PCs, descended from the normal embryo, are distributed throughout the cerebellum. The reduced number of GCs in the chimera is proportional to the number of PCs that remain. The number of IONs is also reduced in the chimera, but is greater than in Lc/+ animals.

We examined the effects of the reduced number of Purkinje cells by studying selected motor activities in Lc chimeric mice. Lc/+ mice exhibit ataxia, intention tremor, and poor balance. No Lc chimera displays any of these traits. To determine whether subtle, but distinct, alterations occur in the functional capabilities of Lc chimeric mice, we conducted a number of discriminative behavioral tests of cerebellar function on the Lc chimeras, on normal chimeras, and on Lc/+ mice.

All three groups of mice, placed in an automated Omnitech Activity Monitor, were active for similar amounts of time (mean: 20 min/hr) during the night and made similar numbers of movements. Measurement of the number and total time of rearing and mean speed reflected cerebellar function. The mean speed of Lc/+ mice was significantly slower, but that of the Lc chimeras and normals did not differ significantly. The time and number of rearings for Lc/+ mice was also reduced significantly. While these parameters were clearly reduced in the Lc chimeras, the reduction was not significantly different from the normals.

To detect whether the animals displayed hypotonia or poor balance, we measured stride length and width of the hindlimbs. The mice were placed on an inkpad and then allowed to walk across a clean sheet of paper. The results for stride length are, so far, inconclusive. The widths of the Lc/+ animals were greater than in the normals, and the widths of the Lc chimeras were variable, overlapping both the normals and the Lc/+ animals.

Tests of other motor skills are still in progress, but no task examined so far clearly demonstrates any major motor deficit in the Lc chimeric mice. Thus, loss of up to 90% of the PCs in Lc chimeras produces only minor, but distinctive, effects on the functional capabilities of the animal. This supports the idea that there is a large amount of redundancy in the mammalian CNS.

## OCULOMOTOR SYSTEM III

304.1 DEFICITS IN SUPPRESSING SACCADIC EYE MOVEMENTS IN PATIENTS WITH CEREBRAL HEMISPHERIC LESIONS. H.A. Buchtel, R.B. Zuckernik* and S. Berent. Ann Arbor V.A. Medical Center and University of Michigan, Ann Arbor MI 48105

Patients with unilateral frontal lobe excisions for the relief of epilepsy have difficulty looking away from salient visual stimuli presented to the left or right of central fixation (Guitton, Buchtel & Douglas, Exp. Br. Res., in press). We have hypothesized that the frontal eye fields or supplementary motor areas play a role in modulating the activity of lower visual-motor areas which, in the absence of such modulation, may organize maladaptive eye movements to salient visual stimuli. In order to generalize these findings to patients with other lesion etiologies, we have used the same behavioral technique with patients having hemispheric damage from vascular disease, tumor and head trauma.

Two tasks were used. In the first task the patient looked toward a brief visual cue located $10^{o}$ to the left or right of fixation. In the second task (anti-saccade task) the patient had to look away from the cue to a spot in the same position relative to straight ahead but on the opposite side. Eye position was monitored by EOM and recorded for later analysis.

Twenty-one brain-damaged patients (10 left, 11 right) and 12 matched control patients without neurological deficits have been studied to date. Approximately 3/4 of the patients had motor symptoms indicating a disturbance of anterior functions. As in the case of patients after surgery for epilepsy, patients with stroke, tumor and head trauma demonstrated a strong tendency to look toward the visual cue on anti-saccade trials. On approximately 32% ± 7% of anti-saccade trials the patients looked to the wrong side (vs 15%±3% for control subjects). Patients with right-hemispheric lesions made more errors than patients with left-hemispheric lesions (37%±6 vs 25%±7). When the visual fields were considered separately according to the relationship to lesion side, no clear difference between contralateral and ipsilateral fields was seen in group data, although half the patients made at least 10% more errors in one direction than in the other. Lesion site or time since the onset of illness may explain the direction of visual field difference.

These findings extend the observation of a saccade suppression deficit to patients with brain damage from stroke, tumor and head trauma. The presumed mechanism remains the loss of modulatory input from cortical areas to subcortical centers that are capable of organizing saccades to visual stimuli.

304.2 DEPENDENCE OF THE VESTIBULAR-OCULAR REFLEX GAIN ON RADIUS OF ROTATION AND TARGET POSITION. E. Viirre*, D. Tweed*, K. Milner* and T. Vilis (SPON: J.P. Girvin). Depts. of Ophthalmology and Physiology, University of Western Ontario, London, Canada N6A 5C1.

It has been found in cats (Blakemore and Donaghy, J. Physiol., 300:317-35, 1980) that when the visual target is close to the eyes and the axis of head rotation behind the eyes, there is an increase in the gain of the Vestibular Ocular Reflex (VOR). It can be shown that such an increase in gain is necessary to maintain fixation on the near target.

The precise relation between the horizontal VOR gain and the variables, radius of rotation (R) and target position, was examined in three Macaca fascicularis monkeys. Each had eye search coils implanted and was trained to fixate a LED target during sinusoidal rotation. It was found that the peak-to-peak VOR gain was close to the predicted gain of 1.6 for an object 16 cm from the eyes and with R=10 cm. This gain remained constant for frequencies of rotation from 0.25 to 2.0 Hz. No phase lag was present at a rotational frequency of 2.0 Hz. The increase in gain was also maintained for several cycles after the lights were extinguished. When a sudden rotational acceleration was applied, the increase in gain was apparent within 10-20 ms. These results indicate that the increase in gain must be mediated by the VOR and not by visually driven oculomotor systems such as optokinetic, pursuit or vergence.

The VOR gain was found to increase from 0.94 ± .05 to 1.86 ± .09 with an increase in R from 0 to 10 cm (target distance 11 cm), and to increase from 1.09 ± .03 to 2.02 ± .17 with a decrease in target distance from the eyes from 90 to 8.5 cm (R=10 cm). Throughout a rotation cycle, the instantaneous velocities of the two eyes were not equal differing in a typical pattern which was determined by the fact that the eye that was closest to the target at any time had the higher velocity. It was also found that with eccentric targets the peak-to-peak VOR gains of the eyes could differ by up to 20%. This difference in VOR gain was observed at a rotational frequency of 2.0 Hz and within 20 ms of a sudden head rotation. Thus each eye must have independent VOR gain control.

It is proposed that the VOR gain control is mediated through a combination of semicircular canal and otolith information and depends on an initial determination of the target position with respect to the head.

304.3 ABDUCTION NYSTAGMUS IN INTERNUCLEAR OPHTHALMOPLEGIA. D.S. Zee and T.C. Hain*, (SPON: D.A. Robinson). Dept. of Neurology, Johns Hopkins Hospital, Baltimore, Maryland 21205

Adduction weakness of one eye and nystagmus on abduction of the other typify internuclear ophthalmoplegia (INO). While interruption of internuclear fibers (VI→III) accounts for the adduction weakness the abduction nystagmus is unexplained. To test the hypothesis that adaptive mechanisms contribute to the abduction nystagmus of INO, we determined the effects of prolonged, monocular viewing (by patching one eye for 3-5 days) on abduction nystagmus in 3 patients with INO. Saccades were quantified by measuring the amplitude of the rapid pulse portion of the saccade (P) and of the final (step) position of the eye (S). The abduction nystagmus was quantified by determining the P-S mismatch (PSM = [P-S]/S) and the time constant of drift ($T_c$).

Patient I had a predominantly right-sided INO but preferentially viewed with the right (paretic) eye. Before patching, for 10° abducting saccades by the left eye (LE), P = 20.7°, PSM = 94% and $T_c$ = 153ms. After 5 days of LE viewing, P decreased to near normal (11.8°) and the abduction nystagmus was markedly attentuated (PSM = 26%.) Likewise, for LE 30° abducting saccades, P decreased from 44.5° to 31.0° and PSM decreased from 52% to 14%. RE adducting saccades showed corresponding decreases in P and increases in PSM. Changes in P and PSM varied with both direction of movement and orbital position. After habitual RE viewing was resumed, saccade metrics and PSM returned to their initial values. Patient II had a bilateral INO with $T_c$ = 94ms. The PSM for LE 10° abducting saccades decreased from 112% after habitual RE viewing to 48% after habitual LE viewing. P also decreased from 24.4° to 17.4°. For RE 10° abducting saccades P appropriately increased (8.8°→14.4°), but PSM changed little (26%→18%). Patient III also had a bilateral INO but with a very rapid postsaccadic drift ($T_c$ = 51ms). After prolonged LE viewing, PSM for LE 10° abducting saccades changed little (85%→66%) and P did not change at all (17.6°→17.7°). For RE 10° abducting saccades PSM did not change (24%→26%) and P increased only slightly (11.75°→13.9°).

Our results indicate that the actions of adaptive mechanisms and which eye is preferentially used for fixation must be considered to interpret the abduction overshoot and abduction nystagmus of INO. In Patient I, in particular, the abduction nystagmus almost disappeared with prolonged viewing by the nonparetic eye. The variability of adaptive affects among different patients with INO may reflect additional lesions that affect structures mediating adaptive control and/or limitations in the adaptive mechanism's capability to suppress extremely rapid and brief postsaccadic drift (e.g., Patient III).

304.4 HYPOTHETICAL MECHANISM OF HEAD-SHAKING NYSTAGMUS (HSN) IN MAN: ASYMMETRICAL VELOCITY STORAGE. Joseph L. Demer. Department of Ophthalmology and Clayton Neurotology Laboratory, Baylor College of Medicine, Houston, Texas. 77030

Head-shaking nystagmus is a jerk nystagmus occurring transiently following a brief period of horizontal head oscillation. This nystagmus is distinct from other forms of pathological nystagmus in that it is not initially present when the head has been at rest for a prolonged period. Clinically, HSN is felt to be a sign of neuro-vestibular imbalance.

HSN was studied in a 21 year old diabetic man who complained of the acute onset several days earlier of vertigo following head movements. After written informed consent, horizontal eye movements were recorded by direct current electro-oculography. No nystagmus was initially present in darkness with the head at rest. Following sinusoidal head rotations in darkness at frequencies from 0.05 to 0.4 Hz lasting 20 to 100 sec (amplitude 60 deg/sec), the head was immobilized but a rightward drift of the eyes developed transiently in each trial. This nystagmus had an initial velocity of 7.5 to 18 deg/sec to the right and decreased in roughly exponential fashion with a time constant of 4 to 13 sec. Vestibulo-ocular reflex (VOR) gain (eye velocity/head velocity) was measured in darkness for 60 to 200 deg/sec steps of head velocity. VOR gain was asymmetrical: 0.62 for slow phases to the left and 0.82 for slow phases to the right. Apparent VOR time constant was 7 sec for slow phases to the left and 10 sec to the right. Although responses to full-field optokinetic stimulation at 50 deg/sec were initially similar, the time constant of optokinetic after-nystagmus (measured in darkness at the conclusion of optokinetic stimulation) was asymmetrical: 1.3 sec to the left and 4.3 sec to the right. Caloric nystagmus evoked by hot and cold irrigations of the auditory canals was bilaterally symmetrical.

These responses were numerically simulated using a mathematical model of the combined vestibulo-optokinetic systems having directional gain and efference copy channels but a single velocity storage element (Demer et al., ARVO Abstracts, 1984, p. 230). In this model, slow phase eye velocity storage is accomplished by a positive-feedback, efference copy loop common to the vestibulo-ocular and optokinetic reflexes. Selection of model parameters matching the observed asymmetrical gain and time constants allowed the model to accurately simulate the HSN observed in the subject. HSN thus appears to be the simply predictable consequence of gain and/or time constant asymmetries in the neural eye velocity storage mechanism. As observed in the subject reported here, the direction of HSN would be predicted to be in the direction of the more effective velocity storage.

304.5 COMPARISON OF SMOOTH PURSUIT AND COMBINED EYE-HEAD TRACKING IN HUMAN SUBJECTS WITH DEFICIENT LABYRINTHINE FUNCTION. R.J. Leigh, J.A. Sharpe, P. J. Rinalli*, M.A. Hamid and S.E. Thurston*. Ocular Motility Lab, Cleveland VA Medical Center and University Hospitals, Cleveland, OH 44106; Playfair Unit, University of Toronto, Ont. Canada, M5T 2S8; Dept. Otolaryngol., Cleveland Clinic, Cleveland, OH 44106.

We studied 8 subjects with deficient labyrinthine function, all with bilaterally absent responses to ice-water caloric stimulation. We measured horizontal gaze (eye position in space) and head rotation using the magnetic search coil technique. Subjects tracked a laser-spot target (a) with eye alone, head still (smooth pursuit-SP) (b) with combined, active movements of eye and head (eye-head-tracking-EHT). The target moved sinusoidally at frequencies of 0.25 Hz or 1.0 Hz with amplitudes of ± 5 or ± 10 degrees. In addition, subjects actively rotated their heads at 0.25 or 1.0 Hz, in darkness, while imagining a stationary target. Subjects also underwent passive, en bloc rotation at 0.25 Hz, 1.0 Hz or lower frequencies, in darkness, while they either imagined a stationary target or performed mental arithmetic. During passive rotation, some subjects were additionally required to look at a head-fixed target ("passive VOR cancellation").

Tracking gain (peak gaze velocity/peak target velocity) was greater during EHT than SP in all subjects for targets moving with a frequency of 1.0 Hz. At 0.25 Hz, EHT gain was greater than SP gain in 4/8 patients. During active head rotation in each subject, the response gain (peak eye velocity in orbit/peak head velocity) was always greater than during en bloc rotation. Nevertheless, during active head shaking, response gain values remained below normal (e.g., at 1 Hz, gains ranged from 0.08 to 0.79). "Passive VOR cancellation" (measured as peak gaze velocity/peak chair velocity) was similar to or greater than values obtained during active EHT.

Although tracking gain was increased in EHT compared with SP, these differences were never large enough to be wholly accounted for by a simple, "linear addition" model in which the smooth pursuit signal cancels the VOR during EHT. In addition, parametric changes or "switches" are required in the model so that transmission of the smooth pursuit signal can be reduced or interrupted during EHT. (Supported by the Veterans Administration, Toronto Western Hospital, MRC of Canada.)

304.6 BRAINSTEM PROJECTIONS OF PRIMATE EXTRAOCULAR MUSCLE AFFERENT NEURONS. John D. Porter. Department of Anatomy, University of Mississippi Medical Center, Jackson, Mississippi 39216.

Although various visual and visuomotor centers (e.g., visual cortex, superior colliculus, cerebellum) receive sensory information from the extraocular muscles, the precise anatomical pathway by which proprioceptive signals are relayed to these centers is unknown. Somata of neurons which provide sensory innervation of primate extraocular muscles are confined to the trigeminal ganglion (J. Comp. Neurol. 218: 208, '83). The present study has utilized the technique of transganglionic transport of wheat germ agglutinin-conjugated horseradish peroxidase (WGA/HRP) from monkey extraocular muscles in order to determine the central synaptic connectivity of these muscle primary afferent neurons.

A cocktail containing WGA/HRP and HRP was injected into various combinations of the four rectus extraocular muscles and monkeys were allowed to survive 24-48 hours. These injections resulted in a discrete pattern of transganglionically-labeled axonal terminals within the ipsilateral trigeminal sensory and main cuneate nuclei. The density of afferent termination varied markedly from animal to animal and from one rostral-caudal level to the next, but was heaviest and observed most consistently within the ventrolateral portion of pars interpolaris of the spinal trigeminal nucleus. A second significant extraocular muscle afferent representation was observed within the ventrolateral segment of the main cuneate nucleus. This projection was restricted to the rostral, reticular, segment of the nucleus, overlapping a region which is known to receive primary afferent input from dorsal neck musculature. Modest to light terminal projections, centered at the border of medullary laminae IV and V, were noted in pars caudalis of the spinal trigeminal nucleus. However, given the variability of this projection, it most likely represents termination sites of periorbital or conjunctival nociceptors. Similarly, light terminal labeling was observed for some cases within the pars oralis and principal trigeminal nuclei.

Taken together, the central termination sites of extraocular muscle afferent neurons are appropriate for relay of proprioceptive information to centers previously implicated in the processing of such information. Beyond serving a simple relay function, target nuclei for extraocular muscle afferents (the main cuneate nucleus in particular) may serve to integrate inputs from eye and neck musculature for the purpose of polysensory coordination of eye/head movements.

304.7 POINTING PERFORMANCE AFTER STRABISMUS SURGERY IS COMPATIBLE WITH THE OUTFLOW THEORY OF VISUAL LOCALIZATION. O.Bock and G.Kommerell (SPON: W.Daunicht). Dept. Ophtalm. Univ. Freiburg, FRG

Egocentric visual localization of strabismus patients was tested before and after surgical rotation of one eye. If the patients used motor (outflow) signals to determine eye position, localization should change by an amount equal and opposite to surgical eye rotation. If, however, sensory (inflow) information was used, localization should remain unchanged.

Patients pointed without visual feedback of the pointing arm at visual targets, presented in a quasi-random order in 9 horizontal positions within the central ±20 deg of gaze (54 target presentations in total). A mobile, head-fixed device (Ott D, Eckmiller R, Bock O; report in preparation) was used to perform the experiments. Subjects were tested monocularly; repeated tests were performed before, and one about 20 h after surgery, when the operated eye was uncovered for the first time. The amount of surgery was determined from pre-, and postoperative measurements of the squint angle.

On repetition of the preoperative tests, marked changes of the pointing performance were observed in some subjects: we found systematic shifts of the pointing responses by up to 10.8 deg.

After surgery, pointing responses when using the operated eye were shifted opposite to surgical eye rotation in 13 of our 14 patients. On the average, the size of the pointing shift paralleled the amount of surgery, although in some subjects the shift was smaller or larger by up to 12.8 deg. In contrast, pointing responses when using the intact eye remained unchanged after surgery. Findings were similar in patients undergoing their first surgery and in those who had been operated on the same eye muscles before.

The considerable (if compared to normals) ambiguity of preoperative pointing is probably related to the well-known ambiguity of relative visual localization (i.e. to the variability of retinal correspondence) in strabismics. This ambiguity could well explain the differences between amount of surgery and pointing shift, found in some subjects. Further, the one subject without pointing shift might have used subtle cognitive cues (e.g. recollection of preoperative target positions) to properly adjust an ambiguous localization after surgery; as professional sharpshooter, he probably used such cues more effectively than others.

Steinbach and Smith (Science, 213:1407,1981) found only small pointing shifts after strabismus surgery in the majority of their patients; it is conceivable that their testing procedure facilitated use of cognitive cues, e.g. by using only 3 target positions.

We conclude that the outflow theory of visual localization, supported by a variety of findings from different paradigms, is also compatible with the pointing performance after strabismus surgery, once the well-known ambiguity of visual localization in strabismics is taken into account. 304.8 MULTIPLY INNERVATED FIBERS IN MAMMALIAN EXTRAOCULAR MUSCLE WITH VARIATION ALONG THEIR LENGTH OF THEIR ELECTRICAL ACTIVITY AND MYOSIN CONTENT J.Jacoby, E.Stefani*, J.Davidowitz, G.Philips and D.J. Chiarandini, Depts. Ophth. and Physiol. and Biophys., N.Y.U. Med. Center, New York, NY 10016 and *Dept. of Physiol., Center for Adv. Studies, I.P.N., Mexico D.F. 14.

Mammalian extraocular muscle, unlike most other mammalian muscle consists of multiply innervated (MIF) and singly innervated (SIF) fibers which are intermingled in two morphologically distinct layers: the global and orbital. Global MIFs generate tonic tension and lack action potentials. On nerve stimulation they give endplate potentials (epp's) and graded, slow voltage dependent responses or slow peak potentials. The contractile properties of orbital MIFs are unknown. Unlike the global MIFs, which exhibit a moderate to poor development of sarcoplasmic reticulum (SR) along their length, the morphological properties of orbital MIFs are complex. Toward their middle the fibers have a very small diameter (5-7 um) and they display well developed SR with small myofibrils (Fibrillenstruktur) and a twitch-like endplate, coextensive with the orbital endplate zone (EPZ) of the muscle. Distally and proximally to the EPZ, the diameter typically increases gradually to 10-15 um, the myofibrils become larger and progressively less defined, approaching an afibrillar morphology (Felderstruktur) at both ends. Superficial nerve endings are scattered in these regions. A monoclonal antibody against chick ALD muscle binds in the Felderstruktur regions but not in the Fibrillenstruktur portion of the fiber. We studied "in vitro" the electrophysiological properties of orbital MIFs in inferior rectus muscle of the rat. We found that orbital MIFs are innervated by multiple axons and that on nerve stimulation they produce a complex response that varies along the length of the fiber. Near the EPZ distally to 2 mm, nerve stimulation produced compound epp's at low stimulus strength and a non-overshooting, fast-rising voltage-dependent response or "spike" at higher stimulus strength. Distal to 2 mm the "spikes" were absent or greatly attenuated. The responses in most cases consisted of large and small epp's, similar to those found in global MIFs. Lucifer yellow injections of fibers identified electrophysiologically as orbital MIFs filled the entire length of the fiber from the distal end to the EPZ, spanning regions of different morphology and electrical activity, supporting morphological evidence of a single continuous fiber. We hypothesize that the apparent dual nature of these fibers along their length is maintained through a dual innervation by a fast motoneuron and one or more slow motoneurons. Supported by USPHS EY01297, EY07009, EY00309, NSF INT 7920212, and CONACyT 790022.

304.9 PONTINE RETICULO-SPINAL NEURONS ARE A COMPONENT OF RETICULAR CIRCUITS CONTROLLING EYE-HEAD SYNERGIES. A.Grantyn[x], A.Berthoz and V.Ong-Meang[x], Lab. de Physiol. Neurosensorielle, CNRS, Paris,France

During orienting towards eccentric targets, eye and head movements are often synergic. It has been suggested (Vidal, P.P. et al, Exp.Brain Res.,46:448, 1982) that pontine reticular neurons may participate simultaneously in the control of these two motor components of orienting. To provide direct evidence for this supposition, we studied behavioral properties of identified pontine reticulo-spinal neurons (PRSNs) considered, on morphological grounds, as candidates for mediating eye-head synergies. Experiments were performed on alert, untrained, head-fixed cats. Orienting responses were elicited by presentation of moving visual stimuli. Axons of PRSNs were penetrated intracellularly close to the abducens nucl. and identified by antidromic responses to ipsilateral spinal cord stimulation (C1, C2) and monosynaptic activation from the contralateral superior colliculus. Two axons were injected with HRP, to visualize their branching pattern in the brainstem. Relationships between neuronal activity and motor events during orienting (eye movements, EMG-activity of dorsal neck muscles) were analysed quantitatively.

Four out of 14 PRSNs did not show any clear relation to eye movement or neck EMG. The activity of the remaining 10 PRSNs was qualitatively similar during horizontal eye-head synergies : 1)Absence of any discharge when eyes are deviated in contralateral direction, 2) Phasic activity showing about the same degree of correlation with ipsiversive horizontal saccades and phasic components of neck EMG, 3) Tonic activity roughly proportional to ipsilateral horizontal eye position but not maintained during prolonged eccentric fixations, 4) Variability of the degree of correlation between discharge profiles and motor events. During dissociation of eye-head synergy, PRSN activity may be related to neck EMG while eye position does not change. The two HRP-labelled neurons displayed discharge patterns described above. Their somata were located rostroventrally to the abducens nucleus and collateral branching in the lower brainstem corresponded to the type characterized by R.Grantyn et al. (Brain Res., 198:221, 1980). Target areas included the abducens and facial nuclei, the vestibular nuclei, the prepositus/intercalatus complex and the caudal pontine and bulbar RF. Morphology of terminal structures presented features of both diffuseness and specificity. Of particular interest were the cases of dense perisomatic clusters containing up to 27 boutons derived from convergent collateral branches of second and higher orders. PRSNs with extensively branched axonal tree appear thus to establish selective connections with particular target neurons.

In conclusion, PRSNs of the periabducens area which project to spinal cord, abducens and facial nuclei, and bulbar sites of origin of parallel reticulo-spinal pathways do generate signals adequate for partial execution of horizontal eye-head synergies.

304.10 PHYSIOLOGICAL CHARACTERISTICS OF NEURONS IN THE MEDIAL VESTIBULAR NUCLEUS AND RETICULAR FORMATION OF THE SQUIRREL MONKEY INVOLVED IN FOVEAL CANCELLATION OF THE HORIZONTAL VESTIBULO-OCULAR REFLEX. Eugene F. May* and Robert A. McCrea. Committee on Neurobiology, Dept. of Pharmacol. & Physiol. Sci., University of Chicago, Chicago, IL 60637.

The rostral part of the vestibular complex and adjacent reticular formation were explored for neurons which carried signals related to foveal cancellation (FC) of the horizontal vestibulo-ocular reflex (VOR). Squirrel monkeys were trained to fixate a small light attached to a vestibular turntable on which they were rotated sinusoidally in the yaw axis. Three groups of neurons were found whose firing rate was related to FC of the VOR, and their response during vestibular and optokinetic nystagmus (OKN), smooth pursuit, and FC of the VOR and OKN was studied.

In the rostral-most part of the medial vestibular n. (MVN) and subjacent reticular formation, cells were found whose head velocity sensitivity increased without changing phase when the monkey cancelled its VOR. The enhancement was most pronounced at higher stimulus frequencies and velocities. The firing rate of these cells was not correlated with other types of eye movement.

In the dorsomedial part of the MVN at the level of the caudal abducens n. and n. prepositus, a second group of neurons was identified whose firing rate was related to ipsilateral eye position, ipsilateral eye velocity (except during OKN) and ipsilateral head velocity. During FC of the VOR, the neurons' firing rate lead ipsilateral head velocity by $5^0$ to $20^0$. The cells' head velocity sensitivity was not apparent at velocities less than $10^0$/s during VOR cancellation, and there was no apparent head velocity or eye velocity sensitivity when the VOR was not cancelled. During OKN and FC of OKN, the firing rate of these neurons was related only to eye position and saccadic eye velocity. These cells may participate in the generation of saccadic and smooth pursuit eye movements, and in cancelling at the level of the motoneuron the vestibular signals carried by secondary VOR neurons during VOR cancellation.

The third group of cells, similar to those described by Eckmiller and Bauswein in the rhesus monkey (Soc. Neurosci Abs., 10: 391, 1984), was located just ventral to the rostral medial vestibular nucleus, adjacent to the ventral border of the abducens nucleus. These cells fired only when contralateral slow phase eye velocities induced by head movements or peripheral retinal slip were suppressed, which suggests that they may play an important role in this ability. They did not fire during spontaneous eye movements except during ipsilateral smooth pursuit. During sinusoidal head rotation, they fired only when the VOR gain was less than 1.0. During FC of the VOR, the firing rate of the cells lead ipsilateral head velocity by $0^0$ to $20^0$; they were sensitive to head velocities as low as $2^0$/s and the gain and phase of the response were constant from 0.1 Hz to 1.0 Hz. In addition, the head velocity response was superimposed on a tonic firing rate whose onset immediately preceded the act of FC and which lasted as long as the FC continued. The amplitude of this component of the signal appeared to be related to the frequency of sinusoidal head rotation. During OKN, the neurons fired only when slow-phase eye velocity did not match the optokinetic stimulus velocity. During FC of OKN, their firing rate was linearly related to the slow phase eye velocity being suppressed; higher firing rates were associated with suppressed slow phase velocities in the contralateral direction.

These data suggest that foveal cancellation of vestibular nystagmus and optokinetic nystagmus may be mediated by different premotor pathways.

304.11 **TRANSSYNAPTIC RETROGRADE STUDIES OF THE NUCLEUS OF EDINGER-WESTPHAL AND THE OCULOMOTOR SYSTEM.** Jonathan T. Erichsen and Craig Evinger. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, NY 11794.

The avian ciliary ganglion contains two subpopulations of cells: the ciliary, which project to the iris and the ciliary body, and the choroid, which project to the choriocapillaris. Neurons of the nucleus of Edinger-Westphal (EW) provide the only known input to the ciliary ganglion, and studies of the afferent projections of EW indicate that it consists of at least three distinct subdivisions. In the present study, we used transsynaptic retrograde transport to determine the peripheral motor targets of subdivisions of EW.

Wheat germ agglutinin (WGA) (8ul at 10ug/ul) was injected into either the iris or the ciliary body. After 24h, WGA (using immunohistochemistry) was found in the cells of the ciliary ganglion but in no central structures. After 3 to 6 days survival, specific labelling was found in one or more subdivisions of EW, as well as in cells of the ciliary ganglion. Control HRP injections into these two target sites always labelled cells of the ciliary ganglion but never within EW. Thus, we conclude that the retrograde label found in EW results from transsynaptic retrograde transport of WGA via the cells of the ciliary ganglion rather than a direct projection from EW to the target sites.

Injections to the iris labelled neurons in the extreme lateral portion of EW throughout its rostrocaudal extent as well as the entire caudolateral subdivision. The location of these labelled cells corresponds to the afferent termination from the pupilloconstrictor pretectal nucleus, area pretectalis (Gamlin et al., 1984). In contrast, injections to the ciliary body also labelled neurons in the rostrolateral subdivision, suggesting that this subdivision mediates the control of visual accommodation.

In addition, injections into the anterior chamber (i.e., iris injections) resulted in distinct terminal labelling within the various sensory trigeminal nuclei that corresponds to projections of the ophthalmic branch of the trigeminal nerve (Dubbeldam & Karten, 1978). We attribute this to anterograde transperikaryal transport through the Gasserian ganglion via the ophthalmic branch. Labelling of cells in the ipsilateral accessory abducens nucleus suggested transsynaptic anterograde transport. Unilateral injections of WGA into extraocular muscles retrogradely labelled the expected oculomotor neurons, but also resulted in transsynaptic labelling of contralateral oculomotor neurons.

304.12 CILIARY GANGLION AFFERENT NEURONS: LOCATION AND CHOLINE ACETYLTRANSFERASE STAINING IN THE CAT. L. Brezina*, A. Strassman*, P. Mason, F. Eckenstein, and R. Maciewicz, Pain Physiology Lab, Neurology Service and Neuroscience Program, Mass. General Hospital and Harvard Med. School, Boston MA 02114.

Ciliary ganglion afferents are cholinergic neurons traditionally thought to reside within the Edinger-Westphal nucleus (EW). However, in the cat ciliary ganglion afferents are located primarily outside EW; EW neurons in contrast have extensive projections to spinal cord and cerebellum. In the present study the distribution of preganglionic parasympathetic neurons that project to the ciliary ganglion was compared to the pattern of cells showing choline acetyltransferase (ChAT) immunoreactivity in the midbrain.

Following horseradish peroxidase (HRP) injections into ciliary ganglion, labeled preganglionic neurons were found largely outside EW, scattered in the ventral periaqueductal gray region capping the oculomotor nucleus (nIII) as well as in the tegmentum ventral and anterior to nIII. Some preganglionic neurons were also observed in the ventral part of the anteromedian nucleus. Midbrain sections processed for ChAT immunohistochemistry revealed a pattern of ChAT- positive neurons outside of nIII that closely parallelled the distribution of preganglionic cells. In contrast, cells showing substance P- or cholecystokinin- like immunoreactivity were found primarily within EW. Using a two-chromogen method (3,3'-diaminobenzidine (DAB) and alpha-napthol/pyronin B or cobalt-DAB and DAB) ciliary ganglion afferent neurons identified by retrograde HRP transport also showed ChAT immunoreactivity.

To determine whether ciliary ganglion neurons have intracranial projections, in the same experiments nuclear yellow was injected into either the deep cerebellar nuclei or the cervical spinal cord. In both cases cells labeled with fluorochrome were found throughout the length of EW; however, there was little overlap of the distribution of ciliary ganglion afferents with the distribution of cells projecting to either cerebellum or spinal cord. No preganglionic neurons were labeled by either cerebellar or spinal injections.

These findings provide further evidence that in the cat ciliary ganglion afferent neurons differ in their immunocytochemistry, location, and projections from cells in EW.

304.13 DYNAMIC DIFFERENCES BETWEEN AIRPUFF- AND LIGHT-ELICITED EYEBLINKS. K.A. Manning* & C. Evinger. (SPON: L.A. Riggs). Dept. Neurobiol. & Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

An eyeblink is a commonly occurring and rapidly accomplished oculomotor activity produced in response to many stimuli. Nevertheless, the neural basis of blinking is not well understood. As a first step towards examining the neural control of blinks, we measured the dynamics of airpuff-elicited (A-) and light-elicited (L-) blinks in unanesthetized rabbits. Specifically, we wanted to find out whether these reflex blinks were similar, except for expected differences in blink latency, or if, in fact, the dynamics of blinks differed depending upon the sensory pathway that produced them.

Lid movement was measured with a photosensitive device activated by a light emitting diode at the end of a light-weight lever arm that was attached to the upper lid margin. This arrangement did not impede lid movement. Blink-related lid position and velocity data produced in response to air and light stimuli of varied duration (25-700ms) and strength were recorded. In several rabbits, the levator palpebrae (LP) and orbicularis oculis (OO) EMGs were also recorded simultaneously. We found that the dynamics of the L- and A-blinks were consistently different, even when blink amplitudes were equal. During the initial downward movement of the lid, maximum lid velocity and acceleration were typically twice as great for A-blinks as for L-blinks. Also, once the change in lid position had begun, time to maximum lid velocity occurred twice as quickly in A-blinks as in L-blinks. The EMG showed the expected reciprocal relation between LP and OO activity for all blinks, but the timing of activation of OO with respect to cessation of LP varied. Cessation of LP activity usually preceded activation of OO during A-blinks, but occurred near the time of, or after, excitation of OO during L-blinks. Unexpectedly, LP exhibited a weak period of activation before cessation of activity during L-blinks. The pattern of OO activity also differed with A- and L-blinks. Airpuff-evoked OO activity began with a burst, while light-evoked OO activity increased gradually and continued for longer durations.

These results indicate that, in the rabbit, different afferent pathways produce blinks with different dynamics. All blinks do not appear to be generated by the same neural circuit. Instead, blinks may be produced differently by various afferent sources. We are repeating these experiments with human subjects.

Supported by NIH grants #EY04829 and EY05773.

304.14 ADAPTIVE PLASTICITY OF REFLEX BLINKS. C. Evinger and K.A. Manning*. Dept. Neurobiology & Behavior, SUNY Stony Brook, Stony Brook, NY 11794

Understanding adaptive plasticity requires developing model systems that are advantageous for physiological and anatomical study. Because of its relative simplicity, the reflex blink of the rabbit offers such a model system. Movements of the upper eyelid involve essentially two muscles: orbicularis oculis to pull the eyelid down and levator palpebrae to pull the eyelid up. Reflex blinks can be elicited by two different, presumed three neuron pathways: trigeminal and visual. We now report that adaptive changes occur in trigeminally evoked blinks in less than 1 hour. Thus, reflex blinks in the rabbit are a simple, mammalian system for neurophysiological investigation of adaptive plasticity.

Before, during, and after lid adaptation, reflex blinks of a moderate size were evoked in unanesthetized rabbits with a weak 50ms airpuff or a 200ms flash of light directed at the eye. These stimuli occurred at a mean interstimulus interval of 10 sec. Position of the upper eyelid and orbicularis oculis EMG were continuously monitored. Experiments began with 30 air puff trials to collect baseline data. To induce adaptation, the upper eyelid experienced a constant, upward tension produced by attaching a 9gm weight to the upper eyelid via a pulley. After attaching the weight, the rabbit underwent 240 airpuff trials over a period of 55min. Sixty airpuff trials followed removal of the weight. In the preweight trials, the airpuff stimulus evoked blinks with a mean amplitude of 1.2mm and a mean acceleration of 357 mm/sec$^2$. The mean amplitude and acceleration of blinks upon removal of the weight rose to 2.3mm and 1508mm/sec$^2$. The increased (422%) intensity of reflex blinks following weight adaptation slowly decayed, so that 40-60 trials after removal of the weight, blinks evoked by airpuffs were back to baseline levels. Changes in the orbicularis oculis EMG mirrored the changes in eyelid dynamics. Light elicited blinks showed no evidence of adaptation, suggesting that the adaptation was modality specific.

Thus, a short period of adaptation to upward tension on the upper eyelid produced an increase in the amplitude and speed of the downward movement of the upper eyelid with a trigeminally evoked blink. Given the relatively simple organization of the blink reflex, this should prove a fruitful preparation for studying the neural control of adaptive plasticity.

304.15 CEREBELLAR CONTROL OF THE CONDITIONED NICTITATING MEMBRANE RESPONSE IN RABBIT: BILATERAL NEURAL PLASTICITY. B.E. Polenchar and M.M. Patterson, Department of Psychology and College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

Recent studies conducted by R.F. Thompson and colleagues (McCormick & Thompson, Neuro.Abst., 1983, 9: 643; McCormick et al., Bull.Psych.Soc., 1981, 18: 103;) have implicated the cerebellar nuclei as an essential component of the memory system for the conditioned nictitating membrane (NM) response in rabbit. Unilateral lesions of the cerebellar deep nuclei abolish the learned NM response in the eye ipsilateral to the lesion, but do not affect the reflex response, or the animal's ability to acquire conditioned responses (CRs) when training is shifted to the contralateral eye. In replicating these effects (Polenchar & Patterson, Neuro.Abst., 1984, 10: 123.), we noted that when training was shifted to the opposite eye after nuclear lesions, there was a significant reduction in the number of trials taken to reach criterion. The present study investigated the possibility that a certain degree of bilateral neural plasticity occurs during initial acquisition (McCormick & Thompson, 1981). In the first experiment, we simply replicated the McCormick and Thompson procedure, while monitoring the responses of both eyes throughout all phases of training. We found that although CRs were acquired concurrently in both eyes during initial acquisition, unilateral cerebellar nuclei lesions tended to abolish CRs in both eyes. However, after the contralateral eye was trained to produce CRs, responding in this eye persisted even after training was shifted back to the ipsilateral eye. In addition, there is often a small amount of ipsilateral recovery after contralateral training. This pattern of results may suggest that initial responses of the untrained eye result from bilateral control of the conditioned NM response by a unilateral cerebellar system. In the second experiment, a multiple unit recording electrode was chronically implanted in the dentate/interpositus (DI) region on one side of the cerebellum and lesioning electrodes were implanted on the other side. The same sequence of pre- and post-operative training was used, while multiple unit recordings were made from the intact nuclei during all stages. While only preliminary results are available at this time, there is strong evidence to suggest that neural unit activity related to the learned response of the trained eye occurs in the contralateral cerebellum, similar to that found in the ipsilateral cerebellum (c.f. McCormick, et al., 1981). In some cases, we found that an increase in ipsilateral DI unit activity occurred in the absence of a response in the untrained (ipsilateral) eye. The pattern of results found thus far indicates that activity of the ipsilateral cerebellum may be projected to the contralateral hemisphere (consistent with McCormick an Thompson's prediction), but does not necessarily produce a response in the contralateral eye.

304.16 PROPERTIES OF VESTIBULAR INPUTS TO THE SITE OF ADAPTIVE CHANGES IN THE VESTIBULO-OCULAR REFLEX (VOR) IN MONKEYS S.G. Lisberger and T.A. Pavelko*, Div. Neurobiology and Dept. Physiology, UCSF, San Francisco, CA.

The accuracy of the VOR is regulated by a long-term adaptive mechanism that is used whenever the VOR is in error. The behavioral adaptations are well understood, but the modifiable neural pathways subserving adaptation remain unidentified. We have used a transient vestibular stimulus in two experiments to define the modifiable pathways according to the response properties and latency of the vestibular inputs they transmit.

First, we used "rapid changes in head velocity" to study the VOR in the dark before and after adaptation to magnifying and miniaturizing spectacles. The vestibular stimulus provided head acceleration from zero to 30°/s in 50 ms, followed by constant head velocity at 30°/s for 300 ms. The sudden head acceleration allowed us to measure the transient response of the VOR (latency and degree of overshoot). The constant head velocity allowed us to estimate the steady-state gain of the VOR (eye velocity divided by head velocity). The transient response changed as a function of steady-state gain. Normally, eye velocity showed slight overshoot so that peak eye velocity was 1.2 times steady-state. When steady-state VOR gain had decreased to 0.3, the transient overshoot was accentuated so that peak eye velocity was 2 times steady-state. When steady-state gain had increased to 1.8, there was no overshoot. Changes in VOR gain did not affect the latency or the first 5 msec of the VOR.

Second, we recorded the activity of 73 vestibular nerve fibers innervating the horizontal canal in 2 normal monkeys. We studied the response to rapid changes in head velocity by averaging instantaneous firing rate for 50-100 consecutive stimuli. Each fiber was then characterized by the degree of overshoot in firing rate and the response latency, as well as by the regularity of discharge with the head still. Afferents with the most regular discharge responded at latencies of 8-18 ms and had little or no overshoot. More irregular afferents responded at latencies of 5-10.5 ms and had substantial overshoot in firing; the peak change in firing rate was 2-6 times as large as the steady-state change.

Our eye velocity data can be accounted for by our nerve recordings if the modifiable VOR pathways receive inputs from afferents with the most regular discharge. In addition, the absence of changes in the first 5 msec of the VOR and the large transient response when steady-state gain is low imply that some pathways cannot be modified. These pathways would receive inputs from more irregular afferents, which have shorter latencies and larger transient responses. (Supported by NIH grant EY 03878.)

304.17 A MODEL FOR TARGET-DEPENDENT GAIN CONTROL IN THE VOR. D. Tweed*, E. Viirre* and T. Vilis. Depts. Ophthalmology and Physiology, University of Western Ontario, London, Canada, N6A 5C1.

Ideal vestibuloocular gain, the ratio of eye rotational velocity to head rotational velocity which will minimize retinal image blur, depends on the location of the visual target and on the linear and angular motion of the head. The ideal gain need not equal -1, it may be different for the two eyes, and it must be continuously modulated according to target location relative to the moving head. Experiments in this laboratory have shown that the gain of the VOR in monkeys has all these properties and closely matches that of an ideal VOR (see accompanying abstract Viirre et al.).

To account for the target-dependent flexibility of VOR gain, we propose a model in which the gain of the vestibuloocular pathway is governed by a target locator which uses vestibular signals to compute the craniotopic motion imparted to the target by rotation and translation of the head. If $\dot{\mathbf{x}}$ is the craniotopic velocity of the target, the formula for its computation based on a head rotational velocity **R** signal from the semicircular canals and a head translational velocity **T** signal derived from otolith organ output is

$$\dot{\mathbf{x}} = (\mathbf{x} \times \mathbf{R}) - \mathbf{T}.$$

The vector **x** is craniotopic target location, given initially by visual, auditory or other sensory input and updated by integrating $\dot{\mathbf{x}}$. For each eye, the desired gaze vector **g** is defined as $\mathbf{g} = \mathbf{x} - \mathbf{e}$, where **e** is the fixed craniotopic location of the centre of that eye. The vectors **g** and $\dot{\mathbf{g}}$ for each eye are readily obtainable from the output of the locator, and they in turn yield $\boldsymbol{\omega}$, the desired angular velocity of the eye, by the equation

$$\boldsymbol{\omega} = (\mathbf{g} \times \dot{\mathbf{g}}) / |\mathbf{g}|^2 - \text{proj}_{\mathbf{g}}\mathbf{R}.$$

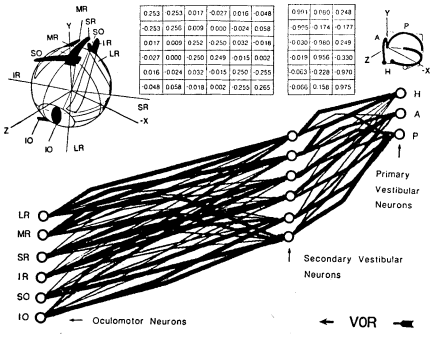
This series of operations bears little resemblance to the classical three neuron direct pathway which simply transmits a reversed head velocity signal to the eyes. However, the direct path can be incorporated in the present model by rearranging the equations to give

$$\boldsymbol{\omega} = -(\mathbf{x}\cdot\mathbf{g}/|\mathbf{g}|^2)\mathbf{R} + \mathbf{T} \times \mathbf{g}/|\mathbf{g}|^2 + (\mathbf{R}\cdot\mathbf{g}/|\mathbf{g}|^2)\mathbf{e} = a\mathbf{R} + \mathbf{b} + \mathbf{c}.$$

In this form, the system can be divided into two parts: a path transmitting **R** and side loop where a, **b** and **c** are computed. The side loop acts on the **R** signal, multiplying it by a and adding **b** and **c**. For a cyclopean eye at the centre of head rotation, with $\mathbf{T} = 0$, a is always -1 and **b** and **c** vanish. Thus, under the classical assumptions, the model collapses to the classical reflex. (Supported by the Medical Research Council of Canada).

304.18 MORPHOLOGY AND A TENSOR NETWORK MODEL OF THE THREE-NEURON VESTIBULO-OCULAR REFLEX ARC IN THE CAT. W. Graf and A. Pellionisz. The Rockefeller University, New York NY 10021, and Dept. Physiol. and Biophysics, New York Univ. Medical Center, New York NY 10016.

The "three-neuron arc" of the vestibulo-ocular reflex connects the semicircular canals of the labyrinth to the eye muscles via primary vestibular afferents, second order vestibular neurons, and oculomotor neurons. The coordinate axes represented by the optimal rotational axes of the semicircular canals and those of the extraocular muscles are available in a quantitative manner. Morphological and physiological data show the principal, accessory and tertiary connections within the reflex arc. A tensor model of the cat vestibulo-ocular reflex arc provides an interpretation of data relating to internal characteristics of CNS networks, resulting in a suitably distributed quantitative model of an overcomplete transformation from three canals to six extraocular muscles:



Neuronal networks in this tensor model accomplish the transformation of a covariant sensory reception vector on primary vestibular afferents into a covariant motor intention vector on second order vestibular neurons, and to a contravariant motor execution vector on oculomotor neurons. The excitatory and inhibitory connections, shown above by the components in two matrices are visualized by line thickness in the corresponding networks. The overall transformation provides a good prediction of the vestibulo-ocular reflex networks as obtained by neuroanatomical and physiological experiments.

304.19 LIMBIC CORTEX NEURONAL ACTIVITY ASSOCIATED WITH SACCADIC EYE MOVEMENTS IN AWAKE RABBITS AND POSSIBLE UNDERLYING AFFERENTS. R. W. Sikes, B. A. Vogt and H. A. Swadlow . Depts. of Anatomy and Physiology, Boston University School of Medicine, Boston, MA 02118 and Dept. of Psychology, University of Connecticut, Storrs, CN 06268.

Cingulate cortex, a major component of the limbic system, has been associated with complex phenomena such as learning, memory and affective responses to pain. While sensory evoked responses of cingulate neurons have been reported, they are nonspecific and habituate rapidly. Furthermore, cingulate neuronal responses have not been linked to any specific motor response in naive animals. This report describes a class of cingulate cortex neurons with responses which are rigorously and consistantly linked to saccadic eye movements in rabbits. Connections to the oculomotor system which may subserve these responses are also described.

Single unit recordings were made in alert, restrained Dutch belted rabbits. Eye movements were elicited by vestibular and optokinetic stimulation, and eye position was determined by detecting the position of a light emitting diode attached to the eye.

A total of 242 units were isolated in posterior cingulate cortex (area 29), and 11% showed clear responses associated with saccadic eye movements. The majority(75%) responded with a short burst of action potentials 20 to 60 msecs after the onset of each saccade. Half of these units were tested with vestibular stimulation in both light and dark, and the responses were equally vigorous. Many units were directional, most responding preferentially to contralaterally directed saccades. The remaining eye movement sensitive units have longer latency responses which appear to be linked to the offset of each saccade. Lesions marking the location of eye movement sensitive units showed that they were located primarily in area 29d either in the superficial portion of layer II-III or at the border of layers V and VI.

Injections of horseradish peroxidase were made into area 29d to determine possible sources of the eye movement signal. Labeled neurons were located in two areas which have been previously associated with eye movement, cortical area 8 and the lateral thalamic nuclei. Neurons in area 8 were only labeled following rostral area 29d injections, but eye movement sensitive neurons were distributed throughout area 29d. Neurons in the lateral thalamic nuclei, however, overlap the distribution of neurons which have been reported to respond to saccadic eye movements. Thus, the eye movement signal may be thalamic in origin.

304.20 NEUROANATOMIC IDENTIFICATION OF A RAPHE NUCLEUS IN THE PONS ASSOCIATED WITH OMNIPAUSE NEURONS OF THE OCULOMOTOR SYSTEM IN THE MONKEY. J.A. Büttner-Ennever* and M.Pause* (SPON: H.G. Ross). Brain Research Institute and Neurological Clinic, University of Düsseldorf,FRG.

Omnipause neurons (OPNs) are considered to form a gating-system which controls the generation of saccades. The neurons are known to lie clustered around the midline in the caudal pons. We report here several lines of evidence which show, that OPN-activity is associated with a specific group of raphe neurons which can be considered as a cytoarchitectural entity. According to the classification of Taber et al. ( J. comp. Neurol . 114 :161, 1960) cell groups near the midline in the pons could be divided into: raphe dorsalis lying above and between medial longitudinal fasciculus, raphe pontis in which cells form distinct clusters, raphe magnus lying ventrally and whose cells resemble the adjacent reticular formation. Interposed between these three nuclei lies, each side of the midline, a narrow row of regularly spaced medium-sized neurons, at the level of the abducens rootlets as they pass through the pontine reticular formation. Unlike raphe pontis and raphe magnus, these cells have horizontally oriented dendrites and can be stained in a Golgi-like fashion with cytochrome-oxidase sensitive methods, indicating a high mitochondrial content. We suggest that this group of neurons be called nucleus raphe interpositus (rip). It can also be identified in rat, cat and man. Single OPNs were identified from microelectrode recordings in awake monkeys, and electrolytic lesions were made at these sites. All OPNs had a high tonic discharge rate (100 - 150 spikes/s) which was interrupted 13 + 7 ms before every saccade. The lesions lay within the borders of the newly defined raphe interpositus. In autoradiographic studies of structures involved in saccadic generation afferent projections to the omnipause region were studied. Only raphe interpositus, and not raphe pontis or raphe magnus received afferents from the deeper layers of the superior colliculus, a site known to send monosynaptic inputs to OPNs (Raybourn M.S.,Keller E.L., J.Neurophysiol ., 40 :861,1977); and a specific saccade-related region of the mesencephalic reticular formation (Cohen et al., Exp.Brain Res ., 57 :605,1985) projects heavily to raphe interpositus but not to the surrounding reticular formation. In the light of these results it appears that OPNs are confined to a group of neurons which differ from raphe pontis and raphe dorsalis and raphe magnus with respect to connectivity and cytoarchitecture. Up to now the cell group has been assigned to raphe pontis or raphe magnus, but now deserves a separate name - nucleus raphe interpositus is suggested here. Supported by DFG/SFB 2oo/A3.

304.21 MECHANISMS OF ACCOMMODATION IN THE CHICKEN. D. Troilo* and J. Wallman (SPON: J. Osinshak), Dept. of Biology, City College, City University of New York, New York, NY 10031

It is unclear how similar avian accommodation is to that of mammals. Controversy exists on two points: (1) Does a change in corneal curvature contribute to accommodation? (2) Is the lens actively squeezed by the ciliary processes, rather than simply relaxing into a more curved state as suggested for humans by Helmholtz?

To address these questions, accommodation was elicited in 4-week-old chicks either by electrical stimulation of the Edinger-Westphal nucleus (EW) or by the topical application of 0.4% nicotine sulfate to the cornea. Refractive changes were monitored with a Hartinger refractometer modified for the small eyes of chickens. Changes in the curvatures of the ocular refracting surfaces were measured with keratometry and photography of the Purkinje images. Ultrasonography was used to determine the axial dimensions of the various ocular components. From these data, schematic eyes for both resting and accommodating states were calculated.

We find that a change in corneal curvature is an integral component of accommodation. Data from keratometry and Purkinje image photography indicate that the corneal surface becomes more curved during accommodation. Ray tracing calculations show increases in corneal surface power of 3.71 D for EW stimulation and 6.14 D for topical nicotine treatment. The mean amplitude of accommodation is 9.16 D for EW stimulation and 15.06 D for nicotine application. Although both corneal and total refractive changes are greater with nicotine, the ratios of corneal power change to total refractive change for the two methods are nearly the same (0.40 vs. 0.41) implying that the mechanism by which refractive change is produced is the same for both techniques.

With respect to the mechanism by which lens shape is changed by the ciliary muscle, we find that during accommodation, both the curvature of the anterior lens surface and the thickness of the lens are less than for lenses in vitro. This finding indicates that lens changes during accommodation could have been produced by the release of normal zonular tension although we cannot exclude the possibility that active lenticular squeezing is at work.

Finally, preliminary experiments show markedly reduced accommodative changes in birds older than 1.5 years. This suggests that chickens may become presbyopic. (Supported by NIH EY-02727)

304.22 COMPENSATORY EYE MOVEMENTS PRODUCED BY THE ISOLATED CNS OF THE LARVAL FROG (RANA CATESBEIANA). D.J. Stehouwer. Dept. Psychol. and the Center for Neurobiol. Sci., Univ. Florida, Gainesville, FL 32611.

Undulatory swimming of larval frogs (tadpoles) results from rhythmic bursts of activity that alternate between motoneurons innervating the axial muscles on the left and right sides of the trunk and tail. The resulting undulations propel the animal through the water and produce lateral oscillations of the head. In order to maintain a stable gaze, the eyes must oscillate around the vertical axis to offset movement of the head. It was hypothesized that these conjugate compensatory eye movements are, like the alternating contractions of the axial muscles, generated at least in part by pattern-generating circuits endogenous to the central nervous system (CNS).

This study was conducted to determine whether compensatory eye movements accompany "fictive locomotion" in the absence of vestibulo-ocular and optokinetic reflexes. In the first experiment, "compensatory" eye movements were observed in a radically reduced preparation consisting of a nervous system isolated from all but the head of the tadpole. Rotation of the eyes in a rostral direction accompanied bursts of activity in homolateral motoneurons innervating the axial muscles, and caudal rotation of the eyes was occasioned by bursts of activity in heterolateral spinal motoneurons. The direction and timing of eye rotations were such that they would have compensated for movement of the head, had it occurred.

In the second experiment, electrophysiological recordings from the oculomotor (III), trochlear (IV), and abducens (VI) nerves of completely isolated nervous systems revealed 1:1 coordination between rhythmic bursting of these nerves and that of spinal motoneurons innervating the axial muscles. Bursts in the oculomotor nerve occurred approximately in synchrony with those of the trochlear nerve, whereas bursts of abducens occurred in antiphase with those of the trochlear and oculomotor nerves. Electrical stimulation of the oculomotor nerve resulted in rotation of the eye in an anterior direction about the vertical axis and rotation of the dorsal pole in an anterior direction about the horizontal axis. Stimulation of the trochlear nerve had little effect other than rotation of the dorsal pole of the eye caudally about the horizontal axis. Stimulation of the abducens nerve resulted in retraction of the eye and rotation caudally about the vertical axis.

These results demonstrate that compensatory eye movements can be produced by an isolated CNS without benefit of vestibulo-ocular or optokinetic reflexes, and are part of a larger integrated motor program that also includes the spinal pattern generators for undulatory swimming. (Supported by NS 19720)

304.23 EFFERENTS OF THE NUCLEUS INTERSTITIALIS IN ANURANS. Neil M. Montgomery. University of Massachusetts, Amherst, Massachusetts, 01003.

In his classic study of the amphibian nervous system J. Herrick ('48) described the cell groups surrounding the oculomotor (n.III) and trochlear (n.IV) nuclei as the nucleus interstitialis of the medial longitudinal fasciculus (nInt.); however, little is known about the connectivity of these cell groups in any nonmammal. Potentially these systems could yield valuable information on the nature of sensori-motor integration in the nonmammalian oculomotor system. To this end, the antrograde and retrograde transport of HRP was used to determine the efferent connections of nInt. in Rana pipiens.

HRP was injected into the cell groups surrounding the oculomotor and trochlear nuclei and the antrograde transport of HRP was charted. Antrogradely labelled axon terminals were observed in the (1) tectum, (2) pretectum, (3) cerebellum, (4) vestibular nuclei, (5) spinal cord, (6) contralateral nInt. and (7) across the ventral medulla along the course of the medial longitudinal fasciculus. Each of these regions was then injected with HRP and the distribution of retrogradely labelled cells in nInt. was charted.

As a result of these injections it proved possible to subdivide nInt. based on its differential efferent projections. Further, these subdivisions corresponded to those described by Tuge ('32) in turtle as areas nInt. A, nInt. B, and nInt. C. Tuge divided nInt. based on its cytoarchitecture with area A the most ventral division and area C the most dorsal. In the present study area A nInt. in Rana pipiens was found to project (1) to the spinal cord bilaterally, (2) to the cerebellum, and to the (3) vestibular nuclei. Area B nInt. projects to the (1) ipsilateral pretectal nucleus lentiformis mesencephali, (2) the contralateral nInt. and (3) the ipsilateral spinal cord. Axonal collaterals were also observed in the ipsilateral nIII and nIV. Cells in area C nInt. project to the (1) ipsilateral spinal cord and (2) the deep layers of the optic tectum.

The determination of potential homologies between these structures and those found in mammals will have to await future research and careful comparisons across a wide range of species;however, it appears significant that this region projects to so many sensory nuclei related to ocular reflexes.

Supported by NSF grant # BNS-8209026.

304.24 CENTRIFUGAL FIBERS OF THE OPTIC NERVE CARRY EYE MOVEMENT SIGNALS. J. C. Letelier*, J. Wallman and G. Marin*. Dept. of Biology, City College, City Univ. of N.Y., New York, NY 10031

Like nearly all vertebrate sensory structures, the retina receives centrifugal fibers from the central nervous system. In birds, this projection is especially prominent and arises from the isthmo-optic nucleus (ION), which is known to receive a retinotopic projection from the optic tectum and to project almost exclusively to the retina, where the axons synapse on amacrine cells and displaced retinal ganglion cells. Afferents to the ION from the abducens and trochlear nuclei have also been reported. Previous electrophysiological studies of the ION, using anesthetized animals, have shown responses to visual stimuli, particularly ones moving temporal-to-nasal in the visual field.

We have recorded single units in the ION of alert, young chickens, while recording eye movements using the magnetic field/search coil method. We find that the neurons show, in addition to the expected visual responses, a strong saccade-related response. During saccades, units in the ION nearly cease firing, and immediately following saccades, they give a brief burst of spikes. This suppression of activity during saccades occurs in the dark and therefore cannot be due simply to the smearing of retinal images by the rapid movement of the eyes during saccades.

We suggest that this eye-movement-related centrifugal activity may be analogous to the action of the centrifugal fibers in the lateral line system of fish, in which afferent sensitivity is reduced during self-generated movements. The association of the centrifugal fibers with displaced retinal ganglion cells may, in addition, imply an involvement of the ION with the optokinetic system. (Supported by NIH EY02937.)

## CATECHOLAMINES: RECEPTORS II

305.1 [$^3$H]CLONIDINE BINDS AT MULTIPLE HIGH AFFINITY SITES IN HUMAN PREFRONTAL CORTEX. M. A. Carlson*, A. C. Andorn*, J. E. Piletz*. (SPON: A. Halaris). Depart. of Psychiatry, Case Western Reserve Univ. Schl. of Med. and Cleveland Metropolitan General Hospital, Cleveland, Ohio 44109

[$^3$H]Clonidine binds to particulate fractions of human prefrontal cortex in a process that demonstrates high affinity, saturability, reversibility and selectivity. At 37°C specific binding (determined as the difference between [$^3$H]clonidine binding in the absence and presence of 1 uM clonidine) reaches a maximal value at 10-15 min but a 50% decrease in specific binding occurs between 15 and 60 min at this temperature. [$^3$H]Clonidine binding reaches a steady-state after 20 min at 21°C and the steady-state is maintained for at least 2 hours. The results reported below were obtained at 21°C. Rate dissociation studies were at least biphasic with $t_{1/2}$s of 1.6 +/- a standard deviation of 0.7 and 9.3 +/- 1.1 min. Saturation analyses at 60 min incubation were at least biphasic when plotted according to Scatchard. The approximated apparent $K_D$'s of the extremes were 0.4 +/- 0.1 and 2.4 +/- 0.9 nM with respective approximated $B_{max}$ of 54.0 +/- 20.0 and 126.0 +/- 40.0 fmol/mg protein. Dose-response studies revealed that clonidine was the most potent agonist with an $IC_{50}$ of 5.9 +/- 1.3 nM, followed by (-)-epinephrine with an $IC_{50}$ of 16.6 +/- 9.9 nM followed by (-)-norepinephrine with an $IC_{50}$ 30.7 +/- 4.5 nM. Serotonin had an $IC_{50}$ of 23,500.0 +/- 8,200 nM. Yohimbine was the most potent antagonist with an $IC_{50}$ of 34.0 +/- 10.7 nM and prazosin had an $IC_{50}$ of 4,150.0 +/- 1980.0 nM. In all cases Hill coefficients varied from 0.4 to 0.8. These results indicate that [$^3$H]clonidine binds with high affinity at potentially multiple affinity states or sites in human prefrontal cortex, with a predominant alpha$_2$-adrenergic selectivity.

305.2 DIFFERENTIAL BINDING PROPERTIES OF TWO ALPHA$_2$-ADRENERGIC ANTAGONISTS IN RAT BRAIN. C.L. Boyajian*, S.E. Loughlin and F.M. Leslie (SPON: R.I. Cone). Department of Pharmacology, University of California, Irvine, CA 92717.

The pharmacological characteristics and autoradiographic distribution of two selective alpha$_2$-antagonists, [$^3$H]rauwolscine (RAUW) and [$^3$H]idazoxan (IDAZ), have been examined. Cryostat-cut brain sections (20μm) were incubated with [$^3$H]RAUW or [$^3$H]IDAZ for 2 hr, at 0-4 °C, in Na-K phosphate buffer, pH 7.7. Incubations were performed in the absence and presence of phentolamine (10 μM) to determine specific binding. For autoradiography, radioligand binding sites were visualized by exposure of tissue sections to tritium sensitive film. For radioligand binding assay, tissue sections were scraped from slides into vials to quantify radioactivity by scintillation spectrometry. Scatchard analysis of saturation curves revealed biphasic plots for both radioligands. Concentrations of radioligand which selectively labelled high affinity sites were consistently used in autoradiography and binding assay experiments. The autoradiographic distribution of [$^3$H]RAUW and [$^3$H]IDAZ were distinct and largely non-overlapping. While [$^3$H]IDAZ binding paralled known regions of noradrenergic innervation, [$^3$H]RAUW binding corresponded closely to dopamine terminal fields. Since recent evidence has suggested that rauwolscine possesses antidopaminergic activity (Scatton, B. et al., Eur. J. Pharmacol., 86:427, 1983), we have extensively characterized the pharmacological properties of this binding site. With the exception of idazoxan displacement of [$^3$H]RAUW, dose-response curves for inhibition of radioligand binding were monophasic with Hill slopes of unity. The rank orders of potency for inhibition of [$^3$H]RAUW and [$^3$H]IDAZ binding by endogenous monoamines were similar, i.e., norepinephrine = epinephrine ≫ serotonin = dopamine. Dose-response curves for inhibition of radioligand binding by numerous dopamine antagonists provided further evidence that [$^3$H]RAUW lacked affinity and selectivity for dopamine receptors. The $K_I$ values for inhibition of both [$^3$H]RAUW and [$^3$H]IDAZ binding by dopamine D1 and D2 antagonists were two to three orders of magnitude higher than for inhibition of [$^3$H]spiroperidol binding. Alpha$_2$-adrenergic agonists and antagonists inhibited the binding of both radioligands with high affinity. However, the ratios of their $K_I$ values for inhibition of [$^3$H]RAUW and [$^3$H]IDAZ binding (RAUW/IDAZ) varied widely, ranging from 0.06 to 16. Whereas alpha$_1$-antagonists were more potent displacers of [$^3$H]RAUW than of [$^3$H]IDAZ, alpha$_1$-agonists displayed very low affinity for either site. Furthermore, rauwolscine exhibited low potency for inhibition of [$^3$H]prazosin binding ($K_I$=660nM). These combined data provide anatomical and pharmacological evidence that [$^3$H]rauwolscine binds to a novel binding site within brain which is distinct from that labelled by [$^3$H]IDAZ, yet which shares common alpha$_2$-adrenergic binding properties. (Supported by NIH grants 18843 and 19319.)

305.3 PLATELET $\alpha_2$-ADRENERGIC RECEPTORS: THE EFFECT OF IN VITRO DESIPRAMINE TREATMENT ON $^3$H-CLONIDINE BINDING. E.S. Werstiuk, S.E. Auffarth* and M. Steiner. Depts. of Neurosciences and Psychiatry, McMaster University, Hamilton, Ont., L8N 3Z5, Canada.

Platelet $\alpha_2$-adrenergic receptor binding parameters have been determined in depressed patients. Reports to date are conflicting, in that some groups have found an increased number (Bmax) of $\alpha_2$-receptor sites in patients, while other groups report no difference between patients and controls. These observed changes in platelet $\alpha_2$-receptors may be specific to certain subgroups of depressed patients, or alternately, they may be secondary, and due to drug effects. This study was undertaken to test if in vitro treatment of platelets with the antidepressant, desipramine (DMI) had an effect on the binding parameters of platelet $\alpha_2$-adrenergic receptors.

Washed platelet suspensions were prepared according to the method of Mustard et al., (Brit. J. Haematol., 1972, 22: 193) from freshly obtained blood. Platelet membranes were prepared by mechanical disruption, and the binding assay was performed at 25°C in Tris-HCl$_2$ buffer solution (50 mM) containing $MgCl_2$ (10 mM) at pH 7.5, and $^3$H-clonidine in a concentration range of 0.1 - 64 nM. The reaction was terminated by centrifugation. Specific binding was defined as the difference between total bound radioactivity and the radioactivity not displaced by $6.4 \times 10^{-5}$M clonidine. $K_D$ and Bmax were calculated by the computer program "Ligand" of Munson and Rodbard (Anal. Biochem., 107: 220, 1980). DMI-treated platelets were obtained by incubating intact platelets in Eagle's medium in the presence of DMI (200 - 700 nM) for 1 hr at 37°C, and membranes were prepared as described above.

In 14 young male subjects (28 ± 2 years) we obtained (Mean ± S.E.M.) values of $K_D$: 10.14 ± 1.95 nM and Bmax: 428 ± 53 fmoles/mg protein. In vitro DMI treatment resulted in significantly increased mean values of Bmax: 614 ± 164 f moles/mg protein. No saturable, specific binding of $^3$H-DMI could be detected in the concentration range 2-16 nM tested. $^3$H-DMI treated platelet membranes however, retained 12% of the initially added radioactivity. This membrane-bound $^3$H-DMI is most likely attached to the imipramine binding sites, and/or partitioned into the platelet membrane nonspecifically. $\alpha_2$-receptors of DMI-treated platelet show significantly increased Bmax values suggesting an alteration in the proportion $\alpha_2$H/$\alpha_2$L states. We are currently investigating the relevance of these findings to the in vivo effects of DMI on platelet $\alpha_2$-adrenergic receptors in depressed patients. (Supported by the St. Joseph's Hospital Foundation. ESW holds a career award from the Ontario Mental Health Foundation.)

305.4 CENTRAL ALPHA-2-ADRENOCEPTORS MEDIATE THE NOCICEPTIVE JAW-OPENING REFLEX. A.L. Curtis* and J. Marwah. Dept. of Life Sciences, Indiana State Univ. and Depts. of Pharmacology, Physiology and Neurobiology, Indiana Univ. Sch. Med., Terre Haute, IN 47809.

The jaw-opening reflex (JOR) elicited by tooth pulp stimulation (TPS) has been utilized as an assay for analgesic drugs. However, the involvement and characterization of adrenoceptors in the JOR has not been previously studied. The JOR in lightly anesthetized rats and rabbits induced by intrapulpal (left maxillary) electrical TPS and quantified by the electromyograms (threshold values) recorded from the ipsilateral digastric muscle was used as the experimental pain index. The threshold for the JOR was significantly elevated by clonidine (6.25-100 ug/kg, I.V.) and was inversely correlated with the frequency of stimulation. All doses of clonidine produced an initial transient pressor response followed by a sustained hypotension and bradycardia. The analgesia elicited by clonidine was antagonized by the alpha-2-adrenoceptor antagonist yohimbine (1 mg/kg, I.V.) but not by the alpha-1-adrenoceptor antagonist prazosin (1 mg/kg, I.V.). Polar alpha-2-adrenoceptor agonists, 4-hydroxyclonidine and naphazoline, did not affect nociceptive thresholds at low doses (up to 50 ug/kg, I.V.). At higher doses (200 ug/kg, I.V.) naphazoline, but not 4-hydroxyclonidine, increased the nociceptive threshold. Naloxone had no effect on clonidine-induced analgesia but did antagonize morphine-induced suppression of the JOR. Reserpine pretreatment did not alter the analgesic effects of clonidine. Yohimbine did not antagonize the elevation of nociceptive threshold produced by pentobarbitol. We propose that clonidine modulates JOR analgesia by specifically activating centrally and postsynaptically located alpha-2-adrenoceptors. (Supported in part by American Heart Association Grants 83-757, 85-118 (E.I.); and NIDA grant DA-03519.)

305.5 $\alpha_2$ RECEPTOR CONTROL OVER NOREPINEPHRINE RELEASE IN RAT THALAMUS. C.W. Bradberry* and R.N. Adams. Department of Chemistry, Univ. of Kansas, Lawrence, KS 66045.

The rat locus coeruleus (LC) is composed of noradrenergic cell bodies which project throughout the forebrain and cerebellum. The release of norepinephrine (NE) from these neurons in several brain regions has been shown to be under two site-specific types of regulation mediated by $\alpha_2$-adrenergic receptors. $\alpha_2$ receptors on the cell body mediate an inhibition of the firing rate of LC neurons (Cederbaum, J.M. and Aghajanian, G.K., Eur. J. Pharm., 44:375, 1977). There are also $\alpha_2$ receptors localized at the nerve terminals which mediate a negative feedback regulation of NE release (Langer, S.Z., Br. J. Pharm., 60:481, 1977). This latter form of regulation appears to occur in rat cortex (Wemer, J. et al., J. Pharm. Exp. Ther. 211:445, 1979) and hippocampus (Frankhuyzen, A.L. and Mulder, A.H., Eur. J. Pharm., 81:97, 1982) as shown by in vitro experiments.

Recently, studies have indicated that the presence of autoreceptor regulatory mechanisms in dopaminergic systems depend on the site of projection (Chiodo, L.A. et al., Neurosci., 12, 1, 1984). The present work investigates the presence of "typical" $\alpha_2$ receptor control over NE release in the thalamus, a region not previously examined for these effects.

Two sets of experiments were performed. The first study examined the effects of α-adrenergic agents on relative NE turnover in the thalamus in vivo. Relative NE turnover was measured by analyzing for thalamic whole tissue content of NE following synthesis blockade by FLA-63. Clonidine (0.1 mg/kg i.p.), an $\alpha_2$ agonist, caused a marked reduction in relative NE turnover. Yohimbine (10 mg/kg i.p.), an $\alpha_2$ antagonist, not only reversed the clonidine effect but caused a substantial increase in relative NE turnover compared to control, suggesting a tonic level of $\alpha_2$ inhibition of NE release.

The second set of experiments investigated the effects of the $\alpha_2$ antagonist yohimbine on potassium-stimulated release of endogenous NE from chopped thalamic tissue. A dose-dependent increase in the release of endogenous NE was observed, indicating the presence of localized $\alpha_2$ receptors regulating the release of NE.

305.6 PHORBOL ESTERS AND ALPHA$_1$-ADRENOCEPTORS: DIFFERING EFFECTS ON OUTWARD CURRENTS IN RAT DORSAL RAPHE NEURONS. Jonathan E. Freedman and George K. Aghajanian. Depts. of Psychiatry and Pharmacology, Yale Univ. School of Medicine, New Haven, CT 06508.

Alpha$_1$-adrenoceptors are known to stimulate phosphatidylinositol (PI) turnover, generating the putative second messengers diacylglycerol (DAG) and inositol trisphosphate. We evaluated this model for the excitatory alpha$_1$ response of serotonergic neurons in the rat dorsal raphe, using extra- and intracellular recording in brain slices.

Phorbol esters, agents which mimic DAG by activating protein kinase C, exerted potent effects on raphe cell firing. In extracellular recordings in the presence of the alpha$_1$-agonist phenylephrine (PE, 2 μM), phorbol-12,13-dibutyrate (20-100 nM) and phorbol-12,-13-diacetate (100-500 nM) fully and reversibly inhibited PE-induced cell firing, while the parent alcohol 4-beta-phorbol was inactive at 1 μM.

Intracellular recordings showed that phorbol esters caused hyperpolarization, a drop in input resistance, and a suppression of the afterspike afterhyperpolarization. Single-electrode voltage clamp experiments revealed that phorbol esters (i) induced an outward (probably $K^+$) current, (ii) suppressed the transient $Ca^{2+}$-activated $K^+$ current, $I_{K(Ca)}$, and (iii) suppressed the voltage-dependent $Ca^{2+}$ current, $I_{Ca}$. Conceivably, this could result from tonic opening of $I_{K(Ca)}$ (i and ii), and inactivation of $I_{Ca}$ (iii), known effects of elevated intracellular $Ca^{2+}$. Alternatively, phorbol esters might suppress $I_{K(Ca)}$ and $I_{Ca}$, and induce another, unidentified outward current.

We have previously found that the major excitatory effects of alpha$_1$-receptors are due to suppression of outward currents (resting $K^+$ currents and the A-current), but that these excitatory effects are offset or modulated by prolongation of $I_{K(Ca)}$. Our present results: 1) do not support a role for C-kinase in mediating alpha$_1$ excitatory effects, which were not elicited by phorbol esters, and 2) leave unresolved the question of whether phorbol esters and alpha$_1$-receptors could share an effect on $I_{K(Ca)}$, which, if true, may help explain the paradoxical inhibition of alpha$_1$ responses by phorbol esters in this and other tissues.

305.7 ANTIDEPRESSANT TREATMENT MODIFIES THE FUNCTIONAL INTERACTION BETWEEN β-ADRENERGIC AND YOHIMBINE-SENSITIVE α-ADRENERGIC RECEPTORS IN RAT BRAIN SLICES. A. Pilc* and S.J. Enna. Depts. Pharmacology and of Neurobiology and Anatomy, University of Texas Medical School, Houston, Texas 77025.

Chronic administration of antidepressants alters the synergistic interaction between α- and β-adrenergic agonists as activators of cAMP production in rat brain slices (A. Pilc & S.J. Enna, Proc. IV World Cong. Biol. Psychiat., in press). Experiments were undertaken to characterize further the pharmacological properties of the brain α-adrenergic component and to examine the manner in which antidepressant treatment alters the relationship between these receptor systems. cAMP production was analysed in rat brain cerebral cortical slices using a prelabeling technique. α-Adrenergic receptors were stimulated with 6-fluoronorepinephrine (6-FNE), while isoproterenol (ISO) was used to activate the β-adrenergic component. The tissue was exposed to both agents simultaneously, or to norepinephrine (NE), for assessing the interaction between the two receptor systems. Although 6-FNE (10 μM) caused a modest (∿ 2-fold) increase in cAMP production, ISO (1.0 μM) elevated second messenger levels over 6-fold and the response to the drug combination, or to NE, was a 14-fold enhancement, indicating a synergistic interaction between the α- and β-receptor components. This interaction was only partially (< 30%) inhibited by prazosin, an $\alpha_1$-adrenergic receptor antagonist. In contrast, the $\alpha_2$-antagonist yohimbine completely eliminated the potentiated response, reducing NE-stimulated cAMP production to a level found with ISO alone. The concentration of yohimbine necessary to inhibit 50% of the α-component associated with the NE response ($IC_{50}$) was 1 μM. Chronic (2 wks) administration of 10 mg/kg imipramine, mianserin, or citalopram reduced the synergistic interaction between 6-FNE and ISO. Moreover, drug treatment significantly enhanced the potency of yohimbine to block the α-adrenergic component of the NE response ($IC_{50}$ = 0.5 μM). These data suggest that β-adrenergic receptor-coupled cAMP production in brain slices is potentiated by $\alpha_2$ - adrenergic receptor sites. Also, it appears that antidepressant administration modifies the synergistic interaction between the α- and β-adrenergic receptors, perhaps by altering the receptivity of the yohimbine-sensitive component.

305.8 **MORPHOLOGICAL CHANGE IN RAT ASTROCYTES INDUCED BY A PHORBOL ESTER IS NOT ASSOCIATED WITH CHANGE IN THE SENSITIVITY OF THE β-NORADRENERGIC RECEPTOR-ACTIVATED ADENYLATE CYCLASE SYSTEM.** **P. Mobley. Dept. of Pharmacology, University of Texas Health Science Center, San Antonio, Tx. 78284.**

**A well known feature of astrocytes maintained in culture is their transformation from flat, polygonal cells lacking processes to stellate, process-bearing cells when exposed to analogs of cyclic AMP or agents which increase the intracellular availability of cyclic AMP. These agents can also decrease the sensitivity of the β-noradrenergic-receptor-activated adenylate cyclase system in astrocytes. The results presented here suggest that these two events are independent of each other.**

**Astrocytes, prepared from the neocortex of newborn Sprague-Dawley rats, were grown and maintained in Dulbecco's Modified Eagle's Medium (DMEM) plus serum (10% fetal bovine, 5% calf) at 37°C in an atmosphere of 5% $CO_2$/95% air. At confluency these cells have a flat polygonal shape and lack processes. After exposure to 300μM isobutylmethylxanthine (IBMX) for 2 hrs, a large proportion of the astrocytes were transformed to process-bearing cells. A similar morphological change was observed in cells exposed to 400nM phorbol 12-myristate 13-acetate (PMA) for 2 hrs. The vehicle for PMA, dimethyl sulfoxide (0.05% final concentration), had no effect on morphology.**

**The effect of IBMX or PMA exposure on the isoproterenol-induced accumulation of cyclic AMP in astrocytes was also determined. In cells treated with 300μM IBMX, washed, and then exposed to 1μM isoproterenol for 10 min, the cyclic AMP response was approximately 50% less than in untreated cells exposed to isoproterenol. Treatment with IBMX did not appear to alter basal levels of cyclic AMP. In contrast, in cells treated with 400 nM PMA, washed and then exposed to 1μM isoproterenol for 10 min, no change in the isoproterenol induced accumulation of cyclic AMP was observed compared to vehicle control. (PMA, 2123 ± 149 pmoles cyclic AMP/mg protein; vehicle, 2071 ± 151 pmoles cyclic AMP/mg protein). Treatment with PMA did not appear to alter basal levels of cyclic AMP.**

**These studies suggest that the decrease in isoproterenol-induced cyclic AMP accumulation in cells treated with IBMX is not a consequence of morphological change. In support of this, a 2 hr treatment of astrocytes with isoproterenol causes only slight morphological change but decreases the cyclic AMP response elicited by re-exposure to isoproterenol by 70-90%. Since phorbol esters are activators of protein kinase C, this data also suggests that similar morphological changes can be induced in astrocytes by both the protein kinase C system and the cyclic AMP-dependent protein kinase system.**

305.9 EFFECT OF SUBACUTE CO-ADMINISTRATION OF DESIPRAMINE WITH NE OR 5-HT RELEASING AGENTS ON β-ADRENERGIC AND 5-$HT_2$ RECEPTORS IN RAT BRAIN WITH OR WITHOUT NE NEURON LESION. S.Matsubara*, M.Mikuni, T.Omori*, T.Kazawa* and I.Yamashita* (SPON:J.Tanji) Dept. of Psychiatry, Hokkaido Univ. Schl. of Med.,Sapporo, Hookaido 060, Japan

We investigated the effects of subacute (3 days) combined administration of desipramine(DMI) with various agents which were reported to promote the release of NE (yohimbine(YOH),(+)-mianserin(MIA)) or 5-HT(methiothepine(MET),(+)-MIA,(-)-MIA), on β-adrenergic and 5-$HT_2$ receptors in rat cerebral cortex. These agents were administered to naive or DSP-4 pretreated male Wistar rats. DSP-4, which selectively decreased the concentration of NE in parietal cortex, was kindly gifted form Dr.S.O.Ogren.

Treatment with MET, (+)-MIA or (-)-MIA alone decreased the numbers of 5-$HT_2$ receptor labelled by 3H-spiperone. These changes were more significant when co-administered with DMI. DMI or YOH alone did not change the numbers of 5-$HT_2$ receptor, whereas the combined administration thereof decreased them. DSP-4 pretreatment did not prevent the effects of (+)-MIA and YOH mentioned above. None of these agents changed the numbers of β-adrenergic receptor labelled by 3H-DHA when administered alone, but the combined administration of DMI with (+)-MIA, (-)-MIA or YOH but not with MET decreased the receptor numbers. These changes were abolished by DSP-4 pretreatment which increased β-adrenergic receptor numbers.

(+)-MIA was more potent to down-regulate 5-$HT_2$ receptor than (-)-MIA, although both were reported to be equipotent in 5-HT releasing effect. We previously reported that 5,7-DHT pretreatment did not prevent the down regulation of 5-$HT_2$ receptors induced by DMI. In addition, YOH promoted the DMI-induced down regulation and this effect was not prevented by the destruction of NE neurons. These results suggest the possibility that 5-$HT_2$ receptor numbers are regulated by postsynaptic α-2 adrenoceptor-mediated mechanisms and are not regulated by the availability of the transmitter, 5-HT. Our results concerning β-adrenergic receptors confirm the crucial role of NE in the regulation of the receptor numbers, and also suggest the possibility of postsynaptic α-2 adrenoceptor-mediated mechanisms, since (+)- and (-)-MIA equally promoted the DMI-induced down regulation of β-adrenergic receptors, although (+)-MIA but not (-)-MIA was reported to be active in NE release.

305.10 ALTERED BETA ADRENERGIC RECEPTOR FUNCTION IN A MONOCYTE-LIKE CELL LINE. D. Hill*, T.Wallace*, J.Van Boxel*, R.Schneider*, P.J. Mills*, and R.K.Wallace. Depts. of Neuroscience and Physiological Sciences, Maharishi International University, Fairfield, Iowa, 52556.

The beta adrenergic receptor (BAR) is being investivestigated in our laboratory as part of an ongoing program to assess the relationship between the nervous and immune systems in specific mental states. There are well established associations between a number of disease states and altered catecholamine (CA) levels, physiological responsiveness, and BAR number and/or affinity. For example, subsensitivity to beta adrenergic agonists in asthma and low lymphocyte BAR affinity in hypertension and aging. More recently, researchers are focusing on the connections between the immune and nervous systems as revealed by the weakened immune response in the lymphocytes from depressed and bereaved patients.

As an initial phase of our investigation, BAR is being studied in a series of cell lines by radioligand binding techniques utilizing (-)- Iodocyanopindolol, [125I] (CYP:NEN). In a monocyte-like cell line (u-937 histiocytic lymphoma, human: American Type Culture Collection) the addition of 5'- guanylylimidodiphosphate Gpp(NH)p failed to affect the BAR affinity, thus indicating a homogeneous low affinity BAR population. However, in a control study using freshly isolated peripheral blood lymphocytes, addition of Gpp(NH)p did right shift the competition curve, thus transforming all the BAR into the low affinity state.

The lymphocyte is a readily available model for determining the relationship between the nervous system, and its effect via CA activation of the BAR, and the immune system, which has lymphocytes as one of its primary effector mechanisms.

This model will be employed to examine the influence of mental stress on lymphocyte BAR and immune function, and its modification through the stress management technique of Transcendental Meditation.

305.11 COMPARISON OF BETA-1 AND BETA-2 ADRENERGIC RECEPTORS IN A SINGLE CULTURED CELL SYSTEM. Mark D. Dibner and Mary A. Bailey*. Neurobiology Group. Central Research and Development Department, E.I. du Pont de Nemours and Co., Experimental Station, Wilmington, DE 19898.

The subtypes of beta-adrenergic receptors have been characterized by comparison in different cells or tissues. This study examines receptors within the same system. The rat C6 glioma cell has both β1 and β2 adrenergic receptors, as demonstrated by displacement of [$^{125}$I]-iodocyanopindolol (ICYP) binding by specific β1 and β2 adrenergic antagonists in intact cells. There are 45% β1 receptors and 55% β2 receptors on these cells. By analysis of ICYP binding saturation and displacement as well as stimulation of cyclic AMP, the β1 and β2 receptors were further characterized. The antagonists ICI-89406 and ICI-118551 are highly selective for β1 and β2 receptors, respectively. In our hands they have no agonist activity (i.e., ability to stimulate cyclic AMP formation) at up to 10 μM. Displacement of ICYP binding by either drug yielded a biphasic curve with the IC50 for high affinity in the low nM range, the second IC50 in the μM range and a small flat region at 100 nM. Thus, β1 or β2 receptors were studied in the presence of 100 nM of the β2 or β1 antagonist. Isoproterenol has a higher affinity for displacing ICYP binding at β2 compared to β1 receptors, but it is more potent in stimulating cyclic AMP accumulation (in whole cells, measured by RIA) at β1 receptors than at β2. Dopamine appears to have a higher affinity for β2 receptors, but it is also more potent at stimulating cyclic AMP at the same receptor, compared to the β1 receptor. We recently described the ability of dopamine to desensitize the beta-adrenergic system in C6 glioma cells. When cells are exposed to 10 μM dopamine for 24 hours, there is a 60% loss of ICYP binding, as determined by Scatchard analysis. Both β1- and β2-adrenergic receptors appear to be affected; with more β2 lost than β1. After exposure to dopamine, isoproterenol-stimulated cyclic AMP accumulation is decreased more at β2 receptors than at β1 receptors. These studies demonstrate specific qualitative and functional differences in beta-adrenergic receptor subtypes in the same cell system. (Beta antagonists were a gift from ICI, Ltd.)

305.12 6-HYDROXYDOPAMINE LESIONS INCREASE NOREPINEPHRINE-INDUCED INOSITOL PHOSPHOLIPID HYDROLYSIS IN THE RAT STRIATUM. Marian S. Kafka, Rodrigo Labarca*, Aaron Janowsky*, Julie A. Blendy*, and Steven M. Paul*. Clinical Neuroscience Branch, NIMH, Bethesda, MD20205

The agonist-induced hydrolysis of inositol phospholipids (PI) has been characterized in the rat striatum by measuring the accumulation of [$^3$H]inositol phosphates (IP) in striatal slices and a particulate preparation (1), pre-labelled in vitro with [$^3$H]myo-inositol. Both carbachol (5-6000 μM) and norepinephrine (NE; 0.5 - 100 μM) stimulated PI hydrolysis. Carbachol-induced [$^3$H]IP accumulation was antagonized by atropine and scopolamine, and NE-induced [$^3$H]IP accumulation was antagonized by prazosin and WB4101, in a concentration-dependent manner. The response to carbachol appears to be mediated by muscarinic cholinergic receptors as the nicotinic agonist, citisin, failed to increase [$^3$H]IP accumulation, and the nicotinic antagonist, mecamylamine, failed to inhibit the effects of carbachol. The response to NE appears to be mediated by $\alpha_1$-adrenergic receptors as l-isoproterenol and clonidine failed to stimulate [$^3$H]IP accumulation, and yohimbine and dl-propranolol did not inhibit the effects of NE. Similar pharmacological relationships were observed using a particulate preparation.

Prior treatment with 6-hydroxydopamine (6OHDA; 2 X 200 μg icv., 4 days apart) increased the maximum accumulation of [$^3$H]IP induced by NE without changing the $EC_{50}$ of the NE-induced [$^3$H]IP accumulation. Carbachol-induced [$^3$H]IP accumulation was not altered by the 6OHDA lesion. Lesions produced by a knife-cut of the medial forebrain bundle (1P, 1.5L from bregma) produced effects similar to 6OHDA lesions. As there appear to be few or no noradrenergic nerve endings in the striatum (2), the effects of dopamine on [$^3$H]IP accumulation were examined. Dopamine (1-100 μM) failed to increase consistently [$^3$H]IP accumulation.

Because lesions of the dopaminergic afferents to the striatum increased $\alpha_1$-receptor-mediated stimulation of PI hydrolysis, it is possible that those afferents exert an inhibitory influence on the striatal PI system.

305.13 **QUANTITATIVE AUTORADIOGRAPHY OF RAT CORTICAL $\beta_1$- AND $\beta_2$-ADRENERGIC RECEPTORS AFTER 6-OHDA TREATMENT.** E.W. Johnson*, T.C. Rainbow, and B.B. Wolfe (SPON: G.B. Koelle). Dept. of Pharmacology, Univ. of Penn. Sch. of Med., Phila. PA 19104.

Intraventricular administration of the neurotoxin 6-hydroxydopamine (6-OHDA) to adult rats results in a reduction of forebrain norepinephrine (NE) levels as well as a 30% increase in the density of $\beta_1$ receptors in rat cerebral cortex. Using quantitative autoradiography, we have localized and quantified discrete regional variations in the density of β-adrenergic receptor subtypes in the rat brain after treatment with 6-OHDA. Due primarily to the increase in anatomical resolution afforded by quantitative autoradiography, we have not only been able to confirm the increase in $\beta_1$ receptors seen previously, but have also been able to demonstrate a significant increase in the density of $\beta_2$ receptors in the rat cortex and in other identifiable regions of the rat brain.

Adult rats were injected intracerebroventricularly on two successive days with 10 μl of 0.1% ascorbic acid in normal saline with or without 200 μg of 6-OHDA. The animals were decapitated one week after the initial injection and the brains were used either for determination of NE levels by HPLC with electrochemical detection or they were freeze-mounted onto cryostat chucks, cut into 32-μm-thick sections and thaw-mounted onto subbed glass slides. Sections from a number of anatomical levels were incubated with ($^3$H)-DMI, a selective label for NE uptake sites. Other sections from each level were incubated with ($^{125}$I)-iodopindolol ($^{125}$I-IPIN), a nonselective β-receptor antagonist, ($^{125}$I)-IPIN plus ICI 89,406, a potent and highly selective $\beta_1$ antagonist, ($^{125}$I)-IPIN plus ICI 118,551, a selective $\beta_2$ antagonist or ($^{125}$I)-IPIN plus isoproterenol. This procedure yielded an estimate of the relative numbers of β-adrenergic receptors, $\beta_2$ receptors, $\beta_1$ receptors or nonspecific sites. After labeling, the sections were apposed to LKB ultrofilm to generate autoradiograms. The autoradiograms were subjected to computerized quantitative densitometry, a process that allows conversion of optical density into molar quantity of ligand bound. HPLC analysis of samples from control and 6-OHDA-treated brains indicated that treatment with 6-OHDA resulted in depletion of 85% of the NE in the cerebral hemispheres. A general decrease in the binding of ($^3$H)-DMI was seen in brain sections obtained from 6-OHDA-treated animals, indicating a widespread loss of neurons containing the uptake site for NE.

As seen in previous studies, the density of $\beta_1$ receptors in the cerebral cortex of 6-OHDA-treated animals was increased about 30%. This increase occurred more in somatomotor cortex than in frontal or occipital cortex. In contrast to previous reports, the density of $\beta_2$ receptors was also increased about 40% over control values. This change occurred mainly in frontal cortex. There was also a greater than 200% increase in the density of $\beta_2$ receptors in the caudal portion of the lateral posterior nucleus of the thalamus (LPT). The density of $\beta_1$ receptors did not change in the LPT. (Supported by NIH Grant NS-19597 and Klingenstein Fellowship.)

305.14 BETA-ADRENERGIC RECEPTOR DENSITY AND N PROTEIN COUPLING IN THE CEREBELLUM OF THE RAT AFTER REPEATED TREATMENT WITH CLENBUTEROL. G.A. Ordway*, J.M. O'Donnell and A. Frazer, (SPON: P. Whybrow) Depts. of Psychiatry and Pharmacology, Univ. of Pennsylvania and VAMC, Philadelphia, PA 19104.

Recently, we found that repeated treatment of rats with the centrally-active beta-adrenergic agonist clenbuterol (CLEN) reduced the ability of isoproterenol (ISO) to elevate the concentration of adenosine 3',5'-monophosphate (cyclic AMP) in cerebral cortical slices. This reduced beta-adrenergic responsiveness in the cortex was not accompanied by a reduction in the density of beta-adrenergic receptors but rather was due to an uncoupling of these receptors from the N protein (J. Pharmacol. Exp. Therap., in press). As CLEN has been reported to have beta$_2$-selectivity, it was of interest to compare its effects in the cortex (a brain area with predominantly beta$_1$ receptors) with those found in a brain area containing mostly beta$_2$ receptors, e.g., the cerebellum. Male rats were injected with CLEN (1-10mg/kg, i.p.) or 0.9% NaCl once daily for periods of one to 16 days. Eighteen hours after the final drug administration, the rats were killed by decapitation and homogenates of cerebellum prepared as described previously (J. Pharmacol. Exp. Therap. 228:640, 1984). Saturation experiments were done using the beta-antagonist $^{125}$I-iodopindolol (IPIN) as the ligand to determine the density of beta-adrenergic receptors and their affinity for IPIN. The "coupling" of these receptors to the N protein was inferred from analysis of the competition curves produced by isoproterenol of the binding of IPIN in the absence and presence of GTP.

In contrast to results measured in the cortex, treatment of rats with CLEN caused a reduction in the density of beta-receptors in the cerebellum; this was both dose-and time-dependent. Eighteen hours after a single injection of clenbuterol (10 mg/kg), beta-receptor density was reduced by 50%; after eight days of administration, the reduction in density was about 80%. CLEN treatment did not change the affinity of the beta-receptors in the cerebellum for IPIN, but did uncouple the beta-receptors in the cerebellum from the N protein. The ability of CLEN to reduce the density of beta-receptors in the cerebellum but not in the cortex may be related to its ability to produce greater beta-adrenergic effects in tissues with predominantly beta$_2$ rather than beta$_1$ receptors. (Supported by Research Funds from the VA and USPHS Grants MH29094 and MH14654).

**305.15** RAPID DOWN-REGULATION OF BETA-ADRENERGIC RECEPTORS BY COMBINING ANTIDEPRESSANT DRUGS WITH FORCED SWIM: A MODEL OF ANTIDEPRESSANT-INDUCED NEURAL ADAPTATION. G.E. Duncan*, I.A. Paul*, R.A. Mueller, P.P. Rowell and G.R. Breese. Biological Sciences Research Center, UNC School of Medicine, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC 27514.

The hypothesis that behavioral responses to antidepressant drugs in the forced swim test are related to a rapid neural adaptation produced by the combination of drug treatment and swim stress was explored. As a measure of adaptation, brain beta-adrenergic receptors were assayed using $^3$H-dihydroalprenolol ($^3$H-DHA) binding to brain membranes from rats that were processed in the forced swim test. The combination of swim stress and imipramine treatment antagonized immobility induced by forced swimming and resulted in a reduction in $^3$H-DHA binding to membranes from forebrain preparations which did not include the corpus striatum. Administration of antidepressant drugs from other chemical classes, including pargyline, iprindole, and nomifensine, also reduced immobility induced by the forced swim and produced a reduction in $^3$H-DHA binding to forebrain membranes. In homogenates of the corpus striatum, $^3$H-DHA binding was not altered by swim stress combined with antidepressant drug treatment. Chlordiazepoxide was without an effect on immobility or beta receptor binding when combined with forced swim. Even though atropine and amphetamine exhibited a positive activity in the forced swim test, they did not reduce $^3$H-DHA binding. Therefore, by combining behavioral and neurochemical analysis of animals processed in the forced swim test, it may be possible to differentiate, with greater confidence, potential antidepressant drugs from "false positives". The present studies support the hypothesis that antidepressant drug action in the forced swim test involves a rapid neural adaptation, as reflected by the down-regulation of beta-adrenergic receptors. Thus, this behavioral paradigm may serve as a model of adaptive mechanisms induced by antidepressant drugs.

**305.16** MEASUREMENT OF IN VIVO BETA ADRENOCEPTOR TURNOVER IN THE RAT STRIATUM. B.L. Largent, A.L. Gundlach, J. Pitha* and S.H. Snyder. The Johns Hopkins University School of Medicine, Department of Neuroscience, *National Institute on Aging, GRC-Francis Scott Key Medical Center., Baltimore, MD.

Recently, an irreversible beta adrenoceptor (BAR) antagonist, bromoacetylalprenololmenthane (BAAM), has been synthesized (Pitha, J. et al., Life Sci. 27:1791, 1980) and characterized against peripheral BARs (Baker, S. and J. Pitha, J. Pharm. Exp. Ther. 220:247, 1982). We have characterized the interaction of BAAM with CNS BARs. Additionally, BAAM was utilized to measure the in vivo turnover rate for BARs in the rat striatum.

BAAM inhibited 125-I-Cyanopindolol (ICYP) binding to BARs in rat cortex, cerebellum, and striatum ($IC_{50}$ of ~ 1-3 nM) with no apparent selectivity for β-1, or β-2 adrenoceptor subtypes. BAAM inhibition of 125-ICYP binding demonstrated two components - a competitive portion and an irreversible portion. The extent of alkylation of BARs by BAAM was time and concentration dependent.

BAR metabolism rates can be measured by irreversibly blocking a portion of a population of BARs and then monitoring the recovery of that population toward steady state levels. Assuming a monoexponential process for the repopulation kinetics, a plot of the data ([Rss] = steady state receptor level and [Rt] = receptor level at time t) as ln ([Rss]/[Rss]-[Rt]) vs time will provide an indication of the t 1/2 for recovery, the synthesis rate, and the degradation rate for the receptors. Since BAAM does not appreciably cross the blood-brain barrier, our studies measuring CNS BAR turnover required direct injection of BAAM into the CNS to alkylate BARs.

Stereotaxic microinjection of BAAM (20 µg/0.2 µl EtOH) into the rat striatum decreased the BAR levels to 25-30°/° of control values, until approximately 30 days after which a recovery period began. After 135 days, an apparent recovery plateau was reached at approximately 60°/° of control levels. At this point it is not clear if receptor level recovery would continue - at a much slower pace - eventually reaching control levels or remain at that degree of recovery. Assuming the control receptor level (~ 135 fmols/mg protein) equals Rss, plotting the data gives the following metabolism parameters: synthesis rate = 1.42 fmols/mg protein-day, degradation rate = 0.0104 $day^{-1}$, and a t 1/2 = 66 days. However, using the apparent plateau recovery level (85 fmols/mg protein) as Rss provides the metabolism parameters: synthesis rate = 1.98 fmols/mg protein-day, degradation rate = 0.0233 $day^{-1}$, and a t 1/2 = 30 days. The comparison of metabolism rates in control receptor states to modulated receptor states, such as following chronic drug treatments, should provide new insight into the regulation of receptors.

**305.17** CHARACTERIZATION OF THE β-ADRENORECEPTOR ON RAT BROWN ADIPOCYTES. B.E. Levin and A.C. Sullivan*. Neurology Service, Veterans Administration, E. Orange, NJ 07019, Dept. of Neurosciences, N.J. Medical School, Newark, NJ 07103, Dept. of Pharmacology, Hoffmann-LaRoche, Nutley, NJ 07110.

Brown adipose tissue (BAT) is a major source of sympathetically controlled thermogenesis in the rat as stimulated primarily by β-adrenoreceptors. The β-subtype has been in doubt because of the difficulty of carrying out detailed binding studies with previously available ligands, all of which were lipophylic, yielding high levels of non-specific binding. We used ($^3$H)CGP 12177 (4-3-t-butylamino - 2-hydroxypropoxy)-{5,7-$^3$H}benzimidazol-2-one), a hydrophilic ligand, to characterize the β-receptor in BAT. Binding was carried out in 5 mM Hepes buffer containing 1 mM $MgSO_4$, pH 8.0 at 37°C for 20 min. Specific binding in the presence of 30 µM isoproterenol was 60-80% of total. Binding to collagenase-separated whole cells gave: $K_d$ = 323 ± 28pM, $B_{max}$ = 26.7 ± 1.4 x $10^{-5}$fmol/cell; binding to partially purified membranes from isolated adipocytes gave: $K_d$ = 499 ± 53 pM, $B_{max}$ = 14.4 ± 0.86 fmol/mg protein. Results of competitive binding studies in purified BAT membranes with various $\beta_1$- and $\beta_2$-specific ligands (in the presence of 1 nM ($^3$H)CGP and 100 µM GTP) showed there to be at least 2 subtypes (about 80% $\beta_1$-, 20% $\beta_2$-):

| | $\beta_1$- | | $\beta_2$- | |
|---|---|---|---|---|
| | $K_d$ | % | $K_d$ | % |
| $\beta_1$-specific | | | | |
| ICI 89409 | 4.40 ± 0.37nM | 83.8 ± 2.6 | 0.36 ± 0.20µM | 16.2 ± 3.0 |
| Metoprolol | 23.4 ± 5.2 nM | 81.2 ± 8.1 | 0.95 ± 0.11µM | 18.9 ± 7.2 |
| $\beta_2$-specific | | | | |
| ICI 118551 | 1.29 ± 0.08µM | 78.9 ± 11.8 | 2.63 ± 0.47nM | 21.1 ± 7.9 |
| Zinterol | 0.68 ± 0.07µM | 82.9 ± 2.0 | 4.87 ± 2.71nM | 17.1 ± 2.5 |
| Other | | | | |
| NE | 1.13 ± 0.03µM | 83.2 ± 2.0 | 395 ± 26 µM | 16.8 ± 2.1 |
| LY 22-8899 | 2.01 ± 0.41µM | 89.1 ± 4.8 | 8.83 ± 1.24nM | 10.9 ± 4.2 |

The latter compound (LY 22-8899) is a thermogenic and lipolytic agent which has its highest affinity for the $\beta_2$-receptor. Nevertheless, there was no evidence for a 3rd type of β-receptor as suggested by the in vitro physiological studies of Arch et al. (Nature 309: 143, 1984); the $\beta_1$-receptor appeared to be the predominant subtype by these competitive binding studies.

**305.18** CHARACTERIZATION OF DOPAMINE RECEPTORS FUNCTIONALLY LINKED WITH CALCIUM CHANNELS. M. Memo, L. Castelletti*, A. Valerio*, C. Missale, M.O. Carruba*, P.F. Spano. Inst. of Pharmacol. Exp. Ther., Sch. of Med., Univ. of Brescia and Dept. of Pharmacol., Chemiother. and Med. Toxicol., Univ. of Milano, Italy.

Dopamine (DA) is a well known prolactin inhibitor factor which can be released in the tubero-infundibolar system and then inter acts with specific receptors in the pituitary cells. It has been suggested that DA decreases prolactin release by modulating in an inhibitory way basal or stimulated adenylate cyclase activity. We now report that DA can prevent the release of prolactin induced by neurotensin by interacting with DA $D_2$ receptors which appear to be completely independent of adenylate cyclase moiety, but are functionally coupled to calcium channels.

Exposure of pituitary cells in continuously perfused columns for 10 min to 50 nM DA prevented the neurotensin-induced increase of prolactin release. This effect of dopamine was dose-dependent with a half maximal inhibitory effect at 5 nM. Like DA, various DAergic agonists such as bromocriptine, lisuride and apomorphine inhibit neurotensin-induced prolactin release. In the same experimental conditions, 50 nM DA completely inhibits neurotensin-induced increase of calcium influx into the cells. The $IC_{50}$ of DA for this effect was 8 nM. The inhibitory action of dopamine was mimicked by bromocriptine, lisuride and apomorphine, with $IC_{50}$ values of 2.5 nM, 7.0 nM and 50 nM, respectively. The inhibitory action of DA was stereospecifically reversed by sulpiride. In the range of concentrations that are effective in inhibiting either the calcium influx and prolactin release,both induced by neurotensin, DA does not alter the cyclic AMP generating system. 50 nM DA does not affect adenylate cyclase activity in rat pituitary gland homogenates and does not modify intracellular concentrations of cyclic AMP in dispersed cells. Moreover, the inhibitory effects of DA on neurotensin-induced both calcium entry and prolactin release, persisted in pertussis toxin-treated cells. The effect of DA appears to be specifically linked to receptor-operated, rather than voltage-operated, calcium channels. DA (50 nM) did not alter the entry of calcium induced by high potassium concentrations or veratridine.

Our results indicate that DA $D_2$ receptors in anterior pituitary are, at least in part, functionally coupled with calcium channels.

306.1 QUANTITATIVE DISTRIBUTIONS OF ASPARTATE AMINOTRANSFERASE AND GLUTAMINASE ACTIVITIES IN THE COCHLEA. G.J. Wiet*, D.A. Godfrey, C.D. Ross and J.D. Dunn. (SPON: D.F. Peterson), Depts. Physiol. and Anat., Oral Roberts Univ., Tulsa, OK 74171.

Aspartate aminotransferase (AAT) and phosphate-dependent glutaminase (PDG), prominent enzymes of aspartate and glutamate metabolism, have been suggested to be important in neurons that may release these amino acids as transmitters. To evaluate possible roles of AAT and PDG in hearing, quantitative microchemical techniques have been applied to study their distributions in the cochlea. Also assayed was choline acetyltransferase (ChAT), the enzyme synthesizing acetylcholine in cholinergic neurons, and a marker for the auditory feedback pathway to the cochlea from the brain stem: the olivocochlear bundle (OCB). Young rats (300-400 g) and guinea pigs (160-200 g) were decapitated, and the temporal bones quickly removed, frozen in Freon chilled with liquid nitrogen, and freeze-dried for one week. Cochleas were dissected by a three-dimensional approach. Samples of inner and outer hair cell regions and outer supporting cell region of the organ of Corti, Reissner's membrane, tectorial membrane, and stria vascularis were removed, weighed (0.02-0.5 μg) and then assayed for AAT, PDG, or ChAT activity. AAT activity was about the same in both synaptic (hair cell) and non-synaptic (supporting cell) zones within the organ of Corti, was almost twice as high as this in the stria vascularis, and was much lower in Reissner's and tectorial membranes. PDG, on the other hand, had its highest activity in synaptic zones, about half that activity in organ of Corti non-synaptic zones, and almost no activity in Reissner's and tectorial membranes and stria vascularis. ChAT activity was highest in synaptic zones, with activities close to 100 times those of the other, non-neural, structures. Seven days after unilateral transection of the OCB in the brain stem of three rats, no significant difference was found between lesion- and control-side AAT and PDG activity, even though the activity of ChAT in the organ of Corti fell to zero. Both the distribution of AAT activity and the lesion results would seem to implicate AAT in an energy metabolism role moreso than a neurotransmitter role in the cochlea. The relatively high activity in the stria vascularis correlates with relatively high activities of other oxidative metabolic enzymes, such as malate dehydrogenase. The distribution of PDG would be consistent with a possible role in neurotransmission; however, the lesion data suggest that it is not associated with the olivocochlear bundle.

(Supported by NIH Grant NS17176).

306.2 LOCALIZATION OF GLYCINERGIC SYNAPSES IN THE COCHLEAR NUCLEUS AND SUPERIOR OLIVARY COMPLEX WITH MONOCLONAL ANTIBODIES SPECIFIC FOR THE GLYCINE RECEPTOR. R. J. Wenthold, H. Betz, K. A. Reeks*, M. H. Parakkal* and R. A. Altschuler. Lab. of Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20205 and Univ. of Heidelberg, Federal Republic of Germany.

Glycine is believed to be a major inhibitory neurotransmitter with highest levels found in the spinal cord and brainstem. Previously, synapses using glycine as a transmitter could not be readily localized because of the lack of a specific immunocytochemical marker. However, the postsynaptic glycine receptor has been purified and monoclonal antibodies produced against it, providing a specific marker for glycinergic synapses (Pfeiffer et al., PNAS 81, 7224). Biochemical and pharmacological evidence suggests that glycine is a neurotransmitter in the auditory system. To determine the precise localization of glycinergic synapses, the immunocytochemical distribution of the glycine receptor was determined in the cochlear nucleus and superior olivary complex.

Rats and guinea pigs were used in the study. For light level localization animals were perfused with paraformaldehyde, 0.1-4%, and for electron microscopic localization, animals were perfused with 4% paraformaldehyde and 0.1% glutaraldehyde. Labeling was determined with both immunofluorescence and immunoperoxidase techniques. At the light microscopic level, two different monoclonal antibodies (GlyR 5a and 7a) gave the same immunocytochemical labeling. Labeling was seen throughout the cochlear nucleus, appearing as puncta often present around cell bodies. Electron microscopic studies in the AVCN were done with GlyR 7a. These show that labeling is restricted to the postsynaptic region of both axo-dendritic and axo-somatic synapses. Several different terminal populations have been described in the AVCN based on vesicle shape and size and terminal morphology. Preliminary analyses suggest that glycine receptors are apposed to terminals containing flattened vesicles. Immunoreactive label was present on cell bodies and processes in nuclei of the superior olivary complex including the medial and lateral superior olivary nuclei and medial and ventral nuclei of the trapezoid body.

306.3 GABA-LIKE IMMUNOREACTIVITY IN THE ANTEROVENTRAL COCHLEAR NUCLEUS. R. A. Altschuler, M. D. Oberdorfer, M. H. Parakkal*, K. A. Reeks*, J. M. Zempel* and R. J. Wenthold. Lab. Neuro-otolaryngology, NINCDS and NEI, NIH, Bethesda, MD. 20205 and Dept. of Neurophysiology, Univ. of Wisconsin, Madison, WI 53706

GABA is a major inhibitory neurotransmitter with a widespread distribution in the mammalian CNS. There is strong evidence supporting a neurotransmitter role for GABA in the cochlear nucleus, with reports suggesting that most GABA in the cochlear nucleus is associated with intrinsic neurons. To determine the morphology and distribution of GABAergic terminals in the anteroventral cochlear nucleus (AVCN) of the guinea pig, antibodies made against GABA were used in an immunocytochemical study. Antibodies were produced in rabbits against GABA conjugated to BSA. GABA specific antibodies were obtained by affinity purification and characterized by immunoblotting. Guinea pigs were perfused with 4% paraformaldehyde and 0.1% glutaraldehyde. Immunoperoxidase or immunogold staining procedures were performed on free-floating vibratome sections with primary antibody at dilutions of 1/1000 to 1/3000. GABA positive terminals were found throughout the AVCN. These terminals were lightly or densely packed with oval/pleomorphic vesicles and made symmetric contacts on cell bodies of stellate and spherical cells. Similar terminals were seen making axo-dendritic synapses in surrounding neuropil and a few contacts suggesting axo-axonal synapses. Terminals containing flattened or spherical vesicles were unstained. A few small cells with GABA immunoreactive staining were also observed in the AVCN. This study suggests that there is an extensive and complex GABAergic input to the guinea pig AVCN. GABA immunoreactivity seen in intrinsic neurons in the dorsal cochlear nucleus may be the source of some of this input.

306.4 EVIDENCE FOR A NEUROTRANSMITTER ROLE FOR GLYCINE IN THE GUINEA PIG COCHLEAR NUCLEUS. C.G. Staatz-Benson and S.J. Potashner. Dept. of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

Glycine has been proposed as a putative neurotransmitter in the mammalian cochlear nucleus (CN). Studies were performed to determine if mechanisms exist in the CN for the high-affinity uptake and the synaptic release of glycine. To measure uptake, the CN was rapidly dissected from anesthetized guinea pigs and divided into the anteroventral (AVCN), posteroventral (PVCN), and dorsal (DCN) cochlear nuclei. The segments were chopped (100 um slices), weighed, pre-incubated (30 min. 37°C), then incubated in Ringer with several concentrations of $^{3}$H-glycine. After 5 minutes, slices were separated from the medium by centrifugation, washed, and homogenized in acid. Each division of the CN accumulated $^{3}$H-glycine by a high-affinity uptake process which was sodium-dependent and temperature-dependent. Kinetic analysis demonstrated Km (uM) and Vmax (nmoles/g cell water/min) values of 34, 97 in the AVCN, 35, 93 in the PVCN and 36, 110 in the DCN. These Km and Vmax values are consistent with those for high-affinity uptake of glycine in other areas of the central nervous system.

To measure glycine release, dissected segments of the CN were first allowed to take up $^{14}$C-glycine. They were then superfused with low-sodium, glycine-free medium which was collected in 2 minute fractions. CN segments were then subjected to electrical field stimulation (2 ms duration, 200 Hz, 40 mA (AVCN); 100 Hz, 60 mA (PVCN and DCN)) for 4 minutes during the superfusion. Radioactivity was measured in the collected superfusate fractions and in the tissue at the end of the superfusion. The electrically-evoked release of $^{14}$C-glycine was quantified as the pSER value; the percent of tissue $^{14}$C-glycine released as a result of stimulation. pSER values were 5.6% in the AVCN, 8.7% in the PVCN and 6.0% in the DCN. Approximately 80-95% of this release was dependent on the presence of calcium in the medium, suggesting that this proportion of the release was from synaptic structures.

These findings suggest that each subdivision of the guinea pig CN contains mechanisms for the high-affinity uptake and electrically-evoked, calcium-dependent release of glycine. The presence of these presumed synaptic activities is consistent with a potential neurotransmitter role for glycine in the CN.

(Supported by Grant NS19036 from NINCDS).

306.5 THE PATTERN OF GAD-LIKE IMMUNOREACTIVE AXON TERMINALS ON IDENTIFIED CELL TYPES IN THE CAT VENTRAL COCHLEAR NUCLEUS. R.L. Saint Marie, D.K. Morest and C. Brandon. Dept. of Anatomy, Univ. Conn. Health Ctr., Farmington, CT 06032 and Dept. of Biological Chemistry and Structure, The Chicago Med. Sch., No. Chicago, IL 60064.

The distribution of GABAnergic axon terminals on identified cell types was examined histochemically using an antibody to glutamate decarboxylase (GAD). The immunoreaction appears in all subdivisions with an intensity proportional to the amount of neuropil present in each region; e.g., the most staining occurs rostrally and dorsally, decreases caudally and ventrally as far as the zone of bifurcations, and increases again in the posterior division. These gradients compare well with biochemical assays of GAD levels in the guinea pig (Wenthold & Morest, 1976).

Each cell type has a characteristic labeling pattern, based on the size, concentration, and distribution of GAD+ endings on its soma. Spherical bushy cell somata in the anterior division are typically contacted by many medium-sized (1-2μ) terminals, some of which are isolated, others are associated with tight clusters of many small (0.5-1μ) endings. This pattern is interrupted by large naked patches which correspond to the unreactive end-bulbs of Held. Also, there is a tendency for the medium-sized endings to gather at the base of dendrites. Globular bushy cells in the anterior division have a pattern similar to that of the spherical cells, but the clusters of immunoreactive terminals are less tightly packed, the naked patches are less well defined, and there is a greater proportion of the medium-sized endings (>1μ). Octopus cells in the octopus cell area have immunoreactive terminals that are more evenly distibuted than those on bushy cells, although these endings also tend to aggregate into small clusters or short rows. Generally, the size of the immunoreactive terminals on octopus cells is larger (1-2.5μ) and the packing density of these terminals is similar on both the dendrites and soma. Stellate and giant neurons also have distinctive labeling patterns, but several varieties have been seen; e.g., some have few endings on their somata. In general, the immunoreactive terminals are evenly distributed on the somata and proximal dendrites, although some cells in the anterior division show a preferential accumulation of labelled terminals at the bases of dendrites. Small cells have been seen which are contacted by some of the largest GAD+ terminals encountered in this nucleus (up to 3μ).

Several of the patterns of immunoreactive terminals in this study resemble those of non-cochlear axons projecting from the trapezoid body and the dorsal cochlear nucleus in Golgi material and correspond to synaptic endings with small pleomorphic vesicles and symmetric junctions.

(Supported by NIH grants NS14354 & EY05601).

306.6 ANTEROVENTRAL COCHLEAR NUCLEUS OF THE MOUSE IN TISSUE CULTURE. M. R. Martin, J. Mazzetta*, R. A. Altschuler and K. Reeks* Laboratories of Neuro-otolaryngology and Neurophysiology, NINCDS, NIH, Bethesda, MD 20205

During the past decade the anteroventral cochlear nucleus (AVCN) has been the site of an intensive investigation into the nature of the transmitter of the auditory nerve. The cumulative evidence strongly implicates excitatory amino acids, with receptors for the three known classes being present. In recent years pharmacological studies have focused on the in vitro tissue slice preparation of the mouse. This preparation, however, has the disadvantage of having a low yield of data, or poor quality recording, and the inability to do patch clamp analysis of the receptors on the neuronal membrane. To overcome some of these limitations we have made an initial attempt to culture the neurons of this region.

Sagittal sections (600 μm) of the cochlear nucleus of 7 day old mice were prepared and the region anterior to the incoming auditory nerve fiber was cut off for use in preparing cultures. Using standard tissue culture techniques both explant and dissociated cultures were prepared. High glucose MEM with 5% horse serum on mouse feeder layers was used. After 12 days in culture the cells were fixed with 4% paraformaldehyde and stained for neuron-specific enolase-like immunoreactivity (NSE-IR). The avidin/biotin complex immunoperoxidase technique was used with a polyclonal antiserum to NSE.

A variety of neurons can be found in both explants and dissociated cultures. NSE-IR positive neuron somas are mostly in the range of 10 to 20 μm in diameter, but larger neurons (up to 40 μm) are also found. Dendrites were also commonly positive for NSE-IR stain. However, the smallest NSE-IR positive neurons (8-10 μm) typically appear spherical with no processes. A number of neurons also have an elongated fusiform shape. By far the majority of neurons are multipolar.

Although a number of neuron types are present, it is hoped that this preparation will lead to a better understanding of the synaptic physiology and pharmacology of this region.

306.7 STIMULUS DEPENDENT NEURAL CORRELATIONS BETWEEN TYPE II AND TYPE IV UNITS IN DORSAL COCHLEAR NUCLEUS. HF.Voigt, Dept. of Biomedical Engineering, Boston University, Boston, MA 02215 and E.D.Young, Dept. of Biomedical Engineering, Johns Hopkins University, Baltimore, MD 21205.

Type II units in the unanesthetized, decerebrate cat dorsal cochlear nucleus (DCN) are thought to provide at least some of the inhibitory input to DCN type IV units. Evidence supporting this claim was provided by a previous, single-electrode, cross-correlation study that indicated brief decreases in the firing probability of type IV units following the occurrences of action potentials in simultaneously recorded type II units (Voigt, HF and Young, ED, J.Neurophys. 44:76-97, 1980). One shortcoming of the single-electrode technique for recording unit pairs is the inability to resolve overlapping action potential waveshapes. This results in cross-correlograms with artifactual zero values in the vicinity of zero delay, and thus obscures the shape of the cross-correlogram near the origin where type II-type IV inhibitory correlations are expected. We report here results obtained from 57 type II-type IV pairs recorded simultaneously with two independently maneuvered microelectrodes. Cross-correlograms were computed from acoustically driven activity because type II units lack spontaneous activity. For 55 type II-type IV pairs we chose to use 60s tones; the frequency was set to the type II unit's best frequency (BF) and the level was chosen to be about 10,20 or 30 dB above the type II unit's threshold. We found, in agreement with the earlier study, asymmetrical, inhibitory troughs (ITs) in the cross-correlograms of 18/55 pairs indicating a brief decrease in type IV firing probability following type II action potentials. Nearly half (12/25) of the type II-type IV pairs encountered with BF differences less than 0.3 octaves showed signs of correlated activity. In contrast only 6/30 pairs with BF differences greater than 0.3 octaves had correlated activity. Cross-correlograms were obtained at two or more levels for 11 of the 18 IT-correlated pairs. For 7 of the 8 pairs that had BF differences less than 0.3 octaves, the size of the IT decreased with increased sound level. In contrast, the ITs of all three of the pairs that had BF differences greater than 0.3 octaves increased in size with higher sound level. Thus we find that the size of the IT in the cross-correlograms of type II-type IV pairs depends on both stimulus level and on BF differences. (Work supported by NIH.)

306.8 CIRCUITRY IN THE MOUSE DORSAL COCHLEAR NUCLEUS. J.A. Hirsch and D. Oertel. Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

Many, but not all, of the large cells in the dorsal cochlear nucleus (DCN) are directly excited by fibers of the auditory nerve. Anatomical evidence shows that most of these cells also receive inputs from granule cells and other neurons in the DCN and from neurons in the ventral cochlear nucleus (VCN). We have studied the neuronal circuitry of the DCN by recording intracellularly from cells in brain slices of the cochlear nuclei. Slices were made with a cut 200 to 300 μm below the pial surface. Some slices contained parts of the DCN, VCN, and the attached root of the auditory nerve, others contained only the DCN. The drugs used were applied in the bath.

All cells tested were excited by 1.0 mM glutamate (5 cells). Glutamate is without effect in the VCN (Oertel, Brain Res. 302: 213, 1984). These results are consistent with much literature which suggests that granule cells make excitatory connections in the dorsal rather than the ventral division and that the transmitter released by granule cells is glutamate.

Spontaneous IPSPs are continually recorded in the DCN. Shocks delivered to the auditory nerve evoke EPSPs followed by trains of IPSPs. For each of the 6 cells tested, 1.0 μM strychnine blocked both the spontaneous and evoked IPSPs; 0.01 to 0.1 mM levels of the GABA antagonists bicuculline (4 cells) and picrotoxin (2 cells) had no effect. All inhibitory synaptic responses we see, therefore, are probably glycinergic.

To distinguish between inputs arising in the VCN from those endogenous to the DCN, we recorded from slices containing only the DCN. Spontaneous IPSPs remained in the absence of the VCN. This result, together with our observation that cells in the DCN but not the VCN are spontaneously active in slices, suggests that spontaneous IPSPs arise from interneurons of the DCN. When we stimulated through electrodes placed on the surface of the DCN, the evoked synaptic potentials resembled the response to electrical stimulation of the auditory nerve and we were surprised.

306.9 **DISTRIBUTION OF RECEPTORS IN THE MOUSE COCHLEAR NUCLEUS: AN AUTORADIOGRAPHIC STUDY.** A. Frostholm, C. Schultz* and A. Rotter. Department of Pharmacology, California College of Medicine, U.C. Irvine, Ca 92717.

Light microscopic autoradiography of radiolabeled ligands was used to describe the distribution of seven receptors in the dorsal and ventral regions of the mouse cochlear nucleus: Muscarinic ACh receptor ($^3$H-quinuclidinyl benzilate); histamine receptor ($^3$H-mepyramine); glycine receptor ($^3$H-strychnine); GABA receptor ($^3$H-muscimol); adenosine receptor ($^3$H-cyclohexyladenosine); benzodiazepine receptor ($^3$H-flunitrazepam); nicotinic ACh receptor ($^{125}$I-alpha-bungarotoxin). Slide mounted sections were incubated under optimal binding conditions and prepared for autoradiography by the method of Young and Kuhar (Brain. Res. 175:255,1979). Silver grains were counted in dark field photomicrographs of coronal sections through the cochlear nuclei.

Highest levels of **$^3$H-muscimol** binding were observed over the granule cell layer of the posterior ventral nucleus (PVCN) and over the pyramidal layer of the dorsal nucleus (DCN). Other regions of the nucleus were unlabeled. The most intense **$^3$H-strychnine** binding was observed over the deep region of the DCN, with slightly lower densities over the molecular and pyramidal layers. Dorsal regions of the PVCN were moderately labeled; occasional clusters of very high labeling were visible over more ventral regions. The granule cell layer was of low density. The deep region of the DCN was moderately labeled by **$^{125}$I-alpha-bungarotoxin;** small patches of extremely high grain density were also scattered throughout this region. The molecular and pyramidal layers were slightly less densely labeled. In the ventral nucleus, a reticulated cascade of very high grain density was observed over the medial area, with globular clusters of high density spreading out laterally. The granule cell layer was unlabeled. Moderate **$^3$H-quinuclidinyl benzilate** binding was seen over the molecular layer, possibly extending into the pyramidal layer, of the DCN. A thin band of moderate grain density was visible over the granule cell layer of the PVCN. All other regions were unlabeled. Moderate, diffuse **$^3$H-mepyramine** labeling was visible throughout the DCN, with slightly higher grain density over the molecular, and possibly the pyramidal layers, than over the deep region of the DCN. The granule cell layer was of low to moderate grain density, while the remainder of the ventral nucleus was unlabeled. Low to moderate levels of diffuse **$^3$H-flunitrazepam** binding were observed over all laminar regions of the DCN, except for the most caudal sections where the deep region was unlabeled. The granule cell layer was moderately labeled, with the remainder of the PVCN being covered by a diffuse pattern of low to moderate grain density. The most intense **$^3$H-cyclohexyladenosine** labeling was seen over the molecular layer, possibly extending into the pyramidal layer, of the DCN. The granule cell layer of the PVCN was also densely labeled. All other areas were of low grain density.

306.10 POSTNATAL CHANGES IN SYNAPTIC CIRCUITRY AND ELECTRICAL PROPERTIES OF CELLS IN THE VENTRAL COCHLEAR NUCLEUS OF MICE. S.H. Wu* and D. Oertel. Dept. of Neurophysiology, Univ. of Wis., Madison, WI 53706.

In mice the external and middle ear cavities are closed for the first 8 days after birth. They are fully open only after about 12 postnatal days. When mice begin to hear, they respond only to low-frequency sounds (<10 kHz). At 16 to 18 days they show mature audiograms with threshold minima at about 20 kHz (review: Shnerson and Pujol, in The Auditory Psychobiology of the Mouse, ed. by J.F. Willott, Thomas, Springfield, pp. 395-425).

We have traced some of the electrophysiological changes associated with maturation by recording from brain slice preparations of the ventral cochlear nucleus (VCN) of mice of various ages. Cells in the VCN responded with excitatory postsynaptic potentials (EPSPs) to electrical stimulation of the auditory nerve in the youngest animals from which recordings were made, 4 days old. EPSPs from such young animals fatigued with repetitive stimulation at rates higher than 1/sec. Synaptic delays were long and variable (0.7 to 3 msec). In animals 6 to 9 days old, EPSPs could sustain rates of 10/sec. Their latencies were shorter (0.9 to 1.4 msec) and less variable. In addition, inhibitory postsynaptic potentials (IPSPs) often followed the EPSPs. Physiologically, therefore, excitatory synaptic connections are evident before the inhibitory synaptic connections. In animals 10 to 13 days old, synaptic responses to stimulation of the auditory nerve could support repetition rates of 200/sec. In adults, synaptic responses can follow at rates up to 630/sec.

The intrinsic electrophysiological properties of cells in the VCN also change as the animals mature. In adult animals, bushy and stellate cells can be distinguished on the basis of their intrinsic electrical properties (Wu and Oertel, J. Neuroscience 4:1577, 1984). The two cell types can be distinguished as early as 7days after birth. In cells that fire repetitively, the stellate cells, the first action potential of a train reaches a higher peak and it is narrower than later action potentials. If an inward calcium current contributes to the rising phase of action potentials, it is too weak to be detected even in the presence of 1 μM tetrodotoxin and 25 mM tetraethylammonium chloride. After 13 postnatal days the properties of cells are like those of the adult.

306.11 EFFECTS OF STIMULUS REPETITION RATE ON ABR THRESHOLD AND AMPLITUDE IN YOUNG AND ADULT MONGOLIAN GERBILS. G.S. McCoy* and E.W Rubel. Dept. Otolaryngology, Univ. VA Med Ctr., Charlottesville, VA 22908

Increased stimulus repetition rate is associated with increased latency and decreased amplitude in the adult auditory brainstem response (ABR). While the effects of repetition rate on ABR latency have been studied during ontogeny, the effects of rate on ABR threshold and amplitude as a function of age have received little attention. In the present study, the effects of stimulus rate on the threshold and amplitude of ABR waveforms in young and adult animals were evaluated.

The ABR waveforms of 16 day old and adult Mongolian gerbils were evoked by click stimuli presented at rates ranging from 1 to 80/sec. Wave I and wave IV thresholds were determined at each of five rates. Amplitudes of waves I and IV were obtained at each of seven rates and three suprathreshold intensity levels (15, 40 and 65dB SL).

At low repetition rates, thresholds for 16 day old animals were 10-15dB higher than those for adults. In adult animals, repetition rate had no significant effect on thresholds of waves I and IV. In 16 day old animals, wave I threshold was not significantly affected by stimulus rate, whereas wave IV threshold increased significantly with increasing repetition rate. In adult animals, wave I amplitude did not vary with stimulus rate at 15 and 40 dB SL, but at 65dB SL amplitude decreased at rates above 20/sec. In 16 day old animals, wave I amplitude decreased with increasing repetition rate at all intensity levels. This finding suggests that low threshold auditory fibers are capable of following high repetition rates in adults but not in young animals. Slopes of wave IV rate-amplitude functions in adults were similar across intensity levels; however, the slope of such functions in 16 day old animals varied with intensity. Increased rate effects at high intensities in young animals may reflect the relatively greater fatigability of synaptic connections in young animals.

306.12 SYNAPTIC POTENTIALS OF NEURONS RECORDED FROM THE CHINCHILLA LATERAL SUPERIOR OLIVARY NUCLEUS. D.M. Caspary, C.L. Faingold and K.P. Berry*. Dept. of Pharmacology, Southern Illinois University School of Medicine, Springfield, IL 62708.

Neurons located in lateral superior olivary (LSO) nucleus receive inputs from both ears and are thought to code for the localization of sound in space. These neurons receive ipsilateral input from the homolateral ventral cochlear nucleus (VCN), while their predominant contralateral input is from the opposite VCN via a secure synapse in the ipsilateral medial nucleus of the trapezoid body (MNTB) (Glendenning et al., J. Comp. Neurol., 232:261-285, 1985). LSO neurons typically are excited (E) by ipsilateral stimulation and this response is strongly suppressed during binaural stimulation. Contralateral stimulation alone does not evoke an excitatory response but is the presumed source of the observed binaural inhibition (I). Results from recent studies suggest that neurons in the MNTB may be the source of a glycinergic input to neurons in the LSO and may be responsible for the observed binaural inhibition (Moore and Caspary, J. Neurosci., 3:237-242, 1983). In the present study intracellular recordings were used to identify and characterize the synaptic potentials mediating the IE response. Intracellular recordings were obtained from 11 IE neurons in the ketamine-barbiturate anesthetized chinchilla. Only neurons displaying ipsilateral excitation and profound binaural inhibition were examined. Contralateral 3.2 msec tone-burst stimulation 30-50 dB above characteristic frequency (CF) threshold evoked large (5-12 mV) IPSPs with durations up to 7 msec. Suprathreshold ipsilateral stimulation at CF elicited sustained EPSPs with 1-3 action potentials arising from the plateau. Stimuli of equal intensity delivered at 0 msec interaural time delay (simultaneous binaural stimulation), rarely evoked action potentials while truncated IPSPs remained visible. In addition, reversal potentials and current-voltage relationships were obtained for some neurons. Preliminary data suggest linear current-voltage relationships with subthreshold current injection.

These findings provide the first evidence that the binaural inhibition observed for principal LSO neurons is mediated by an IPSP and that these are similar in character to IPSPs recorded from spinal cord neurons known to receive an inhibitory amino acid input. It is of interest that although observed IPSPs and EPSPs were of approximately equal amplitude and similar duration, simultaneous binaural stimulation resulted in a total inhibition of the excitatory response.

306.13 THE QUANTITATIVE DISTRIBUTION OF $^3$H-STRYCHNINE BINDING IN THE LATERAL SUPERIOR OLIVARY NUCLEUS OF THE GERBIL. D.H. Sanes*, W.A. Geary II, and G.F. Wooten. Depts. Neurol. and Otolaryngol., Univ. VA Med Ctr., Charlottesville, VA 22908.

The lateral superior olivary nucleus (LSO) integrates excitatory inputs driven by one ear with inhibitory inputs driven by the other ear. Iontophoretic studies indicated that glycine mediates this inhibition (Moore and Caspary, 1983). We have examined the concentration and distribution of $^3$H-Strychnine ($^3$H-SN) binding sites in the LSO of adult gerbils to better understand the organization of the inhibitory projection.

The kinetic characteristics were determined by varying $^3$H-SN concentration, incubation time, and wash time. The kinetic constants, $K_d$=6.4 nM, $B_{max}$=15.8 fm/section, k+1=3.74 x $10^5$/M-s, and k-1=1.82 x $10^{-3}$/s, are comparable to those previously reported (Young and Snyder, 1973). Sections were preincubated in phosphate buffer, incubated in 10 nM $^3$H-SN or 10 nM $^3$H-SN plus $10^{-2}$ M for 20 mins, and washed for 10 secs. Sections were apposed to LKB film or emulsion coated coverslips and the autoradiographic images analyzed on a densitometer. Grain density was converted to ligand concentration using calibrated tritium standards (Geary and Wooten, 1983). Autoabsorption was corrected for by injecting animals with $^3$H-2-Deoxyglucose, extracting alternate sections in chloroform, and comparing the autoradiographic images (Geary and Wooten, in press).

The LSO has an S shape in the coronal plane, with the top of the S lying dorsomedial to the bottom. We have taken densitometric measurements in 3 regions of the nucleus for sections containing both total and non-specifically bound ligand (3 animals; 5 nuclei; 220 measurements). Autoabsorption in dorsomedial and ventral LSO (2 animals; 4 nuclei; 40 measurements) is 27% and 28%, respectively. Specifically bound $^3$H-SN concentrations are corrected for by these amounts.

The dorsomedial, central, and ventral regions have bound ligand concentrations of 215 ± 65 fmoles/mg tissue wet weight ($\bar{X}$±SD), 125 ± 37 fmoles/mg, and 71 ± 25 fmoles/mg, respectively. These measurements are consistent both with preliminary cell density measurements in gerbil showing an approximate twofold difference between the dorsomedial and ventral regions of LSO, and the density of terminals from the medial nucleus of the trapezoid body in the cat (Glendenning et al., 1985).

306.14 RETROGRADE TRANSPORT OF $^3$H-GABA FROM THE COCHLEAR NUCLEUS TO THE SUPERIOR OLIVE IN GUINEA PIG. E.-M. OSTAPOFF, D.K. MOREST AND S.J. POTASHNER. U. CONN. HEALTH CENTER, FARMINGTON CT 06032

Biochemical evidence suggests that some of the descending inputs to the cochlear nucleus use GABA as a neurotransmitter (Potashner et al., 1985). To test this hypothesis, 0.3-1.0 ul of $^3$H-GABA (80 uM SA. 80 Ci/mmol) was injected into the cochlear nucleus. After survival times of 15 min, 5, 10 and 16 hr, the brain stem was prepared for light microscopic autoradiography. After a 15 min survival, only glial cells in the cochlear nucleus and a few trapezoid fibers were labeled. After 5 hr survival, retrogradely labeled neuronal cell bodies and fibers appeared in the superior olivary complex. In the trapezoid body clusters of labeled cells were seen in the lateral nucleus, ipsilaterally, and in the ventral nucleus, bilaterally. Also there were labeled cells in the dorsal periolivary nucleus, ipsilaterally, and in the anterolateral periolivary nucleus and ventral nucleus of the lateral lemniscus, bilaterally. Large and small cells of several types were labeled. In the cochlear nucleus, round or elongated small neurons were labeled in all layers of the dorsal nucleus; no labeled cell bodies were observed in the ventral nucleus, but heavy glial and endothelial labeling made observations here difficult. Survival times of more than 5 hr resulted in non-specific labeling.

When gabaculine, a suicide substrate of GABA-T, was injected 1 hr before $^3$H-GABA, a similar, but more intense pattern of retrograde labeling occurred in the superior olive after 2 and 5 hr survivals.

The following evidence suggests that the cell labeling in the superior olive is due to the high affinity uptake of $^3$H-GABA by synaptic endings in the cochlear nucleus and the retrograde transport of label by GABA-ergic neurons. 1) Since the concentration of $^3$H-GABA used is near the Km for its high-affinity uptake in vitro, contributions from low-affinity uptake should be small. 2) The labeling in the cochlear nucleus and superior olive is selective for certain cells. 3) There was no sign of uptake and retrograde transport by fibers in the restiform body or cochlear nerve, even when the injection site encroached on these structures.

Experiments are in progress with lower concentrations of $^3$H-GABA and different survival times to define the cell types in the cochlear nucleus which may be GABA-ergic. Other experiments are aimed at elucidating the distribution of the extrinsic and intrinsic GABA-ergic projections to the cell surface of specific cell types in the cochlear nucleus.

This study provides evidence for a descending projection system for inhibitory feedback from the superior olive to the cochlear nucleus. (Supported by NIH grants NS14347 and NS19036.

306.15 CALCITONIN GENE-RELATED PEPTIDE IMMUNOREACTIVITY IN THE SUPERIOR OLIVARY COMPLEX OF CAT AND RAT: A SPECIFIC LABEL FOR THE LATERAL OLIVOCOCHLEAR SYSTEM. L. F. Schweitzer,* S. M. Lu,* D. Dawbarn,* and N. B. Cant. Department of Anatomy, Duke University Medical Center, Durham, NC 27710 and MRC Neurochemical Pharmacology Unit, Cambridge, England, CB2 2QH.

Two systems of axons project from the superior olivary complex (SOC) of the brain stem to the cochlea (Guinan, Warr, and Norris, JCN, '83). The lateral olivocochlear system comprises small axons that project mainly to the ipsilateral inner hair cell region. The medial system comprises larger axons that project mainly to the contralateral outer hair cell region. The two systems appear to arise from neurons lying in separate locations in the SOC. Further support for a distinction between the lateral and medial olivocochlear neurons in the SOC is provided by our finding that the lateral olivocochlear neurons are immunoreactive for calcitonin gene-related peptide (CGRP), a recently characterized peptide found in the CNS, whereas the medial neurons are not.

Cats and rats were anesthetized with pentobarbital and perfused through the heart with a PLP fixative (McLane and Nakane, J. Histochem. Cytochem., '74). Sections 50 µm thick were cut on a Vibratome. The sections were incubated in an antibody to CGRP (rabbit, Amersham) diluted 1:1000 or 1:2000. Immunocytochemistry was done with the ABC method (Hsu et al., J. Histochem. Cytochem., '81), and immunoreactive structures were labelled with diaminobenzidine.

In the SOC of the cat, immunoreactivity for CGRP is confined to cells in the dorsal hilus of the lateral superior olivary nucleus (LSO), to cells dorsal to the LSO, and to a few cells located along the margins of the nucleus. The cells are densely labelled as are their dendrites, which penetrate the substance of the LSO, particularly its lateral limb. No immunoreactive neurons are present in any other part of the SOC, but labelled axons and terminals can be traced into the lateral parts of the ventral cochlear nucleus. In the SOC of the rat, cells immunoreactive for CGRP are found within the LSO rather than around its margins, although not all LSO neurons are labelled. As in the cat no other cells in the SOC are labelled. The different distributions of label in the cat and rat parallel the differences between these species in the locations of lateral olivocochlear cells.

Although both lateral and medial olivocochlear neurons stain positively for acetylcholinesterase (Warr, JCN, '74), only the lateral neurons exhibit CGRP immunoreactivity. It may be possible to use the antibody to CGRP to distinguish between the terminals of the lateral and medial axons in the cochlea.

Supported by NIH.

306.16 MORPHOLOGICAL FEATURES OF FIVE NEURONAL TYPES IN THE GERBIL LATERAL SUPERIOR OLIVE. R.H. Helfert and I.R. Schwartz. Departments of Anatomy and Head & Neck Surgery, UCLA School of Medicine, Los Angeles, CA, 90024.

At least five morphologically distinct neuronal types exist within the neuropil of the gerbil lateral superior olive (LSO), excluding the hili. The features of four of these classes are nearly identical in morphology, orientation, and proportions to those found in the cat LSO, and can be classified using the feline terminology of principal (PR), multiplanar (MU), marginal (MA), and small (SM) neurons (Helfert and Schwartz, Neurosci. Absts. 10:844, 1984). The fifth cell type found in the gerbil is similar to the PR neuron, but receives significantly fewer axosomatic synapses. The distribution of this type is similar to that we observed for the gerbil acetylcholinesterase-positive (AChE) neurons.

The gerbil PR neuron is uniplanar and multipolar, oriented rostrocaudally in planes roughly perpendicular to the curvatures of the LSO. In transverse sections the perikarya of the PR cells appear fusiform and bipolar (mean dimensions: 22x10µm). More than 65% of the somata of PR neurons is apposed to synaptic terminals. PR neurons constitute about 70% of gerbil LSO neurons.

Approximately 10% of LSO neurons are MU neurons. They appear round or polygonal in transverse Nissl sections; appear multipolar in transverse Golgi sections; and show a pattern of synaptic input similar to that in PR neurons.

Approximately 5% of LSO neurons are of the MA type. MA neurons are fusiform and bipolar in transverse sections, and are oriented along the contours of the LSO perpendicular to PR neurons.

Another 10% of gerbil LSO neurons are SM cells. They are: either spherical or oval when seen in transverse sections; found throughout the LSO matrix; have a major axis rarely exceeding 10µm; and have less than 10% of their somatic surface in contact with synaptic terminals.

Several neurons with less than 50% of their somatic surfaces apposed to synaptic terminals have been identified in the medial and middle limbs. At the light microscopic level, this fifth neural type is similar to PR cells in both morphology and orientation. They are typically smaller than PR neurons, with average transverse dimensions of 17x7µm. About 5% of LSO neurons are of this type. AChE neurons are located throughout the rostrocaudal extent of the gerbil LSO. They are found in the dorsal hilus and, in contrast to the cat, within the medial and middle limbs and, to a much lesser extent, within the lateral limb. The similarity in size and distribution between the AChE neurons and the PR-like neurons with reduced axosomatic contacts suggest that they may be the same cells. EM studies required to prove this correspondence are in progress.

306.17 CONVERGENCE OF BINAURAL PATHWAYS INVOLVING THE SUPERIOR OLIVARY COMPLEX AND THE DORSAL NUCLEUS OF THE LATERAL LEMNISCUS. Shneiderman, A. and C. K. Henkel. Department of Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

Convergence of binaural pathways to the inferior colliculus is important in neural mechanisms involved in sound localization. In this study we examined an indirect binaural pathway from the lateral (LSO) and medial (MSO) superior olivary nuclei to the inferior colliculus involving the dorsal nucleus of the lateral lemniscus (DNLL). Injections of tritiated leucine or WGA-HRP were placed in LSO, MSO or DNLL in cats and axonal projections were evaluated with light microscopy using autoradiographic and histochemical methods. Both olivary nuclei gave rise to projections to DNLL that were topographically ordered along the known frequency representation in the respective nuclei. In DNLL projections from MSO were ipsilateral and overlapped the regions of the bilateral projections from LSO. These projections appeared to arise as right angle collaterals of axons projecting to the inferior colliculus. Results of injections in DNLL showed that projections from DNLL to the inferior colliculus formed a banded pattern that was more distinct in the contralateral central nucleus than in the ipsilateral central nucleus. DNLL projections extended throughout the pars medialis, pars centralis and pars lateralis of the central nucleus and axons continued in the orientation of the bands into layers III and IV of the dorsal cortex of the inferior colliculus. DNLL also projected to the rostral pole nucleus of the inferior colliculus. Thus, DNLL projections share several similarities to binaural projections directly to inferior colliculus from LSO and MSO. DNLL projections are organized in bands with distinct interband spaces where there is less intense label as do LSO projections. DNLL projections also distribute to all subdivisions of the central nucleus where they may converge on cells with projections from the olivary nuclei and they also overlap olivary projections in the rostral pole nucleus of the inferior colliculus. In contrast to olivary pathways to the inferior colliculus, DNLL projections extend to the caudal third of the central nucleus and to the dorsal cortex where they do not converge with the projections of MSO or LSO. Further studies to define the structure of afferent bands in the inferior colliculus, the interrelationship of bands from specific binaural pathways, and the synaptic relationships of afferents to cells within the central nucleus should provide valuable information about the integration of binaural information in the inferior colliculus.

Supported in part by NIH Grant NS 18627.

306.18 LOW FREQUENCY RESPONSE PROPERTIES OF TRAPEZOID BODY FIBERS. G.A. Spirou*, W.E. Brownell, M. Zidanic* and P. Dulguerov* (SPON: W.A. Friedman). Depts. of Neuroscience and Otolaryngology, Univ. of Florida, Gainesville, FL, 32610.

Single axon recordings were made from the midline trapezoid body of adult cats under barbiturate anesthesia. Seventeen units of low CF were investigated for their rate-level and phase-level responses at high intensity. CF's of the units ranged from .48 to 4.38 kHz. Fourteen of 17 units exhibited phase shifts at high intensity between 90 and 230°. In most units (13 of 14) this was accompanied by a dip in the rate-level function between 25-90%. In two units in which tuning curves for the phase-rate shifts were obtained, minimum threshold occurred below CF. Generally, units were investigated at CF and 1 kHz. Only one unit, CF = .94 kHz, showed a phase-rate shift at CF but not at 1 kHz. Maximum driven rates at 1 kHz were often greater than those at CF, and ranged between 200 and 500 sp/sec. The 3 units not showing phase-rate changes may have had thresholds above the maximum SPL deliverable by our acoustic system, about 105 dBSPL. One large diameter fiber was labeled with HRP over a limited extent and showed the typical branching pattern of these units: the parent fiber continued rostral into the VNLL while the primary branch traveled in the direction of the MNTB. More completely filled axons of the same diameter and branching pattern deliver a calyx of Held into the MNTB.

Receptive fields of high frequency units (>10 kHz) were mapped. These units had low frequency tails which extended through the 1 kHz range. Frequently on/off PST's were found in the low frequency portion of the receptive field. An inhibitory surround 10-20 dB in extent was located under the excitatory tail. Slopes of rate-level functions at low frequency were enhanced at excitatory threshold as the units emerged from their inhibitory trough, and were greater than slopes of the rate-level functions at CF threshold. Changes in rate and temporal pattern of fiber discharge are two possible coding mechanisms for extending the dynamic range of the auditory system into the high intensity range at low frequencies. The presence of rate and phase-level shifts in these 2nd order fibers follows their description in the VIIIth nerve (Kiang et al. JASA 46:106 1969; Liberman and Kiang Hear. Res. 16:75-90 1984), and is further evidence for the security of the primary afferent to bushy cell synapse.

Supported by Grant NS 12209 from NINCDS.

306.19 ANATOMY AND PHYSIOLOGY OF OLIVOCOCHLEAR EFFERENT NEURONS IN THE GUINEA PIG COCHLEA. M. C. Brown. Research Laboratory of Electronics, M. I. T., and Eaton-Peabody Laboratory, Massachusetts Eye & Ear Infirmary, 243 Charles St., Boston, Ma. 02114.

Olivocochlear neurons in the superior olivary complex of the brainstem send axons to the cochlea to terminate in the organ of Corti, forming an olivocochlear efferent system. This report details the physiology and anatomy of olivocochlear neurons in the guinea pig cochlea at the single cell level.

Access to the spiral ganglion of the lower basal turn was created surgically in guinea pigs anesthetized with Nembutal and Innovar-Vet. Here, efferent fibers run in intraganglionic spiral bundles and were labeled with gross injections of horseradish peroxidase (HRP). Two fiber groups assumed to be olivocochlear efferents were distinguished based on their terminations in either inner or outer hair cell regions. Fibers terminating near inner hair cells were thin (< 0.7 um) and unmyelinated. Labeled efferents terminating on outer hair cells included thick myelinated and thin unmyelinated axons and terminated predominantly apical to the injection site.

Recordings of single units yielded presumed afferents with short latency responses (< 2.5 ms) to tone bursts at characteristic frequency (12 to 20 kHz) and irregular spike patterns. Presumed efferents responded with longer latencies (> 5 ms) to tone bursts and demonstrated regular spike patterns as has been reported previously (Fex, J., Acta Physiol. Scand., 55:S189, 1962; Robertson, D., Hear. Res., 15:113, 1984). Out of 51 "efferent" units, 65% were more sensitive to ipsilateral sound and 35% were more sensitive to contralateral sound. 83% gave excitatory responses to sound in one ear only with the remainder showing varying degress of sensitivity to sound presented in either ear. Most efferents were sharply tuned (characteristic frequencies 0.3 to 14 kHz), with tip sensitivities of 10 to 70 dB SPL. Two ipsilaterally excited efferents were intracellularly injected with HRP and yielded large, myelinated axons which branched to innervate 27 and 49 outer hair cells, respectively, over longitudinal extents of 0.5 and 0.66 mm. of the total cochlear length of 18 mm.

Thus the outer hair cell efferent fibers in the anesthetized guinea pig have frequency selective responses and at least in some cases, innervate relatively restricted regions of the receptor epithelium (equivalent to a quarter octave frequency span for afferents). The micropipettes used here are probably biased against the small axons of efferents associated with the inner hair cells, thus physiological data from this class of neurons is lacking. The functional properties of the outer hair cell efferents are consistent with a feedback system that is sharply tuned and which is in operation even in anesthetized animals.

(Supported by NIH grants T32 NS-07047 and PO1 NS-13126.)

306.20 CENTRIFUGAL CHOLINERGIC PROJECTIONS TO SUBREGIONS OF CAT COCHLEAR NUCLEUS. D.A. Godfrey, K.L. Beranek*, L. Carlson*, J.D. Dunn and C.D. Ross, Depts. Physiol. and Anat., Oral Roberts Univ., Tulsa, OK 74171

To estimate what proportion of cholinergic elements in subregions of the cat cochlear nucleus derive from centrifugal pathways, choline acetyltransferase (ChAT) activities were mapped in both cochlear nuclei after placement of surgical cuts. Knife cuts were placed medial to the left cochlear nucleus by direct observation after exposure using a posterior fossa approach and aspiration of part of the cerebellar hemisphere. Seven to ten days later, cats were decapitated, brain pieces removed and rapidly frozen, 20 µm-thick sections cut at -20 ° C and freeze-dried. Sections of cochlear nucleus were microdissected into contiguous pieces which were weighed (about 1 µg) and placed into tubes for assay by a radiometric procedure. Data for 3 cats are shown below: one (Sham) in which the cochlear nucleus was exposed, but no cut placed, one (OCB cut) in which the cut penetrated the brain stem only slightly beyond the level of the olivocochlear bundle, and one (Complete cut) in which the cut penetrated to the ventral surface of the brain stem. Data for subregions are presented as lesion-side mean/control-side mean (%). AVCN, DCN, PVCN: anteroventral, dorsal, posteroventral cochlear nucleus. Differences statistically significant (t-test): x at p<0.05, + at p<0.01, * at p<0.001; ° no. samples insufficient for statistics.

| Region | Sham | OCB cut | | Complete cut | |
|---|---|---|---|---|---|
| AVCN rostral granular | 192/127(151) | 21/127 | (17)* | 23/254 | (9) ° |
| AVCN rostral | 44/49 (90) | 13/29 | (45)* | 9/44 | (21)* |
| AVCN caudal granular | | 54/97 | (56)x | 20/73 | (28)+ |
| AVCN caudal dorsal | | 22/28 | (79) | 6/21 | (30)* |
| AVCN caudal ventral | | 16/21 | (76) | 6/16 | (37)x |
| DCN molec. layer | 30/28 (109) | 28/36 | (77) | 16/31 | (51)* |
| DCN fus. soma layer | 46/44 (106) | 32/60 | (53)+ | 11/49 | (24)* |
| DCN deep layer | 20/17 (117) | 18/24 | (75) | 8/25 | (33)* |
| PVCN caudal | 8/6 (144) | 12/13 | (97) | 3/6 | (60)x |
| PVCN caudal granular | 41/36 (114) | 30/51 | (59) | 14/20 | (71) |

ChAT activities in almost all subregions of the cochlear nucleus were drastically reduced after virtually all its centrifugal innervation was cut. (Data from two other cats were in agreement with this result.) After OCB transection, significant reductions were found in rostral AVCN (in a second cat, the lesion/control % was 23) and its overlying granular region, and in the fusiform soma layer of the DCN. These results suggest that most cholinergic elements in the cat cochlear nucleus derive from its centrifugal innervation, and that branches from the olivocochlear system account for most of these elements in the rostralmost part of the nucleus. The molecular layer of the DCN apparently contains relatively more intrinsic cholinergic elements than most other subregions. (Supported by NIH Grant NS17176.)

306.21 LOCALIZATION AND LIGHT MICROSCOPIC CHARACTERIZATION OF NEURONS IN A REGION OF THE INFERIOR MEDULLARY VELUM ADJACENT TO THE COCHLEAR NUCLEI OF MAN. L. Terr. House Ear Institute, Los Angeles, CA 90057

The tenia of the inferior medullary velum is partly attached to the brain stem surface, including its area occupied by the cochlear nuclear complex. Since neurons of the complex -- particularly those in the dorsal cochlear nucleus (DCN) and caudal part of the ventral cochlear nucleus (VCN) -- may populate the most superficial layer of the brain stem, I examined the possibility of their penetration into the velum. Light microscopic examination of frontal and horizontal sections from postmortem human brains fixed in 4% formalin revealed a few neurons in the region of the tenia adjacent to the DCN surface. These neurons appeared in up to three groups rather than being scattered through the whole strip of the tenia adjacent to the DCN and VCN. The groups are located in the vicinity of the caudorosacral part of the DCN and the anterior boundary of the pontobulbar nucleus. The neurons within the tenia are located immediately under the extraventricular surface of the velum. They form round or oval-shaped regions, as in the organization of typical brain nuclei. The length of the short and long axes is 0.3 mm to 1.5 mm from it. The neurons most remote from the DCN surface in horizontal sections are approximately 1.5 mm. These neuronal groups are about 0.4 mm from the intraventricular surface of the tenia (ependyma). The thickness of the tenia in this region is about 0.7 mm. There are about 40 neurons in the largest area of the neurons accumulation in horizontal sections. The neurons are fusiform, pyramidal, multipolar, and round. There are no specific topographical distribution of these types of neurons in the tenia.

## REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS III

307.1 AUTORADIOGRAPHIC LOCALIZATION OF INSULIN RECEPTORS IN RAT BRAIN: PROMINENCE IN OLFACTORY AND LIMBIC AREAS. J.M. Hill, M.A. Lesniak, J. Roth and C.B.Pert* (SPON: T. Insel). Section on Brain Biochemistry, Clinical Neuroscience Branch, National Institute of Mental Health, and Diabetes Branch, National Institute of Arthritis, Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, Maryland 20205.

Both insulin and insulin receptors are widely but unevenly distributed throughout the central nervous system. While the role of insulin in the brain remains uncertain, insulin has been shown to modulate neuronal firing, stimulate the release of neurotransmitters, and influence food intake in several experimental systems.

In previous studies of insulin receptors in brain, membrane preparations from anatomically discrete regions have been used for localization. In the present study using $^{125}$I-insulin and frozen rat brain tissue under binding conditions optimized for ligand selectivity pattern and high signal to noise ratio (up to 95%) we have visualized the insulin receptor distribution pattern in rat brain with autoradiographic techniques.

By several criteria including specificity (for insulin-related ligands), the brain insulin receptors were qualitatively indistinguishable from insulin receptors previously characterized on brain and other more typical target tissues and distinct from receptors for the insulin-like growth factors. The $^{125}$I-insulin binding sites in brain formed a distinct pattern with high levels of binding in all olfactory areas and in closely related limbic regions. Binding was also prominent in the neocortex and the accessory motor areas of the basal ganglia and the cerebellum. Among ancillary brain structures only the choroid plexus demonstrated a high density of insulin receptors.

When insulin receptors were located on cortical or laminated structures the highest binding occurred in the superficial ("molecular" or "plexiform") layer, i.e. the layer which receives afferent input and/or is rich in the dentritic branches of principle neurons (e.g., external plexiform layer of the olfactory bulb and the molecular layer of the dentate gyrus).

The enrichment of insulin receptors in the olfactory and limbic systems, (a characteristic feature of other known neuropeptides), in addition to their prevalence dendritic fields suggests a neuromodulatory function for insulin in the brain.

307.2 DISTRIBUTIONS OF NICOTINIC AND MUSCARINIC CHOLINERGIC RECEPTORS IN MONKEY CEREBRAL CORTEX. J.B. O'Neill*[1], P.B.S. Clarke*[2], D.P. Friedman[1,3], and A. Pert[2], (SPON: R.M. Brown[3]). Laboratory of Neuropsychology[1] and Biological Psychiatry Branch[2], NIMH, Bethesda, MD 20205 and Neurosciences Research Branch[3], NIDA, Rockville, MD 20857.

The distributions of nicotinic (N) and muscarinic (M) cholinergic binding sites were compared in monkey cerebral cortex. 25 um thick, slide mounted, unfixed brain sections from two female rhesus monkeys were incubated to reveal either N or M binding sites as follows. For N sites, sections were incubated at room temperature for 20 min in pH 7.4, 50mM Tris-HCl, 8mM $CaCl_2$, and 1.7nM [$^3$H]L-nicotine. Slides were rinsed four times for 30 sec in the same buffer at 4°C and then quickly dried under a stream of cool air. Nonspecific binding was determined in the presence of 10uM L-nicotine bitartrate. For M sites, sections were incubated for two hrs at room temperature in pH 7.4, 0.01M PBS, with 0.6nM [$^3$H]Quinuclidinyl benzilate (QNB). They were then washed three times for five min in the same PBS buffer and dried as above. Nonspecific binding was determined in the presence of 1uM atropine sulfate. The sections incubated in [$^3$H]nicotine were apposed to tritium sensitive LKB film for either five or seven months. The sections incubated in [$^3$H]QNB were apposed to the LKB film for five weeks.

Both N and M receptors were found in all cortical regions, but M receptors were more widely distributed across the layers of a given field and had a wider variety of laminar labeling patterns across different fields than N receptors. N receptors were restricted to a band in layer III. This band was densest and widest in the primary sensory areas (A1, S1, and V1), but no other variations in pattern were apparent. The most common pattern for M receptors consisted of a dense band of label extending from layer I through upper layer III, a receptor poor band in lower layer III, and another band of receptors, less dense than the supragranular band, in the lower layers. Other laminar patterns of M receptors ranged from an apparently homogenous distribution across all the cortical layers in orbital frontal cortex, to variations of the bilaminar pattern described above in S1 and V1, to a single dense band in layer III of A1. Only in A1 did the N and M patterns appear similar.

The laminar patterns of distribution of both N and M receptors described here for the monkey differ from those desribed previously in the rat. Nonetheless, in both species, N receptors are located in either layers III or IV, the targets for incoming afferent fibers, suggesting a role for nicotinic regulation of this input. M receptors, by contrast, are densest in the upper and lower cortical layers, a distribution consistent with a role for muscarinic modulation of intracortical processing.

307.3 DISTRIBUTIONS OF NICOTINIC AND MUSCARINIC CHOLINERGIC RECEPTORS IN MONKEY THALAMUS. D.P. Friedman[1,3], P.B.S. Clarke*[2], J.B. O'Neill*[1], and A. Pert[2]. Laboratory of Neuropsychology[1] and Biological Psychiatry Branch[2], NIMH, Bethesda, MD 20205 and Neurosciences Research Branch[3], NIDA, Rockville, MD 20857.

The distributions of nicotinic and muscarinic binding sites were compared in the thalamus of the monkey. 25um thick, slide mounted, unfixed sections from two female rhesus monkey brains were incubated to reveal either nicotinic or muscarinic binding sites as follows. For nicotinic sites, sections were incubated at room temperature for 20 min in pH 7.4, 50mM Tris HCl, 8mM $CaCl_2$, and 1.7nM [$^3$H]L-nicotine. Slides were rinsed four times for 30 sec in the same buffer at 4°C and then dried quickly under a stream of cool air. Nonspecific binding was determined in the presence of 10uM L-nicotine bitartrate. For muscarinic sites, sections were incubated for two hrs at room temperature in pH 7.4, 0.01M PBS, with 0.6nM [$^3$H]Quinuclidinyl benzilate (QNB). They were then washed three times for five min in the same PBS buffer and dried as above. Nonspecific binding was determined in the presence of luM atropine sulfate. The sections incubated in [$^3$H]nicotine were apposed to tritium sensitive LKB film for either five or seven months. The sections incubated in [$^3$H]QNB were apposed to the LKB film for five weeks.

Nicotinic receptors were densest in all three anterior thalamic nuclei (AM, AV, and AD). In addition, both subdivisions of the medial dorsal n. (MDmc and MDpc), the lateral dorsal n. (LD), the lateral posterior n. (LP), and pulvinar complex contained moderately dense labeling. The lateral (LG) and medial (MG) geniculate nuclei and the enitre ventral group contained somewhat less label, and within this group the least heavily labeled nuclei were those of the ventrobasal complex (VPL and VPM). By contrast, the habenular nuclei, the intralaminar nuclei, and the midline nuclei were conspicous by their lack of label. The thalamic reticular n. contained moderately dense label.

Muscarinic receptors, like nicotinic receptors, were dense in the anterior nuclei, but in MD, the parvocellular division was more densely labeled than the magnocellular division, which contained little label. The pulvinar and LD also contained moderately dense labeling, but LP, like the entire ventral group, was less densely labeled. LG and MG again contained moderate amounts of label and the intralaminar nuclei again had little, if any, label. The nuclei of the midline, on the other hand, had a moderate amount of label, as did the lateral habenula, which was not labeled by [$^3$H]nicotine. The thalamic reticular n. contained muscarinic as well as nicotinic receptors.

307.4 DIRECT AUTORADIOGRAPHIC DETERMINATION OF MUSCARINIC M1 AND M2 RECEPTOR SUB-TYPE DISTRIBUTION IN THE RAT BRAIN: RELATIVE BINDING PATTERNS IN CHOLINERGIC NUCLEI AND PROJECTION AREAS. D.G. Spencer, Jr., E. Horvath* and J. Traber*, Neurobiology Dept., Troponwerke, Neurather Ring 1, 5000 Cologne 80, FRG.

The autoradiographic distribution of (3H)-oxotremorine-M and (3H)-pirenzepine binding to rat brain M1 and M2 receptors, respectively, was studied in order to evaluate the hypothesis that M2 receptors are good markers for cholinergic cell bodies and tracts, as opposed to M1 receptors which appear to label post-synaptic fields (Potter et al., TIPS suppl., 22-31, 1983). The binding of 1 nM (3H)-oxotremorine-M to brain slices was highly specific and saturable. Structurally unrelated muscarinic receptor ligands such as scopolamine, carbachol, and arecoline produced complete competition at 1, 10, and 100 uM, respectively. Regional distribution of M2 binding was quite different from that of M1 binding (labelled by 1 nM (3H)-pirenzepine): M2 receptors were found in brain-stem cholinergic nuclei (e.g., cranial nerve nu., parabrachial nu., dorsal and laterodorsal tegmental nu., trapezoid body nu., raphe nu., central gray, interpeduncular nu., and pontine nu.), inferior and superior colliculus, several thalamic areas (e.g., ant. pretectal area and anterodorsal, anteromedial, anteroventral, lateral posterior, posterior paraventricular, reticular, reuniens, and rhomboid nu.), hypothalamic regions, forebrain cholinergic nuclei (e.g., medial septum, diagonal band horiz. and vert. limb nu., nu. basalis, substantia innomenata), caudate-putamen, CA2 and CA3 of hippocampus, amygdala (primarily the basolateral nu.), olfactory bulbs and tubercle, cingulate gyrus, perirhinal cortex, and layers III and V of cerebral cortex; M1 receptors were found only in telencephalic structures such as layers I and II of the cerebral cortex (frontal, parietal, and striate cortex), caudate-putamen, nu. accumbens, olfactory tubercle, CA1 and dentate gyrus of the hippocampal formation, and basolateral nu. of amygdala. This pattern of M1 and M2 binding supports the idea that M2 receptors are closely associated with cholinergic cell nuclei and projection areas. However, M1 receptors can only be detected in telencephalic cholinergic terminal regions; thalamic and collicular terminal zones contained solely M2 receptors. Scatchard analysis of (3H)-oxotremorine-M slice binding in the inferior colliculus revealed one high-affinity site (r = -0.95), with a Kd of 1.88 and a Bmax of 1.42 pmol/mg protein. M2 receptor densities (fM/mg protein) as measured by slice binding had the following rank orders: superior colliculus (243), caudate-putamen (225), medial septum and diagonal band nu. (164) = frontal cortex (163), hippocampus (121), and cerebellum (53). 1 mM N-ethylmaleimide uncouples receptors of many neurotransmitters, thus reducing their ligand affinity. In the present experiments, it reduced the affinity of M2 receptors for (3H)-oxotremorine-M without altering their regional distribution in brain; M1 receptor distribution and affinity for (3H)-pirenzepine were unaffected by this treatment (in agreement with the receptor binding experiments of Flynn & Potter, Proc. Natl. Acad. Sci. 82:580-583, 1985). Taken together, these data strongly support the hypothesis that M1 and M2 receptors are not simply intraconvertable states of a single receptor protein, but may be anatomically and functionally distinct muscarinic receptor sub-types.

307.5 IN VIVO QUANTITATION OF FREE MUSCARINIC RECEPTOR DENSITY: EFFECTS OF DFP AND OF ATROPINE. K. A. Frey, B. Ciliax, D. Wieland* and B. W. Agranoff. Department of Neurology, Division of Nuclear Medicine and Neuroscience Laboratories, The University of Michigan, Ann Arbor, MI 48109.

Previous work from our laboratory has validated the use of [$^3$H]scopolamine and tracer kinetic analysis of a compartmental ligand distribution model for the measurement of muscarinic receptor binding in vivo (Frey et al., Soc. Neurosci. Abstract, 1984). In the present work, a simplification of the previous algorithm is derived which permits direct calculation of regional free receptor density from tracer accumulation in tissue at a single time point following IV bolus injection. Application of this simplified expression further requires knowledge of the regional blood-brain barrier permeability-surface area product for the tracer, the local rate of cerebral blood flow, and the integrated arterial plasma tracer concentration over the experimental period. Male Sprague Dawley rats were injected intravenously with 100 µCi of [$^3$H]scopolamine (specific activity 80-90 Ci/mmol), a continuous withdrawal of arterial blood for 90 min was begun, and 25-50 µCi of [$^{123}$I]HIPDM (Kung et al., J. Nucl. Med. 29:66-72, 1983) were injected IV. Following an additional 45 sec distribution period, the animals were killed and brain regions were counted for [$^{123}$I], and following its decay, for [$^3$H]. Local rates of blood flow were calculated from the [$^{123}$I]-HIPDM uptake using the indicator fractionation method (Van Uitert and Levy, Stroke 9:67-72, 1978). Regional free receptor densities were determined from tissue and plasma [$^3$H]scopolamine levels, the calculated blood flow, and the known blood-brain barrier permeability coefficient (Frey et al., ibid, 1984). In control animals, the simplified method yielded free receptor densities which were in good agreement with our previous results: highest in neocortex, followed by striatum and hippocampus. The cerebellum had 5-fold fewer free receptors than neocortex. Pretreatment of rats with a saturating dose of atropine sulfate (50 mg/kg IV) reduced the free receptor density to 10% of control in all regions studied. Pretreatment with the cholinesterase inhibitor DFP (2 mg/kg IM) reduced the free receptor densities in neocortex and striatum, but did not effect cerebellar binding. These results are consistent with the hypothesis that the free receptor density measured by tracer kinetic in vivo binding techniques is determined by both the total regional receptor concentration and synaptic neurotransmitter levels. The in vivo receptor binding method may thus be useful in detection of alterations in presynaptic activity as well as in receptor numbers.

307.6 IN VIVO AND IN VITRO LABELING OF $^{125}$I-ALPHA-BUNGAROTOXIN SUPRACHIASMATIC BINDING SITES - A QUANTITATIVE EVALUATION OF DISTRIBUTION. M.M. Miller and R.B. Billiar*, Dept. of Obstetrics and Gynecology, Royal Victoria Hospital, McGill University, Montreal, Quebec H3A 1A1.

The distribution of $^{125}$I alpha-bungarotoxin (α-BTX), a putative nicotinic cholinergic receptor ligand was studied both in vitro and in vivo in the suprachiasmatic nucleus (SCN) of the rat hypothalamus. For in vitro studies 20 µ frozen frontal sections containing SCN were incubated with either varying concentrations of radioligand or unlabeled α-BTX and tissues processed for light microscopic autoradiography using NTB-2 and 8 days of development. Areas and perimeters of cresyl-violet-stained sections were measured using a Bioquant Analysis System and grain counts and distributions determined. We observed a distinctive and specific labeling pattern of the SCN. Grains tended to localize diffusely and uniformly in more rostral regions, but clustered densely in the dorsal and lateral mid-SCN, and dorsally in the mid-caudal SCN; in the most caudal regions no labeling was observed. Labeling patterns remained the same regardless of concentration of radioligand. Cold competition controls did not demonstrate grain counts above background levels. For in vivo investigations third ventricular infusion of either $^{125}$Iα-BTX, or unlabeled α-BTX with $^{125}$Iα-BTX was performed, and 24 hours later animals were perfused percardially (glutaraldehyde-paraformaldehyde) and hypothalamic tissues processed. One µserial plastic sections of SCN were incubated with NTB-2 for 47 days. No less than 70 micrographs from each of 4 regions (rostral, mid-rostral, mid, and mid-caudal) were examined in a blind study. Areas and perimeters of 1601 plastic-embedded cells were measured (Bioquant); the mean area of all cells in 360 micrographs from the rostral to caudal extent of the SCN was 71±23 um$^2$. Cells ranged in size from 55±19 um$^2$ (rostral-central) to 93±23 um$^2$ (mid-dorsal). In the rostral SCN, where cells were relatively small (range 55±19 um$^2$ - 83±8 um$^2$), $^{125}$I grains were distributed uniformly (from 0.003-0.005 grains (g)/um$^2$; Σ15±3 - 19±3g/hpf). In the mid-SCN, grains were distributed most densely laterally (.015g/um$^2$; Σ44.2±7 g/hpf), dorsally (.013 g/um$^2$; Σ54±6 g/hpf), and dorsal-laterally (.012 g/um$^2$; Σ44±14 g/hpf), while ventrally labeling was less dense (.007 g/um$^2$; Σ26±6 g/hpf). Cells in these sectors measured 93.3±22, 88.6±30, 74.5±20, and 65±25 um$^2$ respectively. The area of the SCN containing the larger neurons is morphologically different from the rest of the nucleus and receives a substantial number of afferent projections while sending dendrites laterally to the adjoining anterior hypothalamic area or dorsally into the periventricular region. Localization of $^{125}$Iα-BTX within the neuropil of these particular areas of the SCN may indicate a different functional interaction between these cells and those of adjacent areas either within or outside of the SCN. Supported by NIHR1HD94314.

307.7 REGIONAL DISTRIBUTION OF MUSCARINIC CHOLINERGIC BINDING IN TWO SPECIES OF WILD SONGBIRD AS DETERMINED BY TRITIUM-SENSITIVE FILM AUTORADIOGRAPHY. G.F. Ball*, B. Nock, B.S. McEwen, and J.C. Wingfield*. (SPON: P. Marler). The Rockefeller University, New York, N.Y. 10021

Seasonally breeding birds show dramatic changes in the sensitivity of their neuroendocrine systems to light and other environmental stimuli during the reproductive cycle. Recent work involving the blood sampling of free living breeding wild birds has correlated changes in pituitary gonadatropin secretion and gonadal steroid secretion with a variety of naturally occurring stimuli including not only daylength, but also behavioral interactions, weather, and the phenologic progression of spring.

As a prelude to functional studies of the neuroendocrine integration of this myriad of environmental information we have begun mapping, using quantitative autoradiography, the distribution of neurotransmitter receptor binding sites that may be involved in the regulation of the hypothalamo-hypophyseal-gonadal axis. Subjects consist of males from two species of songbird: the European Starling, Sturnus vulgaris, and the Song Sparrow, Melospiza melodia both of which have been extensively studied in the wild. Adult animals were decapitated, and their brains were rapidly removed, frozen on dry ice, and stored at -80°C. Coronal brain sections (25u) were cut and thaw-mounted onto subbed slides. Muscarinic receptors were labelled using ($^3$H) scopolamine, a muscarinic antagonist. Slices were exposed to tritium sensitive LKB film for 1 week. Autoradiograms were analyzed using a computer assisted densitometer.

In both species heaviest binding occurred in certain structures in the paleostriatal complex especially the paleostriatum augmentatum (PA), the lobus parolfactorius (LPO), and Area X. Binding was moderate in the hyperstriatum ventrale and in the optic tectum and low to moderate in areas of the hypothalamus. Overall patterns are quite consistent between the two species. These findings agree well with in vivo autoradiography performed in Zebra Finches by Ryan and Arnold (J.Comp. Neur. 202:211 1981) and with investigations on mammals which have found the greatest amount of binding in the caudate-putamen and the nucleus accumbens, areas thought to be homologous with PA and LPO-Area X, respectively.

307.8 CHARACTERIZATION AND REGIONAL DISTRIBUTION OF ADENOSINE DEAMINASE ACTIVITY IN RAT BRAIN. J.D. GEIGER and J.I. NAGY. Dept. of Pharmacology, Univ. of Manitoba, Winnipeg, MAN. R3E 0W3.

Specific neural systems utilizing adenosine as a neurotransmitter/neuromodulator have yet to be identified. One possible approach to such an identification in rat brain may be localizing neural tracts immunoreactive for adenosine deaminase (ADA), a major degradative enzyme for adenosine (Nagy et al., Science 224:166, 1984), and characterizing adenosine transport sites labelled with [$^3$H]nitrobenzylthioinosine ([$^3$H]NBI) (Geiger et al., J. Neurosci. 5:735, 1985; Geiger and Nagy, Brain Res. Bull., 13:657, 1984). The regional distribution patterns of neural systems immunoreactive for ADA correspond closely with that of adenosine transport sites (Nagy et al., Neurosci. Lett. in press). In order to quantitatively assess this correspondence we have investigated the characteristics and regional distribution of ADA in rat brain.

ADA activity was measured by a HPLC technique modified from that of Hartwick et al. (J. Chromatogr. Sci. 16:427, 1978). Enzyme activity was optimal over a pH range of 7.0 to 8.0 and was linear with protein (brain homogenates) concentrations of 0.1 to 1.6 mg. Using 0.3 mg protein and 500 μM adenosine, the amount of product formed was linear for incubations up to 60 min. The $K_m$ and Vmax values for whole brain were 95.2 μM and 64.2 nmoles product formed (hypoxanthine + inosine)/mg protein/30 min. Of the 40 brain regions examined the five areas containing the highest levels of enzyme activity (listed in decreasing order) were olfactory bulbs, posterior hypothalamus, superior colliculus, medulla oblongata and olfactory cortex. ADA activity in olfactory bulbs was 9 times higher than frontal cortex, the area with the lowest activity. The distribution pattern of adenosine transport sites appears to parallel that of ADA-immunoreactive fibers in brain areas lacking cell bodies immunoreactive for ADA. A poor correlation was noted between levels of [$^3$H]NBI sites and ADA activity in brain structures containing ADA-immunoreactive neuronal parykarya. (Supported by the Medical Research Council of Canada, Health Sciences Centre Research Foundation and Manitoba Health Research Council).

307.9 PRESUMPTIVE GLUTAMERGIC/ASPARTERGIC AFFERENTS TO THE VENTRAL STRIATO-PALLIDAL REGION. T.A. Fuller, F.T. Russchen* and J.L. Price. Depts of Psychiatry, Anatomy & Neurobiology, Washington Univ Sch Med, St. Louis, MO 63110.

Recent biochemical evidence has suggested a substantial glutamergic/aspartergic (Glu/Asp) input to the ventral striato-pallidal region in the rat, but the sources of these afferents have been only grossly localized to neocortex and allocortex (Walaas, Neurosci 6:399; Davies et al, Neurosci Lett 45:105). To investigate this, we have used $^3$H-D-aspartate ($^3$H-D-Asp) as a "neurotransmitter specific" retrograde tracer for Glu/Asp projections (Streit, J Comp Neurol 191:429) and wheat germ agglutinated-horseradish peroxidase (WGA-HRP) as a nonspecific retrograde tracer for all projections. Injections of $^3$H-D-Asp or WGA-HRP were made into the ventral pallidum, ventral striatum or olfactory tubercle, and after 18-48 hr the brains were fixed and prepared for autoradiography or HRP histochemistry.

The results show that injections of $^3$H-D-Asp label specific subsets of the 'total' afferents labeled by comparable WGA-HRP injections. Unlike WGA-HRP, $^3$H-D-Asp did not label the dopaminergic ventral tegmental area or substantia nigra or the noradrenergic locus coeruleus, and only an occasional $^3$H-D-Asp labeled cell was found in the serotonergic dorsal raphe. However, many cells and fibers in cortical and non-cortical areas are labeled by transport of $^3$H-D-Asp. The heaviest presumptive Glu/Asp inputs to the ventral pallidal area arise in the midline and medial intralaminar thalamic nuclei and in the amygdala (particularly the central and basomedial nuclei and the nucleus of the lateral olfactory tract (NLOT)). Fibers to the ventral striatal region arise in the medial frontal cortex, agranular insular cortex, olfactory cortex, olfactory tubercle, as well as in the midline and intralaminar thalamic nuclei, and the amygdala (especially the lateral and basolateral nuclei and the NLOT). Finally presumptive Glu/Asp inputs to the olfactory tubercle arise in agranular insular (rostral aspect) and olfactory cortices, the midline and intralaminar thalamic nuclei, the amygdala (especially the basolateral and basomedial nuclei and the NLOT) and the lateral supramammillary nucleus. The projections from the NLOT to the ventral striatum and the olfactory tubercle are bilateral, and there are also contralateral inputs to the ventral striatum from the agranular insular cortex and the basolateral amygdaloid nucleus. Based upon morphology and cell size, the thalamic cells labeled by injection of $^3$H-D-Asp into these three regions appear to be somewhat different although overlapping populations.

This indicates that specific subsets of afferent neurons to the ventral striato-pallidal area take up and retrogradely transport $^3$H-D-Asp and therefore are presumptively glutamergic and/or aspartergic. (Supported by RSDA MH00330 and NIH NS-0918.)

307.10 THREE-DIMENSIONAL AUTORADIOGRAPHIC LOCALIZATION OF QUENCH-CORRECTED GLYCINE RECEPTOR SPECIFIC ACTIVITY IN THE MOUSE BRAIN USING $^3$H-STRYCHNINE. W.F. White and A. Wang. Depts. of Neurosci., Harvard Med. Sch. and Children's Hosp., Boston, MA 02115.

Diffusable substance autoradiographic techniques have been widely employed for the localization of neurotransmitter receptors in the CNS. Current methodologies suffer from inadequate quantification of receptor specific activity from single sections through three-dimensional morphological regions and differential quench by the tissue. These limitations were addressed here by determining the three-dimensional distribution of $^3$H-strychnine binding site specific activity from quench-corrected autoradiographic data. The analyses were performed using a VAX 11-780 computer and a Megatek 7295 3-D color raster display in the Image Graphics Lab. at Children's Hosp. The brains from C57BL/6J mice were serially sectioned at 10 μm from the cervical cord to the frontal pole. Sections separated by 120 μm were preincubated for one hour in 100 mM NaCl, 50 mM $NaPO_4$, pH 7.4, incubated one hour in 5 nM $^3$H-strychnine, washed in four changes of fresh buffer for a total of one min., dipped in distilled water, and dried with anhydrous air. Autoradiograms were prepared by exposing the sections to LKB Ultrofilm for four weeks. The density of exposed silver grains was quantified using a scanning densitometer (Optronics P-1000) at a resolution of 50 μm, and following background subtraction, converted to specific activity. Differential quench was determined by incubating adjacent sections in $^{125}$I-Bolton and Hunter reagent or $^3$H-succinimidyl proprionate according to the methods of Herkenham and Sokoloff (Brain Res. 321:363-368). The optical densities of autoradiograms prepared from these sections were determined and registered with the data sections. The normalized ratio of optical density between the iodinated and proprionated sections was used to correct quench on a pixel by pixel basis. Data sections were registered into three-dimensional images of binding site distribution. Receptor density was visually represented by color density coding and displayed either as solid mosaics or as isodensity contour lines. These data demonstrate a marked regional distribution of $^3$H-strychnine binding sites in the mouse CNS. Specific binding was confined to gray matter areas with a marked rostro-caudal distribution. The highest levels of binding were seen in the substantia gelatinosa and ventral horns of the spinal cord, the spinal nucleus of cranial nerve V, the hypoglossal nucleus and dorsal motor nucleus of cranial nerve X. Moderate binding was observed in the remaining grey matter of the cord, numerous nuclear groups of the medulla and brainstem, and the corpus quadrigemini. Low levels of binding were found in the thalamus and hypothalamus. Both the cerebral and cerebellar cortices lacked specific binding. These studies demonstrate the usefulness of powerful computer methodologies for the localization of specific neurotransmitter function.

307.11 BENZODIAZEPINE RECEPTOR LABELING IN VIVO WITH [$^3$H]-Ro 15-1788. M.J. Kuhar and N.E. Goeders. Department of Neuroscience, Johns Hopkins University School of Medicine and the Laboratory of Neuroscience, NIDA Addiction Research Center, Baltimore, MD 21205.

The ability to study benzodiazepine (BZD) receptors in vivo can result in many useful applications. Imaging these receptors by PET scanning and other techniques such as autoradiography may provide insight as to the mechanism of action of these drugs and as to the organization and function of various brain regions. However, some reports of the in vivo labeling of brain BZD receptors (Chang and Snyder, Eur. J. Pharm., 48, 213, 1978; Williamson et al., Life Sci., 23, 1935, 1978) are actually "ex vivo" techniques because the tissues were removed, homogenized and washed to reduce nonspecific binding. This investigation was designed to provide a more desirable approach where BZD receptors are labeled in the tissues of intact animals.

Adult male ICR mice (30 to 35 g) were injected via the tail vein with 167 uCi/kg of [$^3$H]-flunitrazepam ([$^3$H]-Flu), [$^3$H]-methyl-clonazepam ([$^3$H]-Clo) or [$^3$H]-Ro 15-1788 and were sacrificed at various time points. For determinations of non-specific binding, mice were pretreated with clonazepam (5 mg/kg, i.p.) 30 minutes prior to the intravenous injection. The brains were rapidly removed and dissected into cerebral cortex, cerebellum and medulla to determine the regional distribution of the ligands at the various time points. In vivo binding was also determined in the presence of a number of peripheral and central-type BZD receptor ligands to investigate the pharmacological specificity of the binding. The saturability of ligand accummulation in the cerebral cortex was also examined.

Of the three drugs tested, only [$^3$H]-Ro 15-1788 resulted in workable specific/nonspecific binding ratios. The binding was specific and was only displaced by central-type BZD receptor ligands. Increasing concentrations of [$^3$H]-Ro 15-1788 resulted in a saturation of available receptors. In addition, the autoradiographic distribution of BZD receptors by the in vivo labeling procedure was similar to that found by in vitro labeling with [$^3$H]-Ro 15-1788. The results of this investigation suggest that Ro 15-1788 is a useful ligand for studying BZD receptors in vivo. (Supported by USPHS Grants DA 00266, MH 00053, NS 15080 and MH 09111 and grants from the Bristol-Myers Company and the McKnight Foundation).

307.12 IMMUNOCYTOCHEMICAL EVIDENCE FOR THE COLOCALIZATION OF $GABA_A$ AND BENZODIAZEPINE RECEPTORS IN DEFINED GABAERGIC SYNAPSES OF THE RETINA. H. Möhler*, J.G. Richards, W. Haefely and J.Y. Wu. Pharm. Res. Dept., F. Hoffmann-La Roche & Co., Ltd., CH-4002 Basel, Switzerland and Dept. of Cell Biol., Baylor College of Medicine, Houston, Texas 77030.

Previous immunohistochemical studies with antibodies to glutamate decarboxylase(GAD) (Wu, J.Y. et al., Mol. Cell. Biochem. 39: 229, 1981) have revealed horizontal cells and a subpopulation of amacrine cells in the vertebrate retina to be GABAergic. Processes of these interneurons arborize in the inner plexiform layer where they form the majority of their synaptic contacts with other amacrine cells and, to a lesser extent, with bipolar and ganglion cell processes. In accordance with these observations and with the proposed GABA-potentiating mechanism of action of benzodiazepines(BZs) in the CNS is the finding that $GABA_A$ and BZ receptors are also observed in the inner plexiform layer after radiolabelling with $^3$H-Ro 15-1788 and $^3$H-muscimol in vitro. Retinal BZ receptors appear to have the binding characteristics (e.g. pharmacological specificity, GABA-shift) of neuronal receptors.

Using monoclonal antibodies(mAb) to the $GABA_A$/benzodiazepine receptor complex isolated from bovine cerebral cortex (Schoch, P. et al., Nature 314:168, 1985), it has now been possible to identify the receptors in defined GABAergic synapses of the rat retina. Receptor antigenic sites were localized immunohistochemically(PAP method) in four distinct bands in the inner plexiform layer and around cells with the characteristic shape and location of amacrine cells. Adjacent sections stained with GAD mAb revealed a similar distribution in the inner plexiform layer. Moreover, ultrastructural studies revealed that the immune reaction for the BZ receptor was exclusively present in synaptic contacts.

The functional role of GABAergic synapses in the transmission between photoreceptors and bipolar and ganglion cells in the retina is not known. BZs attenuate the light-induced increase in dopamine turnover in a subpopulation of amacrine cells, which would be in line with the presence of receptor antigenicity on a small proportion of these cells. Whether therapeutic concentrations of BZs affect retinal function, however, is not clear. The fact that changes in visual perception do not seem to have been observed with BZs in man might indicate that ongoing GABAergic inhibition is usually close to maximal and, therefore, not potentiated by BZs.

307.13 VISUALIZING Kd and Bmax: FLUNITRAZEPAM BINDING PARAMETERS. A.W. Toga, E.M. Santori*, and R.C. Collins. Laboratory of Neuro Imaging, Department of Neurology and Neurosurgery and The McDonnell Center for the Study of Higher Brain Functions, Washington University, St. Louis, MO. 63110.

Autoradiographic receptor binding has improved the study of receptors because of the visual nature of the primary data that is generated. In the analysis of binding kinetics this visual component is lost. The goal of this study was to use current techniques of digital image analysis to visualize Bmax and Kd of benzodiazepine receptors in rat brain.

Fresh rat brain, along with two brain paste filled fiducial columns of PE 205 tubing were freeze-mounted onto an object holder. A blocking apparatus fixed the orientation of the brain and set the fiducial columns orthogonal to the object holder. The brain and two pieces of tubing were embedded in a gelatin matrix.

Flunitrazepam (FLU) binding was assayed utilizing the procedures developed by Young and Kuhar (JPET 212:337-346, 1980). Total binding was determined in triplicate at five FLU concentrations. Nonspecific binding was determined in the presence of 1 uM clonazepan, but only at the two highest FLU concentrations. Sections were processed for quantitative autoradiography.

Autoradiographic data was transformed to concentrations of radioactivity and of each set of triplicates digitally averaged. All arithmetic operations were performed on perfectly aligned images. Image alignment computations were performed using coordinates provided by the fiducials and required no user interaction. Nonspecific binding (NSB) within grey structures is linearly related to the concentrations of FLU. By interpolating a line through the two average NSB binding images and zero, the amount of NSB at any concentration of FLU could be estimated. New specific binding images were generated by subtracting the concentration-dependent amount of NSB from the five total binding images. Each specific binding image was then divided by its respective FLU concentration. Eadie-Hofstee analysis (linear regression of B vs B/F) was performed for all pixels of the image. The slope of the regressions produced an image of Kd. An image of Bmax was generated using the y-intercept. With this procedure inter and intra animal alterations in Kd and Bmax are now amenable to visual survey.

307.14 RECEPTORS FOR NERVE GROWTH FACTOR IN THE RAT CENTRAL NERVOUS SYSTEM. R.J. Riopelle, P.M. Richardson and V.M.K. Verge* (SPON: S.K. Ludwin). Department of Medicine (Neurology), Queen's University, Kingston, Ont. K7L 3N6, and Division of Neurosurgery, McGill University, Montreal, Quebec H3G 1A4.

The regional distribution and biochemical properties of receptors for nerve growth factor (NGF) in the rat central nervous system (CNS) were investigated by receptor autoradiography and steady state binding analysis.

For radioautography, cryostat sections were incubated with $^{125}$I-NGF at 40pM with or without unlabelled NGF (40 nm). In the spinal cord, specific labelling was maximal in layers I, II, and III (Rexed) of the dorsal horn. Much of the binding was abolished by previous avulsion of appropriate dorsal roots, and therefore presumed to be on primary sensory afferents. In the brain, $^{125}$I-NGF bound specifically in the basal forebrain, hippocampus, and other discrete areas.

Plasma membrane fractions were prepared from dorsal spinal cord and several regions of the brain for steady state binding studies. $^{125}$I-NGF bound at high affinity ($K_D$ 20 pM) to membranes from the dorsal spinal cord, hippocampus, and basal forebrain, but not the cerebellum. Lower affinity sites were found in all regions. Radioautographs of SDS gels of solublized affinity-labelled {1-ethyl-3-(3-dimethylaminopropyl) carbodiimide} fractions of spinal cord and basal forebrain revealed one major band of molecular weight greater than 100 Kd. This band was not seen in the presence of excess unlabelled NGF.

For primary sensory and septohippocampal neurons, the results confirm and extend previous observations on specific uptake and retrograde axonal transport of NGF. The functions of NGF-like molecules on responsive neurons during development, maintenance, and repair in the CNS remain to be established. (Supported by MRC Canada and MS Society Canada).

308.1 OSMOTIC STIMULATION OF VASOPRESSIN RELEASE FROM PERIFUSED HYPOTHALAMO-NEUROHYPOPHYSEAL EXPLANTS. C.D. Sladek and R.W. Clough. Departments of Neurology and Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Vasopressin (VP) release in vivo and from hypothalamo-neurohypophyseal (HNS) explants maintained in static culture is stimulated by increased osmolality of the extracellular fluid or culture medium. A perifusion culture system has been utilized to evaluate the time course of this response. HNS explants were prepared from male rats (125-150 gms) and placed individually in 0.5 ml perifusion chambers (Endotronics). Explants were perifused at 1-2 ml/hr with $F_{12}$ culture medium supplemented with 20% fetal calf serum, 1 mg/ml glucose, and penicillin, streptomyocin, and bacitracin. Effluent from each chamber was collected in 10 or 15 min fractions and VP concentration was measured by radioimmunoassay. Following an 18 hr equilibration period, the effect of various osmotic challenges (NaCl) on VP release were evaluated in two experiments.

In the first experiment, 5 explants were exposed to 2 NaCl challenges 3 hours apart which resulted in increments of 15 and 42 mOsmol/kg $H_2O$ respectively. The increases occurred over 45 mintues and were sustained for an additional 30-45 minutes. There was a significant increase in VP release associated with both challenges ($p<.05$) and the larger increase in osmolality resulted in a greater release of VP. However, the response to the increase in osmolality was limited to the initial 30 minutes of the challenge and was not sustained throughout the period of elevated osmolality.

A second experiment was performed to evaluate the relationship between the rate of change in osmolality and VP release. Four explants were exposed sequentially to 3 pulses of NaCl separated by 50 minute washout periods. In all 3, osmolality of the perifusate increased from 292 to 330 mOsmol/kg $H_2O$. This occurred in 10, 30 and 40 minutes in the 3 pulses respectively and the increase was sustained following the third pulse. The absolute increase in VP release was comparable for all 3 pulses; however, it was achieved more slowly during the third pulse and was not sustained during static hypertonicity.

These preliminary observations suggest that the osmosensitive mechanisms endogenous to the HNS explant are sensitive to changes in osmolality, rather than static elevations in osmolality.

Supported by USPHS grant R01-AM-19761.

308.2 $\alpha_1$-ADRENORECEPTOR-MEDIATED RELEASE OF ARGININE VASOPRESSIN (AVP) AND OXYTOCIN (OXY) FROM PERFUSED RAT HYPOTHALAMO-NEUROHYPOPHYSIAL EXPLANTS. M.F. Mazurek*, J.C.R. Randle, D. Kneifel* and L.P. Renaud. Dept. of Neurology, Massachusetts Gen. Hosp. Boston, MA. 02114 and Neurosciences Unit, Montreal Gen. Hosp. Research Institute, Montreal, Canada H3G 1A4.

The prominent noradrenergic innervation of neurosecretory neurons in the hypothalamic supraoptic and paraventricular nuclei suggests an important role for norepinephrine (NE) in regulating AVP and OXY release from the neurohypophysis. Recent electrophysiological data indicate that electrical stimulation of the brainstem A1 and A2 cell groups, where most of these fibers originate, can increase the firing of neurosecretory neurons. Similar results follow exogenous application of NE and alpha agonists. The present in-vitro experiments examined the influence of NE on AVP and OXY release.

Perfused explants of rat hypothalamus were prepared as described previously (Bourque & Renaud, J. Neurosci. Methods 7:203, 1983). In addition, both internal carotid arteries were cannulated to obtain optimal perfusion of the entire explant, and bovine serum albumin (0.1%) and phenol red (10 mg/l) were added to the perfusion medium. The pars distalis was carefully removed, leaving only the neurointermediate lobe attached, enabling easier diffusion of secretory products into the medium. A suction pipette was positioned immediately caudal to the pituitary and medium was collected via a peristaltic pump. Following a 1 hr preincubation, 1 min samples were collected throughout 1 hr experiments. AVP and OXY were measured using highly sensitive radioimmunoassays characterized by HPLC and serial dilution curves. Drugs were added directly to the perfusion medium for periods of 5 to 10 minutes at 20 minute intervals.

NE induced a prompt, sustained and reversible increase in the release of AVP from basal levels of less than 2 pg/min to 45 ± 13 pg/min (mean ± S.E.M) at $10^{-5}$M NE, and >100 pg/min at $10^{-4}$ M NE. Phenylephrine (PHE) ($10^{-4}$M) also stimulated AVP release to 31 ± 10 pg/min. NE elicited a parallel but more modest release of OXY, with values rising from basal levels of <1 pg/min.to 2.6 ± 0.2 at $10^{-5}$M NE, and 16 ± 11 pg/min at $10^{-4}$ M NE. The release of both AVP and OXY in response to $10^{-5}$M NE was virtually abolished in the presence of 5 x $10^{-8}$M prazosin. These concentrations of NE and PHE that increase immunoreactive AVP and OXY release are identical to those that enhance the excitability and promote bursting activity among SON neurons in this preparation (Randle et al., Brain Res. 307: 374, 1984).

These data support the interpretation that the endogenous noradrenergic innervation to hypothalamic neurosecretory neurons is facilitatory to efficient hormone release and mediated by alpha-1 adrenoreceptors. (Supported by the MRC and the FRSQ).

308.3 NEUROPEPTIDE Y AND ENDOGENOUS NORADRENALINE STIMULATE SECRETION OF VASOPRESSIN IN THE RAT. J.O. WILLOUGHBY AND W.W. BLESSING. Centre for Neuroscience and Department of Medicine, Flinders University of South Australia, Bedford Park, South Australia 5042.

Vasopressin-secreting neurohypophyseal neurons are densely innervated by processes of A1 noradrenaline neurons located in the ventrolateral medulla. Neuropeptide Y (NPY) is co-localized in A1 cells and is present in terminals in the supraoptic nucleus (Everitt et al, Neurosci. 11, 443-462 1984). Injection of noradrenaline into the supraoptic nucleus causes dose-dependent vasopressin secretion by activating alpha-1 adrenoceptors (Willoughby et al Neurosci. Lett. Supp 19 S41 1985). This study examines whether NPY releases vasopressin when injected into the supraoptic nucleus and whether endogenous noradrenaline, released by local injections of tyramine, does likewise.

Male Porton rats (250-350 g) were prepared with a chronic indwelling right atrial catheter and bilateral intracerebral guide cannulae directed at the supraoptic nuclei (Paxinos and Watson, bregma -1.3, lateral ± 2 mm). One week later, 1.2 ml blood samples for vasopressin radioimmunoassay were taken from unanesthetized animals before, and 5 and 20 minutes after bilateral injections into the supraoptic nucleus, with 30 guage needles inserted 9 mm below brain surface, through the guide cannulae. The plasma was removed and the red cells, resuspended in saline, were re-injected after the next sample. Agents were administered in 0.25 ul of Ringer's solution. Accuracy of injection sites was histologically confirmed.

Vasopressin responses (mean±SEM) are shown in the table:

| Agent | vasopressin (pg/ml) 5 min | 20 min |
|---|---|---|
| Ringer's (n=8) | 16±5 | 10±2 |
| Noradrenaline (10 nmol, 14) | 118±13 ** | 17±2 ** |
| NPY (1.0 nmol, 6) | 85±18 ** | 52±10 ** |
| Tyramine (100 nmol, 6) | 57±10 * | 24±5 * |

Significantly different from Ringer's * $P<0.05$, ** $<0.01$.

The results indicate that endogenous noradrenaline, released from nerve terminals in the supraoptic nucleus, stimulates vasopressin secretion. In addition there was a prompt and sustained response to NPY. Both noradrenaline and NPY may be co-transmitters participating in the baroreceptor-initiated secretion of vasopressin which is mediated by A1 neurons (Blessing and Willoughby, J. Physiol., in press).

Supported by the National Health and Medical Research Council.

308.4 REGIONAL DISTRIBUTION OF MUSCARINIC AND PUTATIVE NICOTINIC CHOLINERGIC RECEPTORS WITHIN THE RAT HYPOTHALAMO-NEUROHYPOPHYSEAL SYSTEM. K.M. Michels*, R.B. Meeker* and J.N. Hayward. Dept. Neurology and Neurobiology Program, Univ. North Carolina, Chapel Hill, N.C. 27514.

Mechanisms for muscarinic cholinergic (mACh) and nicotinic cholinergic (nACh) stimulation of vasopressin (VP) and oxytocin (OT) release are present in the basal hypothalamo-neurohypophyseal system (HNS) (Barker et al, 1971; Gregg, 1985; Nordmann et al,1971; Sladek, 1983). The specific anatomical site(s) of action of mACh and nACh agonists in HNS are not fully described. Utilizing $^3$H-quinuclidinylbenzilate ($^3$H-QNB) as a probe for the muscarinic cholinergic receptors (mAChR) and using $^{125}$I-$\alpha$bungarotoxin ($^{125}$I-$\alpha$ BTX) as a probe for the nicotinic cholinergic receptors (nAChR), we have verified the presence of high affinity mAChR and nAChR in different regions of HNS. Our new technique for quantitative assessment of binding to fixed tissue sections ($^3$H-QNB with 1% acrolein; $^{125}$I-$\alpha$BTX with 0.5% paraformaldehyde) allowed pharmacological characterization of the receptor, autoradiographic localization and immunohistochemical staining on the same section. A single high affinity ($K_D$ = 8 x $10^{-11}$ M) site was labeled by $^3$H-QNB in the rat hypothalamus and neural lobe with a density of 140-340 fmoles/mg protein. Silver grains from $^3$H-QNB were of moderate density over the neural lobe, of low density throughout the hypothalamus but absent within the supraoptic nucleus (NSO). There was no clear relationship between $^3$H-QNB binding and VP and OT cells within the hypothalamus. In contrast, $^{125}$I-$\alpha$BTX binds to high ($K_D$ = 4 x $10^{-11}$ M) affinity sites in the rat HNS with a density of only 21 fmoles/mg protein. These $^{125}$I-$\alpha$BTX high affinity binding sites are concentrated in the NSO and the nucleus circularis (NC). The density of silver grains is equally distributed over VP and OT immunoreactive neurons and processes in both NSO and NC. We find little or no detectable binding of $^{125}$I-$\alpha$BTX in the neural lobe of the rat. These data demonstrate a regional anatomical distribution of cholinergic receptors within the rat HNS, with putative nicotinic cholinergic receptors (nAChR) localized on the membranes of magnocellular (MgC) neurons in the hypothalamus and muscarinic cholinergic receptors (mAChR) localized on the membranes of MgC neuron terminals in the neural lobe. Furthermore, we find that the nAChR are distributed at several sites on the membranes of VP and OT MgC neurons within the NSO and NC of rat hypothalamus. These data suggest a differential cholinergic regulation of VP and OT release: nAChR at soma-dendritic MgC sites in the hypothalamus and mAChR at axonal terminal MgC sites in the neural lobe.

(This research supported, in part, by NIH Javits Award NS-13411, USPHS GRSA FR-05406, Neurobiology Training Grant and UNC Faculty Development Award).

308.5 MORPHOMETRY OF CAPILLARIES IN RAT NEURAL LOBE AND SUPRAOPTIC NUCLEI. P.M. Gross, N.M. Sposito*, S.E. Nornes*, A.B. Butler and J.D. Fenstermacher. Department of Neurological Surgery, SUNY at Stony Brook, NY 11794-8122.

Capillaries of the neural lobe (NL) are the site of secretion of vasopressin originating from magnocellular neurons in the hypothalamic supraoptic nuclei (SON). The capillary bed of NL is exceptionally dense and the rate of blood flow in NL is extremely high (about 5.7 ml/g/min compared to 1.5 ml/g/min in cerebral grey matter structures such as SON). Using light and electron microscopic morphometry, we studied and compared the capillary beds and ultrastructure of endothelial cells in these two neurosecretory structures. The brains and pituitary glands of adult Sprague-Dawley rats were perfusion-fixed with 2% paraformaldehyde and 2% glutaraldehyde in 0.1 M phosphate buffer. Two micron-thick sections of NL and SON were obtained and stained with toluidine blue for light microscopy; ultrathin sections were taken and stained with uranyl acetate and lead citrate for electron microscopy. Results are presented as the mean ± SD for NL and SON capillaries measured in the number of rats shown in parentheses. *$p < 0.05$.

| | Neural Lobe | Supraoptic Nuclei |
|---|---|---|
| Capillary Bed | | |
| Density (#/mm$^2$) | 1014±51 (6) | 1038±126 (3) |
| Volume (%) | 3.2±0.3 | 3.1±0.2 |
| Surface area (mm$^2$/mm$^3$) | 32.5±2.3 | 29.8±1.8 |
| Endothelial Cells | | |
| Mitochondria (#/micron$^2$) | 0.36±0.11*(3) | 1.41±0.31 (3) |
| Junctions (#/micron$^2$) | 0.45±0.04 | 0.57±0.09 |
| Vesicles (#/micron$^2$) | 11.5±2.5* | 6.2±0.7 |
| Fenestrations (#/cross section) | 5±0.7* | none |

The findings demonstrate that the capillary beds of NL and SON have similar characteristics for density and volume as evaluated from light micrographs but are dissimilar morphologically as assessed by quantitative electron microscopy. The fewer endothelial mitochondria, greater number of endothelial vesicles and fenestrations, and extraordinary surface area and blood flow in capillaries of NL likely explain its high permeability to circulating solutes, i.e., its "absence" of a blood-brain barrier.

308.6 A LIBRARY OF MONOCLONAL ANTIBODIES WHICH BIND TO THE RAT NEUROHYPOPHYSIS. H.J. Cranston, M.J. Durick*, S.J. Hapner and C.M. Paden. Dept. of Biology, Montana State Univ., Bozeman, MT 59717.

Monoclonal antibodies (MAbs) which recognize antigens of the neuronal cell surface are proving to be powerful probes of developmental and functional processes in a variety of systems. In an attempt to produce MAbs against surface antigens of hypothalamic neurosecretory cells, we have employed membranes from fixed rat neurointermediate lobe as immunogens. Because the majority of the volume of the neural lobe consists of axons of neurosecretory cells, this tissue provides a naturally enriched source of neurosecretory cell membranes. Six MAbs which bind to fixed sections of rat neurohypophysis have been obtained to date.

The neurointermediate lobe was dissected from unperfused, decapitated Holtzman rats and post-fixed by immersion in Zamboni's overnight. A crude membrane pellet was obtained following rinsing and homogenization in hypotonic tris buffer. 100 g of protein from this pellet was used as an immunogen in in vitro activations of splenocytes obtained from naive Balb C BYJ mice. Following incubation for 3-5 days, fusions with P-3/X-63-Ag 8.65 myeloma partners were performed using minor modifications of standard protocols. When hybridoma growth became apparent, initial screening for antibody secretion was done using a modified ELISA procedure which detects mouse immunoglobulins in the culture media. Further immunocytochemical screening of spent media from positive wells was then performed on cryostat sections of fixed rat pituitary by indirect immunofluorescence. Antibody producing hybridomas were cloned twice by limiting dilution, and large quantities of MAbs produced by induction of ascites tumors.

Five of the 6 MAbs exhibit different staining patterns on whole pituitary sections. MAb F3-10 stains only the neural lobe in a diffuse manner; MAb 5B is also specific to the neural lobe, but staining is punctate over a diffuse background. MAb 1F binds primarily to the intermediate lobe in a punctate manner, with only faint reactivity present in the neural lobe. MAbs 11A and 7B both exhibit strong punctate staining in neural lobe with fainter staining visible in the anterior lobe as well, while MAb 5G stains anterior and neural lobes equally in a diffuse manner. Although raised against adult tissue, all 6 MAbs also bind to neonatal pituitary.

These results indicate that the rat neurointermediate lobe contains various proteins which are immunogenic in the mouse. While it is not possible to determine whether MAb binding is to neurosecretory or pituicyte processes at the light microscope level, further characterization of binding at the EM level and to sections of hypothalamus is in progress.

This research was supported by a Grant-In-Aid from the Montana Heart Association and by NSF BNS-8408061.

308.7 PURIFICATION OF FIXED NEUROPHYSIN-CONTAINING HYPOTHALAMIC NEURONS BY FLUORESCENCE ACTIVATED CELL SORTING. S.J. Hapner, D. Berglund*, C.J. Welsh*, G.S. Stuart* and C.M. Paden. Dept. of Biology, Montana State Univ., Bozeman, MT 59717.

Fluorescence activated cell sorting (FACS) offers the potential for cytometric analysis and purification of identified neuronal populations labeled by specific fluorescent markers. However, application of flow cytometry to viable neurons is currently limited by a scarcity of cell-type-specific surface markers. Purification of fixed cells using readily available antibodies to intracellular molecules is an alternative approach which could lead to production of new cell-surface antibodies by using the isolated fixed cells as immunogens (P.A. St. John and J.L. Barker, Soc. Neurosci. Abst. 9: 7, 1983). As a step toward this goal, we have succeeded in using FACS to isolate significant numbers of a small neuronal population, the neurophysin-containing neurons of the supraoptic (SON) and paraventricular (PVN) nuclei.

SON and PVN were dissociated from slabs of fresh 8-day-old rat hypothalami using a Palkovits punch. Following mincing and fixation in Zamboni's for 3 hr, cells were incubated with collagenase at 37° C for 30 min, then transferred to Ca free PBS containing 1 mM Mg, 1% BSA, 0.25 M sucrose, 0.1% Tween 20 and DNAase. Dissociation was done by successive trituration through hypodermic needles of decreasing bore (18-25g). Debris was removed by settling and passage through a 44μ nylon mesh. Cells were incubated for 1 hr in a 1:1000 dilution of rabbit anti-rat neurophysins (gift of Dr. Allan Robinson) followed by fluorescein conjugated goat anti-rabbit IgG (Cappel) at 1:100 for 1 hr. Flow cytometry and cell sorting were performed on a Becton-Dickinson FACS 440 using either flourescence or forward scatter triggering and log mode fluorescence analysis. A distinct peak of highly fluorescent cells representing 1.7% of the total population was isolated. This peak was absent from both cerebral cortical cells treated as above and from SON-PVN cells when normal rabbit serum was substituted for anti-neurophysins. Fluorescent microscopy of sorted cells indicated a purity of 85-90%, yielding an enrichment of 50 fold. About 2000 cells were obtained per brain, with morphology varying from round to bipolar with attached processes.

It appears that sufficient numbers of relatively rare neurons can be obtained in this manner for use as in vitro immunogens. In addition, this technique could be used to rapidly examine large numbers of fixed cells for the colocalization of multiple antigens using the dual fluorescence capabilities of the FACS.

This research was supported by a Grant-In-Aid from the Montana Heart Association and by NSF BNS-8408061.

308.8 OXYTOCIN INHIBITS ACTH, EPINEPHRINE, AND NOREPINEPHRINE SECRETION IN THE URETHANE-ANESTHETIZED RAT. D.M. Gibbs, Dept. of Repro. Med., UCSD, La Jolla, CA 92093.

Oxytocin (OT) is a hypothalamic hormone which generally has a stimulatory effect on ACTH secretion both in vitro and in vivo. As part of a study of ACTH-releasing factors in hypophysial portal blood, we tested the effects of iv OT administration on plasma ACTH levels in urethane-anesthetized rats. Surprisingly, iv injection of 10 mcg OT lowered plasma ACTH levels by about 35% ($p<0.01$) and 1 mcg OT lowered ACTH levels by about 13% ($p<0.05$) whereas the similar peptide arginine vasopressin (AVP) had no effect. The 10 mcg dose of OT produced peak OT levels of 340 ng/ml 1 minute after injection and 30 ng/ml 10 minutes after injection. Because of the very high baseline levels of ACTH, epinephrine (EPI), and norepinephrine (NE) in the urethane-anesthetized rat, and because of the involvement of beta-adrenergic pituitary receptors in the stimulation of ACTH secretion, we reasoned that the paradoxical inhibition of ACTH secretion by OT might be mediated by inhibition of peripheral catecholamine secretion. Measurement of plasma catecholamines before and after iv administration of 10 mcg OT revealed a 53% inhibition of EPI ($p<0.01$) and a 43% inhibition of NE ($p<0.05$). Administration of the beta-adrenergic antagonist propanolol (400 mcg) 15 minutes before the beginning of the experiment completely blocked the inhibitory effects of OT on ACTH secretion and in fact unmasked the stimulatory effects of OT normally seen in conscious animals and in vitro.

To determine the site at which OT acts to inhibit catecholamine secretion, bisected rat adrenal glands were superfused with oxygenated Medium 199 at 37 C. Adrenals exposed to $10^{-6}$M OT for 10 minutes secreted more than 30% less EPI and NE than control adrenals suggesting that the inhibition of EPI and NE secretion by OT in vivo occurs, at least in part, directly at the level of the adrenal. AVP had no effect on in vitro catecholamine secretion.

These data support the hypothesis that peripheral catecholamines may at times be directly involved in the control of ACTH secretion. In addition, these experiments suggest that OT, which has recently been identified in the adrenal medulla (Ang, V.T.Y., and Jenkins, J.S, JCEM 58:688, 1984), may have important paracrine functions in the regulation of adrenal catecholamine secretion.

308.9 GnRH RELEASE FROM THE MEDIOBASAL HYPOTHALAMUS (MBH): IN VITRO REGULATION BY OXYTOCIN. M. Gambacciani*, S.S.C. Yen*, D.D. Rasmussen, Dept. of Reproductive Medicine, UCSD, La Jolla, CA 92093.

Both suckling and stress stimulate oxytocin (OT) and inhibit LH secretion in the rat, suggesting that a functional interaction may exist between these endocrine responses. Since OT and GnRH are both localized in hypothalamic neuronal systems with terminals in the external zone of the median eminence (ME), we hypothesized that OT may suppress LH secretion by inhibiting hypothalamic GnRH release. Accordingly, an in vitro incubation system was used to evaluate GnRH release from adult male rat MBHs in response to OT. MBHs were removed following decapitation and incubated at 37°C for 12 min in 0.45 ml of oxygenated Medium 199 containing 0, 0.1, 10 or 1000 pM OT (n=9/group). These media were then replaced by identical media plus 56 mM KCl, and the incubation was continued for 4 min. GnRH release was determined by radioimmunoassay of media from the 12 min (basal) and 4 min ($K^+$ stimulated) incubations. Mean (±SE) basal GnRH release was 9.1±1.1 pg/12 min in the control group; OT treated MBHs released 6.6±0.8 (0.1 pM), 4.5±0.4 (10 pM) and 3.6±0.3 (1000 pM) pg/12 min. $K^+$ stimulated GnRH release was 29.7±6.0 in controls and 24.8±4.3, 14.5±1.5 and 11.3±0.6 pg/4 min in the 0.1, 10 and 1000 pM OT treated MBHs, respectively. Both inhibition of basal and $K^+$ stimulated GnRH release by OT and the inverse linear correlation between OT dosage and GnRH release were significant at $p<0.01$. Equimolar OT receptor antagonist (ANT; d-$(CH_2)_5$Tyr(Me)AVP) completely prevented the inhibition of basal and $K^+$ stimulated GnRH release by 1 nM OT, whereas ANT alone did not alter GnRH release (n=9/group). When just the ME was incubated with medium alone (n=6) or medium plus 1 nM OT (n=6), OT inhibited both basal (9.5±0.5 vs 30.5±5.4 pg/12 min, $p<0.01$) and $K^+$ stimulated (39.3±5.0 vs 102.1±13.7 pg/4 min, $p<0.01$) GnRH release. These studies demonstrate that excedingly low concentrations of OT can inhibit in vitro GnRH release from male rat MBHs by an OT receptor mediated mechanism, and that this inhibition can be exerted at the level of the ME (i.e. the neurosecretory terminals). These results suggest that endogenous OT may indeed participate in the physiological regulation of GnRH release, perhaps mediating stress or suckling induced inhibition of LH secretion. (Supported by a Mellon Foundation Faculty Scholar Award)

308.10 EFFECTS OF AN OXYTOCIN ANTAGONIST ON THE RESPONSES OF PLASMA PROLACTIN, ADRENOCORTICOTROPIN AND β-ENDORPHIN-LIKE IMMUNOREACTIVITY TO 5-HYDROXYTRYPTOPHAN, SUCKLING AND ETHER STRESS. C. A. Johnston and A. Negro-Vilar. Reproductive Neuroendocrinology Section, Lab. Reprod. Dev. Tox., NIEHS, NIH, Research Triangle Park, N.C. 27709

Recent studies from our laboratory demonstrate the necessity of the neurointermediate lobe of the pituitary (NIL) for the L-5-hydroxytryptophan (5-HTP)-induced increase in plasma prolactin (PRL). Because oxytocin has been shown to exert PRL releasing effects both in vivo and in vitro and is found in nerve terminals within the NIL and median eminence, we analyzed the effect of a potent oxytocin antagonist on plasma PRL concentrations during several experimental paradigms where PRL undergoes a dynamic increase. The oxytocin antagonist [1-deaminopenicillamine, 2-O-methyl tyrosine, 8-ornithine] vasotocin (dPOMeOVT), was graciously supplied by Dr. Maurice Manning (Department of Biochemistry, Medical College of Ohio). The effects of dPOMeOVT (30 µg/kg, i.p., 30 or 40 min prior to sacrifice) on the PRL, adrenocorticotropin (ACTH) and β-endorphin-like immunoreactivity (β-END) responses were examined using the following paradigms: (1) suckling stimulus (30 min by 8 pups following 5-1/2 hrs pup-removal), (2) 5-HTP injection (50 mg/kg, i.p., 15 min) or (3) ether stress stimulus (3 min). Plasma PRL, ACTH and β-END were analyzed by radioimmunoassay. Suckling resulted in a 25-fold increase in plasma PRL and substantial milk ejection as indicated by an average weight gain of 4.4 ± 0.3 grams/group of 8 pups in 30 min. The oxytocin antagonist did not affect basal or suckling-stimulated PRL or basal ACTH and β-END. However, the milk ejection reflex was completely suppressed by the oxytocin antagonist (pups of dPOMeOVT-suckled dams actually lost an average of 2.2 ± 0.9 grams/8 pups). 5-HTP administration caused a large increase in PRL, ACTH and β-END. The oxytocin antagonist did not alter basal or 5-HTP-induced increases in the plasma concentrations of any of these three hormones. Ether stress increased plasma concentrations of all three hormones. Blockade of oxytocin receptors did not statistically significantly affect basal or ether stress-induced changes in PRL, ACTH or β-END. These data suggest that although oxytocin has been reported to demonstrate PRL releasing activity both in vitro and in vivo, this activity is apparently not a major component of the basal secretion of PRL, ACTH or β-END; or of the changes induced in the secretion of those hormones by 5-HTP, suckling or ether stress stimulus. Alternatively, the lack of effect of the oxytocin antagonist on PRL release may suggest that the pituitary receptors for oxytocin are distinct from those present in mammary gland or uterine tissues.

308.11 CHOLECYSTOKIN STIMULATES PITUITARY SECRETION OF OXYTOCIN: EVIDENCE FOR ACTIVATION OF CENTRAL NAUSEA PATHWAYS. J.G. Verbalis, C.M. McHale*, and E.M. Stricker, Departments of Medicine and Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15261.

Previous studies in this laboratory have shown that lithium chloride (LiCl), copper sulfate ($CuSO_4$) and apomorphine, agents assumed to cause nausea in rats because of their effectiveness in promoting the acquisition of learned taste aversions, each stimulated dose-dependent secretion of oxytocin (OT) but not vasopressin (AVP) in male rats. These and other results have suggested that plasma OT might represent a relatively quantifiable marker of visceral illness in rats when other stimuli to OT secretion are absent. Because it has been speculated that cholecystokinin (CCK) may reduce food intake in part due to the production of nausea, we studied OT secretion after administration of synthetic sulfated octapeptide of CCK to rats. Both intravenous and intraperitoneal CCK caused dose-dependent increases in plasma OT, but not plasma AVP, 1-2 minutes after injection (*$p<0.01$ compared to basal):

| CCK(µg/kg) | pOT(µU/ml) | |
|---|---|---|
| | i.v. | i.p. |
| 0 | 2.7 ± 0.4 | 1.3 ± 0.3 |
| 0.1 | 2.7 ± 0.4 | 1.6 ± 0.4 |
| 1.0 | 5.9 ± 0.8* | 3.0 ± 0.3* |
| 10.0 | 11.3 ± 0.8* | 13.8 ± 4.0* |
| 100.0 | 19.3 ± 2.2* | 21.5 ± 4.0* |

Plasma OT levels after CCK administration were comparable to levels after injection of nausea producing agents (LiCl, 1.5 mEq/kg and $CuSO_4$, 2.5 mg/kg), but returned to basal values by 15-20 min after injection. Because OT stimulation occurred with CCK doses near the threshold for its reduction of food intake, further studies were done in rats trained to a twice-daily feeding schedule of liquid diet. In control animals, plasma OT was significantly elevated by 5 min after the onset of feeding and rose to a peak of 10-15 µU/ml after consumption of 17 ± 2 ml in 20 min. These results indicate that pronounced gastric distention associated with rapid food ingestion can also provoke OT secretion, although graded levels of stimulation evidently can occur without sufficient gastric malaise to cause total cessation of eating. Using the same feeding schedule, administration of CCK (10 µg/kg i.p.) 5 min after the onset of eating transiently further elevated plasma OT to 15-20 µU/ml immediately after the injection, and as expected reduced total consumption to only 8 ± 2 ml by 20 min. Conversely, administration of CCK 20 min prior to the feeding period similarly elevated plasma OT levels immediately after the injection, but plasma OT then returned to basal levels by the onset of feeding and subsequent consumption was not reduced. These results are therefore consistent with CCK activation of central nausea pathways to account for at least part of its demonstrated effect to reduce food consumption.

308.12 **NEUROENDOCRINE NEURONAL MAPPING IN THE MACAQUE PROSENCEPHALON BY LUCIFER YELLOW BACKFILLING AFTER INFUNDIBULAR STALK TRANSECTION.** T. Song*, K.K. Thind and P.C. Goldsmith. Dept. of OB/GYN and Repro. Sci., U.C.S.F., San Francisco, CA 94143.

Lucifer Yellow (LY), a non-toxic, highly fluorescent dye, was used as a retrograde tracer to reveal the distribution of the neurons which project to the median eminence in primates. 5% LY in 16% solidified polyvinyl alcohol was applied against the proximal end of the infundibular stalk after high surgical stalk transection in Rhesus monkeys. Two days post-surgery, the animals were perfused with 3% paraformaldehyde/0.5% glutaraldehyde in 0.1 M sodium cacodylate buffer (pH 7.4). The brains were removed, Vibratomed (40 microns) in the frontal plane, and the sections examined under the fluorescence microscope.

Cell bodies with LY-fluorescent inclusions were found in numerous brain regions extending from the nucleus of the diagonal band of Broca (NDBB) back to the medial basal hypothalamus. Perikaryal labeling decreased rostrocaudally in cell bodies localized in: NDBB, and both its vertical and horizontal projections; nucleus accumbens; medial but not the lateral septal nucleus; posterior portion of the medial preoptic area; lateral preoptic area; anterior commissural nucleus; anterior hypothalamic area; dorsomedial and ventromedial hypothalamic nuclei; lateral hypothalamic area; anterior ventral periventricular region; lateral part of paraventricular nucleus; and the dorsolateral region of the supraoptic nucleus. In addition, some LY-fluorescent neurons appeared in thalamic regions, including the terminal striate and paracentral nuclei. Moderately labeled cell bodies were scattered in the globus pallidus. Only a few LY-labeled cell bodies could be observed within the anterior portion of the medial preoptic area and the arcuate nucleus, as has been reported in similar studies in rats (Lechan,R.M., et al., Brain Res., 195:13,1980). The median eminence, and supraoptic, paraventricular, and arcuate nuclei all contained moderately fluorescent fibers.

Some LY-labeled sections were irradiated with intense blue light (490 nm) in diaminobenzidine (DAB) until LY fluorescence disappeared, and then were osmicated and processed for electron microscopy (Maranto,A., Science, 217:953,1982). LY-photooxidized DAB had accumulated in lysosomes more than in perikaryal or fiber cytoplasm. No diffusion of LY-DAB label to adjacent structures was observed.

These results suggest similarities and differences between non-human primates and rodents in their final common neuroendocrine pathways, and offer a means to differentiate (1) preoptico- and tubero-infundibular pathways from preoptico-terminal and possible tubero-preoptic components in the primate; (2) neuropeptidergic vs. monoaminergic contributions to these pathways.

308.13 DIRECT EFFECTS OF NOREPINEPHRINE, ACETYLCHOLINE AND ESTROGEN ON THE MEMBRANE EXCITABILITY OF HYPOTHALAMIC PARVOCELLULAR NEURONS. T.P. Condon, O.K. Ronnekliev and M.J. Kelly, Department of Physiology, Oregon Health Sciences Univ., Portland, OR 97201

Medial basal hypothalamic (peptidergic) neurons control gonadotropin secretion in the guinea pig. These neurons receive both noradrenergic and cholinergic innervation and are regulated by gonadal steroid feedback. In the present study we have used the in vitro hypothalamic slice preparation from the female guinea pig to examine the effects of norepinephrine (NE) and agonists, acetylcholine (ACH) and estrogen ($E_2$) on the membrane excitability of arcuate (ARC) and cell poor zone (CPZ) neurons, wherein lie the peptidergic (LHRH) neurons controlling gonadotropin secretion. Sagittal hypothalamic slices from cycling (periovulatory) and ovariectomized, $E_2$-primed (OVX-$E_2$) guinea pigs were prepared as previously described (Kelly et al., Brain Res. Bull. 12:399, 1984). Extra- and intracellular recordings were made with procion yellow (PY)- and KCl/KCitrate-filled electrodes. NE ($10^{-7}$ to $10^{-3}$ M), ACH ($10^{-1}$ M), Methoxamine (MEX;α-agonist, $10^{-3}$ M) and $E_2$ ($10^{-8}$ M) were applied via the media or pressure injection. A number of cells were injected with PY and all slices were processed for peptide immunocytochemistry. The PY-identified ARC-CPZ neurons were small (7-15 μm) fusiform neurons, which were found in an area defined immunocytochemically by LHRH and β-endorphin staining. Sixty percent of the ARC-CPZ neurons (n=65) from intact guinea pigs were inhibited by NE. NE inhibition was characterized by membrane hyperpolarization and decreased input resistance ($R_m$). In contrast, 40% of the cells (n=18) recorded from OVX-$E_2$ animals responded to NE with increased firing, which was characterized by membrane depolarization. This excitatory response appears to be mediated by an α-adrenergic mechanism, since MEX application resulted in mostly excitatory responses. In addition several neurons displaying potent NE inhibition were also excited by MEX. Fifty-five percent of the neurons tested with ACH (n=49) showed excitation and only 30% were inhibited. ACH excitation was accompanied by marked membrane depolarization and decreased $R_m$, with $E_2$ priming having no effect on ACH responsiveness. Forty-eight percent of the neurons tested with $E_2$ (n=35) were inhibited with only 9% showing excitation. This $E_2$ inhibition was associated with membrane hyperpolarization and decreased $R_m$ and was independent of $E_2$ priming. Our findings indicate that NE acts via two distinct mechanisms (receptors?) to directly alter the membrane excitability of ARC-CPZ neurons, whereas ACH has a predominant excitatory and $E_2$ an inhibitory role. These findings further elucidate the noradrenergic mechanism(s) involved in the control of gonadotropin secretion. (Supported by PHS Grants HD 19905, HD 16793, and HD 06332.)

308.14 MORPHOLOGICAL EVIDENCE FOR THE EXISTENCE OF NEURONAL AND HUMORAL ULTRA-SHORT FEEDBACK REGULATORY MECHANISMS IN THE HYPOTHALAMUS OF THE RAT. Zs. Liposits, G. Sétáló, V. Csernus and W.K. Paull. (SPON: D.H. York). Depts. of Anatomy, Univ. Missouri-Columbia, Columbia, MO 65212 and Univ. Medical School, Pécs, Hungary.

The production and liberation of diencephalic hypophysiotrophic hormones are hypothesized to be regulated by ultra-short feedback mechanisms. Theoretically, this autoregulatory process might be executed via both neuronal and humoral channels. In order to elucidate the anatomical base of the former mechanism, corticotropin releasing factor immunoreactive (CRF-IR) neurons of hypothalamic paraventricular nucleus were analyzed by light (LM) and electron microscopic (EM)-immunocytochemical methods in long term adrenalectomized rats, which were also treated with dexamethasone (100 μg/100g b.w.) 24 hours before sacrifice. At LM level, CRF-IR axons were seen to contact CRF-synthesizing perikarya. These anatomical arrangements -at EM level- proved to be axo-somatic synaptic connections, indicating that corticoliberin modulates its own production. Local CRF-IR-axons were also observed to innervate magnocellular neurons in the same nucleus. The presence of CRF-IR material in the presynaptic boutons proves the neuromodulator nature of CRF. The possibility of a humoral type ultra-short feedback action of releasing hormones was studied in hypophysectomized female rats, bearing anterior pituitary grafts (obtained from 10 day neonatal rats) in the III ventricle. In one group of recipients one half of the median eminence (ME) was removed prior to implantation. The animals were allowed to survive for 6-12 weeks and consecutive hypothalamic sections containing the graft were immunostained for FSH-β, LH-β, TSH-β, LH-RH and CRF-immunoreactivities at LM and EM levels. Evaluation of the sections showed the following results: 1)Destruction of the ependymal lining of the III ventricle is essential to the formation of a neuro-glandular junction between the graft and the ME. In this case, only fenestrated capillaries (belonging to the subependymal plexus) separated the glandular tissue from neural, allowing humoral communication between them. 2) Pituitary grafts that received blood supply from the subependymal vessels of median eminence-arcuate region contained active, hypertrophied FSH, LH and TSH-immunoreactive cells that exhibited subcellular organelles characteristic for increased hormone production and release, while grafts which had vascularized outside the hypophysiotrophic area (HTA) from vessels lacking connections with the portal system, showed inactive cells. 3)The partial removal of the median eminence resulted in atrophy of pituitary cells on the side of lesion, without affecting the development of hypertrophied cells at the intact side. The morphological and functional maintainance of pituitary grafts, located within the HTA, proves that this territory receives its blood supply from the pituitary portal circulation. Thus it is very probable that neurohormones released into the portal circulation might also effect their own release or production via this vascular route in an ultra-short feedback manner. Supported by NIH grant NS 19266 to WKP.

308.15 irCRF SECRETION OF HYPOTHALAMIC CELL CULTURE: STIMULATION BY NICOTINIC CHOLINERGIC AGONIST. A.T. Lim* and W.Vale. The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Jolla, CA 92037.

Hypothalamic Corticotropin Releasing Factor (CRF) producing cells play the major, but not exclusive, role in the regulation of the secretion of ACTH and other POMC derived peptides by the anterior pituitary. We report here the measurement and regulation of CRF secretion by monolayer cultures of hypothalamic neurons from neonatal rats.

Hypothalami collected from 2-3 day old Sprague-Dawley rats were enzymatically dispersed, washed, counted and resuspended in culture medium; typically the procedure yielded $1{\cdot}5x10^6$ cells per tissue with greater than 95% viability as determined by trypan blue exclusion. $5x10^6$ cells per well were plated on poly-D-lysine pre-coated dishes and cultured in 10% fetal calf serum enriched B-PJ medium at 37°c with 93% air and 7% $CO_2$. Prior to secretion studies, the cells were washed and replenished in Hepes buffered Krebs Ringer bicarbonate solution followed by further 4h incubation with or without various agents. Media were then collected, acidified, lyophylised and reconstituted in assay buffer for rat CRF assay as previously described; routinely, the double antibody radioimmunassay has a sensitivity of 1.5 pg per tube. (Vale, W., et al. Methods In Enzymology., 103:565, 1983).

Basal secretion of CRF by hypothalamic cultures was 3.2 ± 0.2 pg irCRF/dish (mean ± SEM; n=10). High medium potasium as well as acetylcholine and the nicotinic agonist, nicotine, stimulated secretion of irCRF. Nicotine $EC_{50}$ and $E_{max}$ effects were observed at $0.5 \times 10^{-3}$M and $10^{-3}$M releasing 5.8 ± 0.2 pg irCRF/dish and 11.7 ± 0.4 pg irCRF/dish respectively. In the presence of $10^{-4}$M hexamethonium, $10^{-3}$M nicotine released only 4.5 ± 0.3 pg irCRF/dish. $10^{-9}$M of the synthetic glucocorticoid, dexamethasone, actuely (<4 hrs) enhanced the nicotine induced secretion of irCRF; but 24 hour pretreatment with dexamethasone ($10^{-9}$M) strongly inhibited nicotine stimulated irCRF secretion. The mineralocorticoid, deoxycorticosterone was without effect.

We conclude that (i) irCRF is secreted from primary rat hypothalamic cell cultures, (ii) irCRF secretion is stimulated by a nicotinic cholinergic agonist and (iii) the stimulated release of irCRF can be modulated specifically by glucocorticoid.

308.16 PITUITARY CYCLIC AMP AND PLASMA ACTH RESPONSES TO CRF IN VIVO. G.J. Kant, M.A. Oleshansky, D.D. Walczak, E.H. Mougey,* J.L. Meyerhoff. Dept. Med. Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307.

We have previously reported that acute stress elevates levels of pituitary cyclic AMP in vivo. We have found that the stress-induced pituitary cyclic AMP elevations are highly correlated with increased plasma levels of 3 pituitary hormones, ACTH, β-endorphin and β-LPH, thought to be regulated by the hypothalamic peptide, CRF.

The present experiments were performed to determine whether the observed stress-induced increases in pituitary cyclic AMP could be the result of stress-induced CRF release. In all experiments described below, CRF (5 ug in 0.1 ml) was administered via an indwelling jugular catheter fifteen minutes prior to sacrifice by decapitation. Whole pituitaries were rapidly placed in 90°C sodium acetate buffer to inactivate adenylate cyclase and phosphodiesterase. Following sonication and centrifugation, supernatants were stored at -70°C until assayed for cyclic AMP by RIA using antibodies characterized in our laboratory. Trunk blood was collected in the presence of heparin and trasylol (a peptidase inhibitor) and centrifuged. Plasma was stored at -70°C until assayed for ACTH using a commercially available RIA kit.

In the first experiment, CRF administration increased levels of pituitary cyclic AMP and plasma ACTH. Pretreatment with 0.5 ml of CRF antisera 6 min prior to CRF administration greatly attenuated the CRF-stimulated increase in pituitary cyclic AMP seen in animals pretreated with normal rabbit sera.

In a second experiment, 15 min of footshock increased levels of pituitary cyclic AMP in sham-operated but not in pituitary stalk-sectioned rats, indicating that some factor of central origin was required for the stimulation of pituitary cyclic AMP response to stress. Exogenous CRF did increase levels of pituitary cyclic AMP in pituitary stalk-sectioned rats, demonstrating that the pituitaries were still able to respond to appropriate stimuli and suggesting that CRF might be the factor of central origin required.

We have found that the pituitary cyclic AMP response to stress is greatly affected by the time of day of stress exposure. Fifteen min of restraint stress at "lights on " (0600) increased levels of pituitary cyclic AMP over 10 fold while the same stressor failed to elevate cyclic AMP levels at "lights off" (1800). The plasma ACTH response to stress was also much greater at 0600. Therefore, in a third experiment, we administered exogenous CRF as above to rats at "lights on" and at "lights off". CRF adminstration at light onset markedly increased levels of pituitary cyclic AMP and plasma ACTH; while CRF given at the beginning of darkness had no effect on either cyclic AMP or ACTH levels. These findings may be related to the reported diurnal rhythm in endogenous CRF release.

Taken as a whole, these data support the hypothesis that the primary factor responsible for observed increases in levels of pituitary cyclic AMP following acute stress is CRF.

308.17 EFFECTS OF EPINEPHRINE ON PITUITARY CYCLIC AMP AND PLASMA HORMONES IN VIVO. E.H. Mougey*, G.J. Kant, D.R. Collins*, L.L. Pennington*, J.L. Meyerhoff. (SPON: C.F. Tyner) Dept. Med Neurosciences, Walter Reed Army Institute of Research, Washington D.C. 20307.

Although CRF appears to be the primary stimulus for ACTH release from the pituitary, both in vitro and in vivo studies suggest that catecholamines may also be important regulators of ACTH release. Epinephrine markedly potentiates CRF-stimulated ACTH release from pituitary preparations. In vivo, a combination pretreatment of CRF antisera and chlorisondamine, a blocker of peripheral catecholamine release, attenuates stress-induced ACTH release more effectively than either pretreatment alone.

We have reported that various stressors elevate levels of pituitary cyclic AMP. The stress-induced cyclic AMP response is highly correlated with the release of pituitary hormones thought to be regulated by CRF (ACTH, β-endorphin, β-LPH). Since epinephrine has been reported to potentiate CRF-stimulated pituitary cyclic AMP synthesis and since stress elevates levels of plasma epinephrine, the present study was conducted to characterize the effects of epinephrine on levels of pituitary cyclic AMP and plasma hormones in vivo.

Rats were injected with saline or epinephrine bitartrate (1 mg/kg IP) and sacrificed by decapitation 1, 5, 15, 30 or 60 min post-injection. Rats remained in their home cage until sacrificed. In addition, one group of rats was sacrificed without injection (controls). Whole pituitaries were placed in 90°C sodium acetate buffer for 15 min to inactivate adenylate cyclase. Pituitaries were then sonicated and centrifuged. Supernatants were stored at -70°C until assayed for cyclic AMP by RIA. Trunk blood was collected with heparin/aprotinin and centrifuged at 4°C. Plasma was stored at -70°C until assayed for adrenocorticotropin (ACTH), β-endorphin (β-EP), β-lipotropin (β-LPH), corticosterone (CS) and prolactin (PRL) by RIA.

Saline injection did not increase levels of pituitary cyclic AMP at any of the time periods at which animals were sacrificed. ACTH levels were somewhat elevated 5 min after saline injection but returned to control levels by 30 min. Corticosterone levels were increased at 15 min and remained elevated at 30 and 60 min. Prolactin, β-EP and β-LPH levels were not significantly increased by saline injection.

Epinephrine injection resulted in 4 fold increases in pituitary cyclic AMP levels at 15 min and 14 fold increases by 30 minutes. ACTH, β-EP and β-LPH levels were significantly elevated at 15, 30 and 60 min and CS levels were significantly elevated at 30 and 60 min compared to saline injected animals. Epinephrine injection, however, did not elevate PRL levels.

These data demonstrate that epinephrine can stimulate pituitary cyclic AMP synthesis and pituitary hormone release. Increases in plasma levels of the three hormones derived from the common precurser, proopiomelanocortin, are highly correlated whereas plasma PRL appears to be unaffected by epinephrine stimulation.

308.18 PLASMA CORTICOSTERONE RESPONSES TO ELECTRICAL STIMULATION OF THE BED NUCLEUS OF THE STRIA TERMINALIS. Jon D. Dunn, Dept. Anat., Sch. Med., Oral Roberts Univ., Tulsa, OK 74171.

Previous studies reported from this laboratory have shown that electrical stimulation of cytoarchitecturally distinctive sites within the amygdala results in differential plasma corticosterone responses. To further pursue the question of differential limbic influences on pituitary-adrenal function plasma levels of corticosterone (Cpd B) obtained prior to and following sham or electrical stimulation of the bed nucleus of the stria terminalis (BNST) were determined for adult female rats which had been anesthetized with urethane (1.3 g/kg). All rats were tracheotomized, placed on a heating pad and subsequently positioned in a stereotaxic apparatus. Hippocampal EEG, ECG, heart rate, blood pressure and respiration were routinely monitored; timed blood samples (0.2ml) were obtained from a catherized tail artery. Samples were taken at 0.5 min. prior to and at 5, 10, 15 and 30 min. after initiation of stimulation (monophasic square waves, 100μA, 50HZ, 0.5 msec, 1 sec on/1 sec off for 30 min.). For purposes of plotting corticosterone responses to stimulation a change in plasma Cpd B was considered different from no change when the average of the 5, 10 15 and 30 min. samples deviated by more than 10% from the pre-stimulus level. However, statistics were derived from Cpd B responses grouped according to stimulation site.

Whereas increased ($P<0.05$) plasma Cpd B levels followed stimulation of the medial aspect of the BNST, stimulation of the lateral aspect of the BNST resulted in decreased ($P<0.05$) plasma Cpd B levels. The overall increase in plasma Cpd B following medial stimulation was 14%; the overall decrease was 19%. The largest increase in plasma Cpd B (32%) occurred at 30 min. post-stimulation; the largest decrease (31%) occurred at 15 min. Stimulation of the most rostral or pericommissural aspect of the BNST produced plasma corticosterone responses similar to that observed following medial stimulation. In contrast no change in Cpd B levels were observed following either sham stimulation or stimulation of the corpus callosum, fornix or anterior commissure.

Considering the known amydaloid-septal connections, these data are consistent with our previous findings in that the evoked Cpd B responses paralleled those evoked by amygdaloid stimulation. These data also indicate that differential plasma Cpd B responses can be evoked from limbic forebrain areas other than those of the amygdala and hippocampus.

308.19 HALOPERIDOL INCREASES PLASMA BETA ENDORPHIN AND SERUM CORTISOL IN NORMAL HUMAN MALES. MM Murburg,* D Paly,* RC Veith,* KL Malas* and DM Dorsa (SPON: W Stahl) Departments of Psychiatry and Behavioral Sciences, Medicine, and Pharmacology, University of Washington, and VA Medical Center, Seattle WA 98108.

Dopamine plays a role in regulating pituitary secretion of certain pro-opiomelanocortin derived peptides, such as beta endorphin (βE) and adrenocorticotropin (ACTH) in animals. In rats, for example, the dopamine-blocking neuroleptic haloperidol causes an acute increase in plasma βE and ACTH (Giraud et al: Eur J Pharmacol 62:215-217, 1980), and dopamine inhibits release of βE and gamma endorphin from neurointermediate lobe (Dorsa et al: Endocoids, H Lal, AR Liss, Inc, 1984). To invesigate possible dopaminergic regulation of pituitary function in man, we have tested the effects of a single intravenous (IV) dose of haloperidol on plasma levels of βE and serum levels of cortisol in normal human subjects.

Ten drug and alcohol free normal males, aged 24 to 38, giving informed consent, were randomly assigned (five each) to treatment with intravenous haloperidol 0.03 mg/kg or placebo (sterile saline), which were administered between 10 and 11 in the morning following a 10-hour fast and abstention from caffeine and cigarettes. Arterialized venous blood samples were collected over a 30-minute period prior to injection (three samples) and at 5 to 30-minute intervals following injection (14 samples). Samples were extracted on a silica column (βE) and analyzed by radioimmunoassay for βE and cortisol.

Baseline βE and cortisol values were calculated using the first three (pretreatment) values for each individual. There was a significantly greater % increase from basal values of βE ($F = 6.62$; $df = 1.16$; $p \leq .05$) and cortisol ($F = 43.6$; $df = 1.16$; $p \leq .01$) in the haloperidol-treated, compared to the placebo-treated, subjects by two way analysis of variance. The mean increase in βE concentration for the haloperidol-treated subjects over the 210 minutes studied was significantly greater at 12.8 pg/ml ($p \leq .05$, Wilcoxon one-tailed t test) than the mean increase in βE concentration for placebo-treated subjects, 4.8 pg/ml. The mean change in cortisol concentration for haloperidol- treated subjects was 3.6 mcg/dl, significantly greater than the mean change for the placebo-treated subjects, -4.4 mcg/dl ($p \leq .05$, Wilcoxon one-tailed t test).

This data indicates that administration of intravenous haloperidol to normal human males causes acute release of βE and cortisol into plasma, compatible with dopaminergic regulation of human pituitary βE and ACTH secretion.

308.20 NALOXONE EFFECTS ON PLASMA [VASOPRESSIN] AND [OXYTOCIN] ELEVATED BY HISTAMINE, NICOTINE AND INCREASED [NaCl] IN CSF. J. Summy-Long, C. Denlinger*, D. Palm*, R. Hartman* and L. Rosella-Dampman*. Dept. Pharmacol., M.S. Hershey Med. Ctr., Penn. State Univ., Hershey PA, 17033.

Endogenous opioid peptides (EOP) inhibit release of oxytocin (OT) during dehydration and hemorrhage and thereby allow the preferential release of vasopressin (VP) from the hypothalamo-neurohypophysial system when it is of physiological importance (Brain Res. 309:362, 1984). EOP also attenuate release of OT during parturition (J. Steroid Biochem 20:1502, 1984) and secretion of VP by tail electroshock (J. Pharmacol. Exp. Ther. 226:373, 1983). It has been proposed from in vitro studies that EOP inhibit release of neurohypophysial hormones by an action on the neural lobe. We therefore investigated the effect of an opiate receptor antagonist, naloxone (NAL), on the plasma concentrations of OT and VP elevated by various pharmacologic stimuli, including histamine (HIS), nicotine (NIC) and increased [NaCl] in cerebrospinal fluid (CSF). If OT (or VP) release were attenuated by EOP regardless of the stimulus, the site of opiate action may be in the final common pathway, i.e. the neural lobe or magnocellular neuron. Adult male Sprague Dawley rats were injected s.c. with saline (Sal; 1 ml/kg) or NAL (5 mg/kg) 5 min before HIS (10 mg/kg i.p.), NIC (0.15 mg/kg or 1.5 mg/kg i.p.) or saline (control; 1 ml/kg i.p.). Rats with a cannula in the lateral cerebroventricle were injected intracerebroventricularly (IVT) with 10 μl of artificial CSF (0.16 M NaCl) or CSF containing 1 M NaCl. Animals were decapitated 60 sec (↑ [NaCl] CSF) or 10 min (HIS and NIC) after the stimulus or vehicle. VP and OT were extracted from plasma and quantified by RIA. Differences among groups (n5-15 rats/group) were determined by AOV, Newman Keuls and Student's t tests. The concentrations (pg/ml; x ± SE) of OT and VP in plasma were elevated ($p < 0.05$) by HIS (OT 10 ± 1 vs 36 ± 5; VP 1 ± 0.3 vs 91 ± 13), ↑[NaCl] CSF (OT 19 ± 2 vs 226 ± 77; VP 3 ± 0.1 vs 71 ± 22) and NIC at the high (OT 7 ± 0.5 vs 58 ± 7; VP 3 ± 0.3 vs 38 ± 7) but not low (OT 8 ± 1; VP 2 ± 0.1) dose. NAL increased further ($p < 0.05$) [OT] in plasma after HIS (224 ± 38), NIC (0.15 mg/kg, 25 ± 5; 1.5 mg/kg, 317 ± 49) and ↑[NaCl] CSF (880 ± 207). NAL also increased ($p < 0.05$) [OT] in controls (NAL-CSF 38 ± 6, NAL-SAL 15 ± 2). [VP] was unaffected by NAL in either controls (NAL-CSF 4 ± 0.4; NAL-SAL 3 ± 0.3) or stimulated (NAL-HIS 121 ± 30; NAL-NIC, 0.15 mg/kg 2 ± 0.3, 1.5 mg/kg 40 ± 8.0; NAL-↑[NaCl] CSF 82 ± 9) rats. NAL increased plasma [OT] but not [VP] in response to each stimulus. The data are consistent with the hypothesis that endogenous opioid peptides inhibit release of OT in vivo by an effect on the final common pathway, i.e. the magnocellular neuron or neural lobe (supported by NIH HL32826).

309.1 NEUROMUSCULAR PLASTICITY: A CRITICAL PHASE. C. Winkelmann, B.T. Stokes, P. Gorman*, P.J. Walters*, and P.J. Reiser*. Dept. of Physiology, Ohio State Univ., Sch. of Med., Columbus, OH 43210.

Previous work in our laboratory and elsewhere suggests that a critical developmental phase exists for the final stage of differentiation of the latissimus dorsi muscle group in the chick embryo. It is the hypothesis of our group that this final development of fast twitch muscle characteristics is directly under the influence and is precipitated by alterations in motor unit activity that occur during this period. To test this hypothesis, we have conducted a series of studies on the electromyography of the PLD (posterior latissimus dorsi-fast twitch) and ALD (anterior latissimus dorsi-slow twitch) muscles in situ from 13-20 days of development. In addition, we have studied the normal and altered development (neuromuscular blockade) of the mechanical characteristics of the PLD in vitro during this same time period. Such a regimen has allowed us to distinguish those characteristics of myogenesis that are most dependant on functional innervation during development.

The electromyographic studies revealed that clear differences exist in the spontaneous output of motor units to the ALD and PLD during this period. While burst frequencies and content are essentially the same to the ALD and PLD, a considerable decrease in the interburst interval takes place only to the PLD fibers. During this period, the PLD is also undergoing inordinate changes in its functional characteristics. Normalized peak tension, time to peak tension, maximal rate of force development, and time to half relaxation, all essentially achieve their adult characteristics by changing 334%, 66%, 354% and 437%, respectively, from 14-20 days in ovo. These data provide a temporal framework for the investigation of the effects of functional immobilization on the development of this model neuromuscular system.

Isometric contractile properties of PLD muscles isolated from control (saline injected) and chronically immobilized (days 8-18 in ovo) embryos were compared at 18-19 days in ovo. Embryonic motility observations indicated that the immobilization protocol resulted in a motility reduction of >80% in treated embryos from days 10-18 in ovo. Compared to control embryos, mass, length and cross-sectional area were considerably reduced in immobilized animals. In addition, normalized twitch and tetanic tensions were considerably reduced while the relaxation phase of the response became much longer. The time to peak tension for the twitch response doubled while that for the tetanus did not change. These alterations suggest that the functional activity of the sarcoplasmic reticulum (as revealed in the relaxation kinetics) is much more dependant on activity in developing muscle than is the myosin enzyme composition (rising phase kinetics). (Supported by the Muscular Dystrophy Association)

309.2 **DEVELOPMENTAL EXPRESSION OF TRANSMITTER PHENOTYPE IN DOPAMINERGIC NEURONS.** E.G. Sieloff, M. Lazoff, J. McLean and M.T. Shipley. (SPON. G. Blaha). (University of Cincinnati College of Medicine).

The laminar architecture of the main olfactory bulb (MOB) makes it a useful model for studying the factors that regulate the development of neuronal specificity. To investigate the relationship between neuronal development and neurotransmitter expression in the MOB, we have studied the expression of the enzyme tyrosine hydroxylase (T-OH) in dopaminergic (DA) neurons.

In the adult rat, DA is found only in superficial tufted and periglomerular neurons. These cells are born in the ependymal zone and migrate to their destinations in the most superficial layer of MOB (Hinds, 1968). Three possibilities exist for the developmental expression of the DA phenotype. The enzyme may be expressed: 1) at neuronal birth, 2) as the neurons are migrating from the proliferative zone, or 3) after the neurons are inserted into their definitive circuit matrix.

The expression of T-OH in MOB of developing rats was demonstrated by immunocytochemistry. We found that T-OH activity is expressed only after neurons have migrated to the glomerular and superficial part of the external plexiform layers. The progressive increase in DA neuron cell number parallels the ingrowth and maturation of primary afferent and centrifugal fiber systems that terminate in the glomeruli. By ca. 37 days most DA neurons appear to have reached the periglomerulur region but they are crowded in the deeper parts of the glomeruli. Over the next 20-40 days, the neurons redistribute themselves and encapsulate the glomeruli as in the mature bulb.

Removal of primary olfactory neuronal (PON) input to the MOB causes a transient loss of DA activity in the adult bulb, (Kawano and Margolis, 1982) suggesting that the maintenance of the DA phenotype depends upon PON inputs. The present results suggest that the developmental expression of the DA phenotype may also be modulated by synaptic contacts. Alternatively, the signal for T-OH expression may be the formation of contacts between DA neurons and their target cells in the glomeruli.

Given the ordered and relatively simple structure of the glomeruli and our growing knowledge of the ontogenetic development of their circuitry, it should be possible to identify the factors regulating T-OH expression for these central DA neurons. Such information may improve our understanding of the events influencing the survival and function of dopamine neurons implanted to alleviate Parkinson's disease.

309.3 COMBINED LINEAGE AND DYE-COUPLING STUDIES OF NEUROGENESIS IN XENOPUS LAEVIS. C.F. Ide, J.S. Morrow*, R.W. Snow, J.S. Ahluwalia*, and F.E. Dudek. Dept. of Biol., Tulane Univ., New Orleans, LA 70118 and Dept. of Physiol., Tulane Univ. Sch. Med., New Orleans, LA 70112.

Although gap junctions are generally thought to be important in development, their possible role in determination of neuronal phenotype remains unclear. To define the relative contributions of cell lineage and gap-junctional communication in setting neural cell fate, we simultaneously labeled embryonic cells with a lineage marker (horseradish peroxidase, HRP) and a dye that permeates gap junctions (Lucifer Yellow, LY) to determine the subsequent identity of the dye-coupled neuronal phenotypes.

LY and HRP (4% wt/vol) were simultaneously pressure-injected from micropipettes into single cells of embryos in the midblastula (6-7) stage. The extent of dye injection was determined by briefly viewing LY fluorescence with a silicon intensified target camera. Animals were allowed to develop to embryonic stage 38-40, fixed for 10 min in 1% phosphate-buffered (pH 7.3) paraformaldehyde, and reacted for HRP using diaminobenzidine. Developed embryos were post-fixed for 20 min in 3% paraformaldehyde, embedded in plastic (Immuno-bed) and sectioned at 8 μm. We assayed which phenotypes and/or regions were marked by HRP-LY and which were marked with LY alone. Labeled cells appeared in adhesive gland, olfactory epithelium, retina, lens, prosencephalon, mesencephalon, and rhombencephalon. When HRP-LY was found in mesencephalon, rhombencephalon and/or retina, LY appeared alone in prosencephalon; in other embryos, the opposite was true. A similar relationship was seen between olfactory epithelium and lens.

Since LY appears in phenotypes and regions other than those marked by HRP-LY, cells which are dye-coupled during early development do not necessarily share the same range of potential cell fates. Thus, cells may be interacting via junctional communication at the time they (and their potential progeny) become channeled into different determination pathways. Injection at progressively later developmental stages should reveal if other (and more restricted) specific HRP-LY:LY combinations appear as development proceeds.

309.4 THE AMPHIBIAN MAUTHNER CELL IS DETERMINED DURING VERY EARLY NEURULATION. D.H. Schlenoff* and P.G. Model. Dept.Neurosci., Albert Einstein Coll. Med., Bronx,N.Y. 10461.

The Mauthner cell (M-cell) is a uniquely identifiable neuron found as a single pair in the medullae of fish and premetamorphic amphibians. In the axolotl (Ambystoma mexicanum), they are first recognizable in late tailbud embryos. The cells that give rise to M-cells undergo their final DNA synthesis long before this time, during late gastrulation, just prior to the onset of neurulation. Experiments were conducted to establish the time at which the M-cell is determined, i.e., when it becomes restricted or irrevocably committed to its particular developmental pathway.

Using a classical approach, small pieces of prospective medulla containing the prospective M-cell were unilaterally excised from embryos at various stages of development and transplanted to the flank of host embryos. Light microscopic examination of young larvae revealed that grafts from embryos in which the neural folds had just formed around the neural plate (second half of stage 14) and older embryos contained M-cells, whereas the operated sides of donor medullae did not. Grafts contained both gray and white matter and often formed a ventricle-like area devoid of cells. Many of the grafts from mid-neurula stages contained two M-cells, perhaps indicating that the graft had been removed from inhibitory influences acting on one of the sister cells after the final cell division of the M-cell precursor.

Operations were similarly performed on very early neurulae (first half of stage 14). Grafts from these embryos sometimes contained M-cells and sometimes did not. In those experiments in which grafts did not contain these cells, the medullae of the donors were fully regulated and contained normal pairs. Later, by the second half of stage 14, the M-cell is present in grafts but not in donors. Clearly, determination of the M-cell occurs in the very early neurula. In one instance in which an embryo was operated on in the middle of stage 14, both the graft and the donor contained M-cells: this indicates that the period of determination continued for a short time after the cell in the graft had been committed to the M-cell pathway thereby allowing complete regulation of the donor.

We have established that the fate of the M-cell precursor is specified during very early neurulation, before the determination of many other neurons of the CNS.

309.5 DEVELOPMENT OF SUBSTANCE P IMMUNOACTIVITY IN XENOPUS EMBRYOS. B.C. Gallagher* and S.A. Moody. Department of Anatomy, University of Virginia, Charlottesville, Virginia 22908.

A recent report (Clarke, J.D.W. et al, J. Physiol. (1984), 348, 511-525), indicates that HRP-labeled antibodies to substance P stain Rohon-Beard cells in whole mounts of stages 37/38 Xenopus embryos. Developmental processes which lead to differentiation can be followed using an early-differentiating cell such as the Rohon-Beard neuron, and the production of a phenotypic peptide would aid the identification of these cells. The present study characterizes substance P-like immunoactivity when performed on sections of Xenopus embryos, in order to determine whether the staining is confined to Rohon-Beard neurons using this method and at what stages substance P-like immunoactivity is detected.

In the adult spinal cord of Xenopus, the only immunoactive cell bodies are those of the dorsal root ganglia. At stages 37/38, substance P-like immunoactivity is seen in ventral diencephalic neurons. Trigeminal ganglion cells are stained, as well as peripheral axons of that nerve to the cement gland and central axons in the ventro-lateral tract. In the rhombencephalon, cranial interneurons and large basal plate neurons show substance P-like immunoactivity. Stained axons are present in the cranial myotome with apparent synaptic varicosities. In the spinal cord, Rohon-Beard cells are consistently stained. Ventral neurons no longer stain as frequently, but interneurons stain in this region as well as the cranial region. Substance P-positive axons in the dorsal myotome compartment exhibit apparent synaptic varicosities near myotubes.

At stages 29/30, fewer cells stain but the pattern of immunoactivity is similar to that seen at stages 37/38. At stage 21, the time of axonal outgrowth of many primary neurons (Huang and Jacobson, in press), substance P immunoactivity could not be detected by the method employed in this study.

Using standard immunohistochemical procedures on frozen sections of Xenopus embryos, we have demonstrated that several neurons other than Rohon-Beard cells produce substance P. These cells all appear to be among those first born (primary neurons) in the frog CNS, as described by Lamborghini, J.E., J. Comp. Neurol. (1980) 189, 323-333. These cells are not immunoactive at developmental stages at which axonal outgrowth is beginning, but are strongly immunoactive at stages in which target cells have been contacted. Furthermore, immunoactive axons with several varicosities were found not only in the typical "sensory" areas (i.e., in the cement gland and under the epidermis), but also among muscle cells. Supported by NIH NS20604.

309.6 **RETINAL NEUROGENESIS IN EMBRYONIC AFRICAN CICHLID FISH** **Linda C. Shelton*, Russell D. Fernald and Joelle C. Presson, Institute of Neuroscience, Univ. Or., Eugene, Or. 97403**

**Teleost fish grow throughout life and their eyes enlarge correspondingly. Retinal area increases as a result of new retinal cells of all types being added concentrically from the retinal blastemal zone around the iris margin. In addition, newly generated rods are intercalated into existing retinal tissue which is being stretched. The production of rods, after the generation and differentiation of all other retinal cell types, may recapitulate the generation of retinal cells in the embryo, an hypothesis we wished to test.**

**We have analyzed embryonic retinal neurogenesis in the mouthbrooding African cichlid fish, Haplochromis burtoni. Time of fertilization was obtained by behavioral observation of spawning, and mothers with fertilized eggs kept in isolated tanks. Normally, the eggs hatch into larvae in the mothers mouth, and free swimming fry emerge in 12-14 days. By this time the retina is adult-like in structure and growth pattern. At various times during development, larvae were removed from the mothers' mouth and injected with $^3$H-thymidine. The animals were allowed to survive for 30 minutes to 1 month before they were sacrificed, fixed, embedded in plastic, sectioned at 3-5μ and processed for autoradiography.**

**Embryonic teleost retinal development proceeds along a vitread-sclerad gradient similar to that found in other vertebrates. Differentiation begins just dorsal to the location of the optic nerve in the developing eye cup. Four days after fertilization, the beginning of organization within the (inner plexiform layer) IPL is seen and ganglion cells are located near the vitreal surface. By four and a half days, (inner nuclear layer) INL organization of differentiated cells is evident and at five days, cells in the (outer nuclear layer) ONL are distinct but unidentifiable at the light level. Subsequently, a second developmental gradient occurs along the ventro-temporal to dorso-nasal axis. This appears as a wave of cell division, seen only in the ONL. From $^3$H-thymidine labelling, we know that these cells arise from a source which can be labelled at day 4 and which is in the temporal region of the developing eye. The cells produced appear to be rod nuclei at the light level.**
**Supported in part by NIH EY 05051 to RDF.**

309.7 EMBRYONIC DEVELOPMENT OF THE SONIC MOTOR NUCLEUS IN THE OYSTER TOADFISH, OPSANUS TAU. A.J. Galeo, M.L. Fine and J.A. Stevenson. Depts. of Biology and Anatomy, Virginia Commonwealth University, Richmond, VA 23284.

The sonic motor nucleus (SMN), a likely homoloque of the hypoglossal nucleus, provides the final common pathway for sound production in the oyster toadfish (Opsanus tau). Previous work indicates that SMN neurons increase in size and number for 7 to 8 years postnatally. This study attempts to describe normal embryonic development of the SMN and to experimentally demonstrate cell origin, migratory route and rate of addition of neurons pre- and postnatally using 3H-thymidine autoradiography. Toadfish embryos were reared in the lab, fixed daily and staged following Tracy (1959). The sonic apparatus differentiates late in development. The swimbladder develops (Tracy stage 5, myotome motility) as an outpoocketing of the gut, and the sonic muscle from myotome 2 and its encased sonic nerve grow down from the occipital spinal cord (stage 7, attached larva) and adhere to the swimbladder wall (stage 8, free swimming).

An SMN containing between 27 and 50 cells was first recognizable at 19 days post fertilization. Neuron number increases slightly through stage 6 and more dramatically in stages 7 and 8, with stage 8 averaging about 330 cells. Mean soma area increases gradually between stage 5 (21$\mu m^2$) and 6, levels off at about 30 $\mu m^2$ (early and late 6 and 7), and increases at stage 8 (51$\mu m^2$). Mean nuclear area follows a similar pattern. SMN volume increases from about 2.3 X $10^3$ $\mu m^3$ in stage 5 to 124 X $10^3$ in stage 8. Initially, the SMN is situated entirely within the spinal cord, but it grows forward during development so that by stage 8 the rostral pole extends into the medulla, just beneath the fourth ventricle. This finding provides further support for our suggestion of hypoglossal homology.

3H-thymidine autoradiography demonstrates that SMN cells are added slowly but continuously during embryonic development. Labeled cells are also present in young and young adult (sexually mature) toadfish, in agreement with our previous finding of long-term ontogenetic changes in the SMN. Cells originate in the ventral ependymal lining of the central canal and migrate downward to assume their final position in the nucleus.

309.8 MIGRATION BY PERIKARYAL TRANSLOCATION FROM THE RHOMBIC LIP IN THE CHICK EMBRYO MEDULLA. K. Book*, J. Ganchrow*, and D.K.Morest. Anatomy Dept., U. Conn. Health Center, Farmington, CT 06032.

The matrix zone bordering the rhombic lip is the source of a large number of nuclear groups in the medulla. Golgi, reduced silver, and toluidine blue methods have been used in Hamburger-Hamilton staged embryos (E4-E8) to trace the migration routes to the auditory and vestibular nuclei from the rhombic lip between cranial nerves V and IX. The neuroblasts migrate by elongation and perikaryal translocation. Three main migratory pathways have been identified in this region: medial, ventral, and circumferential. Particular groups of neuroblasts favor specific migration routes depending on their destination and neuronal type. These migration routes have no consistent relationship with radial glial cells (or primitive epithelial cells).

The migration of neuroblasts to nucleus magnocellularis (avian homologue of the cochlear nucleus) provides one example of migration and early differentiation of neuroblasts in this area and has been studied in detail. Prior to migration (E4.5-5) the neuroblasts have their perikarya in the matrix zone and possess a primitive ventral process, which may bend laterally and remain within the rhombic lip or penetrate the mantle zone. This process grows out of the matrix zone, often led by a large foliate growth cone. At this time cochlear nerve fibers, tipped with growth cones, approach and may even enter the matrix zone in this region. By E6 the anlage of nucleus magnocellularis can be located in the mantle layer beneath the rhombic lip. The perikarya of neurons migrating to this nucleus may still remain in the matrix zone while extending a medially directed axon from the ventral process. The axon may bifurcate into medial and lateral branches in the presumptive nucleus or in the transition area between the matrix and mantle zones. This transition area provides a region where the leading and trailing processes of the neuroblasts tend to spread out horizontally. Migration is consummated by a translocation of the perikaryon to the vicinity of the axon's origin. The post-migratory cell becomes oriented either perpendicular to the matrix zone (rostrally) or diagonal to it (caudally); at this stage it sends an axon into the crossed tract, typically with a collateral recurving dorsally. The young post-migratory neurons have few dendrites and are fusiform in shape. At E7-E8 dendrites and axonal branches begin to spread out. (Supported by NIH grant RO1 NS14354.)

309.9 DIFFERENTIATIVE CAPACITY OF AVIAN NEURAL CREST CELLS INTO SKELETAL MUSCLE CELLS IN THE EYE MUSCLE. T. Yamashita* and G.S. Sohal (SPON: T.M. Nosek). *Dept. of Anat., Sch. of Med., Kanazawa Univ., Kanazawa 920, Japan; Dept. of Anat., Med. Coll. of Georgia, Augusta, GA 30912.

It is known that cranial neural crest cells differentiate into neural, skeletogenic, connective, and glandular tissue cells. However, concerning skeletal muscle cells, their differentiative capacity remains obscure.

The cranial neural crest together with the adjacent neural fold of duck embryos at stage 9 of Hamburger and Hamilton was removed or replaced with that of quail embryos at the same stage. The iris of the operated embryos on day 20 was examined by light and electron microscopy and compared with that of normal duck and quail at the comparable stage. Quantitative analysis of nuclear heterochromatin of the skeletal muscle cells in the iris of duck, quail and their chimaera was performed by cutting out the nucleus profiles from electron micrographs, cutting out the heterochromatin profiles from the isolated nucleus profiles, and then weighing them.

Extirpation of the cranial neural crest resulted in formation of small irides containing smooth muscle cells but lacking skeletal muscle cells. Transplantation of the cranial neural crest from quail to duck produced normally-organized irides containing numerous cells which showed a large heterochromatic mass peculiar to quail cells. However, distinction of skeletal muscle cells from the other kinds of cells in the iris, such as smooth muscle cells, mesenchymal cells, and Schwann cells, was difficult under light microscope.

Quantitative analysis of nuclear heterochromatin revealed that 23 (8%) among 283 nucleus profiles of skeletal muscle cells in the chimaera iris showed an enormously large heterochromatic mass of 2.3 $\mu m^2$ or more in area, which was found in 16% of those in the quail iris but in none of those in the duck iris. The proportional value of average heterochromatin size per nucleus profile to average nucleus size was 9% for the chimaera. This value corresponds to that (10%) for the quail but not to that (3%) for the duck.

Based on these findings, it is concluded that avian neural crest cells can differentiate into skeletal muscle cells.

Supported in part by grants from NIH (HD 17800 & HD 18280).

309.10 MONOCLONAL ANTIBODIES THAT DISTINGUISH AMONG NEURONAL SUBSETS IN THE SPINAL CORD OF THE CHICK EMBRYO. M.J. O'Donovan[1], R.T. Caldwell*, J.A. Morrison*, and J.L. Denburg. Depts. of Biology and Physiology & Biophysics[1], Univ. of Iowa, Iowa City, IA 52242.

The nervous system contains many different subsets of neurons. Hybridoma techniques have been used to isolate monoclonal antibodies (MAbs) that selectively bind to and thus identify some of these neuronal subsets. We have applied these techniques to help in the identification of subsets of neurons in the dorsal root ganglion (DRG) and spinal cord of the chick embryo.

Spinal cords were removed from 7 day embryos, sonicated in phosphate buffered saline and centrifuged at 100,000 g for one hour. Each mouse was injected with the insoluble pellets from 7 chicks. Spleens were isolated and fusions were performed in the usual manner. Hybridoma supernatants were screened for binding to frozen sections of stage 28 embryos in the region of the lumbosacral cord. The embryos had been fixed for 2 hours in 4% paraformaldehyde.

In the 7 day chick embryo motor and DRG neurons can be identified morphologically and physiologically. Although less is known about spinal interneurons, those of the hindlimb pattern generator are already functional. Therefore, neuronal subsets of the chick nervous system are already present at this stage of development. We have been able to isolate MAbs that selectively bind to some of these subsets.

As expected most of the MAbs bound to some extent to all the cells in the embryo. A small number bound selectively to the nervous system and the adjacent myotome. However, of particular interest were those that selectively labeled some cells within the nervous system. Three categories of such MAbs have been isolated. These include:

1. Those that bind only to CNS neurons
2. Those that bind only to peripheral neurons
3. Those that selectively bind to neurons in the lateral motor column and the DRG.

These results indicate that there are molecular differences between central and peripheral neurons at this stage of development. The developmental regulation and molecular characterization of these molecules is currently under investigation. In addition, the molecular similarities between motor and DRG neurons could be the result of the early maturation of these cell types or related to their pattern of peripheral and central synaptic connectivity.

(Funded by NIH grant NS 14295)

309.11 A DEVELOPMENTALLY REGULATED GANGLIOSIDE IN THE RAT CENTRAL NERVOUS SYSTEM DEFINED BY A MONOCLONAL ANTIBODY. A. S. Blum*, M. Constantine-Paton and C. J. Barnstable. Lab. of Neurobiology, The Rockefeller Univ. New York, N.Y. 10021.

A monoclonal antibody, JONES, displays discrete binding in the developing rat CNS. Punctate labelling is seen in the ventral forebrain, the optic vesicle, and the rhombic lip of the hindbrain by E9. Later, by PN1, JONES binding reveals a dorsal to ventral gradient distribution across the retina. From PN7, JONES binding decreases in the retina and in the adult, persists only as a punctate band in the outer plexiform layer.

We observed that JONES immunoreactivity in the retina was labile to organic solvent pretreatment of cryostat sections. These data suggested that JONES might recognize a lipid. To test this, postnatal rat retinas were extracted using a modification of the Folch method (Folch,J. et.al., J. Biol. Chem., 226: 497, 1957). The extracted whole lipid fraction was subjected to thin layer chromatography (TLC). We adapted the method of Towbin, (Towbin,H. et.al., J. Imm. Meth., 72: 471, 1984), to blot the separated lipids onto nitrocellulose. They were then reacted with JONES and visualized with a HRP-conjugated second antibody. A single immunoreactive band was found. The complex lipid fraction was then extracted with 0.1M aqueous KCl which separates gangliosides from most other contaminating lipids. This fraction also revealed a single band upon TLC/blot analysis, whereas the residual organic phase lipid did not show any JONES immunoreactivity. Resorcinol staining identifies a ganglioside band comigrating with this immunoblot band. The JONES reactive material in the ganglioside fraction migrates very close to a GM2 standard; however, JONES does not recognize human GM2. Analysis of adult rat retinal gangliosides fails to detect any JONES immunoreactivity. PN7 rat cerebellar gangliosides reveal positive immunoreactivity identical in migration to retinal extracts, but PN7 forebrain gangliosides are negative. Interestingly, JONES fails to cross-react with mouse or chick retina, or bovine gangliosides.

To understand more about the metabolism of the JONES antigen, we have produced a mouse neuroblastoma x rat E15 neuroblast somatic cell hybrid. JONES positive and negative variants of the cell line have been selected by fluorescence activated cell sorting. The JONES reactive ganglioside in the positive subclone shows the same chromatographic properties as that from rat retina, and the JONES unreactive subclone is negative by this method.

The chemical basis for JONES antigenicity is currently being investigated as are the possible functions which this antigen subserves in development.

309.12 DISPERSED CELL CULTURES OF THE INNER EAR OF THE CHICK EMBRYO. S.H. Hauger and D.K. Morest, U. Conn. Health Center, Farmington, CT 06032.

We are studying interactions between the neurons of the cochlear and vestibular ganglia and their peripheral synaptic targets, the auditory and vestibular sensory epithelial cells (hair cells). In an organ culture system, we previously observed a trophic effect of the otocyst on these neurons (Ard et al., Neurosci. '85). In order to identify the cellular basis for this effect we are studying dispersed cell cultures.

From stage 23-42 embryos we removed basilar papillae, labyrinths, and cochlear and vestibular ganglia, dispersed the cells enzymatically, and plated them on a dried film of rat tail collagen.

Cultures of ganglia and epithelia together thrived for 1-2 mo and contained areas of fibroblastic cells surrounding monolayer islands of other cell types. Usually all the cells in a given island were similar in size, shape, and arrangement, suggesting that they were the same type. It remains to be shown that these include hair cells. Some cells resembled typical cultured epithelial cells (flat or slightly rounded, polygonal, cobblestone appearance). To verify the identification of epithelial cells we have used histochemical labeling with an antiserum against cytokeratins (Miles, Tissue Tek). Some, but not all of the putative epithelial cells stained, but the antibodies may not be specific for all cytokeratins.

In the foregoing cultures few cochleovestibular neurons were found. However, our growth conditions supported neurons dissociated from trigeminal and spinal ganglia very well. A variety of media, sera, and additives did not improve cochleovestibular neuron survival. This may reflect the lack of a specific factor needed by these neurons.

To enhance neuronal survival, dissociated cochlear and vestibular ganglia were added to pre-plated cochleovestibular cultures without neurons. Neuronal survival was slightly improved. After 1-2 wk the neurons had processes, eucentric nuclei, and Nissl substance. Some cells were notable for resembling cochlear neurons in situ. These were small and bipolar, with one short process and the other much longer, like the peripheral and central processes, resp., of cochlear ganglion cells. Studies in progress are aimed at identifying cultured hair cells with immunohistochemical and ultrastructural methods and at analyzing their interactions with sensory neurons.

309.13 THE RAT BRAIN SPECIFIC GENE 1B236 IS EXPRESSED IN CULTURES OF FETAL BRAIN. Dominique Lenoir*, Elena Battenberg, Floyd E. Bloom and Robert J. Milner*. Research Institute of Scripps Clinic, La Jolla CA 92037

Using recombinant DNA techniques, we have identified a rat brain specific protein, 1B236, which defines a widely distributed neuronal system (Cell 33:671, 1983). The time course of expression of this gene during rat brain development has been determined using both RNA and protein blotting techniques and immunocytochemistry. We have shown that the 1B236 gene is expressed postnatally, first in hindbrain around day P5, and then follows a caudal to rostral developmental pattern. The appearance of the protein closely follows that of its corresponding mRNA, suggesting that the developmental expression of 1B236 is probably regulated at the level of transcription. In order to investigate more precisely the characteristics of the regulation of this gene, we have developed a micro-explant culture system: a suspension of minced and triturated tissue fragments from dissected regions (telencephalon, midbrain, cerebellum and hindbrain) of day E19 fetal rat brains was cultured on collagen coated culture dishes. 1B236 protein was first detected after 15 days in vitro in hindbrain cultures using immunocytochemical staining with specific antisera raised against synthetic peptides corresponding to different regions of the protein sequence. Preliminary studies using protein blotting techniques show that the time course of expression of 1B236 in vitro mimics that in vivo: 1B236 protein is expressed earlier in hindbrain cultures than in cerebellum and midbrain cultures. The detection of multiple protein bands on the blot suggests the presence of post-translational modifications such as proteolytic cleavage or differential glycosylation. Further studies will better characterize the time course of appearance of the protein and its mRNA in vitro, the influence of glial cells on gene expression and the nature of the post-translational modifications. The late expression of 1B236 indicates that this protein is a marker for the terminal differentiation of particular neurons. In vitro studies of 1B236 gene expression, therefore, provide a very suitable system to study gene regulation during the final stages of neuronal development. 309.14 IDENTIFICATION OF NEURONAL SUBCLASSES IN DISSOCIATED HYPOTHALAMIC CULTURES. R. Ventimiglia* and H. M. Geller. Dept. Pharmacology, Rutgers Medical School, Piscataway, N. J. 08854, and MRC Neuroimmunology Project, Dept. Zoology, University College, London.

In order to facilitate studies of the cell biology of the hypothalamus, we have developed a technique for the culture of dissociated embryonic neurons in serum-free conditions, and have applied immunological techniques to identify the cell types in these cultures. The procedure which gave optimal results involved culture of hypothalami dissected from 16-18 day embryonic rat brains. The tissue was incubated in MEM-Hepes containing 0.05% trypsin and 0.1% collagenase for 15 min at 37 °C. Following removal of the incubation medium and addition of soybean trypsin inhibitor and DNAase, the tissue was triturated 10X with a Pasteur pipette. Attempts to disscociate by other enzymatic means (dispase or trypsin alone) or solely by mechanical disruption, proved unsuccessful. Cells were resuspended in serum-free N2 medium, and $10^4$ cells were plated onto an astrocyte monolayer growing on 13 mm glass coverslips in 24 well tissue culture plates. Cells adhered to the astrocyte monolayer and extended neuritic processes within 1 hr. after plating. Neurons were identified by staining of neurofilaments with monoclonal antibody RT97 (J. Wood, Sandoz Institute) as early as 1 day after plating. In cultures in which the astrocytes had not formed a confluent monolayer, neurons preferentially aligned along the astrocyte layer. When plated on coverslips coated with collagen, laminin, or polylysine alone, cells adhered poorly and showed little neuritic outgrowth. Hypothalamic neurons could be maintained in serum-free medium for as long as 5 weeks. The majority of neurons were 5-15 μM in diameter and classified morphologically as ovoid-bipolar or triangular-multipolar. Neurons impaled after 8 days in culture displayed both $Ca^{2+}$- and $Na^{+}$-dependent action potentials (B. Fulton, personal communication). In an attempt to identify cell-surface markers for neurons in these cultures, we conducted double-label experiments. A monoclonal antibody produced in the Neuroimmunology Unit stained the surface of the vast majority of cells displaying neuronal morphology, but did not label cells which stained with antibodies directed against GFAP or galactocerebroside. A large proportion of neurons which stained with RT97 were also labelled on their surface by monoclonal antibody A2B5 (Eisenbarth, et. al., 1979). Furthermore, neurons reacting with the vasopressin-specific monoclonal antibody BA-2 (M. Hanley, Imperial College) were detected after 4 weeks in culture. Our results indicate that subclasses of hypothalamic neurons in dissociated cultures can be identified using a variety of intracellular and extracellular markers. Growth of these neurons in serum-free conditions provides a system for the study of this brain region at the single cell level. (Supported by N.S.F. and N.I.H, and a Senior Fellowship of the Fogarty International Center, N. I. H.).

309.15 NEUROGENIC DIFFERENTIATION OF PERIOCULAR MESENCHYME CO-CULTURED WITH GUT. Linda C. Smith-Thomas*, Jeffery P. Davis*, Miles L. Epstein. Department of Anatomy, University of Wisconsin, Madison, WI 53706.

During vertebrate development, cranial neural crest (NC) cells migrate extensively within the developing head and give rise to much of the cranial and facial skeleton (LeLievre, 1978, J. Embryol. exp. Morph., 47, 17-38; Morriss & Thorogood, 1978, Development in Mammals, Vol. 3, North-Holland Publishing Company; Noden, 1978, Dev. Biol., 69, 296-312). In avian embryos, mesencephalic NC cells migrate to the optic cup by 52 hrs of incubation (St 14 - Hamburger & Hamilton) and condense to form the periocular mesenchyme. An interaction between these cells and the retinal pigmented epithelium (RPE) then takes place and as a result of this interaction, the periocular mesenchyme cells become committed to chondrogenic differentiation by 3.5 to 4 days (H.H. St 19-22) (Newsome, 1972, Dev. Biol., 27, 575-579). However, the actual onset of chondrogenesis is not until Day 7 (Romanoff, 1960, 'The Avian Embryo,' MacMillan), indicating that the RPE influence is not required to maintain the chondrogenic potential of the ectomesenchyme.

In order to investigate the influence of the gut environment on periocular mesenchyme (POC), explants of HH19-22 quail POC were co-cultured with chick 4.5 to 5.5 day aneural rectum on the chorioallantoic membrane for 7-8 days. Explants were fixed and sectioned on a cryostat. Slides containing sections were incubated with antiserum to vasoactive intestinal peptide (VIP), monoclonal antibody to neurofilament protein (NF), and bisbenzimide. Using the fluorescence microscope we observed many quail cells, visualized by the fluorescence of bisbenzimide, in the positions usually occupied by enteric ganglia. Many of these quail cells displayed VIP-like immunoreactivity and most showed NF-like immunoreactivity. These results indicated that HH St 19-22 POC cells were able to express neuronal phenotypes. Quail cartilage cells and melanocytes were also observed in the grafts.

These observations suggest that 1) the fate of cells committed to chondrogenesis may be changed to neurogenesis, and/or 2) a population of uncommitted cells within the population committed to chondrogenesis may be directed by the gut environment to form neurons.

309.16 VENTROBASAL THALAMUS IN INFANT RATS: EFFECTS OF TRANSPLANTATION AND PERIPHERAL RECEPTOR DAMAGE ON ACETYLCHOLINESTERASE-DEPENDENT STAINING. D.A. Kristt, Univ. of Maryland Sch. of Med., Baltimore, Md. 21201

The neurons of the ventrobasal complex (VB) of the thalamus of infant rat and mouse possess high AChE reactivity transiently during their maturation. Intracellular reaction product is detected from 19 days of gestation until 16-18 days postnatal. These neurons synthesize AChE, and resynthesize it after a challenge with an anti-cholinesterase, DFP. The purpose of the present experiments was to investigate two further points regarding the transient AChE phenomenon. The first question was whether the production of AChE by VB neurons was dependent on the localization of the cells to VB. To examine this issue VB from newborn rat pups was transplanted onto the frontal lobe of litter-mates. Following deep cold-anesthesia a pup was decapitated and the brain placed on a chilled platform where it was rapidly sectioned. A 500um slice was produced that contained the VB. The nucleus could be recognized because it was pinker than surrounding regions. The tissue was placed into a small excavation near the frontal pole of the host. The host was sacrificed at 6 dpn. The site of the implant was densely reactive for AChE. The VB implant contained many neurons densely reactive for AChE, while the remainder of frontal cortex contained relatively few reactive cells or fibers. These findings suggest that cellular environment of the VB is not essential for AChE synthesis to occur. In the second experiment the large mystacial vibrissae - tactile sensory organs - on one side of the face were denervated by undercutting the vibrissal pad neonatally. This resulted in total inactivity of the vibrissae on the lesioned side, and hyperactivity of the intact pad. Alterations in the pattern of staining normally present in VB occurred on both sides of the thalamus, although each VB nucleus was affected in a different way. It must be emphasized that the histochemical protocol in use always produced a consistent pattern of staining in VB. At 6 days of age VBM is uniformly more hyporeactive than VBL (Neuroscience 10:923 '83). The experimentally-induced alterations are not likely to be a histochemical artifact. At 6 dpn, VBM showed increased reactivity ipsilateral to the denervated vibrissae, i.e., both subdivisions were equally intensely stained. This may reflect increased activity of the intact vibrissal pad. Contralateral VB showed a focus of strikingly decreased reactivity limited to the vibrissal representation area of VBM. These data suggest that the functional status of the sensory periphery influences the reactivity, and probably the synthesis, of AChE in VB.

In aggregate all of these results indicate that the synthesis of AChE is an intrinsic characteristic of immature VB neurons that is subject to dynamic regulation. Support: NIH, NSF

309.17 GANGLIOSIDE GLYCOSYLTRANSFERASES ARE REGULATED DURING DIFFERENTIATION IN NG 108-15 CELLS. K.M. Walton and R.L. Schnaar, Depts. of Pharmacology and Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

Gangliosides are present in high concentrations in nervous tissue and may be important in neuronal cell function. Expression of individual ganglioside species is regulated in developing mammalian brain and upon transformation in many cell types. This laboratory has previously published data on a cell model for this regulation using NG 108-15 neuroblastoma x glioma hybrid cells (Dahms, N.M., and Schnaar, R.L. (1983) J. Neurosci. 3, 806-817). This cell line has four major gangliosides ($GD_{1a}$, $GM_1$, $GM_2$, and $GM_3$) and can be differentiated (as defined by increased choline acetyltransferse activity) by increased cell density or increased intracellular cyclic AMP levels. Upon differentiation, the amount of $GM_2$ (per mg protein) increases up to 12-fold over control levels. We have extended this work by examining the effects of cell density and differentiating agents on the glycosyltransferases responsible for $GM_2$ metabolism.

We developed a rapid and simple assay for UDP-GalNAc:$GM_3$ N-acetylgalactosaminyltransferase ($GM_2$ synthetase) using small DEAE-Sepharose columns. After incubation of NG 108-15 cell homogenates with $GM_3$, UDP-[$^3$H]GalNAc, dAMP, $MnCl_2$, and detergents in MES buffer, the reaction was stopped by addition of chloroform/methanol (2/1) and the mixture applied to a 0.5 ml column of the resin (acetate form). The column was washed with 2 ml methanol, the radiolabeled ganglioside eluted with 4 ml 10 mM potassium acetate in methanol, scintillant added directly and radioactivity determined.

Using this assay, we examined the activity of $GM_2$ synthetase in control cells and cells grown with 1 mM butyrate (a differentiating agent). Within two days after exposure, the activity of the enzyme increased over three-fold above control levels and reached a maximum of a six-fold increase after four days. Within four days, the amount of $GM_2$ (per mg protein) increased over eight-fold, and the levels of $GM_3$ decreased by three-fold. The levels of the other two gangliosides remained constant.

These data demonstrate a direct relationship between differentiation, an increase in $GM_2$ synthetase activity, and $GM_2$ expression in butyrate-treated NG 108-15 cells. In addition, these data indicate there may be coordinate control of the synthetases and/or glycosidases responsible for the metabolism of the other gangliosides which do not change concentration during differentiation. Supported by grants HD 14010 and GM 07626.

309.18 A MONOCLONAL ANTIBODY THAT RECOGNIZES A SUBPOPULATION OF ASTROCYTES IN CULTURE. S.David and T. Crossfield-Kunze*. Neurosciences Unit, The Montreal General Hospital Research Institute, and McGill University, 1650 Cedar Ave., Montreal, Canada, H3G 1A4.

It is possible to identify 2 morphologically different types of glial fibrillary acidic protein positive ($GFAP^+$) astrocytes in culture: (i), large, flat cells, and (ii), small, process-bearing cells. Recent studies indicate that these 2 types of astrocytes also differ in their ability to bind 2 cell surface ligands (Raff et al. J. Neurosci. 3: 1289, 1983). The small, process-bearing (type 2) astrocytes bind the monoclonal antibody A2B5 and tetanus toxin, whereas the large, flat (type 1) astrocytes do not bind these 2 ligands. We have now generated a monoclonal antibody (2.6C6) which recognizes a subpopulation of type 1 astrocytes in culture.

This monoclonal antibody was generated using $E_{19}$ corpus callosum as the immunogen. In a double indirect immunofluorescence assay on dissociated cultures of the neonatal rat cerebral cortex (including the corpus callosum), this monoclonal antibody binds to a cell surface antigen on approximately 35% of the large, flat, $GFAP^+$ astrocytes. It does not label the small, process-bearing astrocytes or any other cell type in these cultures. In frozen sections of brains from $E_{20}$ to adult rats, fixed in 4% paraformaldehyde this monoclonal antibody labels cells predominantly in the white matter, e.g. corpus callosum and optic nerve.

Developmental changes in this antigen were quantified by an enzyme linked immunosorbent assay in which homogenates of cerebral cortex from rats aged $E_{20}$, $P_4$, $P_{11}$, $P_{18}$, $P_{25}$ and adult were plated on polylysine coated microwells (100 µg protein/well). The binding of the monoclonal antibody 2.6C6 to the homogenates was then visualized using a secondary antimouse immunoglobulin conjugated to alkaline phosphatase. Preliminary results show no change in this antigen during development.

Experiments in which dissociated cerebral cortical cultures were incubated with either trypsin or neuraminidase indicate that this antigen is sensitive to trypsin but not to neuraminidase. (Supported by grants from the Canadian MRC and the Spinal Cord Research Foundation).

309.19 A DEVELOPMENTALLY REGULATED MONOCLONAL ANTIBODY TO THE CELL SURFACE OF NEURONS IN THE FOREBRAIN OF THE MOUSE. N.L. Baumrind, J.P. Cohen* and A.L. Pearlman. Departments of Cell Biology and Neurology, Washington Univ. Sch. of Med., St. Louis, MO 63110

During development, neurons destined to comprise the cerebral cortex divide in the ventricular zone, then migrate outward through the intermediate zone to the developing cortical plate. In order to identify cell surface markers specific to the stages of this process, monoclonal antibodies to developing mouse cerebral cortex were generated by fusing Sp2/0-Ag14 mouse myeloma cells with the spleen of a rat immunized against cells taken from the cerebral cortex of mice on embryonic day 13 (E13).

A monoclonal antibody (2A1) was obtained which labels cell bodies and processes of cells located outside the ventricular zone but does not label cells still within it. On paraformaldehyde fixed cryostat sections, 2A1 labels antigenic sites present in the mouse as early as E13. At this time, it labels the region which is about to become the cortical plate. At E15, the antibody labels the marginal zone and intermediate zone, regions containing neuronal fibers. Labelling surrounds cells of the developing cortical plate, but is excluded from the ventricular zone where cells are undergoing division. As development proceeds, newly formed fiber tracts such as the corpus callosum exhibit bright staining. Labelling persists in the adult. At all ages observed, cell membranes of the epithelium of the choroid plexus label strongly.

The 2A1 antibody also labels cell bodies and long processes of unfixed, unpermeabilized, cultured cortical cells, supporting the idea that the antigen is located on the cell surface. Labelled cells have morphologies characteristic of cultured neurons. Double-labelling indicates that 2A1 labels most but not all tetanus-toxin positive cells and most but not all A2B5 positive cells, but does not label cells that are labelled by astrocyte-specific antibodies to GFAP. These observations suggest that the 2A1 antibody is directed against a cell-surface component of neurons that have completed their last division and migrated out of the ventricular zone.

(Supported by research grant EY00621 from NEI.)

309.20 MONOCLONAL ANTIBODY TO HUMAN KIDNEY GLOMERULAR BASEMENT MEMBRANE IMMUNOCYTOCHEMICALLY STAINS PERIVASCULAR ASTROCYTES. D.R. Buskirk and M. Hadjiargyrou* The Rockefeller University, New York, NY 10021

Human glomerular basement membrane, obtained from Dr. Howard Fillit, was used to immunize Balb/c mice. After boosting, the splenocytes were fused with NS-1 myeloma cells using standard procedures.

Resulting hybridomas were screened for production of antibodies reactive to kidney by immunofluorescent staining of cryostat sections. Positive hybridoma clones were tested for reactivity to brain, once again by immunofluorescent staining of cryostat sections. One positive clone was identified which reacted with astrocytes in human cerebral cortex. This monoclonal antibody, designated III-70A, stained perivascular astrocytes and their processes. Also stained were white matter astrocytes, but this staining was less intense.

Monoclonal III-70A immunocytochemically stains cell nuclei as well as glomerular basement membrane and astrocytes. The antigen is not known, but has been determined not to be double-stranded DNA both by ELISA and by the antibody's failure to stain the kinetoplast of Crithidia luciliae.

The antibody was found to react with brain sections from a number of different species, including man, cow, rat, and mouse. In each, both perivascular astrocytes and nuclei were stained. However, at higher dilutions of antibody, the astrocytic staining in rats and mice disappeared while the nuclear staining persisted. In man, the antibody titers for both were approximately equivalent.

Although the staining of the cerebral cortex seemed to suggest that the nuclear staining was uniform among cell types, observation of the cerebellar cortex revealed that this was not the case. Although cells of the molecular layer and granule cells stained, the nuclei of the Purkinje cells did not seem to bind antibody. We dot not yet know if this represents a true antigenic distinction of the purkinje cells, or whether the same antigen is present in the nuclei of the Purkinje cells but unavailable for effective immunofluorescent staining.

309.21 CELL SURFACE CHANGES ACCOMPANYING THE NEURAL DIFFERENTIATION OF EMBRYONAL CARCINOMA CELLS. Joel M. Levine* and Patricia Flynn*, (SPON:C.Phelps) Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, New York, 11794.

Murine embryonal carcinoma cell lines can differentiate in vitro into neuron-like cells. To characterize the cell types present in the differentiating cultures, we have analyzed the expression of cell surface ganglioside and glycolipid antigens during the retinoic acid-induced differentiation of 01A1 cells.

The following antibodies and toxins were used to identify cell surface molecules: monoclonal antibody D1.1 directed against an O-acetylated ganglioside, antibody R24 directed against GD3 ganglioside (both of these antibodies bind to neuroepithelial cells but not to mature neurons or glial cells), antibody SSEA-1 which recognizes a glycolipid determinant present on many undifferentiated EC cells lines and on cells of the developing neural tube, antibody A2B5 which recognizes a GQ ganglioside and labels neurons and glial cells, cholera toxin which binds to GM1 ganglioside and tetanus toxin which binds to GD1b and GT1 gangliosides and is a cell surface marker for most neurons.

Undifferentiated 01A1 cells had the following phenotype: greater than 90% of the cells bound anti-D1.1, R24, SSEA-1, tetanus toxin and cholera toxin. Approximately 30% of the cells bound antibody A2B5. The cells did not contain neurofilament polypeptides or GFAP filaments but the cells were labeled with antibodies against vimentin. Thus, the phenotype of the undifferentiated cells resembles that of neuroepithelial cells.

To induce neuronal differentiation, the cells were grown for 3 days as aggregates in DME containing 10% fetal calf serum and $5x10^{-7}$M retinoic acid (RA). Following 2 days of culture as aggregates without RA, the aggregates were dissociated with trypsin and the cells were plated into defined media containing 5 µg/ml fibronectin. Within 1-2 hours, the cells began to put out processes and after 3-5 days in culture, greater than 80% of the cells were labeled with antibodies against the neurofilament triplet polypeptides. The neurons in the differentiated cultures no longer bound anti-D1.1 or R24 but continued to bind tetanus toxin and cholera toxin. Between 20 and 40% of the cells were labeled with A2B5 and less than 1% of the cells were labeled with SSEA-1. The cell surface changes deduced by antibody labeling studies were also evident when the cells were metabolically labeled with 3-H sugars and cellular gangliosides analyzed by TLC and fluorography. Thus, as 01A1 cells differentiate, they lose ganglioside antigens associated with primitive neurectodermal cells but continue to express surface markers characteristic of neurons and glial cells. These cell lines therefore provide a valuable model system for analyzing the function and metabolism of gangliosides during neuronal differentiation.

309.22 PRODUCTION OF MBP+ AND GC+ MEMBRANOUS SHEETS BY OLIGODENDROCYTES IN VITRO. P.E. Knapp, W.P. Bartlett and R.P. Skoff. Dept. of Anat. Wayne State University School of Med., Detroit, MI 48201.

The primary role of oligodendrocytes is to produce myelin. A fundamental step in this process is the elaboration by oligodendrocytes of large amounts of membrane which expand while wrapping around axons. This ability to produce vast expanses of membrane from the ends of cellular processes is unique in the CNS to the oligodendrocyte. The factors which affect production of oligodendrocyte membranes may be unrelated to the signal to commence myelination, which is known to reside in the axon. We have developed a culture system in which oligodendroglia produce large, membranous expansions in the absence of neurons. Using monoclonal antibodies against galactocerebroside (GC) and myelin basic protein (MBP) we describe their development in vitro.

Cerebra from 3d old mice were used to produce mixed brain cell cultures which were grown in 10% fetal calf serum or in a defined medium. Few neurons survive after one week under these conditions. In 10% fetal calf serum the first GC+ cells appear at 3-4 days in vitro (DIV). Their numbers increase and plateau between 14-21 DIV. At 7 DIV approximately 25% of all GC+ cells have processes which have begun to elaborate sheets. Immunolabeled sheets gradually develop as flattened expansions along the length of cylindrical processes. By 17 DIV as many as 70% of GC+ cells have produced these sheets, which are usually round to ellipsoid in shape, reaching diameters of 80-100u. In older cultures an oligodendrocyte may maintain multiple sheet-bearing processes. Preliminary studies combining (3H)-thymidine autoradiography with immunocytochemistry suggest that a minimum of 4d is required after final cell division before production of GC+ sheets begins. MBP+ cells are first seen by 7 DIV and their numbers peak by day 17. Small MBP+ sheets are not seen until after 12 DIV. Between 17-24 DIV, 50-60% of MBP+ cells elaborate sheets. In mature, double-labeled cells the patterns of GC and MBP staining are identical. When brain cell cultures are maintained in a serum-free, defined medium, considerably greater numbers of GC+ and MBP+ cells and sheets are found as compared to cultures grown in serum. In general the maximal percentages of immunolabeled cells with sheets are similar to those seen in serum supplemented cultures although peak percentages are attained 5-7d earlier. The size and shape of these sheets do not differ from those produced by oligodendroglia grown in 10% serum.

Our in vitro observations suggest that the continued presence of neurons is not required for oligodendrocytes to insert GC and MBP into elaborate membrane structures which mimic the unique and complex morphology of oligodendrocytes in vivo. Thus, the process of myelin membrane production, at least in vitro, may be under regulatory mechanisms which are independant of those controlling axonal ensheathment. Supported by NS 15338.

309.23 FAILURE OF OLIGODENDROCYTES FROM JIMPY BRAIN TO DIFFERENTIATE IN VITRO. W.P. Bartlett, P.E. Knapp and R.P. Skoff. Dept. of Anat., Wayne State Univ. School of Medicine, Detroit, MI 48201

Jimpy (jp) is a sex-linked recessive mutation which produces severe hypomyelination throughout the central nervous system (CNS). Biochemical and morphological studies have shown that oligodendrocytes in jp CNS do not produce normal amounts of myelin. Recent observations from our laboratory (Knapp, et al., this Vol). have shown that normal oligodendrocytes can produce large sheets of galactocerebroside (GC) and myelin basic protein (MBP) positive membranes when grown in vitro. In the present study we compare the differentiation of jp and normal oligodendrocytes grown in vitro for up to 24 days, using monoclonal antibodies to GC and MBP.

Mixed brain cell cultures from 3d mouse cerebra were grown in the presence of 10% fetal calf serum. Two morphologically distinct cell types are recognizable in these cultures by 7-10 days in vitro (DIV). Flattened cells, most of which stain for glial fibrillary acidic protein, form a monolayer on the surface of the coverslip. Small, dark, process-bearing cells (PBCs) lie on the surface of this bed layer and normally comprise 10% of the total cell population at this age. While not all PBCs are stained with GC or MBP, immunostaining is confined to cells with this morphology. Coverslips were prefixed in 4% paraformaldehyde for staining with MBP; GC staining was done on live cells postfixed in 4% paraformaldehyde.

The first GC+ cells are seen in both jp and normal cultures by 7 DIV. However, there are 50-90% fewer GC+ cells in jp cultures than in control cultures at all ages examined. In normal cultures, by 7 DIV approximately 25% of all GC+ cells have begun making sheets. In contrast, less than 5% of the GC+ cells in jp cultures have sheets. This percentage does not increase with time. MBP+ cells are rarely seen in jp cultures. Under phase contrast optics, numerous small, rounded-up cells lying on the surface of the bed layer become apparent in jp cultures by 12 DIV. These cells stain with propidium iodide, a fluorescent dye which accumulates in the nuclei of dead cells. Unlike normal cultures, the numbers of these dead cells in jp cultures increases dramatically as the population of PBCs declines. Since the bed layer remains intact, these dead cells probably derive from small, process-bearing cells lying on the surface.

Our results suggest that the gross deficits in expression of GC and MBP and membrane production by jp oligodendroglia in vitro may be due to their premature death. This parallels our previous in vivo observations of increased oligodendroglial cells death in jimpy CNS (Knapp and Skoff, Am. Soc. Neurosci. Abstr. 10(1):428). Supported by NS 15338.

310.1 ALTERATIONS IN OPIATE RECEPTOR OCCUPANCY FOLLOWING AMYGDALOID KINDLING. S. Weiss*, T. Seeger*, N. Ostrowski, R. Post and A. Pert. Biological Psychiatry Branch, NIMH, Bethesda, MD 20205.

Kindling is a process in which repeated intermittent subthreshold stimulation eventually produces a suprathreshold electrophysiological (and behavioral) convulsive response. Kindled convulsive episodes are followed by a post-ictal period of behavioral depression, the duration and severity of which can be attenuated by prior treatment with the opiate antagonist, naloxone. This and other lines of evidence suggest that opioid peptides are released centrally during the ictal process, and may play a protective role against the immediate repetition of the event. We have employed an in vivo autoradiographic technique which allows the visualization of opioid peptide release in the intact behaving rat (Seeger et al, Brain Res. 305:303, 1984), in order to study the pattern of opiate involvement in the ictal and post-ictal state.

Four adult male Sprague-Dawley rats were implanted with bipolar stimulating electrodes aimed at the central amygdaloid nucleus. The rats were kindled to full tonic-clonic (Stage 5) seizures over a period of three months, and then maintained seizure-free for a further three months. One kindling test session was given to insure sensitivity to stimulation, followed by one more week seizure-free. A full, stage 5 seizure was then induced, which was immediately followed by i.v. injection of the high affinity opiate antagonist, $^{3}$H-diprenorphine (50 µCI/kg) through a jugular catheter. Following a 20 min. wait to allow for washout of the label from non-specific sites, the animals were decapitated and the brains frozen intact for slicing. Four unkindled control rats with electrodes implanted in the ventral tegmental nucleus were injected identically and matched to kindled rats on the basis of cerebellar (non-specific) binding levels. Comparisons were than made between anatomically equivalent sections from these matched pairs, exposed on the same sheet of LKB Ultrofilm. Film analysis was by computer-assisted densitometry.

In the kindled group, acute seizure induced significant bilateral decreases in diprenorphine binding at numerous levels of the forebrain. These included 35-40% decreases in specific binding in cingulate cortex, nucleus accumbens, and dorsal hippocampus, while no significant change was seen in the caudate or motor cortex. At more posterior levels, binding in the basolateral amygdala was decreased by 48%, while smaller decreases (20-30%) were found in the ventral hippocampus, cortical amygdaloid nucleus, hypothalamus and sensory cortex. No change was seen in the thalamus or in any more posterior structures. These results suggest widespread occupation of forebrain opioid receptors by endogenous opiates released during the ictal process which prevented the binding of the exogenous radio-labeled opiate ligand. Alternatively, kindling may have induced region-specific changes in opiate receptor binding characteristics.

310.2 ARCUATE NUCLEUS STIMULATION: INDUCTION OF NALOXONE-REVERSIBLE ANALGESIA WITH CONCOMITANT LOCALIZATION OF OPIATE RELEASE USING IN VIVO AUTORADIOGRAPHY. T.F. Seeger and A. Pert (SPON: N. Bacopoulos) Biological Psychiatry, NIMH, Bethesda, MD 20205

The arcuate nucleus of the hypothalamus is the major source of beta-endorphin efferents in the CNS, suggesting that it may be involved in pain control. We have tested this nucleus for induction of stimulation-induced analgesia, and subsequently monitored the same animals for the release of opiate peptides, using the technique of in vivo autoradiography (Seeger et al, Brain Res. 305:303, 1984).

Eight male Sprague-Dawley rats were implanted with bipolar electrodes into the arcuate nucleus. Following recovery, pain sensitivity was quantified using a hot-plate test (latency to lick rear paw with plate at 55 C). Electrical stimulation (applied for 1 min in 3/sec bursts of 100 msec, 50Hz, 50usec pulsewidth, 100 usec delay) caused a significant increase in latency which lasted beyond the period of stimulation. Threshold current for inducing analgesia was 600 uAmp, with maximal effect at 1-1.3 mAmp. Pretreatment with naloxone (5mg/kg i.p. 15 min before testing) had no effect on baseline latency, but blocked the increase due to stimulation. These arcuate-implanted rats differed from a similarly treated group with electrodes in the periaqueductal grey in which analgesia did not outlast the stimulation and was not naloxone-reversible.

Following analgesia testing, all of the rats were implanted with intravenous jugular catheters for the autoradiography procedure. Electrical stimulation was applied to half of them for one minute, after which each rat received an injection of 3H-diprenorphine (50 uCi/kg) while the stimulation continued. After twenty minutes (to allow washout from non-specific binding sites), the rats were decapitated and the brains frozen intact for slicing. The other four rats were prepared identically, but without any stimulation. Each stimulated rat was matched with a control rat on the basis of cerebellar binding levels. Comparisons were made between anatomically equivalent sections from these matched pairs, which were exposed on the same sheet of 3H-Ultrofilm. Analysis of the film was by computer-assisted densitometry.

Significant bilateral decreases (up to 22%) in diprenorphine binding were found in a number of brain regions, including the anterior and medial amygdala, striatal fundus, bed nucleus, preoptic area, hypothalamus, and periaqueductal grey. No changes were found in basolateral amygdala, medial thalamus, cortex, or white matter. This pattern of changes indicates increased receptor occupancy in terminal projection areas of the arcuate nucleus due to stimulation-induced release of beta-endorphin.

310.3 CALCITONIN INDUCED DEPRESSION OF LOCOMOTOR BEHAVIOR IS MEDIATED THROUGH CALCITONIN RECEPTORS IN THE NUCLEUS ACCUMBENS. H.D. Everist, A. Fabbri*, and A. Pert. Biological Psychiatry Branch, NIMH, Bethesda, Maryland 20205 and Policlinico Umberto I°, Universita di Roma, Rome, Italy.

Calcitonin evokes potent effects on locomotor behaviors. Little, however, is known regarding the specific sites of action of this peptide in modifying locomotor output. In this study we have visualized calcitonin receptor distribution in the rat forebrain with autoradiographic procedures and then evaluated the effects of this peptide on locomotor behavior following direct injections into calcitonin receptor rich areas.

For receptor visualization, several 24 u m sections were taken through the rostral part of the brain. These sections were exposed to $^{125}$I-salmon calcitonin (sCT) and then processed for autoradiography using tritium-sensitive film. Autoradiographic analyses revealed exceptionally heavy binding of sCT in the nucleus accumbens. The caudal portion of the nucleus appeared to have somewhat higher labeling than the rostral segment. Little binding was evident in the caudate nucleus or other forebrain regions. Lesions of the ascending dopamine pathway with 6-OHDA failed to alter sCT binding in the n. accumbens. Injections of kainic acid into the n. accumbens, on the other hand, decreased binding on the lesioned side. These findings suggest that sCT binding sites are located on cell bodies intrinsic to the n. accumbens and not on DA terminals that innervate this region.

In subsequent studies, rats were implanted with chronic indwelling cannulae guides aimed for the lateral ventricles, nucleus accumbens or caudate nucleus. Intraventicular injections of sCT (1, 10 or 25 n moles) produced a dose-dependent long lasting decrease in locomotor behavior. Bilateral injections of sCT into the n. accumbens resulted in an even more dramatic response. As little as 0.02 n moles decreased horizontal locomotor activity by 53% in the first 15 minutes. Higher doses (0.1-2.0 n moles) had an even greater effect. Injections of 0.5 n moles into the caudate nucleus, on the other hand, had little effect on locomotor output.

These findings indicate that sCT is an extremely potent modulator of locomotor output. The effect appears to be mediated predominantly through the interaction of this peptide with sCT binding sites on neurons intrinsic to the n. accumbens.

310.4 NALOXONAZINE: EFFECTS ON FOOD INTAKE AND CONDITIONED TASTE AVERSION. D.L. DeHaven, P. Brostrom* and L.R. Steranka. Nova Pharmaceutical Corporation, 5210 Eastern Avenue, Baltimore, MD 21224

Naloxonazine (NAZ) has been reported to be a selective antagonist at mu opioid receptors and to inhibit feeding in rats (Hahn et al., J. Neurosci. 2: 572, 1982; Simone et al., Life Sci. 36: 829, 1985). The present series of experiments attempted to further evaluate the anorectic properties of NAZ and to determine whether the effects of NAZ on feeding might be attributable to the production of a conditioned taste aversion (CTA). In the first experiment, after establishment of a stable baseline for feeding, male Sprague-Dawley rats were food deprived for a 24 hr period immediately before injection of NAZ (2, 5, 10 or 20 mg/kg SC) or vehicle. Food and water intakes were recorded at 1, 2 and 24 hr after treatment. All doses of NAZ effectively inhibited feeding for up to 2 hr after administration, with food intake of treated rats returning to control levels by 24 hr. Water consumption of NAZ-treated rats was also slightly decreased at 1 and 2 hr, but not at 24 hr. The second experiment assessed the ability of the above doses of NAZ to produce a CTA. Animals were conditioned to the aversive properties of LiCl or NAZ by the procedure of Wagner et al. (Pharmacol. Biochem. Behav. 14: 85, 1981), which utilizes a two-bottle choice on the test day. NAZ at the 20 mg/kg dose produced a CTA equivalent to that seen with LiCl (12.7 mg/kg), while 10 mg/kg NAZ produced a slight decrease in the preference ratio of milk intake/milk + water intake without affecting the total amount of milk consumed. NAZ in doses of 2 and 5 mg/kg had no effect. These data suggest that although the production of a CTA by higher doses of NAZ may affect feeding, lower doses of NAZ have pure anorectic properties. Therefore, NAZ may have potential use as an appetite suppressant.

310.5 AN ENKEPHALIN-LIKE PENTAPEPTIDE (BW942C) WITH PARTIAL KAPPA AGONIST ACTIVITY. D.B. Vaupel*, E.J. Cone* and R.E. Johnson* (SPON: L. Porrino). NIDA Addiction Research Center, Baltimore, MD 21224.

BW942C (Tyr-D-Met(O)-Gly-pNO$_2$-Phe-Pro-NH$_2$) is a pentapeptide that has a morphine-like antidiarrheal effect in the rat. Compared to morphine or loperamide, BW942C was more potent and thus showed selectivity as an antidiarrheal agent. Human pharmacological studies at the Addiction Research Center suggested that this peptide may have opioid activity of the kappa-type. For this reason, BW942C was evaluated in the rat urination model which measures the diuretic effects of opioids having kappa- or ketocyclazocine-type activity and antidiuretic effects of opioids with mu or morphine-type activity. Urinary output was determined in normally fed and hydrated, adult male Long-Evans hooded rats placed in metabolic cages. Urine volumes were measured at 2 and 5 hr following s.c. drug or vehicle administration. Six rats were tested at each treatment condition. BW942C (0.01 to 3 mg/kg) was compared to bremazocine (0.0008 to 0.08 mg/kg) and U-50,488H (0.01 to 30 mg/kg), two compounds which exhibit activity of the kappa type. Dose-response curves demonstrated that both bremazocine and U-50,488H were full agonists with peak urine outputs approaching 20 ml over 5 hrs. The water vehicle treated animals produced 3 ml of urine over 5 hrs. BW942C produced a biphasic dose-response curve. Doses of 0.01 to 0.3 mg/kg doubled the urine output from 3 to 6 ml, whereas 1 mg/kg had no effect, and 3 mg/kg completely suppressed urine flow. Thus, BW942C appeared to be a partial kappa agonist at low doses and exhibited mu or morphine-type activity at higher doses in the rat urination model. Most of the BW942C-induced diuresis occurred within the first 2 hrs. In parallel line bioassays, BW942C was 0.1 and U-50,4884 was 0.004 times as potent as bremazocine. In antagonism experiments, naltrexone (0.01 to 0.1 mg/kg) reversed the antidiuretic effect of 3 mg/kg of BW942C to reveal a diuretic effect; higher doses of naltrexone (1 and 10 mg/kg) were required to antagonize this diuresis. The diuretic effects of intermediate doses of bremazocine (0.0132 mg/kg) and U-50,488H (3.89 mg/kg) also were antagonized by the simultaneous administration of BW942C in increasing doses. Maximally effective doses of the full agonists were more difficult to antagonize by BW942C. These data are consistent with the interpretation that BW942C is a weak partial kappa agonist over a limited dose range. This is the first report of a peptide that has activity characteristic of a partial agonist at the kappa opioid receptor. The diuretic activity of BW942C suggests that it has a relatively low intrinsic activity for the kappa receptor which is in part self-limited by its mu or morphine-like activity which emerges at higher doses.

310.6 HIGHLY SELECTIVE MU- AND DELTA- OPIOID AGONISTS AND ANTAGONISTS: ACTION ON SENSORY NEURON CALCIUM-DEPENDENT ACTION POTENTIALS. R.L. Macdonald, M.A. Werz, and D.S. Grega. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48104.

We have previously reported that a subpopulation of DRG neurons grown in primary dissociated cell culture have mu- and/or delta- opioid receptors on their somatic membrane and that binding of opioid ligands to these receptors results in a decrease of calcium-dependent action potential duration (Werz and Macdonald, JPET, 227:394-402, 1983). In the present investigation we have assessed agonists and antagonists with high selectivity for either mu- or delta-receptors. The majority of DRG neurons did not respond to 1 μM [N-MePhe$^3$, D-Pro$^4$]-morphiceptin (MC), a selective mu- ligand, 1 μM [D-Pen$^2$, L-Pen$^5$]-enkephalin (DPLPE), a selective delta-ligand, or 1 μM leucine-enkephalin (L-ENK), a non-selective ligand. However, a small population of DRG neurons responded to both MC and L-ENK but not DPLPE and another small population responded to both DPLPE and L-ENK but not MC. These data are consistent with MC selectively marking neurons with mu- receptors, DPLPE selectively marking neurons with delta-receptors, and L-ENK not distinguishing between these receptor types. We have further characterized responses of DRG neurons to MC with selective antagonists. Responses to 1 μM MC were antagonized by naloxone (dose-dependently over 100 pM-10nM) and also by the somatostatin analog SMS 201-995 (dose-dependently over 1nM-100nM). The selective delta antagonist ICI 174864 was without effect at 10 μM. The irreversible ligands β-funaltrexamine (β-FNA) and naloxonazine (NZ) were also investigated. Ten to 20 neurons within a culture were impaled. The response to MC assessed and the location of neurons responding to MC was noted. The culture was then incubated in β-FNA or NZ at 37°C for 1 hr. Following extensive rinsing, the neurons that had responded to MC previously were reimpaled. Both β-FNA and NZ at 250 nM irreversibly reduced responses to MC by 76%. β-FNA at 1 nM did not affect responses to MC.

Our data using selective agonists and antagonists confirm that both mu- and delta- receptors are present on DRG neuron somata. Investigations of DRG neurons in culture will provide information of the neuronal membrane effects that result following ligand binding to each receptor type.

We thank Dr. Beat Gähwiler for the gift of SMS 201-995, Dr. Hank Mosberg for DPLPE, Dr. Gavril Pasternak for NZ, and Dr. P. Portoghese for β-FNA.

310.7 THE EFFECTS OF N-METHYLMORPHINE ON THE RELEASE OF ANTERIOR PITUITARY HORMONES. R.N. Pechnick, R.E. Poland* and R. George*. Department of Pharmacology, The Brain Research Institute and the Laboratory of Neuroendocrinology, UCLA, Los Angeles, CA 90024 and Division of Biological Psychiatry, Harbor-UCLA Medical Center, Torrence, CA 90502.

The acute administration of morphine sulfate elicits dose-dependent increases in the serum levels of ACTH, GH, and PRL while inducing decreases in LH and TSH. The locus of this action of the opiates is thought to be at the level of the hypothalamus, presumably by affecting the release of hypothalamic releasing inhibiting factors. There are some data suggesting that systemically administered opiates and opioid peptides can act directly on the pituitary or the median eminence to influence hormone release. To test this hypothesis we examined the effects of N-methylmorphine, a quaternary analogue of morphine that does not cross the blood-brain barrier, on the release of corticosterone, GH, PRL, LH and TSH.

Male rats were injected with N-methylmorphine chloride (20.0 and 40.0 mg/kg s.c.) and trunk blood obtained 30 min later. Serum hormone levels were measured by RIA. Both doses of drug caused increases in the release of GH and PRL; however, serum levels of corticosterone, LH and TSH were unchanged. These results indicate that opiate-induced release of GH and PRL may be mediated in part by sites outside of the blood-brain barrier.

310.8 INHIBITION OF [$^3$H]NOREPINEPHRINE RELEASE FROM RAT AND GUINEA PIG BRAIN SLICES BY OPIOIDS. L.L. Werling, S. R. Brown*, and B.M. Cox. Department of Pharmacology Uniformed Services University, Bethesda, MD 20814.

The locus coeruleus is the origin of noradrenergic fibers which project to several areas of the rat and guinea pig central nervous systems, including the cortex, cerebellum, and the hippocampus. Various lines of electrophysiological and anatomical evidence suggest that the activity of these neurons may be influenced by opioid neurons which impinge upon them, and several groups have reported the inhibition of [$^3$H]norepinephrine ([$^3$H]NE) release by opioids, although none of these has identified the type of opioid receptors which mediates this effect. We have demonstrated that μ, δ, and κ selective compounds all decrease the $K^+$ stimulated, $Ca^{++}$ dependent release of [$^3$H]NE from slices of guinea pig and rat brain tissues, but the tissues exhibited differential sensitivity to these compounds. Release from guinea pig cortex, cerebellar cortex, and hippocampus was depressed to a greater extent by treatment with the κ selective U50,488H than by exposure to the μ selective DAGO. [$^3$H]NE release from rat cortical slices was greatly depressed by DAGO, while U50,488H produced a more modest inhibition. Maximal depression by the δ selective DPDPE was intermediate between that produced by DAGO or U50,488H in both species, but DPDPE had a higher potency in rat cortex than in guinea pig cortex. These results suggest that although norepinephrine release may be regulated by opioids in both guinea pig and rat brain, the receptors which are most effective in regulating release are not identical in each species. Additionally, release of norepinephrine may be regulated by more than one type of opioid receptor.

310.9 ENDORPHIN BLOCKADE SYNDROME: EFFECTS OF RATE AND DURATION OF NALOXONE INFUSION IN MALE AND FEMALE RATS. R.F. HAMILTON JR. *, D.H. Malin, C. Vandenberg* and R.J. Townsend III.* (Spon: C.D.B. Bridges) Univ. of Houston-Clear Lake, Houston, Texas 77058.

A single injection of naloxone fails to elicit typical opiate abstinence signs in a normal, non-dependent animal. However, a prolonged injection series (Malin et al, Pharmacol. Biochem. Behav. 17:389, 1982) or a day of continuous naloxone infusion (Malin et al, Pharmacol. Biochem. Behav. 22:791, 1985) did induce a number of opiate-abstinence-like signs.

The present experiment was performed to determine how the frequency of abstinence-like symptoms is affected by the length and rate of naloxone infusion and by sex differences. Thirty female and thirty male rats (all 60 days) were divided into five equal infusion rate groups: 0.0, 0.35, 0.7, 1.4, and 2.1 mg/kg/hr naloxone delivered by subcutaneously implanted Alzet 2ML1 osmotic minipumps. Each animal was observed for 10 min. for standard behavioral abstinence signs after 1, 2, and 3 days of infusion.

A 5x2x3 ANOVA with one repeated measures variable revealed significant, $p < .01$, main effects of infusion rate and days of infusion but not of sex. There were no significant interaction effects. The effect is dose-dependent, since abstinence-like signs showed a significant positive linear trend as a function of infusion rate. The effect declined significantly by day 3, despite continued infusion of naloxone, suggesting some sort of dynamic adjustment to endorphin receptor blockade.

The only significant sex difference was at the infusion rate of 0.7 mg/kg/hr, where there was a sharp drop in the abstinence-like response of the female rats. This accounts for our previous failure to find an effect in females, since this was the infusion rate previously employed. (Supported by Univ. of Houston-Clear Lake Organized Research Grant.)

310.10 **A SEIZURE-PRODUCING LESION ENHANCES KAINIC ACID RESPONSIVITY IN THE HIPPOCAMPAL SLICE PREPARATION.** R.M. Pico and C.M. Gall. Dept. of Anatomy, University of California, Irvine, CA 92717.

Recurrent limbic seizure activity induced by a unilateral electrolytic lesion of the mouse dentate gyrus hilus has been found to cause a transient (10-12 day) bilateral increase in mossy fiber enkephalin immunoreactivity and a persistent (>20 day) loss of mossy fiber cholecystokinin immunoreactivity (C. Gall, Neurosci. Abstr., 10, 1112, 1984). We have begun to investigate the physiological consequence of this fluctuation in endogenous peptide levels using the in vitro hippocampal slice preparation. The present study examined the influence of kainic acid (KA) on hippocampal slices from control (untreated) mice and experimental animals sacrificed either 4 or 14 days after contralateral hilus-lesion placement. KA has been reported to induce spontaneous multiple discharges, interictal spikes, in rat hippocampal slices at low concentrations (0.05-1.0uM) (G.L. Westbrook, & E.W. Lothman, Brain Res., 273, 97-100, 1983). Slices (425um) were maintained with a constant perfusion of oxygenated artificial CSF at 34°C. Field potentials were recorded by electrodes placed in CA3 stratum pyramidale. Experimental and paired control slices were simultaneously monitored. With the addition of only 16 nM KA to the media perfusion, 92% of the 4 day postlesion slices had begun to spike (32 total sliced, 5 mice). Most control slices and virtually all experimental slices had interictal spikes at 100nM KA. Examination of 2 mice (11 total slices) lesioned 14 days prior to testing, revealed no difference in the response to KA when compared to 2 control mice (10 total slices). No response was detected at 16 or 25nM KA, while 100nM KA elicited spikes from 66% of the treatment slices and 50% of the control slices.

These results demonstrate a correlation between the hilus lesion-induced increase in mossy fiber enkephalin content and reduced threshold for KA stimulation of epileptiform activity in the hippocampal slice preparation. Pharmacological studies are in progress to determine the contribution of the mossy fiber peptides to this effect.

310.11 CHANGES IN CENTRAL ADRENERGIC RECEPTOR FUNCTION MAY CONTRIBUTE TO OPIATE DEPENDENCE. H. C. Moises and C. B. Smith.*+ Dept. of Physiology and Dept. of Pharmacology+, The University of Michigan, Ann Arbor, MI 48109.

Considerable evidence indicates that significant components of the opiate withdrawal syndrome may be due to increased central noradrenergic activity in areas such as the locus coeruleus. Our recent findings of increases and decreases in beta and alpha$_2$ adrenergic receptors, respectively, in various brain regions in rats treated chronically with morphine (Neurosci. Abstr. 9:797, 1983) raise the additional possibility that changes in central adrenergic receptor function may contribute to or reinforce such effects. In this study, radioligand binding assays were carried out in conjunction with intracellular recording from hippocampal pyramidal neurons in vitro to determine whether alterations in beta receptor density that occur in hippocampus following chronic morphine treatment are reflected in corresponding changes in postsynaptic sensitivity to noradrenergic stimulation.

Sprague-Dawley rats (175-225g) were injected with increasing doses of morphine (up to 100 mg/kg/injection) or saline, i.p., every 8 h for 14 days. Animals were killed by decapitation either 8 h or 32 h after the last injection and neural membrane preparations and 400 μm thick slices of hippocampus prepared. Slices were maintained at 35.5°C under total submersion and allowed to equilibrate for 1.5 h prior to initiation of drug superfusion and electrophysiological recording. The ability of norepinephrine (NE) to block the late hyperpolarization response of pyramidal neurons to depolarizing current pulses (500 ms, 0.5-1nA) was determined over a range of drug concentrations to assess changes in postsynaptic beta receptor function (Madison and Nicoll, Nature 299:636, 1982).

Following chronic morphine treatment, the $B_{max}$ for binding of $^3$H-dihydroalprenolol ($^3$H-DHA) showed a biphasic change, indicating an initial increase (13.8%, $p<.05$) and subsequent decrease (-26.4%, $p<.005$), relative to controls, in beta receptor number in hippocampus with time during withdrawal. On the other hand, the apparent affinities of the receptors for $^3$H-DHA and for several agonist radioligands were not significantly changed. Electrophysiological testing revealed that the changes in beta receptor density found in early (8 h) and later phases (32 h) of withdrawal were paralleled by a corresponding decrease ($p<.06$) and increase ($p<.01$), respectively, in the $EC_{50}$ for NE in blocking the late hyperpolarization response. These results suggest the possibility that changes in postsynaptic sensitivity to noradrenergic stimulation may be important in the formation or expression of opiate dependence. (Supported by NIDA Grant DA-03365 and The Chicago Community Trust/Searle Scholars Program).

310.12 LOCAL STIMULATION OF GLUCOSE UTILIZATION IN THE SPINAL CORD DURING NALOXONE-PRECIPITATED OPIOID ABSTINENCE. J.A. Bell*, A.S. Kimes and E.D. London (SPON: J.E. Warnick). Neuropharmacology Lab., NIDA Addiction Research Center, Baltimore, Maryland 21224.

The opioid abstinence syndrome is characterized by signs of CNS hyperexcitability. Hyperalgesia is a prominent sign which is distinguished by hyperreactivity to nociceptive stimuli in experimental animals, and by abdominal cramps, and pains in bones and muscles of the back and extremities in humans. Several studies have shown that substance P is associated with neuronal mechanisms concerning nociception in the substantia gelatinosa of the spinal cord.

Previous studies have demonstrated that the spinal release of substance P is inhibited by morphine (Yaksh, T.L., et al., Nature, 286: 155, 1980; Y. Kuraishi et al., Life Sci 33 Suppl 1: 693, 1983). Furthermore, chronic morphine treatment increases levels of substance P in the dorsal horn of the spinal cord (Naftchi, N.E., et al., Peptides Suppl. 1:61, 1981), Bergstrom et al., Life Sci., 35:2375, 1984). Therefore, following abrupt withdrawal of chronic morphine treatment, hyperalgesia could result from hyperactivity of substance P systems in the dorsal horn of the spinal cord. In order to obtain information about the activity of neural pathways in areas of the spinal cord where substance P is active in nociceptive transmission, we studied local spinal glucose utilization (LSGU) during naloxone-precipitated morphine abstinence.

Studies were performed in male Fischer-344 rats which were implanted with one 75 mg morphine or placebo pellet on day 1 and 2 pellets on day 4. LSGU was measured on day 8 by the autoradiographic 2-deoxy-[1-$^{14}$C]glucose ([$^{14}$C]DG) method (Sokoloff L., et al., J. Neurochem. 28:897, 1977) in rats which were partially restrained by lower-body plaster casts, using standard values for the lumped constant and rate constants for the transport and phosphorylation of [$^{14}$C]DG. Naloxone (0.5 mg/kg, s.c.) or saline were injected 2 min before [$^{14}$C]DG (125μ Ci/kg). Rats were killed by an overdose of sodium pentobarbital. The spinal cord was rapidly removed and divided into lumbar, thoracic, and cervical sections, and frozen.

An increase in LSGU was seen in the superficial portion of the dorsal horn in sections of the spinal cord from rats which had received chronic morphine and exhibited marked withdrawal signs following naloxone administration.

These studies indicate that increased metabolic activity, reflected by increased LSGU, occurs in superficial portions of the dorsal horn of the spinal cord corresponding to the location of the substantia gelatinosa. These increases may be associated with a rebound hyperactivity of substance P pathways that could contribute to hyperalgesia during the morphine abstinence syndrome.

310.13 PHYSIOLOGICAL INTERACTIONS OF MORPHINE AND DILTIAZEM IN RATS. M. Szikszay*, G. Benedek* and E.D. London (SPON: D. Jasinski). Neuropharmacology Laboratory, NIDA Addiction Research Center, Baltimore, MD 21224 and Dept. Physiology, Univ. Med. School of Szeged, Hungary.

Calcium channel antagonists (such as diltiazem) can potentiate the antinociceptive and hypothermic effects of morphine in rats (Benedek, G. and Szikszay, M., Pharmacol. Res. Commun., 16:1009, 1984). In order to determine if diltiazem's effect on morphine-induced antinociception is dose-dependent, we measured antinociception by means of hot-plate (53.5°C) and tail-flick (53°C) tests. A subcutaneous injection of 4 mg/kg morphine sulfate caused slight increases of the hot-plate and tail-flick latencies in rats. Simultaneous administration of diltiazem (2, 10 or 20 mg/kg, subcutaneously) caused a dose-dependent potentiation of morphine's antinociceptive effect.

Because it was of interest to determine if such a positive interaction extended to other physiological actions, we studied the effects of morphine and diltiazem alone and in combination on indices of respiratory and cardiovascular function in partially restrained, awake male Fischer-344 rats. A subcutaneous injection of 4 mg/kg morphine sulfate produced hypercapnia, hypoxia and slight acidosis, as compared with values in arterial blood from control rats. Diltiazem alone (10 mg/kg,) did not affect these parameters, but it significantly delayed the times of the peak hypercapnic and hypoxic effects of morphine. Marked hypercapnia and hypoxia were seen at every time point after morphine treatment. Peak hypercapnic effects of morphine and morphine + diltiazem did not differ significantly in magnitude (increases of 5.1 + 0.84 and 4.1 + 0.94 mm Hg, respectively), but diltiazem significantly delayed the onset of the peak effect from 0.38 + 0.06 hr to 1.0 + 0.23 hr, respectively. The maximum effects of morphine and morphine + diltiazem on $Pa_{O_2}$ were of similar magnitude (declines of 17.7 + 2.26 and 15.7 + 2.28 mm Hg, respectively), but diltiazem significantly delayed the time of the peak hypoxic effect of morphine from 0.46 + 0.04 hr to 0.92 + 0.08 hr. Morphine produced a marked elevation of heart rate; whereas, diltiazem alone or in combination with morphine produced a slight tachycardia. Mean arterial blood pressure was not affected by morphine, but diltiazem alone or in combination with morphine reduced blood pressure dramatically (about 25 mm Hg below baseline).

In conclusion, the influence of the morphine-diltiazem interaction on respiration differs from its effect on antinociception and thermoregulation. This observation supports the view that opioid effects on respiration are mediated at different sites than the other aforementioned effects.

310.14 WITHDRAWN

310.15 PARASYMPATHETIC ACTIVITY MEDIATES THE CARDIAC BUT NOT THE VENTILATORY DEPRESSION INDUCED BY ENKEPHALINS IN CONSCIOUS DOGS. G.G. Haddad*and P. Lasala.* (SPON: L. J. Côté ). Departments of Pediatrics (Pulmonary Division) and Neurosurgery, Columbia University, College of Physicians & Surgeons, New York, NY 10032.

We have previously shown that intracisternally (IC) injected enkephalin analogs (DADLE) increase the RR interval and depress ventilation in unanesthetized adult dogs. Because of the known interactions between opioids and the cholinergic system, we asked whether the cardiorespiratory changes induced by DADLE are mediated by the parasympathetic nervous system. Eleven experiments were performed on 4 unanesthetized dogs with chronically implanted cannulae in the Cisterna Magna and aortic catheters. Ventilation was measured non-invasively using barometric plethysmography and the RR interval using a dedicated RR preprocessor and a microcomputer. RR interval and ventilation were recorded continuously and automatically acquired using real time data acquisition techniques. Atropine sulfate was given systemically (20 mcg/kg) at peak action of DADLE (25 or 125 mcg/kg). Approximately 40 minutes post DADLE (peak action), mean RR interval had increased by 49.9% and 92.3%, and mean minute ventilation had decreased by 28.3% and 43.5% at 25 mcg/kg and 125 mcg/kg respectively ($p < 0.05$). $PaCO_2$ increased in every study by 8-14 Torr. Within minutes after the injection of Atropine, mean RR interval decreased to about baseline levels, but mean minute ventilation and $PaCO_2$ did not change. At the end of each DADLE experiment, Naloxone (given IC in doses of 1-10 mcg/kg) increased minute ventilation, reduced $PaCO_2$ and decreased the mean RR interval even further. Atropine or Naloxone had little or no effect (<5%) on cardiorespiratory function when given without prior administration of DADLE. We conclude that the DADLE-induced prolongation of the RR interval is mediated by parasympathetic mechanisms. We speculate that the DADLE-induced ventilatory depression is either due to direct opioid action or to non-cholinergic mediating mechanisms on central respiratory regulation.

310.16 MURAMYL DIPEPTIDE DOES NOT AFFECT OPIOID BINDING IN GUINEA PIG BRAIN. M. S. Ahmed*, J. M. Krueger, and C. M. Blatteis. Univ. of Tenn. Ctr. Hlth. Sci., Memphis, TN 38163.

A muramyl peptide promoting slow-wave sleep and inducing fever has been isolated from the brains of sleep-deprived rabbits. A synthetic immunoadjuvant, muramyl dipeptide (MDP, N-acetylmuramyl-L-alanyl-D-isoglutamine), injected intracerebroventricularly at doses of 50-100 pM, also is somnogenic and pyrogenic. It has been suggested that interleukin 1 (IL1), which possesses similar somnogenic and pyrogenic properties, may mediate these actions of MDP because the production of IL1 by macrophages is stimulated by MDP. Recently, evidence has been provided that IL1 contains an MDP-like structure or MDP binds nonspecifically to IL1. Because IL1 reduces the specific binding of opioid ligands to their receptors in various regions of guinea pig brain, and because of the central role of opioids in immunoregulation and wakefulness, the present study was designed to determine whether MDP shares the capacity of IL1 to interact with opioid receptors. Accordingly, membrane-bound opioid receptor preparations were obtained from the cerebral cortex, hypothalamus, midbrain, pons, and medulla of 12 guinea pigs, in two replications. Aliquots of the membrane homogenates were incubated with the tritiated opioid ligands 2-D-alanine-5-L-methionineamide (DAME) or dihydromorphine (DHM); the volume of the assay mixture was 0.5 ml. Specific opioid binding was calculated as the difference between the counts of radioligand bound in the presence or absence of 1.0 μM levorphanol. MDP at the concentrations of 1.0, 0.2, and 0.02 μM did not affect the specific binding of DAME or DHM in any of these guinea pig brain regions. We conclude, therefore, that the central activities of MDP do not involve any direct interactions with brain opioid receptors. (Supported by NSF grants No. BNS 83-08257 and PCM 83-17217.)

310.17 OPIOID RECEPTORS AND BODY TEMPERATURE IN RATS. M.W. Adler* and E.B. Geller. Dept. of Pharmacology, Temple University School of Medicine, Philadelphia PA 19140.

We have previously reported that subcutaneously (sc) administered opioids can be classified into groups based on their effects (at an ambient temperature of 20°C) on body temperature in rats, response to naloxone, and stereospecificity (Geller et al., J. Pharmacol. Exp. Ther. 225:391, 1983) and that the temperature response to these opioids often differs qualitatively if the drugs are given by the intracerebroventricular (icv) route (Adler et al., Neuropeptides 5:73, 1984). In addition, we have reported on the effects of the endogenous opioid peptides β-endorphin,D-$ala^2$-met-enkephalinamide,D-$ala^2$-D-$leu^5$-enkephalin, and $dynorphin_{17}$ on body temperature in the rat (Adler et al., in: Environment, Drugs, and Thermoregulation, P. Lomax and E. Schönbaum, eds., Karger:Basel, 1983). Based on these and other studies, we have postulated that the thermal actions of the opioid system are explainable by a 2-receptor model. Specifically, μ receptors mediate hyperthermia and κ receptors mediate hypothermia. Further, the μ effects, at least in part, are due to actions in the brain while κ actions are primarily outside of the brain (possibly outside of the CNS). Among the findings in support of this hypothesis are the following: 1)agonists which have predominant activity at the μ receptor produce hyperthermia whether administered sc, icv, or directly into the preoptic anterior hypothalamus (POAH); 2)agonists which have predominant activity at the κ receptor produce hypothermia when administered sc and have either no effect on body temperature when administered by the icv route (e.g., U50,488H, the highly selective κ agonist) or produce a dose-related hyperthermia icv (e.g., EK, which is known to have agonist effects at μ as well as κ receptors in the rat); 3) although icv $dynorphin_{17}$, the purported κ ligand, produces a dose-related hypothermia, the effect may be due to the peptide's rapid removal from the brain and stimulation of κ receptors elsewhere. $Dynorphin_{13}$, injected into POAH, produces only hyperthermia; 4)immunocytochemical and receptor autoradiographic studies indicate that the POAH has scattered prodynorphin fibers and appears to have many μ receptors but very few κ (M. Lewis, personal communication). Supported in part by Grant DA00376 from NIDA.

310.18 NALOXONE, NALTREXONE, AND BODY TEMPERATURE. R. Eikelboom. Dept. of Psychology, Queen's Univ., Kingston, Canada, K7L 3N6.

Naloxone causes a dose-related fall in body temperature (Eikelboom and Stewart, Life Sci., 28:1047, 1981). Naltrexone, a related compound, is more potent and longer lasting on a variety of narcotic antagonist measures (Blumberg and Dayton, Narcotic Antagonists, ed. M. Braude, p.33, 1974). Therefore these two compounds were compared for their effects on body temperature.

Seventy-four male Wistar rats (300 to 350 g) were habituated by repeated experience with all the procedures of the experiment. Rats were injected (IP) with saline or 1, 3, 10, 30 mg/kg Naloxone or Naltrexone (n=8, 2 saline groups n=5). Body temperature (rectal probe inserted 6cm) was measured -45, 0, 45, 90, 180, 270, 360, and 450 min after the injection, as well as 24 h later. There were no significant group differences at the -45 and 0 times but there was a significant dose related hypothermia at 45 and 90 min after the injection (maximum hypothermia was 0.6° C at 45 min). The two drugs were equipotent in terms of their hypothermic effects. At 90 min the effects were reduced for both drugs and by 180 min the groups no longer differed. At 270 and 360 min after the injection there was again a group difference with the naloxone and naltrexone animals exibiting a dose-related hyperthermia (increased temperature) relative to saline injected animals (maximum hyperthermia 0.5°C). At all later times the groups did not differ. Thus, it seems that for both of the body temperature effects the drugs seemed equipotent and their effects had similar time courses.

The effects of 30 mg/kg of naltrexone and naloxone on body temperature during the light and dark part of the cycle were investigated in 50 rats using similar procedures. As might be expected animals were always warmer during the dark. Again, both drugs induced equivalent hypothermic effects both in terms of maximum effects and time course. A comparison of the drug effect during the light and dark reveals that there were no circadian differences.

While both of the temperature effects of these drugs may not be pronounced they have been reported before with nalaxone so they appear real. More importantly it appears that these drugs are equipotent and have equivalent time course in their effects on body temperature. This is in marked contrast to the effects of these drug as narcotic antagonists. The temperature effects of these drugs may be mediated by different mechanisms than their antagonist effects.

310.19 VENTRAL TEGMENTAL MORPHINE INFUSIONS THROUGH VERTICLE BUT NOT ANGLED CANNULA HAVE AVERSIVE EFFECTS IN RATS. H.O. Pettit. Dept. of Psychology, Texas Christian University, Fort Worth, Texas 76129.

In a two part experiment infusions of morphine in the ventral tegmental area were paired with the taste of one of two novel flavored solutions. In the first experiment 19 male rats were given permanent verticle cannula implants aimed at the ventral tegmental area (VTA). Subsequently, the animals were conditioned to associate the effects of 1.0 µg/cannula injections of morphine sulfate or the 0.5 µl physiological saline vehicle with the taste of one of two novel solutions. Following conditioning, taste preferences for the two solutions were measured. Animals drank significantly less of a solution which had been paired with effects of morphine than of a solution which was paired with effects of the saline vehicle. Hence, rats developed conditioned taste aversions (CTAs) and demonstrated that morphine infusions through cannula aimed at the VTA can produce aversive effects. Experiment #2 was designed to examine dose response effects of morphine delivered through cannula implanted on a 20° angle to avoid the possible flow of morphine up the cannula to the periventricular grey region. Before conditioning trials the 40 experimental animals were additionally given a single injection of their respective morphine dose (0.00, 0.01, 0.1 or 1.0 µg/cannula) to attenuate the novelty of morphine effects and to reduce the ill effects of the lesions caused by the injections. The subjects in this experiment did not develop the CTAs observed in experiment #1. The results found in both experiments reveal that aversive effects of morphine injected into the VTA can occur, but they do not seem to be mediated by a central VTA component. Moreover, the present findings reveal that the aversive effects from VTA morphine applications can be attenuated with the use of procedural controls.

310.20 SINGLE UNIT ACTIVITY AND EFFECTS OF MORPHINE IN THE AMYGDALOID NUCLEAR COMPLEX OF THE RAT. W.W. Pugh, N.R. Walker*, M.W. Julian*, and C.G. Lineberry. North Carolina Foundation for Mental Health Research, Raleigh, NC 27611 and Medical Division, Burroughs Wellcome Co., Research Triangle Park, NC 27709

Morphine has been shown to inhibit or depress neuronal responses to noxious peripheral stimulation at spinal, medullary and thalamic levels. Thresholds of reflex tail movements and of vocalization following electrical stmulation to the tail are likewise elevated with systemic morphine administration. Tail flicks are regulated by spinal mechanisms while vocalizations are thought to be mediated at the supra-spinal level, and as such, may be part of the nocifensive or motivational response to pain. Intrathecal injections of morphine block both responses while morphine microinjected into the amygdala suppresses only the vocalization component of tail stimulation. Accordingly, spontaneous single unit activity in the amygdala was recorded extracellularly with glass micropipettes in urethane anesthetized rats. Thirty-four cells have been characterized physiologically with regard to mean firing rates, mean interspike intervals ± standard deviations, interspike interval histograms, and percent bursts and pauses. All cells reported here have been histologically confirmed to be within the amygdaloid nucleus complex by HRP marking of the recording site(s). Average firing patterns were slow (<1 Hz) and irregular. Several of these cells were tested for sensitivity to opiates by systemic administration of morphine (1-10 mg/kg) and/or naloxone (1-10 mg/kg). The majority of cells studied were inhibited by morphine, exhibiting a 50-90% decrease in spontaneous activity. Naloxone readily reversed these effects and typically elevated firing rates above baseline for a period of 30-40 minutes. Conversely, some neurons were moderately excited by morphine and greatly inhibited by naloxone while other cells did not respond to either. Thus, complex responses to morphine in a limbic structure (i.e., the amygdala) may participate in the affective component of nociception.

311.1 ELECTROPHYSIOLOGICAL AND PHARMACOLOGICAL PROPERTIES OF MOUSE BRAIN DOPAMINE-CONTAINING VENTRAL TEGMENTAL AREA NEURONS RECORDED IN VIVO AND IN VITRO.

T. Crisp, M.S. Cannon* and M.E. Trulson. Department of Anatomy, College of Medicine, Texas A&M University, College Station, TX 77843

The present studies examined the electrophysiological and pharmacological properties of dopamine-containing ventral tegmental area neurons in the mouse. These neurons were examined using extracellular single-unit recording techniques in both chloral hydrate anesthetized mice and in vitro mouse midbrain slices. In the in vivo preparation the ventral tegmental area neurons had long duration action potentials (2-5 ms), discharged at a rate of 1-9 spikes/s, and the cells discharge with either a decremental burst pattern or with a regular pattern. Systemic administration of the dopamine agonist, apomorphine, decreased the firing rate of these neurons, and the dopamine receptor blocker, haloperidol, reversed this effect. Similarly, systemic administration of the dopamine-releasing agent, D-amphetamine, suppressed the discharge rate of these neurons. This latter effect was blocked by pretreatment of the animals with α-methyl-p-tyrosine. When recorded in vitro from midbrain slices, ventral tegmental area neurons showed electrophysiological properties that were similar to those found in vivo, however, the neurons recorded in vitro fired at a significantly faster rate and the firing pattern in vitro tended to be more pacemaker-like, especially when recordings were made in an incubation medium which blocked synaptic transmission (e.g., low calcium/high magnesium). The activity of most of these neurons was suppressed by addition of apomorphine to the incubation medium, an effect that was reversed by haloperidol. Pretreatment with α-methyl-p-tyrosine produced no significant change in the discharge pattern or rate for cells recorded in vitro. These data indicate mouse ventral tegmental area dopamine neurons in vivo exhibit the same electrophysiological and pharmacological properties as rat and cat dopamine-containing neurons and that in vitro mouse ventral tegmental area neurons fire with pacemaker regularity in a low calcium/high magnesium medium. The in vitro preparation offers an approach to examining the fundamental properties of ventral tegmental area dopamine-containing neurons in the absence of afferent inputs.

311.2 PARTIAL AND FULL AUTORECEPTOR AGONIST EFFECTS OF DOPAMINOMIMETICS: ELECTROPHYSIOLOGICAL STUDIES. L.T. MELTZER AND C.CHRISTOFFERSEN* WARNER-LAMBERT/PARKE-DAVIS PHARMACEUTICAL RESEARCH, ANN ARBOR, MI.

Recently a number of compounds that are claimed to have selective actions on dopamine (DA) autoreceptors have been synthesized. In addition, it has become evident that the baseline firing rate of the DA neuron being recorded is an important determinant of the magnitude of the observed effect. We evaluated the effects of DA autoreceptor agonists on DA neurons of differing baseline rate. Cells that had a baseline firing rate of <4 Hz were termed slow firing; cells that had a baseline rate of >4 hz were termed fast firing. Experiments were conducted in chloral hydrate anesthetized male S-D rats. Using standard extracellular recording techniques, single DA neurons were identified by their waveform, firing pattern, and subsequent histological verification of recording site. Drugs were administered IP or IV. We first demonstrated that the population of DA neurons that were being recorded from were nigrostriatal neurons. DA neurons that had baseline firing rates up to 8 Hz were antidromically activated from stimulating electrodes in the caudate nucleus. The dose-response curve for inhibition of fast firing DA cells (mean rate = 6.2 Hz) by IV apomorphine (APO) was similar to that previously reported for nigrostriatal DA neurons ($ED_{50}$ = 8 ug/kg; 100% inhibition at 128 ug/kg). APO (1 mg/kg, IP) and (+)-3PPP (5 mg/kg, IP), completely inhibited slow and fast firing DA neurons. Similar to APO and (+)-3PPP, (-)-3PPP (5 mg/kg, IP), completely inhibited slow firing DA cells. In contrast to APO and (+)-3PPP, (-)-3PPP, at 20 mg/kg IP could only partially inhibit (60%) fast firing DA cells. Initial observations that (-)-3PPP produced a dose-dependent antagonism of the inhibitory effects of APO (1 mg/kg, IP) on fast firing DA neurons and that low doses of APO (0.1 mg/kg, IP) or (+)-3PPP (1.25 mg/kg IP), which produced a partial inhibition of fast DA neurons, did not antagonize the effects of APO (1 mg/kg, IP), suggested that the ability to antagonize the inhibitory effects of APO on fast firing DA neurons might provide a test for partial agonist activity. However, further testing revealed that there were some neurons that were partially inhibited by APO (0.5 mg/kg, IP) that could not be completely inhibited by a subsequent dose of APO (1 mg/kg, IP) . Thus, the ability to antagonize the effects of APO (1 mg/kg, IP) on fast firing DA neurons, does not represent an accurate test of partial autoreceptor agonist activity. This may be better reflected by the ability of the test compound, itself, to completely inhibit the activity of fast firing DA neurons. Thus, APO and (+)-3PPP act as full agonists and (-)-3PPP acts like a partial agonist at DA autoreceptors.

311.3 THE ACTION OF DOPAMINE ON THE AFTERHYPERPOLARIZATION RECORDED IN HIPPOCAMPAL PYRAMIDAL CELLS. R.C. Malenka and R.A. Nicoll. Dept.'s of Pharmacology & Physiology, U.C.S.F., San Francisco, CA. 94143

Dopamine (DA) has been reported to have long lasting effects on the calcium-activated potassium conductance ($G_{K(Ca)}$) underlying the slow afterhyperpolarization (AHP) which follows a train of action potentials. However both increases in the AHP, associated with a slow hyperpolarization, and decreases in the AHP, associated with a slow depolarization, have been reported. Using the rat hippocampal slice preparation we have examined the actions of DA on CA1 pyramidal cells paying particular attention to its effects on $G_{K(Ca)}$. Bath applied DA (1-100 μM) significantly reduced the AHP in a dose dependent fashion. This effect was completely reversed after 10-15 minutes of washing and with higher doses of DA was often associated with a small depolarization. The blockade of the AHP likely occurs at a step subsequent to the entry of Ca since Ca spikes recorded in 0.3 μM TTX and 5 mM TEA were not affected by DA. Neither the amount of current injected to elicit the AHP nor its initial amplitude had an effect on the reduction of the AHP by DA. Since DA's actions closely mimicked those of norepinephrine and DA has been shown to interact with β receptors, we examined the effect of β antagonists on DA's actions. At concentrations which have been shown not to block DA stimulated adenylate cyclase, both propranolol and timolol (5 μM) completely inhibited the reduction of the AHP by DA. This strongly suggests that this major action of DA in the hippocampus is due to its cross reactivity with β receptors.

To determine whether there might be some action of DA unrelated to adenylate cyclase stimulation (i.e. mediated by a D2, not a D1 receptor) we examined the actions of apomorphine, a D2 agonist, and those of DA in the presence of β antagonists. Bath application of these agents elicited no consistent change in any measurable electrophysiological parameter. Because DA may inhibit acetylcholine release in other neuronal systems we also looked at whether DA blocked the slow cholinergic EPSP which can be elicited in the hippocampus. Again, DA had no effect.

In some cells using either iontophoresis or puffer application of high concentrations of DA we elicited small (1-5 mV) hyperpolarizations. This action of DA was not antagonized by either chlorpromazine or haloperidol (1 μM) raising doubts that it is mediated by DA receptors. Since the size of these responses was small and their occurrence unpredictable, we have not pursued their pharmacological characterization.

In summary, we were unable to find any neuronal action of DA in the hippocampus that could be attributed unambiguously to its specific interaction with DA receptors. Instead we are forced to conclude that its major electrophysiological action (i.e. a blockage of the AHP) is due to cross reactivity with β adrenergic receptors. Supported by the Scottish Rite Schizophrenia Research Program, NMJ, USA and Grants NS07495 (to R.M.) and MH38256, MH00437 (to R.N.).

311.4 STUDIES ON THE MECHANISM OF DOPAMINE AUTORECEPTOR-INDUCED INHIBITION OF DOPAMINERGIC TRANSMISSION IN RABBIT STRIATUM.

T.C. Westfall and L. Naes*. Dept. of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

It is now well established that autoreceptors are present on dopamine cell bodies, dendrites and axonal terminals which act to decrease neuronal activity and neurotransmission in the mammalian nervous system. The purpose of the present study was to explore the mechanism of the inhibitory effect of dopamine autoreceptors on neurotransmission in the neostriatum of the rabbit. The hypothesis examined was that activation of autoreceptors inhibits the evoked release of dopamine by limiting the availability of calcium necessary for secretion coupling. Autoreceptor function was assessed by examining the effect of dopamine agonists on the release of dopamine produced by field stimulation of superfused slices. Similar experiments were carried out following perturbations that were shown to enhance the release of dopamine presumably by increasing the entry of calcium into nerve terminals. Pertubations included raising the extracellular $Ca^{2+}$ concentration in the superfusion buffer, administration of aminopyridine or the administration of $Ca^{2+}$ ionophore A23187.

Rabbits were decapitated, the brain quickly removed and the striatum dissected. Sagittal striatal slices (0.3 mm) were prepared with a MacIlwain tissue chopper. Following a preincubation, slices were incubated in a physiological buffer containing $^3$H-dopamine ($10^{-7}$ M) and then placed in individual superfusion chambers. Superfusate effluents were continuously collected by a fraction collector. Apomorphine was shown to produce a concentration dependent decrease in the field stimulation induced release of $^3$H-dopamine. The release of $^3$H-dopamine was measured in the absence ($S_1$) or presence ($S_2$) of apomorphine and the $S_2/S_1$ ratio calculated. $S_2/S_1$ ratios were 0.99 ± .2, 0.67 ± .17 and 0.53 ± .08 for control and $10^{-7}$ or $10^{-6}$ on apomorphine, respectively. Although lower concentrations were without effect, aminopyridine ($10^{-4}$ M) produced a marked facilitation of the field stimulation induced release of $^3$H-dopamine resulting in a $S_2/S_1$ ratio of 2.83 ± .59. Apomorphine ($10^{-6}$ M) was still able to decrease the evoked release of $^3$H-dopamine in the presence of aminopyridine with a $S_2/S_1$ ratio of 0.80 ± .3.

The results to date suggest that activation of dopamine autoreceptors does not inhibit the release of dopamine by preventing the entry of extracellular calcium across the nerve terminals.

Supported in part by DA02668, NS16215 and HL26319.

311.5 NEUROPHARMACOLOGY OF MESENCEPHALIC DOPAMINERGIC NEURONS IN VITRO. M. S. Brodie and T. V. Dunwiddie, Dept. Pharmacology, University of Colorado Health Sciences Ctr. and Veterans Administration Medical Research Service, Denver, CO 80262.

Mesencephalic dopaminergic neurons are found primarily in the ventral tegmental area of Tsai (VTA) and in the substantia nigra (SN). Because these areas appear to mediate different types of behaviors, interest has developed in agents that may selectively affect the activity of these subgroups of dopaminergic neurons. In order to study the pharmacology of neurons in these areas in a quantitative fashion, an in vitro preparation containing both the VTA and SN has been developed.

Sprague-Dawley rats were sacrificed, the brain quickly removed, trimmed, affixed to a vibratome chuck, and plunged into artificial cerebrospinal fluid (aCSF) kept at 4°C. Slices (300 um) were cut in the coronal plane in such a fashion that both the VTA and SN were included in a single slice. The slices were transferred to the recording chamber, which was maintained at 35.5°C, and were allowed to equilibrate for one hour before recording was begun.

Intra- and extracellularly recorded action potentials of VTA neurons were similar to those recorded in intact anesthetized rats. Long duration action potentials (2.4-4 msec) were observed with an inflection on the rising phase corresponding to what has been considered to be the initial segment spike. The firing rate of these neurons was 1-3 Hz. The effects of various agents were tested on spontaneous firing rate of VTA neurons. Dopamine (10-100 uM) inhibited the firing rate of all VTA neurons (n=12) exhibiting the characteristics indicated above (type I neurons). Inhibition was also produced by dopamine agonists such as apomorphine, and could be reversed with fluphenazine, a specific dopamine antagonist. A subpopulation of non-dopaminergic neurons in the VTA (type II neurons) that have a shorter duration action potential and faster firing rate, did not respond to dopamine.

Substantia nigra neurons were more sensitive than the putative dopamine-containing type I neurons of the VTA to the inhibitory effects of dopamine. The firing of a majority of SN neurons was completely inhibited by 100 uM dopamine, whereas in the VTA this concentration of dopamine reduced the firing rate but did not produce a complete cessation of activity. These results suggest that there may be important differences in the pharmacology of dopaminergic neurons located in these two regions, and that certain drugs may have a relatively selective action upon dopaminergic neurons in these two groups.

Supported by DA 02702 and the Veterans Administration Medical Research Service.

311.6 CAFFEINE AND MESOLIMBIC DOPAMINE NEURON ACTIVITY: ANTAGONISM OF CAFFEINE BY BOTH DIAZEPAM AND HALOPERIDOL. Gene R. Stoner*, Sidney Werkman*, Lana R. Skirboll, and Daniel W. Hommer. Clinical Neuroscience Branch, NIMH, Bethesda, MD 20205.

Caffeine is probably the most widely used psychotropic drug in the world today and its psychostimulant effects are well known. Although caffeine has recently been demonstrated to potently antagonize the effects of adenosine, it is not clear that the psychostimulant actions of caffeine are exclusively mediated through adenosine system. Since catecholamines, particularly dopamine (DA), have been implicated in the actions of other stimulant drugs and since caffeine has been demonstrated to increase the release of catecholamines both in peripheral tissue and in brain synaptosomes, we examined the effects of intravenously administered caffeine on the activity mesencephalic dopamine (DA) neurons in the rat ventral tegmental area (VTA).

Male Sprague-Dawley rats were anesthetized with chloral hydrate; placed in a stereotaxic apparatus and a burr hole drilled over the VTA. Standard extracellular single unit recording techniques were employed. Once a putitative VTA unit was encountered its identity as a DA neuron was confirmed using previously established criteria. After a five minute period of baseline recording, caffeine in doses of 5, 5, 10 and 20 mg/kg was administered intravenously (n=13). Caffeine produced a significant, dose-dependent decrease in the activity of VTA-DA neurons (ANOVA with repeated measures on dose, $F(1, 24) = 16.1$, $p < 0.03$). Following a cumulative dose of 20 mg/kg of caffeine the firing rate of VTA-DA neurons was 60 ± 8% of baseline. After 40 mg/kg the firing rate decreased further to 46 ± 8% of baseline. Diazepam, 0.5 mg/kg, almost completely blocked the inhibitory effects of caffeine (n=13). Haloperidol 0.5 mg/kg also completely blocked the inhibitory effects of caffeine on VTA neurons (n=8).

Our results suggest that caffeine's psychostimulant effects may in part be mediated by an action on DA systems. Since caffeine's effects can be blocked by haloperidol, caffeine may cause increased release of DA in forebrain regions which in turn leads to a feedback inhibition of DA neuron activity. It is also possible that caffeine could cause release of dendritic DA which could locally inhibit DA neurons. Thus, the actions of caffeine on mesolimbic DA systems may be similar to the actions of amphetamine since amphetamine decreases DA neuron activity by DA release and activation of an inhibitory feedback pathway (Bunney and Aghajanian in The Basal Ganglia, Raven Press, 249-267, 1976).

311.7 SUPERSENSITIVITY OF DOPAMINERGIC NEURONS TO APOMORPHINE IN RATS FOLLOWING CHRONIC HALOPERIDOL. G.D.Vogelsang and M.F.Piercey, CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Although acute neuroleptic treatment results in an effective blockade of post-synaptic dopamine (DA) receptors, chronic treatment is required for effective antipsychotic therapy. The clinical ineffectiveness of acute treatment may be due to increased firing rates of DA neurons observed following acute treatments. Recent experiments focusing on chronic neuroleptic treatment have demonstrated depression in numbers of spontaneously active DA neurons and enhanced DA autoreceptor sensitivity at nerve terminals. The present study further investigates these effects by examining the effects of chronic neuroleptic treatment on cell body autoreceptor sensitivity, indicated by dopamine agonist-induced depressions in DA neuron firing rates.

Microelectrodes filled with 2M NaCl saturated with 2% fast green were stereotaxically placed into the substantia nigra pars compacta of chloral hydrate-anesthetized rats. DA neurons were identified by large positive-negative spikes > 2.5 msec duration and histological localization of iontophoresed dye spots. The average effective dose of i.v. apomorphine (APO) for achieving 50% inhibition (ED50) of the spontaneous discharge of DA neurons in control rats was 9.6±3.2 ug/kg. The APO ED50 for rats receiving chronic haloperidol (1.0 mg/kg/day i.p. for 28 days followed by 3-day washout) was 3.4±0.8 ug/kg ($p<0.001$, t-test). Firing rates of DA neurons were unchanged. It is concluded that chronic haloperidol makes DA cell body autoreceptors supersensitive to agonist stimulation, an action which could contribute to the antipsychotic efficacy of chronic treatments.

311.8 CHARACTERIZATION OF PUTATIVE DOPAMINERGIC (DA) NEURONAL FIRING IN THE VENTRAL TEGMENTAL AREA (A10) OF UNRESTRAINED RATS. A.S. Freeman and B.S. Bunney, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT

We have reported that putative substantia nigra zona compacta (A9) DA cells of unrestrained rats fire in a range of rates and patterns similar to those of conclusively identified DA neurons. In the present study, the firing properties of putative A10 DA cells in freely moving rats were investigated.

A steel well was cemented to the skull overlying the A9 or A10 region of male rats and an injection cannula was implanted into a jugular vein. Prior to recording sessions, a microdrive containing a glass-coated tungsten electrode was inserted into the implanted well. Putative DA cells (n=39) were readily distinguished on the basis of waveform, firing rate (5.0±1.3 spikes/s, $\bar{x}$±SD) and pattern. Most cells (90%) fired a portion (36±21%) of their spikes in bursts which consisted of up to 18 spikes ($\bar{x}$=2.9 spikes/burst).

Previous intracellular studies in gallamine-paralyzed and chloral hydrate-anesthetized (immobilized) rats have shown electrical coupling to occur between A9 DA cells (Grace and Bunney, Neurosci. 10: 333, 1983) and we have observed, extracellularly, a higher incidence of apparent A9 DA neuronal coupling in unrestrained vs. immobilized rats (Freeman et al., Life Sci. 36: 1983, 1985). Ten pairs of A10 cells (26%) in the current sample were also observed to interact in this manner. These findings strongly suggest that synchronization of midbrain DA neuronal firing in the behaving rat is an important means by which these neurons influence their target cells.

Presumed DA neuronal discharge was unrelated to gross motor behavior. However, small movements of the snout and vibrissae (as in sniffing) were often associated with prominent burst firing. Mechanical stimulation of the vibrissae produced a similar change in pattern. Exposure to light flashes (1-3 Hz) did not alter neuronal firing.

In preliminary pharmacological experiments, we have tested the effects of CCK-8 (a substance co-localized with DA in a subpopulation of midbrain cells) on A10 DA neurons. CCK-8 (1-16 μg/kg) produced inconsistent effects on firing. CCK-8 also produced variable effects on firing patterns which were not always related to changes in rate. Preliminary data suggest that CCK-8 enhances the inhibitory potency of apomorphine on A10 DA cell firing. In A9, CCK-8 either stimulated (stimulation block by progluminde, 200 μg/kg) or had no effect on firing rate. Each effect of CCK-8 generally lasted less than 2 min. These effects of CCK-8 are similar to those obtained in immobilized rats. Supported by MH-08987, MH-25642, MH-28849 and the State of Connecticut.

311.9 IN SITU INTRACELLULAR RECORDING FROM NUCLEUS ACCUMBENS NEURONS: I. SPONTANEOUS RHYTHMIC OSCILLATION OF RESTING MEMBRANE POTENTIAL. C.Y. Yim and G.J. Mogenson. Dept. of Physiology, University of Western Ontario, London, Ontario, Canada.

Interest in the unique anatomical and functional association of the nucleus accumbens (NAcc) with both limbic and presumed motor nuclei of the brain prompted a number of extracellular single unit recording experiments to investigate the input-output relationship as well as the effect of dopamine on cellular activity in this nucleus (Yim and Mogenson, Brain Res., 239:405, 1982). In order to further study the electrophysiological characteristics of neurons in the accumbens and the cellular action of dopamine, intracellular recordings were obtained from accumbens neurons in the urethane anesthetized (1.5 g/kg) rat in situ. Recordings were obtained using K acetate (2 M) or K citrate (1.5 M) filled glass micropipettes with impedance of 60-100 M ohm. Only recordings from neurons having resting membrane potentials of >45 mV and action potentials of >50 mV were analysed. Input resistance of accumbens neurons measured with small hyperpolarizing pulses (0.1 to 0.5 nA, 30 ms) was found to be 12-30 M ohm, similar to those reported in earlier studies with striatal slices (Chang and Kitai, Soc. Neurosci. Abstr., 10:703, 1984). An unexpected observation from this in situ preparation was that 65% of the accumbens neurons (n = 54) displayed spontaneous large amplitude rhythmic oscillations of the resting membrane potential. The frequency of the oscillations was from 0.6 to 0.9 Hz and the amplitude ranged from 5 to 20 mV. In some neurons, action potentials occurred at the peaks of the oscillation resulting in the characteristic bursting firing pattern observed in extracellular unit recordings. No comparable EEG, however, could be recorded from the extracellular space. Stimulation of the ventral tegmental area (VTA) with trains of 10 pulses (400 µA to 1 mA) at 10 Hz produced consistently 3 to 10 mV depolarization of the membrane potential and elimination of the spontaneous oscillations. The induced depolarization was accompanied by an average of 20% increase in membrane conductance. The effects of VTA stimulation lasted up to several minutes after cessation of the stimulation. Oscillations were not observed in presumed glia cells and their resting membrane potential was not changed by VTA stimulation either. These empirical findings provide the basis of further experiments in progress.

311.10 IN SITU INTRACELLULAR RECORDING FROM NUCLEUS ACCUMBENS NEURONS: II. VENTRAL TEGMENTAL AREA STIMULATION ATTENUATES EVOKED EPSP FROM AMYGDALA STIMULATION. G.J. Mogenson and C.Y. Yim (SPON: J.J. Seguin). Dept. of Physiology, University of Western Ontario, London, Canada.

Previous experiments using extracellular single unit recording techniques showed that nucleus accumbens (NAcc) neurons are strongly excited by stimulation of the amygdala (AMY) and the hippocampus, and that the excitatory response is preferentially attenuated by stimulation of the ventral tegmental area (VTA), site of the A10 dopamine (DA) cell bodies. These and other results led to the suggestion that DA may act presynaptically to modulate synaptic transmission in the ventral striatum. This possibility was investigated further in the present study. Intracellular recordings were made from NAcc neurons of urethane anesthetized rats in situ using K acetate or K citrate filled micropipettes. Stimulation of the basolateral nucleus of the AMY (400 µA to 1 mA) elicited a depolarizing-PSP (dPSP) - hyperpolarizing-PSP (hPSP) sequence in 52 of 54 (96%) NAcc cells sampled. The amplitude of the dPSP varied between cells and ranged from 6 to >30 mV and was continuously monitored by a peak amplitude detector. Stimulation of the VTA (400 to 800 µA) in trains of 10 pulses at 10 Hz consistently depolarized the resting membrane potential and attenuated the amplitude of the dPSP. Although amplitude of PSPs usually varies with membrane potential, the attenuation of the dPSP by VTA stimulation did not appear to be entirely due to the concurrent membrane depolarization. This is suggested because similar depolarization of the membrane potential by injection of a small depolarizing current through the recording electrode did not produce an equivalent attenuation. Moreover, attenuation of the dPSP as well as depolarization of the membrane potential persisted in some cases for several minutes after termination of VTA stimulations but the time course of recovery differed between the two responses. The late hPSP was not consistently affected by the VTA stimulation in contrast to the effect on the dPSP, and in addition, a greater attenuation of the dPSP was observed when the recording was obtained using K citrate electrodes (-42%) compared to those obtained using K acetate electrodes (-33%). Taken together, these results are interpreted to indicate that AMY stimulation produces an EPSP-IPSP sequence in NAcc neurons. Partial reversal of the hyperpolarizing IPSP by acetate augments the EPSP and produces the dPSP-hPSP sequence observed. VTA stimulation produces membrane depolarization and preferential attenuation of the EPSP probably by different mechanisms, the latter involving a presynaptic mechanism in view of its selectivity. Both effects are likely due to DA released in the NAcc based on earlier observations from extracellular single unit recording experiments.

311.11 VALIDATION OF THE ACCURACY OF VOLTAMMETRIC MEASUREMENT OF BIOGENIC AMINE CONCENTRATIONS IN VIVO. J. Schenk*, A. Hansen, A. Knorr*, W. Stewart, and B. Bunney (SPON: L. Kitahata), Depts. Psychiatry, Pharmacology, Neuroanatomy and Neurosurgery, Yale Univ. Sch. of Med. New Haven, CT.

In vivo voltammetric measurements (IVVM's) have been shown to be useful for measuring oxidizable molecules in the extracellular fluid (ECF) of the brain. The compounds thought to be detected are the biogenic amines and their metabolites, ascorbic acid, and uric acid. Prior to experimentation, a carbon sensing electrode (dia. 8-40 um) is calibrated by applying a potential sufficient to oxidize the species of interest and measuring the resulting oxidation (faradaic) current over a range of concentrations (C). The slope of the signal vs. C line is the electrode calibration factor. Then the electrode is implanted into the brain and IVVM's are begun. Signals can be expressed in terms of C based on the in vitro calibration factor. Often the calibration serves as a normalization procedure for comparing responses obtained at multiple electrodes or between groups of experiments. However, the ultimate goal is to measure signals in terms of "absolute" C changes. These values are needed for making correlations with receptor affinities, uptake carrier affinities, and enzyme Km's. However, the accuracy of in vivo C measurement is unknown. To assess the accuracy of IVVM's of C based on in vitro calibration one needs a "standa*d" compound that can be introduced into the brain quantitatively, that diffuses through the ECF in a defined way, and can be measured in vivo in the ECF by an alternate analytical technique. Our approach to develop this "standard" is to fabricate an Aliquot 336-based ion selective electrode (ISE) (dia. 1-2 um) for ferrocyanide (FeCN6) ion to use to independently measure an ion that can also be detected faradaically. This ion is a good probe since the FeCN6 complex is stable at neutral pH (formation constant = 10^24), its faradaic electrode reaction is known, and a diffusion coefficient for it in the ECF has been reported (Rice et. al. Neurosci. in press 1985) . In our poster, we describe the fabrication and properties of the FeCN6 ISE and illustrate its usefulness for measuring FeCN6 ion in the ECF. Detailed analysis comparing diffusion profiles obtained using ISE's and IVVM's will be presented. Preliminary results suggest that short duration IVVM's (tens of ms.) based on in vitro calibrations gives C values that match those obtained with ISE's. However, relatively long IVVM's (> 1 sec.) result in deviations from ISE values suggesting that the best in vivo voltammetric techniques for C measurements are those utilizing electrolysis times of one sec. or less. 311.12 THE EFFECT OF KNOWN CONCENTRATIONS OF DOPAMINE ON DOPAMINE CELL FIRING RATES IN MIDBRAIN TISSUE SLICES. N.L. Silva, J.O. Schenk* and B.S. Bunney, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510

Previous anatomical studies have demonstrated the existence of dopaminergic (DA) neurons within the pars compacta of the substantia nigra. These cells are readily identifiable by their electrophysiological characteristics and pharmacological responsiveness. DA neurons are typically inhibited by the administration of DA or DA agonists, presumably through an action on cell body or dendritic autoreceptors. Recently, in vitro studies have shown that neurons possessing this characteristic waveform were inhibited by DA. The purpose of this study was to investigate in detail the response of midbrain DA cells to known DA concentrations by analyzing the concentration dependent reduction of DA cell firing rate in the context of equilibrium models.

Rat midbrain tissue slices (300-400 µm) were placed in a humidified chamber which was constantly perfused with an oxygenated nutrient medium (pH 7.4, 300 mOsm/kg, 10 mM glucose) and maintained at 36°C. The perfusate could be rapidly switched between normal and experimental medium using three-way stopcocks. Each neuron encountered was recorded for 3 to 5 minutes prior to the introduction of DA containing medium (0.5-500 µM). DA concentrations in the perfusate were confirmed by high pressure liquid chromatography with electrochemical detection. DA concentrations in the extracellular fluid of the slice were monitored using carbon fiber voltammetric electrodes (dia. 40 µm) implanted 150 µm into the slice. After a maximal change in firing rate was observed, the perfusion was switched back to the normal nutrient medium. Baseline firing rate was always re-established before any additional DA concentrations were tested.

Preliminary studies show that DA interaction at DA-receptive sites in the midbrian slice preparation results in a suppression of firing rate. In these experiments, 2 subpopulations of DA cells were defined according to their response to DA. One group has an apparent DA DA-receptive site dissociation constant (K') of approximately 10 µM while the second group has a K' value of approximately 160 µM. Both groups follow a simple equilibrium relationship having a stoichiometric relationship of 1:1. It is hoped that development of this paradigm will provide a more precise basis for the study of the action of DA, modulatory substances and DA agents on DA neuronal system functioning.

311.13 ELECTROPHYSIOLOGICAL AND PHARMACOLOGICAL EVIDENCE FOR THE EXISTENCE OF TWO TYPES OF NIGROSTRIATAL DOPAMINERGIC NEURONS. D.C. German and P.D. Shepard. Depts. of Physiol. and Psychiat., Univ. of Texas Health Sci. Cntr., Dallas, TX. 75235.

Substantia nigra (SN) dopamine (DA)-containing neurons have been reported to exhibit two predominent patterns of firing. Previous studies in which DA cells were systematically recorded throughout the rostral-caudal extent of the SN have revealed a tendency for cells which fire with an irregular pattern to be located in the rostral half of the nucleus whereas cells which fire with a bursting pattern reside primarily in the caudal half of the nucleus. Comparison of the sensitivity of Bursting and Irregular firing cells to an autoreceptor-selective dose of apomorphine has revealed that Irregular cells were significantly more sensitive to the rate-decreasing effects of the drug than Bursting cells (Shepard & German, Neurosci. Abstr., 8:261.1, 1982; Neurosci. Abstr., 10:280.7, 1984).

The purpose of the present experiment was to use single cell recording and antidromic activation techniques to determine whether these two cell types (a) project to similar neuroanatomical regions, and (b) exhibit similar sensitivity to the rate-depressing effects of the indirect acting DA agonist, d-amphetamine (d-AMP). Male albino rats (250-300 g) were anesthetized with chloral hydrate (400 mg/kg, i.p.) and the femoral vein was cannulated for subsequent drug administration. Standard electrophysiological recording techniques were employed. Only one cell was studied per rat. Cells were classified into groups based upon their interspike interval histogram shape; Irregular cells exhibited a normal-like ISI distribution, whereas Bursting cells exhibited a positively skewed ISI distribution (1000 spikes/histogram). We found that both cell types project to the caudate-putamen, however, the estimated conducting velocities were significantly different (Irregular = 0.32 m/s, Bursting = 0.60 m/s, $p < .001$). We also found that Irregular cells were significantly less sensitive to low doses of d-AMP (0.5 mg/kg, i.v.) but significantly more sensitive to higher doses (1.5-4.0 mg/kg) than Bursting cells. These data indicate that nigral DA neurons which exhibit different firing patterns are characterized by different axonal properties and sensitivities to direct and indirect acting DA agonists. The Bursting neurons are faster conducting, less sensitive to autoreceptor stimulation but more sensitive to the effects of low doses of d-AMP than cells which exhibit an Irregular firing pattern. These two cell types may coincide with the two different cell body morphologies found in the SN (Fallon et al., Neurosci. Lett., 7:157, 1978) and the two predominant types of DA nerve terminals in the striatum (Kaiya & Namba, Neurosci. Lett., 25:251, 1981). Research supported by grant MH-30546.

311.14 **NEURONS LOCATED IN THE VENTRAL GLOBUS PALLIDUS (SUBSTANTIA INNOMINATA) DEMONSTRATE AN APOMORPHINE-INDUCED INCREASE IN ACTIVITY WHICH IS REVERSED BY HALOPERIDOL.** **T.C. Napier, P.E. Simson* and G.R. Breese. Univ. of North Carolina Sch. of Med., Chapel Hill, NC 27514 and Duke Univ. Sch. of Med. Durham, NC 27709.**

**The ventral aspect of the forebrain, traditionally denoted as substantia innominata, is now being characterized as comprising distinct groups of cells. Heimer and Wilson (Golgi Centennial Symposium, Proceedings, M. Santini (ed) Raven Press, NY, 1975, pp. 177-193) anatomically described for the rat an area immediately ventral to the anterior commissure and rostrally situated at the level of the external segment of the globus pallidus. This region, designated as the ventral pallidum, receives afferents ventral striatal regions (as well as the nucleus accumbens) and perhaps serves in a circuit which is parallel to "dorsal" striatum → "dorsal" globus pallidus projections. Since the globus pallidus is known to be influenced by systemically administered dopamine agonists (Bergstrom, Bromley and Walters, Brain Res. 238:266, 1982; Napier, Simson and Breese, Fed. Proc. 5:1387, 1985) this study was undertaken to determine if neurons of the ventral pallidum are also affected by dopaminergic drugs. Using standard electrophysiological techniques, extracellularly recorded single units were obtained from chloral hydrate anesthetized male Sprague Dawley rats. Following 5-10 min of pretreatment monitoring, apomorphine was administered via a cannulated lateral tail vein. The doses used were 1 ug to 1 mg/kg, injected every two min so that each injection doubled the previous dose. Haloperidol (0.1 to 1 mg/kg i.v.) was administered at the conclusion of apomorphine treatments. Using this protocol, the majority of ventral pallidal units responded to apomorphine with an increase in firing rates generally 100% above pretreatment levels. This increase was antagonized by haloperidol. Some cells were not affected by the doses of apomorphine used in these experiments. These studies indicate that, like the dorsal globus pallidus, neuronal activity of the ventral pallidum/substantia innominata are dramatically altered by dopaminergic drugs. 311.15 Depolarization Inactivation of Nigral Dopamine Neurons by Repeated Haloperidol Administration: Analysis by in vivo Intracellular Recording. B.S. Bunney & A.A. Grace, Departments of Psychiat. & Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06510 and Depts. of Psychol. and Psychiat., Univ. Pittsburgh, Pittsburgh, PA 15260.

Acute haloperidol treatment in rats is known to increase the firing rate of nigral dopamine (DA) neurons. However, in 1978 we reported that repeated treatment of rats with haloperidol (0.5 mg/kg for 21 days) resulted in a dramatic decrease in the number of spontaneously firing DA neurons in the substantia nigra. Since these nonfiring cells could not be activated by microiontophoretic application of excitatory substances (e.g., glutamate) but could be activated by inhibitory agents (e.g., GABA), we hypothesized that the DA neurons were in a state of depolarization inactivation or depolarization block. However, by using extracellular recording techniques, we were only capable of providing indirect evidence that the DA cells were depolarized to the extent that they were incapable of generating spontaneous action potentials.

More recently, we have attempted to obtain direct evidence for the depolarization block model of inactivation by recording intracellularly from identified DA neurons in vivo. In control rats, DA neurons have an average resting membrane potential (RMP) of about 55 ± 3 mV, and were either firing spontaneously or would discharge in response to depolarization of the cell membrane. However, following repeated haloperidol administration the impaled DA cells had significantly more depolarized RMPs (41 ± 6 mV) and were incapable of firing action potentials either spontaneously or in response to membrane depolarization. Although it is difficult to rule out injury as a possible source of this depolarized state, we believe that this reflects the actual membrane potential of the DA cell after repeated haloperidol administration since: 1) almost every DA cell impaled had a resting potential near this level, 2) the RMP was stable over time, 3) the input resistances of the cells were not significantly different from controls (29 ± 7 megohms, as compared to an input resistance of 31 ± 7 megohms in untreated rats), whereas injured cells typically have input resistances of <10 megohms, and 4) the depolarization inactivated state could be reversed by hyperpolarizing current injection or by pharmacological means 5 minutes or longer after impalement. Thus, after impalement, hyperpolarization of the cell by current injection restored spontaneous firing of the DA cell. Furthermore, systemic administration of apomorphine caused DA cells in depolarization inactivation to repolarize in a dose-dependent stepwise manner which led to a resumption of spontaneous activity. In summary, repeated haloperidol treatment induced a state of depolarization inactivation in DA neurons by depolarizing the membrane potential to the extent that the spike generating mechanism was inactivated. (Supported by USPHS MH28849, MH25642, and the State of Connecticut)

311.16 POSSIBLE FACTORS DETERMINING THE PROPERTY OF ANTIDROMIC DISCHARGES OF DOPAMINERGIC A10 NEURONS DURING REPETITIVE ACTIVATION. K.Watabe, T.Shinba*, R.Sugita*, and T.Satoh*. Dept. of Physiol., Aichi-Gakuin Univ. Dent. Sch., Nagoya, 464 Japan.

In the noradrenergic(NA) A6 and serotonergic(5-HT) raphe neurons, the latency of antidromic discharges is gradually prolonged to reach an asymptote during repetitive activation. We have suggested that although the way of latency prolongation is apparently similar in the two monoaminergic sytems, the mechanism behind those phenomena may not be identical. The present study aimed at investigating whether latency prolongation upon repetitive stimulation can occur also in dopaminergic(DA) neurons, and if it is the case, what kind of mechanism is operating in these neurons. For this purpose unit activity of meso-accumbens(Acc) A10 neurons was extracellularly recorded in normal and chemically treated rats (haloperidol(HAL) or picrotoxin(PTX) i.p., kainic acid(KA) locally into the Acc, or HAL combined with KA(KA+HAL)). Gradual latency increase during 10Hz stimulation, similar to that observed in the NA or 5-HT neurons, was found in a great majority of neurons of normal and chemically treated rats. The increase in latency, as expressed in % of the initial latency, was greatest in the normal (mean, 11.3%), smallest in the KA+HAL(6.2%), and intermediate in the KA(8.6%), PTX(9.7%) and HAL(10.5%). Some neurons in the KA+HAL rats showed, in the course of latency prolongation, "latency jump" followed by reprolongation of latency. All the neurons showing latency prolongation were apparently dopaminergic, as judged from their slow spontaneous firing and wide duration of spikes. In the antidromic responses during 10Hz stimulation in normal rats, 77% of the initial segment(IS) spikes were not followed by the somadendritic(SD) spikes. In contast, in all the chemically treated rats, the frequency to obtain suppression of antidromic SD spikes was extremely or moderately low; 2.7%, 9.5%, 38% and 55% in the KA+HAL, KA, PTX and HAL, respectively. These results suggest that both axonal and somatic mechanisms are involved in the latency prolongation during repetitive activation. More frequent suppression of antidromic SD spikes and more marked latency prolongation of IS spikes in normal rats may be explained by activation of the afferents from the Acc, which is partly GABAergic, and also by self-regulatory mechanism in A10 DA neurons.

311.17 ELECTROPHYSIOLOGICAL AND PHARMACOLOGICAL PROPERTIES OF PRESUMED DOPAMINE-CONTAINING NEURONS IN THE SUPRAMAMMILLARY REGION OF THE RAT. P.D. Shepard and D.C. German, Depts. of Physiol. and Psychiat., U. of Texas Health Sci. Cntr., Dallas, TX. 75235.

Previous neuroanatomical studies have identified a small collection of catecholamine-containing cells within the supramammillary (SUM) complex (Fuxe, et al., In: Metabolism of Amines in the Brain. G. Hooper, (Ed), pp. 10-22, 1969). These cells appear to be dopaminergic (DA) since they contain tyrosine hydroxylase (TH), but not dopamine-beta-hydroxylase (Swanson, et al., J. Comp. Neurol., 163:467-506, 1975). SUM neurons have been shown to project to a number of limbic areas including the lateral septum (LS) and anterior limbic cortex (ALC). However, recent studies have shown that while approximately half of the LS-projecting cells contain TH, none of the ALC-projecting neurons appear to be dopaminergic (Swanson, Brain Res. Bull., 9:321-353, 1982). The purpose of the present study was to examine the electrophysiological and pharmacological properties of antidromically identified neurons within the SUM complex. In addition, the responsiveness of these cells to DA agonists was assessed to determine whether putative DA-containing neurons possessed rate-modulating autoreceptors. Action potentials from spontaneously active SUM neurons were biphasic and of moderately long duration (2.0-3.4 msec). Cells frequently exhibited slow firing rates (1.35 ± 0.2 impulses/sec) and erratic discharge patterns. Conduction velocities obtained from LS-projecting SUM neurons were not significantly different from ALC-projecting cells. Iontophoretically applied DA was without effect on spontaneously active SUM neurons. Similarly, low doses of apomorphine (5.0 ug/kg, i.v.) produced a significant decrease in the firing rates of only 3 of 11 cells tested. In contrast, D-amphetamine (0.5-2.0 mg/kg, i.v.) produced a significant decrease in 83% of the cells tested. In addition to spontaneously active neurons, several silent cells were encountered which were antidromically activated from the LS. These cells appeared to be tonically hyperpolarized as iontophoretic application of glutamate, but not GABA, was effective in causing the cells to discharge. Spike durations and estimated conduction velocities associated with silent SUM neurons were similar to those obtained from spontaneously active SUM cells. However, in contrast to the latter group, 100% of the silent cells sampled, induced to fire with glutamate, exhibited a statistically significant decrease in firing rate in response to iontophoretic DA. These data indicate that both NON-DA and DA containing cells exist in the SUM and that the DA-containing cells are normally silent in the anesthetized preparation. ## CATECHOLAMINES: ELECTROPHYSIOLOGY

312.1 A FUNCTIONAL AND MORPHOLOGICAL STUDY OF NORADRENERGIC INNERVATION OF THE SUPRAOPTIC NUCLEUS IN THE AGING RAT. W.F. Silverman, C.D. Sladek, and J.R. Sladek, Jr. Depts. of Anatomy and Neurology, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

The hypothalamic supraoptic nucleus (SON) of the rat exhibits a dense plexus of noradrenergic (NA) fibers and varicosities originating in brain-stem reticular formation. This plexus is most concentrated in ventral, vasopressin-rich portions of SON, though in the vasopressin-deficient Brattleboro mutant, and in aged rats, an apparent reorganization to more dorsal, oxytocin-rich areas is observed (Sladek et al., Peptides 1:141, 1981). An experiment to correlate this morphologically demonstrable change in the topographic localization of NA within the SON with the vasopressin responsiveness to an osmotic challenge was performed. Aged (24 month) and young (3 month) Fischer 344 male rats were deprived of water for 72 hours prior to sacrifice. Following decapitation, the brains were frozen and 16 um sections were cut on a cryostat. Tissue was treated for demonstration of glyoxylic acid-induced monoamine fluorescence and examined in a fluorescence microscope. Serum and neurohypophysis were also collected from each subject for future correlative assessment of vasopressin levels with respect to the visualized catecholamine input to the SON.

A dense pattern of fluorescent noradrenaline terminals was concentrated principally in ventral portions of SON among vasopressinergic neurons in young subjects. Challenged subjects did not appear to differ from unchallenged controls with respect to the NA innervation pattern. A less dense fluorescence pattern was observed at all levels in the SON of aged subjects in agreement with previous results obtained by this laboratory. Occasional cells in dorsal SON were observed which exhibited the apparent hyperinnervation by catecholamine terminals characteristic of this nucleus in the aging rat. These results confirm data from previous studies of changes in NA innervation of VP neurons in SON in aging. Previous studies in our laboratory have demonstrated an attenuated VP response to osmotic challenge in aged rats (Sladek et al., Neurobiol. Aging 2:293, 1981). It is conjectured that the reduction in CA in the SON during senescence may be involved in this functional decline. The results of a correlative ultrastructural-morphometric assessment of number and regional density of synapses in the SON of aged and young rats will be presented.

312.2 SP-IMMUNOREACTIVE VARICOSITIES LOCALIZED ON MEDULLARY TYROSINE HYDROXYLASE-IMMUNOREACTIVE CELLS BACKFILLED WITH HRP FROM THE SPINAL CORD. A.P. Nicholas*, M. B. Hancock*, and Sau-Wah Kwan*. (SPON: G. Russell). Department of Anatomy and Department of Human Biological Chemistry and Genetics, The University of Texas Medical Branch, Galveston, TX 77550.

Two-color immunoperoxidase staining was used to visualize black-stained substance P-immunoreactive (SPI) varicosities on amber-stained tyrosine hydroxylase-immunoreactive (THI) cells in the ventrolateral medulla of adult rats in which the thoracic spinal cord was injected with HRP. Animals deeply anesthetized with Nembutal were given multiple, bilateral injections, (4-7 µl total) of 50% HRP (Sigma; type VI) in phosphate buffered saline (0.1 M; pH 7.4) into the thoracic spinal cord through a micropipette inserted between adjacent spinal laminae. After 24-27 hours, the rats were again anesthetized and perfused transcardially with ice-cold 4% paraformaldehyde in 0.1M phosphate buffer (PB; pH 7.4). The brainstem was removed and postfixed overnight in 4% paraformaldehyde in PB. Vibratome sections (25-30 µm) were reacted with 0.035% diaminobenzidine (DAB), 2.5% nickel ammonium sulfate, and 0.01% $H_2O_2$ in 0.1M acetate buffer (pH 6.0) for 30 minutes. HRP-labeled cells showed fine, black granules in their cytoplasm. Sections containing HRP-labeled cells were washed and stored in PB for 24-48 hours. The tissue was then incubated overnight at room temperature in rabbit anti-SP (Immunonuclear; 1:5000), 0.2% Triton X100, and 1% normal goat serum in PB. The sections were then incubated in goat anti-rabbit IgG (1:100), rabbit PAP (1:640), and finally in the nickel-DAB solution used above. SPI processes were stained an intense black. The tissue sections were incubated overnight at room temperature in a 1:1000 dilution of a monoclonal antibody to TH. This was followed by incubations in rabbit anti-mouse IgG (1:100), mouse PAP (1:320), and finally in 0.05% DAB and 0.01% $H_2O_2$ in PB. Amber-stained THI cells enmeshed in SPI processes were observed in the ventrolateral medulla and in the solitary nucleus. Selected thick sections were embedded in Spurr plastic. Blocks of the ventrolateral medulla were cut from these sections and mounted on plastic rods. Semi-thin (1.4-1.8 µm) sections of this material were then cut using an ultramicrotome and glass knives. In these sections, black, SPI beads could be visualized along the borders of individual THI cells. Many of the THI cells were labeled with HRP, indicating that they projected to the spinal cord. The results suggest that SP released from fibers in the medulla may influence activity in brainstem catecholaminergic neurons that send fibers into the spinal cord.

312.3 INTERACTION OF SYMPATHETIC AND PARASYMPATHETIC NEURONS IN THE CARDIAC GANGLION OF NECTURUS. R.L. Parsons and D.S. Neel* Dept. of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

Components of the autonomic nervous system (ANS) regulate the function of many visceral structures. Many organs, such as the heart are dually innervated by both sympathetic and parasympathetic postganglionic fibers. Interaction between these two components of the ANS is known to occur in brain stem and spinal cord nuclei as well as at the target tissue. Recently, evidence has been presented suggesting an interaction between sympathetic and parasympathetic components within peripheral autonomic ganglia in the gut. A direct interaction between sympathetic and parasympathetic elements in a cardiac parasympathetic ganglion is presented in this study.

Experiments were done using acutely dissected or organ cultured parasympathetic cardiac ganglion preparations from Necturus masculosus (mudpuppy). Whole mount preparations of the septal tissue sheet which contained the parasympathetic ganglion were removed and pinned out on Sylgard coated petri dishes. The glyoxylic acid induced fluorescence technique was used to visualize catecholamine containing cells and fibers.

Numerous long brightly fluorescent varicose fibers form a complex network over clusters of parasympathetic ganglion cells and strands of cardiac muscle. In addition to these fibers, there are numerous small brightly fluorescent interneurons (SIF cells) interspersed between individual parasympathetic ganglion cells. Long fibers and processes from the interneurons join to form bundles which arborize over groups of parasympathetic cells. In peripherally located smaller groups of ganglion cells there are no interneurons, but these parasympathetic cells receive innervation from the long continuous fluorescent axons.

Two experimental procedures were applied to support the conclusion that these long fibers were indeed sympathetic postganglionic axons: a) explants of cardiac ganglia were maintained for varying times to produce degeneration of any severed axons; b) chemical sympathectomy was produced by injection of 6-hydroxy dopamine. The intrinsic SIF cells were apparently uneffected by both procedures. After eight days in culture or after 6-OH dopamine treatment all of the long continuous brightly fluorescent fibers, which normally intermingle with clusters of ganglion cells or innervate cardiac muscle, were absent. This indicates their extra-ganglionic origin. All of the isolated groups of parasympathetic ganglion cells not containing SIF cells were totally devoid of any catecholamine containing fibers.

312.4 SUBSET OF ASTROCYTES IN CEREBRAL CORTEX IN DISSOCIATED CELL CULTURE ACCUMULATE GLYCOGEN. P. A. Rosenberg* and M. A. Dichter(SPON: H. Blume). Department of Neurology, Children's Hospital, Boston, Mass. 02115.

Previous reports have demonstrated that norepinephrine (NE) decreases the accumulation of glycogen (GN) in the mouse cortical slice preparation. To identify the cells in which this effect of NE might be taking place, we used cerebral cortex in dissociated cell culture, and combined GN cytochemistry with anti-GFAP immunochemistry. Cultures of E15 rat cerebral cortex were prepared as previously described from this laboratory, and were used at 3-8 weeks. Cultures were fixed in ethanol and stained for glycogen using a modified periodic acid-Schiff technique. They were then incubated with a polyclonal rabbit anti-GFAP serum (courtesy Dr. A. Bignami), washed, and incubated with FITC-conjugated goat anti-rabbit antibody. Two types of nonneuronal cells in the cultures contained GN. One type of GN containing cell formed distinct plaques of cells which were GFAP negative and in which most cells contained GN. These plaques were also GFAP negative when they were not stained for GN, and were not always present in the cultures. The second GN containing cell type resembled astrocytes and were more specifically identified by anti-GFAP staining. Most of these cells appeared to be clearly GFAP positive (greater than 50 %). False negatives for GFAP staining are expected because fuchsin acts as an effective filter for the green emission of fluorescein, and therefore may prevent detection of the antibody in some cells. The GN containing astrocytes were typically found at the periphery of neuronal aggregates, occasionally within such aggregates, or near small groupings of solitary neurons. The overwhelming majority of astrocytes did not contain GN. Glycogen accumulating astrocytes therefore represent only a small subset of astrocytes in the cultures. These findings complement the recent observation that a subset of astrocytes in culture have beta receptors, determined by radioligand autoradiography (McCarthy, K. D., J. Pharm. Exp. Ther., 226: 282, 1983). Since we were able to demonstrate GN in the cultures, as well as its cellular localization, we attempted to demonstrate GN accumulation biochemically, as well as the effect of NE on this parameter. Cultures incubated with 3H-glucose demonstrated NE sensitive 3H-GN accumulation. The EC50 was 4 nM, with a beta receptor specificity. Together, these results suggest that at least one cellular target for NE in cerebral cortex is a specialized subset of astrocytes which accumulate GN subject to beta-adrenergic control.

312.5 DOPAMINE ENHANCED TERMINAL EXCITABILITY OF HIPPOCAMPAL-ACCUMBENS NEURONES MEDIATED BY D-2 RECEPTORS. C.R. Yang* and G.J. Mogenson (SPON: D.L. Jones). Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

The nucleus accumbens (NAC) receives converging glutamatergic afferents from the ventral subiculum of the hippocampus (HIPP) and dopaminergic afferents from the ventral tegmental area (VTA). Earlier we have reported that conditioning stimulation of VTA mesolimbic dopaminergic (DA) neurones attenuated the excitatory responses of NAC neurones to HIPP stimulation (Yang, C.R. & Mogenson, G.J., Brain Res., 324:69, 1984). The possibility that this attenuation is due to DA from the VTA neurones acting presynaptically on the terminals of the HIPP-NAC neurones was investigated with extracellular single unit recording technique. In urethane-anesthetized rats, antidromic action potentials recorded in the HIPP by glass microelectrodes were elicited by stimulating the medial NAC with the 4M NaCl-filled centre barrel of a four-barrelled micropipette assembly. The side barrels contained drug and DA solutions for iontophoresis onto the terminal regions of the identified HIPP-NAC neurones. The stimulating current was adjusted to elicit antidromic responses of HIPP neurones on 30-40% of trials which was considered to be the basal firing index.

Conditioning VTA stimulation (5-10 trains of 10 Hz pulses, 200-600 μA, 0.2 ms pulse duration), or iontophoretic application of DA (20-100 nA) produced a prolonged (mean, 25 min) enhancement of the firing index in 78/110 (71%) and 36/70 (51%) neurones, respectively. Twelve out of 33 (36%) of the neurones tested responded to both treatments. Iontophoretic application of LY-171555, a selective dopamine D-2 agonist, also produced a similar enhancement of firing index in 17/31 (55%) neurones tested. Iontophoretic application of sulpiride (a selective D-2 antagonist, n=7), but NOT SCH-23390 (a selective D-1 antagonist, n=4), blocked the increased firing index resulting from conditioning VTA stimulation. In order to rule out the possibility that the excitability changes produced by the DA input was mediated trans-synaptically, or by interneurones in the NAC, ibotenic acid lesions were made in the NAC of 15 rats 7-9 days before each recording session. Conditioning VTA stimulation and iontophoretic application of DA also produced an enhanced firing index in equal proportion of the HIPP-NAC neurones in these animals, compared to untreated animals.

The above evidence suggests that DA, via its D-2 receptors, exerts a depolarizing action on the terminals of HIPP-NAC neurones to increase their terminal excitability. This action of DA may constitute one of the presynaptic events which reduce excitatory transmitter release from HIPP-NAC neurones.

312.6 AN IN VITRO STUDY OF NOREPINEPHRINE EFFECTS ON LATERAL HYPOTHALAMIC NEURONAL RESPONSES TO GABA. J-T. Cheng, S.A. Azizi, J.K. Chapin and B.D. Waterhouse. Dept. Cell Bio., Univ. Tx Health Science Center, Dallas, TX 75235.

Previous studies from this laboratory have demonstrated that norepinephrine (NE) can consistently augment synaptically-mediated (70%) and GABA-induced (69%) inhibitory responses of lateral hypothalamic (LH) neurons in vivo. The present experiments further characterize the interactions of NE with LH neuronal responses to GABA and attempt to validate the LH slice preparation as a model for future intracellular studies of NE modulatory phenomena. Extracellular activity of LH cells was recorded from diencephalic slices (450 μm) incubated in ACSF at 33° C. Interactions of iontophoretically applied NE, isoproternol (ISO) or phenylephrine (PE) with responses of LH neurons (n=38) to microiontophoretic GABA were characterized using computer-generated ratemeter and histogram records. We observed dual actions of NE on spontaneous activity (SA) and GABA-induced responses of LH neurons. In 8 of 33 cells tested (24%), locally applied NE markedly enhanced inhibitory responses to GABA iontophoresis. GABA inhibition was augmented by NE at doses which had little (<10%) or no effect on SA in 5 of these 8 cases. In 19 cells (58%), iontophoretic application of NE antagonized GABA responses. In 9 of these cases, NE also had an excitatory effect on SA. Overall, in those cells where NE administration increased SA, it either antagonized or had no effect on GABA inhibition. In contrast, spontaneous firing rate was never elevated above control levels in those cases where NE potentiated GABA responses. Additional experiments demonstrated that iontophoretic application of the β agonist, ISO, routinely suppressed SA of LH neurons (n=4) and mimicked the facilitating action of NE on GABA in 3 cases. On the other hand, local administration of the alpha agonist, PE, produced NE-like antagonism of GABA inhibition and exerted an excitatory effect on SA in 3 of 3 cases tested. In addition, the antagonistic effect of NE on GABA responses was not blocked by application of the β antagonist, sotalol. In summary, these findings indicate that the commonly observed in vivo phenomena of NE augmentation of GABA and suppression of LH neuron spontaneous firing can be demonstrated in vitro and result from an interaction with β adrenoceptors. However, NE antagonism of GABA inhibition and excitatory effects on SA were more routinely observed in LH slices and appear to be mediated by alpha receptor activation. Thus, while the LH slice preparation appears to be a useful model for further study of NE/GABA interactions; a comparison of our present and past results emphasizes discrepancies between in vivo and in vitro data and brings into question the in vitro viability of the mechanism(s) responsible for NE enhancement of GABA responses. 312.7 BIOGENIC MONOAMINES AFFECT A SLOW LIGHT-EVOKED ELECTRICAL RESPONSE OF THE RETINAL PIGMENT EPITHELIUM. S.M. Dawis* and G. Niemeyer*. (SPON: J. Fohlmeister). Neurophysiology Laboratory, Department of Ophthalmology, Universitaetsspital, CH-8091 Zuerich, SWITZERLAND.

Biogenic monoamines may be involved in controlling the function of the retinal pigment epithelium (RPE), a single layer of epithelial cells between the photoreceptors and the choroidal circulation. For example, monoamines have been implicated in the circadian rhythm of phagocytosis of photoreceptor outer segment discs by the RPE (Remé, C. et al., Brain Res., 298:99, 1984).

We found that biogenic monoamines can affect the maintained and light-evoked electrical activity of the mammalian RPE. The maintained activity of the RPE in the isolated, arterially perfused cat eye was indirectly monitored with an electrode in the vitreous referenced to an electrode at the posterior pole of the eye. The recorded standing potential (SP) is largely due to a difference in the potentials of the apical and basal membranes of the RPE. A 1 min pulse of diffuse white light (70 cd/$m^2$) was used to evoke a light peak (LP), a slow increase in the SP that reached a maximum amplitude of a few millivolts approximately 6 min after light onset. The LP has been shown to arise from a depolarization of the basal membrane of the RPE (Griff, E.R. and Steinberg, R.H., J. Physiol., 331:637, 1982; Linsenmeier, R.A. and Steinberg, R.H., J. Physiol., 331:653, 1982). At 20 micromolar, dopamine, norepinephrine, serotonin, and melatonin caused an increase in the SP of the eye and abolished the LP; histamine had no effect. These effects were reversible and were mimicked by dibutyryl cyclic AMP.

It appeared as if the monoamine-induced increase in SP saturated the system responsible for generating the LP. One possibility is that either the retinal dopaminergic or serotonergic system is involved in the generation of the LP. Another possibility is that the LP is generated by another retinal mechanism but that the RPE is influenced by monoamines released by the retina or present in the choroidal circulation. Perhaps the observed action of monoamines on the LP is the basis for the circadian rhythm seen in the clinical electrooculogram, an estimate of the amplitude of the human LP (Anderson, M.L. and Purple, R.L., Invest. Ophthal. Visual Sci., 19:278, 1980)

312.8 ELECTROPHYSIOLOGICAL STUDIES OF MONOAMINE SENSITIVE NEURONS IN THE RAT PREFRONTAL CORTEX. S. R. Sesack and B. S. Bunney, Depts. Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510.

Spontaneously active neurons in the medial prefrontal cortex (PFC) of the rat were investigated using single unit extracellular techniques. Animals were prepared for recording by a low cerveau isole transection performed under temporary halothane anesthesia. Microiontophoretic application of drugs through five barrel micropipettes was used to test the sensitivity of prefrontal neurons to monoamines and other neurotransmitters.

The majority of cells throughout the PFC were sensitive to the effects of norepinephrine (NE) and responded with an inhibition of firing rate. Dopamine (DA) also produced inhibitory responses throughout the PFC, however cells exhibiting the greatest sensitivity to dopamine were located primarily in the deepest layers. Serotonin (5HT) sensitive neurons could also be found in the medial PFC and while inhibitory responses to 5HT were common, excitatory responses were also occasionally observed. Several cells in the medial PFC were located which exhibited sensitivity to all three of the monoamines tested.

In addition to monoamines, neurons in the medial PFC were tested for their sensitivity to the neuropeptide cholecystokinin-octapeptide sulfate (CCK-8). Prefrontal neurons were equally divided between those showing an excitatory response to CCK-8 and those failing to respond at all. As previously reported, most DA sensitive cells within the deep cortical layers were sensitive to the excitatory effects of CCK-8 (Chiodo and Bunney, Science 219: 1449, 1983). A few CCK sensitive neurons, however, did not respond to any of the monoamines tested.

During the course of this investigation it became evident that cells in the medial PFC could be divided into 2 broad categories based on their extracellular waveforms. Both types of cells exhibited a biphasic action potential which displayed either an initial positive or an initial negative going segment. Both positive and negative going cells displayed similar sensitivities to the monoamines and CCK. However most of the cells in the deep layers which were primarily sensitive to DA exhibited negatively going waveforms, and the cells which were sensitive to both DA and CCK were also of the negatively going type.

These preliminary results suggest that cells within the medial PFC can be characterized both on the basis of sensitivity to various neuroactive substances and extracellularly recorded waveform. In addition, several cells in the PFC have been shown to respond to more than one transmitter. Experiments are in progress to investigate possible modulatory interactions among the monoamines, peptides, and classical neurotransmitters.

312.9 NOREPINEPHRINE (NE) MEDIATES A SLOW HYPERPOLARIZING SYNAPTIC POTENTIAL (S-HSP) IN PARASYMPATHETIC NEURONS. P.Shinnick-Gallagher, T. Akasu*, J.P. Gallagher and K. Hirai*. Dept. of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX.

In cat parasympathetic ganglia of the urinary bladder, adrenergic fibers encircle and apparently terminate on cholinergic neurons. In the present study we analyzed the synaptic mechanism of the adrenergic innervation using intracellular recording techniques. Supramaximal stimulation of the preganglionic nerve trunk in the presence of hexamethonium (0.5mM) elicited a slow-inhibitory post-synaptic potential (s-i.p.s.p.). Increasing the stimulus intensity revealed the presence of a slower wave on the falling wave of the s-i.p.s.p. Treatment with atropine (0.1μM) blocked the s-i.p.s.p. and unmasked a s-h.s.p. This potential was reversibly abolished in low Ca solution suggesting release of a chemical transmitter. Yohimbine (0.1-1μM), an alpha$_2$-adrenoceptor antagonist, markedly depressed the s-h.s.p. in 56% of the neurons but even higher concentrations (3μM) did not affect s-h.s.p.s in 36% of the neurons. Recently we reported the existence of an adenosine-mediated s-h.s.p. in these neurons. S-h.s.p.s resistant to yohimbine were blocked by caffeine, a $P_1$-purinoceptor antagonist. Bath application of norepinephrine (50μM) produced a membrane hyperpolarization which was also markedly depressed by yohimbine (0.5μM). • Imipramine augmented the amplitude and duration of the caffeine resistant s-h.s.p. and the NE hyperpolarization. These data suggested the pharmacology of caffeine-resistant s-h.s.p. and NE hyperpolarization were similar. Membrane resistance was decreased 40% during the caffeine-resistant s-h.s.p. and 45% during the hyperpolarization produced by bath application of NE (50μM). This s-h.s.p. decreased in amplitude as the membrane was hyperpolarized and reversed polarity around -106mV. Similarly, the NE hyperpolarization decreased in amplitude with membrane hyperpolarization and reversed polarity around -108mV. In high K solution the reversal potentials of the s-h.s.p. recorded in caffeine and NE hyperpolarization shifted to more positive levels, around -78mV and -80mV, respectively. These data indicated that the caffeine-resistant s-h.s.p. and NE hyperpolarization are mediated by an increase in K conductance. These data demonstrate that a non-cholinergic, non-purinergic hyperpolarizing response elicited by preganglionic nerve stimulation in neurons of vesical parasympathetic ganglia is most closely mimicked by the response to exogenously applied NE. In addition, the catecholamine mediated s-h.s.p. produced an inhibition of spontaneous activity in vesical neurons which is ten times longer than the inhibition produced during the s-i.p.s.p. These data suggest that the catecholamine-mediated s-h.s.p. may be the underlying synaptic substrate for the inhibition of transmission in vesical ganglia observed during sympathetic nerve stimulation. (Supported by NS16228)

312.10 **DIFFERENTIAL ORGANIZATION OF THE EFFERENT PROJECTIONS OF THE VENTROMEDIAL MESENCEPHALIC TEGMENTUM IN THE CAT.** T. Scheibner* and I. Törk* (SPON: D. J. Tracey) School of Anatomy, University of N.S.W., Kensington 2033, Sydney, Australia.

The cortical and subcortical projections of the ventromedial mesencephalic tegmentum (VMT) in the cat were studied using the retrograde axonal transport of the highly sensitive tracer, WGA-HRP. One ul of a 1.5% solution of the tracer was injected into the motor, somatosensory, auditory, visual, prefrontal, insular, entorhinal, cingulate and parasplenial cortical areas and into the accumbens nucleus and surrounding septal structures.

An extensive projection was observed to all cortical regions studied with the largest numbers of retrogradely labelled cells being found in the VMT following prefrontal, cingulate, visual and insular cortical injections. Further, the VMT nuclei were observed to contribute differentially to these projections. The largest numbers of retrogradely labelled cells were found in the linearis rostralis nucleus (LR) (25% of the total estimated ipsilateral population of LR, or 1200 neurons). The parabrachialis pigmentosus (PBP), the linearis centralis (LC) and the interfascicular (IF) nuclei contained progressively fewer retrogradely labelled cells. The paranigralis nucleus (PN) was not found to project to any cortical region studied. However, following injection of the accumbens nucleus, the PN contained the largest numbers of retrogradely labelled cells (50% of the total estimated ipsilateral population of PN, or 4000 neurons). The PBP, IF and LC contained progressively fewer labelled cells, and in the LR only 5% of the total estimated ipsilateral population of this nucleus was labelled. Septal and accumbens nucleus injections resulted in the same distribution of labelled cells (concentrating in the ventrocaudal part of the VMT) even though accumbens nucleus injections yielded the largest numbers of labelled cells.

These results indicate that in the cat the cortical projections of the VMT are much more extensive than described in the rat. Furthermore, we observed a strong topographical organization of projections. The VMT neurons which project to subcortical limbic structures are found ventrocaudally, whereas neurons projecting to cerebral cortex are found dorsorostrally. Finally, we identified one population of neurons, found in PN, which does not project to cerebral cortex.

312.11 COMPARATIVE ANATOMY OF THE MESENCEPHALIC VENTROMEDIAL TEGMENTUM. G. Halliday* and I. Törk* (SPON: R. Bandler). School of Anatomy, University of N.S.W., Kensington, 2033, Sydney, Australia.

Nissl preparations of the mesencephalic ventromedial tegmentum (VMT) in four species (rat, cat, monkey and human) were qualitatively and quantitatively compared. In all species five subnuclei could be distinguished: nucleus parabrachialis pigmentosus (PBP), nucleus paranigralis (PN), nucleus interfascicularis (IF), nucleus linearis rostralis (LR) and nucleus linearis centralis (LC). The relative position and extent of these nuclei are illustrated in three dimensional reconstructions from serial sections. The size and number of cells in each nucleus vary between the different species. The data obtained from these nuclei are compared to data from the substantia nigra pars compacta (SNC).

**Extent and Cell Number.** The majority of VMT cells are located laterally in PBP and PN. These lateral nuclei also make up the bulk of the VMT volume. The greatest variation between species in nuclear shape and extent is seen in the medially located LC and LR. LR, although seen in all species, was substantial only in cat. The VMT is small in the monkey, relative to both other species and its own SNC.

| Species | rat | cat | monkey | human |
|---|---|---|---|---|
| VMT volume($mm^3$) | 1.20 | 14.38 | 6.50 | 183.40 |
| SNC volume($mm^3$) | 0.34 | 3.20 | 6.28 | 67.60 |
| VMT cell no. | 27215 | 62691 | 47497 | 690420 |
| SNC cell no. | 11878 | 26027 | 71086 | 436409 |

**Cell Density.** In all cases, the SNC is more densely packed with cells than the VMT. The rat has the highest cell packing density in the SNC and VMT. Among the nuclei of the VMT, IF is the most densely packed. With the exception of the cat, cell densities are higher laterally than medially in the VMT. The table below gives the cell packing density in the VMT and SNC, as cell density x mean soma diameter.

| Species | rat | cat | monkey | human |
|---|---|---|---|---|
| VMT density(cells/$mm^2$) | 309 | 74 | 80 | 120 |
| SNC density(cells/$mm^2$) | 561 | 187 | 260 | 200 |

**Cell Size.** The cells of the VMT are heterogeneous in size and staining properties. In general, the VMT cells are smaller than those found in the SNC. The human has the largest VMT cells and the rat has the smallest VMT cells. IF is made up of the most homogeneous group of small cells in all species and LR has the greatest proportion of large cells in all species.

| Species | rat | cat | monkey | human |
|---|---|---|---|---|
| VMT cell size(um) | 13±3 | 15±7 | 16±5 | 26±9 |
| SNC cell size(um) | 16±4 | 23±5 | 23±5 | 31±7 |

Our findings indicate that the disposition and shape of the VMT and its subnuclei vary across species, and these differences are further reflected in the quantitative analysis.

312.12 EFFECT OF ACUTE AND CHRONIC HALOPERIDOL ON MID-BRAIN DA CELLS IN UNANESTHETIZED RATS. G. Mereu, S.P. Han* and R.Y. Wang (SPON: E. Rubin). Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

Studies from this and other laboratories have shown that acute administration of antipsychotic drugs (APD's) such as haloperidol (HAL) increases whereas prolonged administration (3-4 weeks) reduces in a time-dependent manner the number of spontaneously active dopamine (SA-DA) cells of both $A_9$ and $A_{10}$ areas. Several lines of evidence suggest that such effect reflects a progressive depolarization inactivation induced by the drugs on mid-brain DA neurons. Because the time course of such effect, particularly for $A_{10}$ cells, is well correlated with the clinical response of APD's, it has been proposed that the decrease SA-DA cells might explain the delayed therapeutic effects of the prolonged treatment with neuroleptics. The above studies were performed on chloral hydrate (CH) anesthetized rats. However, differences in the basal activity and in the responses to drugs of DA neurons have recently been reported between anesthetized and unanesthetized rat preparation. Therefore the present experiments were designed to investigate whether anesthesia was affecting the changes in SA-DA cells to acute and chronic HAL treatment.

Under CH anesthesia rats had chronically implanted a device by which the head could be retained in the stereotaxic apparatus without pain. The animals were then adapted to the restraint in a hammock jacket tightly wrapped around the body to minimize the struggling, 2-3 hours each day for 2 weeks. Recording electrodes were lowered in the $A_9$ or $A_{10}$ area through a plastic cylinder which sat on top of the hole previously drilled in the skull.

The preliminary results indicate that in both $A_9$ and $A_{10}$ areas, the number of SA-DA cells is significantly higher in this preparation than CH anesthetized rats (1.45±0.16 vs 0.87±0.03, $P<0.001$ for $A_9$ and 2.34±0.21 vs 1.53±0.04, $P<0.001$ for $A_{10}$). However, acute and prolonged administration of HAL (0.5 mg/kg/day) increases and decreases, respectively, the SA-DA cells (see table) in a fashion similar to that previously observed in CH preparation. In two rats apomorphine (100 µg/kg s.c.) administered after 4 weeks of HAL administration, reversed the SA-DA cells to values close to baseline suggesting that the decrease in SA-DA cells was due to an excessive depolarization by APD's.

In conclusion, the study supports and extends our previous results to unanesthetized preparation.

Time-course of DA cells/track after HAL

| | | | Weeks of treatment | | | |
|---|---|---|---|---|---|---|
| Area | Baseline | Acute | 1 | 2 | 3 | 4 |
| $A_9$ | 1.45±0.16 | 2.01±0.18 | 1.49±0.26 | 1.08±0.16 | 1.33±0.21 | 0.53±0.08 |
| $A_{10}$ | 2.34±0.23 | 4.30±0.48 | 2.50±0.19 | 2.13±0.12 | 1.90±0.13 | 1.12±0.20 |

(Research supported by USPHS grants MH34424, MH38794 and MH00378.)

312.13 COMPARISON OF EFFECTS PRODUCED BY CHRONIC ADMINISTRATION OF d-AMPHETAMINE, HALOPERIDOL AND CLOZAPINE ON THE ACTIVITY OF LOCUS COERULEUS NEURONS. O.A. Ramirez* and R.Y. Wang (SPON: M. Meldrum). Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

The role of norepinephrine (NE) in the pathophysiology of schizophrenic symptoms has been controversial. To determine the participation of noradrenergic transmission during the schizophrenic symptomatology, effects produced by prolonged treatment with d-amphetamine (d-AMP) or antipsychotic drugs (APD's) such as haloperidol (HAL) and clozapine (CLOZ) on NE-containing neurons in the locus coeruleus (LC) were studied.

Groups of male rats received intraperiotoneal injections of d-AMP (5 mg/kg) twice daily for 7 days. Control rats received daily injections of saline. Single unit recordings of NE cells in the LC were obtained 24 hrs after the last injection. After chronic d-AMP (CAMP) treatment the number of spontaneously active cells/track was decreased significantly. Interspike interval histograms of NE cells showed a "disorganized" firing pattern after CAMP treatment. On the other hand, $\alpha_2$ adrenergic receptors became subsensitive to i.v. d-AMP or iontophoretic (IONTO) application of DA (0.1 M) or clonidine (CLON) (0.01 M). CAMP treatment significantly increased the dose of d-AMP required to suppress the firing of LC NE neurons. ID50s for d-AMP in CAMP and control rats were 280.8±40.7 and 55.2±12.2 µg/kg ($P<.001$), respectively. CAMP treatment also increased markedly the ejection current (nA) of CLON and DA necessary for inhibiting the activity of LC NE neurons. The inhibitory effects of DA in LC cells is not mediated by DA receptors, since trifluperazine, an antagonist of DA receptors, was not able to reverse the inhibition produced by DA.

Chronic HAL treatment (0.5 mg/kg subcu. for 3-5 wks) did not change the number of spontaneously active cells/track but markedly decreased the mean firing rate of these cells. On the other hand, chronic CLOZ (20 mg/kg subcu.) produced an increase in both the firing rate and the number of spontaneously active LC cells/track.

In conclusion, the results suggest that during CAMP treatment, which is often associated with schizophrenic symptomatology, the NE transmission is decreased. In addition, because neither HAL nor CLOZ, after prolonged administration, induced a time-dependent reduction of spontaneously active NE cells in the LC, our results do not support the view that a significantly increased NE activity in the brain caused the schizophrenic symptoms. On the other hand, the marked increase of NE activity after chronic CLOZ treatment could contribute to the selective action of CLOZ on $A_{10}$ mesolimbic (particularly at the terminal regions) but not $A_9$ nigrostriatal system. (This research was supported by USPHS grants MH-34424, MH38794 and a RSDA MH-00378. O.A.R. was supported by a Fellowship from the CONICET of Argentina.)

312.14 A METHOD FOR COMBINED LOCAL DRUG INFUSION AND ELECTROPHYSIOLOGICAL RECORDING OF LOCUS COERULEUS NEURONS. L.M. Adams and S.L. Foote, Department of Psychiatry, UCSD, La Jolla, CA 92093

While it is of interest to determine the effects on target cells of changes in the discharge rate of locus coeruleus (LC) neurons, it is difficult to selectively activate these neurons using electrical stimulation; the LC is limited in size and is surrounded by major fiber tracts originating from other nuclei. The high activation threshold of LC axons also makes it difficult to selectively activate them at other locations. Finally, while it would be useful to examine the effects of acute, reversible LC "lesions", it is difficult to inhibit these neurons by electrical means.

We have developed a method for manipulating the electrophysiological activity of LC neurons in a reversible, bi-directional, verifiable way using a combined cannula and microelectrode assembly to record LC unit activity while infusing drugs. A stainless steel microelectrode is cemented parallel to a piece of 27 ga hypodermic tubing (guide canula) which terminates 3 mm above the microelectrode tip. A 33 ga needle with a 27 ga sleeve is connected to a 10 µl syringe by PE tubing. When inserted, the needle protrudes to the same depth as the microelectrode , with 400 µm lateral displacement. Rats were placed in a stereotaxic apparatus under halothane anesthesia. A glass micropipette was used to localize LC neurons, then removed, and the electrode/infusion assembly lowered at the same coordinates The infusion line was pre-filled with a sequence of different drugs and or doses (separated by air bubbles) and the infusion assembly lowered with the needle in place. After baseline firing and sensory responses were established, the "drug series" was infused at a rate of 0.05 µl per min. Finally, electrical current was passed through the electrode to mark the recording site; and Pontamine sky blue dye (0.1 µl) was infused to mark the injection site. The "Prussian blue reaction" was used to produce an intense green spot at the recording site. When these sites were within of the locus coeruleus, dye injections were usually within the mesencephalic nucleus of V.

Infusion of 0.1 µl of 0.02M acetylcholine (ACH) produced a 3-4 min long increase in LC firing rate with a 1 min latency to onset. Larger volumes (0.15 µl) produced greater increases in firing rate lasting 10-12 min. ACH effects were readily reversed with equimolar doses of scopalamine (SCOP). Conversely, 0.6 µl of 0.02M SCOP antagonized the effect 0.1 µl "pulses" of ACH for up to 4 min. The effects of 0.02 M ACH were also rapidly reversed by equal volumes of 0.001 M clonidine. Scopalamine and clonidine reduced basal firing rates without blocking responses to sensory stimuli.

This method for producing verified, quantified activation or suppression of LC neuronal activity will be useful in studies correlating LC activity with behavior or target cell activity. Supported by NS21384, MH4008, Dystonia Med Res Fdn.

312.15 THE FACILITATING ACTION OF LOCUS COERULEUS ACTIVATION ON CA1 PYRAMIDAL CELL EXCITABILITY AND ON TRANSCALLOSALLY ELICITED CORTICAL FIELD POTENTIALS IN VIVO. H.-R. Olpe*, R.S.G. Jones*, J. Laszlo*, P.C. Waldmeier* and L. Maître* (SPON: G.Gmelin), CIBA-GEIGY Ltd., Pharmaceuticals Division, CH 4002 Basel, Switzerland

A depressant action of iontophoretically applied noradrenaline on hippocampal and cortical spontaneously active neurons has been described in vivo. In vitro however, low concentrations of noradrenaline have a disinhibitory effect on hippocampal CA1 neurons (Müller et al. 1981; Madison and Nicoll, 1982; Haas and Konnerth, 1983). In the present study locus coeruleus (L.C.) neurons were activated by injecting small volumes (0.2-2.0 µl) of physiological saline solution containing 0.5 mM glutamate into the area of L.C. by means of a hamilton syringe. Local Glu-injections afford a selective activation of L.C. neurons without affecting passing fibres. Glu-activation of L.C. induced a reversible increase in the CA1 population spike amplitude without altering the slope of the negativity of the epsp recorded in the stratum radiatum. In DSP-4 treated, noradrenaline-depleted animals, the facilitatory effect was abolished.

A multiphasic cortical field potential (TPC) was recorded in the sensorimotor cortex of the anaesthetized rat induced by electrical stimulation of the contralateral homotopic area. The amplitude of the first negativity of the TCP was reversibly increased by local Glu-injections into L.C. This facilitatory effect was strongly reduced in DSP-4 treated, noradrenaline depleted animals. The amplitude of the first negativity was also increased following injections of hydergine (10 mg/kg i.p. / 4 out of 6 experiments). Hydergine is a potent activator of L.C. neuronal activity (Olpe and Steinmann, 1982).

In conclusion, the present findings demonstrate that L.C. activation facilitates the responsiveness of cortical neurons to excitatory, probably glutamatergic inputs.

312.16 CARDIOVASCULAR AND CENTRAL NORADRENERGIC EFFECTS OF INTRAVENOUS COCAINE ADMINISTRATION IN RATS. D.K. Pitts*, and J. Marwah (SPON: L.M. Yunger). Depts. of Pharmacology, Physiology and Neurobiology, Indiana Univ. Sch. Med., Terre Haute, IN 47809.

The present studies examined the cardiovascular effects of intravenous cocaine HCl in pentobarbital (65 mg/kg, I.P.) anesthetized rats. Mean arterial pressure (MAP) was recorded from the femoral artery, and heart rate was derived from the pulsatile blood pressure trace. Cocaine (0.16-5 mg/kg) administered intravenously (I.V., lateral tail vein) over a 30-second period produced an initial dose-dependent increase in MAP within seven to 25 seconds followed by a more prolonged (several minutes) depressor effect. This effect on MAP was accompanied by a significant increase in respiratory rate and bradycardia. Cocaine (1.25 mg/kg, I.V.) administered to conscious-restrained rats produced a pressor response similar to that seen in barbiturate anesthetized animals. The subsequent depressor phase was, however, greatly attenuated. Procaine (0.31, 1.25 mg/kg, I.V.) produced a depression of MAP similar to that seen with cocaine in the barbiturate anesthetized rat. This depressor effect of procaine (1.25 mg/kg, I.V.) was also greatly attenuated in the conscious-restrained animal. These results suggest that the local anesthetic properties of cocaine may be specifically responsible for the hypotensive effects of cocaine in barbiturate anesthetized animals. Preliminary results further suggest that the initial pressor response, but not the subsequent depressor response to IV cocaine is present in urethane (1.25 g/kg, I.P.) anesthetized rats. I.V. cocaine (1 mg/kg) decreased the spontaneous firing rate of single identified noradrenergic locus coeruleus neurons by approximately 50% in urethane anesthetized rats. This effect was reversed by the specific alpha-2-adrenoceptor antagonist, piperoxane. The duration of the effect on locus coeruleus neuron firing rate was significantly greater than that of the relatively brief pressor effect. Our results suggest that cocaine produces both specific (e.g., at locus coeruleus) and non-specific (local anesthetic) effects after systemic administration. In addition, these effects of cocaine are dependent upon the class of anesthetic employed. 312.17 SYNCHRONOUS BURSTING OF LOCUS COERULEUS NEURONS IN TISSUE CULTURE: A COMMON EXCITATORY INPUT OR ELECTROTONIC COUPLING OF NEURONS? P.G. Finlayson* and K.C. Marshall. (SPON: J. Kucharczyk) Dept. of Physiology, Univ. of Ottawa, Ottawa, Canada, K1H 8M5.

Neurons in the Locus Coeruleus (LC), the largest noradrenergic nucleus in the CNS, appear capable of functioning in synchrony. In multiple unit recordings of LC neurons in rats recovering from anaesthesia (Akaike, T. Brain Res. 239: 629-633, 1982) or in unanaesthetized rats (Aston-Jones, G. & Bloom, F., J. Neurosci. 1: 887-900, 1981), synchronous bursts of activity are consistently observed in the two or more recorded neurons. In addition, negative field potentials (FP) temporally synchronized with bursts in LC neurons were also reported in these studies. As similar FPs are observed during paradoxical sleep, a state where LC neurons are quiescent and do not burst, Aston-Jones and Bloom suggested that the negative FP may reflect a concerted excitatory input onto LC neurons. In tissue slices, bursting of LC neurons has not been reported. However, LC neurons in explant cultures from mouse brain do exhibit synchronized bursting, and we have examined the mechanism of this synchronous activity.

Preparation of LC explant tissue cultures has been described (Hendelman et al., Dev. Neurosci. 5: 64-76, 1982). During simultaneous intracellular recordings of pairs of LC neurons in such cultures, bursting activity was monitored, and electrotonic coupling was tested by passing polarizing current pulses into either cell. In other studies, after intracellular injection of the fluorescent dye, Lucifer Yellow, into single LC neurons, cultures were examined for secondarily stained LC neurons (i.e. dye-coupling).

In simultaneous recordings of pairs of LC neurons from cultures 23 to 30 days in vitro, bursting activity in one neuron was always synchronized with bursting activity or barrages of depolarizing events in the second cell. These depolarizing events were synchronized in recorded cells and apparently summate to evoke a burst. In a few neurons asynchronous tonic activity was observed. With injection of current into either neuron in a pair, no current or voltage spread into the second cell was apparent, even when action potentials were elicited. A further indication that these cultured LC neurons are not electrotonically coupled is the lack of dye-coupling with intracellular injection of Lucifer Yellow. Thus, bursting activity in LC neurons appears to be due to a common excitatory input, and not to involve electronic coupling. This common excitatory input onto LC neurons in tissue culture must be derived from cells near or within the LC, as our explant cultures contain little brainstem tissue surrounding the LC.

312.18 MORPHOLOGICAL CHARACTERISTICS OF CULTURED LOCUS COERULEUS NEURONS DEMONSTRATED BY INTRACELLULAR INJECTIONS OF HRP. K.C. Marshall, D.M.A. Richer* & P.G. Finlayson*, Dept. of Physiology, Univ. of Ottawa, Ottawa, Canada K1H 8M5.

Explant cultures of the locus coeruleus (LC) were prepared from brains of neonatal mice (Hendelman, W.J. et al., Dev. Neurosci. 5: 64-76, 1982). After culturing for 21-30 days, cells in tightly clustered groups having large pale nuclei and prominent nucleoli were injected by iontophoretic pulsing through intracellular micropipettes containing 4% horseradish peroxidase (HRP). Only cells having a stable membrane potential of at least -50 mV were injected. Membrane potential and spike generation by depolarizing pulses were monitored throughout the injection period. Most cells exhibited periodic bursting activity which was independent of the current injections. Cultures were incubated in physiological solution for 2 - 3 hours following the injection, fixed overnight and stained using the diaminobenzidine reaction.

Successfully stained cells had rounded cell bodies with 3-5 primary dendrites (about 1/3) or elongated somata with 2 or 3 dendrites (about 2/3). The rounded cells had usual diameters of 20-26 , while the elongated ones had minor and major diameters of 13-20 and 30-40 , respectively. The dendrites were usually 150-300 long and had relatively long (usually 10-20 ) spines. Spines were also observed on the somata of about half of the stained cells, but were short and stubby in comparison with those on the dendrites. The elongated cells with few dendrites seldom assumed a bipolar configuration, but rather had a V or U shape.

In about ½ of the well-stained cells, 2 or 3 axon-like processes were observed to emanate from the soma or primary dendrites. These axon systems were multiple-branching and fine in diameter. They generally gave rise to long-coursing projections within the explant and into the outgrowth zone, as well as local networks within the LC cluster or its immediate surroundings. Less than half of these cells had axonal networks which were characterized by prominent varicosities. The multiple axon-like processes observed in these cells are also observed in Lucifer-Yellow stained cells in these cultures. No systematic differences in morphological characteristics were noted in the younger vs. the older cultures.

The characteristics of these cells appear similar to those noted in several studies of LC neurons in the rat, with the exception of the multiple axon-like processes and the V or U shaped configuration of elongated cells. [There is however an observation of multiple axon-like processes on an LC neuron by Swanson (Brain Res. 110: 39-56, 1976)]. It is not clear whether these features are characteristic of the culture system or represent properties not easily observable in the histological preparations from animals.

313.1 A RAPID, QUANTITATIVE COLORIMETRIC BIOASSAY FOR NEURONOTROPHIC AGENTS. R. Fagnani,* M. Manthorpe, S.D. Skaper and S. Varon. Dept. Biology, Sch. of Med., Univ. Calif. San Diego, La Jolla, CA 92093.

The biological activity of neuronotrophic agents, such as Nerve Growth Factor (NGF) or Ciliary Neuronotrophic Factor (CNTF) is typically determined by (i) presenting serial dilutions of the putative trophic sample to replicate neuronal microcultures, (ii) fixation of the neurons after a selected time in vitro, (iii) microscopic counts of individual neurons, and (iv) construction of dose response curves. The titer of the test sample [in Trophic Units (TU)/ml] is defined as that sample dilution eliciting half-maximal neuronal survival. These neuronal bioassays are time-consuming and tedious, requiring about 90 min to count the neurons in a 96-well microtiter plate and calculate titers.

Here we describe a rapid colorimetric method, based on a previously described lymphocytic cytotoxic assay (J. Immunol. Methods 65: 55-63, 1983), to determine the number of viable neurons in microwells. This procedure involves setting up the serial dilutions and neuronal microcultures in the usual manner but introducing into the culture medium a vital dye, MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide]. This tetrazolium derivative is converted by viable neurons into a blue formazan product which can then be quantitated using an ELISA microplate reader. The amount of blue product which forms is directly proportional to the number of surviving neurons and can be used for the accurate determination of neuronotrophic titers. The microplate reader has been interfaced with a computer and various data output formats are available. The entire procedure of counting and titer calculation now requires only 2 min per microplate, a 50-fold reduction in time over the previous methods. Selected parameters and uses of this neuronotrophic bioassay will be presented.

313.2 INTERACTION OF BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) AND OTHER NEUROTROPHIC FACTORS IN THE REGULATION OF SENSORY NEURON SURVIVAL IN CULTURE. A.M. Davies, Y.-A. Barde and H. Thoenen, Dept. of Anatomy, St. Georges' Hospital Medical School, London SW17 0RE, U.K. and Dept. of Neurochemistry, Max-Planck-Institute for Psychiatry, D-8033 Planegg-Martinsried, FRG.

BDNF, a small basic protein purified from pig brain (Barde et al, EMBO J. 1:549-53 '82), has been shown to promote the survival of neurons isolated from the nodose and dorsal root ganglia, but is inactive on sympathetic and parasympathetic neurons (R.M. Lindsay, H. Thoenen and Y.-A. Barde, submitted). Here we report that BDNF is active on all populations of primary sensory neurons of the embryonic chick; these comprise the geniculate, vestibular, petrosal, jugular, nodose and dorsal root ganglia and the dorso-medial, ventro-lateral and mesencephalic neurons of the trigeminal nerve. BDNF promoted neuronal survival in dissociated cultures and elicited neurite outgrowth from explants. This effect was first evident between embryonic days 4 and 8 (E4 to E8) and was maximal between E10 and E12. To determine whether or not BDNF-responsive neurons also respond to other neurotrophic factors we have studied the trophic requirements of the exclusively proprioceptive trigeminal mesencephalic neurons. In glial-free culture, the survival of more than 70% of these neurons is promoted by a soluble extract prepared from their peripheral target tissue, skeletal muscle (A.M. Davies, submitted). A similar percentage survival was promoted by saturating concentrations of BDNF, and there was no additional survival in the presence of both BDNF and skeletal muscle extract. At subsaturating concentrations the effects of both agents in combination were additive. Both BDNF and skeletal muscle extract were maximally effective during the period of natural neuronal death. We propose that in vivo the survival of sensory neurons is dependent upon the combination of subthreshold amounts of two survival factors. In the case of trigeminal mesencephalic neurons, the central processes are exposed to BDNF and the peripheral ones to the skeletal muscle factor. Although this factor is not yet purified, we know that it is functionally distinct from nerve growth factor (NGF) and BDNF: whereas the skeletal muscle factor supports the survival of mesencephalic neurons, NGF does not in spite of the presence of NGF receptors (A.M. Davies and H. Rohrer, unpublished), and whereas BDNF promotes neurite outgrowth from the ventrolateral part of the trigeminal ganglion, the skeletal muscle factor does not.

313.3 PARTIAL CHARACTERIZATION OF A NOVEL NEUROTROPHIC FACTOR FROM PERIPHERAL NERVE TUMORS. S. Dostaler*, R.J. Riopelle, and P.M. Richardson. Department of Medicine (Neurology), Queen's University, Kingston, Canada K7L 3N6 and Division of Neurosurgery, McGill University, Montreal, Canada H3G 1A4.

Explants of peripheral nerve tumors (neurofibromas) from patients with Von Recklinghausen disease have been shown to release at least two neurotrophic factors one, of which is immunologically cross-reactive with mouse nerve growth factor (NGF) (Riopelle, R.J. and Riccardi, V.M., Neurology, 34, Supp. 291, 1984). Similar trophic factors are found in normal rodent peripheral nerve (Riopelle, R.J. et al., Neurosci. Lett., 25:311, 1981; Richardson, P.M. and Ebendal, T., Brain Res., 246:57, 1982).

A neurite-promoting factor with an apparent MW of 20,000 has been detected in extracts of a neurofibrosarcoma from a patient with Von Recklinghausen disease. On poly-D-lysine and laminin substrata the species, designated NFNTF, promotes neurite outgrowth from dissociated chick embryo sensory neurons that is not inhibited by antibody to NGF, and also from dissociated ciliary neurons. NFNTF was purified by ion exchange and gel filtration chromatography, followed by reverse phase high performance liquid chromatography (RPLC) on μBondapak C-18 in a mobile phase of acetonitrile in trifluoroacetic acid. On RPLC at least one biologically active fraction with retention time differing from that of NFNTF was found. The neurite-promoting activity of this latter fraction was completely inhibited by antibody to NGF.

Sheath cell tumors may prove to be a rich source of neurotrophic factors that are present in minute quantities in normal peripheral nerve tissue. (Supported by the PSI Foundation of Ontario, the Clare Nelson Bequest of the Kingston General Hospital, and MRC Canada).

313.4 ISOLATION OF MAMMALIAN PERIPHERAL NERVE CILIARY NEURONOTROPHIC FACTOR. M. Manthorpe, S.D. Skaper, L.R. Williams, H.J.L. Fryer, and S. Varon. Dept. of Biology, Sch. of Med., Univ. Calif. San Diego, La Jolla, CA 92093.

Past work, using E8 chick ciliary ganglionic (CG) neurons as test cultures, has lent support to the general hypothesis that innervation territories produce trophic factors which control the survival of their innervating neurons during and possibly after the developmental neuronal death period (for review, see Growth and Maturation Factors, Volume 3, G. Guroff, ed., 1985, pp. 77-117). One such factor, Ciliary Neuronotrophic Factor or CNTF, was recently purified from extracts of selected intraocular tissues containing the innervation territories of CG neurons (J. Neurochem. 43: 1468-1478, 1984). The purified chick eye CNTF has an $M_r$ = 20.4 kD and a pI = 5.0 and supports the survival of, in addition to cultured CG neurons, those from dorsal root and sympathetic ganglia. More recently we have recognized the adult rat peripheral nerve to be another very rich source of CNTF activity.

We report here the purification of this mammalian CNTF from extracts of adult rat sciatic nerve using a fractionation protocol nearly identical to that employed for the isolation of the avian eye CNTF. The purified nerve CNTF differs from the eye-derived one in molecular weight (24 kD) and isoelectric point (5.6) but is similar to eye CNTF in its stability to SDS-mercaptoethanol, ability to support embryonic E10 sensory and sympathetic, but not E8 sensory neurons, and non-immunoreactivity to antibodies raised against purified mouse submaxillary NGF.

Supported by NINCDS grant NS 16349.

313.5 CHARACTERIZATION AND PARTIAL PURIFICATION FROM PIG LUNG OF SURVIVAL-PROMOTING AND CHOLINE ACETYLTRANSFERASE (CHAT)-SUSTAINING ACTIVITIES FOR PARASYMPATHETIC NEURONS. T.L. Wallace and E.M. Johnson, Jr. Dept. of Pharmacology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Pig lung, among many tissues examined, was found to be a potent source of Survival-promoting and ChAT-Sustaining activities for chick parasympathetic neurons in culture. The bioassay used to detect these activities involves incubating either intact embryonic (E) chick ciliary ganglia or dissociated neurons for two to three days with tissue culture media, 10% serum, 35 mM KCl and lung extract. Survival was judged by phase contrast microscopy and ChAT activity was determined by a radioenzymatic assay. The survival-promoting activity in a crude extract of pig lung (25,000 x g supernatant fraction) exerted its effects on chick parasympathetic neurons, whereas it had no effect on rat sympathetic, chicken and rat dorsal root sensory, or rat nodosal neurons. This survival-promoting effect on parasympathetic neurons was not due to an indirect action on non-neuronal cells since elimination of these cells using cytosine arabinoside C did not affect survival. The Survival-promoting and ChAT-Sustaining activities bore similar biological properties. Both: sustained ChAT or promoted survival of E7 to E12 chick ciliary neurons, but not neurons that were E14 to E18; were precipitated with the same concentrations of ammonium sulfate or organic solvents; were stable at -40°C, room temperature, 37°C, and to multiple freezing-thawing; were trypsin resistant; and eluted from chromatographic columns in the same fractions. High and low molecular weight (MW) species of each type of activity were found. The high MW species eluted with neuritic-promoting activity for dissociated neurons, whereas there was little or no neuritic-promoting activity eluted with the low MW species. In addition, the low MW species was trypsin resistant, and was eluted with very little $OD_{280}$, suggesting that a high degree of purification has been achieved if the material is a peptide. These findings suggest that one or several molecules exist in pig lung that express both Survival-promoting and ChAT-Sustaining activities, and that because of their specificity for parasympathetic neurons, may be different from previously reported trophic-like factors. This work was supported by a March of Dimes research grant and by a postdoctoral fellowship from the Muscular Dystrophy Association to T.L.W.

313.6 NEURONOTROPHIC ACTIVITIES IN THE TRANSMITTER-STORING ORGANELLE OF CHROMAFFIN CELLS. K. Unsicker and R. LIETZKE*. Dept. of Anatomy and Cell Biology, Univ. of Marburg, Robert-Koch-Str. 6, D-3550 Marburg, F.R.G.

During ontogeny and adulthood neurons are supplied with trophic signals provided by their target cells that ascertain their survival and maintenance of function. It is conceivable but remains to be proven that neurons serving as target cells for other neurons may also store and release neuronotrophic factors (NTFs). We have investigated this issue using a homogeneous population of modified sympathetic neurons, the chromaffin cells from the bovine adrenal medulla, as a putative source of NTFs. Dissociated cell cultures of peripheral and central neurons from embryonic chick and rat and neonatal rat were used as a bioassay system for monitoring the survival promoting effects of the chromaffin cell NTFs. Cell culture media conditioned by purified chromaffin cells, chromaffin cell extracts and the soluble content of chromaffin vesicles all contained NTF activities for a variety of peripheral and central neurons. The NTF(s) from chromaffin vesicles addressed embryonic chick ciliary, dorsal root ganglion, sympathetic and spinal cord neurons, was not inhibited by anti-NGF antibodies and sensitive to trypsin and heat. One Trophic Unit that supported halfmaximal neuronal survival over 24 h amounted to 0.5-10 µg protein depending on the type of neuron tested. Adsorption of the material to polyornithine reduced the activity for ciliary, but not for other ganglion neurons. This suggests the presence of substratum-bound factor(s) with co-trophic effects in the vesicle content. Fractionation of the vesicle proteins on Biogel A 1.5 m revealed that the activity for ciliary neurons had a $M_r$ of 10,000 to 20,000, whereas the activity addressing sensory neurons was in the range of $M_r$ 10,000 to 40,000 with a peak at $M_r$ 20,000 to 30,000. These results suggest that chromaffin cells store and release several proteinaceous NTF activities, which, in vivo, might be relevant to the functional maintenance of autonomic motor and sensory neurons innervating the adrenal medulla.

Supported by grant SFB 103 - C 13 from the German Research Foundation.

313.7 HUMAN NEUROTROPHIC FACTOR: EFFECTS ON MAMMALIAN NEURON SURVIVAL AND NEURITIC OUTGROWTH. Steven T. DeKosky, Stephen W. Scheff, and John Webb*. Depts. of Neurology and Anatomy, Lexington VA and Univ. of Kentucky Medical Centers and Sanders-Brown Research Center on Aging, Lexington, KY 40507

Substances which promote the survival of neural cells in vitro or in vivo, or which promote the outgrowth of neuritic processes in cell culture, have been the target of increasing study over the past several years. The first described neurotrophic factor, nerve growth factor, has both cell survival and neuritic outgrowth inducing properties for a specific subset of central and peripheral nervous system neurons. More recently, factors, usually proteins, have been derived from mammalian brains and shown to promote the survival of neurons in cell culture or in brain tissue transplants. The well characterized factors have been isolated from rodent and other non-human sources.

We report the presence of a stable neurotrophic factor in extracts of normal human brain (HNTF), which promotes survival of mammalian cholinergic neurons in a standardized assay for titration of the presence of such factors. The trophic factor is large (|100 kDal), heat labile, and inactivated by treatment with trypsin. Human cortical tissue preserved for months at -70 C. still contained substantial levels of HNTF. The substance has been found in human cerebral cortex and hippocampus, and also supports survival of fetal rodent hippocampal or striatal neurons in vitro. Under the conditions of this assay, extracts of rat cortex or hippocampus produce cell survival, but do not induce the extensive neuritic outgrowth. The potential role of laminin in inducing the outgrowth seen with HNTF is not yet clear.

If trophic factors play a critical role in nervous system development, repair, or reorganization following trauma, these data indicate that the human central nervous system contains some of the elements critical for this process.

(Supported by NIH grants AG05119, NS21541 and NS0044 and the V.A. Medical Research Service.)

313.8 PURIFICATION OF A HUMAN RED BLOOD CELL PROTEIN WHICH POSSESSES NEURONOTROPHIC ACTIVITY FOR CULTURED CNS NEURONS: ITS IDENTIFICATION AS CATALASE. P. Walicke, S. Varon and M. Manthorpe. Departments of Biology and Neurosciences, School of Medicine, University of California, San Diego, La Jolla, CA 92093.

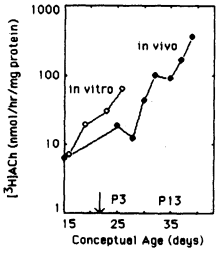
CNS neurons may require specific neuronotrophic factors for their very survival, in analogy to the well documented in vivo and in vitro requirement of sympathetic neurons for Nerve Growth Factor. Recently, we have developed neuronal cell culture bioassays for CNS-directed neuronotrophic agents (Neuroscience 12:33-45, 1984). Using this bioassay, trophic activity has been detected in a variety of conditioned media and tissue extracts. The red blood cell (rbc) was found to be a particularly rich source of a protein exhibiting neuronotrophic activity (Brain Research, 1985, in press).

This protein has now been purified over 1000-fold from human rbc's by ion-exchange chromatography and isoelectric focusing, with a yield of one to two mg of purified material from one unit of aged packed rbc's. The purified protein has been identified as catalase based on its isoelectric point, subunit molecular weight on SDS-PAGE, and ability to degrade hydrogen peroxide. Commercially produced bovine liver catalase, lactoperoxidase, horseradish peroxidase and vitamin E all mimic the ability of the rbc protein to support CNS neuronal survival in vitro. A specific irreversible inhibitor of catalase enzymatic activity, aminotriazole, blocks the trophic activity of both the rbc protein and commercial catalase. Thus peroxidase activity appears to mediate the trophic effects of these proteins. Peroxides, measured by a colorimetric assay, accumulate in the bioassay culture medium in the absence of cells. Removal of this toxic material from the medium may be the basis of the trophic effects of catalase. Supported by NSF Grant BNS 82-18366, ADA Grant 83-10, and a grant from FIDIA Research Laboratories.

313.9 INFLUENCE OF OLFACTORY BULB EXTRACT ON THE SURVIVAL AND DIFFERENTIATION OF CULTURED NEURONS FROM THE BASAL FOREBRAIN. M.P.Lambert and W.L. Klein (SPON: J. Siegel). Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

Embryonic basal forebrain neurons were maintained in cell culture in order to study factors influencing their structural and biochemical development. Presumptive basal forebrain/septal tissue (A.Bjorklund, et al., Acta Physiol. Scan. Supp. 522, 1983) dissected from E16-17 rats and treated with trypsin gave neuronal cell populations that attached well to poly-L-lysine coated plates. Cells maintained in Dulbecco's Modified Eagle Medium (DMEM)/high ascorbate (17.5 mg/l)/ 10% fetal calf serum media showed a time dependent increase in process extension. Processes reached an average length of 214 μ (12x cell body length) by E16/C9. Protein per culture was level up to C8 and then decreased. Cells grown in defined medium showed some neurite development and extension early in culture (C1-2), but lost processes and began shrinking by C3-4. In contrast, cells grown in defined medium containing 25% adult olfactory bulb (OLB) extract showed extensive process development and branching during this period (C1-3). Surprisingly, whole brain extract appeared to inhibit process development as no neurites were observed. These results indicate that OLB, but not other brain regions, from adult rats contain factors that promote neurite outgrowth from embryonic neurons from the basal forebrain. The presence of these factors in OLB is consistent with reports of continuous innervation of the bulb throughout adulthood (A. Cuschieri and L.H. Banninster, J. Anat. 119:277-286, 1975).

The differentiation specifically of cholinergic neurons was determined by measuring Acetyl-CoA: choline O-acetyltransferase, E.C. 2.3.1.6 (ChAT) activity. ChAT activity of cultured cells maintained as above on serum-containing media was compared with ChAT activity of the corresponding brain region in vivo. Results presented in the graph below show that ChAT activity increased in culture from conceptual age 15 to 26 days, comparable to the increase in vivo in the septal region during this period. The greatest increase in ChAT activity in the septal region occurred after P6, and by P17 had reached 90% of adult levels (370 nmol/hr/mg). Future experiments are directed toward measuring levels of ChAT in neurons grown in defined media and assessing the long-term effects of OLB and other extracts on these neurons. (Supported by NIH grant NS18490 to WLK.)



313.10 SOLUBLE STRIATAL EXTRACTS ENHANCE SURVIVAL AND MATURATION OF MESENCEPHALIC DOPAMINERGIC NEURONS IN VITRO. Y. Tomozawa and S.H.Appel, Dept. of Neurology, Baylor College of Medicine, Houston, Texas 77030

Recent studies have suggested that diffusible factors released by neural target tissues enhance survival, growth, and differentiation of neurons within the central, as well as the peripheral nervous system.

Dopaminergic neurons in the substantia nigra project primarily to neuronal targets in the striatum; Prochiantz (Nature, 293, 570, 1981) reported that striatal membranes enhance dopaminergic differentiation in rat mesencephalic cultures.

In the present experiments, soluble extracts from the striatum produce a four fold increase in survival of dopaminergic neurons in mesencephalic cultures prepared from embryonic 14 day old rats, assessed by glyoxylic acid-induced catecholamine histofluorescence. The same soluble extract stimulates high affinity $^{3}$H-dopamine uptake specific for dopaminergic neurons 3.5 to 4.5 fold in the presence of cytosine arabinoside (2μM) in a dose-dependent manner. Such stimulation of high affinity dopamine uptake is significantly reduced following treatment of the soluble extract with trypsin. The striatal extract has no effect on acetylcholine synthesis and choline acetyltransferase in dissociated ventral spinal cord cultures. The soluble factor(s) stimulating survival-differentiation of dopaminergic neurons behave differently from soluble factor(s) stimulating neuronal high affinity GABA uptake on molecular sieving chromatography. NGF, neurotensin and somatostatin have no effect on our bioassay system. The stimulatory effects on dopaminergic neurons are maximal in extracts of the striatum, but are also found in the hippocampus-amygdaloid nucleus area and cerebral cortex, although they are negligible in cerebellum, olfactory bulb, and absent in liver. The effects of soluble striatal extracts on dopaminergic neurons are maximal in mesencephalic cultures from 13 to 16.5 day embryos and drastically decrease thereafter.

313.11 IDENTIFICATION OF A NEUROTROPIC FACTOR PRODUCED BY ASTROCYTES CULTURED FROM RAT CEREBRAL CORTEX. R. Kadle* and R.E. Fellows. Dept. of Physiology and Biophysics, Univ. of Iowa College of Medicine, Iowa City IA 52242.

Survival of dissociated fetal rat brain cells cultured in a serum-free, hormone-free defined medium is enhanced by increasing cell density, suggesting a self-conditioning of medium by tissue specific growth factor(s). At lower densities, neuronal survival can be enhanced by addition of hormones, including insulin, or various established or putative growth factors ranging in size from <1 to >50 kDa. Under serum-free culture conditions, we have observed an absolute requirement for insulin for survival of fetal rat brain cells plated at densities less than 4,000 cells/mm$^2$. At the same time we have been able to grow and maintain CNS neurons plated at much lower densities (<1,000 cells/mm$^2$) in a serum-free defined medium without insulin or other hormones by seeding them on top of an established confluent monolayer of astrocytes. The present study was carried out to determine if the enhancement of neuronal survival might be mediated by a soluble factor or factors secreted by astrocytes into the medium. Astrocyte cultures were prepared from enzymatically dissociated cerebral cortex of 0-1 day old rat pups and grown to confluence in the presence of 15% FBS, after which they were maintained in serum-free defined medium in the absence of insulin. More than 95% of cells in these cultures displayed morphology typical of fibrous astrocytes and positive immunocytochemical staining for glial fibrillary acidic protein. Conditioned medium was collected every 3-5 days and used immediately or stored at -20°. To assay for insulin-like activity, cells dissociated from 17-19 day fetal rat telencephalon (> 80% tetanus-toxin positive) were plated at a density of 3,000 cells/mm$^2$ for determining cell survival and at 8,000 cells/mm$^2$ for measuring $^{3}$H-leucine incorporation. Compared to control cultures grown in defined medium alone, cultures incubated with an ultrafiltration fraction (5 kDa cutoff) of astrocyte conditioned medium showed a significant enhancement of cell survival, similar to that observed in cells incubated with defined medium containing 0.33 uM insulin. Protein synthesis, measured as the incorporation of $^{3}$H-leucine into a TCA insoluble fraction, increased 21% over control when cultures were incubated for 12 hours with the active fraction of astrocyte conditioned medium, compared to 25% over control with 0.33 uM insulin. Neuronal cultures grown in serum-free defined medium also exhibited significant $^{125}$I-insulin binding, in the range of 0.7-1.0 fmol/mg protein. These data suggest that cultured astrocytes elaborate one or more insulin-like factors that may be important for the normal development of CNS neurons.

313.12 A SPECIFIC SEROTONERGIC GROWTH FACTOR FROM 5,7-DHT LESIONED HIPPOCAMPUS: IN VIVO EVIDENCE FROM FETAL TRANSPLANTATION OF RAPHE AND LOCUS COERULEUS NEURONS. F.C. Zhou*, E.C. Azmitia*, S. Auerbach** and B.L. Jacobs**, (*Dept. Biology, NYU, NYC 10003) (**Dept. Psychology, Princeton University, NJ).

Injury induces demonstratable neurotrophic activities in the brain. Specific lesioning of 5-HT fibers from raphe nuclei using 5,7-dihydroxytryptamine (5,7-DHT) (with desipramine pretreatment) in the hippocampal afferent path (cingulum bundle), is able to trigger homotypic sprouting via the other afferent, fornix-fimbria (FF), to reinnervate the hippocampus. This homotypic sprouting of 5-HT fibers is a response to the denervation of 5-HT fibers (Azmitia et al., Nature 274,374(1978); Zhou and Azmitia, Brain Res. 308,53(1984)). The norepinephrine (NE) fibers from locus coeruleus (LC) which travel in the same pathways and terminate in an overlapping area in the hippocampus did not seem to respond to the denervation of 5-HT fibers.

After 5 ug of 5,7-DHT microinjected into the FF (with nomifensine pretreatment), the synaptosomal high affinity uptake (SHAU) of $^{3}$H-5-HT decreased from 137 ± 36 (n=5) in the normal to 50 ± 28 pmol/gm (n=5), and the 5-HT level decreased from 200 + 40 (n=8) to 60 + 40 pg/mg (n=6), while the NE level (170 + 50 pg/mg, n=16) remained similar to the normal (210 + 42 pg/mg, n=16) in the dorsal hippocampus. The growth of the fetal (gestation 14-15 days) 5-HT-raphe and NE-LC neurons were compared when transplanted into the normal versus transplanted into the 5,7-DHT-FF lesioned hippocampus.

Transplants of fetal raphe tissue into the normal dorsal hippocampus produced a hyperinnervation of 5-HT fibers within one month. The SHAU of $^{3}$H-5-HT increased (210 ± 39 pmoles/gm, n=5) 68% above normal level. The concentration of 5-HT (360 ± 140 pg/mg, n=4) rose to 80% above normal. When fetal raphe cells were transplanted into the FF 5,7-DHT lesioned dorsal hippocampus, a dramatic increase in growth of the fetal 5-HT neurons was observed. The SHAU of $^{3}$H-5-HT increased (473 + 182 pmoles/gm, n=5) 345% over intact and 946% over FF-5,7-DHT lesioned hippocampus. The 5-HT concentration increased 255% (510 + 320 pg/mg wt.) over intact and 850% over FF-5,7-DHT lesioned hippocampus.

In contrast, the implanted NE neurons of fetal LC had lower NE levels in the 5-HT partially denervated hippocampus than in normal hippocampus (250 + 50, n=4 versus 420 + 100 pgm/mg, n=3). Thus the 5-HT denervation-triggered trophic signal selectively enhanced the development of the 5-HT neurons but not the NE neurons.

313.13 A SPECIFIC SEROTONERGIC GROWTH FACTOR FROM 5,7-DHT LESIONED HIPPOCAMPUS: IN VITRO EVIDENCE FROM DISSOCIATED CULTURES OF RAPHE AND LOCUS COERULEUS NEURONS. E.C. Azmitia and F.C. Zhou, Dept. of Biology, New York University, New York, NY 10003.

Damage to the CNS triggers a variety of recuperative mechanisms, homotypic (compensatory) collateral sprouting (HCS) is the most specific and beneficial for recovery of function (Azmitia et al., Nature 274,374(1978); Gage et al., Brain Res. 268,271(1983) and Zhou and Azmitia 308,53(1984)). Implicit in HCS is the production by the target area of a trophic factor which stimulates a single group of afferent fibers. We have developed a neurotoxin (5,7-dihydrotryptamine, DHT) injection procedure for eliminating serotonergic fibers afferent to the hippocampus via the cingulum bundle which induces HCS of the undamaged hipp serotonergic fibers entering via the fornix-fimbria (FF). We now present in vivo tissue culture evidence to substantiate the existance of a soluble factor capable of selectively stimulating serotonergic growth.

Mesencephalic raphe neurons from 14 day old rat fetuses were dissociated in EDTA solution by gentle repipetting. The cells at an initial plating density (IPD) between 1.5 - 0.5 X $10^6$ cells/$cm^2$ were grown in 96-well Linbro plates coated with collagen (1 mg/ml) and poly-lysine (25 ugm/ml). Previous studies have shown these cultures contain viable neurons immunoreactive to a specific serotonergic antibody and possess a serotonin high-affinity uptake mechanism (SHAU). The SHAU is linearly related to the (IPD) and is stimulated by dissociated fetal hipp neurons (Azmitia et al., Soc. Neurosci. Abstr., 9,10(1983)). Cultures of dissociated locus coeruleus (LC) neurons were prepared and shown to be immunoreactive to a tyrosine hydroxylase antibody and possess a norepinephrine high-affinity uptake mechanisms (NHAU).

A soluble hippocampal factor was prepared from normal and FF-5,7-DHT (nomifensine pretreated) rats (see Nieto-Sampedro et al., J. Neurosci. 3,2219(1983)). Control aliquots of this preparation were boiled for one hour. All the aliquots were passed through millipore filters (0.2 u pore) before addition (1/50 dilution) to the complete neuronal media (10% FCS in MEM, non-essential aminoacids and 1% glucose).

Addition of the hipp factor stimulated the SHAU in raphe cultures at high IPD (1.5 X $10^6$ cells/$cm^2$) by 57% in three separate experiments after 3 days in culture over that seen when the boiled factor was added. Addition of the 5,7-DHT derived hipp factor stimulated SHAU by 90% in three separate experiments. No stimulation was apparent by either factor at low IPD's. Addition of the hipp factor to LC cultures stimulated the NHAU by 61% in 5 separate experiments over that seen with the boiled factor. In contrast, no apparent stimulation was seen with the factor derived from the 5,7-DHT hipp.

## BRAIN METABOLISM II

314.1 COMPUTERIZED ANALYSIS OF FUNCTIONAL BRAIN IMAGES: APPLICATION TO TOURETTE SYNDROME. G.H. Burrows, D. Bright*, V. Geoffrey* and T. Chase. Experimental Therapeutics Branch, NINCDS, Bethesda, MD 20205; Analytical Chemistry Division, NBS, Gaithersburg, MD 20899.

A computerized procedure for the interpretation of functional images of the human brain has been developed. The method employs LISP, a computer language for symbol manipulation, to drive more conventional image processing routines. Contiguous regions of locally similar functional activity are extracted from the image and used to facilitate the recognition of brain midline, boundaries, and the horizontal level of the image slice. This information is then used to segment the image into roughly homologous regions which can be compared between subjects. To do this a 6x7 grid is separately scaled to each hemisphere in each image yielding rectangular segments roughly 2x2 cm in size. Twenty parameters are calculated from each segment for use in the analysis. This image analysis is performed on a VAX 11/780 computer and a DeAnza 8400 image processor. A large database has been built with over a thousand images and facilities have been completed for accumulating and analyzing data from numerous segment strategies. In addition, LISP is used to write programs for statistical analysis packages.

The procedure has been applied to the study of 12 untreated patients with Tourette syndrome and an equal number of age-matched controls. Each subject was scanned (NINCDS Neuropet tomograph) 30 minutes after receiving 5 mCi of 18-F-fluorodeoxyglucose by intravenous injection. Glucose utilization rates were linearly normalized to the central cerebellum region of each patient. While no consistent difference in overall brain glucose utilization was found, preliminary analysis has shown alterations in certain cortical and subcortical regions mainly at a slice level approximately 84 mm caudal from the vertex. Specifically, glucose values in the region of the frontal and cingulate cortex as well as in the ventral corpus striatum were 17 to 28 percent below control levels ($p < .01$). The clinical severity of motor and vocal tics correlated (Spearmann; $p < .01$) closely with metabolism in these areas. The findings suggest that this computerized procedure may be of use in the analysis of human brain disorders such as Tourette syndrome where no structural abnormalities are available to provide initial localizing information, and where visual inspection of the PET images fails to reveal definite abnormalities.

314.2 CORTICAL AND SUBCORTICAL METABOLIC CORRELATES OF AFFECTIVE ILLNESS USING POSITRON EMISSION TOMOGRAPHY. J.C.Wu1,M.S.Buchsbaum1*,L.DeLisi2*,H.Holcomb2,E.Hazlett1*. 1Brain Imaging Laboratory,UCI,CA 92715,2 NIMH,Bethesda,MD.
Intro:This study extends our previous PET study of affective illness by subdividing bipolar (B) and unipolar (U) depressed subjects and comparing them with normal controls (NC). Methodology: 20 affective (16B,4U,39±12.2yrs,12F,8M) and 24 NC (31±10.4yrs,16M,8F) were studied. Subjects were given 3-5 miCof 18F-2DG while receiving somatosensory stimulation (mild electrical shock to right forearm 1/sec x 30 min)in a darkened and acoustically attenuated room. Subjects were scanned on an ORTEC ECAT II (FWHM=17.5mm). Seven to eight scans parallel to the CM line were obtained. Glucose use was calculated according to the Sokoloff model. Cortical metabolism was measured by peeling off a 2.2 cm cortical rim from the slice. This rim was divided into 4 equal quadrants in each hemisphere. Regions of interest such as the caudate were assessed using an automated template using 3d stereotaxic cooordinates. Results:Affective subjects (B and U) were different from NC in two measures. First, B and U had higher absolute cortical glucose metabolism than NC (NC=19.7±6.3, U=28.6±6.6, B=25.3±8.8; group difference F=4.92,d.f.=2,41,p=.02). Absolute glucose use expressed in micromoles/100g/min. Second, B and U had decreased relative caudate metabolic ratios (NC=1.03±.14, B=0.87±.13, U=0.89±.14,level by structure by group F=2.01,d.f.=3,62,p=.10).

U's were significantly different from B's and NC's on two parameters. First, U's have higher greater absolute antero-posterior gradients than B's or NC's (anteriors greater than posteriors, U=7.0, B=2.2, NC=2.9, group by AP gradient F=7.04, d.f.=3.06,75.07, p=.01). Second, U's have decreased left hemispheric activation relative to the right in absolute terms than B's or NC's (NC=0.8, B=1.2, U=-0.6, group by quadrant by hemisphere F=3.09, d.f.=5.1,95,p=0.012).
Significance: Greater absolute cortical glucose metabolism in affective illness is consistent with hypothesized noradrenergic overactivity. Decreased relative caudate metabolic ratios in affective illness is consistent with decreased dopaminergic activity in affective illness.

314.3 DIFFERENCES BETWEEN ALZHEIMER PATIENTS AND HEALTHY CONTROLS IN PATTERNS OF INTERCORRELATIONS BETWEEN REGIONAL CEREBRAL METABOLIC RATES FOR GLUCOSE. B. Horwitz, C.L. Grady, N.L. Schlageter*, R. Duara and S.I. Rapoport. Laboratory of Neurosciences, National Institute on Aging, National Institutes of Health, Bethesda, MD 20205.

Intercorrelations between resting regional cerebral metabolic rates for glucose (rCMRglc), as determined by positron emission tomography (PET) using [18-F]fluorodeoxyglucose (FDG), provide a measure of the functional associations of different pairs of brain regions (Horwitz et al., J Cereb Blood Flow Metabol 4: 484-499, 1984). The overall set of such correlations allows one to assess integrated activity for the brain as a whole in a specific group of subjects for a particular experimental paradigm. For example, although there is no statistically significant correlation between resting rCMRglc and age (Duara et al., Ann Neurol 16: 702-713, 1984), we found a decrease in the number of statistically significant correlations among parietal lobe regions and between parietal and frontal lobe regions, when comparing 15 healthy men aged 64-83 yr with 15 aged 20-32 yr (Horwitz et al., Soc Neurosci Abstr 10: 1001, 1984).

We report here on the application of this correlation approach to patients with presumed Alzheimer's disease (AD). Patterns of cerebral metabolic correlations in 21 AD patients and 21 healthy age-matched controls in the resting state were compared. On the basis of the Mini-Mental State exam (Folstein et al., J Psychiat Res 12: 189-198, 1975), 10 AD patients were classified as mildly demented (score $\geq$ 21), 8 as moderately demented (20 $\geq$ score $\geq$ 11), and 3 as severely demented (score $\leq$ 10). Cerebral metabolic rates for glucose were determined by PET using [18-F]FDG. Partial correlation coefficients, controlling for whole brain glucose metabolism, were evaluated between pairs of regional glucose metabolic rates in 59 brain regions. Reliable correlation coefficients were obtained by use of the jackknife and bootstrap statistical procedures. Compared with healthy controls, the Alzheimer patients had fewer reliable partial correlation coefficients between frontal and parietal lobe regions. There also was a reduced number of reliable correlations between many bilaterally symmetric brain regions in the Alzheimer's patients, suggesting decreased functional associations between the two cerebral hemispheres in Alzheimer's disease.

314.4 **POSITRON EMISSION TOMOGRAPHY AND PERFORMANCE OF A COGNITIVE TASK.** **I.T. Metz, H.Y. Meltzer, and M. Cooper*. PET Unit--Franklin McLean Institute, Dept. of Radiology, University of Chicago, Chicago, IL 60637.**

**Abnormalities of functioning in frontal cortex have been implicated in some forms of mental illness. We used positron emission tomography to determine whether normal subjects and patients with severe psychiatric illness differ in their regional cerebral metabolism of $^{18}$fluoro-deoxyglucose (FDG). During the uptake period of the FDG, subjects performed a variant of the Wisconsin Card Sorting Test (WCST), a task which has been shown to be related to functioning of the frontal lobes.**

**Seven normal subjects, six RDC schizophrenic patients, and four non-schizophrenic patients were studied. All patients were hospitalized at the Illinois State Psychiatric Institute and had been unmedicated for at least ten days at the time of testing. After preliminary positioning and transmission scans in the PETT VI scanner, subjects were injected with four to ten millicuries of FDG via IV catheter; subjects then performed the WCST for 40 minutes prior to being repositioned and scanned for 30 minutes. For 28 brain regions, we determined activity as a ratio of counts in that region to the average counts for all regions.**

**Both patient groups showed a tendency toward slightly less metabolic activity than the normals in all cortical regions. There was no evidence, however, for a specific effect in frontal regions. Overall, the ratio of frontal to non-frontal cortical activity was virtually identical in the three groups (0.91, 0.90, and 0.92 respectively for normals, schizophrenics, and non-schizophrenics). All three groups also showed a tendency toward higher relative frontal activity on the right than on the left side. Relative metabolic activity in the schizophrenic group was significantly higher than in the normals in basal ganglia regions on both sides.**

**As expected, both patient groups performed more poorly than the normals on the WCST: "conceptual level responding" scores were 56%, 35%, and 40%, while "perseverative errors" were 14%, 16%, and 29% for normals, schizophrenics, and non-schizophrenics, respectively. Across all subjects, there was a high correlation between relative metabolic activity in the right parietal cortex and perseverative error percentage ($r = 0.58$): higher parietal metabolism was associated with higher error rates. No other relationship was found between task performance and a brain region. This relationship may be spuriously due to the large number of statistical tests, or it could reflect underlying anatomical relationships between parietal and frontal cortical regions.**

**These results do not support the hypothesis of a frontal cortex abnormality in psychiatric patients. This failure to support the hypothesis may be due to differences in patient samples between this and other studies. It may also be due to differences in the task conditions: when patients are activated in a manner similar to normal subjects, differences which appear in "resting" conditions may disappear.**

**Supported in part by DE-AC02-82ER60033, DE-AC02-80EV10359, MH37957, MH30938, and Illinois Department of Mental Health.**

314.5 BRAIN PATTERN SPACE: A NEW ANALYTIC METHOD UNCOVERS COVARYING REGIONAL VALUES IN PET MEASURED PATTERNS OF HUMAN BRAIN ACTIVITY. J.R.Moeller*, B.T.Volpe*, J.S.Perlmutter*, M.E.Raichle, M.S.Gazzaniga. Cornell Univ. Med. Col., NY, NY 10021; Washington Univ. Sch. of Med., St. Louis, MO 63110.

One of the main goals of PET image analysis has been to demonstrate that different clinical populations are discriminable on the basis of the differences in their images of mean regional values of PET measured brain activity. At the same time, a major limitation has been that this kind of analysis does not provide a direct means of determining the constituent patterns of covarying regional values that actually produced the differences among population images. By way of example: consider a comparison of a sample of normal subjects with a sample of subjects exhibiting a common pathology in which six regional differences occurred out of forty regions measured. Moreover, suppose that two distinct pathological processes contributed to the pattern of differences: one process affected the first four regions and the second, the last four of the six affected regions. The analysis described above would not reveal this important biological fact. To date, the research strategy employed to resolve this indeterminacy of PET image analysis has been to account for the changes created by a clinical pathology in terms of changes in PET measured brain activity that can be effected by altering specific biological, sensory, and/or cognitive processes. But the adverse side of this methodology is that the scientific value of such PET studies is considerably diminished in the event that the hypothesized association between functional dissociations and the differences in population images is subsequently refuted.

The aim of the present work is to demonstrate a new analytic method which recovers directly from PET data, patterns of covarying regional activity which represent important biological and computational constraints on human brain functioning. The demonstration is based on the PET data from a sample of 25 Normal individuals and a pathological population of 11 Amnestics, in which a subject's brain pattern consists of 26 regional values, measured while the subject is in an alert resting state. The brain patterns of subjects of both populations are plotted as individual points in a 26 dimensional Brain Pattern Space. Discriminate Analysis indicates that these two populations are perfectly discriminable in Brain Pattern Space--even though the mean patterns for the two populations are correlated at the .92 level. Thus, what differentiates these two populations are differences in the way that the brain patterns of different subjects systematically vary within each population.

The main finding is that the between-population differences in covariance are uniquely attributable to the different patterns of covariance exhibited by a specific set of three regions. That is, while there are other sets of regions which exhibit similar patterns of covariance in both the Normals and Amnestics, the different patterns of covariance produced by these three regions account for essentially all the between-population differences that can be reliably estimated from the present two clinical samples. The biological interpretation is that a particular pattern of normal regional covariance has been transformed by the pathology of the Amnestics. The three covarying regions are nominally the caudate region, anterior cingulate region, and medial basal frontal lobe. At a functional level, these data underscore the importance of considering the role attentional mechanisms play in the production of memory disorders. (Aided by NS 033426.)

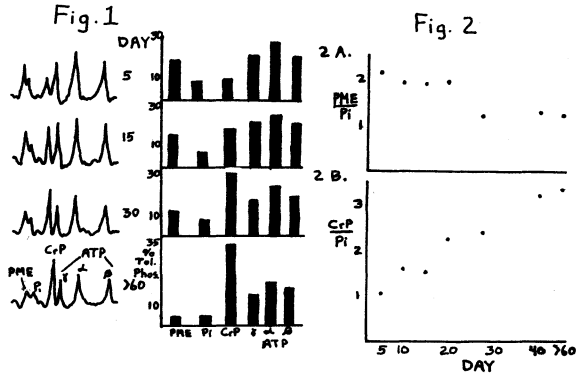
314.6 EFFECT OF SCAN LENGTH ON THE MEASUREMENT OF LOCAL CEREBRAL BLOOD FLOW WITH EMISSION TOMOGRAPHY AND THE CLASSIC AUTORADIOGRAPHIC TECHNIQUE P. Herscovitch* and M.E. Raichle (SPON: D.B. Clifford). Washington University School of Medicine, St. Louis, MO 63110

Several methods for measuring local cerebral blood flow (CBF) with emission tomography are based on Kety's model describing the behaviour of flow-limited tracers. These methods are analogous to the tissue autoradiographic or sampling method (Kety, Methods Med Res 8:228) but use tissue count data obtained in vivo during either a single scan or multiple sequential scans. Eklof (Acta Physiol Scand 91:1) studied the Kety tissue sampling method in rats and found that measured CBF progressively underestimated the true flow as tracer infusion time was increased. This effect was attributed to diffusion limitation of the radiotracers studied. Because this error was appreciable, we elected to study, in humans, the effect of scan length on CBF quantitation in a positron emission tomographic adaptation of the tissue autoradiographic method (Herscovitch et al, J Nucl Med 24:782). Both a radiotracer with a modest diffusion limitation, O-15 water, and a highly diffusible tracer, C-11 butanol, were studied in each of our subjects. The PETT VI tomograph was used to collect cerebral count data in sequential 40 sec time frames following intravenous injection of radiotracer. Frames were combined to calculate CBF for effective scan lengths of 40, 80, 120, and 160 sec. Increasing scan length resulted in average CBF measured with O-15 water decreasing from the 40 sec measurement by an average of 20% at 80 sec, 27% at 120 sec, and 31% at 160 sec. This decline occurred at high as well as lower flows at which water is freely permeable. Furthermore, similar declines in measured flow occurred with the diffusible tracer, C-11 butanol. Simulation studies were used to seek possible explanations for these flow declines. It was found that underestimations of flow that increase with experiment length would result from local tissue heterogeneity, systematic underestimation of tissue activity, or considerable lag in the sampled peripheral arterial time-activity curve with respect to the true input function to the brain. However, these effects could not easily explain the degree of observed time dependence of flow measurement.

In summary, not only the tissue autoradiographic method but also its adaptation to emission tomography yields declining flow values with increasing time. As this phenomenon occurred with a freely diffusible tracer, C-11 butanol, as well as with O-15 water, assumptions in the Kety model other than tracer permeability must be involved.

314.7 PHOSPHORUS-31 NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY OF IN VIVO RAT BRAIN: DEVELOPMENTAL CHANGES. K.H. Taber, J.J. Ford* and R.N. Bryan. Dept. of Radiology - Magnetic Resonance Center, Baylor College of Medicine, Houston, TX 77030.

Phosphorus-31 nuclear magnetic resonance spectroscopy was used to compare the relative concentrations of the phosphorus containing compounds phosphomonoester (PME), inorganic phosphate (Pi), creatine phosphate (CrP) and adenosine triphosphate (ATP) as well as intracellular pH in vivo in neonatal and adult rat brain. Differences were found between neonate and adults in the ratios of CrP and PME to Pi and ATP (Fig. 1). The relative intensity of the CrP peak increased and the PME peak decreased with increasing age. The CrP increase was gradual from 5 days of age to adulthood, a change which is partially accounted for by the concomittant decrease in the T1 relaxation time for CrP. In addition, however, it is extremely likely that the actual tissue concentration of CrP increased during this period. The decrease in the PME peak, on the other hand, occurred rather abruptly between 20-30 days of age. The T1 of PME was also decreasing during this period of time, suggesting that the true change in in PME relative to the remainder of the P-31 spectrum was greater than was apparent from these measurements. Maturational curves for these measures are presented (Fig. 2). The relative size of the ATP and Pi peaks and the calculated intracellular pH did not change with age, although it is likely that the absolute level of both Pi and ATP increased from neonate to adult.



314.8 DETECTION OF $^{13}$C-GLUCOSE INCORPORATION INTO GLUTAMATE AND LACTATE BY MAGNETIC RESONANCE SPECTROSCOPY (MRS) IN RAT BRAIN . G. A. Rosenberg, S. Chavez, and J. R. Brainard. Dept. of Neurology, Univ. of New Mexico Sch. of Med., Albuquerque, NM 87131, and Veterans Administration Medical Center, Albuquerque, NM 87108, and Los Alamos National Laboratory, Los Alamos, NM 87545.

Glucose utilization is essential for brain function. Attempts to follow glucose metabolism are complicated by its multiple metabolic products. Magnetic resonance spectroscopy (MRS) is an insensitive method with a high degree of molecular specificity. In order to determine the potential usefulness of MRS to study glucose metabolism in brain, we followed the metabolism of $^{13}$C-glucose in rats. Adult rats (200-400gms) were anesthetized with an intraperitoneal injection of pentobarbital (50mg/kg). Forty micromoles of $^{13}$C-glucose dissolved in saline was injected as a bolus into the femoral vein. Samples of arterial blood were collected at 5 to 15 minute intervals. After 5, 15, 30 and 60 minutes groups of 2 animals each were sacrificed by funnel freezing the brain with liquid nitrogen. The brain tissue was extracted with perchloric acid under cold conditions. The extracts were analyzed by MRS with a 7 Tesla high resolution spectrometer. We found signals from glutamate in the 5, 15 and 30 minute samples. The label from the enriched glucose was found in the 2,3 and 4 positions. Doubly labelled glutamate was not detected. Lactate was detectable in the samples. The labelling pattern of glutamate suggests that the labelled glucose carbon passed through the Krebs cycle only 1 or 2 times. This low level of activity may have been due to the anesthesia or that the levels of doubly labelled gluatamate were too low to detect. These preliminary studies demonstrate the potential for MRS to follow metabolic pathways in the brain.

314.9 LOW-COST, COMPUTER ASSISTED DENSITOMETRY FOR AUTORADIOGRAPHY: A PRACTICAL GUIDE TO SYSTEM COMPONENTS. P. Ramm, Dept. of Psychology, Trent University, Peterborough, Ont. K9J 7B8

Recently, imaging boards which plug directly into the IBM PC have become available. With such a board, a solid state scanner and commercially available software, it is possible to build an accurate densitometry system, using only off-the-shelf components, for less than $12,000.

Our system consists of a COMPAQ Deskpro personal computer, equipped with 640K of RAM, an 8087 chip, and an external hard disk and tape backup unit. The COMPAQ is highly compatible with the IBM PC, but runs 2-3 times as fast. The imaging component is an Imaging Technology (Woburn,MA) PCVISION frame grabber, which plugs into the COMPAQ motherboard. The PCVISION captures an input video signal 30 times/sec, and simultaneously displays and stores the image in a 512x512x8 bit (256 gray level/pixel) array. The image can be displayed in black and white or in pseudocolor, on an Electrohome ECM 1301 high resolution color monitor. Image contrast or color coding can be easily manipulated. Image data are read using "sample windows", apertures of any desired size which are placed over brain regions under mouse control. A file creation protocol stores data (optic density values) under animal, section, structure and sample number heading. Other routines control "visuals" (contrast, etc.), convert optic density values to tissue equivalent uCi/g or levels of LCGU, perform data normalization, summary statistics, and format the data into a file easily read by the operator or by a statistics package.

The imaging system receives input from an RCA TC2800 solid state CCD camera, mounted on a sturdy copy stand. The camera provides an array of 403Hx512V pixels at a signal to noise ratio of better than 59 dB. Autoradiographs are illuminated on a light box, which contains a fluorescent lamp for visual inspection, and an incandescent spot illuminator for precision imaging. Light output of the spot illuminator can be varied under control of a highly-stable DC power supply.

Total hardware cost of the above system in the US is about $12,000 without the computer, $14-16,000 with. This includes the imaging board, 25 megabyte hard disk and tape unit, camera, copy stand, and precision light source. A simpler system, without a hard disk/tape for example, costs about $12,000 with computer. A proficient programmer could construct useable software within about 100-300 hours, or a mature software package with all necessary hardware specifications and light source construction instructions can be purchased for about $2000.

314.10 MODELING OF LOCAL CEREBRAL GLUCOSE METABOLISM BY $^{19}$F FDG NMR ONE DIMENSIONAL ZEUGMATOGRAPHY. T. Nakada, I. L. Kwee*, and C. B. Conboy*. Neurochem. Res. Lab., VA Med. Ctr., Martinez, CA 94553 and Dept. of Neurology and NMR Facility, Univ. of California, Davis, CA 95616.

We have previously shown that contrary to the concept of the limited nature of 2-fluoro-2-deoxy-D-glucose (FDG) metabolism in vivo, the metabolism of FDG in brain extends beyond the hexokinase reaction and that this metabolism can be monitored non-invasively in vivo using $^{19}$F nuclear magnetic resonance (NMR) spectroscopy (Nakada et al, Fed Proc 44:608, 1985, Kwee et al, Fed Proc 44:609, 1985). Applying the rotating frame zeugmatographic technique, we studied regional metabolism of FDG in vivo in rat brain. FDG (400mg/kg) was injected intraperitoneally in young adult Sprague-Dawley rats (150-250g). To obtain stable contents of each metabolite, the animal was sacrificed by overdose of pentobarbital just prior to each study. The animal was subsequently placed in the NMR probe which contained a one turn oval (2.5 x 3.5cm) surface coil centered over the rat calvarium. After shimming on tissue water hydrogen (proton line width 50Hz), $^{19}$F signals were obtained using a spectrometer operating at 4.69T (Nicolet NMR System NT-200) at 188.2 MHz. Sets of free induction decays (FIDs) were obtained with consecutively incremented RF pulse widths. Two dimensional Fourier transformation of data sets provided sets of spectra representing local contents of FDG and its metabolites. The present study indicates the feasibility of establishing a model of regional glucose metabolism by $^{19}$F NMR spectroscopy.

This work was supported by UCD grants D-1783 (TN), NMR-8540 (TN), and D-1921 (ILK).

314.11 **AUTORADIOGRAPHIC DOUBLE ISOTOPE MEASUREMENT OF LOCAL CEREBRAL GLUCOSE METABOLIC RATE (lCMRG) AND ACID-BASE STATUS (ABS) IN RAT BRAIN.** K. E. Peek, A. H. Lockwood, M. Berridge*, L. Bogue*. University of Texas Health Science Center at Houston, Houston, TX

Data suggest that high glycolysis rates in ischemic brain generate excess lactate resulting in acidosis, a factor that may determine the post-ischemic recovery potential. We developed a double isotope autoradiographic method to measure simultaneously lCMRG and ABS or "pH" in rat brain by exploiting the difference between room temperature vapor pressures of [2-$^{14}$C]-2-deoxy-D-glucose (DG) and its metabolite DG-6-$PO_4$, and 5,5-dimethyl [2-$^{14}$C] oxazolidine-2,4-dione (DMO) (pK 6.13). The separation of the tracer molecules in 20-micron brain sections and plasma form the crux of the method: solvent extraction with methylene chloride (MC), ethyl acetate (EA), and chloroform (C), as well as sublimation were evaluated. Extraction of brain sections yielded:

| | DG + DG-6-$PO_4$ residual (%) | | | DMO residual (%) | | |
|---|---|---|---|---|---|---|
| | 1 h | 1.5 h | 48 h | 1 h | 1.5 h | 48 h |
| EA | 95±12 | | 78±20 | 34±0 | 29±3 | ND |
| MC | 84±6 | | 106±13 | 11±.1 | 13±3 | 8.7±.1 |
| C | 120±12 | 105±12 | 85±8 | 9.4±0 | ND | ND |

± SD, ND = not detected, 1 h C, 48 h EA and C DG, and all DMO ≠ 100%, P<0.01. Residual $^{14}$C after 14-day sublimation at room temperature was 99±3% and 3.0±1.5% for DG and DMO brain sections respectively. Apparent increases in residual $^{14}$C levels after solvent extraction are attributable to a reduction in tissue volume and beta self-absorption after brain lipid removal and would require inclusion of a correction factor in calculations. Therefore, we have chosen sublimation for isotopic separation. Rats are injected iv with 350 uCi/kg DMO and 120 uCi/kg DG, and serial blood plasma samples are obtained for tracer content measurements. Injections are made sequentially, DMO then DG after DMO equilibration permitting extrapolation of steady-state DMO levels after the DG injection; alternatively, isotopes are injected simultaneously and TLC separation of tracers determines plasma levels. Brain slices are cut in a cryostat and exposed to film along with standards to yield a DG + DMO image. After sublimation, a second exposure is made to yield a DG image. Autoradiograms are imaged with computer-controlled Eikonix digital camera. After conversion to isotope content (nCi/g), image processing subtraction techniques allow generation of DG and DMO images of the same section of tissue. Computation of lCMRG and ABS follow, using standard equations. We hypothesize that regions of increased lCMRG around ischemic regions of brain are quantitatively linked to measurable increases in acidosis.

Supported in part by the Cullen Trust for Health Care.

314.12 COMPARISON OF THE TOPOGRAPHIC DISTRIBUTION OF RADIOACTIVITY IN THE HIPPOCAMPAL FORMATION AFTER INJECTION OF (1-$^{14}$C)-GLUCOSE OR ($^{14}$C)-2-DEOXYGLUCOSE. W.E. Stumpf and G.E. Duncan*, Dept. of Anatomy, Univ. of NC at Chapel Hill, Chapel Hill, NC 27514.

After intravenous injection of (1-$^{14}$C)-glucose or ($^{14}$C)-2-deoxyglucose, the relative uptake and retention of radioactivity in different hippocampal subregions was compared. For quantitation of radioactivity, autoradiograms were prepared by thaw-mounting 4um frozen sections on nuclear emulsion-coated slides. Silver grain densities in autoradiograms were evaluated with a computer-assisted video system that allows automated counting of silver grains. Striking differences were found in the hippocampus between ($^{14}$C)-2-deoxyglucose autoradiograms and ($^{14}$C)-glucose autoradiograms (see table below). The CA-3 pyramidal cell field retained considerably more radioactivity than other pyramidal cell fields after injection of ($^{14}$C)-2-deoxyglucose, while after injection of (1-$^{14}$C)-glucose, the retention of radioactivity was similar in all pyramidal cell fields. After (1-$^{14}$C)-glucose injection, the dentate gyrus contained relatively high levels of radioactivity and more $^{14}$C accumulated in the granular layer compared to the molecular layer. After ($^{14}$C)-2-deoxyglucose injection, there was uniformly less radioactivity throughout the dentate gyrus when compared to rats injected with (1-$^{14}$C)-glucose and there was no preferential accumulation of ($^{14}$C)-2-deoxyglucose in the granular layer compared to the molecular layer.

*Table: Silver grain densities in different hippocampal regions after injection of ($^{14}$C)-2-DG or (1-$^{14}$C)-glucose*

| | Silver grains/1000um$^2$ | |
|---|---|---|
| Region | ($^{14}$C)-2-DG | (1-$^{14}$C)-glucose |
| Dentate molecular | 24.9±1.9 | 33.0±4.4* |
| Dentate granular | 23.9±1.7 | 38.5±4.2* |
| CA-1 stratum radiatum | 24.1±1.8 | 33.9±4.2* |
| CA-1 pyramidal | 30.9±3.8 | 41.5±4.2* |
| CA-3 stratum radiatum | 25.7±3.9 | 29.1±3.1 |
| CA-3 pyramidal | 39.0±3.4 | 39.1±4.3 |

Rats were injected i.v. with ($^{14}$C)-2-DG or (1$^{14}$C)-glucose and killed 30 min after the injections. Data are expressed as mean± SEM. * p<.01 compared to ($^{14}$C)-2-DG

These results imply that, in the hippocampal formation, different cellular functions are assessed by determination of the uptake and retention of radioactivity from (1-$^{14}$C)-glucose and ($^{14}$C)-2-deoxyglucose.

314.13 HIGH RATE OF GLUCOSE UTILIZATION IN THE FASCICULUS RETROFLEXUS IN THE BRAIN OF THE CONSCIOUS MOUSE. T. Jay*, F.R. Domer and L. Sokoloff. Lab. Cerebral Metabolism, NIMH, Bethesda, MD 20205

In a previous study the fasciculus retroflexus, a white matter tract, was found to have an unusually high rate of glucose metabolism, 77 to 96 μmoles/100 g/min (Jay, Jouvet and Des Rosiers, Brain Res., in press). Histochemical examination revealed no higher activity of cytochrome oxidase in this tract. Pulsinelli and Duffy (Science, 204:626, 1979) reported that hypoxia increased several-fold the rate of glucose metabolism in white matter. As it was possible that anaerobic glycolysis was responsible for the unusually high rate of glucose utilization, we have therefore attempted to alter the oxygen supply of the fasciculus retroflexus in the mouse. Cannulae were placed in a femoral artery and vein of C57BL6 mice 24 hours prior to the experiments employing deoxyglucose (DG). The experiments involved the exposure of the mouse either to room air, 100% oxygen, or 10% carbon dioxide in 90% oxygen. 15 min later, [$^{14}$C]DG (125 μCi/kg) was administered intravenously and timed blood samples were taken during the next 45 minutes. The animal was killed with pentobarbital intravenously and the brain quickly dissected and frozen for subsequent sectioning and autoradiography. The glucose utilization was calculated from the arterial plasma curve and quantitative densitometry.

| | Air | $O_2$ (100%) | $O_2$ (90%) + $CO_2$ (10%) |
|---|---|---|---|
| Fasciculus retroflexus | 97 ± 4 | 77 ± 6* | 56 ± 3*** |
| Corpus callosum | 35 ± 2 | 28 ± 3* | 21 ± 3** |
| Mamillary body | 98 ± 9 | 78 ± 9 | 60 ± 5* |

The values represent the mean local cerebral glucose utilization (μmoles/100 g/min) ± S.E.M. in four animals per group.
*p < 0.05 **p < 0.01 ***p < 0.001

Significant decreases in the rate of glucose utilization in the fasciculus retroflexus occurred in the animals exposed to oxygen or oxygen and carbon dioxide, with the decrease being more significant with the combination of gases. Similar significant decreases, though smaller, were found in the corpus callosum. A significant decrease occurs only with the gas mixture in the mamillary body, a gray matter area. The high blood flow and high oxygen tension associated with the gas mixture provided the necessary oxygen to decrease the rate of glucose utilization in all of the structures. Still the decreased rate in the fasciculus retroflexus to the level of white matter found normally had not occurred. Therefore, hypoxia does not explain the high normal glucose utilization of this structure.

314.14 THE LOCUS COERULEUS MODULATES CEREBRAL GLUCOSE UTILIZATION DURING AUDITORY STRESS - A. Justice, S. M. Feldman, and L. L. Brown. Dept. of Psychol. New York Univ., New York, NY 10003.

Hypotheses about the function of the locus coeruleus (LC) have included a role in modulation of cerebral metabolism, particularly during periods of increased metabolic demand. Our earlier experiment (Soc. Neurosci. Abs., 10: 1003, 1984) examined the effects of bilateral 6-hydroxydopamine (6-OHDA) lesions of the LC on local cerebral glucose utilization (LCGU) in rats "at rest." We now report that lesions in animals subjected to stressful auditory stimulation have different effects on LCGU than do lesions in animals in a quiet environment.

The LC was infused bilaterally with 6-OHDA (8 μg) or with its vehicle (2 μl saline). Two weeks later animals were processed for determination of LCGU by the quantitative 2-deoxyglucose (2DG) method of Sokoloff. During the terminal experiment white noise was used to increase metabolic demand. An auditory stimulus was chosen because it is a natural stimulus that has widespread effects on the brain. Sound intensity was set at a stressful level (95 db) because the LC has been shown to respond to stressful stimuli; a behavioral assay in different animals confirmed that the stimulus was stressful under the temporal conditions of the 2DG experiment (Justice and Maone, unpublished observations). Lesions were verified by LC cell counts and by fluorescence microscopy.

Two by two analyses of variance (lesion/intact, noise/silence), combining the data of the present experiment with the earlier one, revealed a significant interaction effect for 37 of 109 structures measured, as well as for the average LCGU of all 109 structures (an estimate of whole brain glucose utilization). Simple effects analysis revealed the source of the interactions: Lesions had no significant effects on LCGU in animals in silence (7% lower average for all structures in lesioned animals); by contrast, lesions in animals subjected to noise caused increases in LCGU in 47 structures (18% higher average). Alternatively, noise had less effect on intact than on lesioned animals: 30 vs. 106 structures measured showed significant simple effects (or a 25% vs. 58% increase in average glucose utilization for intact and lesioned, respectively).

We conclude that norepinephrine (NE) from the LC acts to attenuate the metabolic increases caused by intense auditory stimulation. Our results are consistent with findings that NE is released during stress and that it can act as an inhibitory neurotransmitter. Metabolic inhibition during large and widespread increases in activity may also be related to findings that LC-derived NE has an inhibitory effect on induced seizure activity.

314.15 DEMONSTRATION OF INTERDIGITATING FUNCTIONAL COLUMNS IN RHESUS MONKEY USING A DOUBLE-LABEL 2-DG SUBTRACTION TECHNIQUE.
C.J. Bruce, H.R. Friedman and P.S. Goldman-Rakic.
Sec. Neuroantomy, Yale Univ. Sch. Med., New Haven, CT. 06510

We have previously described a double-label version of the 2-DG technique which allows comparison of brain metabolism associated with two distinct conditions within a single subject (Friedman et al., Neurosci. Abstr., 10: 1002, '84). Briefly, $^{14}$C-2DG and then $^{3}$H-2DG were sequentially administered prior to each of two distinct test conditions in the same animal. X-ray and Ultrofilm images of each brain tissue section were made and a computer analysis was devised which digitized the films, converted each image to radioactivity levels, and produced separate images of $^{14}$C and $^{3}$H activity for each section by aligning the two images and then using a subtraction algorithm.

In our earlier work, we validated this double-label 2-DG method by sequentially giving sensory or electrical stimulation restricted to one hemisphere and then the other and finding that the appropriate label predominated in each hemisphere. In the present study the ocular dominance columns of primate visual cortex were stimulated to determine if the technique is also capable of revealing differential patterns of metabolic activity at the level of single columns within a single brain structure.

The monkey viewed drifting square-wave gratings whose orientation changed every 10 seconds in order to stimulate most cells. The left eye was occluded before the $^{14}$C-2DG injection and 30 minutes later the occluder was moved to the right eye and $^{3}$H-2DG was injected. After another 30 minutes the monkey was killed with barbiturate and perfused. Coronal sections (20um) of the occipital lobe were exposed on both films and analyzed to yield separate $^{3}$H and $^{14}$C images of the same section.

In striate cortex (V1) both images had bands of high metabolic activity, roughly 0.5mm wide and most intense in layer IV. The two patterns of label were predominantly interdigitated in that high metabolic activity of one label coincided with low metabolic activity of the other label and vice versa. However, some bands in V1 were coincident in the paired $^{3}$H and $^{14}$C images. Metabolic labeling in V2 was very different: bands of high activity were wider than in V1 and appeared to always be coincident in both labels. We hypothesize that these coincident zones in both V1 and V2 might be aligned with the cytochrome oxidase intense blobs and bands of layer III that respectively mark zones of chronically high metabolic activity in these areas. We conclude that the double-label 2-DG technique can reveal differential functional patterns of metabolic activity within single brain structures and can differentiate between acute, task-specific and chronic, nonspecific metabolic activity. Supported by EY04740, MH38546, and NS19610.

314.16 LOCAL GLUCOSE METABOLIC RATES IN PRIMATE THALAMUS DURING RECOVERY FROM UNILATERAL ABLATION OF CEREBRAL CORTICAL AREAS 4 & 6.
I. Shimoyama*, G. W. Dauth, S. Gilman, K. A. Frey, & J. B. Penney.
Dept. of Neurology, Univ. of Mich., Ann Arbor, MI 48109.

In humans and infra-human primates, a lesion of motor cortex results in an immediate contralateral hypotonic hemiplegia. With time the hemiplegia becomes hypertonic and some recovery of function occurs. Little is known about the central nervous system structures and events responsible for the recovery process. We present data on glucose utilization in the thalamus of animals undergoing recovery from ablation of the motor cortex.

M. fascicularis monkeys (2.5-3.5 Kg) were used. Three groups of 6 animals each include: 1) an unoperated control group; 2) animals studied 1 week after unilateral (left-sided) ablation of cerebral cortical areas 4 & 6; and 3) animals studied 8 weeks after unilateral ablation of areas 4 & 6. The ablations were performed with subpial resection using pentobarbital anesthesia and sterile procedures. The deoxyglucose technique was used to evaluate local cerebral metabolic rate for glucose (LCMRG)(Sokoloff et al, 1977). LCMRG was determined bilaterally for 9 thalamic nuclei: anterior thalamus (AT); centrum median (CM); lateral geniculate (LG); medial geniculate (MG); medial dorsal (MD); pulvinar (PUL); ventral anterior (VA); ventral lateral (VL); ventral posterior (VP). The boundaries of nuclei were determined microscopically from adjacent Nissl stained serial sections. Each nucleus was analyzed as a whole, i.e. not broken down into its various subdivisions. The Wilcoxon Signed Ranks test was used to evaluate differences in the same structures on the two sides of the brain in each group.

In general, for structures with significant left vs right differences, both sides had decreased LCMRG at 1 week, and the left side was reduced substantially over the right. At 8 weeks there was recovery towards control levels for both sides, but the left remained decreased compared to the right. At 1 week the left LCMRG was significantly less than the right in MD, CM, VP, VL, VA, & PUL. At 8 weeks the left LCMRG was significantly less than the right in MD, CM, AT, VP, VL & VA. There were no significant left vs right differences in MG or LG at 1 or 8 weeks after ablation.

The findings indicate a reduction of LCMRG in some thalamic structures receiving direct input from the ablated areas of cerebral cortex (VA, VL, VP, CM, MD) and in some structures without direct projections (PUL, AT). The latter structures are affected over at least one intervening synaptic connection. Some recovery of LCMRG occurs with time in all affected structures, but the degree varies widely. The recovery of LCMRG may be associated with functional recovery in the animal.

314.17 REGIONAL CEREBRAL BLOOD FLOW IN THE AWAKE, UNSTRESSED RAT.
R B Duckrow, R M Bryan, K A Keefer*, B D Hartman* and R B Page*
Departments of Surgery (Neurosurgery), Physiology, Anatomy and Medicine (Neurology), The Milton S Hershey Medical Center, The Pennsylvania State University, Hershey, PA 17033.

Measurement of cerebral blood flow (CBF) usually requires invasive sampling of arterial blood. As a result, CBF measurements have been made using anesthetized or awake-restrained laboratory animals. CBF may be altered by anesthetics, artificial respiration or the stress produced by restraint. Therefore, we developed a method that allows measurement of regional CBF (rCBF) in awake, unstressed, freely-moving rats. Arterial and venous catheters were placed using barbituate anesthesia and routed subcutaneously to exit near the skull. Rats were placed in individual enclosures, and a swivelling tether fixed to the skull guided the catheters outside the enclosure. A recovery period of 5 to 7 days was allowed prior to rCBF measurement. At that time each rat was (1) free of anesthesia, (2) recovered from surgery, (3) isolated from the investigators, (4) in a familiar environment, and (5) able to move about freely. rCBF was measured using [$^{14}$C]-iodoantipyrine. The time delay and dispersion of the arterial tracer concentration profile induced by the long catheter was corrected using a numeric solution of the convolution integral modeled for the catheter. Physiologic parameters measured immediately prior to rCBF measurement indicated that the rats were not stressed:

| | |
|---|---|
| Plasma glucose | 6.26 um/ml |
| Plasma epinephrine | 47 pg/ml |
| Plasma norepinephrine | 182 pg/ml |
| Heart rate | 353 bpm |
| Mean arterial blood pressure | 93 mmHg |
| $PaCO_2$ | 40.6 mmHg |
| $PaO_2$ | 90 mmHg |
| pHa | 7.416 |

rCBF values measured in freely-moving rats were higher than those reported by most investigators but not all. It is difficult to make detailed comparisons because physiologic parameters important to CBF regulation such as $PaCO_2$ and plasma epinephrine were not reported in most studies. However, when regional cerebral glucose utilization (measured using freely-moving rat model) was plotted as a function of CBF for the corresponding region, the relationship was described by a straight line with a slope of 0.49 (r=0.99). This slope represents the arterio-venous difference of glucose across the brain and is consistent with arterio-venous differences of glucose that have been directly measured. This model allows rCBF to be measured without anesthesia or restraint and offers a method of mimicing the natural physiologic state. This work was supported in part by grants from the American Heart Association (83-903 83-906 84-122) and the PHS (NS15926 NS19341).

314.18 REGIONAL GLUCOSE AND β HYDROXYBUTYRATE USE BY DEVELOPING RAT BRAIN
A.L. Miller, L.J. Stone* and J. Kwan.*
Dept. of Psychiatry, The University of Texas Health Science Center, San Antonio, TX 78284

Rates of glucose and D-β-hydroxybutyrate (D-β HB) use were determined in five brain regions of 20-day-old rats. The regions studied were cerebral cortex, thalamus, striatum, cerebellum, and brainstem. The tracers for determining rates of substrate use were [$^{3}$H] fluorodeoxyglucose (FDG) and [3-$^{14}$C]-D-β HB. The animals were sacrificed in a 6 kW, 2450 MHz focused microwave apparatus (Medina and Stavinoha, Brain Res., 132:149, 1977) at two and five minutes after intravenous isotope administration. Radioactivity in neutralized perchloric acid extracts of brain was chromatographically separated into its [$^{3}$H] FDG and [$^{3}$H] FDG-phosphate components and the rate of glucose use calculated as previously described (Miller and Corddry, J. Neurochem., 35:1202, 1981), using 0.6 as the rate of phosphorylation of FDG relative to glucose. Radioactivity in brain metabolites of [3-$^{14}$C]-D-β HB was calculated as the difference between total $^{14}$C in the extract and $^{14}$C in D-β HB in the extract. The latter was estimated from the product of brain D-β HB content (nmol/mg protein) and blood D-β HB specific activity (dpm/nmol). Blood and brain D-β HB specific activities were assumed to be equal to one another. Rates of D-β HB use were then calculated in the same fashion as glucose use rates. All animals were fed ad lib. Eight minutes prior to isotope administration they were injected intraperitoneally with normal saline or DL-β HB (10 mmol/kg).

Blood D-β HB levels averaged 0.21 μmol/ml in saline-injected and 3.13 μmol/ml in hyperketonemic rats. Rates of glucose utilization were significantly heterogeneous between regions in both groups: thalamus > cerebral cortex > striatum > brainstem > cerebellum. Rates of D-β HB use varied significantly between regions only in the saline group, with the brainstem rate being significantly lower than other regions. Regional rates of D-β HB use did not correlate with regional rates of glucose use in either group. Whole brain glucose utilization is lower in hyperketonemic 20-day-old rats (Miller et al., Dev. Brain Res., 4:443, 1982) and, in this study, we found this to be true in each brain region examined. In fact, the 20-35% decreases in regional glucose use were just sufficient, in the hyperketonemic rats, to have maintained energy production constant.

Thus, in 20-day-old rats, regional heterogeneity of brain glucose use is similar to that in adult rats. D-β HB use is much less regionally heterogeneous. When brain regional rates of D-β HB use are increased 7-9-fold in acute hyperketonemia, there are compensatory decreases in regional rates of glucose use sufficient to keep regional rates of energy production unchanged.

Supported by grant HD-15053 from the U.S. Public Health Service.

314.19 SIMULTANEOUS QUANTITATION OF LOCAL CEREBRAL BLOOD FLOW, GLUCOSE UTILIZATION AND METABOLISM/FLOW COUPLE BY $^{14}$C DOUBLE-LABEL AUTORADIOGRAPHY. M.D. Ginsberg, D.W. Smith*, M.S. Wachtel*, M. Gonzalez-Carvajal*, and R. Busto*. Cerebral Vascular Disease Research Center, Univ. Miami School of Medicine, Miami, FL 33101.

Local glucose metabolism (lCMRgl) and blood flow (lCBF) may be evaluated simultaneously in the animal brain by dual-tracer autoradiography by means of 2-deoxyglucose (DG) and iodoantipyrine (IAP), respectively, provided that activities of the two radiotracers can be resolved on film. The use of beta-emitters for this purpose minimizes problems associated with rapid isotopic decay, radioactive contaminants, limited availability, and increased expense. Using two $^{14}$C-labeled tracers, Furlow et al (JCBF Metab 3:62, 1983) reported complete removal of IAP and complete retention of DG from tissue sections following chloroform wash. However, our preliminary data refuted these findings, showing approx. 6% retention of IAP and 15% disappearance of DG with a 48-hr chloroform wash. This led us to reformulate the method. In preliminary studies, chloroform was found to be superior to toluene, benzene, and 2,2-dimethoxypropane in maximizing retention of DG. In contrast to n-hexane, chloroform permitted retention of equal percentages of DG and DG-6-phosphate, its metabolite. 5-day chloroform wash with continuous agitation reduced IAP by approx. 94% while allowing 60-65% retention of DG. Computer simulations confirmed that propagated error was minimized at high extracted percentages of IAP.

In a series of nitrous oxide-anesthetized rats, lCMRgl and lCBF were determined simultaneously. Single-label IAP- and DG-containing sections were used to quantitate per cent retention of IAP and DG following chloroform wash, and a linear model was used to compute DG and IAP activities, which were converted to lCMRgl and lCBF in the usual manner (Sokoloff et al, J Neurochem 28: 897, 1977; Sakurada et al, Am J Physiol 234: H59, 1978). Pre- and post-wash films were mechanically aligned, scanned by a digitizing densitometer, and the data used to construct pseudo-color displays of lCMRgl, lCBF and the lCMR/lCBF ratio (the metabolism/blood flow "couple"). Region-of-interest measurements were taken simultaneously from all three images via a computer-interfaced image-processor. Values obtained by the double-label strategy were highly correlated with values obtained from comparable single-label animals (r=0.94 for lCMRgl and 0.90 for lCBF). Absolute agreement between double- and single-label results was found to depend critically upon the values assigned to the $^{14}$C-methacrylate standards used for conversion of film optical density to radioactivity units.

Supported by USPHS Grant NS 05820.

314.20 CORRELATION OF BRAIN FUNCTION AND NEUROANATOMY WITH A COMPUTER STEREOTACTIC ATLAS. L.S. Hibbard*, J.S. McGlone* and R.A. Hawkins (SPON: R.A.W. Lehman). Department of Anesthesia, M.S. Hershey Medical Center, The Pennsylvania State University College of Medicine, Hershey, PA 17033

Neurometabolic experiments using quantitative autoradiography can produce data in amounts large enough to require computer methods for its storage and analysis. Earlier, we reported a 3D reconstruction program system to perform these tasks on rat brain metabolic data and showed that the reconstructed 3D maps of several experiments can be combined to form average maps which may be compared by subtracting one from another, pixel-by-pixel, testing each difference for probable significance (L.S. Hibbard and R.A. Hawkins, Am. J. Physiol. 247:E412, 1984). There remained, however, a need to correlate the reconstructed functional data with neuroanatomy. With our experience combining image data, it appeared that a computerized stereotactic atlas could provide a practical solution to this problem.

Our strategy is to represent neural structures as serial coronal templates, or masks, to be superposed onto the coronal experimental images. The structural masks were created by interactive graphics from a normal control 3D glucose utilization map constructed as the mean of twelve experiments.

To superpose the atlas and experimental data, we define an atlas coordinate system whose origin is located on, and whose z-axis is coincident with, the line defined by the image centers of mass, and whose xy-plane is parallel to the coronal image planes. The z-coordinates of the atlas masks are fixed by the location of the origin and the inter-section spacing of the serial images from which they were taken. Because the experimental data are also reconstructed about the z-axis, superposition requires assigning z-coordinates to the experimental images. Axial sections of the atlas and experimental data in the xz-plane are generated, overlayed, and one is translated with respect to the other by steps along z. The value of the cross-correlation is calculated at each step and the maximum value corresponds to the relative z translation needed to superpose the experimental data onto the atlas. When this operation interleaves the experiment images with the atlas masks, the mask boundary must be interpolated at the experiment image z-coordinate. Once done, the mask is used to sum up the pixel values of the metabolic function over that image. This process, repeated for all experiment images within the z-range of the neural structure of interest, produces the value of the metabolic function within that structure.

This project has been supported by a grant from the Whitaker Foundation (LSH) and by NIH grant NS16737 (RAH).

## CYCLIC NUCLEOTIDES II

315.1 IN-VITRO AND IN-VIVO PROTEIN PHOSPHORYLATION IN DROSOPHILA HEADS. J. Buxbaum* and Y. Dudai (SPON: H. Soreq). Department of Neurobiology, The Weizmann Institute of Science, Rehovot 76100, Israel.

Identification of endogenous substrates for cAMP-dependent protein kinase in Drosophila is of interest since mutants exist in this organism that are lesioned in components of the cAMP cascade and also in plasticity (e.g., reviewed in TINS 8(1) 18 (1985)). Such mutations are expected to exert their effects by altering phosphorylation of specific proteins; the identification of the latter may thus shed light on mechanisms of neuronal plasticity. We have analyzed phosphorylation patterns in wild-type Drosophila head preparations, which are a rich source of neural tissue. Two main types of subcellular fractions were used: 1000g sup (S1) and a washed 30000g pellet (P2). Phosphorylation in vitro was assayed by measuring the incorporation of $^{32}$P from [$^{32}$P]γATP into proteins resolved by SDS-PAGE. Ca. 40 phosphoproteins were thus detected in S1, and some of them (MW 16K, 23K, 37K, 50K, 87K, 97K and 165K daltons) displayed cAMP-dependent phosphorylation. In most of our in vitro studies we have concentrated on the P2 fraction. Optimal phosphorylation of this fraction was observed following a 20 sec reaction in the presence of 10mM $Mg^{2+}$ and 10μM ATP. No phosphorylation was detected in the absence of $Mg^{2+}$. cAMP increased the phosphorylation of ca. 10 bands, the most prominent having MW of 17K, 19K, 21K, 36K, 50K, 67K and 92K. The concentration of cAMP producing half-maximal phosphorylation was about 0.3μM, but heterogeneity was detected in the cAMP response; thus the 50K protein started to display a decrease in phosphorylation at cAMP>0.1μM, a behavior characteristic of the regulatory subunit of cAMP-dependent protein kinase. p-hydroxymercuribenzoate (1mM) abolished phosphorylation in the presence of cAMP, whereas in the absence of cAMP only the 50K protein was phosphorylated. This suggests that the kinase requires an active SH and that the regulatory subunit protects the SH, as previously reported for other systems. $F^-$ and vanadate greatly potentiated phosphorylation. $Zn^{2+}$ (5mM), in the absence of $Mg^{2+}$, stimulated cAMP-independent phosphorylation of a different set of proteins. In vivo phosphorylation was studied by feeding flies with carrier-free $^{32}$Pi in sucrose. Optimal incorporation of $^{32}$P into proteins (determined again by SDS-PAGE) was found to occur after 24 hr of feeding. Following feeding, the flies were frozen in liquid $N_2$ and subjected to acetone substitution for 24 hr. Subsequently S1 was prepared. Some 50 phosphoprotein bands were observed, with major multiple bands occuring at ca. 20K, 30K, 50K and 200K daltons. In general, the pattern of phosphorylation in vivo was different from the pattern observed in vitro. Existing mutants in the cAMP cascade are being analyzed using the same in vitro and in vivo techniques. (Supported by the Fund for Basic Research, The Israel Academy of Science, Jerusalem).

315.2 MULTIPLE FORMS OF MEMBRANE-ASSOCIATED PHOSPHOPROTEIN PHOSPHATASES IN DROSOPHILA MELANOGASTER HEADS. Sara Orgad* and Yadin Dudai (SPON: I. Ginzburg). Department of Neurobiology, The Weizmann Institute of Science, Rehovot 76100, Israel.

The phosphorylation state of membrane proteins is assumed to affect various neuronal properties, e.g. ion permeability. Membrane-bound phosphoprotein phosphatases (PPPases) are therefore expected to play a role in the regulation of neuronal activity. Drosophila offers some advantage in studying the structure, regulation and function of PPPases, since mutations might be isolated that should affect specific subpopulations of these enzymes (as is, for example, the case for certain enzymes of the cAMP cascade; reviewed in Trends in Neurosci. 8(1) 18 (1985)). We have set out to characterize membrane bound PPPases in Drosophila as a first step toward the isolation of mutants in these regulatory enzymes. For our studies we are using a washed particulate preparation from fly heads, which is enriched in membranes of neuronal origin. The particulate preparation was treated with 0.2% Triton X-100 to solubilize the enzymes. When aliquots of the detergent-treated preparation were subjected to sucrose gradient centrifugation and the fractions assayed for PPPase activity by using [$^{32}$P]protamine as a substrate, four major peaks were observed, with sedimentation coefficients of ca. 4S, 9S, 10S and 11S, respectively. The 9S peak was usually the predominant one. When p-nitrophenylphosphate was used as a substrate to assay for acid (pH 5.5) or alkaline (pH 8.8) phosphatase, a single major peak of ca. 6S was observed. Triton-treated membrane preparations from the heads of a previously existing putative acid-phosphatase-null mutant and from the heads of a previously existing putative alkaline-phosphatase-null mutant of Drosophila did not reveal a reduction in the level of PPPases activity, indicating that the PPPases detected by us do not share catalytic subunits with acid phosphatase or with alkaline phosphatase (as was suggested for some mammalian systems). The total PPPase activity in Drosophila head membranes was stimulated ca. 2-fold by mM concentrations of $Mn^{2+}$ and of EDTA, was inhibited (by ca. 97%) by mM concentrations of $Zn^{2+}$ and was partially inhibited (by 25-60%) by μM concentrations of $Ca^{2+}$ and vanadate and by mM concentrations of $F^-$. The organophosphate diisopropylfluorophosphate inhibited all the major solubilized PPPase peaks, suggesting that the enzymes contain serine in their active sites. We are currently using antibodies, which have been raised against purified catalytic subunits of PPPase from mammalian brain (i.e., the ca. 35K subunits), for further purification of PPPases from Drosophila head membranes. (Supported by grants from the US-Israel Binational Science Foundation, Jerusalem, and from The Ministry of Health, Jerusalem).

315.3 A CYCLIC AMP-REGULATED MEMBRANE PHOSPHOPROTEIN OF $M_r$ 260,000 LOCALIZED TO CEREBELLAR PURKINJE CELLS. S. I. Walaas, A. C. Nairn*, and P. Greengard. Lab. of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

The second messengers cyclic AMP and cyclic GMP, both of which achieve most or all of their effects through regulation of protein phosphorylation systems, appear to be important in the regulation of neuronal function in the cerebellum (Bloom, F.E., Rev. Physiol. Biochem. Pharmacol., 74:1-103, 1975; Nairn, A.C. and Greengard, P., Fed. Proc., 42:3107-3113, 1983). However, little is known about the exact molecular mechanisms through which cyclic nucleotide-mediated regulation takes place in the cerebellum. In this study, we report the presence of a 260 kilodalton (kDa) neuronal membrane phosphoprotein (PCPP-260, Purkinje Cell Phosphoprotein of 260 kDa) which is a substrate for cAMP-dependent protein kinase and which is highly enriched in cerebellar Purkinje cells.

PCPP-260 was discovered when particulate preparations from rat cerebellum were phosphorylated with activated endogenous or exogenous cyclic AMP-dependent protein kinase. Activation of cyclic GMP-dependent, calcium-calmodulin-dependent or calcium phospholipid-dependent protein kinases did not phosphorylate the protein. We have therefore used cyclic AMP-stimulated phosphorylation as an assay, and found PCPP-260 to be present in all mammalian cerebella so far tested, including human cerebellum. The protein, which can be visualized by Coomassie blue-staining of particulate preparations separated by one- or two- dimensional gel electrophoresis, has been found by peptide mapping studies to have one major phosphorylation site. Analysis of PCPP-260 in cerebella from mutant mice, deficient in either Purkinje cells (pcd, nervous) or granule cells (weaver), indicates that the protein in the cerebellum is restricted to Purkinje cells. Subcellular fractionation of rat cerebella indicates that PCPP-260 is an integral membrane protein. Similar studies of phosphoproteins in other brain regions show that a closely related membrane phosphoprotein of 265 kDa also exists, albeit in much lower concentration, outside the cerebellum. These phosphoproteins may be related to the previouosly described cerebellum-specific glycoproteins $P_{400}$ (Mallet, J. et al., Brain Res., 103:291-312, 1976) or GP-A (Croswall, D.E. and Kelly, P.T., J. Neurochem., 42:534-546, 1984). PCPP-260 may be involved in cyclic AMP-regulated functions in Purkinje cell membranes. (Supported by United States Environmental Protection Agency under Assistance Agreement CR-810608-01).

315.4 EVALUATION OF THE RESPONSE TO CANNABIMIMETIC DRUGS IN NEUROBLASTOMA CELLS. W.A. Devane*, J.W. Spain*, C.J. Coscia and A.C. Howlett* (SPON: M.A. Walz). Depts. of Pharmacology and Biochemistry, St. Louis University School of Medicine, St. Louis, MO 63104.

We have previously demonstrated that the cannabimimetic drugs, $\Delta^9$-tetrahydrocannabinol (THC) and desacetyllevonantradol (DALN), inhibit adenylate cyclase in a neuroblastoma cell line (N18TG2) (Howlett and Fleming, Mol. Pharm. 26:532, 1984). Lymphoma, glioma and certain other neuroblastoma cells failed to respond. Thus, the effects of the cannabimimetic drugs are not universally observed in membranes from all cell types. The inhibition occurred in the nanomolar range, and was immediate and reversible. The effects of the cannabimimetic agents were dependent on the concentrations of guanine nucleotides (half-maximal at 800 nM GTP) and divalent cations (< 1 mM $Mg^{2+}$ or $Mn^{2+}$). Pertussis toxin blocked the inhibition of adenylate cyclase by cannabimimetic drugs. These data suggest that the G proteins mediate the cannabimetic effects.

We examined the interaction between the opioid and cannabimimetic drugs because the opioid drugs also inhibit adenylate cyclase via the G proteins in N18TG2 cells. Delta opioid receptors were detected on N18TG2 plasma membranes using D-$ala^2$-D-$leu^5$-enkephalin (DADLE). No mu or kappa receptors were detected. Neither the binding affinity nor capacity of DADLE were altered in the presence of $\Delta^9$-THC or DALN. Both inhibition of adenylate cyclase in membrane preparations and the decrease in cyclic AMP accumulation in intact cells were produced by the cannabimimetic agents and by the opioid agents, morphine, etorphine, and D-$ala^2$-$met^5$-enkephalinamide. Whereas the effects of the opioids were reversed by naltrexone or naloxone, the cannabimimetic responses were unaffected. The response of maximally effective concentrations of both DALN and etorphine were neither antagonistic, additive, nor synergistic. These results suggest that the opioid and cannabimimetic drugs operate via distinct, noninteracting receptors that can be coupled to the same effector. (Supported by DA03690 and MH40005.)

315.5 EVIDENCE FOR THE INHIBITORY SUBUNIT (Ni) OF ADENYLATE CYCLASE IN NERVOUS AND HEART TISSUE OF APLYSIA. S.D. Critz, J.F. Harper* and J.H. Byrne. Univ. of Texas Medical Sch., Houston, Tx. 77225.

It is now well established that cAMP plays a critical role in modulating a variety of neuronal responses in Aplysia californica. Previous studies have focused on the neurotransmitter activation of adenylate cyclase which presumably occurs via the excitatory GTP-regulated subunit (Ns). An additional site of regulation that has not been examined however, is neurotransmitter activation of the inhibitory subunit (Ni). As a first step in examining this question we show by two techniques that Ni is present in Aplysia tissue. Bordetella pertussis toxin (IAP)-catalyzed ADP ribosylation was used as a specific probe for Ni (Katada and Ui, PNAS 79: 3129, 1982). Desheathed ganglia were homogenized in 1 ml ice cold 50mM Na/Hepes, 1mM EDTA, 0.1 mM ß-mercaptoethanol, 300 mM sucrose, pH 7.6. Two mls of this solution less sucrose were added and the suspension centrifuged at 10,000 RPM for 10 min at 4°C. The pellet was washed in sucrose-free buffer then resuspended in 100 ul IAP-activating buffer (200 mM Tris/Cl, pH 8.0, 2.0mM EDTA, 4 mM $MgCl_2$, 1mM ATP, 2 mM DTT, 0.2mM GTP, 25 ug pyruvate kinase, 15mM $K^+$PEP, and approximately 5 uCi $^{32}$PNAD) with or without 500 ng IAP. This mixture was incubated at 30°C for 60 min. The reaction was then terminated by addition of 100 ul 20% TCA and the samples were gently washed 5 times to remove excess $^{32}$PNAD. Samples were then solubilized, run on 10% SDS gels and prepared for autoradiography by routine methods. We observed a single labeled protein at 40K MW in IAP treated samples. This labeled protein was present in all ganglia tested: abdominal, pleural-pedal, and cerebral. Labeling was also observed in identically prepared heart tissue. In contrast, no label was seen in Aplysia tail muscle. The labeled protein occurs at the same molecular weight as that reported previously for Ni in a variety of other tissues (Manning and Gilman, JBC 258:7059, 1983).

An assay for Ni activity was also performed on neural tissue by measuring adenylate cyclase activity at various GTP concentrations. In other systems in which both Ns and Ni exist a biphasic dose-response relationship to GTP stimulated activity has been found (Rodbell, Nature 284:17, 1980). We observed a stimulatory effect of GTP on adenylate cyclase at low concentrations of GTP, which peaked at approximately 100 uM. With higher concentrations of GTP inhibition of activity was observed, suggesting that Ni inhibitory activity overcomes Ns stimulation of adenylate cyclase.

These findings provide preliminary evidence that Ni is present in Aplysia tissue. Ni may serve as an important site for the regulation of cAMP synthesis and perhaps neuronal plasticity.

315.6 ASSOCIATION OF KINASES AND OTHER PROTEINS IN THE cAMP-CASCADE WITH THE MEMBRANE-CYTOSKELETON OF APLYSIA NEURONS. T. Saitoh, M. Schonberg*, J.H. Schwartz, Howard Hughes Med. Inst., Columbia Univ. Coll. Phys. & Surgeons, New York, NY 10032.

Extracting with 0.1% NP-40 in 2M glycerol, Solomon and his colleagues (Cell 18:431, 1979) obtained a cytoskeleton fraction lacking membrane but containing loosely associated proteins. We adapted this method by using 0.1% saponin, which does not solubilize membrane, to prepare a membrane-cytoskeleton complex in order to study the compartmentalization of $Ca^{++}$/calmodulin-dependent kinase II (PNAS 80:6708, 1983). Conditions that lead to cAMP-dependent or $Ca^{++}$/calmodulin-dependent phosphorylation were found to dissociate this kinase from the complex (J. Cell Biol. 100:835, 1985). We now have characterized both the membrane-cytoskeleton complex (residue fraction) and the extract produced by this procedure.

The membrane-cytoskeleton complex contained all of the proteins ($M_r$ 90,000, 55,000, 40,000, 35,000, and 24,000) that bind $^{125}$I-$Ca^{++}$/calmodulin kinase as determined by Western blotting. Half of the total regulatory subunits of the cAMP-dependent kinase were also associated with the complex. This association is selective, because a characteristic subset of the five neuronal 8-$N_3$-cAMP-binding species was preferentially attached. The complex contained essentially all of the newly-synthesized glycoproteins labeled after introsomatic injection of $^3$H-fucose into the giant cerebral neuron, indicating that the internal membrane systems of the cell (Golgi and smooth endoplasmic reticulum) is preserved. Indeed, the complex appeared quite similar to untreated cells when examined by electron microscopy, even though 37% of the total protein was extracted. Plasma membrane also was preserved: the complex was enriched in membrane glycoproteins that bind concanavalin A. Although more than half of the adenylate cyclase activity is not recovered after the extraction, we found 60% of the remaining enzyme in the complex together with putative Gs ($M_r$ 55,000) and Gi ($M_r$ 41,000) subunits. These were $^{32}$P-ADP-ribosylated in the presence of cholera toxin or pertussis toxin.

Some particulate material is extracted from nerve cells by saponin. A fraction sedimented from the saponin extract at 100,000 xg for 1 h contained neurofilaments, rough endoplasmic reticulum, and small bits of membrane, but no $^3$H-fucosyl glycoproteins. The parts of the cell from which this fraction is derived are uncertain, but it contained about 10% of the total concanavalin A binding activity and 40% of the remaining cyclase, and these appear to have distinctive properties.

315.7 TRANSDUCING PROTEINS AND THE REGULATION OF ADENYLATE CYCLASE IN APLYSIA NEURONS. M. Schonberg*, A. Stapleton*, T. Saitoh, Howard Hughes Medical Institute, Columbia Univ. Coll. Physicians & Surgeons, New York, NY 10032.

Application of serotonin increases the synthesis of cAMP in Aplysia neurons and stimulates adenylate cyclase in membranes isolated from nervous tissue. Because it is dependent on GTP, stimulation of cyclase by serotonin probably is mediated by a stimulatory G transducing protein (Gs). A further indication for an Aplysia Gs subunit is that cholera toxin stimulates cyclase activity in membranes isolated from Aplysia ganglia and causes the ADP-ribosylation of an $M_r$ 55,000 protein that is membrane-associated. We now report evidence for an inhibitory G subunit of cyclase (Gi).

Pertussis toxin produces the $(^{32}P)$ADP-ribosylation of an $M_r$ 41,000 protein in Aplysia neuronal membranes. It is thought that ADP-ribosylation inactivates Gi in other animals. We find that cyclase activity is markedly inhibited at concentrations of GTP-gamma-S greater than $10^{-3}$M; this inhibition is blocked by pertussis toxin, as would be expected if the Aplysia Gi is inactivated. In adddition, pertussis toxin potentiates the activation of the cyclase produced by suboptimal concentrations of serotonin.

We partitioned neuronal membranes into two fractions (accompanying abstract). The proportion of adenylate cyclases of putative Gs to Gi, revealed by the $(^{32}P)$ADP-ribosylation produced by cholera toxin or by pertussis toxin, was quite different in these two fractions. The properties in the two particulate fractions seem to differ from each other. The stimulation of cyclase activity by various effectors (GTP-gamma-S, $MnCl_2$, cholera toxin, serotonin, and $Ca^{++}$/calmodulin) in the two different membrane fractions was different. The degree of the interference of $Mn^{++}$ stimulation, GTP-gamma-S stimulation of cyclase activity by pertusis toxin and cholera toxin was different in the two fractions. The distinctive behavior of the cyclase in different membranes might partly be explained by differences in the proportion of the two types of transducing subunits.

315.8 PHOSPHODIESTERASE AND ADENYLATE CYCLASE ACTIVITY IN APLYSIA BAG CELL NEURONS: EFFECT OF CALCIUM AND A CALMODULIN ANTAGONIST. C.L. Bruehl & R.W. Berry. Dept. Cell Bio. & Anat. Northwestern Univ Medical School, Chicago, IL 60611

In the bag cell neurons of Aplysia, cyclic AMP and calcium are known to be crucial for normal electrical and biochemical function (Kaczmarek & Strumwasser, J.Neurophysiol.,52:340, 1984; Bruehl & Berry, J.Neurosci., in press). Since, in other systems, calcium regulates cAMP levels, we looked for such an interaction by assaying the $Ca^{2+}$ sensitivity of phosphodiesterase (PDE) and adenylate cyclase in homogenates of bag cells. In a 0 $Ca^{2+}$/EGTA medium, PDE activity was measured at $3.4 \pm 0.6 \times 10^{-8}$ moles cAMP hydrolyzed/min/mg protein. When EGTA was replaced in the medium by varying amounts of $CaCl_2$, PDE activity was steadily increased (see below), rising to almost 3 times controls at 300 uM. When the calmodulin inhibitor R 24 571 was included in the reaction along with calcium, PDE activity was markedly reduced. R 24 571 had little effect on PDE activity when assayed in a 0 $Ca^{2+}$/EGTA medium. While stimulation is seen only at relatively high calcium concentrations, the results suggest the presence of at least one calcium/calmodulin-sensitive form of phosphodiesterase in the bag cells. In addition, $Ca^{2+}$ stimulated adenylate cyclase activity. If these effects accurately reflect the situation in vivo, then calcium entry during bag cell discharge would be expected to increase cAMP turnover. Supported by NSF BNS-82- 19630.

Calcium Sensitivity of Bag Cell PDE and Adenylate Cyclase

| $[Ca^{2+}]$ | PDE (moles cAMP hydrolyzed/min/mg) | Adenylate Cyclase (moles cAMP/min/mg) |
|---|---|---|
| 0 $Ca^{2+}$/EGTA | $3.4 \pm 0.6 \times 10^{-8}$ | $10.2 \pm 0.7 \times 10^{-12}$ |
| + R 24 571 | $3.7 \pm 0.2 \times 10^{-8}$ | ---------- |
| 1 uM | $3.7 \pm 0.2 \times 10^{-8}$ | $10.9 \pm 0.1 \times 10^{-12}$ |
| 10 uM | $4.5 \pm 0.3 \times 10^{-8}$ | $14.9 \pm 0.4 \times 10^{-12}$ |
| 30 uM | $6.5 \pm 0.2 \times 10^{-8}$ | $16.1 \pm 0.5 \times 10^{-12}$ |
| + R 24 571 | $3.1 \pm 0.1 \times 10^{-8}$ | ---------- |
| 100 uM | $8.5 \pm 0.4 \times 10^{-8}$ | $17.0 \pm 0.3 \times 10^{-12}$ |
| 300 uM | $1.1 \pm 0.5 \times 10^{-7}$ | $39.2 \pm 1.8 \times 10^{-12}$ |
| + R 24 571 | $6.9 \pm 0.6 \times 10^{-8}$ | ---------- |

315.9 CALMODULIN ACTIVATES ADENYLATE CYCLASE FROM RAT ADENOHYPOPHYSIS. D.V. Greenlee. Dept. of Zoological and Biomedical Sciences and the College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

Calmodulin (CaM) is a ubiquitous, $Ca^{2+}$ binding protein which activates numerous types of enzymes upon formation of the $(Ca^{2+})_n$•CaM•enzyme complex. A few adenylate cyclases, for example, from bovine brain and from Bordetella pertussis (Greenlee, et al. (1982) Biochemistry 21:2759), are known to be calmodulin responsive. Recent literature suggests that adenylate cyclase from rat anterior pituitary is also CaM sensitive, although a detailed analysis of the calmodulin specificity for the enzyme has not been reported. The current results corroborate the existence of a CaM-sensitive adenohypophyseal cyclase and characterize in detail the $Ca^{2+}$ sensitivity of the enzyme.

Adenohypophyseal membranes were prepared by homogenization of adult male Sprague-Dawley rat pituitaries in buffer containing 1mM EGTA. Following centrifugation of the membranes, the pellet was washed once more with EGTA and resuspended for assay of adenylate cyclase activity. This treatment apparently removed endogenous CaM and further washing did not enhance cyclase stimulation by added calmodulin. In the presence of 200μM EGTA, addition of $CaCl_2$ caused only a dose-dependent inhibition of basal cyclase activity. In the presence of 200μM EGTA and CaM, $CaCl_2$ addition caused a biphasic response of cyclase activity—low $Ca^{2+}$ concentrations stimulated cyclase while higher concentrations inhibited the enzyme. In contrast to brain cyclase, which is activated by nanomolar concentrations of CaM, adenylate cyclase from anterior pituitary required micromolar CaM for activation. Consequently, $Ca^{2+}$ dose-response curves for calmodulin activation were shifted to higher concentrations as CaM levels were increased. For example, employing calmodulin concentrations of 10μM, 50μM, and 100μM, optimal added $Ca^{2+}$ concentrations were 125μM, 250μM, and 350μM, respectively. Using optimal $Ca^{2+}$ concentrations for each concentration of CaM, calmodulin activated pituitary cyclase in a dose-dependent manner. Fluphenazine (50μM), a phenothiazine drug known to bind CaM in the presence of $Ca^{2+}$, completely inhibited calmodulin (2μM) activation of adenylate cyclase. Excess EGTA (5mM) also completely abolished CaM activation of cyclase activity. These results indicate that 1) a calmodulin-sensitive adenylate cyclase exists in rat anterior pituitary and 2) this enzyme differs from brain cyclase in its responsiveness to calmodulin.

315.10 PROTEIN KINASE C ACTION ON HORMONE RECEPTOR ACTIVITY IN PITUITARY CELLS. S.T. Summers*, P.L. Canonico and M.J. Cronin, Dept. of Physiology, Univ. of Virginia, Charlottesville, Virginia 22908.

Tumor promoters (TP) are capable of substituting for diacylglycerols to activate the calcium and phospholipid-dependent, protein kinase C. In determining if these agents affected hormone receptor activity in anterior pituitary (AP) cells, we found a potentiation of growth hormone (GH) releasing factor (GRF) stimulated GH release and an abolition of dopaminergic inhibition of prolactin release (Eur J Pharmacol 111: 1985, in press). To investigate the mechanism for such effects, we then studied GRF receptor coupling to the cyclic AMP (cAMP) generating system. TPs markedly potentiated maximal GRF-initiated cAMP accumulation (2.1 ± 0.2-fold at 15 min). This was specific, in that it was produced by the TPs phorbol myristate acetate (PMA), phorbol dibutyrate (PDB) and the non-phorbol teleocidin, whereas a phorbol that is inactive as a TP (4-alpha-phorboldidecanoate) had no effect. Furthermore, a synthetic diacylglycerol, 1-oleoyl-2-acetyl glycerol mimicked the action of TPs. This suggested that protein kinase C activity could modulate the coupling of GRF receptor to the adenylate cyclase system in these heterogenous AP cells. In order to more precisely define this mechanism, we turned to the 235-1 cell line derived from a prolactin-secreting rat AP tumor. These cells respond to prostaglandin E1 (PGE1) and forskolin with an increase in cellular cAMP and prolactin release. The cells also show enhanced prolactin secretion after exposure to TPs. Our original observations in normal AP cells of potentiated cAMP responses to secretagogues after TPs has been confirmed in 235-1 cells. Cotreatment with PMA or PDB potentiated the cellular accumulation of cAMP in response to PGE1 by 78% at 10 minutes. TPs also increased cAMP levels in response to forskolin by 36% at 10 minutes. While TPs did not directly affect adenylate cyclase activity in membrane preparations, membranes from cells pretreated with PMA or PDB have increased basal and forskolin-stimulated adenylate cyclase activity.

| | Adenylate Cyclase Activity (pmoles/mg/min) | |
|---|---|---|
| Forskolin (uM) | Vehicle Pretreat | PMA (100 nM) Pretreat |
| 0 | 113 ± 1 | 166 ± 9 |
| 0.1 | 247 ± 17 | 316 ± 4 |
| 1.0 | 499 ± 19 | 734 ± 17 |
| 10.0 | 1090 ± 40 | 1700 ± 40 |
| 100.0 | 2690 ± 70 | 4100 ± 13 |

In conclusion, we have demonstrated that TPs, presumably via the activation of protein kinase C, can potentiate cAMP and secretory responses to hormonal stimulation in AP cells. The ability of TPs to amplify the response to hormones as well as forskolin suggests a site of TP action at the regulatory and/or catalytic subunits of the adenylate cyclase holoenzyme. (RCDA1K04NS00601, AM32632, NS18409, AM22125, ACS149B)

315.11 cAMP-DEPENDENT PROTEIN KINASE ACTIVITY AND PROTEIN PHOSPHORYLATION IN AtT-20 CELLS. G. Rougon*, J. Barbet*, H.U. Affolter* and T. Reisine. (SPON: J. Axelrod). Lab. of Cell Biology, National Institute of Mental Health and Lab. of Mathematical Biology, National Cancer Institute, Bethesda MD 20205.

The AtT-20/D16-16 tumor cell line is derived from the mouse anterior pituitary and is capable of synthesizing and secreting adrenocorticotropin (ACTH). Both of these functions are stimulated by a variety of physiological and pharmacological agents. In this study, we investigated the possible role of cAMP-dependent protein kinase as well as other kinases in the regulation of ACTH formation and release. AtT-20 cells were preincubated with $^{32}PO_4^{3-}$ for 3 to 4 hr at 37°C and then stimulated for 10 min by adding to the radioactive medium forskolin (an activator of adenylate cyclase) or phorbol ester (a stimulator of protein kinase C). After lysis of the cells and subcellular fractionation, the cytoplasmic, nuclear and membrane fractions were analyzed by single and two-dimensional gel electrophoresis. Forskolin increased the phosphorylation of several proteins among which the most affected were three at 70-75 Kdaltons (pI≈ 4.5, 6 and 7), one at 40 Kdaltons (pI≈ 5) and two at 34 Kdaltons (pI≈ 4.5 and 6.5) in the cytoplasm, one at 44 Kdaltons (pI≈ 8) and one at 28 Kdaltons (pI≈ 7.5) in the membrane, and one at 75 Kdaltons (pI≈ 7.5) and one at 22 Kdaltons (pI≈ 9) in the nucleus. The protein phosphorylation induced by forskolin was dramatically reduced by the heat-resistant inhibitor of cAMP-dependent protein kinase (Walsh's inhibitor) delivered intracellularly by targeted liposomes. Like forskolin, phorbol esters also increased the phosphorylation of many proteins but appeared to specifically induce the phosphorylation of a protein of ≈ 20 Kdaltons (pI 6-7) in the cytoplasmic fraction. Thus, both cAMP-dependent protein kinase and protein kinase C regulate the phosphorylation of different as well as similar cellular proteins. The role of these phosphorylation events in the control of ACTH synthesis and release by physiological stimuli is presently under study.

315.12 EFFECT OF ANGIOTENSIN II ON ADENYLATE CYCLASE ACTIVITY IN NEUROBLASTOMA X GLIOMA HYBRID CELLS. J.E. Watkins* and J.A. Weyhenmeyer (SPON: C. Hockman). College of Medicine, University of Illinois, Urbana, IL 61801.

Physiological and pharmacological studies have suggested that angiotensin II (ANG II) plays a role in the neuromodulation of blood pressure, fluid intake, hormone release and memory. Although the existence of specific high affinity ANG II binding sites in brain has been well documented, there is a general paucity of information regarding the cellular (physiological) effect of ANG II ligand/receptor interaction. Gilbert et al. (Biochem. Pharm. 33: 2527, 1984) have reported that angiotensin I, II, and III stimulate a calcium-dependent increase of cGMP in murine neuroblastoma cells (N1E-115). We have recently demonstrated that a neuroblastoma x glioma hybrid cell line, NG108-15, contains high affinity ANG II binding sites that have similar kinetic characteristics to ANG II receptors in mammalian brain (Brain Res. Bull., in press, 1985). The purpose of this study was to examine the effect of ANG II/ANG II receptor interaction on adenylate cyclase activity in the NG108-15 hybrid cells.

Neuroblastoma x glioma hybrid cells were grown to confluency in Falcon tissue culture plates containing 50 ml of Dulbecco's Modified Eagles medium (DMEM) with 10% fetal calf serum, under conditions of 90% air and 10% $CO_2$ at 37° C in a humidified atmosphere. The cells were challenged with 25 mM ANG II in DMEM containing 100 mM 3-isobutyl-5-methylxanthine (IBMX) or DMEM/IBMX alone (control). Triplicates of ANG II-stimulated and control samples were taken between 10 and 110 sec at 20 sec intervals, and prepared for analysis according to the method of Fletcher et al. (BBRC 70:1297, 1976). The resulting aliquots of cell lysates were analyzed by high performance liquid chromatography using a Servachrome Si100:polyol:DEAE column with a mobile phase of 200 mM $NaH_2PO_3$. Standard cAMP, ANG II-stimulated and control samples were injected, monitored at 254 nm, and the retention time and plate heights recorded. The quantitative amounts of cAMP were determined by plotting plate height vs injection quantity of the cAMP standard using linear regression analysis. Our results demonstrate a significant time-dependent increase in cAMP levels of ANG II-stimulated cells as compared to controls. At 50 and 110 sec after ANG II-stimulation, cAMP levels were 35% and 300% higher that control values, respectively. These data suggest that ANG II/ANG II receptor interaction stimulates adenylate cyclase activity in brain cells, and provide additional support for the proposed transmitter/modulator role for ANG II in CNS tissues.

315.13 INTRACELLULAR INJECTION OF cGMP-DEPENDENT PROTEIN KINASE RESULTS IN INCREASED INPUT RESISTANCE IN NEURONS OF THE MAMMALIAN MOTOR CORTEX. T. Bartfai*, C.D. Woody, E. Gruen*, A. Nairn* and P. Greengard (SPON: D. Birt). UCLA Medical Center, Los Angeles, CA 90024, and The Rockefeller University, New York, NY 10021.

Intracellular pressure injection of purified, cGMP-dependent protein kinase into neurons of the precruciate cortex of awake cats caused increases in the input resistances (Rm) of 20 out of 26 injected cells, measured with 1nA, 40ms, rectangular, bridge balanced, hyperpolarizing and depolarizing pulses. The mean input resistance increased within seconds (as rapidly as measurements could be made) after injection from 6.4 ± 1.1 (S.E.M.) Mohms to 11.2 ± 2.1 Mohms and remained elevated for two minutes or longer. In these experiments the cGMP-dependent protein kinase was incubated with 10 micromolar cyclic GMP 30 min prior to filling the electrodes. Pressure injection of the cGMP-dependent protein kinase without preincubation with cGMP in 17 other cells caused smaller increases in Rm that were slower in onset, reaching a maximum value 60-90 seconds after injection. Only one of 26 "control-cells" injected with heat inactivated cGMP-dependent protein kinase, with (n=8) or without (n=18) pre-incubation with 10 micromolar cGMP, showed increased input resistance; all the others showed no change or small decreases in Rm over the 2 min period of observation. Up to sixty-five percent of cells of this same cortical area given extracellular application of acetylcholine or intracellular application of 1 mM cGMP in earlier studies showed increases in input resistance of a magnitude comparable to that observed on injection of the activated, cGMP-dependent protein kinase. The results indicate that intracellular injection of the cGMP-dependent protein kinase into neurons of the precruciate cortex of the awake cat can mimic the actions of extracellularly applied acetylcholine and intracellularly applied cGMP.

315.14 ACTIVATION OF ADENYLATE CYCLASE IN CULTURED MOUSE DORSAL ROOT GANGLION NEURONS; INVOLVEMENT OF POTASSIUM CONDUCTANCE: D.S.Grega & R.L.Macdonald, Dept. of Neurol, Univ. of Mich., Ann Arbor, MI, 48109.

Modulation of neuronal activity in some vertebrate and invertebrate systems is the result of alterations in the cyclic AMP (cAMP)-second messenger system. Adenylate cyclase (AC) is pivotal for its activation. To stimulate this system at various levels, we are using a number of compounds to alter the activity and excitability of cultured mouse dorsal root ganglion neurons (DRG).

Cell culture and intracellular recording techniques are as previously described (Werz & Macdonald, J.PET 227:394, 1983). Some neurons are impaled or reimpaled (after potassium acetate impalement) with a micropipette filled with cesium acetate (CsAc) and cesium, a potassium channel blocker, is injected intracellularly. Drugs are applied to single neurons by pressure ejection from micropipettes with tip diameters of 2-5 μm. Stock drug solutions are made in saline except for forskolin (FOR) and prostaglandin $E_1$ ($PGE_1$) which are dissolved in DMSO. DMSO control in saline does not significantly alter action potential duration (APD).

Forskolin (FOR), an adenylate cyclase (AC) activator, initially prolongs action potential duration (APD) with a decrease in after hyperpolarization (AHP) and subsequently shortens (APD) with an increased AHP with 1-2 sec puffs in a concentration dependent fashion from 100μM with 361% prolongation with 55.5% shortening to 1 μM with 16.2% prolongation with 4.7% shortening. FOR does not produce a significant change in resting membrane potential (-60mV) conductance. Cholera toxin (CT, 10 μg/ml), which activates AC by binding to the $G_s$ protein and $PGE_1$ (1 μM) which activates AC via the membrane surface receptor, mimic the FOR effect of prolongation and shortening. APD prolongation persists with longer (sec to min) application of FOR or CT. Analogs of cAMP, dibutyryl cAMP (100 μM) and 8-Bromo-cAMP (1 mM), which mimic the end product of increased AC activity, produce APD prolongation and shortening. 2', 5'-dideoxyadenosine (DDA), an AC inhibitor, partially inhibited the FOR-induced APD prolongation (38%) with mixed results on the subsequent shortening. Intracellular injection of Cs blocked the FOR induced APD prolongation (96%) with predominantly a reduction in the subsequent APD shortening (91%) indicating the involvement of a potassium conductance.

The data suggest that the APD prolongation is due to an immediate increase in AC and cAMP which eliminates a voltage or calcium-dependent potassium conductance. The APD shortening appears to be either a reaction to the prolongation or a more temporally distant result of increased AC/cAMP. Single electrode voltage clamp and patch clamp techniques will be employed to further elucidate this biphasic phenomenon.

315.15 UPTAKE-DEPENDENT SEROTONERGIC STIMULATION OF cGMP LEVELS IN HUMAN PLATELETS DURING ELECTROCONVULSIVE TREATMENT. M.-L. Tjornhammar*, B. Martenson*, M. Asberg* and T. Bartfai* (SPON: B. Howard). Department of Biochemistry, Arrheniuslaboratory, 10609 Stockholm and Department of Psychiatry, Karolinska Hospital, 10401 Stockholm.

Elevation of cGMP levels in human platelets by serotonin has earlier been reported by several laboratories but the molecular mechanism of this response was not known. Unlike other neurotransmitter mediated increases in cGMP levels, this process was not dependent on the presence of extracellular Ca-ions. It did not involve the type 1 and 2 serotonin receptors on platelets, but it could be blocked by the serotonin uptake inhibitors, imipramine and alaproclate. Concentration dependent stimulation of cGMP levels by serotonin was only observed in the presence of $Na^+$ and $Cl^-$ ions and at temperatures above 18°C, indicating the requirement for an active 5-HT carrier. Thus, measurements of the 7-10 fold serotonin mediated increases in cGMP levels may serve as sensitive indicators of the changes in the serotonin uptake system that has intensively been studied in depression.

The high sensitivity of the method permits use of the small volume blood samples that were drawn before, during and after consecutive sessions of electroconvulsive treatment given to depressed patients. (Supported by the Swedish Medical Research Council and NIMH grants.)

315.16 EFFECTS OF MODIFICATIONS OF THE 4-(3,4-DIHYDROXYPHENYL)-1,2,3,4-TETRAHYDROISOQUINOLINE STRUCTURE ON DOPAMINE SENSITIVE RAT RETINAL ADENYLATE CYCLASE ACTIVITY. L. L. Truex, M. M. Foreman, R. M. Riggs*, and D. E. Nichols. The Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285 and Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.

The effects of dopamine on various physiological and biochemical processes are attributed to the stimulation of either a $D_1$ or $D_2$ receptor. One biochemical index of the $D_1$ receptor response is the amplification of dopamine-sensitive adenylate cyclase activity. The purpose of these studies was to examine the effects of modifications of the 4-(3,4-dihydroxy-phenyl)-1,2,3,4-tetrahydroisoquinoline structure on rat retinal adenylate cyclase activity. Rat retinas were homogenized in 150 vol/wt of 2.0 mM Tris · HCl pH 7.4 with 2 mM EGTA using a teflon-glass homogenizer. Each reaction mixture contained the following final concentrations in a volume of 0.2 ml:2mM $MgSO_4 \cdot 7\ H_2O$, 0.5 mM EGTA, 1 mM IBMX, 0.01 mM GTP, 80 mM Tris · HCl (pH 7.4), 0.5 mM ATP with approximately 5 x $10^6$ DPM of $^{32}$P-ATP and 20-30 µg retinal homogenate protein. Following an incubation of 20 min at 30°C, the reaction was terminated by adding 200 µl of a solution containing 1% SDS, 20 mM ATP, 0.7 mM cyclic AMP with 1.0 x $10^4$ DPM $^3$H-cyclic AMP in 80 mM Tris · HCl pH 7.4 and heating to 85°C for 2 min. Cyclic AMP was isolated from the mixture using the column chromatographic technique of Salomon (Adv. Cyc. Nuc. Res., 10:35-55, 1979). In these studies, the major structural modifications that were evaluated included alteration of the N-side chain length, substitution of a thiophene for the isoquinoline and removal of one hydroxyl group of the catechol ring. Elongation of the N-side chain length resulted in a progressive decline in $D_1$ agonist activity with H > Me > Et > Pr. The substitution of a thiophene for the isoquinoline resulted in an approximate 10-fold increase in $D_1$ agonist activity, indicating that the type of ring structure associated with the phenethylamine pharmacophore can influence the expression of $D_1$ agonist activity. The modification of the catechol ring to a monohydroxyphenyl analog resulted in greatly diminished $D_1$ agonist activity indicating an absolute requirement of a catechol structure for maximal activity. Finally, the $D_1$ agonist effects of the N-unsubstituted dihydroxyphenyl analogs were confirmed by the concentration dependent attenuation of the adenylate cyclase response by SCH23390, a selective $D_1$ antagonist.

## MOLECULAR BIOLOGY OF GENE EXPRESSION AND NUCLEIC ACIDS IV

316.1 THE DISTRIBUTION OF TYROSINE HYDROXYLASE HOMOLOGOUS RNA IN THE CENTRAL NERVOUS SYSTEM OF THE RAT. T.J.Mahalik, N. Chaudhari, W.E. Hahn and T.E. Finger. Dept. of Anatomy, U. of Colorado Med. School, Denver, CO.

Tyrosine hydroxylase (TH) is the rate limiting enzyme in the catecholamine biosynthetic pathway. In rat PC8b cells, induction of TH enzyme activity by 8-bromo cAMP and dexamethasone is directly related to an increase in levels of TH-homologous mRNA (Lewis et al. J. Biol. Chem. 258:14632:83). Although the TH gene appears to be regulated at the transcriptional level in PC cells, very little is known about the manner in which TH expression is controlled in the central nervous system (CNS). The purpose of our study was to map the distribution of TH-homologous sequences in the rat brain at the regional and single cell level in a series of dot blot and in situ hybridization experiments.

For dot blots, dissected regions of the CNS from adult Sprague-Dawley rats were homogenized and were blotted onto nitrocellulose with sodium iodide (Bresser et al. DNA 2:243:83). Slide-mounted tissue sections were prepared for in situ hybridization by standard methods. RNA transcripts of a TH cDNA, containing both coding and non-coding TH-homologous sequences (Lewis et al. J.Biol. Chem. 258:14632:83), were synthesized in vitro with SP6 polymerase, and were used as probes in hybridization experiments.

We observed TH homologous RNAs in the olfactory bulb and substantia nigra. In addition, we observed positive hybridization signals in the cerebral cortex, the cerebellar cortex, and the caudate nucleus; these areas normally do not contain catecholaminergic cell bodies. In situ hybridization revealed the presence of TH-homologous sequences in the cortex and in the granule cell layer of the hippocampus. Control hybridizations with pBR322 transcripts or with sense transcipts of the TH cDNA resulted in only background labeling in both dot blot and in situ hybridization experiments.

The results of our experiments suggest that TH-homologous RNAs are present in CNS regions which do not contain catecholaminergic cell bodies. Our findings may mean that the TH gene is under loose transcriptional control, or that numerous transcripts in the CNS contain a sequence that is homologous to a portion of TH mRNA. We are currently carrying out experiments to resolve the issues raised by our initial observations.

This work was supported by NIH grants NS00772, NS09199 and NS10813.

316.2 SEQUENCE HOMOLOGY BETWEEN TYROSINE HYDROXYLASE mRNA AND A RAT ADRENAL cDNA. S. Edmonds* and K.L. O'Malley* (Sponsor: K. Isenberg), Department Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

As part of our ongoing project to characterize catecholamine biosynthetic enzymes, we have isolated a cDNA clone from a rat adrenal medulla library by cross hybridization with a rat tyrosine hydroxylase (TH) clone. The TH clone was isolated from the rat pheochromocytoma cell line, PC 12. Nitrocellulose filters of both adrenal and PC 12 size fractionated mRNAs were hybridized with the adrenal clone. A major band of 5.6 kb was detected in both RNA species, as well as a band of 1900 bp. The 1900 bp band co-migrated with TH mRNA as determined by hybridization with a nick translated TH cDNA. Southern blot analysis revealed several hybridizing bands homologous to the adrenal clone. A 9.5 kb rat genomic band hybridizing intensely with the adrenal cDNA also hybridized with the rat TH probe. These results demonstrate that the adrenal clone shares sequences in common with the TH gene and/or is closely linked to it in the genome. Hybrid selected mRNA translation products are immunoprecipitated with both dopamine beta-hydroxylase and phenylethanolamine N-methyltransferase antisera suggesting this clone may code for another catecholamine pathway enzyme.

316.3 TISSUE SPECIFIC EXPRESSION OF TYROSINE HYDROXYLASE RNA. E.J. Lewis, M.L. Delano*, W.R. Aldrich*. Neuroscience Program, Tufts Univ. Med. Sch., Boston, MA 02115

Tyrosine hydroxylase (TH), the rate limiting enzyme for synthesis of catecholamines, has a tissue specific distribution for its synthesis. TH is synthesized in cell bodies present in the adrenal medulla, the sympathetic ganglia and certain nuclei of the brain. To determine whether the pattern of distribution of TH RNA is the same as that of TH-synthesizing cell bodies, RNA was extracted from various tissues in rat and analyzed by Northern blot. RNA was extracted from the midbrain tegmentum and olfactory bulb, both of which contain dopaminergic neurons and from the midbrain tectum, the cerebellum and the frontal lobe, regions that do not contain catecholaminergic cell bodies. The probe used contained 280 bases of $^{32}$P-labelled antisense TH RNA, corresponding to a translated portion of mRNA$^{TH}$. This probe was derived from the cDNA clone pTH.4 (J. Biol. Chem. 258:14632, 1983) which was subcloned into the SP65 vector. Following hybridization of Northern blots, a band of 1800-1900 nucleotides was observed in total RNA extracted from the adrenal gland, the superior cervical ganglia, the midbrain tegmentum and the olfactory bulb. No qualitative differences were observed in the migration of the putative mRNA$^{TH}$ from these tissues. There was no band corresponding to mRNA$^{TH}$ in RNA extracted from frontal lobe, the midbrain tectum or the cerebellum. In all areas of the brain tested, hybridization was also observed to a series of distinct bands of molecular weights higher than that of mRNA$^{TH}$. The migration of these RNAs was apparently identical for RNA from all brain areas and the relative intensity of the bands (per ug RNA) was greatest in the cerebellum. These RNAs were far less abundant in RNA extracted from liver or kidney, although three of these RNAs were prominent in heart RNA. These bands of hybridization persisted despite stringent washes of filters in 7.5 mM NaCl at 63$^{o}$C. When RNAs were probed with an anitsense TH RNA transcript containing only 110 bases of the original 280 base probe, hybridization was confined to the 1800-1900 base mRNA$^{TH}$, observed only in RNA extracted from tissues which contain TH cell bodies. It is thus unlikely that the high molecular weight cross-hybridizing RNA species represent partially processed precursors to mRNA$^{TH}$, because they do not appear when the 110 base probe is used.

The results of these experiments suggest that TH RNA is specifically localized to areas which synthesize TH protein. Although the specific nature of cross-hybridization of the TH probe to other RNAs is not known, it is likely that these bands represent RNAs containing a short region of sequence homology to mRNA$^{TH}$, but may be functionally unrelated. Caution should be taken in interpretation of experimental results when pTH.4 is utilized as a probe for brain RNA that is not separated by size, as in dot blot or in situ hybridization. (Supported by NIH grant GM3991)

316.4 REGULATION OF TYROSINE HYDROXYLASE BY NERVE GROWTH FACTOR AND CELL-CELL CONTACT IN PRIMARY CULTURES OF BOVINE ADRENAL CHROMAFFIN CELLS. S. Saadat*, J. Mallet and H. Thoenen (SPON: H. Thoenen) Dept. of Neurochemistry, Max-Planck-Institute for Psychiatry, D-8033 Martinsried, FRG.

We have previously reported that the specific activity of tyrosine hydroxylase (TH) was increased by nerve growth factor (NGF) (Acheson, A.L., Naujoks, K. and Thoenen, H. (1984) J. Neurosci. 4, 1771-1780) and cell-cell contact (Acheson, A.L. and Thoenen, H. (1983) J. Cell Biol. 97, 925-928) in bovine adrenal chromaffin cultures. The increase of TH by cell contact was inhibited by α-amanitin, whereas the increase of TH by NGF was not inhibited. Cycloheximide inhibited the increase of TH in both cases. This suggested that TH synthesis was induced at the transcriptional level by cell contact and at a posttranscriptional level by NGF.

To study the induction in more detail at the mRNA level, a cDNA probe specific for bovine TH was prepared. Total RNA was isolated from chromaffin cultures, separated by agarose gel electrophoresis and the RNA was blotted onto nitrocellulose. Hybridization with nick-translated TH cDNA revealed a band with a size of 1.8 kb. Quantitative changes in the TH mRNA levels in chromaffin cultures are investigated after the addition of NGF, or by increasing the cell density of chromaffin cells to 300,000 cells/cm$^2$ by replating cells that were kept at a density of 30,000 cells/cm$^2$.

316.5 shi$^{mld}$*jp$^{msd}$ and shi*jp DOUBLE MUTANT MICE : UNEXPECTED INTERGENIC INTERACTIONS OF ALLELIC HYPOMYELINATION MUTATIONS. S. Billings-Gagliardi, M.E. Pomeroy*, and M.K. Wolf. Department of Anatomy, University of Massachusetts Medical School, Worcester, MA 01605.

Mutations at the shi (chromosome 18) and jp (X-chromosome) loci each produce CNS hypomyelination with complex, but clearly distinguishable, biochemical and morphological phenotypes. Double mutant mice which carry both shi and jp mutations (shi*jp) have a phenotype with features of each single mutant disease, but in milder form. The shi mutation has a presumed allele, shi$^{mld}$. On the B6C3 background, shi$^{mld}$ phenotypically resembles shi but has more major dense line in its myelin. The jp mutation also has a presumed allele, jp$^{msd}$, which resembles jp but has more numerous myelin sheaths. We have sought more information about these two genetic loci and their interactions by comparing the morphological phenotype of shi$^{mld}$*jp$^{msd}$ double mutant mice with the phenotype of shi*jp. Three successive generations of crossing proven, genetically marked B6C3 Tajp$^{msd}$/+ females to B6C3 shi$^{mld}$/shi$^{mld}$ males produced marked, doubly-affected B6C3 shi$^{mld}$/shi$^{mld}$*Tajp$^{msd}$/Y males as well as crossover B6C3 shi$^{mld}$/shi$^{mld}$*Ta+/Y controls. In the putative double mutant shi$^{mld}$*jp$^{msd}$ mice, myelin was reduced in amount in the cerebellum, optic nerve, and forebrain at postnatal days 21-24 relative to either shi$^{mld}$ or jp$^{msd}$. The few sheaths present were thinner than are normally found in jp$^{msd}$. As in shi$^{mld}$, myelin surrounded only part of the axon circumference in many cases; sheaths included cytoplasm between lamellae, and had an abnormally dense intraperiod line. All sheaths examined thus far have lacked any major dense line. By contrast, B6C3 shi$^{mld}$ CNS myelin clearly shows some major dense line formation at this age. Oligodendrocytes were reduced in number relative to shi$^{mld}$, and the parallel arrays of oligodendrocyte microprocesses so prominent in shi$^{mld}$ were not obvious in the available sample. The lipid-filled cells characteristic of jp$^{msd}$ white matter were numerous. Thus the jp$^{msd}$ mutation makes some, although not all morphological features of the shi$^{mld}$ phenotype more severe, and the shi$^{mld}$ mutation tends to behave similarly toward the jp$^{msd}$ phenotype. The morphological phenotype of B6C3 shi$^{mld}$*jp$^{msd}$ double mutant animals therefore suggests an intergenic interaction which is either additive or synergistic depending upon the characteristics considered. This conclusion differs sharply from results obtained in B6C3 shi*jp mice, in which the two mutant genes exert partial reciprocal suppression.
Supported by NIH grant NS11425 (Javits Award).

316.6 MOLECULAR BASIS FOR HETEROSIS FOR BRAIN MYELIN CONTENT IN MICE. R. Miskimins*, H. Ebato*. T.N. Seyfried and R.K. Yu. Dept. of Neurology, Yale University School of Medicine, New Haven, CT 06510

We have shown previously that brain myelin content was significantly higher in the $F_1$ hybrid (B6 x D2) than in either C57BL/6J (B6) or DBA/2J (D2) parental strain of mice (Ebato, H., Seyfried, T.N. and Yu, R.K. J. Neurochem., 40:440, 1983). This represents a classical example of heterosis, that is, the $F_1$ hybrid possesses a trait in excess of either parent. This heterosis for myelin content involved several parameters including amount of myelin isolated, concentrations of brain myelin protein, cerebroside, $G_{M1}$ ganglioside and the activities of CNPase, 5'-nucleotidase and carbonic anhydrase. In order to determine the molecular level at which this heterotic effect was regulated we performed the following experiments.

Poly(A)$^+$ messenger RNA (mRNA) was isolated from the brains of B6, D2 and $F_1$ (B6 x D2) hybrid mice at 16-17 days of age. The mRNA was translated in vitro in a rabbit reticulocyte lysate system. A significant heterotic effect was seen for the production of myelin basic protein (MBP) by the mRNA from the brains of the $F_1$ hybrid mice as compared with MBP production of both parental strains. The relative distribution of the MBP's produced was the same for all three strains. The amounts of total polysomal RNA, recoverable poly(A)$^+$ RNA and the rate of incorporation of labelled amino acid were not significantly different among the three strains of mice. Northern blot analysis of polysomal poly(A)$^+$ RNA with a cDNA probe for MBP showed that the amount of mRNA coding for MBP present in the polysomes was significantly greater in the $F_1$ mice. This analysis showed a single band in all three strains. Northern blot analysis of poly(A)$^+$ RNA from the total brain again showed $F_1$ to contain the greatest amount of RNA coding for MBP. The blots from this RNA showed a second band of greater length that was present in a much smaller amount. Taken together we believe these results imply that heterosis for brain myelin content in the $F_1$ hybrid mice may be regulated at the transcriptional level.

316.7 **ISOLATION OF A POSSIBLE NEURONAL NICOTINIC ACHR ALPHA SUBUNIT cDNA CLONE FROM THE RAT PC12 CELL LINE**

by Jim Boulter, Gary Martin, Karen Evans, Dan Goldman, Pam Mason Doug Treco, Steve Heinemann and Jim Patrick. Molecular Neurobiology Laboratory, The Salk Institute, San Diego, CA 92138

Advances in understanding the molecular biology of the muscle nicotinic acetylcholine receptor (nAChR) have been facilitated by recombinant DNA methodologies. We employed a similar approach to the study of the nerve nicotinic acetylcholine receptor by isolating cDNA clones coding for this protein. Using mouse muscle nAChR cDNA probes and Northern blot hybridization analysis, we have shown that the mouse α-subunit cDNA hybridizes to mRNA sequences in non-muscle tissue such as brain, adrenal medulla, and the clonal rat sympathetic nerve cell line PC12. We constructed a cDNA library using mRNA from PC12 cells and $\lambda gt_{10}$ as vector. The library was screened with the mouse nAChR α-subunit cDNA and three independent, overlaping clones were isolated from the 950,000 plaques examined. The longest of the three clones, λPC12α48, contains insert DNA of approximately 2100 base pairs. Partial deduced amino acid sequence of this clone reveals homology with cloned nAChR α-subunits from calf, human, mouse and Torpedo of approximately 50% while, in the region compared, the calf, human and mouse muscle α-subunit homology is approximately 95%. A comparison of the deduced amino acid sequence of the PC12α48 clone with similar regions in mouse γ, δ and calf β cDNA clones yields homologies of 21%, 30% and 33% respectively. S1 nuclease analysis of heteroduplexes formed between PC12α48 cDNA and mRNA isolated from PC12 cells or denervated rat diaphragm show that the PC12α48 cDNA protects mRNA species from PC12 (non-muscle nAChR) but not from rat diaphragm (muscle nAChR). Radiolabeled PC12α48 cDNA hybridizes to poly $(A)^+$ selected RNA from calf adrenal medulla- but not cortex, and to rat adrenal gland, rat hypothalamus and, at lower stringency, rat cerebellum and hippocampus. Finally, Southern blot analyses of mouse genomic DNA demonstrates that the PC12α48 cDNA clone is the product of a gene distinct from the gene encoding the muscle nAChR α-subunit.

316.8 MOLECULAR CLONING OF AN OLFACTORY NEURON SPECIFIC PROTEIN. K.E. Rogers*, M. Grillo*, M. Poonian*, U. Gubler* and F. L. Margolis. Roche Inst. Molec. Biol. and Dept. Molecular Genetics, Roche Res. Ctr., Nutley, N. J. 07110.

Olfactory marker protein (OMP) is a neuron-specific protein of Mr=18,500, located exclusively in olfactory chemoreceptor cells. It is synthesized only by mature neurons and not by their progenitor cells and is thus developmentally regulated. Although the biochemical properties of OMP have been extensively characterized, its function remains unknown. Therefore, we have recently begun to examine OMP at a more fundamental molecular level.

Prior to cloning OMP-mRNA was characterized in this laboratory. Using *in vitro* translation and immunoprecipitation, we demonstrated that OMP is synthesized directly from rat olfactory mucosal poly(A)$^+$RNA without the formation of a larger polypeptide precursor. In addition, it was demonstrated that the size of OMP mRNA is 2500-3300 nucleotides. This exceeds the minimum coding requirement for OMP(500 bases) by at least a factor of five. Using sucrose gradient fractionated OMP-mRNA as a template, double stranded complementary DNA (cDNA) was synthesized. The cDNA was introduced into the *Eco RV* site of the plasmid pMG 5. *E. coli* DH1 was transformed with the insert-containing plasmids, creating a partial olfactory mucosal cDNA library. Colonies were screened for OMP inserts using a synthetic heptadecameric oligodeoxynucleotide probe with a degeneracy of sixteen which had been predicted from the known amino acid sequence of OMP. Previously, this probe had been shown by Northern blot analysis to hybridize exclusively to mRNA containing the OMP message. Three OMP-positive colonies were detected out of 10,000 colonies originally screened. Restriction analysis of the plasmids contained in these clones with *Eco* R1 and *Hinc* II endonucleases demonstrated that the insert sizes were 2100-2300 nucleotides. Excision of the inserts with *Bam HI* indicated the presence of an additional *Bam* H1 restriction site in the sequences of all three clones Southern analysis of the *Bam HI* restriction fragments with the synthetic oligodeoxynucleotide probe indicated that the probe hybridized only to the larger 1350 nucleotide fragment. Translation of hybrid selected olfactory mucosal poly(A)$^+$RNA followed by immunoprecipitation of OMP was used as an additional confirmation of the identity of these clones. The linearized insert-containing plasmids, but not unmodified pMG 5 or pBR 322 plasmids, were able to select translatable OMP-mRNA. The nucleotide sequences of these OMP cDNA clones are now being determined. The availability of these clones should facilitate our attempts to understand the mechanisms involved in regulating the cell specific expression of this unique protein.

316.9 **ISOLATION OF cDNA CLONES FOR VASOPRESSIN AND OXYTOCIN FROM AN EXPRESSION LIBRARY OF RAT HYPOTHALOAMIC POLY(A)-RNA.** Norbert E. Kremer and Jeffrey F. McKelvy, Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

In order to study the regulation of gene expression of the neurohypophysial peptides, vasopressin and oxytocin, it is desirable to have hybridization probes of a variety of sizes and sequence specificities. We have isolated cloned cDNAs for the precursors of these peptides from the rat, since in this animal both the neuroendocrine and CNS functions of these peptides may be studied. A cDNA expression library in the phage vector lambda gt11 was made from rat hypothalamic poly(A) RNA and kindly provided by Drs. R. Goodman and G. Mandel. Double-stranded cDNA was made through the use of RNAse H and ligated to the vector by means of EcoRI linkers; before amplification the library contained an estimated two million independent clones.

Clones were initially selected for expression of neurophysin immunoreactivity using the anti-rat neurophysin antibody RN-4 of Dr. A. Robinson and goat anti-rabbit/alkaline phosphatase conjugate. Positives in the initial screening arose at a rate of about one per twenty thousand plaques. Clones were plaque-purified and then further screened with monoclonal antibodies to rat vasopressin and oxytocin precursors (kindly provided by Dr. H. Gainer). These monoclonal antibodies allowed classification of the expression-positivie clones as vasopressin-like or oxytocin-like. Further characterization of the cDNA inserts is being made using synthetic oligonucleotide probes made according to the cDNA sequence predicted from the published rat genomic sequences.

When the cDNAs so derived are labelled with $^{32}P$, and used to probe RNA blots of rat hypothalamic RNA, RNA species of molecular weights appropriate for vasopressin and oxytocin may be identified.

These clones will be useful for the study of the physiological regulation of vasopressin and oxytocin. Furthermore, the precursor genes, or parts thereof, when cloned into expression vectors, may be used to program the synthesis of large amounts of defined portions of the precursors. These synthetic precursor molecules will be useful in the study of neuropeptide processing enzymes in vivo and in vitro.

316.10 ALKALINE RIBONUCLEASE IS PRESENT IN AXOPLASM OF THE GIANT AXON OF THE SQUID. N.A. Ingoglia, Dept. of Physiology, New Jersey Medical School, Newark, NJ 07103

Alkaline ribonuclease is a cytosolic enzyme capable of hydrolyzing cellular RNA. Its activity has been shown to be inhibited by a 50-60 kD protein which is linked to it by sulfhydryl bonds. The removal of this inhibitory protein by sulfhydryl blocking agents results in activation of the enzyme, and subsequent hydrolysis of RNA. It appears that this enzyme plays a role in the control of protein synthesis by regulating the availability of RNA. Alkaline ribonuclease is present in human brains and the activity of the enzyme inhibitor complex has recently been shown to be altered in patients who have succumbed to Alzheimer's disease. (Sajdel-Sulkowska and Marotta, Science 225:947, 1984).

In the present experiments we have investigated the possibility that the enzyme is present in axoplasm. Since axonal RNA is at least 85% transfer RNA (Lasek et al., Nature 244:118, 1973) and transfer RNA in axons appears to act as an amino acid donor in posttranslational protein modification (Ingoglia et al., J. Neurosci. 3, 12:2563, 1983), the implication of finding alkaline ribonuclease in axoplasm would be that its function might be to regulate protein modification in addition to, or rather than, synthesis of protein. Axoplasm was obtained from the giant axon of the squid and aliquots of the 80kxg supernatant were incubated with or without p-chloromercuribenzoate (PCMB), a sulfhydryl bridge blocking agent, and $^3H$-RNA which served as substrate. Alkaline ribonuclease activity was monitored by measuring the hydrolysis (liberation into a TCA soluble fraction) of $^3H$-RNA. Reactions were run for 1 hr at 37°C and compared with 0°C, unreacted controls or controls incubated without biological material. Alkaline ribonuclease activity (without PCMB) was 4 to 5 times greater than 0°C controls and twice that of similar reactions run in the 80kxg supernatant fractions of rat brain homogenates. The data suggest the presence of active alkaline ribonuclease in squid axoplasm. While the addition of PCMB caused a five fold increase in alkaline ribonuclease activity in rat brain, its addition to axoplasm caused a 55% decrease in alkaline ribonuclease activity.

The results indicate that axoplasm contains alkaline ribonuclease which may play a role in the regulation of tRNA dependent protein modification by amino acids, but contrary to findings in higher vetrebrates, its activity does not appear to be regulated by a protein inhibitor. Supported by NINCDS grant NS19148 from NIH.

316.11 POSTTRANSLATIONAL INCORPORATION OF ARGININE AND LYSINE INTO RAT BRAIN SOLUBLE PROTEINS IN VITRO. G. Chakraborty* and N.A. Ingoglia. Department of Physiology and Neuroscience, New Jersey Medical School, Newark, NJ 07103

The posttranslational modification (PTM) of rat brain proteins has been reported to involve a tRNA dependent addition of Arg but not Lys or other amino acids to endogenous substrates (Barra et al., 1973, J. Neurochem. 20, 97). These experiments required the removal of molecules of less than 5kD for expression of the reaction. In similar experiments (except that molecules of less than 125kD were removed), we have demonstrated the PTM of axonal proteins by Arg and Lys (as well as other amino acids) (Ingoglia et al, 1984, Advances in Neurochemistry 6, 119). In the present experiments we have investigated the possibility that by changing the molecular exclusion properties of a rat brain supernatant preparation, that not only Arg, but Lys could also be incorporated into rat brain proteins.

No significant incorporation of $^{3}$H-amino acids into proteins occured when the unfractionated soluble supernatant was incubated with $^{3}$H-amino acids and an appropriate reaction mixture. However, when the soluble supernatant was fractionated by Sephadex G25-40 chromatography, the void volume (containing molecules 5kD) was able to incorporate $^{3}$H-Arg (264.99 $\pm$ 40.82 DPM/ug Protein) but not $^{3}$H-Lys (2.15 $\pm$ 0.52 DPM/ug Protein) into endogenous proteins. These data confirm the findings of Barra et al (1973). When the soluble supernatant was fractionated by Sephacryl S-200 chromatography, comparable amounts of $^{3}$H-Arg were incorporated into proteins (172.13 $\pm$ 44.25 DPM/ug Protein) but $^{3}$H-Lys was now also incorporated into proteins (32.02 $\pm$ 10.93 DPM/ug Protein).

SDS-PAGE of $^{3}$H-Arg or $^{3}$H-Lys modified proteins revealed similar labelling patterns of proteins of approximately 70, 53, 38, 22 and 12-18kD. The addition of the inactive supernatant to the active G25-40 or S-200 void volume to a final concentration of 10% resulted in the inhibition of both reactions by 50% (Arg) or 85% (Lys).

The data suggest the presence of separate inhibitory substances in rat brain (for Arg 5kD; for Lys 125kD) which regulate their posttranslational incorporation into endogenous proteins. (Supported by NINCDS Grant NS-19148 from NIH.)

316.12 EXPRESSION OF GENES ENCODING TYPES I AND IV COLLAGEN DURING MYOGENESIS OF SKELETAL MUSCLE CELLS IN CULTURE. J.S. Rao,* W.J. Lindlbad,** and Barry W. Festoff Neurobiology Research Lab, VAMC, Kansas City, MO. and Dept. of Neurology, University of Kansas Medical Center, Kansas City, KS., ** Dept. of Surgery, Medical College of Virginia, Richmond VA. (SPON: R. Miller)

During myogenesis, skeletal muscle cells in culture produce collagen types I and IV. This was examined at the molecular level by cell-free translation and dot hybridization techniques. Total RNA was extracted from skeltal muscle cells (from day 3 myoblasts and day 10 myotubes) during myogenesis and translated in a cell-free translation system. The translation products were characterized on SDS-PAGE before and after collagenase digestion. In this manner, the translation of both procollagen types I and IV was demonstrated. To quantitate the amount of these procollagen types during myogenesis, extracted RNA was hybridized to the following cloned cDNA probes: P$\alpha$1R1 for pro-$\alpha$1 mRNA; P$\alpha$2R2, for pro-$\alpha$2(I) mRNA and pPE41 for pro$\alpha$1(IV) mRNA. When compared to myoblasts, myotube cultures had decreased levels of pro$\alpha$1(I) but increased pro$\alpha$2(I) as determined by solid support hybridization with P$\alpha$1R1 and P$\alpha$2R2 respectively. Myotube cultures also had increased levels of pro 1(IV) as determined by dot hybridization with pPE41. These results demonstrate that synthesis of interstitial collagen (type I) is decreased while synthesis of basement membrane collagen (type IV) is increased during myogenesis.

## ACETYLCHOLINE: RECEPTORS

317.1 PRESYNAPTIC CONTROL OF 3H-ACETYLCHOLINE (3H-ACH) RELEASE FROM CORTICAL SLICES OF YOUNG AND AGED FISHER 344 RATS. C. J. Spencer*, R. D. Schwarz and T. A. Pugsley*. (SPON: R. F. Bruns). Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

Considerable debate exists in the literature about the effects of aging on the function of central cholinergic neurons. There are conflicting reports on changes in the activity of both the synthetic and degradative enzymes for ACh, and on changes in both nerve terminal choline uptake and ACh release. In contrast, most studies have confirmed an age-related decrease in the number of muscarinic receptors while their affinity is not affected. The present study examines aspects of presynaptic control of $^{3}$H-ACh release from slices of cerebral cortex in young (3-6 mos) compared to aged (24-26 mos) male Fisher 344 rats.

The cortex was removed and cut into 0.3 x 0.3 mm slices. These were incubated in Krebs-Ringer Hepes buffered medium, pH 7.2 (KRH) with 0.01 $\mu$M $^{3}$H-choline for 15 min at 37$^{o}$ C. After washing, the slices were again incubated for 15 min in KRH medium with the addition of a depolarizing agent; muscarinic agonists or antagonists were added at this time. Release was terminated by cooling and rapid separation of slices from medium by centrifugation. $^{3}$H was determined in both fractions by scintillation spectrometry.

Spontaneous release of $^{3}$H was the same for both age groups. With increasing concentrations of $K^{+}$ (10-40 mM) or veratridine (0.1-100 $\mu$M) the release of $^{3}$H-ACh increased very similarly in both young and aged. Oxotremorine (0.01-100 $\mu$M) decreased $K^{+}$-stimulated $^{3}$H-ACh release in a concentration-dependent manner in both groups; this decrease was reversed by atropine. There was little variation between young rats in response to oxotremorine. In contrast the oxotremorine effect on the aged rats varied markedly from individual to individual. However, a comparison of the data pooled within each age group showed no difference between young and aged; a maximal decrease of 50% occurred at approximately 10 $\mu$M for both. Since presynaptic receptors may control $Ca^{++}$ entry, the effect of $Ca^{++}$ on $K^{+}$-stimulated $^{3}$H-ACh release was examined. The addition of increasing concentrations of $Ca^{++}$ (0.13-2.6 mM) resulted in increasing $K^{+}$-stimulated $^{3}$H-ACh release. Young animals showed less variation than aged animals yet the pooled results revealed no significant difference between the two age groups. In addition, choline acetyltransferase activity in the cortex of both young and aged rats is currently being examined.

In general, the presynaptic control of $^{3}$H-ACh release by muscarinic agonists and the utilization of extracellular $Ca^{++}$ appear not to be altered consistently by aging. There may indeed be an effect of age on mechanisms controlling ACh release, but it may be specific to each individual studied. Rodents, like humans, appear to age and acquire cholinergic deficits at different rates.

317.2 PHARMACOLOGY OF MUSCARINIC RECEPTORS CONTROLLING ACH RELEASE IN THE RAT IRIS. T. Mattio*, E. Giacobini and V. Hoban*. Department of Pharmacology, Southern Illinois University School of Medicine, Springfield, IL 62708 USA

The release of acetylcholine (ACh), both in central and peripheral nerve tissues, seems to be modulated by a presynaptic muscarinic receptor. In the albino rat iris, which contains a dense cholinergic plexus, we have demonstrated the presence of a muscarinic autoreceptor. The electrically stimulated release of ACh (50 Hz, 20 mA, 5 ms biphasic square wave) was increased in the presence of muscarinic antagonists. Pirenzepine increased ACh release in a dose dependent manner from $10^{-3}$ M (by 90%) to $10^{-7}$ M (by 27%). Scopolamine also showed a dose-dependent increase in ACh release. At $10^{-4}$ M and $10^{-5}$ M scopolamine increased ACh release by 88% and 41%, respectively. Atropine increased ACh release from $10^{-3}$ M (by 70%) to $10^{-7}$ M (by 55%). Oxotremorine decreased the stimulated release of ACh at $10^{-3}$ M and $10^{-5}$ M. Both pirenzepine and atropine antagonized this effect. 2-Aminopyridine, 3-aminopyridine and 3,4-diaminopyridine were without effect on ACh release, however, 4-aminopyridine increased ACh release by 55% at $10^{-3}$ M. Hemicholinium ($10^{-3}$ M) increased the stimulated overflow of ACh in the iris. These results demonstrate the effects of muscarinic antagonists and agonist on the release of ACh. This release is controlled by a presynaptic muscarinic receptor which when stimulated decreases ACh release and when blocked increase ACh release. In the iris the aminopyridines are not as effective as has been found at neuromuscular junctions. Hemicholinium which prevents the reuptake of choline after ACh hydrolysis shows a marked increase in ACh overflow after electrical stimulation. This overflow is most probably due to the effect on uptake and not to an effect on the muscarinic autoreceptor. The rat iris offers several advantages in studies of actions of drugs on muscarinic receptors and ACh release. (Supported by grant AFOSR-83-0051 to E.G.)

317.3 FUNCTIONAL AND BIOCHEMICAL STUDIES OF THE PUTATIVE $M_1$ SELECTIVE MUSCARINIC AGONIST MCN-A-343 [3-(m-CHLOROPHENYLCARBAMOYLOXY)-2-BUTYNYLTRIMETHYLAMMONIUM] CHLORIDE. M. Watson, T.W. Vickroy, H.I. Yamamura and W.R. Roeske. Departments of Pharmacology and Internal Medicine, University of Arizona Medical School, Tucson, AZ 85724.

McN-A-343 stimulates ganglionic muscarinic receptors, thus increasing blood pressure and heart rate. It has been suggested that McN-A-343 produces a selective stimulatory muscarinic effect upon sympathetic ganglia which overrides weaker muscarinic effects in the heart and vasculature. McN-A-343 has also been proposed to selectively interact with muscarinic receptors (MR) which show high affinity for pirenzepine (PZ) in radioligand binding studies. Thus, we have investigated the properties of McN-A-343 in rat cerebral cortical and cardiac membrane preparations and intact cell preparations. The formation of cardiac cyclic AMP (cAMP) is regulated by an inversely coupled complex between MR, β-adrenergic receptors (BAR), adenylate cyclase and other membrane constituents. In adult rat intact cardiomyocytes attached to culture plates, the BAR agonist (-)isoproterenol (ISO) produces a potent ($EC_{50}$=22 nM) and rapid (15s) increase (10x) in endogenous cAMP levels. The effect of ISO is completely reversed by the cholinergic agonists acetylcholine (ACH) and carbamylcholine (CAR) in this system. This reversal is blocked by 3OnM atropine (ATR). McN-A-343, while its $K_{act}$ (concentration producing 1/2 maximal response) is 19nM, has little efficacy, showing 1/10 the effect of ACH. Inhibition studies were conducted to observe the binding and regulation of McN-A-343 to putative MR subtypes in cerebral cortical and cardiac membranes labeled with the classical muscarinic antagonist [$^3$H](-)quinuclidinyl benzilate ([$^3$H](-)QNB), the nonclassical putative $M_1$ MR selective antagonist [$^3$H]pirenzepine ([$^3$H]PZ) and the potent MR agonist [$^3$H](+)cismethyldioxolane ([$^3$H](+)CD). Binding studies in 10 mM Na-K, 50 mM Na-K and modified Krebs phosphate buffer at 25°C in the presence and absence of the relatively non-hydrolyzable GTP analog, guanyl-5'-yl imidodiphosphate [Gpp(NH)p] show that McN-A-343 has a lower affinity for MR in a higher ionic strength buffer and also when Gpp(NH)p is present. McN-A-343 is shifted to about 5x lower affinity by Gpp(NH)p in the heart. Although McN-A-343 data is better fit to a 2-site model in [$^3$H](-)QNB labeled and [$^3$H](+)CD labeled cerebral cortical membranes and in [$^3$H](-)QNB labeled intact neuronal cells, only 1-site was seen versus [$^3$H]PZ labeled membranes. An extremely high affinity McN-A-343 site (2 nM) seen in [$^3$H](+)CD labeled and [$^3$H](-)QNB labeled cerebral cortical homogenates was also seen by direct binding. McN-A-343 showed 2-sites in cardiac membranes versus [$^3$H](-)QNB, but not versus [$^3$H](+)CD. Although the relative selectivity of McN-A-343 varied with assay conditions, it was up to 4 fold selective for cerebral cortical MR, as compared to cardiac MR. Thus, McN-A-343 acts as a weak partial agonist and is somewhat selective for putative $M_1$ MR sites in the cerebral cortex, in contrast to other agonists such as ACH and CAR.

317.4 TWO PHYSIOLOGICALLY AND PHARMACOLOGICALLY DISTINCT SUBCLASSES OF MUSCARINIC RESPONSES IN CEREBRAL CORTICAL NEURONS. D.A. McCormick and D.A. Prince. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Application of acetylcholine (ACh) to presumed pyramidal neurons in layers II-III of the anterior cingulate cortical slice evokes a short latency inhibition due to activation of GABAergic interneurons, followed by a delayed direct prolonged voltage-dependent depolarization presumably due to decrease in a $K^+$ conductance ("M-current"). We characterized the pharmacological properties of these ACh responses by comparing the actions of various drugs on the cholinergic inhibition and slow excitation of pyramidal neurons. One or 10 μM atropine or scopolamine completely blocked all responses to ACh, while 0.1 μM atropine, 10 μM hexamethonium, and 10-100 μM dihydro-beta-erythroidine did not; indicating that these actions of ACh are mediated through muscarinic receptors. Pirenzepine (PZ) distinguished between these receptors in a dose-dependent manner: 1 μM PZ diminished, while 10 μM PZ blocked the slow excitatory response (Fig. 1).

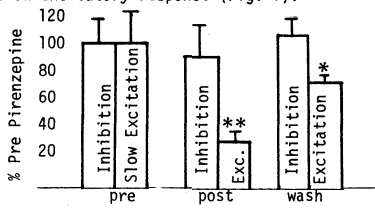

Fig. 1 Effect of PZ (10 μM) on inhibitory and slow excitatory response of pyramidal neurons to ACh. Pre, post and wash data from same neurons (n=6). Mean +/- sem. ** - $p<0.01$, * - $p<0.05$.

The inhibitory response was unaffected by these doses, but was diminished or blocked by 50 μM PZ. Thus PZ was 5-50x more effective in blocking the slow depolarizing vs. the hyperpolarizing response. These responses also differed in their sensitivities to various cholinergic agonists. Carbachol, metacholine, propionylcholine, and oxotremorine-M evoked both inhibitory and slow excitatory responses, while pilocarpine, suberyldicholine, and DL-muscarine were much more effective in activating slow excitation than the inhibition. Oxotremorine elicited the inhibitory response only but blocked the slow excitatory response evoked by ACh.

These results indicate that ACh has two muscarinic actions on cortical neurons: 1) a slow excitation of cortical pyramidal cells produced by presumed decrease in the "M-current" mediated via high affinity PZ-muscarinic receptors; and 2) a rapid excitation of GABAergic interneurons probably produced by an increase in cation conductance mediated via low affinity PZ-muscarinic receptors.

Supported by NIH grants NS 12151, 06477, 07331 and fellowships from HDFA and the Giannini Foundation.

317.5 INTERACTION BETWEEN MUSCARINIC ACETYLCHOLINE RECEPTOR AND NEUROPEPTIDES IN THE RAT HIPPOCAMPUS. R. Miyoshi*, S. Kito, K. Mizuno* and H. Matsubayashi*. Third Department of Internal Medicine, Hiroshima University School of Medicine, Hiroshima 734, Japan.

The cholinergic cell bodies located at the medial septal nucleus and nucleus of the diagonal band, project via the fimbria/fornix to innervate the pyramidal cells of the hippocampus. From histochemical studies, it seems clear that nerve cell bodies containing vasoactive intestinal polypeptide (VIP), cholecystokinin octapeptide (CCK-8), somatostatin and enkephalins are present in the hippocampus. As for substance P, it is reported that substance P positive perikaria are not present within the hippocampus, but its receptors have been known to exist substantially. This is also the case with vasopressin, a memory-related peptide. The authors observed interaction between muscarinic acetylcholine receptor (mAchR) and somatostatin in the rat hippocampus through binding experiments, and presented the results at the last Annual Meeting of Society for Neuroscience. It was noticed that somatostatin reduced the affinity of mAchR agonist binding, and this effect was dose-dependent and limited to agonist binding. In this paper, the authors studied interaction between mAchR and other peptides in the rat hippocampus. Used peptides were VIP, CCK, enkephalins, substance P and vasopressin. mAchR agonist binding experiments were performed with use of $^3$H- oxotremorine-M-acetate ($^3$H-oxo-M) as radioactive ligand and acetylcholine of $10^{-4}$ M was used as non-radioactive ligand. It is accepted by most pharmacologists that there are two or three subtypes in mAchR agonist binding sites. In our experiments, the presence of two components of mAchR agonist binding sites was observed when Krebs Henseleit solution was used, whereas a single binding site was obtained by switching the buffer to Na-K phosphate solution. $P_2$ fraction of the rat hippocampus was incubated in Na-K phosphate buffer at 30° C for 8 min. Scatchard analysis of saturation experiments revealed that both VIP and vasopressin decreased the affinity of $^3$H-oxo-M binding like somatostatin. These peptides did not influence to a $B_{max}$ value of $^3$H-oxo-M binding sites. In the contrary, snbstance P decreased a $B_{max}$ value with a Kd value unchanged. The effect of these peptides was dose-dependent. It is assumed that these peptides are acting as neuromodurators at the either presynaptic or postsynaptic level.

317.6 RETINAL ALTERATIONS OF CHOLINERGIC PARAMETERS FOLLOWING INTRAOCULAR INJECTIONS OF THE CHOLINE MUSTARD AF64A. C. Estrada, D. Triguero* and P. Gómez-Ramos. Departamento de Fisiología y Departamento de Morfología, Facultad de Medicina, Universidad Autónoma, 28029 Madrid. SPAIN.

The compound ethylcholine mustard aziridinium ion (AF64A) is thought to have a selective toxic effect on cholinergic neurons. In the present report morphologic and biochemical changes induced by AF64A were analyzed in the rat retina. Unilateral intraocular injections (5 μl) of either 10, 25 or 50 nmol were performed in adult rats. The animals were killed 1, 7 or 30 days after the injections, and the retinas were excised and examined under light microscopy. Choline acetyltransferase (ChAT) activity was evaluated both in control and experimental retinas. Muscarinic receptor binding sites were determined by measuring the binding of tritiated quinuclidinylbenzilate ($^3$H-QNB) to the 27,000 x g pellet of retina homogenates.

One day after injections of 10 nmol AF64A, ChAT activity was decreased to 33±6% of the control values. This reduction persisted one week (33±6%) and one month (37±10%) later. The histological study one week after the injections showed cytoplasmic swelling in some neurons located in the innermost part of the Inner Nuclear Layer (INL) and occasionally in the Ganglion Cell Layer (GCL), where the retinal cholinergic neurons are thought to be localized. One week after injections of 25 and 50 nmol only residual ChAT activities of 11±1% and 2.2±0.6% of the control values were observed in the experimental retinas. The examination of the later group of retinas showed a great reduction of the retinal thickness together with a disappearance of most cells in the Outer Nuclear Layer (ONL). The Outer Plexiform Layer (OPL) could not be distinguished. The neurons of the INL and GCL, although normal in appearance, seemed to be reduced in number.

The amount of muscarinic receptor binding sites showed no alteration at any dose or any time after the AF64A administration.

The results observed after the administration of the lowest dose used (10 nmol) are in accordance with a selective toxic effect on cholinergic neurons although higher doses produce a more generalized and nonspecific effect.

317.7 CELLULAR LOCALIZATION OF $M_1$ AND $M_2$ MUSCARINIC ACETYLCHOLINE RECEPTORS IN CINGULATE CORTEX. Brent A. Vogt. Depts. of Anatomy and Physiology, Boston University School of Medicine, Boston, MA 02118

There are regional variations in the densities of $M_1$ and $M_2$ muscarinic acetylcholine receptors in the central nervous system. For example, $M_1$ sites are concentrated in the substantia gelatinosa, cerebral cortex and caudate-putamen, while large numbers of $M_2$ sites are in the hypoglossal nucleus, cerebellum and ventral horn. There is, however, no information available regarding the cellular locations of these receptor subtypes in the CNS. In this study ablation/degeneration techniques have been used to identify the neuronal and afferent axonal positions of these receptors.

Ablations were placed in rats either in the anterior thalamic nuclei (ATN) via thermocoagulation or in area 29 of posterior cingulate cortex with the neurotoxin ibotenic acid. Two weeks postoperatively the animals were sacrificed, blocks removed and frozen and 16 μm thick sections cut with a cryostat. Alternate sections were then incubated in either $^3$H-propylbenzilylcholine mustard (PrBCM, 2.4 nM) which is a muscarinic antagonist that binds to both $M_1$ and $M_2$ receptors or $^3$H-pirenzepine (PZ, 15 nM) which binds selectively to $M_1$ sites. Some sections were coincubated in atropine (1 μM) to assess nonspecific binding. Standard autoradiographic procedures were employed and grain densities per 2500 $\mu m^2$ quantified with a high resolution automated grain counting system.

Normal, specific binding of PrBCM is heterogeneous with peak binding in layers Ia and IV. This binding is reduced following ATN lesions by 30% and 15%, respectively. In contrast, PZ binding is essentially homogeneous throughout the cortex, although it is lowest in layer Ia and highest in layer Ic (275 vs 354 grains/2500 $\mu m^2$). Ablations of the ATN fail to alter this latter binding pattern. However, specific binding of PZ is reduced by almost 80% following neuronal degeneration produced by ibotenic acid injections. In these same cases peaks in PrBCM binding in layers Ia and IV remain following ibotenic ablations as does approximately 30% of the binding in all other layers. It is possible that much of this latter binding is associated with $M_2$ receptors.

The following conclusions are drawn from these observations. First, muscarinic receptors on ATN axons may be of the $M_2$ subtype because normal PZ binding is lower in those layers which receive most thalamic input and no change occurs after thalamic lesions. Second, neuronal dendritic receptors are of the $M_1$ subtype, since radical reductions in PZ binding follow neuron removal. Thus, ligands for the $M_1$ and $M_2$ receptors may be used as differential probes to activate or block acetylcholine receptors in dendritic or axonal positions.

Supported by NINCDS grant 18745.

317.8 THE INTERACTION OF GALLAMINE WITH RAT BRAIN $M_1$ MUSCARINIC RECEPTORS, STUDIED BY COMPETITION BINDING WITH $^3$H-PIRENZEPINE. R.E. Burke. Dept. of Neurology, Columbia University, New York, N.Y. 10032.

Pirenzepine (Pir) distinguishes subclasses of muscarinic receptor, M1 and M2, for which it has high and low affinity, respectively. Gallamine has muscarinic antagonist properties and , like Pir, it distinguishes subclasses (Ellis & Hoss, 1982; Stockton et al, 1983; Dunlap & Brown, 1983). Gallamine binds with high affinity in tissues with mainly M2 sites (hindbrain, heart), and lower affinity in tissues with mainly M1 sites (forebrain). Thus, gallamine-recognized heterogeneity appears to parallel that defined by Pir. However, the binding of gallamine to the M1 and M2 subtypes, defined by Pir binding, has not been characterized at either site in binding experiments which examine one or the other subtype exclusively. Because a filtration assay for $^3$H-Pir reveals linear Scatchard plots with a KD equal to that for the M1 site (Watson et al, 1983), such binding represents an interaction primarily with the M1 site.

$^3$H-Pir binding was performed as described by Watson et al. Study of association rates showed that equilibrium was achieved at ½ hr. incubation at 25°C in the presence of 100 nM gallamine. $^3$H-Pir dissociation rate was not affected by 30 nM gallamine. Competition binding studies showed complete inhibition of $^3$H-Pir binding at gallamine ≥ 1000nM. Competition binding studies with cortical membrane preparations, analyzed with the LIGAND program, were best described with a one-site model with Ki= 24 nM. Similarly, studies with striatal and hippocampal membranes were fit with a one site model, with Ki= 28 and 23 nM, respectively. In medulla-pons memebrane preparations, gallamine had an $IC_{50}$ of 22 nM. A Schild plot analysis of the effect of gallamine on $^3$H-Pir KD, determined by Scatchard plots, was consistent with a competitive interaction, with Ki= 28 nM.

We conclude that gallamine interacts with the M1 site in competitive fashion, and that gallamine recognizes only one site within the M1 muscarinic receptor subpopulation.

317.9 THE EFFECTS OF SPIROMUSTINE ON THE CHOLINERGIC SYSTEM IN THE RAT BRAIN. N.S. Nadi* and T.G. Staunton* (Spon: R.J. Porter). Medical Neurology Branch and Surgical Neurology Branch, NINCDS, Bethesda, MD 20205

Acetylcholine plays an important role in the control of motor activity, arousal, learning and memory processes in the central nervous system (CNS). Recently, during the clinical trials of a potential anti-brain tumor mustard spiromustine (SHM), it was noted that patients developed episodes of confusion, obtundation and hallucinations which were reversed by physostigmine (Staunton, T.G. et al. Ann of Neurol, in press). These observations indicated that some of the effects of SHM were mediated through the cholinergic system. The effect of SHM on the CNS of rats was investigated following an intravenous injection of 2.5 mg/kg of SHM. Three brain areas, the frontal cortex, the basal ganglia and the hippocampus were examined for high affinity choline uptake (HAT), choline acetyltransferase (CAT), muscarinic receptors and succinate dehydrogenase levels at 3, 20, 68, and 92 hours after injection. At 20, 68 and 98 hours after injection a statistically significant decrease in HAT was observed in hippocampus and the basal ganglia, but not in the frontal cortex. No change in HAT was observed in any brain region at the 3 hour time point. A statistically significant decrease in CAT was seen in the frontal cortex only. Muscarinic cholinergic binding was studied using $^3$(H) quinuclidinyl benzilate (QNB) as the ligand. All three areas studied showed a significant decrease of 20-30% in the binding of QNB. Other mustards such as AF64A have been shown to interact with the HAT and the CAT systems. (Mantione, C. et al. Science 213, 579, 1981). However no effect of AF64A on the cholinergic binding site was demonstrated. SHM is the first mustard to our knowledge to have an effect on both the pre- and postsynaptic functions of acetylcholine. At the concentration of 2.5 mg/kg, SHM does not have an effect on the activity of the succinate dehydrogenase. Higher concentrations, 5 mg/kg, do cause a decrease in the activity of succinate dehydrogenase of 30% in the hippocampus and the frontal cortex. The existence of a link between the change in succinate dehydrogenase activity and the alterations in the cholinergic system are being studied. Our data to date indicate that cholinergic neurotoxicity is one of the mechanisms of action of SHM. The effect of SHM on other neurotransmitter systems is currently being examined to establish its specificity. SHM could be useful as a chemotherapeutic agent in the management of malignancies of neuroectodermal origin, especially if these are demonstrated to have an active choline transport system.

317.10 DENERVATED FROG SKELETAL MUSCLE HAS ACETYLCHOLINE-ACTIVATED CHANNELS WITH UNIQUE CONDUCTANCE AND LIFETIME PROPERTIES. C.N. Allen and E.X. Albuquerque. Dept. Pharmacol. & Exp. Therap., Univ. Maryland Sch. Med., Baltimore MD 21201.

Chronic denervation of either mammalian or amphibian skeletal muscle results in a spread of acetylcholine (ACh) sensitivity to nonjunctional regions of the muscle. Results of fluctuation analysis studies demonstrate that the ACh-activated channels of the extrajunctional regions have a lower conductance than those of the junctional region. We used the patch clamp technique to evaluate the characteristics of the ACh channels of the extrajunctional region of chronically denervated skeletal muscles. The interosseal muscles of Rana pipiens were denervated, under chloral hydrate anesthesia, by removing a 1.5 cm section of the right sciatic nerve. The left side remained innervated and served as a control. The muscles were enzymatically dispersed and the single fibers mounted in a recording chamber using a parafilm-paraffin oil adhesive. Innervated muscles contained a single population of ACh-activated channels with a conductance of 28 pS at membrane potentials between -40 and -170 mV. Following chronic denervation (42-44 days), two classes of ACh-activated channels having conductances of 17 and 28 pS could be recorded from a single cell attached patch. The conductance of the larger channel is 65% greater than the low conductance channel and is therefore not the result of the simultaneous activation of two low conductance channels. Histograms of the lifetimes of the channels of innervated and denervated muscles were fit by a single exponential function at all the membrane potentials tested. Both classes of channels from the denervated muscle had lifetimes longer than those of the innervated muscle over the entire membrane potential range. The lifetimes of the innervated muscle channels showed an e-fold increase with a hyperpolarization of 70 mV. The low and high conductance channels of denervated muscle had an e-fold increase in lifetimes with membrane potential changes of -100 mV and -120 mV, respectively. These data indicate that nerve transection causes a new class of ACh-activated channels to appear which have lifetime and conductance properties different from those of innervated muscles. (Supported by USPHS Grant NS-12063 and U.S. Army Med. Res. and Develop. Command Contract DAMD-17-84-C-4219.)

317.11 BIOSYNTHESIS OF THE TORPEDO CALIFORNICA ACETYLCHOLINE RECEPTOR α-SUBUNIT IN SACCHAROMYCES CERVISIAE. N. Fujita[*1], N. Nelson[*1], T. Fox[*2], T. Claudio[3], J. Lindstrom[4], and G. Hess[1]. [1]Biochemistry, and [2]Genetics and Development, Cornell University, Ithaca, NY 14853; [3]Physiology, Yale University, New Haven, CT 06511; [4]The Salk Institute, San Diego, CA 92138.

The entire structural gene for the α-subunit of the T. californica acetylcholine receptor, isolated as a cDNA cloned fragment, was inserted into the yeast expression vector pMAc561. The resulting plasmid, pYTcα1 was used to transform the Saccharomyces cervisiae strain TD4 to the $Trp^+$ phenotype.

Total cellular proteins were separated by SDS-polyacrylamide gel electrophoresis, blotted to nitrocellulose and reacted with a mouse monoclonal antibody against the T. californica receptor α-subunit. Yeast cells that contained the plasmid pYTcα1 contained a protein that was immunoreactive and had the same mobility as the α-subunit from T. californica membranes. Yeast cells containing pMAc561 without the α-subunit and untransformed cells did not contain this protein.

Insertion of the α-subunit into the yeast plasma membrane was confirmed by immunofluorescent detection on intact spheroplasts. Spheroplasts of transformed cells containing pYTcα1 were incubated with an α-subunit-specific monoclonal antibody, washed and decorated with a second antibody conjugated to fluorescein iso-thiocyanate. To control for the possibility that antibodies might penetrate the plasma membrane, even though they were not permeabilized, spheroplasts were also treated with antibody against porin, a major protein of the outer mitochondrial membrane. In contrast to the result with the anti-α-subunit antibody, treatment with anti-porin did not result in positive immunofluorescence, unless the spheroplasts were first permeabilized by treatment with Triton-X100.

Plasma membranes containing the α-subunit reacted with [$^{125}$I]-α-bungarotoxin with a $K_d$ value of 0.2 μM. Plasma membranes which did not contain the α-subunit did not react.

The results indicate that yeast can express the α-subunit of the nicotinic acetylcholine receptor efficiently and insert it into its plasma membrane.

This work was supported by a grant from the Cornell Biotechnology Program, which is supported by the New York State Science and Technology Foundation and a consortium of industries.

317.12 AUTORADIOGRAPHIC AND ELECTROPHYSIOLOGICAL EVIDENCE FOR NICOTINE RECEPTORS ON ASCENDING FOREBRAIN DOPAMINE NEURONS. P.B.S. Clarke[1], D.W. Hommer[2], L.R. Skirboll[2], and A. Pert[1]. Biological Psychiatry[1] and Clinical Neuroscience[2] Branches, NIMH, Bethesda, MD 20205.

Although binding of the putative nicotinic receptor ligand alpha bungarotoxin is low or absent in the substantia nigra (SN) (Clarke, P.B.S., et al, J. Neurosci., in press), high affinity specific binding of $^3$H-nicotine ($^3$H-N) is densely represented in the SN pars compacta (SNC) with little labeling in the pars reticulata (SNR) (Clarke, P.B.S., et al., Brain Res., 323:390, 1984). Using autoradiography and electrophysiology, we examined the relationship between this nicotinic binding site and the nigrostriatal dopamine (DA) system.

Autoradiography: Rats (n=6) received a unilateral injection of 6-OHDA into the medial forebrain bundle and were sacrificed 5 weeks later for $^3$H-N receptor autoradiography (as in ref. 1 but using $^3$H-L-nicotine and computer-assisted densitometry). Striatal DA was assayed by HPLC. Electrophysiology: SNC and SNR were recorded in chloral hydrate anaesthetised rats. Units were distinguished by spike shape, firing rate and pattern, response to apomorphine and haloperidol (both 0.1 mg/kg iv), and by histological verification of recording site.

Unilateral 6-OHDA lesions resulted in a near-total depletion of DA in the ipsilateral striatum and a marked reduction in Nissl staining in the ipsilateral SNC. Concomitantly, $^3$H-N labeling was reduced in the ipsilateral striatum and SNC compared to the contralateral side. Labeling was also reduced in the cell body and terminal areas of the mesolimbic DA pathway, but not in the frontoparietal cortex which lacks a DA innervation.

DA neurons of the SNC were stimulated by both iv (2-128 μg/kg) and sc (1 mg/kg) L-nicotine bitartrate (dose as base). The stimulant action of sc nicotine was blocked by the centrally active antagonist mecamylamine (MEC, 2 mg/kg iv) but not by the peripheral antagonist chlorisondamine (CHL, 0.1 mg/kg iv). In contrast, although SNR neurons were markedly stimulated by iv nicotine, pretreatment with either MEC or CHL was effective in blocking this effect.

Thus, the autoradiographic distribution of $^3$H-nicotine binding sites within the SN is consistent with electrophysiological findings that the SNC is one of the sites of nicotine's central actions.

317.13 PRESYNAPTIC MODULATION OF ACETYLCHOLINE RELEASE. G.V.W. Johnson and R.S. Jope. Department of Pharmacology, University of Alabama, Birmingham, AL 35294.

The modulation of stimulated acetylcholine release is still a poorly understood process. One putative modulator that has been discussed is phospholipase $A_2$. Three inhibitors of phospholipase $A_2$, quinacrine, chloroquine and 4-bromophenacyl bromide, reduced the rate of $K^+$-stimulated acetylcholine release from rat cortical slices. The effects of quinacrine, the most potent of these inhibitors of $K^+$-stimulated acetylcholine release, was studied in greater detail using [$^2H_4$]choline as a tracer to distinguish between the release of newly synthesized and endogeneous acetylcholine. Incubation with varying concentrations ($10^{-6}$ M to $10^{-3}$ M) of quinacrine produced similar inhibition profiles for the release of both newly synthesized and endogeneous acetylcholine, except the release of newly synthesized acetylcholine was inhibited to a greater extent at the two highest concentrations of quinacrine. Incubation of cortical slices in the presence of quinacrine resulted in acetylcholine accumulation within the tissue, apparently due to the inhibition of release, and a reduction in the production of labelled acetylcholine, indicating an inhibitory effect on acetylcholine synthesis. Quinacrine also was a potent inhibitor ($IC_{50}$ = 5 x $10^{-6}$ M) of synaptosomal high affinity choline transport.

The effects of AH5183, the most potent known inhibitor of the vesicular loading of acetylcholine (Anderson et al., Molec. Pharmacol. 24:48, 1983), were also examined on these processes. AH5183 inhibited the $K^+$-stimulated release of newly synthesized acetylcholine to a greater degree than of endogeneous acetylcholine. AH5183 also induced an accumulation of endogeneous acetylcholine in the cortical slices. Synaptosomal high affinity choline transport was inhibited by AH5183 with an $IC_{50}$ of approximately 2 x $10^{-5}$ M.

These data suggest that the AH5183-induced inhibition of $K^+$-stimulated acetylcholine release is directly related to this compound's inhibition of the transport of acetylcholine into the vesicles. Quinacrine which has also been reported to be a potent inhibitor of vesicular acetylcholine loading, also effectively inhibited $K^+$-stimulated acetylcholine release. In addition, quinacrine is known to inhibit phospholipase $A_2$. It is unclear whether quinacrine and AH5183 are inhibiting acetylcholine release through similar sites. However, these results do raise the interesting possibility that phospholipase $A_2$, which has been reported to be located in synaptic vesicles (Moskowitz et al., Sci. 216:305, 1981), may play a modulatory role in the vesicular loading and release of acetylcholine.

318.1 POSTSYNAPTIC POTENTIALS IN AXOTOMIZED AND X-REGENERATED CAT MEDIAL GASTROCNEMIUS (MG) MOTONEURONS. R.C. Foehring, G.W. Sypert, and J.B. Munson. Dept. of Neuroscience, University of Florida, College of Medicine, Gainesville, Florida 32610.

We tested whether alterations in mono- or polysynaptic inputs to MG motoneurons (MNs) accompanied axotomy and/or subsequent regeneration. The medial gastrocnemius (MG) and lateral gastrocnemius-soleus (LG-S) nerves were sectioned peripherally, removing all muscle afferent input from the triceps surae. The nerves were re-sutured to the distal stump of the other triceps nerve (X-regeneration). We examined composite monosynaptic Ia EPSPs from LG-S nerve, and polysynaptic PSPs from the sural nerve, by intracellular recording from MG MNs up to 9 months post-operatively. Ia monosynaptic EPSPs were reduced in amplitude following nerve section and recovered incompletely following regeneration. There was no evidence for myotypic respecification of Ia input following X-reinnervation.

* Action Potential Amplitude

Electrical stimulation of sural afferents (3xThreshold) resulted in an early EPSP followed by an IPSP in normal fast MNs (FF+FI+FR). In a few cases the EPSP (voltage-time integral) was dominant (+; EPSP/IPSP>1); in most cases there was an EPSP/IPSP mixture (+/-; 0.05<EPSP/IPSP<1). Normal type S MN PSPs typically were dominated by the IPSP (-; EPSP/IPSP<0.05). In X-regenerated MNs an increased number of type S units had the EPSP-dominant or mixed pattern. It did not matter which muscle (LG or Soleus) was X-reinnervated. Consistent results were obtained from MG self-regenerated MNs. We feel the altered PSP pattern in type S motoneurons may relect neural plasticity within the spinal cord, probably of the last order interneurons in the early EPSP circuit. Sprouting of new connections and unmasking of existing synapses are both consistent with these data. Supported by NIH grant NS15913, the MRS and RERDS of the VA, and the W.L. Gore Co.

318.2 EXERCISE INDUCED REMODELLING OF FAST & SLOW TWITCH NEUROMUSCULAR JUNCTIONS IN RAT. M.H. ANDONIAN AND M.A. FAHIM. Andrus Gerontology Center, University of Southern California, L.A., CA 90089-0191.

The effect of endurance exercise on morphometric parameters of rat neuromuscular junctions (NMJ) was examined in two functionally distinct muscles, the tonic soleus (SOL) and the phasic extensor digitorum longus (EDL). Sprague-Dawley rats (180-220 grams) were trained on a rodent treadmill for 30 min./day, 30 m/min (≅ 70% $VO_2$ max) up a 10% grade for 30 consecutive days without electrical stimulation. Under Metofane anesthesia, EDL and SOL muscles were dissected from these animals and three age-matched controls stained with the zinc-iodide osmium technique. Camera lucida drawings were made 20-30 endplates (>90% visible) from each muscle. Morphometric measurements, including the perimeter of the endplate, area, extent length and fiber diameters were made by digitizing the drawings on a computer controlled bit pad.

The NMJs of the control SOL and EDL were relatively simple and unbranched in appearance. Those of the exercised animals were larger, and more complicated. Fiber diameters of the exercised SOL and EDL were 15%-25% larger than controls. Fiber diameter, endplate perimeter, area and extent lengths of the exercised SOL and EDL muscles were normalized for changes in fiber diameter found to be signficantly ($P < .001$) greater than controls. Exercised SOL and EDL endplates had significantly ($P < .05$) more branches and sprouts than the controls.

These data suggest that the increased neural stimuli muscles receive during training results in remodelling at the NMJ. The less actively recruited EDL shows greater changes than the continually active SOL which suggests that basal muscular activity is also a factor in determining the structure of the NMJ.

318.3 TRAINING EFFECTS ON THE RECOVERY OF FULL WEIGHT-BEARING STEPPING IN ADULT SPINAL CATS. R.G. Lovely, R.J. Gregor, R.R. Roy, and V.R. Edgerton. Brain Research Institute and Department of Kinesiology, UCLA, CA 90024.

Some cats cordotomized when adults can recover full weight-bearing stepping (Neurosc. Abst. 47.1, 1982; Neurosc. Abst. 184.1, 1984). The time course for their recovery and the effects of training have not been examined. This study was designed to monitor changes in the locomotor capabilities of adult spinal cats trained over a 5 month period and to compare their performance with an untrained cordotomized group.

Transection of the spinal cord at T12-T13 was performed on 16 adult mongrel cats. One month post-transection, 14 cats were capable of full weight-bearing (FWB) stepping on a motor driven treadmill if the tail was pinched or crimped. Within the treadmill apparatus, the animals were stabilized by a harness about the shoulder girdle and the forepaws were on a platform 1" above the treadmill belt. Top speeds for FWB were 0.05-0.2 m/s at this time. Of the 14 FWB cats, 8 were selected at random for 30 minutes of treadmill exercise per day, 5 days/week (TE group). The rest were assigned to a transected non-exercised group (TNE). Daily records were kept on treadmill speeds, time at each speed, step rate at each speed, and the number of steps that were not FWB. The number of FWB steps times treadmill speed was used as a measure of performance.

The TE cats reached a performance plateau 25-75 days after initiating the exercise regimen. Maximum FWB speeds were 0.4-0.85 m/s. Only 2 TE cats required tail pinching to take more than 30 consecutive steps after 5 months of training. On some days, 5 of the 8 TE cats could locomote for the entire session without trainer assistance of any kind. In TNE cats, maximum FWB speeds were 0.15-0.35 m/s 6 months post-transection and no more than 5-7 consecutive steps could be taken without tail pinching.

The performance of 3 TE cats declined after initial improvement. Declining performance was associated with increasing frequency of landing on the dorsum of the paw at paw contact, ankle hyperextension, and insufficient extensor activation to support body weight.

Although some recovery occurred without training, TE cats performed better than TNE cats 6 months post-transection. While training may have affected the neurological apparatus controlling stepping, it may also have facilitated performance by retarding the progression of muscle abnormalities (Roy et al., accompanying abstract) and joint abnormalities that can occur as a result of transection. Supported by NIH grant NS 16333.

318.4 LONG-TERM EXERCISE EFFECTS ON THE MECHANICAL PROPERTIES OF THE SOLEUS MUSCLE IN ADULT SPINAL CATS. R.R. Roy, R.J. Gregor, R.G. Lovely, K.M. Baldwin, and V.R. Edgerton. Brain Research Institute and Kinesiology Dept., UCLA, CA 90024 and Physiology Dept., UCI, Irvine , CA 92717.

This study was designed to determine the effects of daily exercise on the skeletal muscle below the level of the lesion in low thoracic (T12-T13) transected (T) adult cats. One group of transected cats was trained (TE) on a treadmill 30 min/day, 5 days/week such that the cats had to fully support their body weight when exercising (Lovely et al, accompanying abstract). Another group of transected cats were non-exercised (TNE). The soleus (SOL) was chosen for study because it is severely affected by spinal transection (Roy et al., JAP 56:1594, 1984) and it is heavily recruited during treadmill exercise in T cats as indicated by EMG and tendon force records (unpublished observations). Six months after transection, the *in situ* isometric contractile properties of TNE and TE SOL muscles were determined at 36±1°C and compared with data from sedentary, control (C) adult cats. SOL wet weight (MW) and maximum tetanic tension (Po) decreased by 36 and 41 %, respectively, in the TNE group, whereas the TE cats showed only a 14 and 18 % decline in the same parameters. The maximum twitch tension (Pt) showed a similar pattern. The SOL in the TNE and TE groups had shorter contraction times (CT) and one-half relaxation times (1/2 RT) than did control cats. Although the relative amount of maximum tension produced at 20 Hz (%Po) was decreased in both groups, the change in TNE cats was 15 % larger than in the TE group.

Thus, our preliminary results suggest that in the SOL there is an ameliorating effect of daily exercise involving full weight support on the atrophy and the "conversion" towards a faster muscle associated with spinal transection in adult cats.

318.5 THE EFFECTS OF HYPERTHYROIDISM UPON SLOW OXIDATIVE AND FAST GLYCOLYTIC MOTONEURON ENERGY METABOLISM. D.W. Sickles, *T.G. Oblak* and J. Scholer.* (SPON: G. Standage) Department of Anatomy, Medical College of Georgia, Augusta, GA 30912

Motoneurons innervating different types of muscle fibers are specialized with respect to quantitative differences in the activity of enzymes of oxidative metabolism (Sickles and Oblak, J Neurophysiol. 51;529, 1984). Despite extensive efforts to elucidate regulatory mechanisms of muscle fiber differentiation, similar studies in motoneurons have not been considered. The thyroid status of the animal influences physiological and histochemical properties of the muscle; hyperthyroidism increases speed of contraction and converts slow oxidative (SO) fibers to fast oxidative glycolytic (FOG) (Fitts et al,. Am J Physiol 238: C15, 1980). This study was undertaken to determine whether motoneuron metabolism is thyroid hormone regulated. Eight 170 g male Sprague-Dawley rats were fed T3 (1mg/kg food) and T4 (3mg/kg food) in their diet for 6-7 weeks, 6 controls were given only the powdered chow. The latter gained an average of 91% of starting weight, experimentals only 64.7%. At the termination of the experiment plasma T4 levels were elevated 57.8% and heart/body weight ratios were 54.7% higher in experimentals. Fiber populations of the soleus changed from 86.9% SO, 10.1% FOG, 2.8% Intermediate to 20.4% SO, 43.9% FOG and 34% Int. No significant change in tensor fascia lata (94% fast glycolytic fibers) fiber populations were observed. The NADH-TR (oxidative metabolism) and α-glycerophosphate dehydrogenase (glycolytic) activities of the soleus were changed by +46.2% and +357.1%, respectively. NADH-TR activity of TFL muscle fibers was slightly increased (5.4%). A 16.6% increase in soleus (SO) motoneuron NADH-TR activity was observed in hyperthyroid rats; only a 4.9% change in TFL motoneuron NADH-TR activity was found- (see Sickles and Oblak, J Neurophysiol 51: 529, 1984 for method details). We conclude that thyroid hormone causes an increase in the oxidative metabolism of motoneurons, indicating a direct thyroid CNS effect. We have verified the quantitatively greater effect of thyroid hormones upon SO muscle fibers and, in addition, we have shown a differential effect of the hormones on motoneuron oxidative metabolism.

Supported by NIH grant #OH 02020

318.6 EFFECT OF SYNERGIST TENTOMY ON THE OXIDATIVE METABOLISM OF RAT SOLEUS MUSCLE AND MOTONEURONS. J.K. Pearson*, D.W. Sickles* (SPON: M. Mulroy), Department of Anatomy, Medical College of Georgia, Augusta, GA 30912

Tenotomy of synergists (gastrocnemius and plantaris) to the soleus muscle of the rat results in conversion of muscle fiber type populations from 84% slow oxidative (SO) and 16% fast oxidative glycolytic (FOG) to a pure population of SO fibers within 60 days after tenotomy (Iannuzo et. al., Life Sciences 19: 1517, 1976). This system has been used as a model of "functional overload" which suggests increases in tension and/or overall activity. We have assessed the changes occuring under these conditions in the soleus muscle using histochemical methods for ATPase (Guth and Samaha, Exp. Neuro. 28: 365, 1970), NADH-tetrazolium reductase (NADH-TR; oxidative metabolism) (Scarpelli et. al., J. Biophys. Biochem., Cytoche. 4: 747, 1958), and menadione-linked α-glycerophosphate dehydrogenase (α-GPDH; glycolytic metabolism) (Wattenberg and Leong, J. Histochem. Cytochem. 8: 296, 1960). Motoneuron metabolism varies in accordance with the type of muscle fibers innervated (Sickles and Oblak, J. Neurophys., 51: 529, 1984). The effects of functional overload on motoneuron metabolism has never been examined. We determined the changes in motoneuron NADH-TR activity and correlated these with changes in muscle fiber type population. Sprague-Dawley rats (150-174g) underwent tenotomy of the left plantaris and gastrocnemius (including removal of 1/2 of the muscles) under pentobarbital anaesthesia. Sham operated and unoperated animals served as controls. Sixty days later, soleus motoneurons were identified via intramuscular injections of HRP (Sigma Type IV) (Sickles and Oblak, J. Neurophys 51: 529, 1984). No significant differences in muscle or motoneuron enzyme activities were observed between sham and unoperated animals. The ATPase staining of the experimental muscles did show a conversion from FOG to SO fibers. The NADH-TR activity of the soleus decreased 13.7% from control, while the NADH-TR activity of the motoneurons showed a parallel decrease of 16.3%. The α-GPDH activity in the experimental soleus was decreased from control. We have shown that tenotomy of synergists to the soleus does not increase the oxidative metabolism of the soleus muscle and conclude this is not a model for increased activity. The change in the myosin ATPase does suggest that tension rather than activity may control the expression of myosin type. The decrease in the oxidative metabolism of the motoneuron paralleled the decrease in NADH-TR activity of the muscle fibers demonstrating a strong relationship of this parameter within the motor unit.

318.7 EVIDENCE FOR THE CONTINUING ROLE OF TARGETS IN CONTROLLING MOTONEURON TERMINALS IN ADULT MAMMALS. R. Butler. Department of Anatomy, McMaster University, Hamilton, Ontario, L8N 3Z5.

A review of the evidence regarding interneuronal synaptogenesis indicates that the transformation of growing axons into specialized nerve terminals is clearly regulated by their synaptic targets. This is especially true for vertebrate neuromuscular junctions where peripheral motor axon terminal differentiation seems to be under local control by certain post synaptic membrane specializations, especially the basal lamina. There are also suggestions that these dynamic relationships are maintained with increasing age in normal adult muscle and that neuromuscular junctions can undergo continual remodelling. I have undertaken two sets of experiments which support the concept that mature targets can modify alpha motoneuron morphology. The first deals with the reinnervation of intact targets by regenerating alphas. Following crush injuries to the nerve to the tenuissimus muscle in adult cats, single regenerating alphas were found with different intrafusal effects in different muscle spindles, implying that different branches of the same alpha were functionally innervating different types of intrafusal muscle fibre simultaneously. Reconstructions showed that different branches of these single alphas also had morphologically different types of endings (focal plates and engrappe), simultaneously, on different types of intrafusal muscle fibre. The converse series of experiments deals with the influence of regenerating targets on intact motoneuron terminals. In order to make available a very different target for alpha motoneurons with focal endplates, an extraocular muscle containing multiply innervated slow tonic fibres was excised from a rat and transplanted into its own hindlimb, using the fast twitch extensor digitorum longus as host. The transplant and host were then treated with bupivacaine. The muscle degenerates and subsequently regenerates allowing the intact neurons and their terminals the option of innervating very different targets. My observations indicate that not only can intact alphas innervate the regenerated transplant but also their existing focal endplates are modified to a multiple innervation on regenerated extraocular fibres. These results support the suggestion that neuromuscular targets maintain a continuing dynamic influence on motoneurons in the adult. Supported by the Ontario March of Dimes and the Muscular Dystrophy Association of Canada.

318.8 SPECIFIC CHANGES IN TRANSPORTED RETINAL PROTEINS DURING COMPRESSION OF THE RETINOTECTAL PROJECTION IN GOLDFISH. Myong G. Yoon and Frank A. Baker*; Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada. B3H 4J1.

In addition to the ability of regeneration of optic fibers after axotomy, an adult goldfish is also capable of reorganizing the topographic pattern of the visual projection from the retina to the mid-brain visual center, the optic tectum. If the caudal half of the tectum is ablated, the remaining rostral hemitectum accommodates optic fibers not only from the proper temporal half of the retina but also from the previously inappropriate nasal half in an orderly compressed topographic pattern. This field compression suggests that extensive reorganization of synaptic contacts may occur in the halved tectum. To test whether retinal ganglion cells undergo specific changes in their metabolism and axonal transport of proteins during the field compression the caudal half of the left tectal lobe was excised after bilateral optic nerve crush in adult goldfish. At various intervals between one and four months after surgery, retinal proteins transported in the right optic nerve (regenerating to the halved left tectal lobe) were labelled with $C^{14}$-proline and those in the left optic nerve (regenerating to the whole right tectal lobe) with $H^3$-proline. For each time-point, both optic nerves were mixed together and co-processed for SDS gel electrophoretic separation of the differentially labelled proteins. The relative labeling spectra of various proteins were compared between the two isotopes for each time-point. A group of rapidly-transported proteins with molecular weights between 180 and 210 kilodaltons (Kd) increased differentially in the right optic nerve ($C^{14}$) compared with the left optic nerve ($H^3$) during the 45-55 days post-operative period. This specific change suggests that the 180-210 Kd proteins may be involved in the retinotectal field compression, which occurs at about the same period in adult goldfish.

(Supported by grants from MRC and NSERC of Canada).

318.9 PLASTICITY OF SYNAPTIC VESICLE NUMBER IN ADULT RAT SUPERIOR CERVICAL GANGLION FOLLOWING DEAFFERENTATION AND GANGLIONIC BLOCKADE. K.F. Greif Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

Changes in the number of synaptic vesicles in the adult rat superior ganglion (SCG) following deafferentation or pharmacological blockade of synaptic activity have been monitored using a monoclonal antibody directed against a 65 kD integral membrane protein associated with synaptic vesicles (SV) (Matthew et al, J. cell biol. 91:257, 1981). Previous studies have shown that levels of this antigen undergo significant postnatal changes during normal development and after neonatal deafferentation.

SCGs in adult rats were deafferented by bilateral section of the cervical sympathetic trunk. Levels of antigen were measured by radioimmunoassay at 7 or 30 days following surgery. For studies of synaptic activity, rats were injected twice daily for 7 days with chlorisondamine (10 mg./kg, s.c.) and then sacrificed immediately.

Seven days following bilateral deafferentation, levels of SV were significantly increased to 46% above control levels. No decrease in SV levels was observed in iris, a primary SCG target tissue, suggesting that the increase in SV in the SCG is not the result of blocked axonal transport. Immunohistochemical staining of frozen sections of SCG confirmed the loss of labelling in presynaptic terminals, indicating that increased amounts of SV accumulate in ganglion cell perikarya. By 30 days after surgery, SV levels decrease to 30% of control levels, a value similar to that observed 30 days after neonatal deafferentation. After 7 d. treatment with chlorisondamine, enhanced increase in SV levels over that in saline-treated animals is observed, consistent with a real increase in antigen levels in the presence of intact presynaptic terminals.

These results suggest that activity of ganglionic neurons contributes to the regulation of synaptic vesicle numbers in the adult rat SCG and that significant plasticity in vesicle numbers can occur. However, the time course of response differs from that observed in neonatal animals. These findings are of interest in view of reported changes in plasticity of phenotypic expression of neurotransmitters in the SCG in adult and aged rats.

318.10 STIMULATION OF PLASTICITY CHANGES WITHIN THE LESIONED ADULT RAT RETINA. J. E. Turner. Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103.

We report for the first time that by employing a new lesion paradigm in the adult rat retina there is evidence for plasticity changes involving a dramatic increase in the cellularity of the inner nuclear layer which may be due to a transformation of photoreceptor cells. A small incision perpendicular to the long axis of the optic nerve is made through the sclera, choroid and retina on the dorsal surface of the eyes of young adult male Sprague-Dawley rats. The retina is gently detached at the lateral edges of the incision with a small glass stylus and the wound closed with microsutures and 10-0 thread. Experimental lesion groups received a desheathed peripheral nerve implant into the lesion site while controls had none. Eyes were analyzed for light and electron microscopic morphometric observations at 1, 2, 4, 6 and 8 weeks after lesion. The retinal detachment process causes an irreversible degeneration of the photoreceptor cell (PRC) outer segments followed by PRC cell survival in controls for at least 6 to 8 weeks after lesion. In experimental lesion sites there was a rapid disappearance of PRCs which was correlated with a dramatic increase in the cellularity of the underlying inner nuclear layer (INL). The increase in INL cells was not due to increased Muller cells, retinal pigment epithelium or macrophages. Cells in the diminishing outer nuclear layer (ONL) were seen in transitional states between normal PRC and INL neuron morphologies. In addition, the sum of cell counts in the intact control ONL added to these in the underlying intact INL were not significantly different from counts of cells in the expanded INL of comparable experimental retinas where the ONL had completely diminished. In experimental retinas an increase in INL thickness was also accompanied by a greatly thickened underlying inner plexiform layer. The transformation process appears to be initiated and/or greatly accelerated by the presence of a peripheral nerve implant. Thus the retina is capable of being induced to initiate rather profound cellular changes. Supported by Grant EY 04377 from the National Eye Institute awarded to J.E.T.

318.11 PARTIAL DEAFFERENTATION INDUCES INCREASED DOPAMINE RECEPTOR DENSITY AND DOPAMINE-SENSITIVE ADENYLATE CYCLASE, WHILE DECREASING ($Na^+$-$K^+$)-ATPase AND OUABAIN BINDING IN THE OLFACTORY TUBERCLE. R.B.LINGHAM*, A.C.SWANN, V.HOLCOMBE*, S.A.KHAN*, G.A.ROBISON, AND Z.GOTTESFELD. Depts. Pharmacol. Psychiatry, and Neurobiology & Anatomy, Univ. Tex. Med. Sch., Houston, TX 77025.

Destruction of a major non-catecholaminergic input from the olfactory bulb (OB) elicits collateral sprouting of dopaminergic (DA) axons in the olfactory tubercle (OT). This phenomenon has been identified by the increased density of axon terminals containing tyrosine hydroxylase (TH) and by enhanced uptake of DA into synaptosomes of the OT (Gilad, G.M. and Reis, D.J., Brain Res. 160:17, 1979). The functional consequences of this innervation are presently not known. This study examined the effect of lesioning the OB on 1) density of DA receptors, 2) the DA-sensitive adenylate cyclase (AC) and 3) ($Na^+$-$K^+$)-ATPase activity as well as 4) levels of $^3H$-ouabain binding in OT membranes.

Rats (200-300 g) were lesioned or sham-operated under chloropent anesthesia. Animals were killed at specific time intervals post-operative and the OT were removed and processed for further chemical analyses. Membranes were prepared by standard techniques of homogenization and differential centrifugation, then assayed for AC (Salomon, Y. Adv. Cyc. Nucl. Res. 10:35, 1979) and DA receptor binding (Reisine et al., Life Sci. 21:335, 1977). ($Na^+$-$K^+$)-ATPase activity, in homogenates or microsomes, and $^3H$-ouabain binding were measured according to Swann and Albers (Biochem. Biophys. Acta, 382: 437, 1975) and Swann (J. Pharmacol. Exp. Ther., 228:304, 1984), respectively.

The results indicate that DA-, NaF- and forskolin-stimulated AC activity increased as early as 7 days and reached a maximum (25%) by 20 days post-lesioning. DA-receptor binding increased (25%) during this time period and correlated with the increase of TH activity in the sprouting DA fibers (Gilad and Reis, ibid). Higher levels of GTP- and NaF- stimulated AC activities were found in detergent extracts of OT membranes from 20-day lesioned rats. ($Na^+$-$K^+$)-ATPase activity and ouabain binding decreased 30% and 25%, respectively, 20 days after lesioning.

In summary, lesion-induced DA sprouting in the OT is associated with 1) increased AC activity, 2) a comparable increase in DA-receptor binding, 3) increased levels and/or activity of the stimulatory GTP-binding protein associated with AC and 4) decreased ($Na^+$-$K^+$)-ATPase activity and specific ouabain binding.

Supported in part by NIH grants GM27378, NS 19325, MH37141, AA0615801 and NSF grant BNS-8401818.

318.12 LESION-INDUCED TRANSNEURONAL CELL DEATH AND DEGENERATION S.F. Hoff, Department of Pharmacology, The Chicago Medical School, North Chicago, IL 60064.

After unilateral ablation of the entorhinal cortex, we have reported both degenerative and non-degenerative changes in synaptic density throughout the entire ipsilateral and contralateral molecular layer of the hippocampal dentate gyrus in adult rats. The ipsilateral dentate granule cells are partially denervated by the lesion (85% loss of input). In addition we have observed a complete cycle of synapse turnover within the ipsilateral (but not contralateral) CA4/Hilus region of the hippocampal formation, along with a significant bilateral increase in the density of the mossy fiber terminals (MFT) arising from the granule cell axons. The purpose of the present study was to determine if a degenerative process was involved in the bilateral transneuronal response to a distant injury.

Male Sprague-Dawley rats (90 days old) received a complete unilateral electrolytic lesion of the entorhinal cortex. The animals were allowed to survive for 4, 10, 60 or 180 days post-lesion and were then sacrificed and prepared for electron microscopy. Over the experimental time course, EM montages were taken across the CA4/Hilus region along a path joining the midpoints of the dorsal and ventral blades of the dentate granule cell layers. Approximately 161,000 square microns of neuropil have been evaluated for this study.

Within the ipsilateral CA4/Hilus region we have observed a 40% decrease in synaptic density at 4 days post-lesion, which was followed by a return to normal density by 180 days post-lesion. Also, there was a 2.25 fold increase in MFT density during the experimental time course. During this study, twenty-three synaptic profiles were classified as degenerating (15 dendritic elements and 8 axonal terminals). These profiles represented about 0.12% (23/19561) of the total synaptic profiles counted in the ipsilateral side. Also, two degenerating cell bodies were observed in the CA4/Hilus area at four days post-lesion.

Within the contralateral CA4/Hilus area, we have observed no change in the normal synaptic density over the time course. However, there was a 2.5 fold increase in the density of MFT. In this area only six degenerating profiles were observed and these accounted for 0.05% (6/12833) of the total synaptic profiles. No degenerating cell bodies were seen.

The small amounts of degeneration reported in this study do not account for the initial 40% loss in ipsilateral synaptic density or the pronounced increase in density of the MFT. Along with an apparent non-degenerative mechanism of synapse turnover, the degenerative process may represent a simple "dying back" of some synaptic contacts during rearrangement of the circuitry interactions of the dentate granule cells and CA4/Hilus neurons.

318.13 HIPPOCAMPAL SYMPATHETIC INGROWTH IN RATS AND GUINEA PIGS: QUANTITATIVE MORPHOMETRY OF TOPOGRAPHICAL DIFFERENCES. J.N. Davis and R.M. Booze, VA Med. Center and Depts. of Med. (Neurology) and Pharmacology , Duke University Medical Center, Durham, NC 27705.

Sympathetic ingrowth is an unusual neural rearrangement after brain injury in which peripheral noradrenergic nerve fibers grow into the hippocampus in response to damage of the septo-hippocampal pathway. We quantified histofluorescent catecholaminergic fibers in the hippocampus of rats and guinea pigs to study the regulation of the ingrowth response.

Unilateral fornix or medial septal lesions were placed and the animals sacrificed two to six months after the lesions. Every tenth cryostat section through the hippocampus was processed for catecholamine histofluorescence (de la Torre and Surgeon, 1976). Adjacent sections were collected for cresyl violet staining (to aid in matching sections) and acetylcholinesterase staining (to verify cholinergic depletion).

Sympathetic ingrowth was found to occur in both species as a specific response to injury of the septo-hippocampal pathway. As for rats, ingrowth in guinea pigs was found to be dependent on cholinergic depletion and originating from the superior cervical ganglion. However, a species difference was observed in the topographical distribution of sympathetic ingrowth. In rats, noradrenergic ingrowth fibers were found above and below the granule cell layer, the dentate hilus, and the pyramidal cell layer $CA_3$. Ingrowth in guinea pigs also occurred in the dentate gyrus and area $CA_3$ but, unlike the rat, was prominent throughout area $CA_1$. Quantitative estimates of fiber numbers confirmed these observations and further found significant species differences in the intrahippocampal lamellar distribution of ingrowth fibers. Within area $CA_3$ of rats, the stratum oriens, stratum pyramidale, and stratum radiatum, were all found to contain similar numbers of fibers. In contrast, the guinea pig hippocampus had the greatest number of fibers localized to stratum pyramidale in areas $CA_1$ and $CA_3$. These species differences in fiber topography were not associated with any known anatomical characteristics of the hippocampus of the two species, i.e. we found no differences in the topography of mossy fibers (Timm's stain), cholinergic septal afferents (anterograde HRP), or in GAD-immunoreactive neurons.

The use of quantitative morphometric techniques has identified significant species differences in the topographical distribution of noradrenergic sympathetic ingrowth fibers in the hippocampus. These differences are challenging to current theories concerning tropic factor regulation of hippocampal ingrowth.

318.14 PLASTICITY IN NEUROTRANSMITTER SYSTEMS OF THE SPINAL CORD FOLLOWING SCIATIC NERVE CRUSH.

C. Somps*, M.W. Luttges and L.J. Fisher, Aerospace Engineering Sciences, University of Colorado, Boulder, Colorado 80309.

Time-dependent alterations in spinal cord function have been observed following damage to peripheral nerves. Such changes include somatotopic reorganization and altered depth profiles for primary afferent depolarization recorded within the dorsal horn. Altered electrical responses from cross-cord and ascending pathways have been observed as well. The mechanisms responsible for these changes are unknown. However, the localized nature of the changes and the relative constancy of spinal cord morphology and protein synthesis, suggest that neurotransmitter systems may be involved in the observed plasticity. To explore this possibility, the uptake and compartmentalization of spinal cord neurotransmitters (GABA, glutamate, acetylcholine) were examined in regard to specific localizations in both dorsal and ventral horn regions. Neurotransmitter systems were examined 3, 6, & 9 days following unilateral sciatic nerve crush in mice. On each post-crush day, spinal cord tissues were removed, minced, and incubated in GBSS containing radiolabeled transmitter (GABA, glutamate) and transmitter precursor (choline chloride). After washing and homogenization, tissue samples were subfractionated using differential and density gradient centrifugations. To assure methodological constancy, double labeling was used to permit simultaneous processing of tissues from different experimental preparations. The specific activity of radioactivity recovered from synaptosome enriched subfractions was determined using corresponding Lowry protein measures based upon bovine serum albumin standards. Recovered radioactivity showed characteristic variations with time post-crush. Specific activities of recovered radioactivity were 20% below controls at 3 & 6 days post-crush for synaptosome fractions obtained from GABA, glutamate, and choline chloride labeled tissues. At 9 days post-crush, specific activities returned to near control levels for both choline chloride and glutamate. However, GABA levels at 9 days exceeded control values by more than 40%. The time course and direction of these changes are correlated with previously observed electrophysiologic differences in 6 as opposed to 9 day post-crush tests. The localization of changes to the lateralization and the level of the damaged afferents is described. That these changes corroborate neurophysiological changes indicates a short time-course (days) set of alterations in neurotransmitter systems that may underlie damage-induced changes in spinal mechanisms.

318.15 ABSENCE OF ANATOMICAL CHANGE IN THE THALAMOCORTICAL PROJECTION OF RACCOONS DURING THE PERIOD OF PHYSIOLOGICAL REORGANIZATION. D.D. Rasmusson & D.M. Nance, Depts. of Physiology & Biophysics and Anatomy, Dalhousie University, Halifax, N.S. Canada B3H 4H7

Physiological changes have been demonstrated at the level of the primary somatosensory cortex (SI) after digit amputation in raccoons and monkeys. One possible mechanism for this is an anatomical alteration in the thalamocortical projection, perhaps via sprouting.This possibility was studied by injecting one fluorescent dye into the reorganized 5th digit area and another dye into the normal 4th digit area of SI and examining the location of labelled cells in the ventrobasal thalamic area (VB). We have previously found that in the intact raccoon, the VB populations for these two digits are distinct with virtually no cells projecting to both cortical regions (Physiol. Can., 1984, 15, 173).

The present experiment was conducted in six raccoons four months following amputation of the 5th digit. The injection sites were made on the basis of the sulcus patterns and in five animals these sites were verified by electrophysiological recordings prior to injection. The dyes used were fast blue (FB) and nuclear yellow (NY) in four animals and FB and diamidino yellow (DY) in two animals. Crystals of NY and FB were used in one case, while 0.2 ul injections were used in the other animals (FB and NY, 5% solutions; DY, 1%).

The specific hypothesis tested was that cells in 4th digit VB would project into reorganized 5th digit cortex and would be seen either as double-labelled cells or as an intermingling of cells with each label. In 4 cases the results clearly contradicted this hypothesis: almost no double-labelled cells were seen and the populations were separate as in the normal animal. In the other two cases, many double-labelled cells were seen but the injection sites were found to be overlapping, due to diffusion of NY. The location of double-labelled cells within VB in these two animals was consistent with the topography of the overlap zone and was not consistent with the receptive field locations seen physiologically. Thus, these experiments suggest that anatomical changes in the thalamocortical pathway are not responsible for the observed physiological reorganization and that changes at another level of the somatosensory pathway must be responsible.

Supported by M.R.C. of Canada

318.16 EFFECTS OF CROSS-ANASTOMOSIS OF DIGITAL NERVES ON PRIMARY SOMATOSENSORY CORTEX OF THE RACCOON. B.G. Turnbull and D.D. Rasmusson, Dept. of Physiology and Biophysics, Dalhousie University, Halifax, N.S. B3H 4H7

Multi-unit recordings were made from the primary somatosensory cortex (SI) of four chloralose-anesthetized raccoons, 3-4 months after cutting and cross-repairing the ventral nerves of the ulnar side of the 4th digit and the radial side of the 5th. Thus, the regenerating 4th digit nerve fibres would reinnervate the glabrous skin of the 5th digit and vice versa. If the cortex simply mirrors the new peripheral innervation then each digital area of SI should be divided in half; e.g. that half of the 4th digit area which had represented the ulnar side of the digit should now respond only to the radial 5th digit, while the radial 4th representation should be unchanged. The extent to which the experimental evidence did not bear this out would indicate that central mechanisms were involved in altering the interchanged peripheral inputs.

The results showed that the affected cortical areas responded to stimulation of the reinnervated digits, but also reflected additional changes. Input from the crossed nerves was not topographically organized: map inversions and discontinuities were evident. These distortions could be explained by random regeneration of fibres across the nerve repairs. In addition to these expected inputs, the affected areas of SI also retained some responsiveness to stimulation of the original digit. For example, units in the ulnar 4th region of SI had receptive fields on both the 4th and 5th digits. These results cannot be explained by peripheral overlap from the other, intact digital nerves: the location of receptive fields and the overall topography within the affected cortex was inconsistent with this explanation and, furthermore, many of these responses remained after sectioning the other nerves during the recording session. These results suggest that the somatotopic map in SI cortex reflects central influences in addition to the altered peripheral input.

319.1 EXPRESSION OF MHC CLASS I MOLECULES IN NORMAL BRAIN, AREA POSTREMA, AND OLFACTORY EPITHELIUM. J.P. Whelan* and L.A. Lampson. Department of Anatomy, Univ. of Penn., School of Medicine, Phila., PA 19104.

Class I molecules, which include HLA-A,B,C in man and H-2 K,D,L in mouse, are known to play an important role in the immune response. Effector phase cytotoxic T cell-recognition of foreign antigens is often dependent upon the co-recognition of appropriate class I on the target cell. Although classically described as ubiquitous, it is becoming increasingly apparent that the distribution of class I molecules varies among cell types. Neural tissues, in particular, display a paucity of class I molecules when compared to lymphoid controls (Lampson, et al. J. Immunol. 130:2471, 1983). Recently, it has been shown that the weak expression of HLA-A,B,C on neuroblastoma cell lines can be increased when the cells are treated with $\gamma$-interferon (Lampson and Fisher, PNAS 81: 6476,1984). In order to determine whether a similar modulation of class I occurs under physiological conditions in vivo, we have extended our studies to a mouse model.

An antiserum that reacts with $\beta_2$-microglobulin ($\beta_2$-m), the invariant chain associated with all class I molecules, was used in an avidin-biotin immunoperoxidase assay on both frozen and formaldehyde-fixed paraffin sections. (1) In normal mouse brain, strong stain was found in blood vessel and choroid plexus endothelium but not in the cell bodies of neurons or glia, or in myelin. This result in tissue that had been perfused with fixative confirms our earlier work in human neural tissues. (2) The area postrema, which lacks a blood/brain barrier, failed to exhibit any positive stain. Combined with the lack of positive staining in other areas of the CNS, these data suggest that weak class I expression is not only a property of neural tissue in immunologically privileged sites. (3) The olfactory mucosa, which contains an actively proliferating neural epithelium, failed to give positive staining, whereas the non-sensory respiratory epithelium did show positive stain for $\beta_2$-m. Since all layers in olfactory epithelium fail to stain, including the germinal neuroblast layer, it appears that weak class I expression may be a feature of developing, as well as post-mitotic neuronal cells. Still to be determined is whether class I modulation occurs on neurons during disease or trauma, and such work is in progress.

(Funded by NS16552 and CA14489 from the USPHS.)

319.2 REGIONAL DISTRIBUTION OF THY 1.1 IN RAT BRAIN. (SPON: J. Trubatch). C.B. Pert, J.M. Hill and R.J. Weber*. Neuroimmunology Unit, Section on Brain Biochemistry, Clinical Neuroscience Branch, National Institute of Mental Health, Building 10, Room 3N256, 9000 Rockville Pike, Bethesda, Maryland 20205-1000.

Thy-1 is a transmembrane glycoprotein of molecular weight 17,500 present predominantly on the surface of thymocytes and neurons (Williams, A.F., et al., Cold Spring Harbor Symp. Quant. Biol. 41: 51-61, 1977). Although function of Thy-1 is unclear a cell-cell adhesion role has been proposed. Because of its presence on thymocytes and neurons, the molecule constitutes a structural link between the immune and central nervous systems.

To examine the localization of Thy-1 in rat brain, we have incubated frozen sections of rat brain with a mouse monoclonal antibody to rat Thy 1.1, MRC OX-7, followed by an iodinated goat anti-mouse immunoglobulin. The sections are then exposed to X-ray film. Thy 1.1 was found to be unevenly distributed in rat brain with distinct regional differences related to laminar patterns within brain regions. This was especially evident in the cerebellum, where the granule cell layer was densely labeled, and in the hippocampal formation, where dense binding occurred in the pyramidal cell layer.

Within the hypothalamus the superchiasmatic and supraoptic nuclei were labeled. Labeling also occurred in the substantia nigra, pars reticulata, interpeduncular nucleus and central grey of the midbrain region.

Most brain regions with abundant Thy 1.1 labeling were neuron-rich areas. This observation is consistent with the previously reported findings that Thy 1.1 is found primarily on neurons.

319.3 THE DEVELOPMENTAL APPEARANCE OF THY-1 ANTIGEN IN THE AVIAN NERVOUS SYSTEM. P.L. Jeffrey, A.M. Sheppard*, and C.M. Sinclair*. Children's Medical Research Foundation, University of Sydney, N.S.W., Australia and Biochemistry Dept., Monash University, Clayton, Vic., Australia.

A monoclonal antibody against chicken Thy-1 glycoprotein (BSJ-1) was utilized to investigate the developmental appearance of Thy-1 in the chicken nervous system by (a) an immunohistochemical technique using a modified peroxidase antiperoxidase technique and (b) quantitative distribution by an ELISA technique and $^{125}$I-Fab binding.

In forebrain Thy-1 could first be detected at embryonic day (Ed) 8 and the largest increase of Thy-1 levels occurred during the last week of embryonic development which coincides with the major period of neuronal development and synapse formation but precedes the major myelination period.

Thy-1 is first found in the cerebellum and retina at Ed 12. By Ed 18 the cerebellum molecular layer is strongly positive. Heavy particulate staining around the Purkinje cell perikaryal membranes present at Ed 18 is lost in the period to 1 day hatch and is due to the specific loss of perisomatic synapses at this time. A decrease of staining seen in the cerebellar white matter post hatch is due to the masking effect of myelination and not from a loss of Thy-1 from neuronal membranes.

The optic fibre layer and the inner most portion of the inner plexiform layer (IPL) of the retina are positive for Thy-1 at Ed 12. By Ed 18 the staining has progressed across the IPL with 4 lines of stratification being apparent. Day 1 post hatch shows similar pattern but by day 8 post hatch the synaptic stratification of the IPL cannot be seen. No staining was found on the outer plexiform layer further strengthening the retinal ganglion cell localisation for Thy-1. Embryonic spinal cord at Ed 12 and sciatic nerve at Ed 15 express Thy-1 and reach maximum values around 8 days post hatch and the staining diminishes with increasing age due to the masking effect of myelination.

Thy-1 is not transiently expressed on neurons except for the examples of Purkinje cells, spinal cord and sciatic nerve noted here and its role appears to be involved in the processes of the mature, functioning neuron and not in the formation of synaptic connections.

Supported by a grant from the National Health and Medical Research Council of Australia.

319.4 BINDING AND INTERNALIZATION OF TETANUS TOXIN TO PC12 CELLS. K. Sandberg and T.B. Rogers. Department of Biological Chemistry, University of Maryland School of Medicine, Baltimore, MD 21201

Tetanus Toxin (T.T.) is a potent neurotoxin which binds selectively to neural tissue. In the present study, the binding of $^{125}$I-T.T. (1-4 x $10^6$ cpm/pmol) to the pheochromocytoma cell line PC12 was examined in order to investigate T.T.'s mechanism of action. The PC12 cells contain complex gangliosides in higher concentrations and bind more $^{125}$I-T.T. than most neuronal cell lines. This is consistent with the evidence that the T.T. receptor is a ganglioside. In this study, the specific binding of $^{125}$I-T.T. was measured on PC12 cells grown in 12 well trays (3.8 $cm^2$/well) and was defined as the total binding minus that occuring in the presence of T.T. antibody (3 units/well). Optimal binding occured in 0.25 M sucrose buffer at pH 7 containing 20 mM Tris, 30 mM NaCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$ and 0.25% BSA. The cells were incubated with 0.1-0.4 nM $^{125}$I-T.T. (100,000 $^{125}$I-T.T. cpm/well).

The amount of $^{125}$I-T.T. bound to PC12 cells was analyzed as a function of differentiation since various differentiation conditions are known to alter ganglioside composition (Walton, K.M. and Schnaar, R.L., Soc. Neurosci. Abst. 10:760, 1984). PC12 cells were grown under the following conditions: $10^{-5}$M dexamethasone (DEX); 100 ng/ml nerve growth factor (NGF); or, at high density (8 x $10^5$ cells/$cm^2$). Both NGF treatment (582 ± 64 fmol/mg) and high density plating (397 ± 40 fmol/mg) increased the amount of $^{125}$I-T.T. bound per mg protein compared to control cells (263 ± 21 fmol/mg) grown under nondifferentiating conditions ($10^4$ cells/$cm^2$). Dex (283 ± 15 fmol/mg) had an insignificant effect on T.T. binding. These results are interesting in light of the findings that NGF and high density plating have been found to elevate ganglioside levels in these cells compared to control and Dex treated cells (Ibid).

Internalization of $^{125}$I-T.T. (defined as the remaining amount of $^{125}$I-T.T. bound after a 5 min incubation in the presence of 0.4 µg/ml pronase at 37°C) has also been examined. The majority of $^{125}$I-T.T. bound (>60%) to PC12 cells at 0°C is not internalized in contrast to the amount bound (>95%) at 37°C. Most of the bound $^{125}$I-T.T. (>85%) is internalized within 5 min, after the cells incubated at 0°C are transferred to 37°C. While metabolic inhibitors (0.2 µg/ml oligomycin + 0.2 µM rotenone) do not inhibit binding, they do inhibit internalization of $^{125}$I-T.T. (>40%). These experiments demonstrate that $^{125}$I-T.T. binding to PC12 cells is regulated by differentiation conditions and that internalization is dependent upon metabolic energy.

Support by USARMDC contract DAMD17-83-C-3114.

319.5 MONOCLONAL ANTIBODY CAT-301: RECOGNITION OF A SURFACE ANTIGEN ON SUBSETS OF CELLS IN HUMAN CENTRAL VISUAL AREAS AND BIOCHEMICAL PURIFICATION OF THE ANTIGEN FROM GUINEA PIG BRAIN. S. Zaremba*, E. Waldvogel* and S. Hockfield, Cold Spring Harbor Laboratory, P.O. Box 100, Cold Spring Harbor, NY 11724

Monoclonal antibody, Cat-301, recognizes subsets of neurons in central visual areas of cats and monkeys (Hockfield et al., Cold Spring Harbor Symp. 48:877, 1983) recognizing an antigen on surfaces of neuronal cell bodies (Hockfield and McKay, PNAS 80:5758, 1983). We now report on studies to determine whether Cat-301 recognizes cells in human visual areas that may be anatomically and functionally homologous to cells previously identified in cats and monkeys. Such cross-reactivity might permit immunohistochemical analysis of neuronal organization in post-mortem tissue from normal individuals, providing correlation with studies on neuronal organization in experimental animals.

Monoclonal antibody Cat-301 recognizes discrete cell types in human central visual areas and recognizes an antigen on neuronal cell surfaces, a subcellular localization identical to that found in other species. As in the Macaque monkey, antibody positive cells are found in substantial numbers in human primary visual cortex and in fewer numbers in secondary visual cortex. Ongoing experiments are designed to determine whether antibody positive cells are arranged in regular patches when viewed in tangential sections, an arrangement previously shown to reflect the ocular dominance organization in the Macaque. In human lateral geniculate nucleus (LGN), Cat-301 positive cells are found in the magnocellular layers, similar to the distribution previously observed in primates. It is hypothesized that these cells are homologous to the Cat-301 positive cells in cat LGN which previously have been shown to possess anatomical and developmental characteristics of Y-cells.

Biochemical purification of the antigen(s) recognized by Cat-301 is essential to determining whether identical molecules are recognized by the antibody in different brain areas and in different species. Purified antigens are also necessary in order to ask whether the Cat-301 antigen is a member of a multigene family whose members might be expressed specifically in different neuronal subsets. A nitrocellulose dot blot assay has now been set up to screen various tissue extracts for immunoreactivity. Deoxycholate extracts of guinea pig brain stem and spinal cord, concentrated by ultrafiltration, have been shown to possess specific immunoreactivity in amounts amenable to purification. We have been unable to identify Cat-301 antigens on Western blots of deoxycholate extracts known to possess immunoreactivity. Instead, the antigen(s) are being purified from deoxycholate extracts by immunoaffinity chromatography and other biochemical techniques.

This work was supported by NIH Grant RO1 NS18040.

319.6 A MONOCLONAL ANTIBODY AGAINST A NEURONAL CELL SURFACE ANTIGEN. T. Crossfield-Kunze* and S. David. (SPON: A.C.Peterson). Neurosciences Unit, The Montreal General Hospital Research Institute and McGill University, 1650 Cedar Ave., Montreal, Canada, H3G 1A4.

We have generated several monoclonal antibodies using dissociated cells of embryonic day 19 rat corpus callosum as the immunogen. Spleen cells of Balb/c mice immunized with these cells were fused with a Sp2/0 myeloma cell line. Primary wells were screened by an enzyme linked immunosorbent assay (ELISA) and positive wells were cloned by limiting dilutions.

One of these antibodies (2.4A5) binds to a cell surface antigen on neurofilament positive ($NF^+$) cells, as shown by a double indirect immunofluorescence assay on dissociated cell cultures of the neonatal rat cerebral cortex. No other cell types were labelled in these cultures. The labelling of $NF^+$ cells occurs in patches and is more prominent on the processes than over the cell bodies. Indirect immunofluorescence labelling by this antibody of frozen sections of embryonic and early postnatal rat brains fixed in 4% paraformaldehyde, results in faint labelling of neurons in the cerebral cortex and hippocampus.

In preliminary studies in which the developmental changes in this antigen were quantified by an ELISA, a decrease in this antigen was observed after postnatal day 25.

Experiments in which dissociated brain cultures were treated with trypsin or neuraminidase demonstrate that this antigen is sensitive to trypsin but not to neuraminidase.

319.7 ALTERATIONS IN NEURAL CREST MIGRATION BY A MONOCLONAL ANTIBODY THAT AFFECTS CELL ADHÉSION. M. Bronner-Fraser. Dept. of Physiology and Biophysics, University of California, Irvine, Ca., 92717

Neural crest cells migrate extensively during development along pathways that are lined with extracellular matrix molecules, including fibronectin, hyaluronic acid, and type I collagen. It has been proposed that adhesive interactions between the extracellular matrix and the neural crest cell surface may play a role in neural crest cell migration.

Here, the possible role of a 140kD cell surface complex in neural crest adhesion and migration was examined using a monoclonal antibody JG22, first described by Greve and Gottlieb (1982, J. Cell. Biochem. 18: 221-229). Addition of JG22 to neural crest cells in vitro caused a rapid change in morphology of cells plated on either fibronectin or laminin substrates. The cells became round and phase-bright, often detaching from the dish or forming aggregates of rounded cells. Other tissues such as somites, notochords, and neural tubes were unaffected by the antibody in vitro even though the JG22 antigen is detectable in embryonic tissue sections on the surface of the myotome, neural tube, and notochord.

The effects of the JG22 on neural crest migration in vivo were examined by a new perturbation approach in which both the antibody and the hybridoma cells were microinjected onto neural crest pathways. Hybridoma cells were labelled with a fluorescent cell marker which is non-deleterious and which is preserved after fixation and tissue sectioning. In the mesencephalic region, the JG22 antibody and hybridoma cells caused a marked reduction in cranial neural crest migration in 83% of the injected embryos. The volume occupied by neural crest cells was reduced by about 50% on the injected side relative to the control side. In 26% of the affected embryos, there was a build up of neural crest cells within the lumen of the neural tube. In addition, there was some migration along aberrant pathways. Neural crest migration in the trunk was affected to a much lesser extent. In both cranial and trunk regions, a cell free zone of one or more cell diameters was generally observed between neural crest cells and the JG22 hybridoma cells. Two other monoclonal antibodies, 1-B and 1-N (kindly provided by Dr. C. Buck), were used as controls. Both 1-B and 1-N bind to bands of the 140kD complex recognized by JG22. Neither affects neural crest adhesion in vitro. When these control hybridoma cells and antibodies were microinjected into the mesencephalon, no effects on neural crest migration were observed. This suggests that the observed alterations in neural crest migration are due to functional block of the 140kD complex by JG22. (supported by NIH HD15527-04 and Basic Research Grant 1-896 from the March of Dimes)

319.8 CELL SURFACE LOCALIZATION OF THE LIMBIC ANTIGEN: AN ULTRASTRUCTURAL IMMUNOCYTOCHEMICAL ANALYSIS. P. Levitt and V. Cooper. Dept. of Anatomy, Medical College of Pennsylvania, Philadelphia, PA 19129.

A new type of molecular specificity, expressed among functionally related neurons, was recently discovered with a monoclonal antibody that localized an antigenic determinant within cortical and subcortical regions comprising the limbic system (Levitt, Science 223:299-301, 1984). Immunoperoxidase staining of the antigen at the light microscopic level appeared to be distributed at the cell surface, principally around neuronal somata and within the neuropil. An electron microscopic immunocytochemical study was undertaken to characterize the specific subcellular distribution of the limbic antigen.

Adult Sprague-Dawley rats were perfused transcardially with 4% paraformaldehyde, 0.1% glutaraldehyde and processed for pre-embedding immunoperoxidase staining, applying the limbic system monoclonal antibody to vibratome sections. Semithin and thin sections were collected from medial prefrontal cortex, septum, amydala, hippocampus, nucleus tractus solitarius and lamina II of the spinal cord and the distribution of the antigen on specific cellular elements in each region was examined. Horseradish peroxidase reaction product was found consistently along the cell surface of neurons and their dendritic processes. In all areas examined, neither myelinated nor unmyelinated axons were stained. Thus, the afferent fibers arising from neurons of one limbic region which project to another do not contain immunodetectable antigen. Astrocytes and oligodendrocytes also were unreactive in all regions examined. Within any area, however, all neuronal cell types were stained. For example, hoppocampal pyramidal, granule and polymorphic neurons were immunoreactive as were cells in all layers of prefrontal cortex. Reaction product was distributed in dense clusters that were spaced unevenly along the surface of the somata and large dendritic processes. Only the smallest of dendritic profiles were completely ringed with reaction product. The postsynaptic specializations of some terminal complexes were stained, but most were not immunoreactive. The reaction product that was present within the cytoplasm of stained neurons was usually associated with membrane cisternae, consistent with the transport of the antigen for insertion in the plasma membrane. The presence of the limbic antigen only on the somatic and dendritic surfaces and its absence on axons and axon terminals indicates that the molecule is inserted into the membranes of limbic targets, which is consistent with the antigen's suggested role as a recognition marker among functionally related neurons.

319.9 COINCIDENT EXPRESSION OF LACTOSERIES CARBOHYDRATES AND β-GALACTOSIDE-SPECIFIC LECTINS BY SUBSETS OF DRG NEURONS. L. Regan*, J. Dodd, S. Barondes and T. Jessell. Department of Neurobiology, Harvard Medical School, Boston, MA. and Department of Psychiatry, University of California, San Diego, CA.

Functionally distinct classes of dorsal root ganglion (DRG) neurons express unique lactoseries and globoseries carbohydrate phenotypes (Jessell & Dodd, Phil.Trans.R.Soc.Lond.B., 308,271,1985). Similar or identical carbohydrate structures have been implicated in cell-cell recognition and adhesion during embryonic development. These observations raise the possibility that cell-surface carbohydrates represent sensory neuron differentiation antigens that contribute to the laminar segregation of sensory terminals in the dorsal horn (DH) of the spinal cord (SC).

The small-diameter DRG neurons that project to the superficial laminae (I,II) of the DH express the N-acetyllactosamine lactoseries backbone structure that is a potential ligand for β-galactoside-specific lectins found in many vertebrate tissues, including the nervous system (Barondes, Science 223,1259,1984). We have examined the possibility that carbohydrate-binding proteins with specificity for N-acetyllactosamine structures are selectively localized and developmentally regulated in DRG and in the DH of the SC, using antibodies raised against two soluble β-galactoside-binding lectins isolated from rat lung. These proteins are biochemically and immunologically distinct, with apparent molecular weights of 14.5Kd and 29Kd (Cerra, Gitt and Barondes, J.Biol.Chem., in press,1985).

Proteins separated by polyacrylamide gel electrophoresis from extracts of DRG and SC were transferred to nitrocellulose paper and probed with the anti-14.5Kd and anti-29Kd antisera. Both DRG and SC extracts contained 14.5Kd and 29Kd immunoreactive proteins. These proteins were the only detectable immunoreactive species in DRG and SC extracts. Sections of adult rat DRG and SC were incubated with anti-29Kd or anti-14.5Kd antisera and processed for immunocytochemistry. The majority of the small-diameter DRG neurons expressed the 29Kd lectin, whereas the large-diameter DRG neurons were not labelled. Most small- and a few large-diameter DRG neurons were labelled by anti-14.5Kd. The central terminals of small DRG neurons in the superficial DH of the SC also expressed the 14.5Kd and 29Kd lectins. Double immunofluorescent staining revealed that all DRG neurons that express the N-acetyllactosamine carbohydrate structure also express the 14.5Kd and 29Kd lectins. The 14.5Kd lectin was detectable in DRG neurons and sensory fibres entering the SC as early as embryonic day (E) 14. By E 18 both the 14.5Kd and the 29Kd lectins were detectable in sensory fibres terminating in the DH. These lectins do not appear to be expressed by DH neurons.

The early and selective expression of β-galactoside-specific lectins by N-acetyllactosamine-bearing sensory afferent terminals suggests a number of strategies for examining the role of both classes of molecules in the development of afferent input to the dorsal horn of the spinal cord.

## LEARNING AND MEMORY: PHYSIOLOGY IV

320.1 HIPPOCAMPAL STIMULATION DOES NOT IMPAIR SPATIAL REFERENCE MEMORY ACQUISITION. M.L. Shapiro, B.K. Knowlton+, D. Hughey, and D.S. Olton. Department of Psychology, Johns Hopkins University, Baltimore, MD, 21218. +Department of Neuroscience, Stanford University, Stanford, CA, 94305.

The hippocampal system is required for normal memory in humans and non-human animals. However, not all memory processes require the system. This experiment shows that electrical stimulation of the hippocampus that produces hippocampal seizures impairs performance of a working memory task but not the acquisition of a reference memory task.

20 male, albino rats were implanted with bipolar, bilateral stainless steel electrodes in the CA1 layer of the hippocampus. Each rat was placed on the stem of a T-maze and allowed to enter either arm of the maze; only one of the arms contained a food reward. After entering an arm, a rat was treated in one of three ways. The hippocampus was stimulated to produce an electrophysiological seizure (1) immediately after the rat entered the arm (group 1; n=7) or (2) four hours after entering the arm (group 2; n=6), or (3) sham stimulation was given (group 3; n=7). Both the arm containing reward and the type of treatment given to each rat were consistent across trials. Each rat was given one trial per day, and the number of days required to enter the arm containing food reward for five consecutive trials was the acquisition measure of reference memory.

Hippocampal stimulation had no effect on acquiring the reference memory task (mean = 16 days; 1 way ANOVA by groups, P>.90).

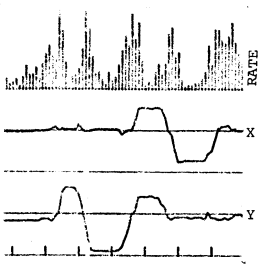
The same rats were given hippocampal stimulation while being tested on a working memory task on a 12 arm radial maze. Each arm contained a food reward. Entering each arm without returning to a previously visited arm defined optimal performance. Each rat was forced to 6 arms, given hippocampal stimulation resulting in electrophysiological seizures or sham stimulation, and permitted to choose freely among the 12 arms. Retroactive errors (returning to arms visited prior to seizure) increased from 3% after sham stimulation to 50% after seizure stimulation.

In summary, hippocampal stimulation resulting in seizure activity selectively disrupts performance of working memory tasks but not acquisition of reference memory tasks. These results converge with those from lesion and pharmacological studies to suggest that the hippocampal system is not required for acquiring reference memory information.

320.2 PEAK DISCHARGE RATES OF DENTATE GYRUS NEURONS CORRESPOND TO CHOICE POINTS ON A SPATIAL WORKING MEMORY TASK. B.L. McNaughton, Dept. Psych., University of Colorado, Boulder, CO 80309.

Single and multiple unit activity was recorded in the granule cell layer of the fascia dentata of a rat performing a working-memory task on a radial 8-arm maze. The performance of this task is disrupted by hippocampal damage (Olton et al., Brain Res. 139, 295, 1978). On each trial, the animal was first presented with a random set of four arms. After the food was recovered from the ends of the arms, a one minute delay was interposed, which was followed by presentation of the complete set of eight arms, four of which still contained food reward. The animal performed eight complete trials per recording session, with an intertrial interval of 2 min, and made an average of 1.2 errors per trial. Unit activity was recorded throughout sessions by computer, as was the animal's position at 10 points per second. During the intertrial and intratrial intervals, the most obvious correlate of unit discharge was the animal's movement. This is in agreement with an earlier report by Rose (Neurobiology of the Hippocampus, 449, 1983) which showed that granule cell discharge had a strong movement correlate within a small recording chamber. In contrast, while the animal was actually running the task in the present studies, the peak firing corresponded neither to the animal's peak velocity nor to peak acceleration. Rather, the peak rates were most often associated with the point immediately preceding arm entry. Not infrequently, this peak rate corresponded to a period of reduced velocity or immobility. Occasionally, the animal made one or more partial entries into incorrect arms before making a correct choice. These periods were accompanied by sustained high discharge rates. A similar, but less striking, pattern was also observed in multiple unit records from CA1. While these observations are still open to several interpretations, they do raise the interesting possibility that hippocampal neurons are engaged in particularly intense information processing immediately preceding arm entry.

Supported by PHS grant NS 20331.



Dentate unit firing rate and corresponding X and Y coordinates while animal was engaged in working memory trial on 8-arm maze. Peak rates correspond to choice points rather than velocity or acceleration maxima. (Time scale 10 sec/div.)

320.3 LONG-TERM STUDIES OF PLACE FIELD INTERRELATIONSHIPS IN DENTATE GYRUS NEURONS. B. Jones Leonard, B.L. McNaughton, C.A. Barnes, Dept. Psych., Univ. Colorado, Boulder, CO 80309.

Several techniques have been reported which permit the discrimination of several spike trains simultaneously from a single probe. The method illustrated here, called the "stereotrode" (McNaughton et al., J. Neurosci. Meth. 8: 391, 1983), is based on the principle that cells with different ratios of distances from two adjacent electrode tips will have different spike-amplitude ratios when recorded on two channels. We report here data from an ensemble of 3 neurons in the fascia dentata (FD) which was monitored over a 17 day period. The study was designed to assess FD place field interrelationships resulting from the removal of distal visual cues while the rat performed forced-choice trials on a radial 8-arm maze.

A male Fischer-344 rat was implanted with a pair of movable stereotrodes which were subsequently positioned in FD. A spike preprocessor calculated 4 parameters for each action potential on each of the X and Y channels. The animal's position on the maze was recorded at 20 Hz by means of a tracking system. Spike parameters, spike event times, and spatial coordinates were stored and later analyzed by means of a cluster analysis program. Three clearly discriminable FD units displayed consistent clusters and reliable place fields on the maze and in the rat's home cage over the 17 days of observation. The experiment reported here consisted of 3 phases during a single recording session. In phase one, the animal was introduced into a darkened room, and 20 trials were collected. Eighteen more trials were run in phase two with the room lights on. During phase three, the room was again darkened, this time in the presence of the rat.

During phase 1, two units exhibited an apparent breakdown of reliable place specificity while a third cell maintained its specificity with respect to maze cues, but shifted this firing to a different arm. In contrast, during phases 2 and 3 all units reverted to the same place fields observed on previous days. These results confirm previous reports by O'Keefe and by Kubie and Muller, showing persistence of place specificity following removal of the determining cues, provided the animal is given an initial spatial reference. They also suggest that individual cells may rearrange their place specificities independently of one another.

320.4 ACQUISITION OF A CONDITIONED-AVOIDANCE RESPONSE (CAR) IN HYPOPHYSECTOMIZED (HYPOX) RATS AFTER DIFFERENT PERIODS OF RECOVERY FROM THE SURGICAL STRESS. A. Ratner, D.B. Yelvington* and G.K. Weiss.* Department of Physiology, University of New Mexico School of Medicine, Albuquerque, New Mexico 87131.

Acquisition of a condition-avoidance response (CAR) was measured in hypophysectomized (HYPOX) male rats two days, seven days, and three weeks after recovery from the surgical stress. Rats were tested daily in a two-way shuttle box. Testing consisted of ten trials per day with a constant intertrial interval of sixty seconds. A CAR was defined as movement of the rat to the opposite side of the shuttle box within five seconds of presentation of a light (conditioning stimulus - CS). If the animal did not move to the safe side of the box he received a 0.3 ma scrambled shock delivered for fifteen seconds or until he escaped to the opposite side of the box. No significant difference was found in the acquisition of a CAR in SHAM-operated and HYPOX rats given one or three weeks recovery after surgery. However, HYPOX rats allowed only a two day recovery period showed a significantly lower level of acquisition performance when compared to the SHAM rats. The HYPOX rats, after two days of recovery also showed a significant decrease in latency between the presentation of the light (CS) and the avoidance response. Open field observations showed that the motor abilities of the HYPOX rats were not decreased. We were also unable to show any differences between SHAM and HYPOX rats in the thresholds for "any movements", paw movement and the jump-flinch response. These findings indicate that post-surgical recovery time can affect acquisition performance and further suggests that acquisition performance in HYPOX rats may be related to the general physical and metabolic state of the animal.

320.5 NUCLEUS BASALIS INVOLVEMENT IN CONDITIONED NEURONAL RESPONSES IN THE RAT FRONTAL CORTEX. G.C. Rigdon*, W.H. Lyness and J.H. Pirch. Dept. of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

Neurons in the rat frontal cortex demonstrate altered firing rates in response to conditioned stimuli. Microinjection of inhibitory compounds into the nucleus basalis suppresses the generation of conditioned unit responses in the frontal cortex (Rigdon and Pirch, 1985). Three experiments were designed to test the hypothesis that the basal forebrain cholinergic system is involved in the generation of conditioned cortical neuronal responses in the rat. Most of the cholinergic innervation to the cortex is supplied by projections from the nucleus basalis. A two-second tone cue immediately followed by rewarding medial forebrain bundle stimulation was used to elicit the conditioned neuronal responses in the following experiments. Experiment One was designed to investigate the effects of blocking cholinergic receptors on the conditioned responses of the cortical neurons. Microinjection of atropine, a cholinergic muscarinic receptor antagonist, into the frontal cortex suppressed the conditioned responses of 21 of 24 cortical single units. The nucleus basalis region was lesioned with kainic acid, a neurotoxin, in Experiment Two. The lesion resulted in a significant decrease in choline acetyltransferase activity in the frontal cortex ipsilateral to the nBM lesion. Only 25% of the neurons recorded in the cortex on the side of the nBM lesion exhibited conditioned responses. This was significantly lower than the percentage of neurons that exhibited conditioned responses in the cortex of untreated animals (70%). The firing rates of units in the nBM region were monitored during the cue-event paradigm in Experiment Three. Of the 38 unit recordings from the nBM region, 28 (74%) exhibited conditioned responses. The results from the experiments reported here provide evidence for a role of the basal forebrain cholinergic system in the generation of conditioned single unit responses in the frontal cortex. (Supported by the Tarbox Parkinson's Disease Institute and USPHS MH29653).

320.6 SINGLE UNIT CORRELATES OF CONDITIONING-RELATED TONE DISCRIMINATION IN THE FRONTAL CORTEX OF URETHANE ANESTHETIZED RATS. H.K. Rucker*, M.J. Corbus*, and J.H. Pirch (SPON: P. Meyer). Dept. of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

This study was designed to ascertain whether neurons in the frontal cortex of urethane anesthetized rats show firing rate changes related to discriminative conditioning. Single unit responses to reinforced (CS+) and non-reinforced (CS-) tone cues were analyzed in 50 neurons that demonstrated a significant response to the CS+ and/or the CS-. Rewarding medial forebrain bundle (MFB) stimulation was used as reinforcement. Prior to the recording session, male adult rats were implanted with MFB stimulating electrodes and allowed to recover. Self-stimulation parameters were obtained and the animals were subsequently trained to associate either a 1KHz or 8KHz tone with MFB stimulation. For unit recording, rats were anesthetized with urethane (1.2 - 1.5 g/Kg, i.p.) and subjected to additional training. Cortical slow potential (SP) responses were recorded with Ag-AgCl electrodes as an index of discrimination (Pirch et al. Intern. J. Neurosci. 25: 207-218, 1985). Extracellular single unit action potentials were recorded with glass microelectrodes. Data acquisition trials were composed of a 2 sec. prestimulus period and two 1000ms response periods following the tone onset, with MFB stimulation applied at the termination of all CS+ tone presentations.

The mean SP response (integrated area) for 18 rats following training under urethane was 79 ± 7 (S.E.) μVsec. for the CS+ and 15 ± 3 μVsec. for the CS- ($p < 0.001$ by paired-$t$). Seventy-eight percent (n=39) of the units analyzed demonstrated an excitatory response to the CS+ significantly greater than the response to the CS-. Sixteen percent (n=8) were inhibited by the CS+; only one unit of this group showed a significant response (inhibition) to the CS-. Six percent (n=3) showed a significant response to the CS- only (two units inhibited and one facilitated). All unit analyses were performed on peristimulus histograms of 25 trials each. Units were frequently held for more than 1.5 hours with stable responses. We conclude that this model represents a stable and reliable in vivo system for studying synaptic mechanisms underlying conditioning-related changes in firing rates of neurons in the rat frontal cortex. (Supported by USPHS MH29653 and the Tarbox Parkinson's Disease Institute at Texas Tech University Health Sciences Center)

320.7 TRYPTOPHAN DIFFERENCES IN SELECTIVELY BRED TASTE-AVERSION PRONE AND TASTE-AVERSION RESISTANT RATS. R. L. Elkins and G. F. Carl. The Med. College of Ga. and the VA Medical Ctr. Augusta GA 30910.

Thirteen generations of selective breeding based on efficiency of taste aversion (TA) acquisition has resulted in significant and marked divergence of strains of TA-prone (TAP) and TA-resistant (TAR) Sprague-Dawley derived rats. During TA conditioning fluid deprived rats consume a novel 0.01% saccharin solution prior to an intraperitoneal cyclophosphamide injection. Aversions are assessed with two-bottle preference tests that provide simultaneous ad lib access to the saccharin solution and plain water. A 15-day percentage preference score is computed for each subject to express the degree to which saccharin solution (CS) ingestion contributed to total fluid intake. These preference scores are the basis of breeder selection. TAP non-sibling breeder pairings are based on the lowest TAP preference scores, and TAR pairings are similarly configured from the highest TAR scores. Strain divergence is an associative phenomena as indicated by standard (pseudoconditioning) control procedures. Separation has been maintained with new CS flavors and modes of illness induction, but has not extended to shock-motivated environmental avoidance learning or to food reinforced bar-press responding.

HPLC analyses of tryptophan and other large neutral amino acids (LNAAs) in blood of TAP and of TAR S-13 males having mean CS preference scores of 2.85 and 95.98, respectively, have revealed lower tryptophan levels in TAP than in TAR rats (mean tryptophan levels = 323.85 and 397.71 µmoles/l, respectively, $p < 0.01$). The ratio of tryptophan to the sum of the other LNAAs in blood is thought to control tryptophan uptake into brain and tryptophan brain concentration (Fernstrom, J. D., Physiological Reviews, 63:484, 1983). This ratio analysis supported lower tryptophan uptake in TAP rats ($p < 0.01$). These findings are consistent with a serotonin influence on TA learning. Tryptophan is a serotonin precursor, and central serotonin depletion has been associated with enhanced TA conditionability (Lorden, J. F. & Margules, D. L., Physiological Psychology, 5:273, 1977).

320.8 INTERSTIMULUS INTERVAL EFFECTS ON SPINAL CONDITIONING USING A LOW INTENSITY CS. R.G. Durkovic and S.M. Onifer*. Department of Physiology, Upstate Medical Center, Syracuse, NY 13210.

As a simplified neural model of mammalian associative learning, Spinal Conditioning has been shown to exhibit major characteristics of intact animal classically conditioned responding (Behav. Neural Biol. 43:12, 1985). In the spinal preparation it is necessary for the conditioned stimulus (CS) to activate both Aα and Aδ cutaneous fibers in order to demonstrate differences between CS-US paired and CS, US unpaired groups, at least for forward conditioning with a 1 sec interstimulus interval (Exp. Neurol. 86:81, 1984). With such a CS intensity, forward and backward conditioning effects have been observed (Soc. Neurosci. Abstr. 6:191, 1980).

The present study was undertaken to examine the effects of interstimulus interval (ISI) on spinal conditioning using a CS that activated only Aα cutaneous fibers. Ten groups of animals were studied, each with a different ISI. CS alone trials were interspersed among thirty conditioning trials to assess response alterations in all groups. The CS was a 10/s shock to the left saphenous nerve for 1.5 sec. The unconditioned stimulus (US) was a 30/s shock to the left superficial peroneal nerve for 0.5 sec which activated Aα and Aδ fibers of that nerve. Flexion reflex responses to CS presentations were obtained from the tibialis anterior muscle of the same hindlimb.

With simultaneous CS-US onset and with CS onset before US onset no significant differences were observed between the 0, +0.25, +0.5, +1.0, +3.0 sec ISI groups and an explicitly unpaired control group (ISI=30 sec). In contrast, with US onset before CS onset (backward conditioning) significant increases in reflex response to the CS were produced with maximum flexion reflex facilitation with a -0.25 sec ISI and a drop off of facilitation with longer backward ISI's (-0.5, -1.0, -3.0 secs).

The results suggest that the backward conditioning results observed in earlier studies employing a more intense CS were brought about almost exclusively by the Aα cutaneous fiber component of the CS. Such a result differs from the Aδ fiber activation requirement observed for forward conditioning and suggests that in this preparation the neural circuitry involved in backward conditioning is different from that involved in forward conditioning.

Supported by NSF grants BNS 80-23943 and BNS 84-15917.

320.9 AN INPUT FROM LOCUS COERULEUS IS NECESSARY FOR DISCHARGE MODIFICATION OF AVIAN LATERAL GENICULATE NEURONS DURING VISUAL LEARNING. J.L. Broyles* and D.H. Cohen. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

We previously reported that a large class of neurons in the avian equivalent of the mammalian dorsal lateral geniculate (LGNe) shows enhancement of light (CS)-evoked responses over visual conditioning. This class consists of cells showing decreased discharge in response to the unconditioned stimulus (US), foot-shock. Cells with US-evoked increases in discharge show habituation of their CS-evoked responses. These findings indicated that CS-US convergence is necessary for associative modification of LGNe discharge. However, such convergence is not sufficient, since the US input must have specific properties, in contrast to the CS input. We subsequently reported that a projection from the locus coeruleus (LC) to LGNe relays the US input responsible for decreased discharge of LGNe cells. The present experiments were designed to evaluate whether eliminating this US input by interruption of the coeruleo-LGNe pathway also eliminates the modifiability of LGNe neurons.

The activity of single LGNe cells with US-evoked decreases in discharge was isolated. After 5 unpaired CS and US presentations, an electrolytic lesion was made in the ipsilateral coeruleo-LGNe pathway. Another block of unpaired CS and US presentations was then given, followed by paired CS-US presentations. Consistent with previous findings, the lesion changed US-responsiveness in 81% of the cells. In 27% the US-evoked response transformed to increased discharge; 45% showed less decrease in discharge; and 9% became unresponsive. Of the cells held for at least 15 conditioning trials, only 9% showed any enhancement of their CS-evoked response, and this was of much lower magnitude than in intact animals. The lesion did not affect CS-evoked responses. It appeared to decrease maintained activity, but the effect was not statistically significant.

In very preliminary experiments, a lesion was made in the contralateral coeruleo-LGNe pathway. Although the coeruleo-LGNe projection is bilateral, it is predominantly ipsilateral. Therefore, animals with lesions of the contralateral pathway constitute an interesting control. The few cells studied to date showed response enhancement over conditioning, but of a lower magnitude than usually seen in intact birds.

These experiments show that the coeruleo-LGNe pathway is necessary for associative modification of LGNe neurons. Since another study showed that electrical stimulation of LC is effective as a US, we conclude that the LC input is both necessary and sufficient for transmitting effective US input to LGNe.

320.10 A NEW HYPOTHESIS FOR THE NEURAL BASIS OF ANESTHESIA. S. A. Raymond. Anesthesia Research Laboratories, Brigham and Women's Hospital, Harvard Medical School, Boston, MA 02115

Several mechanisms have been proposed for the general anesthesia induced by various pharmacological agents. 1) excitatory synaptic connections may be "blocked". 2) The action of inhibitory synapses for presynaptic inhibition may be enhanced. 3) conduction may fail presynaptically at regions of relatively lower conduction safety along axons or in axonal teledendra. Or as suggested below, 4) activity-dependent processes in neuronal membranes may be disturbed.

The action of local anesthetics (chloroprocaine, lidocaine, bupivacaine), volatile inhalational agents (halothane and nitrous oxide) and general anesthetics administered by injection (ketamine) has been studied on single frog sciatic axons in vitro. The threshold, conduction latency, and waveform of the action potential recorded through suction electrodes were monitored as a function of anesthetic concentration over the range in which anesthesia occurs in amphibians, mice, and humans. For the several agents studied to date, it has been consistently observed that activity-dependent processes are inhibited at concentrations 3 to 5 times lower than those required to elevate resting threshold, to slow conduction or to diminish the action potential by an equivalent percentage. Superexcitability is a lowering of threshold by 5 to 50% that reaches a maximum within 20 msec following impulse discharge and recovers to baseline over about 1 sec. The magnitude and duration of superexcitability following single impulses or trains of 8 pulses was reduced by all agents at anesthetic concentrations. Similarly depression, a phase of raised threshold which builds up as activity rates exceed 1 pulse every 2 sec and recovers over several minutes to an hour or more following a period of activity at 2-4 Hz, became undetectable at concentrations 1/3 to 1/10 those required to block impulse conduction. Individual fibers showed marked variations in susceptibility, but reduced activity-dependence was consistently the first detectable event associated with the presence of the drug.

Even under conditions where anatomical connectivity as tested by reflexes is not altered by the anesthetic, a reduced activity-dependence may disrupt the normal relation between patterns of impulse activity and dynamic connectivity of the nervous system, leading to the incapacity to make sense of environmental stimuli. The hypothesis that disruption of activity-dependent changes in nerve membrane is the basis of general anesthesia makes the testable prediction that an agent that diminishes activity-dependence should produce unconsciousness and prevent short term memory even if it does not suppress or block impulse conduction.

320.11 TEMPORAL ORDER AND BLOCKING IN A NEURAL NETWORK MODEL OF CLASSICAL CONDITIONING. D.S. Levine, Department of Mathematics, University of Texas at Arlington, Arlington, TX 76019.

This numerical work tests a classical conditioning model based on a neural network with associative ("Hebbian") modifiable synapses. It has been claimed (Sutton, R. and Barto, A., Psych.Rev. 88: 135,1981) that such a model could not simultaneously explain two sets of data: that the conditioned response (CR) precedes (anticipates) the unconditioned stimulus (US), and that the optimal time interval between conditioned stimulus (CS) and US is larger than zero. The argument was that the optimal CS-US interval in a network with associative synapses will be zero unless the network includes a certain delay, and this delay will prevent the CR from preceding the US. To overcome this difficulty, these authors proposed a more elaborate synaptic modification rule and two traces for each stimulus.

Computer simulations were done to test an alternative neural explanation for these data, one which uses the "Hebbian" rule and involves no delays. The poor conditioning when CS and US are less than 500 msec apart was seen as an example of blocking, where one stimulus is masked by another, more salient, stimulus. In this case, the US itself blocks the CS. A model neural network with associative synapses (Grossberg, S., Int. Rev. Neurobiol. 18: 263, 1975) was shown capable of reproducing both the anticipatory CR and the non-zero optimal CS-US interval. The same network could also reproduce conventional blocking data: first, $CS_1$ is conditioned to the US; then, $CS_1$ and $CS_2$ are presented together repeatedly, followed each time by the US; finally, $CS_2$ is presented and no CR occurs.

320.12 NEURAL DYNAMICS OF ADAPTIVE PATTERN RECOGNITION: PRIMING, SEARCH, ATTENTION, AND CATEGORY FORMATION. G.A. Carpenter* and S. Grossberg. Center for Adaptive Systems, Boston Univ., Boston, MA 02215.

We show how a neural network can learn recognition categories by building up bottom-up codes and top-down expectancies in response to a temporal stream of input patterns. The internal representations formed in this way stabilize themselves against recoding in response to irrelevant input patterns by using the matching properties of the learned top-down expectancies. This code-stabilizing mechanism also suppresses noise in the input patterns, and can subliminally prime a network to anticipate an input pattern or class of input patterns.

A nonspecific vigilance, or attentional, parameter determines how fine the learned categories will be. If, for example, vigilance increases due to a negative reinforcement, then the system will automatically search for and learn finer recognition categories. Although a novel input pattern may automatically engage the top-down matching and parallel search mechanisms of the network, once a recognition category for the input pattern is established, the input pattern can access the category directly on future recognition trials.

This search mechanism is not a serial mechanism. Rather, it is driven by the engagement of a nonspecific orienting burst that is contingent upon a prior mismatch event. This orienting reaction has been used to explain and predict properties of the mismatch negativity, processing negativity, and P300 evoked potentials and noradrenergic involvement in cortical plasticity.

The model's flexible and dynamic relationship between matching, orienting, attention, and learning proves its worth by very rapidly learning and self-stabilizing perceptual categories of any prescribed refinement. The coarseness of the categories is in no respect prewired, nor is an identity match performed. In fact, the learned top-down expectancies become more abstract as the categories become broader. The learned code is an emergent property of the total network response, given a prescribed level of attentional tuning.

## LEARNING AND MEMORY: ANATOMY IV

321.1 MORPHOLOGICAL BASIS OF SHORT-TERM HABITUATION IN APLYSIA. C.H. Bailey and M. Chen. Ctr. for Neurobiol. & Behav., Depts. Anat., Neurol. and Psychiat., Columbia Univ., P&S, and NYS Psychiat. Instit., N.Y., N.Y. 10032.

To complement our ultrastructural studies of long-term habituation and sensitization in Aplysia (Science, 220:91), we have begun a quantitative analysis of the structural events at identified sensory neuron synapses that may accompany a short-term memory trace.

Utilizing an in vitro preparation, we have labeled identified synapses by intrasomatic injections of small amounts of HRP while simultaneously producing short-term habituation in individual cells employing single, massed training protocols of either 1-35 (isi=30 secs) or 1-250 (isi= 10 secs) stimuli. The sensory-to-follower cell EPSP was monitored throughout and in all cases demonstrated significant depression (compared to trial 1) at the end of training. Immediately following the last stimulus, the desheathed abdominal ganglion was fixed with 6% glutaraldehyde. Parallel ganglia treated exactly the same but without training served as controls. Following histochemical processing, postfixation and embedding, serial thin sections were taken through each ganglion and labeled sensory neuron varicosities were reconstructed and analyzed through a blind procedure. Eight sensory neurons from eight different animals, 4 untrained cells as controls and 4 cells trained for short-term habituation, were used in this study. To examine in detail the fine structure of synaptic terminals of each cell, we completely reconstructed 422 sensory neuron varicosities.

We focused our analysis, as we had in our long-term studies, on the active zones at sensory neuron varicosities. Both the incidence as well as the total surface area of active zones were unchanged between control and habituated cells, although habituated cells in the 1-250 group did show a trend towards reduced active zone area compared with their controls. To facilitate an analysis of the relationship between the active zone and neighboring synaptic vesicles, we divided the volume of the sensory neuron varicosity immediately above each active zone into different sectors. The total vesicle population was defined as all vesicles within a vertical distance of 240 nm (the approximate height of 3 vesicles) over the entire active zone area. A readily releasable pool was defined as all vesicles that came within 30 nm of the presynaptic active zone membrane. At habituated terminals the releasable pool was half that found at control terminals (7.6 $\pm$ 0.6 S.E.M. vs. 14 $\pm$ 0.8, 1-35 and 6.7 $\pm$ 1.4 vs. 15.8 $\pm$ 1.6, 1-250). The ratio of releasable to total vesicles was .26 and .30 for control cells but only .11 at the terminals of habituated cells, suggesting that an impairment in vesicle mobilization at sensory neuron active zones may contribute, in part, to the synaptic decrement that underlies homosynaptic depression.

These data indicate that a short-term memory trace can be specified in morphological terms and provide additional insights into the family of structural changes at sensory neuron synapses that may contribute to the progressive development of memory storage.

321.2 LONG-TERM HABITUATION OF ACOUSTIC STARTLE AND LICK SUPPRESSION FOLLOWING LESIONS OF THE CEREBELLAR VERMIS. R. N. Leaton and W. F. Supple, Jr. Department of Psychology, Dartmouth College, Hanover, N.H. 03755.

Mechanisms for short-term habituation of the acoustic startle response are apparently intrinsic to the S-R pathway in the lower brainstem and involve some form of synaptic depression within that pathway (Davis et al., 1982; Thompson & Spencer, 1966). Long-term habituation in this response system seems to involve an extrinsic inhibitory mechanism (Jordan & Leaton, 1983), but little is known of its anatomical locus. We have recently shown (Supple & Leaton, 1984) that the vermis of the cerebellum is essential for long-term habituation of the acoustic startle response. The present experiments extend these earlier findings (1) by examining the response specificity of the effects and (2) by testing at two stimulus intensities to avoid confounding floor and ceiling effects.

In Experiment 1 the acoustic startle response and lick suppression were measured simultaneously to 1-sec, 10-kHz pure tone stimuli in rats with partial aspirations of the cerebellar vermis (n=10) and sham operated rats (n=10). Six stimuli were presented on an approximately 10-sec ISI in each of 5 daily sessions. Long-term habituation was assessed by the response decrements across days. The vermis lesioned rats failed to show long-term habituation of the acoustic startle response, replicating our previous findings. Both groups showed significant long-term habituation of lick suppression. Thus the effects of vermal lesions on long-term habituation are at least partially response specific.

In Experiment 2 independent groups of vermal lesioned and sham operated rats were tested at two intensities of a 1-sec white-noise startle stimulus (97 or 107 dB). Testing was given in two one-trial sessions on each of 8 days and retests were given following tests for short-term habituation. Vermal lesioned animals failed to show significant long-term habituation at either test intensity. Initial response levels and short-term habituation were not affected by the vermal lesions. Activity samples taken during the startle sessions revealed no differences between vermal lesioned and control groups. The conclusion that vermal lesions block long-term habituation of the acoustic startle response is not confounded by floor or ceiling effects or by differences in general activity during startle sessions.

321.3 **INTRINSIC NEURONS IN THE AMYGDALOID FIELD INNERVATED BY THE MEDIAL GENICULATE NUCLEUS MEDIATE CLASSICAL FEAR CONDITIONING IN THE RAT.** J. Iwata, J.E. LeDoux, D.J Reis. Lab of Neurobiology, Cornell Univ. Med. Coll., NY, NY 10021

Although the auditory cortex is generally believed to be the principal efferent target of the medial geniculate nucleus (MG), we have found that neurons in the MG also project to a striatal field (STR) involving the caudal neostriatum (caudate-putamen; CPU) and archistriatum (dorsal amygdala; AMY) (LeDoux et al, J. Neurosci. 4: 683-698, 1984; LeDoux et al, this vol.). Interruption of these connections by electrolytic lesion of one MG and the contralateral STR disrupts the conditioning of emotional responses to acoustic stimuli (LeDoux et al, Ann. N.Y. Acad. Sci., in press). Destruction of intrinsic neurons in STR by injection of ibotenic acid (IBO) also disrupts conditioning when the contralateral MG is lesioned (Iwata et al, Neurosci. Abs. 1984). In the present study we have sought to determine whether conditioning is mediated by intrinsic neurons in the AMY or CPU portion of STR.

Rats were prepared with unilateral electrolytic lesions of MG. Contralaterally, IBO (0.15 ul; 15 ug/ul) was injected into the posterior CPU (n=11) or dorsal AMY (n=23). Controls were unoperated (n=16) or received unilateral MG lesions with vehicle injections (0.3ul of 0.2M phosphate buffer; ph, 7.4) in the center of the contralateral STR (n=13). After 14 d the animals were instrumented for computer assisted recording of arterial pressure (AP) and subjected to classical conditioning procedures involving the pairing of a pure tone (800 Hz, 82 db, 10 sec) with footshock (1.7 mA; 0.5 s). The next day CS elicited changes in AP and the duration of activity suppression ("freezing") were measured during extinction trials presented in the animal's home cage. The animals were sacrificed and the brains removed and processed using standard histological procedures. The lesions were reconstructed and localized using a computer based image analysis system.

In unoperated controls the CS elicited increases in AP (20 ± 3 mmHg) and induced freezing (106 ± 3 sec). These responses were unaffected by MG lesions combined with injection of vehicle in the STR or combined with injection of IBO in the CPU. Lesion of the MG combined with injection of IBO in the contralateral amygdala had no effect in 12 rats but in 11 additional rats reduced both the AP (6 ± 1 mmHg) and freezing (30 ± 8 sec) responses by more than 2 standard deviations relative to the vehicle control group.

Computer analysis of lesion location revealed that the effective AMY lesions consistently damaged dorsal portions of the central nucleus and the overlying fundus striati. Ineffective lesions overlapped the location of effective lesions but occupied far less volume (effective: 2.14 ± 0.64 $mm^3$; ineffective: 0.64 ± 0.15 $mm^3$; p .01). CPU lesions (2.39 ± 0.37 $mm^3$) were similar in size to effective AMY lesions.

Thus, selective destruction of intrinsic neurons in the amygdaloid field innervated by the MG disrupts fear conditioning when the contralateral MG is destroyed. Fear conditioning is therefore medidated by projections from MG to the amygdala. (Support: Am. Heart Assoc. and NIH-NHLBI)

321.4 PARASAGGITAL KNIFE CUTS LATERAL TO THE BED NUCLEUS OF THE STRIA TERMINALIS AND MEDIAL TO THE AMYGDALA SEVERELY ATTENUATE THE CARDIAC ORIENTING REFLEX AND CLASSICALLY CONDITIONED BRADYCARDIA IN THE RABBIT. Paula Skedsvold* and D. A. Powell (SPON: J. Freeman). Neuroscience Lab., WJB Dorn VA Hospital and University of S. C., Columbia, SC

Using a Kopf Scouten knife assembly one group of New Zealand albino rabbits received bilateral knife cuts which were 2 mm from the midline and extended from 1-2 mm in front of the anterior commissure to a posterior location just in front of the anterior preoptic area. A second group received sham cuts in which the knife assemby was lowered into the brain but no cut was made. After a 1-2 wk recovery period all animals were subjected to a 30 min session in which the cardiac orienting reflex (OR) was assessed and 2 subsequent sessions of classical conditioning in which heart rate (HR) was assessed on a beat x beat basis. Orienting was assessed in response to successive presentations of twenty 75 dB, 1216 Hz, 4-sec duration tones separated by a 90-sec intertrial interval. HR was assessed for 10 beats prior to tone onset, for the entire duration of the 4-sec tone, and for 10 beats following tone offset. The first day of classical conditioning began immediately followed the assessment of the cardiac component of the OR. During conditioning 25 presentations of the 1216 Hz tone and 25 presentations of a 304 Hz tone were presented in a random order. One of the tones was consistantly followed by a 3 mA paraorbital electric shock as the unconditioned stimulus. HR was assessed as during orienting. A third group of sham animals received a random sequence of the tones and shocks, viz., the tones and shocks were not paired as during classical conditioning. This group served as a pseudoconditioning control group.

The results revealed that animals which received parasaggital knife cuts, as described above, showed very little HR change in response to either CS+ or CS- compared to sham animals which revealed HR slowing as the conditioned response. Animals with knife cuts also revealed an attenuated bradycardiac OR compared to sham animals. These cuts severed fibers comprising the sublenticular and posterior internal capsule carrying information from prefrontal cortex, insular cortex, and amygdaloid structures which have been implicated in autonomic control. Together with other lesion and stimulation studies from our laboratory, the present findings suggest that these forebrain structures are involved in a sensory processing mechanism which elicits primary bradycardia in response to either novel stimuli or nonaversive stimuli that have been consistently reinforced with an aversive stimulus and thus come to serve as signals for noxious stimulation.

321.5 AMYGDALA CENTRAL NUCLEUS AS MEDIATOR OF DIFFERENTIAL PAVLOVIAN CONDITIONING OF BRADYCARDIA IN RABBITS. C.G. Gentile*, T.W. Jarrell*, A.H. Teich*, P.M. McCabe and N. Schneiderman. Dept. of Psych., Univ. of Miami, Coral Gables, FL 33124.

The present study examined the role of amygdala central nucleus (ACE) in the retention of differential Pavlovian conditioning of bradycardia in rabbits. It has been demonstrated that ACE lesions produce a marked impairment in the acquisition of the bradycardia conditioned response (Kapp et al., Physiol. Behav., 23:1109, 1979). Furthermore, auditory stimuli paired with eye shock elicit different patterns of ACE single unit firing than unpaired stimuli (Pascoe and Kapp, Neurosci. Abs., 10:602, 1984). These data suggest that ACE may mediate differential bradycardia conditioned responses.

Electrodes were implanted bilaterally in ACE or in control sites just dorsal and rostral to ACE. Two days following surgery, animals were subjected to differential Pavlovian conditioning in which one tone (CS+) was paired with periorbital shock and a second tone (CS-) was presented alone. Each animal received one conditioning session per day until evidence of differential heart rate (HR) responding was obtained. Bilateral electrolytic lesions were then made. Thirty minutes after lesioning, animals received an additional conditioning session.

Both control and ACE groups demonstrated differential HR responses prior to lesioning. In the control group, lesions had no effect on differential HR responses or bradycardia response magnitude. However, the ACE lesion group failed to demonstrate differential HR responses after lesioning. Furthermore, bradycardia conditioned response magnitude was greatly attenuated. In both groups, lesions had no effect on the HR orienting response, unconditioned response, or baseline.

These findings suggest that ACE plays a role in the retention of differential Pavlovian conditioning of bradycardia in rabbits. Bilateral ACE lesions abolished differential HR responses and profoundly attenuated bradycardia response magnitude.

321.6 THE MEDIAL GENICULATE NUCLEUS AS MEDIATOR OF DIFFERENTIAL PAVLOVIAN CONDITIONING OF BRADYCARDIA IN RABBITS. T.W. Jarrell*, C.G. Gentile*, P.M. McCabe, and N. Schneiderman. Dept. of Psych., Univ. of Miami, Coral Gables, FL 33124.

The present study examined the role of the medial geniculate nucleus (MGN) in the mediation of differentially conditioned bradycardia responses to auditory stimuli in rabbits. Kapp et al. (Physiol. Behav., 23:1109, 1979) provide evidence that the central nucleus of the amygdala (ACE) plays an important role in the acquisition of classically conditioned bradycardia in rabbits. In addition, there is evidence that an auditory stimulus that has previously been paired with eyelid shock elicits different patterns of ACE unit firing than one that has not been paired with shock (Pascoe and Kapp, Neurosci. Abs., 10:602, 1984). These data suggest that ACE may receive information about auditory conditioned stimuli that is important for differential responding.

Intial injections of horseradish peroxidase into the ACE produced cell body and fiber labeling at the ventral and medial borders of MGN. The role of this region in the mediation of differential Pavlovian conditioning of heart rate (HR) decelerations and corneo-retinal potential (CRP) responses was then examined. Bilateral electrolytic lesions were made in the medial portion of MGN or in control sites dorsal or rostral to MGN. Ten days following surgery, lesioned animals and unoperated control animals were subjected to 7 days (1 session/day) of differential Pavlovian conditioning consisting of trials in which one tone (CS+) was paired with periorbital shock and a second tone (CS-) was presented alone. The 7 acquisition days were followed by 2 days of extinction in which both tones were presented alone.

Each group demonstrated bradycardia responses to both the CS+ and CS-. In the control-lesion and unoperated groups, the CS+ consistently elicited larger bradycardia responses than the CS-. However, animals with bilateral MGN lesions did not demonstrate differential bradycardia responses. In the MGN group, bradycardia responses to both the CS+ and CS- were similar in magnitude to responses to the CS- in the control-lesion and unoperated groups. Evidence of CRP differential conditioning was present in each group.

The present findings suggest that a region just medial to MGN or fibers passing through this region selectively mediate HR differential conditioning in rabbits. The fact that bradycardia responses are still present after lesions at the medial border of MGN suggests that other auditory regions may also be involved in the mediation of the bradycardia conditioned response.

321.7 THE SEPTO-HIPPOCAMPAL ROLE IN THE ACQUISITION OF TASTE POTENTIATED ODOR AVERSION LEARNING. F. Bermudez-Rattoni, G. Roldan*, M.A. Sanchez* and M.L. Marquez. Departmento de Fisiologia. Centro de Investigaciones en Fisiologia Celular, Universidad Nacional Autonoma de Mexico.

In flavor-aversion conditioning, odor (O) and taste (T) display different parameters of conditioning. O must be paired with immediate toxic injections but T can be followed by delayed toxin. However, when an OT compound is followed by delayed toxin, the O component becomes aversive indicating it has been potentiated by the T component.

In testing a neural model for the potentiation of O by T, it was shown that "reversible" and irreversible lesions of the amygdaloid complex disrupts potentiated O aversions but not T aversions. Moreover, we have demonstrated that the cholinergic limbic system is apparently involved in the potentiation of O by T in toxic conditioning. Thus agonists and antagonists of cholinergic activity, applied in the dorsal hippocampus or amygdala affect O-toxin associations more than T-toxin associations. In the present experiment, the role of the septal area and the doral hippocampus were tested in the conditioning of potentiated odor by taste aversions. Four groups of rats were given large electrolytical lesions, bilaterally in the dorsal hippocampus (BH), unilaterally in the dorsal hippocampus (UH), bilaterally in the septal area including medial and lateral areas (S) and sham operations (SH). Following postoperative recovery, each group received OT acquisition; almond odor and saccharin were combined into a drinking solution and followed by delayed lithium chloride (190 mg/kg, i.g.).

Extinction tests with almond odor alone and saccharin alone showed that the SH group developed strong O and T aversions, however S and BH lesion groups showed a significant disruption of the O aversion when compared to the SH controls and UH groups. (All groups exhibited strong taste aversions.)

These preliminary results suggested that the septo-hippocampal system are particularly involved in the process by which the odor is indexed into the visceral system.

321.8 DISRUPTION OF NEOPHOBIA, CONDITIONED ODOR AVERSION AND CONDITIONED TASTE AVERSION IN RATS WITH HIPPOCAMPAL LESIONS. J.S. Miller*, A.J. Nonneman, K.S. Kelly*, J.L. Neisewander* and W.L. Isaac*. Psychology Dept., Univ. of Kentucky, Lexington, KY 40506.

Many studies have implicated limbic system structures, including the hippocampus (HPC), in the control of flavor aversion learning. Flavor aversion conditioning consists of pairing a distinctive flavor (CS) with illness (US). Since flavor consists of both odor (O) and taste (T) components, this aversion may develop to either the O or T elements of a flavor. Few studies have examined the role of the hippocampus in odor aversion learning, but physostigmine injections into the dorsal HPC disrupt conditioned odor aversions (Bermudez-Rattoni & Garcia, Soc. Neurosci. Abstr., 10:256, 1984). The effects of HPC lesions on taste aversion conditioning seem to depend on the strength of conditioning (Nonneman & Curtis, Physiol. Psychol., 6:249-256, 1978). Weakly conditioned T-illness associations are disrupted and strongly conditioned associations remain unaffected.

Relative to T, O serves as a weak cue for conditioning aversions. However, when O and T are conditioned in compound, the subsequent aversion to the odor cue alone is often stronger than if O had been conditioned alone. This phenomenon is known as taste potentiated odor aversion. In this study we tested the hypothesis that HPC lesions would disrupt taste potentiated odor aversions less than odor aversions.

Each rat received a bilateral electrolytic HPC or sham lesion. During conditioning, half the rats in each group were exposed to the compound O-T CS (1.5% almond extract + .1% saccharin) for 15 min. followed by an i.p. injection of LiCl (64 mg/kg) or saline. The other half was exposed to the O CS alone followed by LiCl or saline. On test days, all rats were exposed to the O CS alone to assess the strength of learned odor aversions. On the final test day the rats that had been conditioned to the O-T compound were exposed to the T CS (.1% saccharin) alone to determine the strength of any acquired taste aversion. The HPC lesions eliminated the neophobic response to the O CS and significantly reduced neophobia to the O-T CS on the first CS exposure. The lesions also eliminated conditioned odor aversion and significantly attenuated acquired taste aversion.

321.9 THE EFFECT OF MATERNAL BEHAVIOR SENSITIZATION OR EXPOSURE TO PUPS ON PROTEIN PHOSPHORYLATION IN THE FEMALE RAT AMYGDALA. P.J. Brooks*, B. Bank*, H. Steiman* and D.L. Chute. Department of Psychology and the Division of Life Sciences, University of Toronto, Toronto, Ontario, Canada M1C 1A4.

Work in this laboratory has focused on the relationship between behavioral plasticity and protein phosphorylation in the brain. The purpose of the present study was to determine whether changes in protein phosphorylation could be demonstrated as a result of maternal behavior sensitization (MBS). MBS is the phenomenon in which virgin female rats, which initially avoid newborn pups, will come to show maternal behavior following several days of pup exposure. An additional aim of this work was to determine the effect of pup exposure alone on brain protein phosphorylation.

Twelve female rats were cast into three behavioral groups (n= 4 per group). One group received no pup exposure and served as a control (group C). The remaining subjects were tested daily for maternal behavior using three rat pups (2-8 days old). Four animals were allowed pup exposure until they became fully maternal (sensitized-group S), while pups were removed from the other four animals before any maternal behavior was exhibited (pup exposed-group E). Rats were killed by decapitation, the heads were immediately frozen in liquid $N_2$ and stored at -70 until biochemical processing. Based on lesion studies suggesting the importance of the medial preoptic area (MPOA) and corticomedial amygdala (CMA) in MBS[1], these areas were dissected out along with a portion of frontal cortex (FC) as a control brain area. Tissues from all animals in a behavioral group were pooled and homogenized. Samples from the different brain areas were incubated with $\gamma P^{32}$-ATP and analyzed using SDS-PAGE followed by autoradiography and optical density scanning.

No reliable between group differences were seen in the MPOA or FC. In the CMA, $P^{32}$ incorporation into a protein band of Mr 23K was 2-3 fold greater in groups S and E compared to group C. No differences were seen between groups S and E in the CMA.

These results suggest that exposure of female rats to pups can result in phosphorylational changes in the brain similar to those seen in several learning and neuroplastic paradigms. Further work is needed to determine the relationship between the phosphorylation changes seen in the study and the behavioral changes which occur in MBS.

321.10 CEREBELLAR INTERPOSITUS/DENTATE NUCLEI AFFERENTS SEEN WITH RETROGRADE FLUORESCENT TRACERS IN THE RABBIT. J.K. Thompson*, D.G. Lavond & R.F. Thompson. Dept of Psychology, Stanford University, Stanford, CA 94305.

Recent behavioral experiments have demonstrated an essential role of the deep cerebellar nuclei in learning and memory. Lesions of the nuclei prevent or abolish classical conditioning of the rabbit eyelid response without affecting the unlearned reflexive response caused by corneal airpuff. Evidence suggests that the cerebellum may be the site of neuronal plasticity associated with this learning and memory--the "engram". Lesions of the climbing fiber (inferior olive) input prevent learning or cause extinction of an already learned response. Direct stimulation of the dorsolateral pons or of the lateral reticular nucleus act as effective conditioned stimuli while stimulation of the IO acts as an effective unconditioned stimulus.

The present experiment was designed to survey the possible routes of auditory input to the deep nuclei. The route of a naturally occuring CS (i.e., tone) is uncertain. A total of 26 rabbits were anesthetized and stereotaxically injected with fluorescent tracers into the deep nuclei (N=24) or overlying cerebellar cortex (N=2). The dyes used included bisbenzimide, propidium iodide, Evans blue, True Blue, Nuclear Yellow and Fast Blue. The rabbits were allowed to survive for 18 hours to 3 weeks depending upon the transport rate of the dye. Most rabbits were injected with a different fluorescing dye on each side.

Labelled cells were commonly found within the inferior olive contralaterally, the pontine nuclei bilaterally, the trigeminal sensory and spinal nuclei bilaterally, and the lateral reticular nucleus bilaterally. In addition, cells were labeled at many levels throughout the reticular formation, in the perihypoglossal nuclei, in nucleus ambiguous, in the raphe, in the cuneate nucleus, in vestibular nuclei, in the red nucleus contralaterally, and occassionally in the nuclei surrounding the superior olive.

There was a noticeable absence of direct auditory projections from the cochlear nuclei, the superior olive, the trapezoid nucleus, and the nuclei of the lateral lemniscus. Double labelled cells were found in the lateral reticular, reticular, and trigeminal nuclei. A few ipsilateral cells were found in the IO and in the VIIIth nerve. A number of labelled cells were found in the contralateral cerebellum. More lateral injection of the nuclei resulted in predominantly ipsilateral labelling in trigeminal nuclei, and less labeling of dorsolateral pons and the lateral reticular nucleus.

321.11 A COMPARISON OF CEREBRAL ACETYLCHOLINE OR SOMATOSTATIN DEPLETION ON AVOIDANCE CONDITIONING, ACTIVITY AND WORKING MEMORY IN RATS. G.R. Sessions, M.D. Matthews*, N. Swerdlow, C. Bakhit* and G.F. Koob. Department of Behavioral Sciences and Leadership, U.S. Air Force Academy, Colorado Springs, CO 80840, and Division of Preclinical Neuroscience and Endocrinology, Scripps Clinic and Research Foundation, La Jolla, CA 92037.

Decreases in cortical achetylcholine (ACh) and degeneration of cholinergic neurons of the nucleus basalis of Meynert have been linked with senile dementia of the Alzheimer's type. Decreases in cortical somatostatin have also been observed in Alzheimer's patients. Lesions of the nucleus basalis magnocellularis (NBM) in the ventromedial region of the globus pallidus of the rat have been shown to reliably deplete markers for cortical ACh. Intracerebroventricular (ICV) injections of cysteamine have similarly been demonstrated to reliably deplete hypothalamus, hippocampus, and cortex of somatostatin. Both of these procedures have been shown to induce deficits in passive avoidance retention in rats. In an effort to further the investigation of the usefulness of animal models in the study of Alzheimer's Disease, we compared the effects of depletion of cerebral ACh or somatostatin on tasks involving learning, working memory, and activity in the rat.

Rats received bilateral lesions of the NBM via intracerebral injections of ibotenic acid or depletion of somatostatin by ICV administration of cysteamine. Activity testing and active avoidance conditioning were conducted in a two-compartment shuttle box. The active avoidance task involved a one-way procedure utilizing a light CS. The test of working or short-term memory involved measuring spontaneous alternations in a Y-maze.

Results revealed that the NBM-lesioned animals were significantly more active in the shuttlebox, exhibited significantly fewer alternations in the Y-maze, but showed no differences in active avoidance acquisition as compared with their controls. The cysteamine-injected animals sustained significant depletions of somatostatin in cortex, hippocampus and hypothalamus (25-59 per cent) but showed no deficits on any of these measures.

These results are consistent with previous work showing increased activity and working memory deficits in rats with lesions of the NBM. Findings suggesting deficits in active avoidance conditioning were not supported. Failure to obtain deficits in somatostatin-depleted animals on measures of working memory and active avoidance acquisition suggests that memory deficits observed in such animals may be limited to consolidation processes.

321.12 EFFECTS OF TRAINING ON A REACHING TASK ON DENDRITIC BRANCHING IN THE NEOCORTICAL REGION OF HIGHEST METABOLIC ACTIVITY DURING REACHING PERFORMANCE. G. S. Withers, J. R. Larson, and W. T. Greenough. (Spon: S. Balagura) Depts. Psychol. & Anat. Sci. and Neur. & Behav. Biol. Prog., Univ. Illinos, Urbana-Champaign, IL 61820 & Dept. Psychobiol. Univ. Calif., Irvine, CA 92717.

A previous study indicated larger layer V pyramidal neuron apical dendritic fields in dorsolateral anterior cortex opposite trained forelimbs following unilateral or bilateral training of rats to reach into a tube for food (Larson & Greenough, Soc. Neurosci. Abstr., 7, 65, 1981). In that study, the neocortical sample region was that of lowest threshold for elicitation of forelimb movement by epidural electrical stimulation, the location of which varied considerably across subjects. More recent analyses of 2-deoxyglucose uptake during reaching have indicated a very precise and consistent anterior cortical region of high activity (Fuchs et al., Soc. Neurosci. Abstr., 9, 54, 1983). In the present experiment we quantified apical dendritic branching of neurons in that region. Young adult rats were trained, over 33 50-reach sessions, to reach with the preferred forepaw (PRAC), the nonpreferred forepaw (REV), both forepaws (ALT), or nontrained (CONT). The cortical region identified in the 2DG study was projected onto Golgi sections through anterior cortex and apical dendritic branching of layer Va and Vb pyramidal cells within it was analyzed. The number of branches at each order of bifurcation from the apical dendrite, the length of terminal and bifurcating branches, and total dendritic length were analyzed. There were sublaminar differences, but no interactions of laminar position with training condition, so data from Va and Vb neurons were pooled. Results indicated more extensively branched apical dendritic fields, with longer terminal branches and more bifurcations, in hemispheres opposite trained forelimbs across all groups. Trained vs. nontrained hemisphere differences in the between subject (ALT vs. CONT) comparisons were larger than in the within subject comparisons (trained vs nontrained hemispheres of PRAC + REV), but significant effects of training were seen in both cases. Within groups, ALT and CONT showed no significant interhemispheric differences, while the trained hemispheres of REV rats had significantly more total dendritic length, more branches across all orders, and more second order branches than untrained hemispheres; those of PRAC rats had significantly more second order branches. This supports previous findings that training alters dendritic branching of adult neocortical neurons. The within subject effects of training are unlikely to arise from general hormonal or metabolic consequences of training, as opposed to events specific to the hemisphere governing movement of the trained forelimb. Supported by NSF BNS82-16916.

321.13 NEURAL SUBSTRATES OF SPONTANEOUS EXPLORATORY BEHAVIOR. L. D. Devenport and R. L. Hale* Department of Psychology, University of Oklahoma, Norman, OK 73019.

Within even the most stable terrestrial habitat, mammals may expect to experience unheralded change. Adjustment to such fluctuations is probably the basis for the small but continuous rate of spontaneous exploration that they emit without provocation. This behavior permits detection of more favorable places, times, rates, topographies, and so forth (Devenport, 1983). The neural basis of exploration of any kind--with the notable exception of novelty-induced spatial exploration (O'Keefe & Nadel, 1978)--has received little study. The present experiments examined the relative contributions of prefrontal cortex and the hippocampus to the production of spontaneous exploration along three dimensions.

Lesions were produced by aspiration or electrolysis and were intended to be complete. Rats with parietal ablations and sham operations served as controls. Exploratory activities chosen for observation were 1) temporal exploration of barpress rates in an operant chamber involving the degree of sampling of interresponse intervals; 2) route exploration within the radial arm maze indexed by the variety of successive arm choices; 3) standard instances that included rearing, visual scanning, sniffing, etc. Reward contingencies were established that neither favored or impeded the expression of exploratory responses: A reward replacement procedure was used in the maze, a random-interval schedule in the operant setting. Data were gathered from 16 days of observation.

Rats bearing hippocampal lesions exhibited very limited exploration of any sort, each category being significantly lowered to about the same extent relative to controls. Prefrontal damage yielded a single mild impairment of route investigation in the maze. The effects on exploration were not accompanied by other performance impairments as measured by such conventional indices as running time or barpress rate.

These results suggest that spontaneous exploration, along a variety of dimensions, as well as that induced by novelty (O'Keefe & Nadel, 1978), may be controlled by a limited part of the CNS.

321.14 EFFECTS OF DORSAL AND MEDIAL CORTEX LESIONS ON THE ACQUISITION AND RETENTION OF A GO-NO-GO DISCRIMINATION BY TURTLES. W. Grisham* and A. S. Powers. Bryn Mawr College, Bryn Mawr, PA 19010.

The telencephalon of turtles and other reptiles has 3 areas that are designated as being cortical; the lateral or pyriform cortex, the dorsal cortex (DC), which has been designated as a visual/general cortex, and the medial cortex (MC), which has been described as being equivalent to the hippocampus.

A deficit in the reversal of a simultaneous pattern discrimination after dorsal cortex lesions has previously been reported by this lab. It was hypothesized that the basis for this reversal deficit was an inability to withhold responses to the S-. Accordingly, DC lesions were made in animals that had already learned a go-no-go pattern discrimination ($n = 4$). It was predicted that if DC lesions resulted in an inability to withhold responses, performance on the discrimination would deteriorate post-operatively. The effects of DC lesions were compared to those of medial cortex lesions ($n = 4$) and sham lesions ($n = 3$). All animals showed nearly perfect retention post-operatively. The hypothesis was therefore rejected.

The experiment was repeated with animals that had no preoperative training. The performance of animals with DC lesions ($n = 4$) was compared to the performance of animals with MC lesions ($n = 3$) which were both compared to the preoperative data of the subjects in the previous experiment as well as added shams ($n = 2$). Animals with DC lesions required a greater number of days of training to reach criterion relative to controls ($t = 2.71$, $p < .05$). No consistent effect of MC lesions was found.

Since no retention deficit was found, the underlying basis for this acquisition deficit cannot be either a loss in motor function or a motivational loss. Also, since DC-lesioned animals showed good differential response latencies between the S+ and S- (despite the deficit), a sensory impairment seems unlikely. It is concluded that the deficit was associative and arose as a result of a retardation in the acquisition of excitatory stimulus properties by the S+. Further, this study shows that the dorsal and medial cortex are functionally different.

322 SYMPOSIUM. TOWARDS A SECOND GENERATION UNDERSTANDING OF NEURAL CIRCUITS: THE ROLE OF MODULATION. E. Marder, Brandeis University (Co-Chairperson); J. C. Weeks, UC Berkeley (Co-Chairperson); P. A. Getting, University of Iowa; R. L. Calabrese, Harvard University.

What do we need to know to understand how a neuronal circuit actually operates, either to generate behavior or process information? Previously, conventional wisdom held that it was only necessary to identify the constituent neurons of a circuit and describe their synaptic interactions and intrinsic excitability characteristics. However, in recent years it has become clear that these properties are contingent upon many variables including the presence of hormones and neuromodulators. In this symposium we will use several well-characterized invertebrate preparations to illustrate that modulation of neuronal excitability, synaptic strength, and dendritic structure (features previously assumed to be relatively invariant) enables neuronal circuits to express a variety of outputs or "states", both during development and in the mature animal. Comparison of circuits with quite different functions, from a variety of phyla (molluscs, arthropods and annelids), will allow us to articulate for the general audience the novel principles emerging from the second generation of study of small neuronal circuits. The speakers will presuppose no knowledge of the peculiarities of their preparations, but will illustrate basic concepts derived from them.

J.C. Weeks will discuss the effects of blood-borne peptide and steroid hormones on neuronal structure and motor pattern output during metamorphosis of the tobacco hornworm, Manduca sexta. P.A. Getting will discuss the hypothesis that motor networks are not "hard-wired" but that inputs can reorganize the interactions within a network and thereby alter the function of the network. R.L. Calabrese will present data that show that the neuropeptide FMRFamide is present in the leech and that it affects the period of the heartbeat central pattern generator and the myogenic properties of hearts. E. Marder will present data from the stomatogastric ganglion of decapod crustaceans that show that a large number of different neurotransmitters and neuromodulators appear to act on the same neuronal circuit so that it can produce a variety of neural outputs.

323 **SYMPOSIUM: ORIGINS OF ORIENTATION SELECTIVITY IN MAMMALIAN VISUAL CORTEX. M.P. Stryker, Univ. of Calif. San Francisco, (Chairman); P.H. Schiller, M.I.T.; J.G. Malpeli, Univ. of Illinois; A.M. Sillito, Univ. Col., Cardiff; D. Ferster, Northwestern Univ.; P.P. Heggelund, Univ. of Oslo.**

**The mechanism by which cortical neurons construct oriented receptive fields out of the non-oriented visual input from the LGN is not fully understood. Hubel & Wiesel first proposed that orientation tuning arises from convergent excitation from geniculate neurons whose receptive field centers are aligned along the axis of orientation of the postsynaptic cell. In addition, the presence of ON and OFF regions in simple cell receptive fields suggests that presynaptic geniculate cells with ON- and OFF-center receptive fields are arranged in adjacent rows. Antagonism between the rows could contribute to the attenuation of cortical responses to non-optimally oriented stimuli. Intracellular studies of synaptic potentials in simple cells favor this view, since EPSPs and IPSPs are both well oriented, always having the same preferred orientation in any one cell (FERSTER).**

**That antagonism between ON- and OFF- center inputs plays little role in orientation selectivity is suggested by the observation that suppression of ON-center cells with intraocular APB has little effect on cortical orientation selectivity (SCHILLER). Not only does excitation alone appear to provide an inadequate explanation for orientation, but evidence will be presented for a contribution by inhibitory connections. Application of GABA antagonists to cortical cells can abolish orientation selectivity (SILLITO), suggesting that inhibition between neurons with different orientation preferences is important in establishing selectivity. Alternatively, the spatial arrangement of unoriented inhibitory inputs may contribute to orientation selectivity in a manner similar to that originally suggested for excitation from the LGN (HEGGELUND).**

**Whatever the mechanism, it appears that orientation selectivity is set up independently several times within a single column; inactivation of layer 4 after cobalt injections into the LGN leaves other cortical layers functioning almost normally (MALPELI).**

## MOLECULAR BIOLOGY OF GENE EXPRESSION AND NUCLEIC ACIDS V

324.1 CLONING OF A HUMAN CHOLINE ACETYLTRANSFERASE cDNA. W. Strauss, D. Hilt, C. Puckett*, J. Kamholz*, E. Neale, P. Nelson, and M. Nirenberg, Lab. of Dev. Neurobiol., NICHD, Lab. Biochem. Gen., NHLBI, Lab. Mol. Biol., NINCDS, NIH, Bethesda, MD 20205. L. Hersh, Dept. of Biochem., U. Texas Hlth Sci. Ctr, Dallas, TX. 75235.

A cDNA clone corresponding to human brain choline acetyltransferase (ChAT) has been identified tentatively by immunologic screening of a λgt11 library prepared from human basal ganglia mRNA. Approximately $2.75X10^5$ recombinant phage plaques were assayed for the production of β-galactosidase-ChAT fusion protein that was reactive with AB865, a monospecific rabbit antibody directed against affinity purified ChAT from human placenta. Twenty-two plaques reacted with AB865 of which 8 were assayed a second time. One positive clone, λChAT7, containing an 1100 bp insert was identified. Assuming that only one-sixth of the clones in the library contain inserts in the correct orientation and reading frame for expression, the data suggest that the abundance of ChAT mRNA in the human basal ganglia is 0.006%. Lysogens of λChAT7 were made in E. coli Y1089 and grown in the presence of 10 mM IPTG to induce the synthesis of β-galactosidase fusion protein. A 160 kD protein synthesized by the λChAT7 lysogen was recognized by both anti-β-galactosidase and AB865 antibodies on western blots. Incubation of AB865 with proteins from induced lysogens of λChAT7, but not λgt11, reduced the immunohistochemical staining of cholinergic neurons. Northern blots of total cellular RNA prepared from human neuroblastoma (MCIX C) cells that synthesize ChAT demonstrated that the DNA insert excised from λChAT7, purified by agarose gel electrophoresis and labeled by nick translation hybridized to a band of RNA approximately 4200 nucleotides in length. The insert from λChAT7 hybridized with a RNA band of the same size in poly $A^+$ mRNA prepared from NS20Y cells, a clonal mouse neuroblastoma cell line with high ChAT activity, but not from N1E-115 cells, an adrenergic neuroblastoma derived from the same tumor (C1300) that lacks ChAT activity. These data suggest that the λChAT7 insert hybridizes to choline acetyltransferase mRNA. We currently are working to confirm this hypothesis by hybrid-arrested and hybrid-promoted translation.

324.2 IDENTIFICATION OF DNA COMPLEMENTARY TO DOPA-DECARBOXYLASE mRNA. V. R. Albert, and T. H. Joh, Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Dopa-decarboxylase (DDC) is an important neurotransmitter synthetic enzyme, essential for the production of the catecholamines (dopamine, norepinephrine and epinephrine) as well as the indolamine serotonin. Despite its neuron specific function, DDC is also expressed in relatively large amounts in tissues where no monoamine neurotransmitters are synthesized. These include liver, kidney, some peptide-producing cells, and in areas of the brain and spinal cord which contain no monoamines. In order to better understand the unusual expression of this enzyme at the molecular level, a cDNA clone complementary to DDC mRNA was isolated. Because of the low abundance of this enzyme, it was necessary to employ a method whereby large numbers of recombinant clones could be screened directly. Thus a bovine adrenal cDNA library containing over $10^7$ recombinants was generated in the expression vector, lambda gt11. In this vector, cDNAs were inserted into the β-galactosidase gene, resulting in the expression of β-galactosidase fusion proteins. These fusion proteins were screened immunologically using highly specific antibodies previously raised to the protein purified from bovine adrenal medulla. Screening of 700,000 recombinants resulted in the isolation of a single positive clone. This clone, lambda DDC 46, was positively identified as a DDC clone by its ability to hybrid select mRNA coding for the 56,000 MW protein which was specifically immunoprecipitated with DDC antibody. By Northern blot analysis the 2.1 kb insert hybridizes to a bovine adrenal mRNA of approximately 2.3 kb. A similar size message can also be detected in bovine liver and kidney mRNA. RNA coding for rat DDC is slightly smaller, approximately 2.2 kb, in brain, liver and adrenal. Although preliminary immunochemical comparisons of the enzyme in various bovine tissues had suggested there might be tissue specific differences, no such differences were found at the moleular level. Furthermore, Southern blot analysis reveals that a single gene codes for this enzyme in bovine tissue. (Supported by NIH Grants, NS19002 and MH24285.)

324.3 BRAIN GLUTAMATE DECARBOXYLASE (GAD) CDNA CLONED ON THE BASIS OF ITS ANTIGENICITY AND ABILITY TO PRODUCE GABA. D.L.Kaufman*, J.F.McGinnis*, T.L.Wood* and A.J.Tobin. Dept. of Biology, Univ. of California, Los Angeles, CA 90024.

GAD converts the amino acid glutamate to GABA, the major inhibitory neurotransmitter in the mammalian central nervous system. Lesions in the GAD gene have been suggested as the cause of several neurogenetic disorders, including Huntington's disease, Parkinson's disease, and epilepsy, in which altered synthesis of GABA may cause the observed motor dysfunction.

We have used recombinant DNA techniques to isolate a cDNA clone encoding GAD from a library prepared in the bacterial expression vector gt-11. Putative GAD clones were detected by screening the library with an antiserum to purified rat GAD (Oertel et al., 1981) and purified until plates contained only immunologically positive plaques. DNA isolated from these phage contained a 2.4 kb cDNA insert. Protein analysis by immunoblotting was consistent with the production of a fusion polypeptide that reacts with antibodies to both E. coli beta-galactosidase and rat GAD. The fusion protein reacted with three independently derived anti-GAD sera: sheep anti-rat GAD, sheep anti-pig GAD, and rabbit anti-mouse GAD. These sera were graciously provided by Drs. I. Kopin, D. Martin, and J. Vaughn. In immunoblotting experiments all three anti-sera recognized two polypeptides (60 and 63 kd) in cat, human, and mouse brain extracts.

We confirmed the identity of the putative GAD clones by demonstrating enhanced GAD enzymatic activity in bacteria infected with lambda-GAD. We have partially purified the fusion proteins by gel filtration and ion-exchange chromatography. All of the GAD enzymatic activity in the purified fusion protein can be removed from solution by immunoprecipitation with anti-beta-galactosidase. The fusion protein converted uniformly-labeled $^{14}$C-glutamate to equimolar amounts of $^{14}CO_2$ and $^{14}$C-GABA.

RNA blotting analysis reveals that GAD mRNA (approximately 3.7 kb) is present in human, cat, mouse, and rat brain, but not in liver or kidney. These data are consistent with the GAD gene being transcribed in a tissue-specific manner. Our data do not reveal the presence of (1) multiple mRNA species which could give rise to the several forms of GAD which have been isolated from mammalian brain and (2) the presence of any homologous GAD-like genes transcribed in liver or kidney.

324.4 MOLECULAR CLONING OF cDNA AND GENOMIC DNA SEGMENTS CODING THE NERVE CELL-SPECIFIC PROTEIN, SYNAPSIN I. L.J. De Gennaro and M.W. Kilimann (SPON:M.Reddington) Max Planck Institute for Psychiatry,Dept.Neurochemistry D-8033 Martinsried, West Germany

Synapsin I is a phosphoprotein associated with the neurotransmitter vesicles of presynaptic termini. It appears to be present in all neuronal cells, but not in non-neuronal tissues. Synapsin I biosynthesis is developmentally regulated and correlates with synaptogenesis. The tissue specific and developmentally regulated expression of synapsin I make it an interesting subject for a molecular genetic study. We have isolated cDNA clones from rat brain RNA coding for this protein. Synapsin I mRNA was specifically enriched to a relative abundance of ca. 10% by immunoadsorption of polysomes. Employing this enriched mRNA, a cDNA library was prepared and screened by differential colony hybridization with ss-cDNA prepared from synapsin I mRNA or total poly (A)+ RNA. Thirteen plasmids which exhibited distinctly stronger hybridization with the synapsin probe were futher characterized by restriction mapping. They all proved to be colinear. In hybridization-selection experiments several of these plasmids specifically selected synapsin I mRNA which was identified by in vitro translation and immunoprecipitation of the translation products. In Northern blot experiments, probe prepared from one of these cDNAs hybridized to two RNA species of ca. 5800 and 4500 bases in length. These putative synapsin I mRNA species were found in RNA from brain and PC12 cells, but not from liver, skeletal muscle or cardiac muscle. The cDNA clones described above have also been used as probes for the identification of synapsin I genomic segments contained in a rat genomic DNA library cloned in the EMBL-3 phage vector. These genomic segments have been analyzed by restriction mapping, R-loop analysis, and DNA base sequencing.

324.5 IDENTIFICATION OF MULTIPLE RAT STRIATAL TACHYKININ mRNA'S BY cDNA CLONING AND PRIMARY STRUCTURE ANALYSIS. J.E. Krause and J.M. Chirgwin*. Dept. Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Substance P (SP) and substance K (α-neurokinin; SK) represent two mammalian members of the tachykinin peptide family. Whereas much basic neurobiology of substance P systems has been learned from anatomical and physiological studies performed in the rat, a biochemical and molecular biological examination of tachykinin biosynthesis and its regulation has been hindered since the primary structure of rat preprotachykinin(s) and the characteristics of its expression are not well understood. Thus, the present experiments were performed both to understand the primary structure of rat substance P precursor protein(s) from molecular cloning experiments and to provide tools for the study of the regulation of tachykinin gene expression.

Poly(A)$^+$ RNA was isolated from the rostral portion of the caudate nucleus, the site of striatonigral substance P cell bodies. A cDNA library was constructed in pUC 19 and consisted of 1.2-1.5x10$^5$ recombinants. Colony hybridization analysis for tachykinin-encoding sequences was performed by using $^{32}$P-end labeled synthetic oligonucleotides, corresponding to partial SP (a 14-mer; $T_m$=42°) and partial SK (a 20-mer; $T_m$=60°) sequences. Approximately 20 positive colonies were isolated based upon specific hybridization to SP-related (20/20) and SK-related (19/20) sequences. The results from extensive restriction enzyme mapping and cross-hybridization analyses demonstrated the relatedness of the 20 clones and were used to classify them into three subsets. The cDNA inserts from selected clones of each subset were directionally subcloned into M13 for nucleotide sequence analysis using the Sanger dideoxy method. Partial nucleotide sequence analysis confirmed the presence of near full length tachykinin encoding cDNA sequences in each subset of clones. Certain regions within the putative coding sequence of each subset of clones displayed a high degree of homology to recently described bovine preprotachykinin cDNA clones (Nawa et al., Nature 306:32, 1983), whereas other regions within the coding sequence contained additional sequence information. This, combined with the results from RNA blotting experiments using poly(A)$^+$ RNA from different CNS and peripheral tissues, suggested the presence of multiple preprotachykinin mRNA species. Currently, $S_1$ nuclease mapping experiments are being performed to quantitate the steady-state levels of each subset of preprotachykinin mRNAs in different CNS regions.

Therefore, these results demonstrate the existence of multiple mRNA species coding for the rat preprotachykinins. The cDNA's corresponding to these mRNA's should prove useful for investigating the regulation of rat tachykinin gene expression.

Supported in part by NIH grant NS21937 to J.E.K.

324.6 STRUCTURAL ORGANIZATION OF THE HUMAN AND RAT TACHYKININS GENES. H-U Affolter*, A. C. Young* and T. I. Bonner* (SPON: V. Hook). Lab. of Cell Biology, National Institute of Mental Health, Bethesda, MD 20205.

The genes coding for the human and rat preprotachykinins RNA were isolated from genomic libraries. A rat library was screened with a synthetic oligonucleotide (72-mer) derived from the known bovine cDNA sequence. A 1 kbp fragment of the rat gene containing the first exon as well as promoter region was used to probe a human genomic library. Detailed restriction maps were established and portions of the genes sequenced and compared to the bovine gene. The genes consist of 7 exons of identical length as well as 6 introns of similar length. Two of the exons code for the tachykinins substance P (exon 3) and substance K (exon 6). The rat gene was furthermore found to contain on the coding strand and within the 6th intron a "brain ID" sequence. While the exons are highly conserved in the coding region, crosshybridization experiments and partial sequence comparison revealed no obvious sequence homologies in intronic regions. There is, however, a 200 nucleotide region of substantial homology (80%) preceding exon 1 by 40 bases. This region presumably reflects conserved regulatory sequences.

The expression of the rat gene in various regions of the brain as well as the adrenal, spinal cord and the liver was analyzed using the northern blot technique as well as RNA protection experiments. RNA hybridizing to various probes derived from the rat gene was detected in the striatum, the hypothalamus and in the adrenal. Determination of the structure of these tachykinin genes will allow for the future identification of the processes regulating the expression of substance P and K in the central nervous system as well as peripheral tissues.

324.7 THE HUMAN VASOACTIVE INTESTINAL PEPTIDE GENE: POSSIBLE REGULATION BY ALTERNATIVE SPLICING? I. Gozes[1], M. Bodner*[1,2], Y. Shani*[1], R. Avidor*[1], E. Gileadi*[1] and M. Fridkin*[2]. Departments of [1]Hormone Research and [2]Organic Chemistry, The Weizmann Institute of Science, 76100 Rehovot, Israel.

We have recently isolated the human gene coding for vasoactive intestinal peptide (VIP). This was achieved by screening a human genomic library using synthetic oligodeoxynucleotides as specific hybridization probes. Six exons were thus far discovered and sequenced. Among the RNA coding sequences are two short exons, separated by a 0.75Kb DNA stretch, one encoding VIP and the second encoding PHM-27 (a peptide having an N-terminal histidine and C-terminal methionine amide, closely related in sequence and activity to VIP). Each of these two exons encodes its respective hormone, as well as the post-translational processing signal sequences. In general, the overall structure of the VIP gene is quite similar to the structure of genes coding for the peptides, glucagon and growth-hormone-releasing-hormone. These peptides are members of a family of peptides showing similarity in their primary amino acid sequences. Thus, the similarities among these peptides are both at the peptide level, as well as at the gene level.

The 3' splice sites of the VIP and the PHM-27 encoding exons contain an identical stretch of 9 nucleotides. At the cDNA level, the 3' splice sites contain the same stretch of six nucleotides which are identically spliced. The occurrence of VIP and PHM-27 on two separate exons of the human genome and the homology of their 3' splice site may allow alternative RNA processing, yielding cells producing one peptide or the other. To study this question, we have constructed specific oligodeoxynucleotide probes to either the VIP exon or the PHM-27 exon, and used them as hybridization probes to screen various tissues for the respective mRNA. Our preliminary results suggest that differential RNA processing may well occur. To corroborate these findings, we are in the process of constructing specific RNA probes for hybridization on the one hand, and cloning the respective cDNAs on the other.

Supported by: NIH; BSF; Israel Academy; Forshheimer Center; Bergmann Prize; and Samuel Freedman Career Development Chair; all to I.G.; and Interpharm Inc. to M.F.

324.8 CLONING AND CHARACTERIZATION OF MESSENGER RNA FROM RAT BRAIN THAT MAY LACK A POLY(A) TAIL. D.A. Harris, A.A. Sherbany*, and J. Brosius*. Depts. of Neurology and Human Genetics, and Center for Neurobiology & Behavior, Columbia Univ. College of Physicians & Surgeons, New York, N.Y. 10032.

There is evidence that a substantial number of mRNA molecules in rodent brain lack the poly(A) tail usually found at the 3' end of eukaryotic messengers. Moreover, many of these poly(A)$^-$ mRNAs appear to be brain-specific and to be synthesized only postnatally during brain development (Hahn, W.E., et al., Cold Spring Harbor Symp. Quant. Biol., 48:465, 1983; Chikaraishi, D.M., et al., ibid., p. 309). To document rigorously the existence and properties of this class of RNA, we have been attempting to clone and characterize these molecules using recombinant DNA techniques. The clones obtained will be useful for determining whether poly(A)$^-$ RNAs in brain are simply poly(A)$^+$ RNAs that have been artifactually truncated at their 3' ends, or whether they are distinct polysomal messengers capable of undergoing translation into protein.

Polysomal RNA from rat brain was fractionated on oligo-(dT)-cellulose, and poly(A)$^-$ RNA was tailed with bacterial poly(A) polymerase and used as a template for synthesis of cDNA. Single-stranded cDNA was annealed with a cocktail consisting of liver and kidney cytoplasmic RNA and brain poly(A)$^+$ RNA, and hybrids were removed by chromatography on hydroxyapatite. This purification step was expected to remove sequences derived from ribosomal RNA, which are major contaminants, as well as sequences that are not brain-specific or that are shared by the poly(A)$^+$ and poly(A)$^-$ RNA populations. The purified cDNA was then cloned into the plasmid pBR322.

Recombinants were screened by hybridizing bacterial colonies with a cloned ribosomal RNA probe, and by using the cDNA inserts as probes in Northern blots with brain, liver, and kidney RNA. At least six clones not derived from ribosomal RNA were identified, four of which have been sequenced. Several of these cDNA candidates fail to hybridize with a corresponding RNA in Northern blots of either poly(A)$^-$ or poly(A)$^+$ RNA from brain; this result is obtained when the cDNAs are used either as nick-translated probes or as single-stranded probes of higher specific radioactivity cloned in phage M13. We therefore estimate that these clones are derived from low-abundance RNAs. We are currently employing affinity chromatography with ribosomal DNA-Sephacryl to deplete poly(A)$^-$ RNA preparations of ribosomal RNA, and thereby enrich for messenger sequences; we expect that this purified RNA will permit more sensitive detection of poly(A)$^-$ species. Although scarcely represented at the RNA level, the sequences that we have identified are readily detectable by Southern hybridization in genomic DNA, where they appear to be derived in most cases from single-copy genes.

At present, it is not possible to determine definitively whether the clones we have identified represent a class of brain RNA that is structurally distinct from poly(A)$^+$ RNA. Our results indicate, however, that if such species exist, then at least some of them are present only at low levels in total brain RNA.

324.9 CLONING OF NONADENYLATED POLYSOMAL RNA FROM RODENT BRAIN. B.J. Snider* and M.R. Morrison. Depts. of Biochemistry and Neurology, Southwestern Graduate School, UTHSCD, Dallas, Texas, 75235.

RNA complexity measurements have revealed the presence of a large complex population of nonadenylated polysomal RNAs in rodent brain that are distinct from the polyadenylated (Poly(A)$^+$) RNA population (Chikaraishi, D.M., Biochemistry 18:3249, 1979, and Hahn, W.D., Cell 18:1341, 1979). Recently, two representatives of this class have been identified in a rat genomic library screened for rare brain RNA transcripts (Chikaraishi, D.M., Cell. and Mol. Biology, 4:2187). In order to further characterize this RNA population, we are constructing a cDNA library representing nonadenylated polysomal RNAs from rat brain. Because even small levels of nuclear RNA in cytosolic preparations could artefactually elevate observed levels of cytoplasmic RNA complexity, we used a cloned probe homologous to the abundant small nuclear RNA U1 (provided by T. Manser and R.F. Gesteland, University of Utah) to quantify nuclear contamination. Homogenization of brains in hexylene glycol produced a cytoplasmic fraction with significantly less nuclear contamination than homogenization in buffers containing sucrose and Triton X-100. Whole rat brains are homogenized in hexylene glycol and polysomes are prepared by centrifugation over a sucrose cushion. RNA is isolated from the polysomal fraction by treatment with Proteinase K followed by phenol extraction and ethanol precipitation. Poly(A)$^+$ and poly(A)$^-$ RNAs are separated by two passages over oligo(dT) cellulose. Poly(A)$^+$ RNAs are prepared for cloning by adding a poly(A) tail to their 3' ends with E.Coli Poly(A) Polymerase. After the addition of approximately 80-100 adenylate residues per RNA, the first cDNA strand is synthesized using Reverse Transcriptase (RT) and an oligo(dT) primer. Since the RNA population contained roughly 98% ribosomal RNAs (rRNA), cDNAs representing rare nonribosomal RNAs are selected for further cloning by a subtraction hybridization procedure. After synthesis of the first cDNA strand, the RNA template is hydrolyzed and the cDNA is annealed to an excess of brain polysomal nonadenylated RNA (the template RNA) to a Rot of 1000 and then to an excess of nonadenylated RNA prepared from liver polysomes to a Rot of 5000. The single-stranded cDNA (10-20% of starting cDNA) is recovered by HAP chromatography. This cDNA is A-tailed with terminal deoxynucleotidyl transferase and a second strand synthesized with AMV RT and an oligo(dT) primer. The double-stranded cDNAs will be cloned into M13mp8 and λgt10 and these libraries will be screened for clones representing rare nonadenylated RNAs by using several positive and negative screens. Analysis of clones generated by this method should provide clues to the role of nonadenylated RNAs in brain development and function.

324.10 GENES REGULATED BY NERVE GROWTH FACTOR IN PC12 CELLS. D.G.B. Leonard*, L.A. Greene* and E.B. Ziff* (SPON: R. I. Frank). Depts. of Biochemistry and Pharmacology, New York Univ. Med. Ctr., New York, NY 10016.

PC12 cells are a rat pheochromocytoma-derived cell line which has a chromaffin-like phenotype in cell culture. When treated with nerve growth factor (NGF), the cells acquire a sympathetic neuron-like phenotype, characterized by the cessation of proliferation, the extension of neurites and the acquisition of electrical excitability. In order to identify genes that may be important to the characteristics of differentiated sympathetic neurons, cDNA libraries made from both NGF-treated and -untreated PC12 cells were differentially screened. cDNA was made from polyA$^+$ RNA and inserted into the lambda gt10 vector (Huynh, T.V., R.A. Young and R.W. Davis in DNA Cloning Techniques: A Practical Approach. D. Glover, ed. IRL Press, Oxford. In Press). Both libraries contain greater than 1 million recombinant clones. Each library was screened with single-stranded $^{32}$P-labeled cDNA prepared from three different cell types: 1) untreated PC12 cells; 2) PC12 cells treated with 50 ng/ml NGF for 2 weeks; and 3) a spontaneously arising mutant cell line (F4) which was clonally-derived from PC12 cells and which lacks a number of differentiated PC12 properties including catecholamine synthesis and the capacity to bind or respond to NGF. Clones with different autoradiographic signals between the three cDNA types were picked and rescreened. At the present time, Northern analysis has confirmed that 6 clones represent mRNAs which are quantitatively different in the three cell types. One clone specifically hybridizes to a mRNA of approximately 820 nucleotides which is more abundant in the NGF-treated PC12 cells than in the untreated cells and is relatively rare in the F4 cells. In contrast, another cDNA clone appears to recognize two mRNA species of approximately 4600 and 1400 nucleotides which are abundant in the untreated PC12 cells, present at lower levels in the NGF-treated PC12 cells and undetectable in the F4 cells. Three additional clones were identified which hybridize with mRNAs that are present in equal amounts in NGF-treated and -untreated PC12 cells, but are either undetectable or much less abundant in the F4 cells. Further characterization of these and other clones will be discussed.

This investigation was supported by NIH Grants NS16036 and GM-30760, and by ACS Grant MV-75B. DGBL was supported by Training Grant 5T32 GM07308-10 from the National Institute of General Medical Sciences.

324.11 NERVE GROWTH FACTOR RAPIDLY INDUCES ORNITHINE DECARBOXYLASE mRNA IN PC12 PHEOCHROMOCYTOMA CELLS. S. Feinstein* (1), Sharon Dana* (2), Lisa McConlogue* (2), Philip Coffino* (2) and Eric M Shooter (1). (1) Dept. of Neurobiology, Stanford Univ. Sch. Med., Stanford, CA 94305 and (2) Dept. of Microbiology, Univ. of California, San Francisco, CA 94143.

The mechanism by which nerve growth factor (NGF) stimulates ornithine decarboxylase activity (OrnDCase; EC.1.1.17) in the rat pheochromocytoma cell line PC12 was investigated. As previously demonstrated, NGF rapidly induces OrnDCase activity in a dose dependent manner, with maximal enzymatic activity at 4 - 6 hours after exposure to NGF. Activity subsequently returns to near basal levels. A cloned OrnDCase cDNA was used to analyze the levels of OrnDCase RNA. In response to NGF administration, OrnDCase RNA levels are induced. The time course of the OrnDCase induction paralleled that of the enzyme activity induction, and the magnitude of both inductions was quantitatively the same. Increased concentration of OrnDCase RNA is clearly detected at the earliest time point examined, 2 hours. No change was observed in the size of OrnDCase RNA. The dose response curves for both OrnDCase RNA and enzymatic activity inductions were also similar. Thus, increased OrnDCase RNA levels fully account for, and are responsible for, the induction of activity. Further, one-third of the OrnDCase RNA induction is unaffected by cycloheximide treatment, but fully blocked by actinomycin D treatment, suggesting that NGF acts through at least two mechanisms to mediate the OrnDCase induction. The first mechanism is cycloheximide insensitive and the second mediated through an event requiring ongoing protein synthesis. Both mechanisms require ongoing transcription, as evidenced by the complete sensitivity of the induction process to actinomycin D.

324.12 **EXPRESSION OF THE EGG LAYING HORMONE GENE FAMILY IN THE HEAD GANGLIA OF APLYSIA CALIFORNICA.** M. SHYAMALA*., J.R. NAMBU* AND R.H. SCHELLER. Department of Biological Sciences, Stanford University, Stanford, CA.94305

The egg laying hormone (ELH), which is encoded in a small multigene family, promotes release of eggs from the ovotestis and also modifies the activity of neurones in the abdominal and head ganglia. A member of the gene family expressed in the bag cells encodes ELH and a distinct subset of the family expressed in the atrial gland encodes the peptides A and B. In situ hybridization studies using radiolabelled cloned DNA probes have indicated that the ELH gene family is expressed in neurones of the abdominal, buccal, cerebral, and pleural ganglia in addition to the bag cells and the atrial gland. Immunohistochemical studies using anti-ELH antibody have revealed a network of cells producing ELH immunoreactive proteins in all of the major ganglia of the nervous system except the pedal ganglia. In order to study the nature of the ELH gene family transcripts expressed in the various ganglia, a radiolabelled cDNA probe was employed to screen a cDNA library constructed from ring ganglia (cerebral, pedal, and pleural ganglia) poly A(+) RNA. Several clones that are homologous to the ELH cDNA probe were isolated and characterized. Restriction endonuclease mapping and blotting of ten clones indicated that one of the clones represents an A and/or B peptide gene transcript and the other clones represent transcripts from the ELH gene. A further analysis ot two ot the clones by DNA sequencing confirmed the presence of A peptide and ELH gene transcripts in the ring ganglia. This data was strengthened by Northern blotting which indicated the presence of A and/or B peptide related transcripts in cerebral and pedal ganglia and ELH related transcripts in all of the head ganglia.

## NEUROTRANSMITTERS AND RECEPTORS IN DISEASE: MPTP MODEL OF PARKINSON'S DISEASE

325.1 AUTORADIOGRAPHIC DISTRIBUTIONS OF NEUROTRANSMITTER RECEPTORS OF HUMAN BRAINS WITH PARKINSON'S DISEASE AND PRIMATE MODELS OF MPTP-INDUCED PARKINSONISM. S. Kito, R. Miyoshi*, K. Mizuno*, H. Matsubayashi* , K. Nitta* and Y. Yamamura. Third Department of Internal Medicine, Hiroshima University School of Medicine, Hiroshima 734,Japan.

Distributions of neurotransmitter receptors in human brains of two parkinsonian patients were autoradiographically studied with use of various radioactive ligands such as $^{3}$H-lisuride (a dopamine $D_2$ receptor agonist), $^{3}$H-spiperone (a dopamine receptor antagonist), $^{3}$H-QNB (a muscarinic acetycholine receptor antagonist) and $^{3}$H-substance P, and these results were compared with morphological observations through conventional neuropathological techniques. The method of in vitro autoradiography used in this study was the one originally established by Kuhar et al. Cryostat sections of autopsied human brains were prepared and scatchard plots of saturation analysis were obtained by the same way as binding experiments with use of brain homogenate. These preliminary experiments are needed to decide optimal conditions for autoradiography. After obtaining scatchard plots, the authors proceeded to autoradiographic techniques in which incubated sections were apposed to a sheet of $^{3}$H-sensitive film and exposed for several weeks. The observed autoradiograms were computer-analysed by IBAS II of Zeiss company. Through these studies it was found that $^{3}$H-lisuride known as one of anti-parkinsonian ergot alkaloids specifically bound not only to dopamine receptors, but also to serotonergic and alpha$_2$-adrenergic receptors. In the parkinsonian brain, the density of specific $^{3}$H-lisuride binding sites was increased in the striatum, globus pallidus, cingulate gyrus, while it was decreased in the cerebellar cortex, parahippocampal gyrus, pre- and postcentral gyri. Specific binding sites of muscarinic acetylcholine receptor were increased in the putamen. Results of conventional neuropathological studies were consistent with pathology of Parkinson's disease with remarkable neuronal loss in the substantia nigra, otherwise no notable changes. Changes of $^{3}$H-lisuride binding sites in the cerebellum, parahippocampal gyrus and other cerebral cortices were regarded to represent adrenergic and serotonergic receptors.

Autoradiographic studies on three Macaca fuscatus models of MPTP-induced parkinsonism using $^{3}$H-QNB and $^{3}$H-spiperone were done likewise and the results were disscussed in comparison with human parkinsonian brains and control monkeys. In these monkey models, there was an increase of $^{3}$H-QNB binding sites in the putamen, which had been observed also in human brains. Muscarinic acetylcholine receptors were somewhat decreased in the hippocampus.

325.2 EFFECT OF CHRONIC LEVODOPA OR BROMOCRIPTINE TREATMENT ON DYSKINESIA AND [$^{3}$H]SPIPERONE BINDING IN MPTP LESIONED PARKINSONIAN MONKEYS. P. Falardeau*[1], R. Boucher[2], P. Bédard[2] and T. Di Paolo[1] (SPON: A. Dupont), [1]School of Pharmacy, Laval Univ., Quebec G1K 7P4 and Dept. of Molecular Endocrinology, Laval Univ. Hosp. Center, Quebec G1V 4G2; [2]Neurobiology Lab., Dept. of Anatomy, Laval Univ., Quebec G1J 1Z4, Canada.

Dyskinesia is one of the most frequent side effects of L-DOPA treatment in Parkinsonian patients while bromocriptine has been reported to induce little or no dyskinesia. DOPA-induced dyskinesia generally appear after long term treatment suggesting that the drug plays a role in the genesis of these movements. Moreover, they often appear on the side first affected by the disease implying that the extent of the nigral lesion and the resulting supersensitivity to dopamine (DA) may be important. The aim of this study was to compare in monkeys with a parkinsonian syndrome induced by 1-methyl-4-phenyl-1,2,5,6-tetrahydroxypyridine (MPTP) the effect of treatment with L-DOPA/carbidopa (Sinemet (R)) or bromocriptine to see if some animals develop dyskinesia and if this could be correlated with differences in post-synaptic striatal DA receptors. Five ovariectomized macacca facicularis monkeys developed a severe parkinsonian syndrome after intraveneous administration of the toxin MPTP. Injections were repeated every third day until the animals appeared bradykinetic. This was generally apparent two days after the injection. Then, one monkey remained untreated while two animals were treated daily for five months with L-DOPA/Carbidopa (100/25 mg increased after a month to 150/37.5 mg) and two with bromocriptine orally (10 mg increased after a month to 15 mg and after 2 months to 20 mg). Both drugs relieved the parkinsonian symptoms but the animals on Sinemet developed after two weeks prominent lingual dyskinesia which remained visible after each dose until the end of the experiment. In the two animals on bromocriptine no dyskinesia were observed. After sacrifice, the levels of DA, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) and [$^{3}$H]spiperone binding were studied bilaterally in the anterior and posterior caudate nucleus, anterior and posterior putamen, and in the nucleus accumbens. The loss of DA, DOPAC and HVA were equivalent in the Sinemet and the bromocriptine treated animals (> 90%) and there was a complete disappearance of the substantia nigra pars compacta. In all structures studied, the Bmax for [$^{3}$H]spiperone binding was on average 10% higher in the Sinemet than in the bromocriptine treated animals while the affinity ($K_D$) was unchanged. We therefore believe that L-DOPA and bromocriptine affect denervated postsynaptic DA receptors differently, that bromocriptine is less likely to induce agonist supersensitivity and that this probably explains the lesser tendency to induce dyskinesia after chronic treatment.

Supported by the Parkinson Foundation of Canada.

325.3 LONG-TERM EFFECTS OF MPTP ON BRAIN AND PERIPHERAL CATECHOLAMINE AND INDOLEAMINE CONCENTRATIONS OF MONKEYS. P. Bédard[1], R. Boucher[1], P. Falardeau*[2] and T. DiPaolo[2], [1]Neurobiology Lab., Dept. of Anatomy, Laval Univ., Québec, G1J 1Z4, [2]School of Pharmacy, Laval Univ., Québec, G1K 7P4 and Dept. of Mol. Endocrinology, Laval Univ. Hosp. Center, Québec, G1V 4G2, CANADA.

5 Maccaca Fascicularis monkeys developed a severe parkinsonian syndrome in the days following intravenous administration of the toxin MPTP. These animals were then divided in three groups. One monkey remained untreated while two animals were treated daily for five months with supramaximal doses of Sinemet (R) and two with bromocriptine orally. Both drugs relieved the parkinsonian symptoms. These 5 animals plus one normal monkey were sacrificed 3 days after their last drug treatment. Plasma prolactin concentrations were elevated in the untreated MPTP monkey compared to values from an intact control monkey. MPTP caused a rapid decrease of homovanillic acid (HVA) concentrations in the CSF of these monkeys within days of the toxin injections and this remained until sacrifice of the animals 5 months later. By contrast, CSF 5-hydroxyindoleacetic acid (5-HIAA) concentrations are elevated a few days after MPTP and these values return to control after 5 months. Five months after MPTP, epinephrine (E) and dopamine concentrations in the adrenal medulla of the monkeys are decreased while norepinephrine (NE) concentrations are unchanged. By contrast, NE is increased in the adrenal cortex of the MPTP monkeys while E and DA are unchanged. Catecholamines and indoleamines were assayed in the caudate, putamen, nucleus accumbens, amygdala and frontal cortex of these monkeys. In general MPTP treatment increased 5-hydroxytryptophan (5-HTP), 5-hydroxytryptamine (5-HT) and 5-HIAA concentrations in the brain regions analyzed and L-DOPA or bromocriptine treatment corrected these changes. Similar results are obtained for NE concentrations in the caudate and putamen while no effect of MPTP was observed in the accumbens and a decrease was observed in the frontal cortex. Significant changes of E concentrations after MPTP were observed only in the n. accumbens where a decrease was observed. Dopamine and its metabolites dihydroxyphenylacetic acid (DOPAC) and HVA were significantly reduced in the caudate, putamen, n. accumbens and frontal cortex. Our results show that MPTP in the long-term not only affects the caudate-putamen dopaminergic system but also dopaminergic noradrenergic, adrenergic and serotonergic systems in the brain and in the periphery. Supported by the Parkinson Foundation of Canada.

325.4 RETINAL CATECHOLAMINE METABOLISM FOLLOWING MPTP TREATMENT. *C.G. Wong. Dept. Ophthalmology, Doheny Eye Foundation Bldg., USC School of Medicine, 1355 San Pablo St., Los Angeles, CA 90033.

Recently 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) has been shown to cause a syndrome similar to Parkinsonism in both man and monkeys by selective destruction of dopaminergic cells in the substantia nigra. The rabbit retina is a uniquely relevant model for studying the actions of MPTP on dopamine (DA) metabolism since other neurotransmitters such as NE or 5-HT and resulting complex interactions are not present. In this study MPTP is shown to affect DA metabolism in the pigmented rabbit retina. Rabbits were injected daily intramuscularly (IM) for 14 days at either 0.1 mg/kg or 2 mg/kg and sacrificed either 24 hrs. or 14 days after the last injection. In a second study, rabbits were injected IM with either 4 mg/kg or 2 mg/kg for 6 days daily and then sacrificed at 3, 10, and 17 days after the last injection. In a third study, four groups of rabbits were injected IM once with one of the following doses of MPTP: 0.1, 0.5, 1.0, and 2.0 mg/kg. The rabbits were then sacrificed either 24 hrs. or 16 days later. Both intravenous and intraocular injections were done also.

Overall, DA levels after a single injection of MPTP were depressed over the observed time period while that of chronically treated animals were elevated. DOPA levels were markedly elevated in all chronically treated animals except for the first time point at the higher dose of 4 mg/kg. Thus, after a single IM injection of 2 mg/kg 16 days later both DOPA and DA levels were depressed 42% and 57% of control, respectively. However, with one injection of 1 mg/kg, at both 24 hrs. and 16 days later, DOPA levels were elevated 233% and 396%, respectively, while DA levels were depressed 40% and 67%, respectively. With 0.5 mg/kg after 24 hrs., both DOPA and DA levels were depressed to 23% and 66% of normal while after 16 days, DOPA had returned to normal with DA still depressed at 83% of control. DOPA levels of animals treated chronically IM with 2 mg/kg were elevated 3, 10, and 17 days by 158%, 140%, and 132%; DA levels were within normal range after 3 days while elevated at 10 and 17 days by 353% and 156%, respectively. DOPA levels of animals treated chronically IM with 4 mg/kg were depressed 53% after 3 days while elevated 246% and 169% both 10 and 17 days after the last injection; DA levels were not significantly different after 3 days while elevated both 10 and 17 days later by 139% and 129%, respectively.

These results clearly demonstrate the dramatic changes in retinal DA metabolism following MPTP treatment by various routes. Whether the mechanisms of MPTP toxicity in the mammalian retina is similar to its selective toxicity on dopaminergic cells in the primate CNS remains to be shown. The possibility is raised, however, that the rabbit retina may provide a useful model system for studying MPTP toxicity.

325.5 EVALUATION OF CILADOPA HYDROCHLORIDE AS A POTENTIAL ANTIPARKINSON AGENT. W.C. Koller, J.Z. Fields, R. Rybicki*, J. Gordon and M. Perlow. Hines-Loyola Medical Center, Chicago Medical School, University of Illinois, Chicago, IL 60141

Ciladopa HCL (S (-)[4-(2-hydroxy-2-3',4'-dimethoxyphenyl 1) ethyl}-1-piprazinyl]-2,4,6-cycloheptatriene-1-one) is a pharmacologically active enantiomer of a troponylpiperazine derivative. Initial studies (Ayerest Laboratories) indicate that this compound enhances dopaminergic activity. Ciladopa may be a novel dopamine agonist as it is not an ergot derivative. Thus the drug may represent a new pharmacologic approach for the treatment of Parkinson's disease. We have therefore investigated ciladopa in animal models of central dopaminergic activity.

Ciladopa in rats induced dose-dependent (2.5 to 20 mg/kg) behavioral changes consisting of locomotion, head bobbing, and sniffing. Doses greater than 20 mg/kg caused toxicity. Behaviors such as rearing, grooming, and gnawing observed after apomorphine (0.25 and 0.5 mg/kg) did not occur with ciladopa. Haloperidol pretreatment (doses greater than 0.05 mg/kg) blocked ciladopa's effect. Sulpiride pretreatment (10 to 40 mg/kg) caused partial blockage. In guinea pigs ciladopa (2.5 to 20 mg/kg) produce a dose-dependent increase in locomotion and gnawing but at a lower intensity than apomorphine (0.4 and 0.8 mg/kg). Higher doses of ciladopa (40 and 80 mg/kg) caused less of a behavioral effect than lower doses suggesting partial agonism. Haloperidol pretreatment (doses greater than 0.10 mg/kg) blocked ciladopa's effect whereas sulpiride pretreatment (10 to 40 mg/kg) had no effect. Ciladopa's action either in rats or guinea pigs was unaltered by pretreatment with reserpine (2.5 mg/kg, 16 hrs. prior) or with alpha-methyl-para-tyrosine (200 mg/kg, 2 hrs. prior), indicating direct agonism. In rats with unilateral 6-OH dopamine lesions ciladopa caused contralateral turning (2.5 and 5.0 mg/kg), however, in some animals ipsilateral turning (similar to amphetamine) preceded contraversive turning. In dogs ciladopa (0.1 to 1.0 mg/kg) caused dose-dependent emesis. Rectal temperature in mice was reduced in dose-dependent fashion (2.5 to 10 mg/kg). Ciladopa at low doses (1.0 to 2.5 mg/kg) decreased locomotion suggesting activation of pre-synaptic dopamine autoreceptors.

Ciladopa is a dopamine agonist with a novel pharmacologic profile that is potentially useful for the treatment of Parkinson's disease.

325.6 REPEATED ADMINISTRATION OF L-DOPA PLUS BENSERAZIDE IN 6-OHDA LESIONED RATS: BEHAVIORAL AND BIOCHEMICAL SIGNS OF DOPAMINE RECEPTOR SUPERSENSITIVITY. C. Rouillard*, P.J. Bédard, P. Falardeau*, T. DiPaolo (SPON: R. BOUCHER). Lab. Neurobiology, Dept. Anatomy and Dept. Molecular Endocrinology, Univ. Laval, Québec, Canada, G1K 7P4.

Treatment with L-DOPA plus a peripheral inhibitor of Dopa decarboxylase is an effective treatment of Parkinson's disease. But a majority of these patients develop dyskinetic movements suggesting some type of supersensitivity related to the treatment but facilitated by denervation. We investigated behaviorally (circling) and biochemically ($^3$H-Spiroperidol binding) the effect of repeated administration of L-DOPA plus benserazide in rats bearing a unilateral lesion of the nigrostriatal pathway performed with 6-OHDA. The animals were divided in three groups; the first group receiving 8 injections of L-DOPA (100 mg/kg i.p.) plus benserazide (50 mg/kg i.p. ½ hour before) separated by 48 hours while the second group received only the first and the last injections and the third served as control and received no injection. Circling was monitored during five hours after each injection. Seventy-two hours after the last dose, the animals were sacrificed by decapitation and the striata rapidly removed for subsequent binding studies. The two groups of rats having received L-DOPA showed a significant increase of the circling response (109% and 39% respectively for L-DOPAx8 and L-DOPAx2). This increase was mostly in the first three hours while the duration of the response seemed to be unchanged. In the L-DOPAx2 group, we saw a small, non significant increase of the Bmax on the lesioned side compared to the same side of the control group. However, in the L-DOPAx8 group, the Bmax was increased by 22% ($p < 0,05$) on the lesioned side while it was decreased by 18% (n.s.) on the intact side. These results suggest that the increased behavioral response may be explained by DA receptor supersensitivity on the lesioned side combined with an increased difference in sensitivity between sides. The present results also indicate that the action of L-DOPA is different from that of Bromocriptine which under similar conditions mostly desensitizes the intact side and has little or no effect on the lesioned side (Rouillard et al., Neurosci., 10: 237, 1984). This may explain the difference in incidence of dyskinesia seen in Parkinsonian patients treated with these two drugs. (Supported by MRC and Parkinson Foundation of Canada).

325.7 CHOLINERGIC AND SOMATOSTATINERGIC RECEPTOR ALTERATIONS IN SENILE DEMENTIA OF THE ALZHEIMER'S TYPE (SDAT) AND IN ITS ANIMAL MODEL. K. Gulya[1]* T.W. Vickroy[1], M. Watson[1], W.R. Roeske[1], E. Perry[2]*, R. Perry[2]*, S.P. Duckles[1] and H.I. Yamamura[1].[1]Depts. of Pharmacology, Univ. of Arizona, Tucson, and [2]Dept. of Neuropathology, Newcastle General Hospital, Newcastle upon Tyne, England.

Biochemical and receptor binding experiments were carried out to study the cholinergic and somatostatinergic transmitter systems in post-mortem human brain samples from SDAT and age-matched patients. Alterations of the cholinergic system after ibotenic acid-induced lesions of the nucleus basalis magnocellularis (nBM) of rat were also studied. Presynaptic cholinergic markers (choline acetyltransferase,CAT; sodium dependent binding of the choline uptake inhibitor [$^3$H]hemicholinium-3, [$^3$H]HC-3) and muscarinic receptor radioligands such as [$^3$H]-*cis*-methyldioxolane ([$^3$H](+)CD), [$^3$H]pirenzepine ([$^3$H]PZ) and [$^3$H](-)quinuclidinyl benzilate ([$^3$H](-)QNB were used to detect changes in the central cholinergic nervous system of SDAT patients compared with age-matched controls. Similar comparisons were carried out in rats with ibotenic acid-induced lesions of nBM (animal model for SDAT) compared with control animals. Somatostatin receptor binding using the iodinated nonhydrolyzable dicarba analog [$^{125}$I]CGP 23,996 was also studied. These measurements were carried out in the hippocampal gyrus and cingulate and parietal cortices in humans and in the anterior cerebral cortex in rats. The results are:

| Marker | SDAT | | | Rat |
|---|---|---|---|---|
| | hippoc. gyrus | cingulate cortex | parietal cortex | anterior cerebral cortex |
| CAT | 48 * | 36 * | 31 * | 59 * |
| [$^3$H]HC-3 | n.d. | n.d. | n.d. | 59 * |
| [$^3$H](+)CD | 133 | 109 | 107 | 79 |
| [$^3$H]PZ | 75 | 116 | 77 | 90 |
| [$^3$H](-)QNB | 83 | 106 | 104 | 89 |
| [$^{125}$I]CGP 23,996 | 48 * | 47 * | 46 * | n.m. |

Significantly *$p < 0.05$ by Student's t-test. Data are shown as percent of control values. n.d. = not detected, n.m. = not measured.

We demonstrated a significant decrease in [$^3$H]HC-3 binding to ibotenic acid-lesioned rat cerebral cortices and somatostatin receptor binding in all regions from SDAT samples. CAT activity was significantly reduced in SDAT tissue as well as cortical tissue from the ibotenic acid-lesioned animals. There is no muscarinic receptor loss in SDAT or in its animal model. The selective loss of putative presynaptic cholinergic markers and the reduction of somatostatin receptor binding indicate the co-involvement of these neurotransmitter systems in the neuropathology of SDAT. Supported by NIMH Grants.

325.8 NEUROPEPTIDE Y IMMUNOREACTIVITY IS REDUCED IN ALZHEIMER'S DISEASE CEREBRAL CORTEX. M. Flint Beal, Michael F. Mazurek*, Geetinder Chattha*, Edward D. Bird and Joseph B. Martin. Department of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Neuropeptide Y is a 36 amino acid peptide which has been found in high concentrations in cerebral cortex and is contained in cortical neurons. We measured concentrations of this peptide in cerebral cortex using a sensitive and specific radioimmunoassay. Postmortem brain tissue from 12 patients with Alzheimer's disease (AD) and 13 neurologically normal controls was dissected and extracted in boiling 2N acetic acid. The diagnosis of AD was confirmed neuropathologically in all cases. Neuropathologic examination in controls was normal. Post-mortem intervals were 11.5 $\pm$ 1.6 hrs in controls and 11.3 $\pm$ 2.0 hrs in AD brains.

Antibody to neuropeptide Y conjugated to bovine serum albumin was raised in rabbits. Neuropeptide Y was iodinated using the chloramine T reaction and purified using HPLC. The radioimmunoassay showed no significant cross-reactivity with other neuropeptides tested. The assay sensitivity is approximately 8 pg/tube. Twenty one cortical regions were examined. Significant ($p<.05$) reductions in immunoreactivity were seen in the following Brodmann areas: A4, 68%; A6, 58%; A12, 56%; A17, 76%; A20, 64%; A21, 54%; A22, 66%; A24, 61%; A32, 67%; A45, 49%; and A47, 52%. Smaller reductions which were not significant were seen in Brodmann areas: 8,9,10,11,25,28,38,44,46 and 3-1-2. HPLC showed that more than 90% of neuropeptide Y immunoreactivity co-migrated with standards in both Alzheimer's and control brains. Smaller peaks were seen at the void volume which may represent higher molecular weight species.

Somatostatin neurons have previously been shown to degenerate in AD cerebral cortex. These studies demonstrate loss of a second neurochemical marker of cortical neurons in Alzheimer's disease. The regions particularly affected include temporal lobe, frontal lobe and occipital cortex. Since neuropeptide Y is co-localized with somatostatin in a considerable proportion of cortical neurons the loss of immunoreactivity may in part reflect degeneration of these neurons.

Supported by Alzheimer's Disease Research Center Grant - NIA IP50AG05134 and MN1NS 31867 - Brain tissue Resource Center, McLean Hospital.

325.9 Nicotine Receptors in Human Frontal and Infratemporal Cortex: Comparison between Alzheimer's Disease and the Normal. D.D. Flynn and D.C. Mash, University of Miami School of Medicine, Miami, FL and Harvard Medical School, Boston, MA.

Reductions in the presynaptic markers, choline acetyltransferase and M2 muscarine receptors (Mash et al., 1985), have been attributed to degeneration of neurons located in the basal forebrain. Despite widespread reductions in these markers, postsynaptic M1 receptors remain unchanged in Alzheimer's disease (AD). The possibility that nicotinic-cholinergic transmission is impaired in AD brains has not been previously examined. The present study was undertaken to establish assay conditions for nicotine receptors in human postmortem cortical samples in order to determine the status of these sites in AD.

Cortical samples obtained 2-12 hours postmortem, were homogenized and assayed in Tris Ca++ buffer at pH 7.4. Membranes were incubated with (-) 3H-nicotine (7.5-30 nM) in a total volume of 1 ml for 30 minutes at 25° C. Nonspecific binding was determined by the addition of an excess of (-) nicotine and was generally less than 10% of the total binding. Membranes were collected after dilution with buffer at 4° C on filters presoaked in 0.1% polyethyleneimine. (-) 3H-nicotine binding was enhanced by the addition of Ca++ and abolished in the presence of EDTA. Association and dissociation were rapid at 25° C with $t_{½}$ values of 3 min and 5 min., respectively. Scatchard analysis of (-) 3H-nicotine binding revealed an apparent single class of binding sites with a dissociation constant, Kd, of 7 nM in agreement with the previously reported value in the rat brain (Clarke et. al., 1984). There was no effect of postmortem interval on the number of 3H-nicotine sites assayed in rat frontoparietal cortex.

In the human frontal cortex the number of binding sites, $B_{max}$, decreased with normal aging (27-85 yrs) from 2.0 pmol/g to 0.8 pmol/g. The receptor affinity and concentration in AD frontal cortex (Brodmann 10) were comparable to that in age-matched controls. In AD infratemporal cortex (Brodmann 38), the number of sites was significantly decreased by 50% ($p < 0.001$). The diagnosis of AD was confirmed neuropathologically and choline acetyltransferase activity was decreased (50-80%) in both cortical areas.

These results demonstrate that postsynaptic nicotine sites are spared in the frontal cortex in AD. In the infratemporal cortex, significant numbers of nicotine receptors remain, despite severe reductions in choline acetyltransferase activity. Further studies of the distribution and status of these sites in AD may provide a rationale for using nicotinic agonists to improve some of the cognitive deficits associated with AD. Supported by NS 19065 and NS 09211.

325.10 CALCIUM CHANNEL ANTAGONIST BINDING SITES IN FRESH HUMAN BRAIN CORTEX. F. Lafaille*, N.P.V. Nair, S. Lal*, A. Olivier*, J. Strattford*, R.M. Ford* and R. Quirion. Douglas Hospital Research Centre, Verdun, Quebec H4H 1R3 Canada, Montreal Neurological Institute and Montreal General Hospital, Montreal, Quebec Canada.

Recent data have demonstrated the presence of high affinity binding sites for calcium channel antagonists in the brain. Interestingly, these sites are mainly located in areas enriched in synaptic contacts. We have now characterized calcium channel antagonist binding sites in fresh human brain cortex using [$^3$H]PN-200-110, a highly potent dihydropyridine derivative. Fresh human brain cortex is obtained from patients undergoing surgery for removal of tumors (n = 7) or epileptogenic focus (n = 8). Only apparently normal surrounding tissues are used for assays. Samples are kept on ice before homogenization in Krebs Ringer buffer using a Brinkmann polytron at setting 5 for 17 sec. (mean delay of 52 min between removal of tissues and processing). Homogenates are then centrifuged three times for 15 min at 39,000 g and the final pellet is resuspended in Krebs buffer to yield a protein concentration of 2-2.5 mg/ml. 200 µl of this preparation is then incubated for 60 min in Krebs buffer at 37°C with various concentrations of [$^3$H]PN-200-110 (0.03 - 5.0 nM; 84 Ci/mmol, New England Nuclear) in presence and absence of 10 µM nimodipine to assess specific binding. Incubations are terminated by rapid filtration through GF/B filters followed by two 4 ml washes using cold Krebs buffer. Under these conditions, [$^3$H]PN-200-110 binds to a single class of high affinity sites is fresh human brain cortex. $K_d$ values ranged between 0.15 - 0.57 nM without apparent differences between samples obtained from tumor or epileptogenic tissues. The densities of sites ($B_{max}$) are also independent of the disease state but varied between cortical regions. The highest density is found in the temporal lobe (182.3 fmol/mg protein) followed by the fronto-temporal (180), frontal (180), fronto-parietal (177), temporo-parietal (110) and parietal (87) lobes. This demonstrates the differential distribution of high affinity calcium antagonist binding sites in fresh human brain cortex.

In another series of experiments, we observed that the saturation curves of [$^3$H]PN-200-110 in cortical samples obtained at autopsy (delays of 12-48 hrs after death) are biphasic suggesting the existence of two population of sites for this ligand. However, our data obtained from fresh human brain tissues indicate that the appearance of the low affinity site is probably an artifact related to autopsy delays. This reveals the difficulty in using autopsy tissue to study human brain calcium channel antagonist binding sites.

325.11 HUMAN GAMMA-GLOBULIN AND ALPHA-GLOBULIN DECREASE LIGAND BINDING AT NEUROTRANSMITTER RECEPTORS. A. C. Andorn*, F. Klemens*, P. Martello* and M. Pappolla*. ( SPON: M. Maguire) Dept. of Psychiatry, Case Western Reserve Univer. Schl. of Med. and Cleveland Metropolitan General Hospital, Cleveland, OH, 44109.

[$^3$H]Spiroperidol binds specifically at dopaminergic sites in human caudate and at multiple sites with predominant serotonergic selectivity in human prefrontal cortex (Andorn, A.C. in Usdin, E and Riederer, P. (edts) Neurotransmitter Biochemistry of the Human Brain, MacMillan, 183, 1981; Andorn, A.C. Huang, E. H. and Warren, A. Life Sci., 34, 2461, 1984). Human gamma-globulin and human alpha-globulin decrease the specific binding of this ligandin both caudate and prefrontal cortex in a dose-dependent fashion. The mean $IC_{50}$ for gamma-globulin in cortex was 3.4 ± a standard deviation of 0.8 mg/ml assay (N=12). In caudate the $IC_{50}$ was 2.8 ± 0.5 mg/ml assay (N=6). The mean $IC_{50}$ for human alpha-globulin in the cortex was 1.1 ± 0.1 mg/ml assay (N=6) and in caudate was 1.4 ± 0.8 mg/ml assay (N=6).

The effect of both gamma-globulin and alpha-globulin was due to a direct effect on the binding sites in that maximal decrements in [$^3$H]spiroperidol binding could be produced by preincubation of the particulate protein in globulin followed by removal of free globulin with extensive washing of the tissue. The effect of the globulins was therefore not due to $^3$H-ligand serum protein interactions. The effect of gamma- and alpha-globulin was selective in that it was not mimicked by human serum albumin, and further, preincubation of the tissue in human serum albumin did not prevent the effect of either gamma- or alpha-globulin. Immunoglobulin A was effective at decreasing specific [$^3$H]spiroperidol binding in cortex with an $IC_{50}$ of 0.9 ± 0.3 mg/ml assay (N=3).

Aberrant serum proteins have been demonstrated in the neuropil in a variety of illnesses including presenile and senile dementia (Wisniewski, H. M. and Kozlowski, P.B., Annal. N. Y. Acad. Sci., 396, 119, 1982). We have also demonstrated the presence of gamma-globulins, alpha-globulins and various immunoglobulins, in the neuron itself, in the axons and in the Lewy bodies associated with Parkinson's disease. These findings suggest that macromolecular leaks of the blood-brain barrier that permit the extravasation of serum proteins may have important consequences for neurotransmitter receptor function.

325.12 NALOXONE PREVENTS HYPERTHERMIA-INDUCED CONVULSIONS AND DEATH IN THE RAT PUP. M.M.Puig and M.L.Laorden.*
Dept. Anesthesiology, New York University Med. Ctr., New York, NY 10016 and Dept. Pharmacology*, Murcia University Sch. Med., Spain.

The possibility that endogenous opioid peptides (EOP) are involved in producing febrile convulsions in children was studied in a rat pup model in which the effect of the opioid-antagonist naloxone (Nx) was tested in hyperthermia-induced seizures. Unrestrained 15-day-old male Sprague-Dawley rats were placed in a ventilated constant temperature chamber at 40°C and 55% humidity. Rectal temperatures were measured with a thermistor permanent probe connected to a recording thermometer. Three groups of 15 pups from different litters were randomly sampled and injected intraperitoneally with: 1) 0.2 ml saline (S), 2) 5 mg/kg or 3) 10 mg/kg of Nx. Temperatures were recorded after injection immediately after placing the pups in the chamber (time 0), and at 10 min intervals for 60 min; animals were observed for onset of generalized seizures and/or death. In group 1 (S), temperature rose from 35.7 ± 0.53°C (mean °C ± SE) at time 0, to 41.9 ± 0.10 °C at 60 min. Seizures were observed in 13% of the animals at 30 min (mean temp. 40.8 ± 0.19 °C) which rose to 93% at 40 min (41.5 ± 0.3 °C) and 100% at 50 min (42.0 ± 0.10 °C). At 50 min, 66% deaths were observed which increased to 86% at 60 min. Conversely, in group 3 (10 mg/kg Nx), no seizures nor deaths were observed at any time point after exposure to increased temperature, and temperatures were significantly lower than controls, at 30, 40 and 50 min. (35.5 ± 0.21 at time 0; 38.7 ± 0.20 at 30 min; 39.5 ± 0.15 at 40 min; 40.5 ± 0.15 at 50 min and 41.0 ± 0.10 at 60 min). Group 2 (5 mg/kg Nx), although also showing decreased temperature at 30 to 50 min when compared to group 1 (S), was partially protected from seizures (67% at 40 min versus 93% in controls) and death (46% at 50 min versus 66% in controls). No seizures nor deaths were observed when the same protocol and Nx dosages were repeated using randomly selected groups of 5 rats at a chamber temperature of 27°C.

Our results show that high dosages of naloxone completely prevent hyperthermia-induced seizures and death in the rat pup. These results indicate that: 1) EOP participate in the etiology of hyperthermia-induced seizures; 2) due to the high naloxone dosages required, EOP receptors other than mu may be involved and 3) based on (2), the EOP released is probably not a strong mu-agonist. These results suggest a possible clinical use of Nx in febrile convulsions in children and other hyperthermic states.

## GABA AND BENZODIAZEPINES: RECEPTOR CHARACTERIZATION AND LOCALIZATION II

326.1 MONOCLONAL ANTIBODIES TO A $GABA_A$/BENZODIAZEPINE RECEPTOR COMPLEX : HIGH RESOLUTION MAPPING IN RAT AND HUMAN BRAIN. J.G. Richards, P. Schoch* and H. Möhler*, Pharmaceutical Res. Dept., F. Hoffmann-La Roche & Co., Ltd., CH-4002 Basel, Switzerland.

The receptors mediating the therapeutic effects of benzodiazepines are localized exclusively in neuronal membranes of the CNS as part of an oligomeric complex with $GABA_A$ receptors and their associated chloride channels ; the receptor complex is presumed to be a tetramer composed of two α(50kd) and two β(55kd) subunits.

To date, attempts to map the distribution and density of benzodiazepine receptors in the CNS have been dominated by radiohistochemical techniques whose resolution, however, is limited by radiation scatter and possible diffusion of radioligands.

Species and subunit-specific monoclonal antibodies(mAb), raised against a purified $GABA_A$/benzodiazepine receptor from bovine cerebral cortex(Schoch, P. et al., Nature 314:168, 1985 ; Häring, P. et al., Proc. Natl. Acad. Sci. USA, in press), have now been used to map the receptor complex by immunohistochemical techniques(PAP method) with a far superior resolution. The distribution and density of receptor antigenic sites in rat brain, spinal cord and retina as well as in post-mortem human brain was similar to that of benzodiazepine and GABA receptors radiolabelled with $^3$H-Ro 15-1788 and $^3$H-muscimol respectively. The immune reaction(surrounding neuronal perikarya and dendrites) was extremely intense in cerebral cortex, olfactory bulb(particularly the external plexiform layer), ventral pallidum, islands of Calleja, globus pallidus, hippocampus, dentate gyrus, substantia nigra reticulata, cerebellum(granular > molecular layer), spinal cord(dorsal horn and around the central canal) and retina(in four distinct bands in the internal plexiform layer and around isolated amacrine cells) but was absent in brain white matter, pineal, pituitary, adrenals and superior cervical ganglia. The subunit-specific mAb showed an identical distribution in the CNS. These observations indicate that most benzodiazepine receptors are colocalized with the $GABA_A$ receptor complex. Accordingly, the appearance of antigenic sites in rat brain during ontogeny was found to coincide with that of the radiolabelled receptor complex.

Furthermore, in subcellular studies of the rat substantia nigra, for example, the immune reaction was localized exclusively in the pre- and postsynaptic membranes of axosomatic and axodendritic contacts.

The mAb are currently being used(together with GAD mAb) for the subcellular localization of receptors in defined GABAergic synapses and for the identification of possible pathological alterations of the receptor complex in human CNS diseases, such as epilepsy.

326.2 BENZODIAZEPINE RECEPTOR: IMMUNOCHEMICAL AND IMMUNOCYTOCHEMICAL CHARACTERIZATION. J.-Y. Wu, H. S. Lin, C.-T. Lin, Y. Xu, J.-W. Liu and S. C. Wei. Dept. of Physiology, The Penn State Univ., College of Med., Hershey, PA 17033.

The crude mitochondrial fraction, P2 membrane, from rat brain was used as the starting material for benzodiazepine receptor (BZR) purification. The purification procedures involved the covalent labeling of BZR by photoaffinity labeling using [$^3$H]-flunitrazepam (FNZP) as ligand, followed by solubilization and analysis on SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and finally by repetitive preparative SDS-PAGE. The purified BZR migrated as a single protein band on analytical SDS-PAGE corresponding to a molecular weight of 50,000-dalton. Furthermore, the position of the purified BZR on analytical SDS-PAGE matched with that of [$^3$H]FNZP-labeled BZR. The purified BZR preparations were used for the production of polyclonal as well as for the screening of monoclonal antibody against BZR. Antibodies against BZR could be detected in rabbits after three bi-weekly injections of 50 μg each of purified BZR. The specificity of the antibodies was established from immunodiffusion and Western blot transfer tests in which only one single precipitin band and one protein band with 50,000-dalton was obtained when either partially purified or purified BZR preparation was used. The specificity of monoclonal antibody was established by ELISA test using purified receptor preparation as antigen and by Western blot transfer test using either purified or partially purified BZR preparations as described above. Preliminary immunocytochemical studies using polyclonal antibodies and indirect peroxidase techniques have revealed that BZR is localized primarily on the postsynaptic membrane of the neurons receiving GABAergic innervation such as Purkinje cells in the cerebellum, pyramidal cells and some interneurons in the hippocampus. No staining in glial cells was observed. The localization of BZR from our immunocytochemical studies is consistent with the notion that BZ and GAGA systems are closely linked structurally and functionally (Supported in part by PHS grant NS 20922).

326.3 ALTERATION IN BENZODIAZEPINE RECEPTORS CAUSED BY GLYCOSIDASES. Paul Sweetnam and John F. Tallman, Dept. of Psychiatry, Yale University School of Medicine and Abraham Ribicoff Research Facilities of the Connecticut Mental Health Center, New Haven, CT 06508

The ability to photolabel benzodiazepine receptors in vitro from various regions of the rat brain with $^3$H-flunitrazepam has allowed for the structural examination of these receptors by Sodium dodecyl sulfate polyacrylamide gel electophoresis (SDS PAGE) under reducing conditions. Results for all regions studied revealed the labelled receptor to consist of a single major band of radioactivity with the apparent molecular weight of approximately 50K. Under our conditions of labeling we do not significantly label any higher molecular weight forms of the receptor. Exposure of the benzodiazepine receptors to the glycosidases, neuraminidase (N) or endoglycosidase H (E), results in the specific removal of sialic acids (N) and complete asparagine-linked carbohydrate moieties (E), respectively. This type of structural modification of the receptor resulted in a decrease in the the molecular weight, as determined by increased mobility, for all regions examined (Cortex+N+E, 8-10K; Hippocampus+N, 7K,+E, 12K; Cerebellum+N, 0K,+E 4K). These results point to a heterogeniety in the posttranslational glycosylation of the benzodiazepine receptor. This may be due to brain region specific differences in glycosylation.

A causal relationship has also been established between the removal of these carbohydrate moieties and a subsequent alteration in agonist/antagonist benzodiazepine binding. Cortical agonist binding following either glycosidase treatment resulted in no apparent shift in the $K_d$, but a significant decrease in the $B_{max}$. The $B_{max}$ change may be the result from a large decrease in affinity or denaturation of a subpopulation of benzodiazepine receptors. Antagonist binding also showed no apparent $K_d$ shift, but a significant increase in the $B_{max}$. The increase may have resulted from the activation of "hidden" benzodiazepine receptors or a shift of low affinity sites to sites of higher affinity. Cerebellum agonist or antagonist binding was not altered, in terms of either $K_d$ or $B_{max}$, by either enzyme treatment, correlating well with the small amount of carbohydrate removal seen following such treatments.

The ability of these enzymes to modify the apparent molecular weight of the benzodiazepine receptors and the strong correlation to altered ligand binding, in a regional specific manner, generally parallels the description given of type-1 and type-2 benzodiazepine receptors. These results indicate that differing glycosylation mechanisms may alter binding specificity of the receptor in such a manner as to be consistent with idea that regional distribution of type-1 and type-2 sites are due in part to carbohydrate composition of the receptor.

326.4 IMAGING BENZODIAZEPINE RECEPTORS IN MAN WITH C-11-SURICLONE AND POSITRON EMISSION TOMOGRAPHY. J.J. Frost*, R.F. Dannals*, H.T. Ravert*, A.A. Wilson*, J.M. Links*, R. Triffiletti, M.J. Kuhar, S.H. Snyder, and H.N. Wagner, Jr. (SPON: M. Lo). The Johns Hopkins Medical Institutions, Baltimore, MD.

Suriclone is a potent cyclopyrrolone, anti-anxiety drug which binds to the benzodiazepine receptor complex (BZR) with high affinity. Suriclone binds to a site on the BZR distinct from the site where benzodiazepines bind. The KD of suriclone at 37°C is 0.03 nM. C-11-suriclone (SUR) was synthesized by reacting C-CH3I with the appropriate amine precursor. SUR (1 ug/kg) was injected IV into a baboon alone or with 1 mg/kg of Ro 15-1788, a benzodiazepine antagonist, and serial PET scans of the brain were obtained. High radioactivity concentrations were observed in the cerebral cortex and cerebellum which contain high densities of BZR, intermediate concentrations in thalamus and low concentrations in the striatum. When Ro 15-1788 was given a uniform distribution of radioactivity was observed; the radioactivity was reduced to ca. 25% of control values in the brain which was contained within the PET slice.

SUR (0.2 ug/kg) was next administered to a human subject. From 30-60 minutes after injection high radioactivity concentrations were observed in the cerebral cortex and cerebellum, intermediate concentrations in the thalamus and a low concentration in the caudate. Radioactivity in the cerebral cortex and cerebellum decreased slowly with time, implying that binding of SUR to a high affinity site had occurred.

These results demonstrate utility of SUR for measuring binding to the benzodiazepine receptor complex non-invasively in man. Displacement studies in normal volunteers and studies in patients with selected neuropsychiatric disorders are in progress.

326.5 GABA B RECEPTOR-MEDIATED INHIBITION OF cAMP CONTENT IN PRIMARY CULTURES OF CEREBELLAR GRANULE CELLS. J. Xu* and W. J. Wojcik (SPON: J. Cohen). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

We have previously reported a loss of GABA B receptors from cerebella of neurologically mutant mice deficient in granule cells. This indirectly suggested that a population of GABA B receptors could be associated with this cerebellar cell type. We now prepare primary cultures of cerebellar granule cells and use these cultures as a model system to determine the presence of GABA B receptors. Since the GABA B receptors have been shown to affect adenylate cyclase, we measured GABA B receptor-mediated effects on cAMP content from intact cells.

Granule cell cultures were prepared from cerebella of 8-9 day old Sprague-Dawley rat pups. The cells were cultured for eight days during which time the cells produced extensive neurites. On the eighth day, the cultures were tested by incubating them in an appropriate buffered salt solution. The cellular cAMP content was measured by a fluorometric-HPLC method. The cAMP phosphodiesterase inhibitor, 3-isobutyl-1-methylxanthine (IBMX), was included in every experiment to prevent the metabolism of cellular cAMP. The effect of baclofen and IBMX on cAMP content was not different from that seen with IBMX alone. In fact, the addition of IBMX slightly increased cAMP content, indicating a very low basal adenylate cyclase activity. Since we have previously observed only an inhibitory effect of baclofen on adenylate cyclase, the low basal adenylate cyclase activity did not allow us to observe any inhibition of cyclase by baclofen. Therefore, we added forskolin to the incubation to stimulate cAMP production. With 10 uM forskolin, cAMP content increased linearly during the first nine minutes of incubation. Baclofen (1 mM) was capable of attenuating the forskolin-stimulated cAMP accumulation by 50-60%. The EC 50 for baclofen was 5 uM and concentrations greater than 200 uM were maximally effective. It appeared that baclofen was interacting with the GABA B receptor since the rank order of agonist potencies, tested at 100 uM, was (-)baclofen (±) baclofen GABA, while the (+)baclofen, isoguavacine and muscimol were non-responsive. Furthermore, the inhibitory action of 100 uM GABA and (-)baclofen could not be antagonized by 100 uM bicuculline. Other receptor agonists as PGE1, isoproterenol and serotonin were found to have no effect on basal cAMP and/or forskolin-stimulated cAMP content. However, these cultures contained the cholinergic muscarinic receptor, since carbachol and oxotremorine decreased cAMP content.

In summary, the presence of GABA B receptors have been demonstrated on cerebellar granule cells in culture. Our results prove that agonists at the GABA B receptor can attenuate cAMP formation.

326.6 ISLET ACTIVATING PROTEIN (IAP) PREVENTS GABA B RECEPTOR-MEDIATED INHIBITION OF ADENYLATE CYCLASE. W. J. Wojcik and J. Xu*. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

We have shown GABA and baclofen, a GABA analog, to inhibit basal and forskolin-stimulated adenylate cyclase activity in a crude synaptosomal membrane preparation from various brain regions. This effect is believed to be mediated through a GABA B receptor coupled to an inhibitory guanine nucleotide (Ni) regulatory unit of adenylate cyclase. Agonists of the GABA B receptors inhibit via activation of the Ni unit adenylate cyclase activity. Primary cultures of cerebellar granule cells were the source of GABA B receptors coupled to adenylate cyclase for these studies. Using crude membrane preparation from these cultured cells, we showed that the baclofen-mediated response requires GTP. The Km for GTP was about 0.5 μM in the presence of a maximal concentration of baclofen (300 μM). The observed Km of GTP is similar to that of other receptors coupled to Ni linked to adenylate cyclase. It is of interest that the GTP curve was monophasic, having only a stimulatory phase on cyclase activity. This presumably reflects the activation of the stimulatory nucleotide unit. There did not appear any downward deflection with higher concentrations of GTP.

We also show a loss in the baclofen inhibitory response to cyclase after treating the cells with IAP inactivates the Ni unit by an ADP-ribosylation of the Ni. After a 14 hour exposure to IAP (330 ng/ml, List Biologics), we observed a 52% loss in the baclofen-mediated inhibition of basal adenylate cyclase activity and a 60% loss in the baclofen inhibition of forskolin-stimulated cyclase. Similar treatment with IAP also antagonized the baclofen induced decrease of forskolin-stimulated cAMP accumulation by 67% in intact granule cells in primary culture. In conclusion, baclofen inhibits adenylate cyclase activity by stimulating GABA B receptors coupled to the Ni unit of adenylate cyclase.

326.7 BIOCHEMICAL AND FUNCTIONAL CHARACTERIZATION OF GABA-MODULIN IN A NEURONAL CELL POPULATION. F. Vaccarino, H. Alho, A. Guidotti and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

GABA-modulin is a brain basic protein that appears to down regulate GABA receptors allosterically, in vitro. In subcellular studies of rat brain homogenates, GABA-modulin migrates with the synaptosomal fraction, moreover it can be differentiated biochemically from the basic proteins present in myelin (J. Neurochem. 44: 278, 1985). To study the location and function of GABA-modulin, an antiserum was raised in rabbits that contain an antibody highly specific for GABA-modulin (50% tracer bound with ? pmol of protein) but shows some cross reactivity with basic myelin proteins. In order to eliminate this cross-reactivity, the antiserum was pre-absorbed with an excess of myelin basic proteins. After pre-absorption, no immunoreactivity was detected with purified myelin basic proteins (up to 70 pmoles) or with a crude extract of rat brain myelin after HPLC fractionation, while a crude extract of synaptosomes analyzed through HPLC showed a major immunoreactive peak which coeluted with purified GABA-modulin. Immunoreactivity was also detected in an enriched population of granule cells prepared from cerebellum of neonatal rats. Granule cells in primary culture are not myelinated and contain approximately 5% glial cells (Developm. Brain Res. 10: 227, 1983). Immunohistochemical studies in the granule cell culture with the antiserum against GABA-modulin preabsorbed with basic myelin proteins failed to reveal any staining in the glial cells while granule cells were very brightly stained with a pattern characteristic of neuronal membrane proteins. HPLC fractionation of a crude granule cell extract revealed a single immunoreactive peak coeluting with purified GABA-modulin; SDS-PAGE separation of the same cell extract followed by immunoblotting showed a major immunoreactive band with molecular weight identical to GABA-modulin. The material purified from granule cell cultures is identical in molecular weight (17,000), amino acid composition, biological activity and immunoreactivity characteristics with GABA-modulin purified from synaptosomes. Granule cells contain 1.2 µg/mg protein of GABA-modulin-like protein.

Intact granule cells in culture express all the components of the GABA/benzodiazepine/$Cl^-$ receptor complex; moreover, GABA receptors are up-regulated by benzodiazepines and down regulated by GABA-modulin. Thus, these cultures represent an excellent model for studying in detail the mechanism of action of GABA-modulin on the regulation of GABA receptors.

326.8 NEURONAL LOCATION OF A BRAIN NEUROPEPTIDE (DBI) PUTATIVE PRECURSOR OF THE ENDOGENOUS LIGAND FOR BRAIN BETA-CARBOLINE RECOGNITION SITES. H. Alho, P. Ferrero*, A. Guidotti and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp. Washington, D.C. 20032

An endogenous neuropeptide (DBI) that displaces β-carbolines from their specific brain recognition sites has been isolated and purified from rat and human brains (Guidotti et al., PNAS 80: 3531, 1983). DBI injected intraventricularly into rats facilitates conflict in Vogel's behavioral tests.

Immunohistochemical studies were conducted with a DBI antiserum raised in rabbits. Its affinity and specificity were documented with conventional techniques. In rat brain, DBI immunoreactivity is highly localized in nerve terminals of several telediencephalic and amygdaloid nuclei, in pyramidal and basket cells of hippocampus and in cells and fibers of the cerebellar molecular layer. Even without colchicine treatment, some cells in the hippocampus and cerebellum could be visualized. In rats receiving kainic acid (3.7 nmol icv) 6 days before sacrifice DBI immunoreactive staining of cells and fibers disappeared from specific hippocampal areas revealing the neuronal localization of DBI. In specific brain structures the immunohistochemical location of DBI is very similar to that of GABA especially in the molecular layer of cerebellum and in hypothalamic nuclei, but DBI may be present also in neurons that are not GABAergic.

DBI contains two replicas of an octadecaneuropeptide (ODN) (18 amino acids) suggesting that DBI may function as a precursor of ODN. The latter may act as an endogenous ligand for benzodiazepine recognition sites. The ODN has been sequenced and synthesized and an antiserum against the ODN was produced in rabbits. This serum exhibits a slight cross reaction with DBI but fails to bind with several other neuropeptides. The ODN antisera preabsorbed with the synthetic peptide showed no specific immunostaining. The ODN immunoreactivity was localized mainly in brain areas with DBI immunostaining. For instance, ODN immunoreactive neurons were found in pyramidal cells of hippocampus and cerebral cortex and in cells and fibers of the molecular layer of cerebellum.

In conclusion DBI and ODN are located in selected neuronal populations of rat brain. DBI may be a precursor of a new family of brain neuropeptides that bind to benzodiazepine/β-carboline recognition sites and may have a physiological role in regulating the behavioral patterns elicted by conflict situations (anxiety or aggression).

326.9 STRUCTURE-ACTIVITY RELATIONSHIP OF NEUROPEPTIDES DERIVED FROM DBI, THE PRECURSOR FOR BRAIN ENDOGENOUS LIGANDS OF β-CARBOLINE RECOGNITION SITES. R. Santi*, A. Guidotti and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

An octadecaneuropeptide (ODN) obtained by tryptic digestion of DBI was purified and shown to have the following structure: Gln-Ala-Thr-Val-Gly-Asp-Val-Asn-Thr-Asp-Arg-Pro-Gly-Leu-Leu-Asp-Lys. This structure was confirmed by synthesis and HPLC characterization of the natural and synthetic compound. In vitro, synthetic and natural ODN displaced $^3$H-beta-carbolines binding from specific recognition sites of brain synaptic membranes (Neuropharmacology 23: 1359, 1984). However the use of crude synaptic membranes from brain represents a limitation for neuropeptide binding studies because of their high proteolytic activity. Hence we used neuronal cell cultures of rat neonatal cerebellar interneurons enriched in granule cells (Dev. Brain Res. 10: 277, 1982). These cells in addition to GABA and $Cl^-$ channel receptor sites contain high affinity ($K_D$ 3.5 nM) and saturable (Bmax 450 fmol/mg protein) $^3$H-methyl-beta-carboline-3-carboxylate (beta-CCM) binding sites. We have found that ODN added to this cerebellar interneurons, maintained in Locke's solution at pH 7.4, displaces $^3$H-beta-CCM from its binding sites with a Hill slope close to 1, and a Ki of 4 µM and 1.5 µM at 18° and 0-4°, respectively. ODN appears to act competitively. The α-amide derivative of ODN fails to displace $^3$H-beta-CCM. In contrast, smaller synthetic peptide fragments of ODN such as: Arg-Pro-Gly-Leu-Leu-Asp-Leu-Lys (octapeptide); Pro-Gly-Leu-Leu-Asp-Leu-Lys (heptapeptide) and Gly-Leu-Leu-Asp-Leu-Lys (hexapeptide) displace $^3$H-beta-CCM binding with a Ki ranging from 5 to 10 µM. Two other DBI fragments structurally unrelated to ODN, including a heptamer (Phe-Ile-Tyr-Ser-His-Phe-Lys) and a tetramer (Thr-Tyr-Val-Glu) failed to displace $^3$H-beta-CCM from its binding site to cerebellar granule cells in concentrations up to 50 µM. The ODN contains the sequence responsible for the $^3$H-beta-CCM displacing activity of DBI. Moreover the studies with smaller fragments of ODN and ODN α-amidated derivative reveal that within the ODN structure the activity is located in the last eight to six carboxylterminal amino acids. We are now testing the displacing activity of several other ODN derivatives and their stereoisomers in order to determine the minimal structural requirement for this biological activity.

326.10 DMCM (methyl-6,7-dimethoxy-4-ethyl-β-carboline-3-carboxylate) SEIZURES DISCRIMINATE SENSITIVELY BETWEEN VARIOUS TYPES OF BENZODIAZEPINE RECEPTOR LIGANDS. E.N. Petersen, T. Honoré and L.H. Jensen. A/S Ferrosan, Research Division, Sydmarken 5, DK-2860 Soeborg, Denmark (SPON: European Neuroscience Association)

DMCM is a convulsant characterized as an inverse agonist at BZ receptors (Petersen, Eur.J.Pharm., 94:117, 1983). DMCM is convulsant in mice at doses displacing about 50% of $^3$H-flunitrazepam ($^3$H-FNM) from its receptors in vivo (Braestrup et al., Science, 216:1241, 1982). Benzodiazepine (BZ) receptor ligands from several chemical classes have been studied for antagonism of DMCM-induced and pentylenetetrazol (PTZ)-induced seizures and compared to their in vivo displacement of $^3$H-FNM. No correlation was found between the DMCM and PTZ antagonisms further substantiating the different mechanisms of action of these convulsants. Furthermore, we found a wide scattering among the 90 compounds tested with respect to the DMCM antagonism and the $^3$H-FNM displacement in vivo. Generally the BZ were found unexpectedly weak against DMCM seizures as 50-90% BZ receptor occupancy was necessary to obtain protection. Premazepam (MDL 181) was found inactive even at doses occupying >97% BZ receptors (300 mg/kg i.p.). The BZ receptor antagonists Ro 15-1788 and ZK 93426 as well as the partial inverse agonist CGS 8216 were more effective than most BZ as only 50-60% BZ receptor occupancy was required for protection. Partial inverse agonists of the β-carboline type were moderately to weakly active against DMCM-induced seizures. Some agonistic β-carbolines (PTZ antagonists) exerted surprisingly potent DMCM antagonism (<10% BZ receptor occupancy). Braestrup et al., J.Neurochem., 41:454, 1983 have provided evidence for a deviating BZ receptor binding profile of $^3$H-DMCM compared to $^3$H-FNM. The present results suggest that compounds may antagonize DMCM induced seizures by interference with the DMCM binding site (a BZ site) either by direct competition or allosterically (BZ receptor antagonists and benzodiazepines?) or a combination of binding and efficacy of the ligand at the DMCM binding site (β-carbolines?). Downstream inhibition of the expression of the DMCM induced seizures by a DMCM binding site unrelated mechanism may also occur as found with the antiepileptic valproate. Moreover the results show that only some β-carbolines possess unexpectedly high potency against DMCM seizures suggesting that the DMCM binding site is not just a β-carboline site but might be a BZ receptor subtype with high structural specificity. The BZ apparently do not fit to this subtype very well at body temperature and the atypical BZ premazepam apparently has no affinity for this DMCM sensitive subtype even in doses displacing >97% of $^3$H-FNM in vivo.

326.11 ZOLPIDEM (SL 80.0750-23N) : A NOVEL NON-BENZODIAZEPINE HYPNOTIC. S.Z. Langer, H. Depoortere*, S. Arbilla* and P. George*. Department of Biology, Laboratoires d'Etudes et de Recherches Synthélabo (L.E.R.S.), 58, rue de la Glacière, 75013 Paris, France

Zolpidem (SL 80.0750-23N : N,N,6-trimethyl-2-(4-methylphenyl)imidazo[1,2-a]pyridine-3-acetamide hemitartrate), is an imidazopyridine derivative, which after oral or i.p. administration to rats and cats produces a rapid onset short acting sedative effect. Zolpidem displaces with different affinities $^3$H-diazepam binding to membranes of rat cerebral cortex ($IC_{50}$ = 60 nM), cerebellum ($IC_{50}$ = 17 nM) and hippocampus ($IC_{50}$ 109 nM). Zolpidem has low affinity for the peripheral benzodiazepine (BZD) receptor in the rat kidney labelled with $^3$H-Ro-5-4864 ($IC_{50}$ = 1900 nM). The affinity of zolpidem for the central BZD receptor in the rat cortex labelled with $^3$H-Ro-15-1788 ($IC_{50}$ = 141 nM) is significantly enhanced in the presence of GABA 100 µM (ratio $IC_{50}$ - GABA / $IC_{50}$ + GABA = 3.35 + 0.27, n = 4), indicating an agonist type of interaction with high intrinsic activity at the BZD receptor. In cortical recordings of curarised rats, zolpidem (0.3 mg/kg p.o.) disrupts the pattern of wakefulness and induces sleep periods of short duration. In the range of 0.1 - 1 mg/kg i.p., zolpidem induces sleep periods of 10 - 60 min in a dose-dependent manner. At 0.1 and 1 mg/kg (i.p.), zolpidem induces large slow wave sleep, with some sleep spindles at 12 - 14 Hz. In marked contrast with the profile observed with BZDs, the power spectral analysis of the electrocorticogram recordings with increasing doses of zolpidem (0.1 - 1 mg/kg i.p.) show fast onset transient increases in the energy frequency bands 1 to 16 Hz and a dominant peak in the delta frequency band (1 - 4 Hz). The sleep pattern of zolpidem is however mediated through BZD receptors as it is antagonized by Ro 15-1788. No rebound effects occur on withdrawal. In freely moving cats chronically implanted with electrodes, zolpidem does not affect total duration of the different sleep phases (Arbilla S. et al., Br. J. Pharmacol., 1985, in press). In man, zolpidem is an hypnotic which increases the duration of slow wave sleep and does not affect rapid eye movement sleep (Nicholson A.N. and Pascoe D.A., Br. J. Pharmacol., 1985, in press). In summary, our results indicate that zolpidem, which is chemically different from BZDs, activates central but not peripheral BZD receptors. Zolpidem possesses BZD receptor agonist properties, and has a higher affinity for cerebellar than hippocampal BZD recognition sites. In addition, zolpidem is a short acting hypnotic, which induces a physiological pattern of slow wave sleep. Therefore, imidazopyridines like zolpidem represent a novel class of agonists at BZD receptors, which possess clear pharmacological differences and potential therapeutic advantages over classical BZDs.

326.12 NEUROPHARMACOLOGICAL AND BEHAVIOURAL EFFECTS OF ZOLPIDEM, A NOVEL SHORT-ACTING HYPNOTIC. B. Zivkovic*, K.G. Lloyd, D.J. Sanger*, G. Perrault*, E. Morel*, S.Z. Langer and G. Bartholini*. Laboratoires d'Etudes et de Recherches Synthélabo (L.E.R.S), 58 rue de la Glacière, 75013 - Paris, France.

Recent studies have demonstrated that zolpidem (SL 80.0750-23N; N,N,6-trimethyl-2-(4-methylphenyl) imidazo [1,2-a] pyridine-3-acetamide) potently displaces benzodiazepine receptor ligands from their central recognition sites and induces a rapid onset, short-lasting hypnotic effect in experimental animals and man (Langer et al., this meeting; Nicholson and Pascoe, Br. J. Pharmacol. 1985, in press). The present studies were performed in order to establish the neuropsychopharmacological profile of the compound and to compare its spectrum of activity with that of benzodiazepines.

Qualitatively, zolpidem shares some properties with benzodiazepines (Table); these effects were antagonised by the benzodiazepine antagonist Ro15-1788, indicating involvement of benzodiazepine sites in the action of zolpidem.

| | Pentetrazole$^+$ Tonic Convul. Mouse | Loaded Grid$^+$ Test Mouse | Conflict* Drinking Rat | Rota-Rod$^+$ Rat |
|---|---|---|---|---|
| Zolpidem | 7.7 | 17 | 1 | 6 |
| Midazolam | 0.5 | 1 | 1 | 3 |
| Flunitrazepam | 0.05 | 0.1 | 0.3 | 0.6 |
| Diazepam | 0.4 | 1 | 3 | 5 |

$^+ED_{50}$ (mg/kg, i.p.); *Minimal effective dose (mg/kg, i.p.).

However, zolpidem differs from benzodiazepines in various aspects. Thus, in spinalised rats zolpidem reduced the hind limb flexor reflex only when injected at doses which induce narcosis (10 mg/kg, i.v.) while diazepam is active at 2 mg/kg, i.v. In decerebrate cats zolpidem enhanced dorsal root potentials with a potency similar to that of diazepam ($ED_{50}$=0.3 mg/kg, i.v.) and duration of action similar to that of midazolam (half life of the effect 25 min). However, in contrast to diazepam, this effect was not accompanied by a corresponding presynaptic inhibition of the monosynaptic reflex recorded from the L-7 ventral root.

In rats trained to discriminate chlordiazepoxide (5 mg/kg, i.p.) from saline, zolpidem failed to generalize with the chlordiazepoxide-associated-lever up to a dose (3 mg/kg, i.p.) which induced a strong decrease in the overall rate of responding, indicating that the compound and benzodiazepines do not share the same discriminative stimulus properties.

Together, these results demonstrate that zolpidem possesses anticonvulsant and anxiolytic activities, but in contrast to benzodiazepines is virtually devoid of myorelaxant properties.

## BRAIN METABOLISM III

327.1 DURATION OF 2-DEOXYGLUCOSE-6-PHOSPHATE (2dGlc-6-P) IN BRAIN by R.K. Deuel, T.W. Anderson* and R. Stephani,* Departments of Pediatrics and Neurology, Washington University School of Medicine, St. Louis, Missouri, 63110

$^{31}$P NMR spectroscopic monitoring of the time course of 2dGlc-6-P in brains of conscious rats revealed peak concentrations at 40-60 minutes after an iv bolus of 500 mg/kg, with decline to half the peak concentration by 120 min. (Deuel, et al, Science, in press). This time course is much shorter than that reported with $^{14}$C-labeled tracer doses of 2dGlc. To directly test if the 500 mg/kg dose induces a shorter half life of 2dGlc-6-P in brain than a tracer dose, NMR methodology could not be used as it would not detect very low concentrations of 2dGlc-6-P. An autoradiographic experiment was therefore performed. 250 mg conditioned rats given an 0.25 cc iv bolus containing 50 µCi/kg $^{14}$C-labeled 2dGlc, plus 500 mg/kg of unlabeled 2dGlc were paired with rats given an 0.25 cc bolus containing only the labeled tracer. Timed arterial samples were taken for scintillation counting, glucose assays, and hematocrits. Four pairs of rats were sacrificed at 50 minutes, four at 120 minutes and four at 240 minutes after bolus injection. Animals were perfused through the heart, and the brain rapidly removed, blocked and frozen. To determine if regional differences in the time course of 2dGlc-6-P existed, 30 µ frontal and parietal coronal sections were used to prepare autoradiograms that were analyzed by densitometry for tissue concentration of $^{14}$C. The remainder of each brain was solubilized and aliquots subjected to scintillation counting. In contrast to the increasing divergence of $^{14}$C tissue concentration over time that was predicted between pair members if the 500 mg/kg dose accelerated tissue 2dGlc-6-P hydrolysis, isotope concentration in whole brain as well as in selected grey matter structures showed a constant ratio between the pairs over time, suggesting that the large dose has no effect upon the duration of cerebral $^{14}$C-2dGlc-6-P. Supported by NIH grants GM-30331 and the McDonnell Center for Study of Higher Brain Function of Washington University.

327.2 NO EVIDENCE FOR IN VIVO DEPHOSPHORYLATION OF GLUCOSE-6-PHOSPHATE IN RAT BRAIN. G. Dienel, T. Nelson*, T. Jay* and L. Sokoloff. Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20205

Quantitative trapping of deoxyglucose(DG)-6-phosphate during the 45 min experimental interval is assumed in the determination of local rates of cerebral glucose utilization by the [$^{14}$C]DG method (Sokoloff et al., J. Neurochem., 28:897, 1977). Recently, Huang and Veech (J. Biol. Chem. 257:11358, 1982) reported evidence for a very high rate of dephosphorylation of brain glucose-6-phosphate (G-6-P) on the basis of the differential rates of loss of $^3$H and $^{14}$C from brain glucose isolated at intervals after an intracarotid injection of a mixture of [2-$^3$H]- and [U-$^{14}$C]glucose. Detritiation of G-6-P at the hexosephosphate isomerase step followed by dephosphorylation of G-6-P will cause a progressive decrease in the $^3$H/$^{14}$C ratio of brain glucose with time after the injection. Huang and Veech isolated glucose from freeze-blown brain samples by passage of the neutralized brain extract sequentially through a Dowex AG1-X8 formate column and a Dowex AG1-X8 borate column; the borate eluate was defined as the glucose fraction without any proof of purity. Our laboratory, using more specific methods to purify brain glucose, could not confirm the differential loss of $^3$H compared to $^{14}$C from brain glucose (Nelson et al., Trans. Amer. Soc. Neurochem. 16:147, 1985). The purpose of this study was to determine the $^3$H/$^{14}$C ratios in brain glucose isolated according to the procedures of Huang and Veech. Rats were injected with a mixture of [2-$^3$H]- and [U-$^{14}$C]- glucose via the carotid artery, and were killed by freeze-blowing at about 7 or 9 min. after the injection. Deproteinized brain extracts were neutralized and passed over tandem Dowex AG1-X8 formate and borate columns. The $^3$H/$^{14}$C ratios of the borate-column eluate of the brain samples were significantly ($p < 0.01$) lower than those of the blood samples taken at kill time, and both were less (22% and 11%, respectively) than that of the injectant which was carried through the same extraction and purification steps. Thin layer chromatographic analysis of the borate column eluate demonstrated the presence of other radiolabeled compounds in addition to glucose. The borate-column eluates were then further purified by sequential (1) passage over Dowex-50 to remove basic metabolites, (2) derivitization of its glucose component to gluconic acid with glucose oxidase, and (3) separation of gluconic acid from neutral metabolites contained in the borate column eluate by passage over Dowex 1-formate. The $^3$H/$^{14}$C ratios of the gluconic acid derived from brain samples were slightly below that of the injectant, but they were no less than that of the blood samples. The slight decrease in the brain ratio can be ascribed to the glucose delivered to the brain by the blood. Thus, there is no evidence for detritiation in the brain glucose pool, and we confirm the results of Nelson et al. (1985).

327.3 DEMONSTRATION OF UNILATERAL ACTIVATION OF THE RAT SOMATOSENSORY SYSTEM BY MEANS OF A SEQUENTIAL DOUBLE-LABEL AUTORADIOGRAPHIC METHOD. J. L. Olds*, K. A. Frey, C. A. Bay* and B. W. Agranoff (SPON: J. Schacht). Neuroscience Lab/Cyclotron PET Facility, University of Michigan, Ann Arbor, MI 48109.

Most of the variability inherent in the autoradiographic imaging of LCMRglc by means of the 2-DG method can be attributed to inter-subject differences in global cerebral metabolism. Thus, for studies involving small changes in glucose utilization, one is obligated to use very large numbers of animals, which in many cases is a prohibitive factor. We recently addressed this problem by means of a quantitative sequential double-label autoradiographic method employing $^{18}F$- and $^{14}C$-labeled fluorodeoxyglucoses (Olds et al., Brain Res., in press). We report here the successful application of the sequential double-label method employing $^{3}H$- and $^{14}C$-labeled deoxyglucoses to demonstrate an activation of the somatosensory pathway in response to passive manipulation of the right forepaw. The described method takes advantage of the differential β-energies of the two isotopes and uses two autoradiographic exposures: one to LKB-Ultrofilm, and the other to Kodak SB-5 X-ray film. Self-absorption of tritium was minimized by a lipid extraction with hexane (Olds et al., Trans. Amer. Soc. Neurochem. 16:148, 1985). A pixel-by-pixel subtraction of the digitized images was employed to facilitate isotopic separation. Each 20 μm brain section thus produced two data sets: one representing LCMRglc under the resting state, and the other representing LCMRglc under the stimulated state. Unilateral mechanical manipulation enabled us to emphasize the differences in brain metabolism separated by the 2-state paradigm. We found that the experimentally perturbed condition produced activation of the somatosensory cortex contralateral to the stimulated limb, while the control condition led to a clearly distinguishable image from the same brain section. An analogous experiment revealed the anticipated pattern that follows auditory stimulation. This method makes possible a form of analysis not previously available in DG studies in which each animal serves as its own control. The method has particular applicability to the analysis of symmetrical changes in LCMRglc, in which the intrinsic variability of subject-to-subject regional brain metabolism might otherwise greatly reduce sensitivity. (Supported by NIH Grant NS 15655.)

327.4 CELLULAR AND SUBCELLULAR LOCALIZATION OF DEOXYGLUCOSE UPTAKE IN ANTIDROMICALLY STIMULATED SUPERIOR CERVICAL GANGLION. P. Yarowsky, A. Boyne and R. Johnson*. Dept. of Pharmcol. Exp. Therap., Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

With the $^{14}C$ deoxyglucose method, we have previously demonstrated a correlation between impulse activity and enhanced postsynaptic metabolic activity in the rat superior cervical ganglion (RSCG) in vivo during antidromic stimulation of the external carotid (EC) nerve (Yarowsky et al., Brain Res. 334:330, 1985). The spatial resolution obtainable with $^{14}C$ does not permit an analysis of which postsynaptic elements were metabolically activated. We therefore have employed methods for both $^{3}H$ autoradiography and ultrastructural preservation of water-soluble compounds with quick freezing, freeze substitution and the 'dry' emulsion method of Nagata et al. (Histochemie 18:1077, 1969).

The collagenase-pretreated and desheathed RSCG was pulse-labeled with [$^{3}H$]deoxyglucose (2-DG) during antidromic stimulation of the EC nerve at 30° C, rinsed in Locke solution and then quick frozen, THF substituted, osmicated and embedded in Epon/Araldite. Light-level autoradiograms (LM ARG) were prepared by mounting 5 μm sections with a drop of glycerol on slides and applying a loop of K5D emulsion. EM autoradiographs (EM ARG) were made by cutting 90 nm sections onto glycerol. The sections were carbon-coated and looped with L4 emulsion.

LM ARG of antidromically stimulated tissue confirmed the localization of enhanced glucose utilization in the caudal pole of the RSCG, previously seen with $^{14}C$ autoradiography. The pattern of enhanced uptake in the caudal pole was compared in three anatomical compartments, somata of neurons, somata of glia and neuropil, by superposition of the LM ARG with stained sections. The grain densities of the compartments were: neuropil, 8/100 $\mu m^2$; neuronal somata, 26/100 $\mu m^2$ glia somata 17/100 $\mu m^2$. Neither the rostral pole of the antidromically stimulated RSCG, an internal control, nor the caudal pole of unstimulated preparations demonstrated similar uptake.

In order to eliminate possible effects of afferent stimulation via the EC nerve, RSCG were chronically decentralized (4 d) prior to pulse labeling or pulse labeled either in the presence of Locke solution containing low $Ca^{+2}$ (0.2 mM) and high $Mg^{+2}$ (8 mM) or in Locke solution containing the ganglionic blocker hexamethonium (3 mM). No differences in the pattern or the grain density distribution were found.

Preliminary analysis of EM ARG from antidromic stimulated tissue showed several putative sources of radioactivity. These were, in order of the highest grain density: (1) neuronal cytoplasm (2) neuronal mitochondria (3) neuronal nuclei (4) glial cytoplasm and (5) dendrites. No labeling of afferent synapses, pre- or postsynaptically, was observed. (Supported by NSF grant BNS 81-19481.)

327.5 LOCAL CEREBRAL GLUCOSE UTILIZATION DURING GENERALIZED SEIZURES IN NEWBORN MONKEYS. D.G. Fujikawa, B.E. Dwyer*, R.R. Lake* and C.G. Wasterlain*. Epilepsy Res. Lab. and Nucl. Med. Serv., V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. of Neurology and Brain Res. Inst., UCLA Sch. of Med., Los Angeles, CA 90024.

Recent evidence indicates that cerebral energy demands may exceed substrate supply during status epilepticus (SE) in newborn monkeys. Since this suggests increased brain glucose utilization we measured local cerebral metabolic rates for glucose (l-CMRgl) in newborn monkeys during bicuculline-induced seizures, using the $^{14}C$-2-deoxyglucose (2DG) autoradiographic technique. Cerebral cortical glucose concentrations were obtained in a separate group of control and 30 minute seizure animals with the funnel-freezing method (Fujikawa, D.G. et al., Neurology, 35 (Suppl.1):196, 1985). This allowed us to estimate the lumped constant (LC) in cerebral cortex with a nomogram (Pardridge, W.M. et al., J. Cereb. Blood Flow Metabol., 2:197-202, 1982), which permitted a more accurate estimation of cortical glucose utilization during seizures.

Six 2 week old marmoset monkeys had femoral vessel cannulations under methoxyflurane anesthesia, and after 4 hr of recovery they received ketamine, 50 mg/kg I.P., in accordance with the funnel-freezing protocol. Seizure animals (n=3) were given bicuculline, 10 mg/kg I.M., and when seizures began, 2DG (0.3 μCi/g) was given I.V. Control animals (n=3) were given 2DG 15-30 min after ketamine. The animals were decapitated after a 45 min interval of arterial blood sampling. Brains were processed for autoradiography and blood samples for liquid scintillation counting and plasma glucose determinations. Using the Pardridge nomogram, we found that the cortical LC was 0.42 in control and 1.0 in seizure animals. We used the 0.42 value to calculate l-CMRgl in all animals and the 1.0 value to correct the l-CMRgl in cortex during SE.

Most brain regions showed a 150-600% uncorrected increase in l-CMRgl during SE. Local CMRgl was unchanged in lateral geniculate nuclei, cerebellum and optic tract; it was decreased in inferior colliculi. In frontal cortex control l-CMRgl was 21.3 ± 2.6 μmol/100g/min (mean ± S.E.M.); it appeared to increase 4-fold during SE. When the LC value of 1.0 was used, the corrected l-CMRgl in frontal cortex was 35.6 ± 1.2 μmol/100g/min, a 170% instead of a 400% increase, but still significantly elevated ($p<0.01$).

Our results suggest that during neonatal SE glucose utilization in cerebral cortex increases almost 2-fold and that LC correction is essential to prevent overestimation of l-CMRgl. Together with our previous data showing preferential blood flow to brainstem and marked depletions of cortical glucose and high energy phosphates during neonatal seizures, our findings suggest that cortical energy demands and glucose utilization exceed glucose supply. This could lead to cortical energy failure and cell damage and could be the basis for the increased vulnerability of the immature brain to damage from SE. (Supported in part by NIH Grant NS-13515.)

327.6 FOCAL CEREBRAL ISCHEMIA: EFFECT OF $CO_2$ ON CEREBRAL BLOOD FLOW HETEREOGENEITY. B. Bose*, S.C. Jones*, H.T. Friel*, C. Chernicky, K.L. Barnes, J.R. Little*. Cleveland Clinic Foundation, Cleveland, OH 44106.

Previous investigators have observed temporal cycling in the cerebral cortex of cerebral blood flow (CBF), vascular volume, the level of metabolic substrates and the spatial microheterogeneity of CBF. The aim of this study is to determine the effect of normocapnia, hypocapnia and hypercapnia on the spatial heterogeneity of CBF in the rat middle cerebral artery occlusion model.

Sprague-Dawley rats (350-400 gms) were lightly anesthetized with pentobarbital, tracheotomized, and their right common carotid artery (RCCA) isolated. The femoral arteries and veins were cannulated bilaterally. The right middle cerebral artery (RMCA) was exposed and the RCCA and RMCA were occluded for a duration of two hours. At the end of this period $PaCO_2$ was adjusted to 25 mmHg, 35 mmHg, or 60 mmHg. After heparinization (100 IU), the rats were injected with boluses of 4% thioflavine S (0.7 mg/kg) 45 sec prior to sacrifice and $^{14}C$-iodoantipyrine (100 μCi/kg) 10 sec prior to sacrifice. An arterial blood sample was obtained for 30 sec prior to sacrifice with a calibrated withdrawal pump. The head was frozen in liquid Freon-22 after sacrifice by guillotine. Autoradiograms were made from 20 μm frozen brain sections. Alternate 20 μm sections were examined under fluorescent light to visualize the cortical microvasculature.

In normocapnic animals, regularly spaced columns of CBF perpendicular to the cortical surface were observed in the contralateral, non-infarcted (control) hemisphere. Several widely spaced columns were observed in the center of the severely ischemic area. In hypocapnic animals flow columns were visualized on the contralateral (control) side but were absent in ischemic areas of the infarcted hemisphere. In hypercapnic rats there was a homogeneous distribution of flow (no columns) on the control side; flow columns were present in the ischemic penumbra and umbra. This data demonstrating the presence of flow columns in severely ischemic areas in normocapnic and hypercapnic animals is contrary to previous findings and may be technique dependent. Furthermore, these columns seem to retain their $CO_2$ sensitivity to hypocapnia for a least two hours following the onset of a severe focal ischemic insult.

327.7 **HEMODYNAMIC AND METABOLIC ALTERATIONS FOLLOWING CORTICAL INFARCTION IN THE RAT.** W.D. Dietrich, M.D. Ginsberg, R. Busto*, and B.D. Watson*. Departments of Neurology and Anatomy and Cell Biology, Univ. of Miami School of Medicine, Miami, FL 33101.

Both clinical and experimental studies have demonstrated that the effects of focal brain injury are not restricted to the primary focus of damage, but may be quite diffuse and appear in brain regions remote from the primary injury site. Efforts to study stroke mechanisms responsible for widespread hemodynamic and metabolic abnormalities have been hampered by the lack of appropriate animal models. Recently we have developed in the rat a reproducible model of cortical infarction initiated by intravascular thrombosis. In the present study, cortical infarction was induced photochemically in rats by irradiating the intact skull for 20 minutes with green light following the systemic injection of Rose Bengal. Regional cerebral blood flow (rCBF) and local glucose utilization (lCMRglu) were studied autoradiographically at several time periods following irradiation.

Autoradiographic rCBF studies at 30 minutes demonstrated a central ischemic zone surrounded by zones of cortical hyperemia. Asymmetries between hemispheres in brain regions remote from the irradiated zone were apparent at this early time period. For example, rCBF within the frontal cortex was depressed ipsilaterally compared to the contralateral homologous zone. By four hours, the zone of focal ischemia had increased in size and its margins were no longer hyperemic. rCBF was significantly depressed in several ipsilateral cortical brain structures but not in any contralateral brain structures. By five days, rCBF was depressed in both ipsilateral and contralateral cortical areas. Although rCBF was still depressed in some cortical regions at 15 days, significant differences were obtained only within the contralateral auditory and visual cortices.

At 4 hours and 5 days following photochemically induced cortical infarction, lCMRglu was markedly reduced within the lesion center, and irregular regions of moderate-to-marked glucose hypermetabolism were noted within the marginal zone of the developing infarct. Significant differences in glucose utilization were also demonstrated at four hours within ipsilateral brain structures remote from the site of focal injury, including the striatum and hippocampus. By five days, glucose utilization was severely depressed in all ipsilateral cortical areas, but not within any structure contralaterally. This progressive decline in cerebral metabolism followed the earlier progressive decline in cerebral blood flow, and may suggest a cause and effect. It is likely that similar processes are occurring in patients following stroke. Thus the present experimental model should facilitate the understanding of these stroke mechanisms. Supported by NIH grant NS 05820.

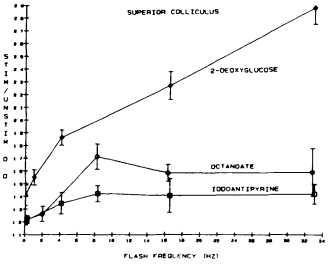
327.8 THERE IS A LOOSE RELATIONSHIP BETWEEN CEREBRAL BLOOD FLOW AND METABOLISM DURING VISUAL STIMULATION. R. Sundermann*, D. Gitelman* A.W. Toga and R.C. Collins. Depts of Psychiatry; Neurology and Neurological Surgery; and the McDonnell Center for the Study of Higher Brain Functions, Wash. U. Sch. of Med., St. Louis, MO 63110

Previous studies (Sokoloff, Fed. Proc. 40:2311, 1981) have indicated a tight relationship between regional blood flow (rCBF) measured with $^{14}$C-iodoantipyrine (IAP) autoradiography and local cerebral glucose utilization (LCGU) measured with $^{14}$C-2-deoxyglucose (2-DG) autoradiography when various grey and white matter structures are compared. As yet no tight coupling between rCBF and LCGU has been demonstrated in response to a range of intensities of physiologic stimulation. We report here the examination of the relationship among 1) graded physiologic visual stimulation, 2) rCBF, 3) LCGU and 4) uptake of $^{14}$C-octanoate (OCTO), a fatty acid metabolized in mitochondria (Rowley & Collins, Brain Research, in press.

Albino rats (300 g) were anesthetized with halothane for placement of catheters and enucleation of one eye. This denervates contralateral visual centers which serve as internal control areas in data analysis. Four hours after halothane, groups of rats were exposed to a flashing checkerboard pattern at different frequencies but will luminal flux held constant for all rats. Quantitative film autoradiography was performed on animals killed at 30 secs for IAP; 2 min for OCTO; and 45 min for DG.

With increasing flash frequency there was a progressive increase in DG labelling in the intact compared to the deafferented superior colliculus (Toga & Collins, J. Com. Neurol. 199:443, 1981). IAP and OCTO labelling increased up to 8Hz but then plateaued. The pattern of the response to graded visual stimulation differed among rCBF, LCGU, and OCTO labelling in the lateral geniculate and visual cortex as well.

The results indicate that the tight relationship between cerebral blood flow and metabolism that is observed when different structures are compared becomes loose when single structures are examined at different intensities of stimulation. Different control mechanisms must exist.



327.9 CEREBRAL BLOOD FLOW AND OXYGEN METABOLISM ARE REGIONALLY UNCOUPLED DURING FOCAL PHYSIOLOGICAL ACTIVATION: A POSITRON EMISSION TOMOGRAPHIC STUDY. Marcus E. Raichle and Peter T. Fox*. (Departments of Neurology and Radiology (Division of Radiation Sciences), Washington University School of Medicine, St. Louis, MO USA 63110).

A large literature has established that cerebral blood flow and metabolic rate are closely coupled to one another throughout the normal resting brain. No studies, however, have directly investigated the coupling of blood flow and metabolism during focal, physiological increases in neuronal activity in normal human subjects.

Regional flow:metabolism coupling during focal brain activation was tested in 9 normal volunteers using $^{15}$-oxygen-labeled compounds ($H_2{}^{15}O$, $O^{15}O$, $C^{15}O$) and positron emission tomography. One resting-state (Set 1) and 3 stimulated-state (Sets 2-4) sets of measurements were obtained during each 2.5-3.0 hr scanning sequence. Focal activation was induced with unilateral vibration of the fingers (D1-5; 130 hz, 2 mm amplitude). Stimulation was begun 0 sec (set 2), 60 sec (set 3) or 300 sec (set 4) before isotope delivery and continued throughout data acquisition (40 - 180 sec).

Discrete, focal increases in rCBF occurred in the postcentral gyrus of the hemisphere contralateral to stimulation in every subject. Stimulus-induced changes in regional cerebral blood flow (rCBF), oxygen metabolic rate ($rCMRO_2$) and the extracted fraction of oxygen (COEF) were calculated within this region as the % $\Delta$ change from the set 1 values.

Regional uncoupling of rCBF and $rCMRO_2$ was found in the zone of focal neuronal activation induced by tactile stimulation. Blood flow increases (mean = 29%) were significantly greater ($p < .000001$, Anov) than metabolic increases (mean = 5%) as measured during identical stimulus conditions, in identical brain regions, in the same subjects. A highly-significant decline in rOEF (mean = -19%) further confirmed that the rCBF increase provided $O_2$ far in excess of the demand from the small $rCMRO_2$ increase. Stimulus duration (Set 2-4)had no significant effect on rCBF, rOEF or $rCMRO_2$. This was not, therefore, a transient overshoot in rCBF nor, conversely, a transient lag in $rCMRO_2$. Uncoupling was highly-focal, being restricted to the zone of rCBF increase. Throughout the remainder of the brain a close correlation (mean r=0.87)between rCBF and $rCMRO_2$ was maintained, across the entire range of rCBF and $rCMRO_2$ values. These observations indicate that the relation of hemodynamics and metabolism is more complex than previously believed.

327.10 **MATURATIONAL CHANGES OF GLUCOSE METABOLIC PATTERNS IN THE HUMAN INFANT DETERMINED BY 18F-2-FLUORODEOXYGLUCOSE POSITRON EMISSION TOMOGRAPHY.** Harry T. Chugani* and Michael E. Phelps (SPON: Jeffrey P. Lieb). Departments of Neurology and Pediatrics, and the Division of Nuclear Medicine and Biophysics, UCLA School of Medicine, Los Angeles, Ca 90024, USA.

The development of positron emission tomography (PET) has made it possible to monitor functional maturational changes in the infant brain through the use of appropriate isotopes. Because normal infants cannot currently be studied with PET for ethical reasons, we have employed a strategy where infants with a diversity of pediatric neurological disorders are studied with PET and 18F-2-fluorodeoxyglucose (FDG). In this manner, developmental changes in local cerebral metabolic rates of glucose (LCMRglc) can be characterized, and at the same time, relevent clinical information obtained to assist in the management of these infants. Our patient population consisted of infants with questionable neonatal seizures, definite neonatal seizures, cerebral embolism from cardiac sources, and otherwise normal infants with facial nevi where the Sturge-Weber syndrome was a consideration. All infants were studied in the awake state, with eyes and ears open, and during continuous EEG recording. In infants between 5 and 26 days of age the glucose metabolic pattern was dramatically distinct from adult patterns, with prominent metabolic activity in the sensorimotor cortex, thalamus, midbrain/brainstem and cerebellum (particularly the vermis). The remainder of the cortex and striatum were relatively hypometabolic. During the second and third months of life, a relative increase in LCMRglc was noted in much of the cortex and striatum, although the frontal cortex and several association cortical regions remained relatively hypometabolic. By 1 year of age, the glucose metabolic pattern clearly resembled that seen in the adult, with prominent frontal and association cortical activity. Our findings are consistent with the known functional organizational changes of the infant brain at 12 weeks of age with respect to EEG activity, sleep-wake patterns and behavior. The gradually increasing cortical glucose metabolism observed in our patients during this period coincides with the suppression of intrinsic subcortical reflexes present in normal newborns. Cognitive or hypothesis-forming development occurs in the human infant towards the end of the first year, and indeed, by this time LCMRglc has increased in frontal and association cortices, areas intimately involved with higher cortical function. The use of PET constitutes a novel approach to the study of the developing human brain, and will undoubtedly also prove to be a powerful tool in which abnormal brain development can be studied.

327.11 THE EFFECT OF DIAZEPAM SEDATION ON CEREBRAL GLUCOSE METABOLISM IN ALZHEIMER'S DISEASE. N.L. Foster*, A. VanDerSpek*, J.C. Sackellares*, M.S. Aldrich*, R.H. Hichwa*, S. Gilman, and B.W. Agranoff. (SPON: M. Bromberg). Depts. of Neurology, Anesthesiology, Internal Medicine and Psychiatry, University of Michigan Medical Center, Ann Arbor, MI 48109.

To examine the effects of mild sedation on glucose utilization in the cerebral cortex, three patients with probable Alzheimer's disease received 5-10 mCi of $^{18}$F-fluorodeoxyglucose (FDG) on two separate days. On one occassion subjects were at rest with eyes patched and ears open, and on the second they received intravenous diazepam titrated to achieve and maintain stage II sleep by clinical and EEG criteria. Rates of glucose utilization were then estimated using positron emission tomography (PET). Cerebral cortex in twelve interleaved horizontal slices in the canthomeatal plane were analyzed using irregular regions of interest. Thus approximately 85% of cortex was measured. Above the level of the cerebellum, cerebral cortex was divided into 4 contiguous regions in each hemisphere, each representing a quarter of the anteroposterior extent of the cortex. Visual cortex was analyzed separately.

PET images showed similar patterns of glucose uptake at rest and with sedation. When normalized to average cortical values, no change in cerebral glucose utilization was seen in any region:

| | % CHANGE WITH MEDICATION (±SD) | |
|---|---|---|
| | LEFT | RIGHT |
| ANTERIOR FRONTAL | 0 ± 1 | 1 ± 3 |
| POSTERIOR FRONTAL | 0 ± 2 | 3 ± 1 |
| ANT TEMPEROPARIETAL | 0 ± 3 | 1 ± 0 |
| POST TEMPEROPARIETAL | 5 ± 1 | 2 ± 4 |
| VISUAL CORTEX | -6 ± 6 | |

Likewise, relative hemispheric cortical metabolism remained unchanged. Two patients who required small doses of diazepam (13.5 and 35.5 mg. over the duration of the study) to achieve sedation showed only minimal (<6%) change in overall glucose utilization, while the third, who received 60.5 mg., had a 49% decrease with medication.

While further study is needed to determine the effect of diazepam sedation on average cerebral cortex metabolism, regional glucose utilization, normalized to overall cortical values, appears to be unchanged by mild diazepam sedation. This technique may permit the study of patients otherwise unable to cooperate with FDG-PET procedures.

(Supported in part by a grant from the W.T. Buchanan Research Fund for the Study of Alzheimer's Disease and Related Dementias).

327.12 A CORRELATIONAL ANALYSIS BETWEEN PSYCHOPHYSICAL PAIN ASSESSMENT, SOMATOSENSORY EVOKED POTENTIALS, AND LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) IN NORMAL VOLUNTEERS AND PATIENTS WITH SCHIZOPHRENIA. H.H. Holcomb, W.E. Semple*, M.S. Buchsbaum*, R.M. Cohen*, A.C. King*, J.D. Cappelletti*, L.E. DeLisi*, and L. Flinchbaugh*. Clinical Brain Imaging, LCM, NIMH, Bethesda, MD 20205.

Because patients with schizophrenia differ from normals in their appreciation of pain we have used a (1) nonparametric pain assessment scale, (2) positron emission tomography (PET) of fluorine-18 2-deoxyglucose (F18-2DG) utilization in conjunction with a prolonged, repetitive, noxious, cutaneous, electrical stimulation and (3) a 16 lead somatosensory evoked potential (EP) mapping system to assess the behavioral, neurophysiological and cerebral metabolic response to pain. Normal volunteers (n=23) and drug free schizophrenics (n=19) completed a five minute pain assessment task shortly before receiving thirty minutes of repetitive 1/second electrical shocks to the right wrist. Coincident with the onset of the stimuli ( 2,9,16, and 23 milliamps presented randomly, each lasting one millisecond) 5 millicuries of F18-2DG was administered intravenously. During the stimulation session EP's were collected from 16 left hemispheric scalp leads. Immediately thereafter a second pain assessment was completed and the subject was transferred to the PET scan room where 7 transverse brain images were acquired for LCGU determination. We then generated correlation matrices between pain assessment performance, LCGU, and EP amplitude to determine the relationships between these pain associated behavioral and biological measurements. Both at the left sylvian region near the inferior parietal lobule and the left posterior frontal region, normal subjects exhibit significant correlations between LCGU and pain assessment performance. Those with the best performance exhibit the highest mean glucose metabolic rates. The brains of patients with schizophrenia fail to exhibit such a relationship. The P200 EP amplitude measured by a scalp electrode overlying the inferior parietal lobule is also significantly correlated with psychophysical pain assessment in normal volunteers, but not in schizophrenics. When P200 EP amplitude, averaged over the first 16 minutes of stimulation, is correlated with LCGU, markedly different patterns appear in the two diagnostic groups. Whereas normals exhibit a small number of significant correlations (11) between anatomically appropriate brain regions and their contiguous scalp electrodes, schizophrenics show an unusually large number of significant correlations (111) between many brain regions and all scalp electrodes. These finding suggests that patients with schizophrenia fail to utilize discrete brain regions for specific sensory processing tasks.

## BIOCHEMICAL AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT II

328.1 LIGHT-DEPENDENT REGULATION OF GABA RECEPTORS DURING DEVELOPMENT. Paul Madtes Jr. National Eye Institute, NIH, Bethesda, MD 20205.

The mechanism by which the development of neurotransmitter systems is regulated is unknown; however, the factors which are involved are being identified. Evidence is accumulating which indicates that the neurotransmitter itself directly regulates the formation of synapses between neurons utilizing that agent in the mature synapse. In particular, the presence of γ-aminobutyric acid (GABA) in the culture media increases the number of neurite-extending cells and the density of neurotubules, rough endoplasmic reticulum, Golgi apparatus, coated vesicles, and other vesicles in cultures of cerebellar granule cells (Hansen et al., 1984). GABA also has the ability to promote synaptogenesis *in vivo* as well as in cultured neuroblastoma cells (Spoerri and Wolff, 1981). Uptake and release of GABA by growth cones isolated from neonatal rat brain suggests that during development this neurotransmitter functions in the regulation of synaptogenesis (Gordon-Weeks et al., 1984). Our laboratory has addressed the developmental interactions among the components of the GABA system in the rabbit retina. When uptake is blocked by *in vivo* treatment with nipecotic acid, thereby increasing the synaptic level of GABA, an increase in the number of receptors occurs (Madtes and Redburn, 1983). GABA agonists in an *in vitro* preparation mimicked this effect, thus confirming the conclusion that this induction involves a direct action at the postsynaptic site (Madtes and Redburn, 1983). Further study demonstrated that the induction is maximal around eye opening, about 10-11 days after birth (Madtes, 1984). We now report that this induction is light-dependent. Pregnant New Zealand white does delivered and reared their pups in total darkness. At selected ages, the pups were sacrificed under red light and the retinas were treated with nipecotic acid. Retinal homogenates were measured for high-affinity $^3$H-muscimol binding. The number of binding sites ($B_{max}$) 9 days and 12 days after birth did not vary as a function of rearing conditions; untreated control tissue from both light- and dark-reared pups had equal $B_{max}$ values. As previously reported, the $B_{max}$ values for control tissues increased 2.5-fold from 9 to 12 days. In contrast, $B_{max}$ values for tissue from the nipecotic acid-treated, light-reared pups were 150% higher than untreated control values at 9 days and 50% higher at 12 days. This induction effect was absent in dark-reared animals. The apparent affinities remained constant under all conditions tested. These results indicate that the presence of light during development is required for the induction of GABA receptors to occur; however, it is not essential for achieving the basal level of receptors which appear during development. These findings suggest that light-dependency is one factor involved in the regulation of the developing retinal GABA system.

328.2 MATURATIONAL CHANGES IN A RETINA-PINEAL GLAND CIRCUIT: SURGICAL AND PHARMACOLOGICAL EFFECTS. L.D. Lytle, D.M. Bronstein*, K.A. Haak*, and G. Torres*. Laboratory of Psychopharmacology, Department of Psychology, University of California, Santa Barbara, CA 93106.

Synthesis of the pineal gland hormone, melatonin, varies diurnally, and is greatest during darkness and lowest during the light phase. Diurnal melatonin synthesis changes with alterations in the activity of N-acetyltransferase (NAT), an enzyme which limits the conversion of pinealocyte serotonin to N-acetylserotonin, an intermediate product which is then O-methylated to form melatonin. In adult rats dark-associated increases in pineal gland melatonin synthesis decline rapidly in animals exposed even briefly to light. These changes in pineal gland NAT activity are controlled by fluctuations in the amount of norepinephrine neurotransmitter molecules released from postganglionic sympathetic nerves onto pinealocyte β-noradrenoceptors. Photic information influences the activity of these noradrenergic nerves via a circuit which begins with the photosensitive cells of the retina, and which includes neurons in the retinohypothalamic tract, suprachiasmatic nuclei, paraventricular hypothalamic nuclei, medial forebrain bundle, intermediolateral nuclei of the spinal cord, and the pre- and postganglionic sympathetic neurons of the superior cervical ganglia (see, for example, D.C. Klein and R.Y. Moore, *Brain Res. 265*:348, 1979).

We studied possible maturational changes in the retina-pineal gland circuit by measuring changes in dark associated pineal gland NAT activity following brief exposure to light in normal, or in surgically or pharmacologically treated developing animals. Different aged (4-8, 16, or 50 days old) male or female albino rats were exposed to fluorescent light (Vita-Lite, DuroTest Corp., NJ; 200 lumens) for a 1 min period during the middle of the dark phase of a 12:12 hr light:dark cycle (lights on at 0700 hr) or were removed from their littermates and mothers but remained in complete darkness for 1 min. Animals were returned to their litters and were killed 30 min later, and pineal glands were assayed radiometrically for changes in NAT activity. In other studies, newborn rats were enucleated surgically or left intact and then were tested for possible light-induced inhibition of NAT activity at 8 days of age, or 3 or 7 day old rats were exposed to light or injected i.p. with the β-noradrenoceptor antagonist drug propranolol 30 min prior to death. Light-induced inhibition of NAT activity was only detected in rats 5 days or older. Light-inhibition of the enzyme activity was not observed in 8 day old blind animals. Light or propranolol inhibited NAT activity in 7 day old rats, but only propranolol reduced the enzyme activity at 3 days of age. Taken together, these data suggest that the retina-pineal gland circuit may become functional as early as 5 days postnatally. However, pinealocyte β-noradrenoceptors (antagonized by propranolol) may reach functional maturation earlier than other components in the circuit mediating lighting effects on the pineal gland. 328.3 IMMUNOCYTOCHEMICAL LOCALIZATION OF CALCIUM BINDING PROTEIN IN THE PURKINJE CELLS OF THE FROG CEREBELLUM. A.G.Gona, S.Al-Rabiai* and S.Christakos. Univ. Med. & Dent. of New Jersey, New Jersey Med. Sch., Newark, NJ 07103.

In a recent immunocytochemical study on the developing rat cerebellum, Legrand et al (Cell Tiss. Res., 233:389, 1983) found that labelling for vitamin D-dependent calcium binding protein (CaBP) of Mol. Wt. 28,000 dalton was entirely restricted to the Purkinje cells, and that it appeared very early in Purkinje cell development. In view of our interest in Purkinje cell development in the frog cerebellum, we undertook these studies to determine (a) if Purkinje cells of the adult frog cerebellum are immunocytochemically stainable with antiserum prepared against rat renal CaBP, and (b) if the precociously developed Purkinje cells of the frog tadpole cerebellum are similarly stainable. Premetamorphic tadpoles and adults of the bullfrog, Rana catesbeiana, were sacrificed by decapitation and their brains fixed in Bouin's solution. Paraffin sections (8 um thick) of the brains, cut in the sagittal plane, were deparaffinized and sequentially exposed to antiserum to CaBP, sheep antirabbit γ-globulin and PAP, with PBS rinses between steps. The sections were then developed in 3,3'-diaminobenzidine and $H_2O_2$. To verify the specificity of the immunostaining, adjacent sections were treated with antiserum preadsorbed with CaBP, instead of the antiserum. The results showed that both the precociously developed Purkinje cells of the tadpole cerebellum and the mature Purkinje cells of the adult frog are specifically stainable with antiserum prepared against rat renal CaBP. In the region of the auricular lobe, the stained cells included not only precociously developed Purkinje cells, but also cells of smaller size, presumably immature Purkinje cells. It is concluded that the morphologically unique Purkinje neuron of the vertebrate brain acquired the biochemical specialization of CaBP very early during evolution, for some yet unknown function. The presence of immunoreactive CaBP in the smaller neurons and in the Purkinje cells from the larval stage to the adult frog suggests the importance of this calcium binding protein in the Purkinje cell development.

328.4 ADULT OLFACTORY RECEPTOR NEURONS EXPRESS VIMENTIN. D.I. Gottlieb, J.E. Schwob and N.B. Farber*. Dept. Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

During the development of the nervous system, the intermediate filament protein vimentin is found in the proliferating neuroepithelium and neural crest. As development proceeds, postmitotic neurons cease expressing vimentin, and neurofilament proteins begin to accumulate. We have shown that the receptor neurons of the olfactory epithelium deviate from this general pattern in that they continue to express vimentin in the adult rat.

Vimentin-like immunoreactivity was localized in cryostat sections of adult rat tissue using a mouse monoclonal antibody (designated SBV-21) which was generated against bovine vimentin by Dr. Stephen Blose. Vectastain ABC reagents (Vector Laboratories) were used to visualize tissue-bound primary antibody. SBV-21 heavily labels all portions of the primary olfactory projection, including the sensory neuron cell bodies in the olfactory epithelium, the fascicles of the olfactory nerve, and their axonal arbors in the glomeruli of the olfactory bulb. In contrast, anti-neurofilament antisera stain only rare, scattered receptor cells and a small number of axons in the olfactory nerve; anti-GFAP antiserum stains glial processes in the interstices between bundles of olfactory axons.

Direct examamination of the olfactory nerve layer of the olfactory bulb with EM immunohistochemistry shows dense staining of olfactory axons with SBV-21. Some vimentin-like immunoreactivity is also seen in supporting cells in this layer.

The vimentin-like immunoreactive material in the olfactory nerve layer was characterized by SDS-PAGE and immunoblotting. SBV-21 stains only one protein of $M_r$ = 55kD. This band comigrates with vimentin in crude cytoskeletal material from the neonatal rat brain prepared according to the method of Dahl et al. (Eur. J. Cell Biol., 24:191-196, 1981). SBV-21 does not stain neurofilament triplet proteins or GFAP, both of which are also present in these blots.

In conclusion, the vast majority of olfactory receptor neurons and their axons contain vimentin or a protein of identical immunological character and electrophoretic mobility, while identifiable expression of neurofilament proteins is confined to a very small subpopulation. Olfactory receptor neurons are unique among mammalian neurons in that they die and are replaced during adult life normally and following injury. It is interesting to speculate that the expression of vimentin is a marker for the arrest of this neuronal system at an immature state of development.

328.5 EFFECTS OF POLYAMINES ON GROWTH AND NEURITE FORMATION OF CULTURED RAT CEREBELLAR NEURONS. G.M. Gilad and V.H. Gilad*. The Center for Neuroscience and The Isotope Department, The Weizmann Institute of Science, Rehovot, Israel.

Treatment of newborn rats with exogenous polyamines (PA) leads to increased numbers of sympathetic neurons. In adult early PA treatment accelerates regeneration of crushed nerves. It is unknown whether PA exert their in vivo effects directly, on the neurons themselves, or indirectly. Tissue culture studies may clarify some of these questions. We therefore sought to characterize the effects of PA on growth, survival and neurite formation of dissociated cells (mostly granule neurons) from 6d old rat cerebellum grown under controlled in vitro conditions. At 2d after plating, when 93% of neurons have neurites, ornithine decarboxylase (ODC) activity was still high indicating elevated PA biosynthesis. Addition of 5mM alpha-difluoromethylornithine (DFMO) at plating time, completely inhibited ODC activity and led 24h later to inhibition of cell aggregation with a drastic (90%) inhibition of neurite formation . However, after 48h with DFMO cell aggregation and neurite formation increased and approached the 24h control values. Similar, but more drastic and irreversible effects were observed with 2mM putrescine (put), 0.1mM spermidine (Spd) and 0.1mM spermine (Spm), or with 0.5mM monodansyl cadaverine (DC) an inhibitor of transglutaminase(TG).Washing cultures after 24h and addition of fresh medium led to recovery from the PA effects. Addition of 0.1mM aminoguanidine, an inhibitor of diamine oxidase at plating time prevented the effects of put and spd but not of spm. We conclude: a) inhibition of intracellular PA production delays but does not prevent neuronal growth; b) extracellular PA inhibit cell aggregation and neurite outgrowth; c) the PA effects are due to their oxidative metabolism, and d) TG catalyzed reaction may participate in neuronal growth. - Supported by grants from the Muscular Dystrophy Association and the American Paralysis Association.

328.6 SPECIFIC ALTERATION OF NCAM-MEDIATED CELL ADHESION BY AN ENDONEURAMINIDASE. U. Rutishauser, M. Watanabe*, J. Silver, and E. Vimr*. Dept. of Developmental Genetics and Anatomy, Case Western Reserve Univ. Sch. of Med., Cleveland, Ohio 44106; Dept. of Veterinary Pathobiology, Univ. of Illinois at Urbana-Champaign, Urbana, Illinois 61801

A phage endoneuraminidase that specifically cleaves alpha-2,8-linked polysialic acid has been found to be a useful probe for examining the biological role of this sugar moiety on the neural cell adhesion molecule NCAM. In accordance with other studies, the enzyme caused a 3.3 fold increase in the rate of NCAM-dependent aggregation of membrane vesicles from chicken embryonic brain, but without the nonspecific effects encountered with commercial exoneuraminidases. The enhancement of aggregation was closely correlated with removal of sialic acid as assessed by electrophoretic mobility. Extension of this analysis to cultures of spinal ganglia indicated that removal of sialic acid by the endoneuraminidase results in an increase in the thickness of neurite bundles. This enhancement of fasciculation was reversed by addition of anti-NCAM Fab, suggesting that the enzyme treatment was not toxic and did not cause nonspecific effects on adhesion. Again, the effect of the enzyme was correlated with the removal of sialic acid. Injection of the enzyme into the eyes of 3.5-day chicken embryos produced a striking array of abnormalities in those parts of the neural retina that contain the highest concentrations of NCAM. These perturbations included a dramatic thickening of the neural retina in the posterior pole, a failure of cells in this region to elongate radially as in normal development, formation of an ectopic optic fiber layer along the ventricular margin, and an incomplete attachment of the presumptive pigmented epithelium with the neural retina. These results provide strong evidence that the polysialic acid on NCAM has a direct effect on NCAM-mediated adhesion and that the amount of this carbohydrate is critical for normal morphogenesis of the retina. Supported by NIH Grant HD 18369 and NSF Grant BN82-18700.

328.7 POSTNATAL DEVELOPMENT OF THE SEROTONERGIC INNERVATION OF CEREBRAL NEOCORTEX IN THE RAT. M.E. Blue and M.E. Molliver. Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The 5-HT innervation of neocortex has been characterized in terms of the development of regional and laminar patterns of innervation and of axon morphology. In prenatal stages, the raphe-cortical projection is bilaminar with two sheets of axons, one above and one below the cortical plate, (Lidov & Molliver, BRB 9:559, 1982). The present analysis (employing immunocytochemistry with 5-HT antibody of H. Lidov) shows extensive arborization of 5-HT axons throughout all areas of neocortex during the first postnatal week; distinctive regional patterns of 5-HT innervation are evident in neocortex, and the specific laminar distribution of axons differs from that in the adult. At postnatal day 4 (P4), the fetal innervation pattern is retained with a high density of 5-HT axons in layers I and VI, and in SI there is additional arborization of numerous terminal-like fibers in layers IV and VI; in contrast, there are few axons in layers V or in II+III. There is thus a band of moderate density in layer IV, extending across SI; it does not extend into motor cortex (AGl) which lacks a layer IV. After P6, 5-HT axons arborize extensively in layers II-III and layer V. By day 21, the adult pattern of innervation (Kosofsky & Molliver, in prep) is established in SI: a low density of 5-HT axons in layer IV contrasted with a high density in layers I-III and V-VI. These results lead to the following conclusions: 1) There is a reversal in the laminar innervation pattern during development in SI, since the innervation of layer IV is initially dense and later sparse. 2) The primordial bilaminar ingrowth of 5-HT axons leads to a dual pattern of innervation to the supra- and infra-granular layers, perhaps arising from different sets of raphe cells. 3) Within these two zones, there is a gradient in the sequence of innervation that corresponds to the birthdates and cytologic maturation of cortical neurons, e.g., layer IV is innervated before layers II-III; layer VI before V. 4) Cyto-architectonic differences in innervation are established early in development, at the initial arborization of 5-HT innervation within SI and AGl. To study the morphology of developing axons, the density and spacing of varicosities were quantitatively analyzed in 5-HT axons at different ages. In newborn rats (P4-P10) varicosities along 5-HT axons are far more numerous and considerably more closely spaced than in adults. The average intervaricose distance increases by 300% from P6 to P90. These data suggest that 5-HT neurons form numerous release sites along their axons early in development, and we propose that subsequent axon growth occurs along intervaricose segments with a consequent decrease in synaptic release sites per unit length of axon. (Supported by NIH Grants NS15199, NS21011, NS07396 and by UCP R-340-83.)

328.8 MORPHINE ENHANCES INDEPENDENT FEEDING IN INFANT RATS. C. A. Capuano*, J. Giordano*, D. Bowling* and G. A. Barr* (SPON: G. Gourevitch). Biopsychology Program, Dept. Psychology, Hunter College, City University of New York, N.Y., N.Y. 10021, and Dept. Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

The observation that acute administration of opiate agonists to adult rats increases food intake while opiate antagonists decrease food intake has led to the hypothesis that endogenous opioid systems in part mediate feeding. Although evidence exists that opioid receptors are present in the central nervous system of the rat embryo as early as day 14 postconception, further evidence suggests that the full expression of endogenous opioid systems mediating feeding in the rat is not complete before 14 days postpartum (Aroyewun & Barr, *Neuropharmacol.*, **21**: 757, 1982). Specifically the opiate antagonists naloxone and naltrexone, even at high doses, did not attenuate independent ingestion of milk until 14 days of age.

The present study was undertaken to characterize further the functional ontogeny of opioid systems associated with self-feeding in infant rats. Sated rat pups 3, 5, 7, 14, and 21 days of age were allowed free access to milk that was spread in a thin layer on the floor of the test chamber. Intake was measured following i.p. injection of 0.03, 0.1, 0.3, 1.0 mg/kg of the opiate agonist morphine sulfate, or the saline control. Morphine stimulated milk intake at 3 and 5 days of age within 2 hours of injection, and within 4 hours of injection at 7 days of age and older. Facilitation of intake was delayed at the older ages due to increased sedation. In a final experiment, administration of the opiate antagonist naltrexone HCl (5.0 mg/kg) immediately following morphine injection (0.3 mg/kg) decreased the stimulation of milk intake by morphine to control levels. Naltrexone, by itself, had no effect on feeding. Thus morphine's effects are likely to be mediated by opioid receptors.

The fully functional endogenous opioid system(s) mediating feeding in the adult rat are not fully mature prior to 14 days of age since opiate antagonists are inactive until that age. However, the present results suggest that opioid receptors associated with independent feeding in rat pups are present as early as 3 days postpartum. It is possible that, while the receptors are present and functional early, the ability of deprivation to release endogenous opioids relevant to feeding matures later. This would be consistent with the early appearance of opiate enhancement of feeding and the later appearing inhibition of feeding in deprived pups by opiate antagonists. Finally, the present findings strengthen the argument that the physiological organization of independent feeding in the rat pup, while not fully mature, is continuous with adult feeding and represents the forerunner of later ingestive behavior in the rat.

328.9 CRITICAL DEVELOPMENTAL PERIODS FOR EFFECTS OF ORNITHINE DECARBOXYLASE INHIBITION ON BRAIN DEVELOPMENT AND BEHAVIOR. J.M. Bell, D.S. Madwed*, W.L. Whitmore* and T.A. Slotkin. Dept. of Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Ornithine decarboxylase (ODC) and its metabolic products, the polyamines, coordinate macromolecule synthesis in developing neural tissues. Inhibition of this enzyme by α-difluoromethyl-ornithine (DFMO) interferes with subsequent cellular replication and maturation. Recent morphological evidence indicates that DFMO is selective for certain brain regions or toward particular phases of cellular differentiation. The present study examined the effects of prenatal vs. postnatal DFMO treatment on brain regional development and sensorimotor behaviors. DFMO was injected into pregnant rats on gestational days 15-17 (prenatal treatment), or into pups from postnatal day 1 through 20. Postnatal DFMO administration did not result in severe body growth reductions, but did cause a profound and progressive deficit in DNA, RNA and protein content in the cerebellum, a region which undergoes major phases of replication and differentiation after birth. Regions having mostly prenatal periods of major replication (cerebral cortex and midbrain + brainstem) also showed minor adverse effects of postnatal DFMO, comparable to those on general body growth. However, inhibition of DNA synthesis ([$^3$H]thymidine incorporation) was detectable in all regions. In contrast, prenatal DFMO treatment resulted in loss of specificity toward cerebellar development and instead exerted a more profound effect on nucleic acids and proteins in cerebral cortex. Thus, DFMO is selective because of regional differences in the timing of replication. DFMO administration also had comparable functional behavioral consequences. Prenatal DFMO administration resulted in severe deficits in sensorimotor development during the immediate postpartum period. The righting, negative geotaxis and pivoting responses were more severely affected in the prenatal relative to the postnatal DFMO treatment group. However, behaviors which develop later were more sensitive to postnatal DFMO; the most severe sensorimotor deficit was in swimming ontogeny, which was profoundly delayed in the postnatal DFMO treatment group. Similarly, the postnatal DFMO group displayed greater deficits in the horizonal and vertical components of an open field test assessed after weaning. These results support the view that the ODC/polyamine system participates in brain development particularly during periods of rapid cellular differentiation. Inhibition of ODC by DFMO during appropriate critical periods results in regional selectivity of effects which produce specific patterns of alterations in sensorimotor development. (Supported by USPHS HD-09713)

329.1 MAMMALIAN CEREBRAL CORTICAL SLICES RESPOND TO VISIBLE LIGHT AT LOW INTENSITIES BY AN ENHANCEMENT OF TRANSMITTER RELEASE. Patricia D. Wade, Jonathan Taylor* & Philip Siekevitz. Rockefeller University, New York, NY 10021.

Intensities of visible light estimated to penetrate the head of the rat enhance release of $^3$H-GABA from cerebral cortical tissue. $^3$H-GABA release experiments. The conditions for $^3$H-GABA release were as in a previous study (Brain Res. 305:259 (1984)). Upon decapitation of male Sprague-Dawley rats, removal of the brain and removal of meninges from the brain, about 0.5mm thick slices were taken from as many regions of cortex as possible. The slices were incubated with $^3$H-GABA in Ringer's for ½ hr. at 36°±0.5°C and then rinsed repeatedly until a baseline level of released radioactivity was established. Then the slices were subjected to elevated $K^+$ (26.4mM) in light or in dark (photographic dark room) conditions. In the light condition, the slices which were in no particular cellular orientation to the light, received white light continuously for 27 min. from a tungsten halogen lamp (Sylvania DWY 650W 120 V). Ultraviolet transmission was prevented by a glass plate. Media were changed and collected every 9 min. and samples from 3 such changes from tissue in either light or dark were counted for radioactivity. Release of transmitter from the tissue in the light was enhanced compared to that in the dark at light intensities of about 0.6mW/cm$^2$ and 1.3mW/cm$^2$. At these two intensities, the average summed and normalized ratios of release in light over release in dark for 27 min. were 1.46±0.13 (std. error of the mean) in 8 expts. and 1.86±0.23 in 4 expts., respectively. Control experiments suggest that the enhancement of release by light is probably not by such non-specific means as: increased temperature, adsorption of GABA to the tissue surface and subsequent release by light or $K^+$, or increased leakiness of the cell membrane. Visible light penetrating the heads of rats. White light was shown on the surface of heads from which the brains had been removed. A photodiode used to measure intensity was placed in the rats' cranial cavities 1 or 2mm central to the dura mater. The percentage of incident light reaching the photodiode within the heads of approximately 8-23 week-old (young adult) rats was 5-12%. These measurements were used with estimates of sunlight intensities to obtain estimates of penetration under natural lighting conditions. We found that the energy necessary for the enhancement of transmitter release can be expected to penetrate a rat's cranial cavity in daylight (sunlight to overcast days) in young adults. An implication from these results is that ambient light may reach the brain in vivo and affect the release of transmitter from cerebral cortex.

Some of the questions still to be answered are: whether released GABA is from neuronal or glial cells, whether other transmitter systems are affected by light, and what wavelengths of light support the GABA release.

329.2 INCREMENT AND DECREMENT SENSITIVITY IN THE LOCUST PHOTORECEPTOR. L.R. Owens and T.E. Cohn. U.C. Berkeley, School of Optometry, Berkeley, CA. 94720.

Responses of locust photoreceptor cells were examined using receiver operating characteristic (ROC) analysis. Stimuli were brief luminance increments and decrements of equal modulation superimposed upon a steady background of low intensity. Under these conditions, fluctuations in the number of quanta are important for they represent an irreducible source of variability which can limit visual sensitivity. Quantum fluctuation predictions were examined by matching experimentally measured ROC curves to predicted curves based on theory (Thibos et al., 1979, Biol. Cybernetics,33:57). Results are based on data from 5 different cells with 100 to 300 stimulus trials each. The test condition involves the presentation of the stimulus plus background versus background alone. Distributions of response with and without stimulus were used to generate an ROC curve. The coordinate points of a poisson ROC fall very near a straight line when plotted with cumulative Gaussian scales for axes. The line is characterized by its intercept with the negative diagonal, called d', and its slope. d' is a measure of the discriminability of the test conditions. The greater d' is, the more discriminable are the 2 conditions. Evidence favoring the quantum fluctuation model would be: d' for decrement stimuli greater than d' for increment stimuli; and ROC slopes greater than unity for decrements and less than unity for increments. For all 5 cells, d' was greater for decrements than for increments, in agreement with the quantum fluctuation model. Mean d' for decrements = 1.86 while d' for increments = 1.24 (S.D.=.14). The slope prediction was not always verified, yet the quantum fluctuation model could not be rejected either. We examined two hypotheses concerning variability intrinsic to the photoreceptor (multiplicative or additive noise) using the models described by Lillywhite, 1981 (Vision Res.21:291). The data presented here fit the additive noise model surprisingly well, while the multiplicative model fit poorly. The additive noise mean value = 98.3 events/10 msec (S.D.=33.2). Perhaps the level of background intensity used here (17 log quanta/sec-sr) is in the range where additive noise begins to have an effect on sensitivity.

329.3 LOW FREQUENCY VOLTAGE OSCILLATIONS IN HAIR CELLS ISOLATED FROM THE APEX OF THE CHICK COCHLEA. P.A. Fuchs, Dept. of Physiology, Univ.Colorado Health Sciences Center, Denver, CO 80262.

Intracellular voltage recordings from hair cells of turtles, (Crawford and Fettiplace, 1981, J. Physiol. 312:377-412) and frogs (Ashmore, 1983, Nature 304:536-538; Lewis and Hudspeth, 1983, Nature 304:538-541) have revealed that these cells behave as electrical resonators, or filters tuned to unique frequencies. Voltage 'ringing' to injected current steps, and spontaneous voltage oscillations at or near the resonant frequency are signal features of this electrical tuning. In the turtle cochlea each cell's electrical resonance corresponds to, and in large part accounts for, its acoustic frequency selectivity. It is of interest to ask how general such an electrical tuning mechanism might be. Low frequency voltage oscillations were observed in hair cells isolated from the cochlear apex (the presumed low frequency response region) of 15 to 29 day post hatch chicks. All the cells reported on here were obtained from the apical 10% of the cochlea (average 402 μ out of an average total length of 4129 μ). Hair cells in the chick cochlea vary in morphology from tall, inner hair cells nearest the neural insertion, to short outer hair cells. Only (probable) tall cells were chosen for recording (for seven cells the average dimensions were: length, 20.9 ± 0.8μ width, 9.1 ± 0.8 μ and maximum length of ciliary bundle 8.6 ± 0.2 μ, mean ± s.e.m.).

Intracellular recordings from isolated cells were made with the whole-cell suction electrode technique at a temperature of 21-23°C. The resting potential of the cells averaged -73 ± 3 mV. Depolarizing current steps from this level elicited spikelike responses which, though somewhat variable, could be as much as 70 mV in amplitude. When the membrane potential of the cell was raised to -50 mV with steady current, the cell generated repetitive oscillations which occurred at a steady rate in any one cell, and ranged from 4 to 12 Hz. amongst the cells in this study. These oscillations were not purely sinusoidal, but had sharp depolarizing peaks and more prolonged hyperpolarizing troughs, and were 20 to 50 mV in amplitude in different cells. The frequency and amplitude of the oscillations depended on the level of depolarization, being faster (by 1 to 3 Hz.) and smaller (down to 5 mV) at potentials more depolarized than -50 mV. Current steps caused the oscillations to phase-lock such that the average voltage response consisted of a 'ringing' whose frequency varied with the polarity and amplitude of the current step. Thus voltage responses similar to those obtained from electrically tuned hair cells of lower vertebrates also occur in hair cells of the bird cochlea. The underlying ionic mechanism of these voltage oscillations, and their contribution to the normal function of these cells, remain to be determined. Supported in part by grants BRSG-05357 and NS21454 from the NIH.

329.4 VOLTAGE CLAMP ANALYSIS OF MEMBRANE CURRENTS PRESENT IN ISOLATED CONE PHOTORECEPTORS. A.V. Maricq* and J.I. Korenbrot. Dept. of Physiology, University of California, San Francisco, Ca 94143.

Individual cone photoreceptors were obtained by enzymatic dissociation of the isolated retina of the lizard, Sceloporus orcutti. Most of the cells showed a prominent axon and synaptic ending, however only a fraction of them retained their outer segments. Although there was a progressive loss of cells, the photoreceptors could be maintained for several days under tissue culture conditions with little change in their morphology and electrical properties.

Single cone cells were studied in the whole cell clamp mode. Patch electrodes were filled with potassium aspartate with 4 mM ATP, and buffered with Hepes and EGTA. Under current clamp, depolarizing current pulses produced a regenerative voltage response with a peak amplitude of about 25 mv. Hyperpolarizing current pulses produced a distinctive voltage peak reminiscent of the "nose" observed in the photovoltage response to bright lights when recorded with conventional intracellular electrodes. Addition of 5 mM CsCl to the bath selectively eliminated the hyperpolarizing voltage peak, but did not affect the regenerative response to depolarizing pulses.

In voltage clamp experiments with cells held at -60 mv, hyperpolarizing pulses produced a slowly activating inward current which could be entirely abolished by external 5 mM CsCl. Depolarizing pulses above -40 mv resulted in a rapidly activating inward current. Depolarizing pulses above -20 mv produced an additional, slower activating outward current that was apparent first as a decrease in the inward current, and eventually as a net outward current at pulses above 10 mv. This net outward current decayed with a time course of hundreds of ms. The inward current activated by depolarization was studied with the outward current blocked by internal cesium. This inward current was carried by $Ca^{++}$ and by $Ba^{++}$ when $Ba^{++}$ substituted for $Ca^{++}$. External $Co^{++}$ abolished all of the inward current, i.e., there was no evidence that a fraction of the current was carried by $Na^+$. In contrast to some $Ca^{++}$ channels in other cells, where internal fluoride abolishes $Ca^{++}$ currents, we found that the current was preserved when 50 mM CsF was present in the pipette. Comparison of cells with or without axons and synaptic endings revealed a difference in the membrane currents present; $Ca^{++}$ currents were greatly diminished in cells lacking axons indicating a non-homogeneous distribution of $Ca^{++}$ channels over the cell surface.

329.5 RAPID DECLINE IN CYCLIC GMP IN INTACT FROG PHOTORECEPTORS FOLLOWING BRIGHT ILLUMINATION. C. Blazynski, A.I. Cohen, Ophthalmology, Washington University School of Medicine, St. Louis, MO 63110.

Absorption of photons by rhodopsin in rod outer segments initiates a biochemical cascade resulting in the hydrolysis of cyclic GMP. In evaluating the loss of cyclic GMP as a necessary component of transduction, several laboratories have attempted to determine if the onset of the light-induced loss could occur before the known time when rod dark current begins to be suppressed by light. Two laboratories, utilizing intact retinas, and freezing to stop action, reported no loss of cyclic GMP until 2-3 sec after the onset of photopic illumination (Kilbride & Ebrey, 1979; Govardovskii & Berman, 1981). Other laboratories, utilizing portions of photoreceptors, report much more rapid losses of cyclic GMP (Liebman & Pugh, 1979; Woodruff & Bownds, 1979; Cote et al., 1984). We dark-adapted frogs for at least 17 hr and isolated their retinas under infrared illumination. Under infrared, pieces of these retinas, at 22°C, were mounted in an apparatus we devised which first illuminates a piece of dark-adapted frog retina and then propels it so that in 50 msec its photoreceptor surface makes firm contact with a dry, liquid helium cooled copper mirror. Outer segment freezing occurs in a few msec. Several samples were fixed using freeze-substitution, and light microscopy revealed that outer segments were usually folded by the impact to an acute angle with the retinal plane. In a cryostat, two or three 6 μm slices of outer segments were shaved off and assayed. Dark cyclic GMP values were compared with values obtained after multiples of 100 msec of 16000 lux, white illumination. This illumination bleached 4% of rhodopsin in 100 msec. Without exception, the means of 8-10 samples per time point showed a progressive decline in cyclic GMP with time, with values at 250 msec or longer being significantly ($p<.05$) different from the dark level. Dark values of cyclic GMP (mean ± SEM) were 103 ± 5 pmole of cGMP/mg protein. After 100, 200,300,500,1000 and 2000 msec of illumination plus a 50 msec fall to freeze, the values determined were 95 ± 4, 86 ± 3, 79 ± 5, 75 ± 4, 70 ± 4, and 62 ± 2 pmoles cGMP/mg protein, respectively. Our procedure differs from those of previous studies using intact retinas in that all initial manipulations were performed under infrared, our continuous illumination was brighter, outer segments alone were sampled, and freezing was more rapid. Studies with scotopic illuminations are in progress.

329.6 THE EFFECT OF L-CIS-DILTIAZEM AND C-GMP ON ROD OUTER-SEGMENT CONDUCTANCE. J.H. Stern, U.B. Kaupp & P.R. MacLeish. Laboratory of Neurobiology, Rockefeller University, 1230 York Ave., NY, NY 10021.

Solitary rods were obtained by enzymatically dissociating the retina of the tiger salamander, Ambystoma Tigrinum. The effect of c-GMP and l-diltiazem on the membrane conductance of excised patches and of whole cells was examined. Patches of outer-segment membrane were excised after obtaining gigaohm seals with a suction pipette. The bathing medium consisted of a calcium-free salt solution while the pipette contained the same solution but with 1.8mM $CaCl_2$. Cyclic-GMP reversibly activated a conductance in more than 90% of the patches with a dose-response relationship similar to that found by Fesenko et al.( Nature, 313, 310-313, 1985). The voltage dependence of the c-GMP-induced current was similar to that of the generator current in an intact rod in that it was approximately described by the equation $i=i_0(e^{V/25}-1)$, where i=the c-GMP-induced current, $i_0$=the limiting current for large negative bath potentials, and V=the voltage across the excised patch.

The l-isomer of the calcium-channel blocker, cis-diltiazem, blocked the c-GMP induced current in excised patches. Blockade by l-diltiazem applied to the bathing medium was rapid and reversible. The dose-response relationship for l-diltiazem blockade rose steeply in the micromolar concentration range suggesting a cooperative effect of the channel blocker on membrane conductance. l-diltiazem also affected the shape of the current-voltage curve suggesting that the block was voltage dependent. These effects were specific in that the d-isomer of cis-diltiazem was much less effective as a blocker at comparable concentrations.

Given the action of l-diltiazem on excised patches, it was natural to study its effect on intact cells. We used the intracellular-dialysis (whole-cell) technique to voltage clamp and to introduce substances into cells. In one series of experiments the inclusion of up to 2.3mM l-diltiazem in a one micron (internal diameter) suction pipette did not suppress the light response of dark-adapted, dialyzed rods. Similar results were obtained when dialysis was confirmed by inducing a light-sensitive current in light-adapted cells with concomitant dialysis of c-GMP or 8-Br-c-GMP and l-diltiazem. The absence of block by intracellular l-diltiazem can be explained by one or more of the following: extremely rapid intracellular metabolism, a conductance mechanism inaccessible to the blocker or a difference between the whole-cell and excised-patch conductance mechanisms. Finally, superfusion of dark-adapted rods with salamander salt solution containing 25 to 50 micromolar l-diltiazem but no added calcium ions led to a readily-reversible, partial block of the light response.

329.7 GUANOSINE 3':5'-CYCLIC MONOPHOSPHATE (cGMP) ACTIVATES A LIGHT-SENSITIVE CURRENT IN AN ISOLATED, DIALYZED ROD OUTER SEGMENT. K.-W. Yau, K. Nakatani* and L.W. Haynes. Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Membrane current was recorded from the outer segment of a toad rod by drawing it partially into a suction pipet containing Ringer's solution[1]. After verifying that the outer segment had a light-sensitive dark current, the inner segment as well as the basal portion of the outer segment outside the pipet were broken off with a probe. This left an open-ended outer segment "envelope" whose interior could be dialyzed with a low Na-high K bath solution. Upon adding cGMP to the bath an inward current appeared at the plasma membrane. Changing bath Ca concentration had no obvious effect on this current. The current increased sigmoidally with cGMP concentration, indicating positive cooperativity of cGMP molecules in turning on the current. Both the Hill coefficient (2.5 ± 0.3 (S.D.)) and the $K_{\frac{1}{2}}$ (52 ± 15 μM (S.D.)) were rather similar to those previously measured from excised membrane patches of rod outer segments[2,3]. Without GTP in the bath the cGMP-dependent current was light-insensitive, but in the presence of 1 mM GTP the current could be completely suppressed by a light flash. With both GTP and ATP present, however, the light-induced suppression of current was more transient and required significantly brighter flashes. The results described here supported the conclusion from excised patch experiments[2,3] that a cGMP-sensitive conductance was present in the plasma membrane of the rod outer segment, and indicated further that this conductance was indeed light-sensitive. The observed effects of GTP and ATP were consistent with present knowledge[4] of the mechanisms controlling light-activated cGMP hydrolysis. From the maximum current inducible by cGMP, we have estimated that ~1% of the light-sensitive conductance is normally open in darkness. The effective free cGMP concentration (present in the intact outer segment in darkness) calculated from this figure and the dose-response relation would be a few μM.

329.8 VISUAL TRANSDUCTION IN ROD PHOTORECEPTORS FROM TOAD RETINA: EFFECTS OF CYCLIC GMP AND CALCIUM IONS ON CELL-ATTACHED AND CELL-FREE PATCHES OF OUTER SEGMENT MEMBRANE. Gary Matthews, Dept. of Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.

The experiments summarized here examine the roles of calcium (Ca) and cyclic GMP (cGMP) in phototransduction by comparing their effects on light-sensitive channels of intact rods with their effects on cell-free outer segment patches. Recently, a component of dark noise that likely originates in the light-sensitive channels has been identified in cell-attached (1,2) and whole-cell (3,4) patch-recordings from rod photoreceptors. In experiments using patch-pipettes filled with 0 Ca Ringer, I found that the single-channel current estimated from this noise component averaged 18.6 ± 2.0 fA (mean ± s.e.; N=14), which is 5-6 times larger than that reported previously (3,4) in experiments with 1.0 mM external Ca. This suggests that one action of external calcium is to reduce the single-channel current, possibly by occupying the channel but moving through less readily than sodium. The power spectrum of the noise was fitted by a single-Lorentzian, with average corner frequency corresponding to an exponential time-constant of 0.44 ± 0.04 msec. This time-constant gives an estimate for the average open-time of the light-sensitive channels.

Dibutyryl cGMP increased the dark current and the dark noise of cell-attached patches. Noise analysis showed that dibutyryl cGMP increased the frequency of channel-opening in the dark, but did not affect single-channel conductance or open time.

In agreement with previous reports (5,6), the conductance of cell-free outer segment patches was increased by perfusion of the internal face with Ringer containing cGMP. Perfusion with 0 Ca had only non-specific effects. cGMP on the external face was ineffective. The voltage-current relation of the cGMP-dependent current showed outward rectification, as does the light-sensitive current of intact rods. In low external Ca, the cGMP-dependent single-channel current was 20.8 ± 2.2 fA (mean ± s.e.; N=6), similar to that of the light-sensitive channel in low external calcium. With 1.0 mM external Ca, the cGMP-dependent single-channel current fell to about 5 fA, similar to that of light-sensitive channels in intact rods bathed in 1.0 mM external calcium (3,4).

The results suggest that cGMP directly interacts with and opens the light-sensitive channel in cell-free outer segment patches, implying that cGMP is the internal transmitter that keeps the channels open in the dark. Models of the interaction of cGMP with the channel will be discussed. (Supported by NIH Grant EY03821.)

329.9 ELECTROPHYSIOLOGY OF ISOLATED TASTE CELLS FROM THE MUDPUPPY. S. C. Kinnamon, M. McPheeters, and S. Roper, Rocky Mountain Taste and Smell Center, University of Colorado Health Sciences Center, Denver, CO 80262.

The molecular events underlying taste transduction are unknown. To study chemosensory transduction in detail and elucidate these events, we have developed a technique for isolating individual taste cells from mudpuppy lingual epithelia. Mudpuppy taste cells are large, and when isolated are amenable to both intracellular and single channel recording techniques.

Taste cells were isolated by incubating the lingual epithelium in calcium-free amphibian physiological saline (APS) containing 1% papain, 1% collagenase and 0.25% EGTA for 35 min at room temperature, followed by a wash in APS containing concanavalin A (Con A). With gentle suction, taste buds were removed from the epithelium and individual cells plated on coverslip coated with anti-con A antibody.

Intracellular recordings were obtained from isolated cells and compared with recordings from taste cells in intact epithelia. Taste cells in intact epithelia had high resting potentials (-55 ± 11 mV) and generated action potentials in response to depolarizing current injections; action potentials were typically followed by a calcium-dependent hyperpolarizing after-potential with a duration of several hundred msec. In contrast, isolated cells had somewhat lower resting potentials (-31 ± 15 mV) and failed to elicit active membrane responses to depolarizing current injection, even when hyperpolarized to -80 mV for several minutes before stimulation.

Intracellular recordings were also obtained from taste cells in response to chemosensory stimulation. Taste cells in intact epithelia responded to focally-applied potassium chloride (pressure-ejected from an extracellular micropipette) with an action potential; action potentials were also obtained from most cells in response to citric acid. Subthreshold depolarizing responses were obtained from some cells in response to l-arginine. Isolated cells also responded to chemosensory stimulants: subthreshold depolarizing responses were produced by potassium chloride (all cells) and to l-arginine (some cells). Citric acid elicited subthreshold depolarizations in some cells and hyperpolarizations in other cells.

These data indicate that isolated taste cells retain chemosensory receptors and at least some of the membrane properties characteristic of taste cells in intact epithelium. Thus, it should be possible to examine the molecular events underlying chemosensory transduction in these isolated cells. Supported by grants from Proctor & Gamble, NIH #NS20382, and NIH #AG03340.

329.10 SYNAPSIN I IS PRESENT IN BOTH EFFERENT AND AFFERENT NERVE ENDINGS IN SKELETAL MUSCLE. P.De Camilli[1], M.P.Canevini[1], R.Zanoni[2], M.Vittadello[2], C.Triban[2] and A.Gorio[2]. [1]CNR Center of Cytoph. Via Vanvitelli 32, 20129, Milano, Italy and [2] Fidia Res. Lab. Abano Terme, Italy.

Synapsin I (Syn I) is a major neuron-specific protein, phosphorylated at multiple sites by cAMP-dependent and by Ca/calmodulin-dependent protein kinases. Syn I is concentrated at synapses (being present at virtually all synapses), where it is localized on the presynaptic side. In nerve endings it is associated with the surface of 40-60 nm synaptic vesicles (De Camilli et al., JCB 96, 1337 and 1355 (1983), Huttner et al. JCB 96, 1374 (1983), Navone et al., Science 226, 1209 (1984)). Due to this specific localization Syn I is thought to play an important regulatory role in synaptic vesicle function and, possibly, in neurotransmitter release. We report here that Syn I is also present in at least one type of sensory endings, the spiral endings of muscle spindles.

Frozen sections of fixed skeleteal muscles were double-labeled for Syn I (by immuno-rhodamine) and either for neurofilaments (by immuno-fluoresceine) or for Ach-receptors (by fluoroscein-conjugated $\alpha$-bungarotoxin). Neurofilament stain served as a marker for axons, $\alpha$-bungarotoxin as a marker for motor synapses. Syn I immunoreactivity was found at all efferent axon endings, i.e. at terminals of motor neurons, (including terminals of $\gamma$ fibers) as well as at varicose terminals of autonomic nerves surrounding blood vessels. In addition, sensory endings of the spindles were also highly immunoreactive for Syn I. In both efferent and afferent nerves Syn I immunoreactivity was highly compartmentalized in the most distal portion of the axon, and a rather sharp transition was observed from the neurofilament-rich axon to the Syn I-containing terminal.

Our results indicate the existence of previously unknown functional similarities between afferent and efferent nerve terminals. We do not have, as yet, information on the subcellular localization of Syn I in sensory endings. Small vesicles, similar to vesicles present in efferent terminals, are present in spiral sensory endings. The function of these vesicles is at present unknown. Our result suggest that they might share some important functional properties with synaptic vesicles of efferent endings.

329.11 OSMOTIC EXPERIMENTS WITH MUSCLE SPINDLES: ELECTROPHYSIOLOGY AND ULTRASTRUCTURE. D. C. Quick. Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

Muscle spindles were dissected from the cat tenuissiumus muscle and mounted in a perifusion chamber to record static electrophysiological responses (no effort was made in these experiments to dynamically stretch the spindles). In some cases, the capsule was left intact; in others, the capsule was torn open. Experimental solutions were pumped into the chamber, consisting of either a standard Ringer solution, double-osmolar Ringer (Ringer plus 0.3 M sucrose), or half-osmolar Ringer (Ringer minus 0.75 M NaCl). Action potentials in the sensory nerve of the spindle were amplified and recorded continuously on tape for later analysis. After each experiment, a glutaraldehyde solution was pumped into the chamber and the spindle was preserved for electron microscopy.

In standard Ringer, spindles fired at a steady or very slightly falling rate; primary sensory units were more likely to decline slightly than secondaries. In the majority of cases, after introduction of double-osmolar Ringer, the sensory units slowed their firing rate by about 4 to 5% per minute, over a course of 15 minutes or more. Eventually, firing ceased. The effect was reversible - if standard Ringer was reintroduced to the chamber, the firing began to increase by 4 to 5% per minute. Fewer experiments were done with half-osmolar Ringer, but the uniform finding was that firing rate increased. Electron microscopy of spindles fixed under hyperosmolar conditions showed an increased cytoplasmic density of both the intrafusal muscle fibers and the sensory nerve endings. In cases where a dramatic decrease of sensory firing *rate had been observed (but not necessarily a cessation at the* time the spindle was fixed), it was usual to find that the sensory ending had pulled away from the intrafusal muscle fiber at some points. Points of relatively greater adhesion were aligned with the Z- and M-lines of the intrafusal muscle, where desmosomes are often found. In some sections, detachment from the muscle fiber appeared to be nearly complete, even at the Z- and M-lines, but in all cases the sensory endings adhered tenaciously to their basal lamina.

The finding that muscle spindle sensory endings can continue discharging after almost complete detachment from the intrafusal muscle suggests that the endings may respond to gross deformation, rather than deformation at small, discrete points. The basal lamina may be a crucial element in the mechanical linkage between intrafusal muscle fibers and sensory nerve endings.

330.1 ALTERED AXONAL TRANSPORT OF ACETYLCHOLINESTERASE IN THE SCIATIC NERVE OF ALLOXAN-DIABETIC RATS: EFFECT OF GANGLIOSIDE TREATMENT. A. Gorio, P. Marini*, R. Bianchi*[1] and M. Vitadello. Fidia Research Laboratories, 35031 Abano Terme (PD), Italy, and [1]Institute "Mario Negri", Via Eritrea, 62, Milano, Italy.

The anterograde axonal flow of of AchE was monitored in rats (by the test section method Couraud and Di Giamberardino, J. Neurochem.,35:1053, 1980) five weeks after the injection of alloxan (100 mg/Kg). A 20% reduction of anterograde axonal flow of the enzyme was noticed in diabetic rats compared to the control ones. Sedimentation analysis revealed that such a reduction was mostly due to an impairment of the anterograde transport of $G_1$-$G_2$ molecular forms with a minor, although significant, reduction of $G_4$ form. In contrast the anterograde flow of $A_{12}$ was not affected. Treatment with a mixture of bovine brain ganglioside ($GM_1$, 21%; $GD_{1A}$, 39.7%; $GD_{1B}$, 16% and $GT_{1BT}$, 19% nomenclature according to Svennerholm), starting 7 days after intoxication with alloxan and lasting for 30 days, antagonized the abnormalities of AchE axonal flow. On the other hand no effect was observed in control rats treated with gangliosides, suggesting that gangliosides were effective in improving axonal transport abnormalities induced by diabetic syndrome rather than in activating directly AchE.

330.2 MONOCLONAL ANTIBODIES AGAINST AXONALLY TRANSPORTED PARTICLES FROM RAT SCIATIC NERVE. D.R. Studelska*, T.K. Kimlinger*, J. Katzmann* and S. Brimijoin. Depts. Pharmacology and Laboratory Medicine, Mayo Clinic, Rochester, MN 55905.

Some intracellular materials are transported rapidly (100-400 mm/day) and bidirectionally along nerve axons. Much of this traffic is believed to be associated with vesicles and other membrane-limited organelles. Although microtubules are crucial for rapid axonal transport, recent studies on dissociated axoplasm suggest that the vesicle surface may participate in determining the direction of movement. To explore this possibility we undertook to investigate axonal vesicles by producing monoclonal antibodies against their surface antigens.

Female Balb/c mice were immunized with partially purified vesicles collected from the proximal side of an 18 hr ligation placed on the rat sciatic nerve. The purification was monitored by assays of dopamine-β-hydroxylase (DBH), a membrane-bound enzyme of adrenergic vesicles. The steps in purification were: 1) homogenization and differential centrifugation of desheathed nerve in cold isotonic sucrose; 2) sucrose density gradient ultracentrifugation of the supernatants; 3) Sephacryl S-100 gel filtration of the slow-sedimenting peak of DBH activity; 4) concentration of fractions containing 85 nm DBH-bearing vesicles. The mice initially received s.c. injections of vesicles in complete Freund's adjuvant. Immunization was repeated a month later by i.p. injections without adjuvant and again 3 days before the spleen cells were isolated for fusion with FO (first fusion) or NS1 (second fusion) myeloma cells. Media from primary fusion cultures were assayed with an ELISA. Freshly prepared sucrose gradient fractions containing the slow sedimenting DBH vesicles were bound to microtiter plates at alkaline pH and incubated with culture supernatants overnight at 4°C. The plates were then washed and exposed for 2 hr to alkaline phosphatase-conjugated goat anti-mouse IgG, after which binding was detected colorimetrically. Positive primary cultures were cloned by one or two subcultures at limiting dilution. The resulting clones were reassayed twice with the ELISA before expansion as ascites tumors in pristane-treated mice.

The first fusion produced 18 positive clones from 5 different primary cultures. Different patterns of immunoreactivity with sucrose gradient fractions of nerve extracts showed that some of the clones isolated from the same primary cultures produced different antibodies. A second fusion produced 61 positive clones from 18 different primary cultures. Several of these antibodies may recognize slowly transported or stationary antigens (e.g., of the cytoskeleton and axolemma). However most of the antibodies tested to date are directed against materials that accumulate rapidly with ligation. In addition, some appear to recognize antigens that are transported in only one direction along the axon. (Supported by NIH grant NS 11855.)

330.3 TRANS-SYNAPTIC TRANSFER OF WHEAT GERM AGGLUTININ-HORSERADISH PEROXIDASE (WGA-HRP) IN THE NERVOUS SYSTEM. M. El-Kalliny*, R.D. Broadwell, and B.J. Balin* (SPON: T. Rogers). Divs. of Neurosurg. and Neuropath., Univ. of MD, Balto., MD 21201.

The transfer of endogenous macromolecules (proteins, peptides) between neurons is very likely a consequence of the secretory process (i.e., synthesis, packaging, storage, and release of the molecule). The Golgi complex occupies a nodal point in the scheme of the secretory process. This organelle within cells in general is responsible for the packaging of molecules destined for export and exocytosis. WGA, a plant lectin, conjugated to HRP is an ideal tracer molecule with which to investigate the neuronal secretory process. Unlike native HRP and specific ligands that enter cells by fluid phase and receptor mediated endocytoses and become sequestered in endosomes (prelysosomes) and dense bodies (lysosomes), WGA-HRP is taken into cells by adsorptive endocytosis and is localized within the innermost (trans) Golgi saccule and lysosomes. Our in vivo studies indicate that WGA-HRP is endocytosed by cell bodies, dendrites, and axon terminals. Internalized cell surface membrane tagged with WGA-HRP is directed to endosomes with subsequent transfer of the tracer to the trans Golgi saccule; the tracer then is packaged into Golgi-derived vesicles (40-70 nm)/vacuoles (80-100 nm) and secretory granules (100-200 nm), depending upon the type of neuron. A population of these Golgi-derived, peroxidase-positive structures likely represents primary lysosomes that fuse with endosomes and secondary lysosomes; another may be destined to replenish cell surface membrane in the dendrites, perikaryon, and axon; and a third population undergoes transport by axoplasmic flow to the axon terminal for exocytosis. This transport is independent of the endoplasmic reticulum, which is not peroxidase-positive. Native HRP fails to label Golgi saccules in the neuron and consequently is not transported in Golgi-derived products; however, anterogradely transported tubules and dense bodies are peroxidase-positive in neurons exposed to native HRP and WGA-HRP. These structures may arise from perikaryal lysosomes. Exocytosis and anterograde trans-synaptic transfer of WGA-HRP, but not of native HRP, does occur. Peroxidase-positive organelles identified in post-synaptic neurons include endocytic vesicles and tubules, endosomes, dense bodies, and less frequently the trans Golgi saccule. WGA-HRP and/or fragments thereof conceivably enter post-synaptic cells by fluid phase and adsorptive endocytoses. The potential for macromolecules (excluding virus) in neurons to be delivered across the synapse, whether in the anterograde or retrograde direction, is determined in large measure by the secretory process and involvement of the Golgi complex. NINCDS Grant #NS18030.

330.4 INTRACELLULAR TRAFFICKING OF TRANSPORTED GLYCOCONJUGATES IN DENDRITIC COMPARTMENTS OF OLFACTORY BULB NEURONS. John G. Wood* and John W. Scott (Spon: T.A. Harrison), Department of Anatomy, Emory University School of Medicine, Atlanta, Georgia 30322.

Although considerable information is available defining the intracellular route taken by macromolecules undergoing transport (primarily retrograde) in axons, there is as yet little equivalent information for dendritic transport. The linear orientation of mitral cell basal dendrites makes these cells ideally suited for such studies. WGA-peroxidase conjugates were iontophoretically injected in a site restricted to the deepest one-third of the external plexiform layer in the rat olfactory bulb. After 3 and 24 hrs, the animals were sacrificed by vascular perfusion of fixatives, and 80 µm vibratome slices of bulb tissue were processed for peroxidase visualization and examination at the light and electron microscopic levels. At the light microscopic level labeled mitral cell soma were observed with labeled basal dendrites both proximal and distal to the injection site. The dendrites and somata were lightly labeled, often with a filamentous appearance, and with frequent darker bodies which were larger in the proximal dendrite. At the electron microscopic level, large labeled processes were confirmed as mitral cell dendrites that were frequently observed to be in synaptic contact (dendro-dendritic) with granule cell dendrites. In dendrites between the soma and the injection site, the label was associated with membranous profiles resembling classical endocytotic vesicles. In those labeled dendrites emanating from a cell soma on the side distal to the injection, the intracellular localization of reaction product was invariably restricted to tubulo-vesicular profiles located primarily subadjacent to the dendrolemma. In these same profiles an irregular pattern of strips of extracellular labeling was observed, which was concentrated in the synaptic cleft at sites of reciprocal dendro-dendritic contacts between mitral cell and granule cell dendrites. The results suggest that WGA-peroxidase undergoing dendritic transport in mitral cells escapes degradation in the soma, and may subsequently be preferentally delivered to synaptic sites.

330.5 **A METHOD FOR THE STUDY OF AXONAL TRANSPORT BY DIRECT VISUALIZATION IN INDIVIDUAL MAMMALIAN AXONS IN-VIVO.**
T. Spagnolia, R. Rumpf, W. J. Levy, and D. H. York. University of Missouri Health Sciences Center, Columbia, Missouri 65212

For the direct visualization of axon transport in-vivo, we pass the sciatic nerve of a rat through a perfusion chamber designed for controlled temperature and flow. The rat is anesthetized with Na Pentobarbital and has had a previous dissection of sciatic nerve throughout its course distal to the gastrocnemius. Platinum stimulating electrodes are placed approximately at the sciatic notch and silver recording electrodes are placed distal to the chamber, as are EMG recording electrodes in the intrinsic foot muscles. The chamber itself sits on an AVEC DIC type microscope with rectified Normaski optics. This is a Nikon optiphot using a Dage MTI vidicon tube and control box. A Panasonic 800 line monitor and a Pansonic 500 line 3/4 inch VTR are used for image viewing and storage. The DIC optics use a 100x oil immersion objective (NA1.25) and condenser (NA 1.3). The microscope stage has been custom machined to allow placement of the rats, such that the sciatic nerve passes through the chamber bewteen the objective and the condenser. Temperature is maintained by a control heating environment. The chamber itself is a 25 mm diameter chamber with a coverslip bottom. Ports for in-flow and out-flow of solution connected to an 10-roller peristaltic pump, with temperature monitoring and a removable coverslip top which sits on a silicon elastomer spacer, 100 microns thick. The nerve is fed through the chamber in which Dulbecco's solution with the addition of 5 millimolar ATP and a carboxygen bubbling. An enzymatic dissociation regiment is used consisting of collagenase, trypsin and hyaluronidase which are passed through in seqeuence at 20 minute intervals with minimal agitation. This dissociates the extracellular matrix external to the Schwann cells. Continuous electrical monitoring shows that there is preservation of the nerve action potential and EMG. Examination of the axons under both phase contrast and rectified Normaski light microscopy, as well as osmic acid staining, shows no gross alteration of morphology in the vast majority of axons, compared to the predissociation state. There is some widening of the Schmitt-Lanterman clefts and nodes of Ranvier. Once the axons are dissociated, 50µ microscissors are used to pare a sufficient number of axons away from the nerve so that a single layer remains on the bottom. A coverslip is then advanced on top of these by a threaded ring on the chamber to narrow the intercoverslip distance and produce good optical visualization. Direct observation of axon transport in individual axons is then possible. The axons are in continuity with the spinal cord neuron proximally and the muscle and target organ distally. Electrical stimulation can be carried out during this observation period, using the proximal electrodes. Axon transport was observed with particle movement in both directions, predominantly retrograde. The fast rate is consistent with previous reports of approximately 400 mm per day. This model should provide opportunities to study axon transport and axon function in-vivo in animals of various ages and with various disease processes. Chamber manipulations or manipulations of the animal, which would involve the central neuron and target organ, can be carried out separately.

330.6 TRANSLOCATOR PROTEIN (KINESIN) FOR RAPID AXONAL TRANSPORT MEDIATES ANTEROGRADE MOVEMENT OF BEADS ALONG PURIFIED MICROTUBULES. B.J.Schnapp, R.D.Vale*, T.Mitchison*, T.S.Reese and M.P.Sheetz*. Lab or Neurobiology, NINCDS, NIH, at the Marine Biological Lab., Woods Hole, Mass. 02543.

A soluble factor in axoplasm from the squid giant axon attaches to organelles or carboxylated latex beads and promotes their translocation along purified microtubules (Vale et al, Cell, 40:559, 1985). This factor, which has now been purified from squid optic lobes and bovine brain (Vale et al,Cell,in press) is a protein complex having an apparent molecular weight of approximately 600 Kd and is called kinesin. When kinesin is adsorbed to latex beads and the beads added to microtubules purified from squid optic lobes, video microscopy shows that single microtubules have beads moving along them in one direction only. Microtubules in axons are all oriented in the same direction with their plus ends toward the nerve terminals (Burton and Paige, PNAS, 78:3269, 1981). To determine the polarity of bead movement, microtubules were polymerized from purified bovine brain tubulin by nucleation from centrosomes isolated from a neruoblastoma cell line (Mitchison and Kirschner, Nature, 312:237, 1984). Microtubules polymerized off centrosomes are oriented with their plus ends free and their minus ends toward the basal bodies. When the movement of kinesin-coated beads was assayed on these centrosomal microtubules, all bead movement occured from the minus to the plus ends, corresponding to anterograde transport in the intact axon.

Single microtubules dissociated from the extruded axoplasm of the squid giant axon support the movement of vesicular organelles in both directions (Schnapp et al, Cell, 40:455, 1985). Bidirectional movement of both beads and organelles along centrosomal microtubules is also observed in the presence of a crude supernatant fraction from squid axoplasm. We are using the centrosomal bead movement system as a polarity assay to dissect out those components in the squid axoplasm which determine the direction of organelle movement.

330.7 REGIONAL DIFFERENCES IN MICROTUBULE-POLARITY RATIOS CORRESPOND TO THE DIRECTION OF AXOPLASMIC TRANSPORT IN LOBSTER AXONS. T.A. Viancour, D.S. Forman and D.L. Shevitz*. Biol. Sci., Univ. Maryland Baltimore County, Catonsville, MD 21228, and U.S.U.H.S., Sch. Med., Anatomy, Bethesda, MD 20814-4799.

We have investigated the relationship between microtubule polarity orientation and the direction of axoplasmic transport and found a significant correspondence between the two. The investigation was suggested by the findings of Forman et al (J. Neurosci., 3, 1279-1288, 1983), which reported a regional difference in the predominant direction of axoplasmic transport of particles and mitochondria in 'fast opener' and 'closer' motor axons in the walking legs of lobster (Homarus americanus). In those axons, anterograde transport predominates in a thin, less than 1µm thick, circumferential rind of axoplasm adjacent to axonal membranes, and retrograde transport predominates throughout the rest of the axoplasm.

Microtubule polarities in the identifiable 'opener' axons were determined by the directions of curvature of protofilament hooks which were formed on existing microtubules by incubation in a PIPES buffered solution containing bovine microtubule protein (see Heidemann and Euteneuer in Methods in Cell Biology, v24, pp207-216, Acad. Press, 1982).

Within 0.5 µm of the axonal membranes, roughly half the microtubules have positive ends oriented toward axonal cell bodies and half have the opposite orientation. Throughout the remaining axoplasm nearly all of the microtubules are oriented with positive ends oriented away from axonal somata. There appears to be an abrupt transition from the axolemmal to the lumenal polarity distribution and the polarity ratios of the two regions are significantly different. Preliminary observations suggest that axolemmal microtubules of the same polarity may be clustered.

The regional difference in microtubule orientation is therefore identical to the regional difference in the predominant direction of particle movement in these axons. This correspondence indicates an important relationship between transport direction and microtubule polarity. Furthermore, these findings indicate that microtubule organizing centers may be located within distal axonal segments.

330.8 ACTIVE SINUSOIDAL SHORTENING OF AMPUTATED AXONS SHARES CHARACTERISTICS WITH NORMAL AXON GROWTH.
B.F.Schneider*, E.B.George*, M.J.Katz, and R.J.Lasek (SPON: S.T.Brady). Neurobiology Center, Case Western Reserve University, Cleveland, OH 44106

When axons are amputated from their cell bodies in culture, they undergo an energy dependent process of sinusoidal shortening. We found that this process spontaneously occurred in some intact axons and that it never occurred in transected processes of non-neuronal cells. Because, this suggests that active sinusoidal shortening may be a natural process peculiar to axons, we compared it to the process of normal axonal growth.

Dissociated neuronal cultures were prepared from embryonic (7-12 day old) chick dorsal root ganglia. After 16-24 hours in culture, axons were transected using a glass microneedle. The sinusoidal shortening process required both glucose and pyruvate in the medium, and could be inhibited by either iodoacetate (2.5 mM) or potassium fluoride (15 mM). Thus, the shortening apears to depend on active glycolytic metabolism.

Measurements of sinusoids in shortening axons were made sequentially after amputation, using time-lapse videomicroscopy. 118 measurements on 42 axons were used to calculate the rate of shortening. The average rate of shortening was 1.25 ± 0.7 um/min (1.8 mm/day). The fastest rates (99th percentile) observed for sinusoidal shortening ranged between 5.5 um/min (7.9mm/day) and 6.25 um/min (9.4 mm/day). These rates are similar to the calculated maximum rate of 6.5 um/min (9.3 mm/day) for axonal elongation in the same type of cultures (Katz et al, Cell Motility 4:351, 1984). We interpret these maximum rates as representing the optimal intrinsic rates of these processes. These rates are all comparable to the rate of slow transport in developing axons (5-10 mm/day).

The similar metabolic requirements and the similar rates of change in axon length suggest that the processes of sinusoidal shortening and normal axonal growth share similar underlying mechanisms.

330.9 MECHANISM OF CYTOPLASMIC STREAMING IN GIANT CHARACEAN ALGAE CELLS: POSSIBLE RELATIONSHIP TO SLOW AXONAL TRANSPORT. R. Kachar* and T.S. Reese. (SPON: M.Dubois-Dalcq). Laboratory of Neurobiology, NINCDS, NIH, Bethesda, MD 20205.

Evidence has accumulated that cytoplasmic streaming in giant characean algae cells depends on an actomyosin-driven shearing force generated along stationary actin filament cables at the cell cortex (Kamiya, Ann. Rev. Plant Physiol. 32:205, 1981). The binding and continuous unidirectional movement of organelles along actin cables can be visualized directly by video microscopy after dissociation of the cytoplasm of the algae Chara (Kachar, Science, 227:1355, 1985). Individual organelles move at mean rates of either 11.2±0.1 or 62.1±1.1 μm/sec. Freeze-fracture electron microscopy after direct freezing demonstrates that the organelles moving at 62 μm/sec, which is also the rate of cytoplasmic streaming in intact cells, correspond to vesicular and tubular fragments of endoplasmic reticulum. In fast frozen intact cells, examined by freeze-fracture or freeze-substitution, the endoplasmic reticulum is a tridimensional network of continuous tubular and cisternal structures which is integrated, along with the other organelles, into the cytomatrix to form a cohesive cytoplasm. It is likely that the streaming of the whole cytoplasm depends on the shearing force generated along stationary cortical actin cables by myosin or a myosin-like ATPase at the surface of the endoplasmic reticulum (see Williamson, Eur. J. Cell Biol. 20:177, 1979); the continuous endoplasmic reticulum network in these cells provides the effective means of mobilizing cytoplasm distant from the cortical actin filament bundles, where the motive force is generated (Bradley, J. Cell Sci. 12:327, 1973).

The movement of neurofilament bundles and other cytoplasmic elements down the axon, though several orders of magnitude slower than the cytoplasmic streaming in Chara, might depend on a similar mechanism. Segments of the smooth axoplasmic reticulum typically lie near the axolemma (Rambourg & Droz, J. Neurochem. 35:16, 1980).This continuous, extensively branching axonal reticulum is the only membranous organelle that regularly intrudes into the neurofilament bundles (Schnapp & Reese, J. Cell Biol. 94:667, 1982). Furthermore, individual actin filaments, though not actin cables, are present in the subaxolemmal region (Metuzals & Tasaki, J. Cell Biol. 78:597, 1978; Hirokawa, J. Cell Biol. 94:129, 1982). It is not known whether myosin is associated with the subaxolemmal endoplasmic reticulum, but it is clear that anatomical relationships comparable to those postulated to power cytoplasmic streaming in Chara are present in the axon. The lower rate of slow axonal transport need not rule out a myosin-based system because these systems are known to vary widely in their intrinsic rates (Sheetz et al., J. Cell Biol. 99:1867, 1984).

330.10 REDISTRIBUTION OF ACTIN ALONG WITH MICROTUBULES AND THEIR ASSOCIATED COUPLERS IN RAT SCIATIC NERVE AXONS FOLLOWING ADMINISTRATION OF B,B'-IMINODIPROPIONITRILE (IDPN). R.G. Nagele*, S. Wang*, M.C. Kosciuk* and H. Lee*. Univ. of Med. and Dent. of New Jersey-Sch. of Osteopathic Med. and Rutgers Univ., Camden, NJ 08103.

To date, the most compelling evidence for the direct participation of microtubules (MTs) in the fast axonal transport of membrane bound organelles (MBOs) has emerged from studies on the toxic axonopathies induced by IDPN in rodents. IDPN induces a reorganization of the axonal cytoskeleton in which MTs aggregate into a single cluster and neurofilaments (NFs) are displaced toward the periphery of the axon (Papasozomenos et al., J. Cell Biol., 95:672,1982: Griffin et al., J. Neurosci., 3:557, 1983). This cytoskeletal reorganization has no effect on fast axonal transport which occurs exclusively within MT clusters. In the present study, we have used IDPN-treated rat sciatic nerve axons as a model system to test the following hypotheses: (1) If microtubule-neurofilament couplers, which link these cytoskeletal elements in a variety of neurons(Nagele, R.G. and Roisen, F.J., Brain Res., 253: 31, 1982), are involved in the fast axonal transport of MBOs, then they should be redistributed in IDPN-treated axons so as to remain associated with MTs and MBOs. (2) If the fast axonal transport mechanism is based on an actin-myosin contractile system associated with MTs, then these motility-related proteins should colocalize with MTs and become concentrated within IDPN-induced MT clusters.

Sciatic nerves on each side of adult male rats were injected subepineurally with 5 μl of IDPN (diluted 1:1 in saline). Controls were injected with an equal volume of saline. Animals were sacrificed at intervals and segments of sciatic nerve containing the injection site were fixed for electron microscopy or prepared for the localization of actin using indirect immunofluorescence.

Results show that adjacent MTs within individual MT clusters are separated by a rather uniform distance. Measurements of inter-MT spacing revealed a clear tendency for MT clusters to become more compact during the first 12 hours postinjection. Couplers remained associated with MTs and MBOs during their segregation from NFs and were not found in peripheral regions of axons that contained only NFs. This finding strongly suggests that MTs are the "parent" structure to which couplers are attached and further supports an important role for couplers in fast axonal transport. Indirect immunofluorescence revealed that actin, like tubulin, is concentrated within MT clusters in IDPN-treated axons. This colocalization of actin and MTs along with knowledge that fast axonal transport occurs exclusively within MT clusters of IDPN-treated axons adds strong support to the notion that at least part of the molecular mechanism for fast axonal transport involves an actin-myosin contractile mechanism.

330.11 AXONAL TRANSPORT OF CLATHRIN-ASSOCIATED PROTEINS. D. J. Gower* and M. Tytell†, Depts. of Surgery, Section on Neurosurgery* and Anatomy†, Wake Forest Univ. Med. Sch., Winston-Salem, NC 27103.

Clathrin is the primary protein that makes up the lattice-like structure which forms the "basket" surrounding a coated vesicle. The closure of the basket is postulated to depend upon 2 proteins of 30-36 k daltons, known as the clathrin associated proteins (CAPs). Clathrin is known to be axonally transported in association with the proteins of slow component b (Garner and Lasek, JCB 88:172, 1981), but it has not been determined whether the CAPS are transported with it. We have investigated this question because the result will provide some insight into the state of axonal clathrin.

A unilateral intraocular injection of 0.5 mCi of $^{35}S$ methionine was administered to nine adult male Hartley guinea pigs under anesthesia. Groups of three animals were sacrificed at 6 hours, 5 days and 30 days, to label the proteins of fast component (FC) and slow components b and a (SCb & SCa), respectively. The ipsilateral optic nerve was removed from each animal, as well as the contralateral optic tract in the 30-day animals. The tissue was homogenized in "clathrin buffer" (100 mM MES pH 6.5, 1 mM EGTA, 0.5 mM $MgCl_2$, 0.02% sodium azide, 7 mM β-mercaptoethanol and centrifuged at 20,000 x g for 30 minutes. The supernate was TCA precipitated and the protein redissolved in lysis buffer (9M urea, 5% BME, 5% ampholines, pH 4-9, 8% Triton X-100, pH adjusted to 7.5). A stock of partially purified clathrin plus CAPs was prepared from guinea pig brain by a modification of the method described by Shook and Puszkin (Methods of Enzymology, vol. 98:30, 1983). The purified clathrin and each of the four specimens from optic nerve and optic tract were comigrated on two dimensional SDS-polyacrylamide gels and analyzed by fluorography.

The CAPs were found to be primarily transported with the proteins of SCb. These data imply that axonal clathrin is transported in a form that may be competent to polymerize into the coated vesicle lattice. In this light, the paucity of coated vesicles within the axon suggests that, in addition to the presence of CAPs, the clathrin may require a distinctive intracellular environment to form baskets. Those conditions probably exist only at synaptic terminals and in the soma. (Supported by Grants from Southern Med. Assoc. to DJG, NC United Way and Bowman Gray Med. School to MT & DJG.)

330.12 INTRACELLULAR DIFFUSION OF $CA^{++}$ AND THE FAST AXONAL TRANSPORT. D.C. Chang, Physiol. Dept., Baylor College of Medicine, Houston, TX 77030.

It is evident that in the cytoplasm some ions (such as $Na^+$ and $Ca^{++}$) are bound or sequestered into organelles. Ealier studies suggest that $Ca^{++}$ ions inside the nerve cell are transported by a facilitated mechanism. We injected radioisotope labelled $Ca^{++}$ ions into the giant axon of squid to investigate whether the movement of these ions is coupled with the mechanism of fast axonal transport.

The spatial distribution profile of the labelled ion along the giant axon was determined at different times after the intracellular injection. The axon was rapidly frozen in liquid nitrogen and cut into small segments while still frozen. The radioactivity of each segment was then counted by a scintillation counter. We found no evidence that the distribution of $Ca^{++}$ is affected to any significant extent by the fast axonal transport. First, the ionic distribution curve was almost symmetrical. Second, the peak of the ionic profile coincided with the location where the labelled ions were injected. If the ions were carried by the fast axonal transport, there would be a shift of the ionic profile toward the direction in which the ion-sequestering vesicles moved.

For the purpose of comparison, we have also studied the intracellular transport of radioactive $Na^+$. The distribution profile of $Ca^{++}$ is considerably narrower than that of the $Na^+$ indicating that the effective diffusion of $Ca^{++}$ is much slower than $Na^+$. But even in the case of $Na^+$, the effective diffusion within the axoplasm was significantly slower than that of a free solution. This result is different from the finding in the earlier study of $K^+$ transport within the giant axon of sepia. The implication between the effective diffusion coefficient and the activity of free ions in the axoplasm will be discussed. (Work partially supported by an ONR contract.)

330.13 BEADING OF NERVE FIBERS AND FAST AXOPLASMIC TRANSPORT. S. Ochs and Jersild, R., Jr., Depts. of Physiology/Biophysics and Anatomy, Indiana University School of Medicine, 635 Barnhill Drive, Indianapolis, IN 46223.

In one theory of axoplasmic transport, fluid channels in a structured network within the axoplasm are assumed to be the path by which various components are transported in nerve fibers. To test that concept nerves were stretched to cause the fibers to become beaded. Beading appears as a series of constrictions 10-25 um in length at intervals of 20-50 um along the fibers, collapsing fluid channels and possibly blocking transport. Cat L7 dorsal root ganglia were injected with $^3$H-leucine and after 2 hr of downflow of labeled proteins *in vivo*, the sciatic nerves were removed and placed in a chamber with a weight of 1-35 gm tied to the distal end of the peroneal branch to initiate and maintain beading. The tibial branch remained unstretched. The *in vitro* preparation was kept at 38°C and oxygenated with 95% $O_2$ + 5% $CO_2$ for times up to 5 hr after which a portion of the peroneal nerve was frozen *in situ* for freeze-substitution while still under stretch. Freeze-substitution is required to hold the labile shape of the beaded fibers during histological preparation. Fibers in the unstretched tibial nerves were mostly cylindrical while those in the stretched peroneal nerves showed the series of constrictions along their fibers typical of beading. In cross-section the axonal area in the constrictions was reduced to <5% of normal. A close packing of microtubules and neurofilaments in the constrictions was observed in slam-freeze preparations examined by EM. Beading did not, however, cause a block of transport as shown by the normal outflow pattern of labeled proteins. The fronts were, however, a little retarded in the stretched peroneal nerves compared to the unstretched tibial nerves and had somewhat less labeled material in the crests. Considering the marked reduction of axonal cross-sectional area with little evidence of fluid channels remaining, and the possibly greater viscosity which may be present if beads are maintained for the whole time of downflow, this would appear to require an active propulsion through these regions of resistance. Such is envisioned in the transport filament hypothesis where ATP is utilized to drive carriers, to which various transported components are bound, against viscous resistance. Supported by NIH PHS ROI NS 8706-15 and NSF BNS 82-17727.

330.14 ARE ELEVATED LEVELS OF FAST TRANSPORT ESSENTIAL FOR OUTGROWTH OF GOLDFISH OPTIC AXONS? Janet R. Sparrow and Bernice Grafstein. Dept. of Physiology, Cornell University Medical College, New York, NY 10021

Although many regenerating neurons do not exhibit changes in axonal transport during regeneration, goldfish retinal ganglion cells show large increases in axonal transport during regeneration. For instance, the amount of fast-transported protein, which comprises organelle constituents, including plasmalemma, is increased as early as one day following axotomy, and by 2 weeks postoperatively the amount is 3-5 fold greater than normal (Giulian et al., 1980, J Biol Chem 255: 6494; McQuarrie and Grafstein, 1982, Brain Res 235: 213). We have therefore investigated whether this increase in fast transport is necessary for sustained outgrowth of the axons.

Following optic nerve crush, intraocular injection of the drug monensin (Hammerschlag et al., 1982, J Cell Biol 93: 568) reduced fast transport of $^3$H-proline-labelled protein in the regenerating axons to the level normally present in unlesioned axons. During the first week of regeneration, outgrowth proceeded at a nearly normal rate; between 8 and 11 days, however, the axons advanced very little. The effects of diminished fast transport on the regeneration of these axons was not limited to the early stages following axotomy: administration of monensin beginning at the time that the axons arrive in the optic tectum delayed visual recovery.

We also sought to determine whether the elevated levels of fast transport occurring after a single axotomy are sufficient to support regeneration at an enhanced rate. Outgrowth of the optic axons was accelerated by subjecting the axons to two lesions separated by an interval of 2 weeks (the "conditioning lesion" paradigm (McQuarrie and Grafstein, 1981, Brain Res 216: 253)). Since the amount of fast-transported protein in conditioned nerves is markedly greater than in nerves regenerating after only one lesion (McQuarrie and Grafstein, 1982, Brain Res 251: 25), we administered monensin on the day preceding and the day after the second lesion, which reduced fast-transport in the conditioned nerves to the level present after a single axotomy. Nevertheless, the axons regenerated at the accelerated rate typically seen in conditioned nerves.

We conclude that 1) elevated levels of fast axonal transport become essential for sustained outgrowth of goldfish optic axons after a week of regeneration; and 2) the elevated levels of fast transport seen after a single lesion of the goldfish optic nerve are sufficient to support outgrowth at an accelerated rate.

## GLIAL AND NEURONAL MEMBRANE COMPOSITION II

331.1 STEROID HORMONES STABILIZE LIPOSOMAL MEMBRANE FROM ALTERATION BY TUBULIN. Paul Y. Sze, Ellen C. Armstrong, Grace G. Deanin and Malcolm W. Gordon. Chicago Med. School, North Chicago, IL 60064, Univ. of Conn., Storrs, CT 06268 and Univ. of New Mexico Medical School, Albuquerque, NM 87131.

There is an increasing body of evidence that the plasma membrane is a cellular target site of steroid hormone actions, in addition to genomic mechanisms involving intracellular receptors. In central neurons, specific binding sites for glucocorticoids and gonadal steroids have recently been identified in synaptosomal plasma membrane. To understand steroid interaction with membranes, we have used an artificial membrane system consisting of a single lipid and a single protein. Liposomes (small unilamellar vesicles) were prepared from dipalmitoylphosphatidylcholine (DPPC) with 0.1 M calcein encapsulated. The addition of tubulin to the liposomes resulted in an alteration of bilayer conformation, with subsequent leakage of the encapsulated dye at phase transition. Dye release was a sigmoidal function of tubulin concentration, with maximal release obtained at 0.1 mg/ml. We found that when corticosterone was incorporated into the liposomal membrane, the bilayer became resistant to alteration by tubulin, as determined by dye release. Binding of tubulin was not reduced by steroid incorporation, nor was the phase transition temperature of the bilayer significantly changed. Other hormonal steroids examined (including hydrocortisone, testosterone, 17β-estradiol and progesterone) showed similar stabilizing effects on the bilayer toward tubulin, and their effects were found to be far greater than that of cholesterol, a substance known for its role in regulating membrane fluidity. Most interestingly, among the hormonal steroids examined, the glucocorticoids showed the strongest effects in stabilizing the bilayer against the tubulin-induced alteration. For example, corticosterone as low as 0.002 M% was sufficient to produce an effect comparable to that obtained by cholesterol at 10 M%. The effect of hydrocortisone at 0.008 M% was similar to that from cholesterol at 0.1 M%. On the other hand, deoxycorticosterone, a synthetic steroid that antagonizes many of the biological activities of glucocorticoids, was found to further destabilize the bilayer toward the tubulin-induced effect. It appears from our data that at least in the interaction between DPPC bilayer and tubulin, glucocorticoids act on the bilayer as "super-cholesterols". We propose that in cell membranes, the steroid hormone binding sites (possibly a phospholipoprotein) serve as carriers and determine specificity, whereas the primary actions of the hormones are on lipid bilayers.

331.2 INCORPORATION OF DOCOSAHEXAENOIC ACID INTO GLYCEROLIPIDS AND CONVERSION TO LIPOXYGENASE REACTION PRODUCTS IN THE RAT BRAIN IN VIVO AND IN MONKEY BRAIN SYNAPTOSOMES IN VITRO. Dale L. Birkle* and Nicolas G. Bazan. (SPON: H.E.P. Bazan). Louisiana State Univ. Med. Ctr., LSU Eye Center, New Orleans, LA 70112.

Docosahexaenoic acid (22:6, n-3) is highly enriched in the glycerolipids of synaptic plasma membranes, and accumulates as free 22:6 following ischemia, electroconvulsive shock and bicuculline-induced status epilepticus. This accumulation may be mediated by the phospholipase $A_2$-induced release of 22:6 from membrane lipids. Recently, we reported the conversion of 22:6 via a lipoxygenase to oxygenated metabolites, including 11-hydroxy-docosahexaenoic acid (11-HDHE), in a central nervous system tissue, the canine retina (Biochem Biophys Res Comm 1984, 125:741). Production of HDHEs is not affected by inhibitors specific for lipoxygenases that use arachidonic acid (20:4,n-6) as a substrate, therefore a distinct mechanism for the production of HDHEs has been proposed. Because of the specific enrichment of 22:6 in synaptic plasma membrane, it is of interest to investigate the metabolism of this highly unsaturated fatty acid in the brain. [1-$^{14}$C]22:6 (1 μCi, $Na^+$ salt) was injected bilaterally into rat lateral cerebral ventricles. At 5, 15, 30, 60 and 120 min after injection, rats were decapitated and the heads frozen in liquid nitrogen. Labeling of phosphatidylcholine, phosphatidylethanolamine and triacylglycerol was most active, and incorporation reached a plateau at 60 min. A second group of rats was injected intraventricularly with [1-$^{14}$C]22:6 and 60 min later treated with 10 mg/kg (i.p.) bicuculline. Rats were killed by high power microwave irradiation (6.5 kW for 1.25 sec) 5 min after drug treatment, during the status epilepticus phase. Lipid extracts were prepared from cerebrum. Extracts were analyzed by high performance liquid chromatography to determine the presence of lipoxygenase reaction products (HDHEs). Approximately 6% of the total radioactivity of the lipid extract was lipoxygenase reaction products. The profile of products was different from the profile observed previously in the canine retina. Preliminary evidence suggests an enhanced production of HDHEs in cerebrum from bicuculline-treated rats. A third experiment explored the synthesis of lipoxygenase reaction products of 22:6 and incorporation into glycerolipids in synaptosomes prepared from monkey cortical grey matter. Synaptosomes were incubated for 60 min at 37°C in the presence of 0.5 μCi [1-$^{14}$C]22:6, and in the presence or absence of 45 mM $K^+$. Characterization of the metabolism of 22:6 in synaptosomes, and the possible significance of 22:6 accumulation and synthesis of HDHEs in neurons will be discussed. Supported by NIH EY07073 and The Esther A. and Joseph Klingenstein Fund, Inc, New York.

331.3 HEME COMPETITIVELY INHIBITS BINDING OF FLUORESCENT BIS-ANS TO MYELIN BASIC PROTEIN. Stephen J. Morris*, Diane Bradley*, Peter E. Braun and Gerald L. Stoner (SPON: R.L. Irwin). Lab. of Experimental Neuropathology, NINCDS, NIH, Bethesda, MD 20205, USA and Dept. of Biochem., McGill Univ., Montreal, Quebec H3G 1Y6, Canada.

Although the traditional view of purified myelin basic protein (MBP) structure in solution is that of a random coil polymer [1], some experimental evidence suggests that MBP has definite long-range order [2,3]. A model of MBP conformation based on analysis of the amino acid sequence predicts the presence of a 5-strand antiparallel β-sheet [4].

Our fluorescence spectral data of the sole Trp residue in MBP shows that it acts as the acceptor for resonance energy transfer (RET) from one or more Tyr residues. Both Trp fluorescence and RET can be collisionally quenched by $I^-$ and acrylamide (A), but not by $Cs^+$ or $Co^{2+}$, implying that the fluorophores are in an exposed, positively charged environment. The quenching coefficients (Q) for $I^-$ and A are ~15 $M^{-1}$. Heme, which has previously been reported to bind to MBP [5,6], also quenches both Trp fluorescence and RET with an apparent Q of $1.0 \times 10^5$ $M^{-1}$, some 6,700-fold larger, suggesting [7] that heme has relatively high affinity for MBP. The negatively charged fluorescent probes 1,8-ANS and 2,6-TNS have been reported to bind to MBP with $K_d$ of $2\text{-}3 \times 10^{-5}$ M and $B_{max}$ of ~1:1 [2,8]. Our data produces similar values. Bis-ANS binds to albumin more avidly and specifically than ANS or TNS [9]. We find an apparent $K_d$ and $B_{max}$ for bis-ANS binding to MBP of $\sim 4 \times 10^{-6}$ and 0.5:1. Heme competitively inhibits bis-ANS binding with an apparent $K_i$ of $\sim 6 \times 10^{-7}$ M.

The affinities of ANS and heme for MBP, along with the RET and fluorescent amino acid quenching data demonstrate that MBP contains considerable structural specificity, implying long-range interactions in the molecule as predicted. Tyr → Trp RET demands a maximum separation of these fluorophores of <15 Å. The binding site for the heme and ANS derivatives must be within the same distance constraints. ANS prefers positively charged, hydrophobic environments. The first requirement is satisfied by the β-sheet model which places Tyr-14 ~5 Å from Trp-117 on an adjacent strand. The second and third requirements would be met if the heme/ANS binding site were located on the β-sheet near these residues.

331.4 IS THE C-TERMINUS OF JC, BK, AND SV40 VIRUS LARGE T-ANTIGENS ANCESTRALLY RELATED TO MYELIN BASIC PROTEIN Gerald L. Stoner. Lab. of Exp. Neuropathol., NINCDS, NIH, Bethesda, MD 20205.

Myelin basic protein is phosphorylated in a ProArgThrProProPro sequence on Thr-99[1]. A similar sequence occurs in the C-terminus of the large T antigens of JC and BK virus (ProLysThrProProPro) and of SV40 virus (ProProThrProProPro)(699-704)[2]. The latter is known to be phosphorylated on Thr-701[3]. Beyond these sites, there is no obvious homology between MBP and the primate papova virus large T antigens. However, in severely immunocompromised hosts both JC and SV40 virus can infect oligodendroglial cells. In man JC virus causes the demyelinating disease, progressive multifocal leukoencephalopathy(PML)[4]. Therefore, the possibility of a distant ancestral relationship was explored with the SEQDP program[5]. SEQDP compares the optimal alignment of two sequences with the average scores of 100 randomized sequences of the same amino acid composition. Evolutionary distance is measured by the z value ([score - mean score]/standard deviation)[6]. It was found that the central segment of MBP (60 residues) was more closely related to the papova virus T antigen C-terminal sequences than to any of 90 other triproline-containing sequences in the NBRF protein sequence data base. The z values obtained (~2.5-5) are consistent with an ancestral relationship[6]. It is concluded that interaction with an unknown protein kinase may have conserved these sites in sequences which have otherwise diverged widely. Similar analysis of several sites of O-glycosylated threonine residues which also precede triproline sequences indicated no detectable ancestral relationships, suggesting that those similarities represent convergence rather than divergence. It seems most probable that triproline sequences have been utilized as recognition sites for post-translational modification of nearby residues because they are inherently rigid. This rigidity may promote specific recognition of an otherwise flexible portion of the molecule[7]. Regardless of the evolutionary mechanisms which may have been involved in their selection, the sharing of sites between papova virus T antigens and MBP suggests two novel mechanisms of demyelination: (1) During oligodendrocyte infection the T-antigen site might compete for the unknown protein kinase which phosphorylates Thr-99 of MBP. (2) If the T-antigen triproline sequence is immunogenic, it might induce an immune response cross-reactive with MBP and capable of triggering CNS pathology in the absence of oligodendrocyte infection.

331.5 EXPRESSION OF MYELIN PROTEINS IN DEVELOPING RAT SCHWANN CELLS A. F. Hahn*, B. Kachar*, H. deF. Webster. Lab. of Experimental Neuropathology, NINCDS, NIH, Bethesda, MD 20205.

Previous immunocytochemical studies of $P_2$ protein describe a selective distribution of immunoreactivity in myelin sheaths surrounding large axons of rat peripheral nerves (Trapp et al., 1979; Winter et al., 1982). To better characterize Schwann cell expression of $P_2$ protein during development, we examined the appearance and density of anti-$P_2$ immunoreactivity and related them to axon and myelin sheath size in a well defined fiber population. Myelin protein expression was studied immunocytochemically in rat cranial nerves during development (postnatal day 1,2,3,4,5,8,15,20). At the level of the sphenoid bone, cranial nerves III, IV, and VI lie within the dura surrounding V and functionally defined fiber populations can be studied in single transverse semithin or thin sections. We found this site well suited for studying myelin protein immunoreactivities and their relationships to: (1) onset of myelination (2) axon diameter (3) myelin spiral length (4) fiber function. Polyclonal antisera reacting specifically with $P_0$ glycoprotein and basic proteins $P_1$ and $P_2$ were used in the PAP method to immunostain serial semithin epon sections. Immunoreactivity of individual sheaths in the VI nerve was measured by densitometry. Numbers of compact myelin lamellae, myelin spiral lengths, and axon diameters were determined on electron micrographs of adjacent thin sections. At birth, anti-$P_0$ staining was found on sheaths with 2 or more compact lamellae; neither $P_1$ nor $P_2$ immunoreactivity was observed. On day 2, myelin sheaths with 4-5 and 5-8 lamellae were stained respectively by anti-$P_1$ and anti-$P_2$. On day 3, the percentages of myelinated fibers that were immunostained were substantially higher, $P_0 > P_1 > P_2$. By day 4, anti-$P_0$ and anti-$P_1$ immunoreactivity was present in 95% of myelin sheaths; 35% were stained by anti-$P_2$. For $P_2$, staining intensity and the percentage of myelin sheaths stained continued to increase; by day 20, 85% were anti-$P_2$ positive. Staining intensities were not uniform in all sheaths in identically processed sections. Intensity variation was greatest with anti-$P_2$, less with anti-$P_1$, and least with anti-$P_0$; staining became more uniform with increasing age. Preliminary quantitative results suggest that intensity of anti-$P_2$ immunoreactivity correlates better with the amount of myelin present (myelin spiral length and number of myelin lamellae) than with axon diameter. Differences in detection of immunoreactivity and its intensity may reflect relative amounts of this minor PNS myelin constituent that can be detected by the method rather than selective expression of $P_2$ by certain myelin-forming Schwann cells. Qualitative comparisons of VI and V indicate that expression of $P_2$, $P_1$, and $P_0$ myelin proteins is independent of fiber function.

We thank J.N. Whitaker for $P_1$-and $P_2$-antisera, B.D. Trapp for $P_0$-antiserum and J. Fex for the use of the digital image processor.

331.6 SOME NEW BASIC PROTEINS IN CHICKEN POSTSYNAPTIC DENSITIES. Z.Y. Yang* and J.A. Babitch. Dept. of Chemistry, Texas Christian University, Fort Worth, Texas 76129.

Postsynaptic densities (PSD) were previously reported to contain 20 to 30 proteins, based on one-dimensional SDS-PAGE. So far only a few of them have been identified. Most of their physical and biochemical properties are still to be investigated. PSDs were obtained from 10-day-old chicken brains by treatment of crude synaptosomes with 0.5% Triton X-100 and then were further purified on sucrose gradients. The isoelectric focusing gel system, improved by substitution of 3[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate(CHAPS) for NP-40 and increased cathode buffer concentration, produces better resolution and a stable pH gradient spanning the range 4-9. Some new basic proteins were detected in these improved IEF-SDS two-dimensional gels. They are: 82K (pI>9.1); 58K (pI 8.1 to 8.8 heterogeneous); 40K (pI 9.0) and 24K (pI 8.9). Nonequilibrium pH gradient-SDS gels further show some extremely basic proteins with pIs higher than 9: 81K, 53K, 47K, 45K, 36K, and two at 34K. All together we observed 11 major basic proteins. They amount to about half of the total PSD proteins appearing on these gels. These basic proteins are distinguishable from those of brain mitochondria, the major potential contaminants. This is further confirmed by experiments mixing $^3H$-labeled liver mitochondrial proteins with synaptosomes during PSD isolation. Some PSD proteins can be phosphorylated by endogenous protein kinase(s) in the presence of $Ca^{2+}$ and [$\gamma$-$^{32}$P]ATP. A major basic protein of mol. wt. 82K is strongly phosphorylated along with some other basic proteins. However, none of the others are major proteins. To evaluate their $Ca^{2+}$- binding properties, PSD proteins on nonequilibrium pH gradient-SDS gels were electrophoretically transferred to nitrocellulose membranes, which were then incubated with $^{45}Ca^{2+}$ for 30 min. Excess $^{45}Ca^{2+}$ was washed off with double distilled water. The autoradiograms show $Ca^{2+}$-binding proteins of 70K (probably a subunit of neurofilaments or a microtubule associated protein), 61K ($\alpha$-tubulin), 54K ($\beta$-tubulin), 46K (actin) and an acidic protein with low molecular weight, probably calmodulin. No basic proteins showed $Ca^{2+}$-binding capacity. Supported by the TCU Research Fund and NIH.

331.7 MOUSE NEUROBLASTOMA CELLS: A MODEL SYSTEM FOR STUDYING SPECTRIN EXPRESSION S.R. Goodman*, I.S. Zagon, D.B. Coleman*, and P.J. McLaughlin (SPON: T. Lloyd). Dept. of Physiology and Anatomy, The M.S. Hershey Medical Center of The Pennsylvania State University, Departments of Physiology and Anatomy, Hershey, PA 17033

To begin the study of the synthesis and assembly of the spectrin based cytoskeleton in a neuron-like cell type, we have chosen S20Y mouse neuroblastoma cells as a model system. To study expression of neuroblastoma spectrin, 20 million log phase (8-10% differentiated) or confluent phase (55-60% differentiated) cells were incubated in Eagles EMM-unlabelled methionine + $S^{35}$ methionine (200 μCi/ml, 1126 Ci/mmole) for 4h at 37°C. Cells were solubilized in triton X-100 at high ionic strength as described elsewhere (Glenney, J.R. and Glenney, P., Cell 34: 503, 1983). Addition of antibodies against mouse brain spectrin under these stringent conditions allowed specific immunoprecipitation of $S^{35}$-labelled neuroblastoma spectrin with a 240 kDal α subunit and a 235 kDal β subunit in a 1:1 molar ratio. No $S^{35}$-labelled neuroblastoma spectrin (rbc type) could be immunoprecipitated with anti-mouse rbc spectrin IgG. Chymotryptic two-dimensional peptide mapping analysis of $S^{35}$-labelled or $I^{125}$-labelled neuroblastoma spectrin demonstrated that the 240 kDal and 235 kDal subunits are distinct from each other, share little overlap with mouse rbc spectrin α and β subunits, but are nearly identical to mouse brain spectrin α and β subunits respectively. Indirect immunofluorescent staining of neuroblastoma cells with an antibody against mouse brain spectrin demonstrated a brightly stained cell body, no nuclear staining, and staining of all processes with bright staining of the growth cones. Intense perinuclear staining of fibers which radiated into the neurites was observed in most cells. The model system described should allow us to study the synthesis and assembly of spectrin subunits and associated proteins in a homogenous neuron-like cell system. Supported by NIH grants NS-19357 and HL-26059 to SRG, and NS-21246 to ISZ. SRG is an Established Investigator of the American Heart Association.

331.8 PHOSPHORUS METABOLISM AND $^{3}H$-SAXITONIN BINDING ASSOCIATED WITH PHOSPHOLIPASE $A_2$-INDUCED CONDUCTION BLOCK. J.W. Kaskow, L.G. Abood, W. Hoss and R.M. Herndon. Center for Brain Research, University of Rochester School of Medicine, Rochester, NY 14642.

Recently, an investigation of enzymatic treatments on nerve conduction revealed that phospholipase $A_2$ ($PLA_2$), which disrupts myelin, causes profound conduction block; β-glucosidase and proteases were without effect (Kaskow et al., Soc. Neurosci. Abstr. 10:1179, 1984). The objective of this study was to investigate the biochemical changes responsible for the conduction block associated with exposure of desheathed bullfrog sciatic nerves to $PLA_2$ from bee venom. At a concentration of $PLA_2$, which produced at least a 50% block in nerve conduction, there resulted a 45% decrease in both phosphatidylcholine (PC) and phosphatidylethanolamine (PE) with no significant change in phosphatidylserine. In addition, there occurred a 58% and 78% decrease in ATP and phosphocreatine (PCr), respectively, and about 50% increase in AMP. Using $^{32}P$-orthophosphate, it was demonstrated that $PLA_2$ decreased $^{32}P$ influx, increased $^{32}P$ outflux, while having no effect on ATP and PCr turnover. $^{3}H$-Saxitonin binding was inhibited 85% by $PLA_2$ treatment. These findings suggest that $PLA_2$, by hydrolyzing PC and PE, disrupts sodium channels and depletes high energy phosphates, leading to conduction failure because of a decrement in sodium conductance and an inability to maintain ionic gradients. Supported by HHS Grant DA 00464 (LGA).

331.9 A RARE CELL SURFACE ANTIGEN FOUND ON MOTOR NEURONS P.D. Kushner, H. Sternberg*, D. Stephenson*, and G. Cole* ALS and Neuromuscular Research Foundation, Pacific Medical Center, San Francisco, CA. 94115.

We have identified a cell surface component of motor neurons which is shared with few other CNS neurons and is present in phylogenetically diverse species. We discovered this component using an antibody made to Torpedo electroplax synaptosomes. Electron microscopic immunolocalization reveals that this component resides on the plasma membrane of neurons and appears externally distributed. This external distribution has been confirmed on a differentiated teratoma culture of human origin, NT2/D1. Molecular weight analysis in the presence of reducing agent, reveals that the epitope is found on two polypeptides of electrophoretically separated, Torpedo synaptosomes, $M_r$ = 67,000d and 180,000d. Without reduction two different molecular weight species are observed, 130,000d and over 250,000d. These data, along with the observation that antibody recognition is destroyed upon pretreatment of Torpedo synaptosomes with trypsin, is indicative that the epitope resides on proteinaceous molecules. The determinant appears to be partially concealed by disulfide linkages because, upon thiol-reduction, the antibody signal is enhanced (both by radioimmunoassay and immunogel analyses). Because the molecular weight findings are similar to published accounts of the Torpedo acetylcholinesterase catalytic subunit (67,000d, reduced and 130,000d, unreduced) and because esterase is abundant in Torpedo synaptosomes, we tested the possibility that this antibody might recognize a component with esterase catalytic activity. We performed immunoprecipitation and subsequent enzyme activity analyses. We find that, indeed, this antibody does precipitate acetylcholinesterase activity from Torpedo synaptosomes and that this activity is inhibited by BW284C51 and does not utilize butyrylthiocholine as substrate.

331.10 CHARACTERIZATION OF A POLYSPECIFIC ANTISERUM THAT DISRUPTS NEURONAL-ASTROGLIAL INTERACTIONS IN VITRO. J.C. Edmondson, J.M. Alter* and M.E. Hatten. Department of Pharmacology, New York University Medical Center, New York, NY 10016.

Our laboratory has developed a polyspecific antiserum that quantitatively disrupts specific neuronal-astroglial interactions in monolayer cultures from early postnatal mouse cerebellum, as reported previously (Society for Neuroscience Abstracts, 10:759, 1984). Fab fragments prepared from the antiserum randomize the distribution of neurons with respect to glial cells in culture and also cause stunting of glial process outgrowth. Here we report further cytological and biochemical characterizations of this immune activity.

By immunofluorescence localization, the antiserum stains the entire surfaces of neurons and astroglia in cerebellar cultures, purified cerebellar neurons, purified cerebellar astroglia, PC12 cells and some glioma lines, but not PTK2 (kangaroo kidney epithelial) cells. By HRP labelling at the electron microscopic level, the antiserum stains the surfaces of both neurons and astroglia (identified as containing 10 nm filaments), and also heavily labels the interfaces between the two cell types.

Preabsorption of the antiserum with whole dissociated cerebellar cells from normal cerebellum results in loss of the biological activity. Preabsorption with PC12 cells, a cell type that does not interact specifically with cerebellar cells in vitro, does not remove the biological activity. Preabsorption with cells from the midline portion of the homozygous weaver mutant mouse, a mouse which suffers defects in astroglial differentiation and glial-guided migration, also does not remove the biological activity.

When cultures are grown in the presence of $^{3}H$-fucose, solubilized gently in Triton X-100, immunoreacted with the antiserum, precipitated with Protein A Sepharose and run on SDS-PAGE, at least five prominent species are seen in autoradiograms, indicating that the antiserum recognizes a family of glycoproteins. The three higher molecular weight components, 250, 210 and 140 kd, are removed if the antiserum is preabsorbed with PC12 cells. The remaining bands are 105 kd and a diffuse band centered around 85 kd. Immunoprecipitation with weaver-preabsorbed antiserum is currently in progress. Supported by NIH grant NS15429 (MEH).

331.11 STRUCTURES OF TWO NEURONAL CELL ADHESION MOLECULES B.C. Sorkin*, M. Grumet*, B.A. Cunningham* and G.M. Edelman. Dept. of Developmental and Molecular Biology, The Rockefeller University, NYC, NY 10021

The neural cell adhesion molecule, N-CAM, mediates neuron-neuron and neuron-myotube adhesion. We have refined our topographical model of N-CAM, consistent with a variety of biochemical and molecular biological data. The most distinguishing feature of N-CAM is the presence of polysialic acid on one or more of the three asparagine-linked oligosaccharides in the central domain of the molecule; sugars other than sialic acid were sulfated in some of these carbohydrates, both in vitro and in ovo. In contrast, primary cultures of neurons incorporated sulfate into N-CAM, but not into that material released by endoglycosidase F. The carboxy terminal third of the molecule that is associated with the cell membrane contains covalently bound fatty acid, phosphoserine and phosphothreonine in both polypeptide chains. The two components yield different phosphopeptides after trypsinization, and the ratio of phosphoserine to phosphothreonine in the larger species is almost four times as high as in the smaller. These and other data indicate that the amino acid sequences of the two polypeptides differ in this part of the molecule.

The neuron-glia cell adhesion molecule, Ng-CAM, which is present on the surface of post-mitotic neurons, mediates neuron-glia adhesion and may play a role in neuron-neuron adhesion. Ng-CAM contains less sialic acid than N-CAM and consists of three polypeptide chains with Mr's of 200,000, 135,000 and 80,000. The components of Mr=135,000 and 80,000 are immunologically related to the Mr=200,000 species but not to each other and only the Mr=200,000 and 80,000 components are phosphorylated in vitro, suggesting that the Mr=135,000 and 80,000 components are derived from the Mr=200,000 polypeptide. Despite their differences, N-CAM and Ng-CAM share at least one oligosaccharide determinant that is also present on myelin-associated glycoprotein. Methods similar to those used with N-CAM have been used to generate a topographical model of Ng-CAM.

Supported by NIH Grants HD-09635, HD-16550, AI-11378 and AM-04256.

331.12 MODULATION OF NEURAL CELL ADHESION MOLECULE EXPRESSION DURING IN VITRO DEVELOPMENT AND MALIGNANT TRANSFORMATION. D.R. Friedlander, R. Brackenbury* and G.M. Edelman. Dept. of Molecular Biology, Rockefeller University, 1230 York Ave., New York, N.Y. 10021.

During normal development, the neural cell adhesion molecule N-CAM changes in amount and structure. In the latter, a sialic acid-rich embryonic, or E form, changes to several adult, or A forms, that have less sialic acid (E to A conversion). The potential functional significance of these examples of cell surface modulation (Edelman, G.M., Science, 192:218-226, 1977; PNAS 81:1460-1464, 1984) is suggested by experiments in which the binding rate of N-CAM reconstituted into synthetic vesicles is strongly dependent on the amounts and chemical form of the molecule (Hoffman, S. & G.M. Edelman. PNAS 80:5762-5766, 1983). To gain insight into the control of N-CAM expression, we have examined two in vitro systems which exhibit prevalence modulation and E to A conversion.

Changes in the amount of N-CAM were observed in neuroepithelial cells from 7 day chick embryos after transformation by Rous sarcoma virus (RSV). The transformed cells were morphologically altered, were more motile, and, as revealed by specific immunoblotting, immunofluorescence, and immunoprecipitation analyses, expressed 7-10 fold less N-CAM than uninfected cells or cells infected with transformation-defective RSV. Expression of N-CAM was temperature-dependent in cells infected with mutants of RSV that are temperature-sensitive for transformation. Experiments using N-CAM cDNA probes suggest that the alteration in amount of N-CAM occurs at the transcriptional level.

E to A conversion was observed in explants of mouse cerebellum, chick spinal cord and chick retina. After 3-6 days in culture, increased proportions of A forms were synthesized, and the rate of E to A conversion and the proportions of the different A forms were similar to those observed in vivo. Pulse-chase experiments, metabolic labeling with $^{3}$H-glucosamine and treatment with neuraminidase indicated that the synthesis and glycosylation of the N-CAM polypeptide chains in vitro were normal. In long term pulse-chase experiments, the E form of N-CAM that was synthesized during the first day after explantation persisted for several days, although in reduced amounts. At these later times, newly synthesized N-CAM was predominantly in A forms, indicating that in cultured neural tissue, the E form of N-CAM is not processed into A forms but is gradually degraded and replaced by newly synthesized A forms. Together, these results indicate that N-CAM expression may be altered by changes in mRNA transcription or stability, and post-translationally, by changes in levels or activity of sialyltransferases. These in vitro systems should be useful in defining the molecular mechanisms involved in the control of N-CAM expression.

## BIOLOGICAL RHYTHMS IV

332.1 INTRACELLULAR CURRENT INJECTION INTO PUTATIVE PACEMAKER NEURONS PHASE SHIFTS THE BULLA OCULAR CIRCADIAN PACEMAKER. D.G. McMahon and G.D. Block, Dept. of Biol., University of Virginia, Charlottesville, Va. 22901

In an effort to elucidate the mechanisms of entrainment of circadian rhythmicity we have investigated the role of changes in transmembrane potential in phase shifting the ocular circadian pacemaker of the marine mollusc Bulla gouldiana. The Bulla eye contains a circadian pacemaker which expresses a circadian rhythm in the frequency of spontaneous optic nerve impulses in vitro. A group of electrically coupled basal retinal neurons (BRNs) have been identified as the likely site of the circadian oscillator within the retina. Intracellular recordings from these neurons reveal that they respond to entrainment stimuli with changes in membrane potential (e.g. depolarize to light). It has been proposed by Eskin (1972) and ourselves (1984) that changes in membrane potential could play a role in phase shifting molluscan circadian pacemakers. We now report that changing BRN membrane potential by intracellular current injection directly into the putative pacemaker neurons is sufficient to phase shift the ocular circadian pacemaker. In addition, suppressing light-induced depolarizations by injection of hyperpolarizing current substantially reduces light-induced phase shifts.

Pairs of Bulla eyes were dissected from the animal in the late subjective day. Eyes were maintained in sterile ASW and darkness at 15 °C. At various times following dissection a BRN in one eye was penetrated with a glass capillary microelectrode filled with 4M KAc (80-120 MΩ). Following impalement, depolarizing or hyperpolarizing current was injected into the BRNs. In some experiments both eyes were exposed to light (5000 lux) while hyperpolarizing current was injected into the BRNs of one eye to suppress the light-induced depolarization. Phase shifts were measured on the second circadian cycle following treatment.

Injection of depolarizing current mimics the phase shifting action of light, producing phase delays in the early subjective night (SN, mean phase shift=-1.6h), advances in the late SN (+1.5h), and no shift during the subjective day (SD,+0.1h). Injection of hyperpolarizing current produces advances in the late SD (+1.2h), and no shift in the early SN (0.0h). Injection of hyperpolarizing current during light pulses in the early SN reduced the light induced phase delay by 0.9h.

Either depolarizing or hyperpolarizing the BRNs is sufficient to phase shift the pacemaker. Interestingly, these treatments produce advances approximately 12h out of phase, suggesting that they are acting on different phase response curves. The results suggest that changes in BRN membrane potential play a critical role in the entrainment of the Bulla eye. NS-15264 to G.D.B.

332.2 CIRCADIAN PACEMAKER COUPLING IN BULLA: EFFERENT OPTIC NERVE IMPULSES INDUCE PHASE SHIFTS IN OCULAR PACEMAKER. G.D. Block, L.-H. Yen*, A.E. Lusakas*. Dept of Biology, University of Virginia, Charlottesville, VA. 22901.

The eyes of the molluac, Bulla, contain circadian pacemakers which are mutually coupled (Science 221:87). An analysis of the timing of interocular coupling signals indicates that phase shifts occur during the time that the contralateral eye spontaneously produces compound action potentials (CAPs- Neurosci. Abstr. 10:89.2). These impulses are conducted through the cerebral ganglion and generate epsps in basal retinal neurons- putative circadian pacemaker cells (Neurosci. Abstr. 10:89.3). The coincidence of ocular phase shifts and spontaneous impulse activity suggests that CAPs are the coupling signal. To test this hypothesis we attempted to phase shift the ocular rhythm with efferent optic nerve impulses generated either by electrically stimulating the optic nerve or by illuminating the contralateral eye.

For electrical stimulation eyes were removed from 12 animals and the optic nerve of one eye from each pair stimulated (1/10 Hz) for 2 hr beginning at CT 12 or CT 20. Intracellular recording experiments indicated that electrically evoked impulses generated epsps in basal retinal neurons. Optic nerve activity of stimulated and control eyes was then recorded in darkness for 48 hr and the phase difference between the two CAP rhythms measured on the second cycle. We found that stimulation at CT 12 generated a -0.8 hr mean phase delay (N=6) compared with the unstimulated control eye while stimulation at CT 20 induced a mean +0.8 hr advance (N=6).

Efferent impulses were also generated by illuminating the contralateral eye. Each eye and attached ganglia were placed in separate compartments of a "Y" dish in which slits were cut for the optic nerves. One compartment was illuminated with a miniature light guide while the seawater in the other eye compartment was made opaque with nigrosin dye. Control preparations consisting of detached eyes were placed in identical chambers. Two hr light pulses were delivered at CT 12. At the end of the light pulse both eyes were isolated and CAP activity recorded in darkness for 48 hr. We found a mean phase delay of -0.9hr (N=4) between pulsed and unpulsed detached eyes while the mean difference between attached eyes was only -0.1 hr (N=4).

These results suggest that efferent impulses phase shift the ocular pacemaker. While entrainment mechanisms are poorly understood, it appears that depolarization of basal retinal neurons is a critical step in the light entrainment pathway (McMahon & Block, this volume). Since spontaneous and induced efferent signals likewise depolarize basal retinal neurons, transmembrane potential may be similarly important in the coupling pathway. 332.3 FMRFAMIDE BLOCKADE OF OPTIC NERVE PACEMAKER ACTIVITY AND FMRFAMIDE IMMUNOREACTIVITY OF OPTIC NERVE EFFERENT FIBERS AND RETINAL NEUROPIL OF BULLA AND APLYSIA. Jon W. Jacklet. Neurobiology Research Center and Dept. Biology, SUNYA, Albany, NY 12222.

The amidated tetrapeptide FMRFamide isolated from molluscan ganglia functions to regulate the cardiovasular system and modulate activity of specific neurons. FMRFamide-like immunoreactivity of neurons is reported for animals from coelenterates to mammals, and a gene that encodes FMRFamide is identified in Aplysia neurons (Schaefer et al., Cell in press, 1985).

The isolated eyes of Bulla and Aplysia contain circadian pacemaker neurons, whose synchronized endogenous activity is recorded as compound action potentials (CAPs) from the optic nerve (ON) of isolated eyes. FMRFamide in Hepes buffered (pH 7.8) artificial sea water superfused over the eye reversibly blocks the CAPs. In Bulla (n=6) CAP frequency is reduced by 0.2 at 10 nM FMRFamide, by 0.5 at 100 nM and completely blocked at 1 μM. In Aplysia (n=8) CAP frequency is reduced by 0.3 at 1 μM and by 0.7 at 10 μM.

Immunocytochemistry using FMRFamide antisera obtained from Immuno Nuclear Corp. (antibody 72432) and rhodamine-labeled secondary antisera in a procedure similar to one used by Kistler et al. (J. Neuroscience 5:72-80, 1985), on sectioned Bulla neural tissue resulted in labeling of specific neurons in the cerebral and pedal ganglia. Fibers in the neuropil, interganglionic commissures and peripheral nerves were also labeled. About 10 efferent fibers (1 μm dia) in the ON were labeled. They extend to the retinal neuropil where they form a network of varicose endings. Some of them branch in the nerve and send terminal processes into the nerve sheath as well. Labeling was especially high in fibers within the neuropil adjacent to the circadian pacemaker neurons. In addition to the fibers, there are 2-3 small (< 10 μm) immunoreactive retinal neurons near the boundary between the photoreceptors and the pacemaker neurons.

In contrast only a few immunoreactive fibers were observed in the Aplysia retina, although there were immunoreactive neurons and fibers in the central ganglia. This correlates with the relative insensitivity of the Aplysia eye to FMRFamide. The high sensitivity of Bulla CAP activity to superfused FMRFamide and the intense FMRFamide-like immunoreactivity of the small intrinsic neurons and efferent fiber terminals in the neuropil adjacent to the circadian pacemaker neurons suggests a physiological role for FMRFamide release in control of the circadian pacemaker of Bulla.

332.4 VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) AND PEPTIDE HISTIDINE ISOLEUCINE (PHI) CO-LOCALIZE IN NEURONS OF THE RAT SUPRACHIASMATIC NUCLEUS (SCN). R.Y. Moore, J. Speh and J.P. Card. Dept. of Neurology and Neurobiology, SUNY-Stony Brook, NY 11794.

VIP is a 28 amino acid polypeptide which is contained within neurons of a number of functionally distinct systems in the central nervous system. We have demonstrated previously that the ventrolateral subdivision of the SCN contains a large number of VIP-immunoreactive neurons and receives dense and overlapping visual inputs from the retina and lateral geniculate complex (cf. Moore, '83 for review). Recently, Tatemoto and Mutt ('81) isolated and characterized a glucagon-secretin-like peptide, PHI. This 27 amino acid peptide exhibits extensive sequence homology with VIP and its distribution in rat brain is very similar to that of VIP (Beinfeld, '84). PHI-like peptides and VIP also appear to be produced from a common precursor (Itoh et al, '83) indicating that both peptides should be found in the same neurons.

The present study was undertaken to test this hypothesis and to further characterize the distribution of VIP neurons and their efferent projections in the rat hypothalamus. Antibodies to VIP and PHI were obtained commercially and the distribution of each peptide was analyzed immunohistochemically in serial coronal sections through the hypothalamus. The distribution of VIP- and PHI-like immunoreactivity is identical and analysis of serial adjacent sections indicates that both antisera are identifying the same neurons. Neurons exhibiting both VIP and PHI immunoreactivity are found in the medial preoptic area and the SCN. The distribution of immunoreactive neurons in the SCN is consistent with our previous observations on the localization of VIP in this nucleus (Card and Moore, '81). Scattered immunoreactive perikarya are present at the rostral and caudal poles of the SCN, but the majority of cells are located in the ventrolateral aspect of the nucleus at intermediate levels of the rostrocaudal axis. The densest concentration of immunoreactive fibers is found in the immediate vicinity of their cells of origin. However, immunoreactive axons also extend throughout the nucleus and into the immediately adjacent hypothalamus. A small group of fibers pass dorsally into the periventricular nucleus and course rostrally towards the organum vasculosum of the lamina terminalis. A second, larger group of immunoreactive fibers pass dorsally through the anterior hypothalamic area adjacent to the periventricular nucleus and terminate along the ventral border of the paraventricular hypothalamic nucleus. One component of this bundle continues caudally through the dorsal aspect of the periventricular nucleus and terminates at the level of the premammilary nuclei. These data demonstrate that VIP and PHI are co-localized in the hypothalamus and provide further information on the efferent projections of the SCN. Supported by NIH grants NS-16304 and NS-19714.

332.5 IMMUNOCYTOCHEMICAL LOCALIZATION OF NEUROPEPTIDE Y IN THE RAT SUPRACHIASMATIC NUCLEUS. J.P. Card and R.Y. Moore. Departments of Neurology and Neurobiology and Behavior, SUNY @ Stony Brook, Stony Brook, New York, 11794.

The suprachiasmatic nucleus (SCN) of the hypothalamus is the primary site in the central nervous system responsible for the generation and regulation of circadian rhythms. Several studies have shown that the SCN receives a projection from the lateral geniculate complex which exhibits neuropeptide Y (NPY)-like immunoreactivity. This projection arises from neurons in the intergeniculate leaflet and terminates selectively within the ventrolateral subdivision of the SCN. Microinjection of NPY in the area of the hamster SCN produces phase shifts in locomotor activity and the direction of the shift is dependent upon the time during the circadian cycle that NPY is administered (Albers & Ferris, 1984). These findings, together with the fact that the geniculate projection is virtually coextensive with the terminal field of retinal afferents, suggest a complex interaction of visual afferents in entraining the neuronal activity of SCN neurons to photic influences of the environment. In the present investigation we have utilized electron microscopic immunocytochemical localization of NPY to analyze the morphology and synaptology of the geniculohypothalamic projection upon the SCN. Consistent with previous light microscopic findings (Card and Moore, 1982; Moore et al., 1984), NPY was localized in varicose axons which are confined to the ventrolateral subdivision of the SCN. Ultrastructural analysis indicates that NPY is present in axon terminals which contain dense mitochondria and a mixed population of lucent, pleomorphic vesicles and small dense core vesicles. Peroxidase reaction product is present throughout labeled terminals but is most intense in the population of dense core vesicles. The dense core vesicles are concentrated at the peripheral border of the axon terminal and have never been observed in the vicinity of synaptic contacts. Immunoreactive terminals establish asymmetric synaptic contacts with distal dendrites and spines of SCN neurons. Other, unlabeled terminals synapse upon these same dendrites and although the source of these terminals has not been established, some of them exhibit distinctive morphology which has previously been associated with retinal afferents in the SCN (Güldner, 1978). These data demonstrate that NPY is contained within a morphologically distinct class of SCN afferents and that the terminals exert their effect on SCN neuronal activity via axo-dendritic synaptic contacts. This is similar to the synaptic organization of retinal afferents in the SCN and provides further information on the means through which visual input to the SCN is integrated in the control of circadian rhythmic phenomena. Supported by NIH grants NS-16304 and NS-19714.

332.6 **ANISOMYCIN, INJECTED EITHER PERIPHERALLY OR DIRECTLY INTO THE SUPRACHIASMATIC NUCLEUS (SCN), INDUCES PHASE SHIFTS IN THE CIRCADIAN RHYTHM OF LOCOMOTOR ACTIVITY OF HAMSTERS.** **S.T. Inouye, J.S. Takahashi and F.W. Turek. Dept. Neurobiology & Physiology, Northwestern University, Evanston, IL 60201.**

**In order to investigate the role of protein synthesis in the generation of circadian rhythms in mammals, we examined the effects of anisomycin, a potent protein synthesis inhibitor, on the circadian locomotor activity rhythm of hamsters. In one study, male hamsters maintained in LD 14:10 were transferred to constant darkness and two weeks later the animals were injected subcutaneously with 12 mg anisomycin in complete darkness at various circadian times. Peripheral injections of anisomycin induced phase-dependent phase shifts in the free-running rhythm of locomotor activity, while saline injections had no effect. Delays were produced when injections occurred between CT22 to CT4 (CT12=onset of activity) with a peak at CT0, while advances were produced following injections around CT9 to CT10. The phase response curve for anisomycin is different from that for light suggesting that these two agents produce phase shifts through different mechanisms. Cycloheximide (10 mg), another protein synthesis inhibitor, yielded a phase response curve similar to that for anisomycin. Alpha-methyl-p-tyrosine methyl ester (150 mg/kg, i.p.) and physostigmine (0.5mg/kg, i.p.) injections, which mimic two known side effects of anisomycin, had no effect on the locomotor activity rhythm. These results suggest that the effects of anisomycin are due to its inhibition of protein synthesis and not to inhibition of either catecholamine synthesis or acetylcholinesterase.**

**Because a likely site of action of anisomycin on the circadian system is the SCN region of the hypothalamus, we examined the effects of microinjecting anisomycin directly into the SCN on the activity rhythm. A microinjection guide assembly consisting of an outer guide tube (23G) and an inner stainless steel pin extending 1.0mm beyond the outer guide cannula was aimed at the SCN and implanted chronically using stereotaxic procedures. Animals were blinded by occular enucleation at the same time. For injections, an inner cannula (30G) connected to a microdrive with polyethylene tubing was placed in the guide cannula. After a stable free running rhythm of locomotor activity was established, anisomycin dissolved in saline (1ul) was injected into the SCN area at around CT0 (the phase at which peripheral injections produce the largest phase delay). Administration of 25ug anisomycin at CT0 induced phase delays if the tip of the cannula was located within 1mm of the SCN. Injections of 5 ug anisomycin induced phase delays if the site of injection was within approximately 0.5mm of the SCN. Taken together these results demonstrate that an inhibitor of protein synthesis perturbs a mammalian circadian system and that the site of action appears to be located in the suprachiasmatic region of the hypothalamus.**

332.7 ENTRAINMENT OF RAT CIRCADIAN RHYTHMS BY DAILY INJECTIONS OF MELATONIN: SYNCHRONIZATION IN CONSTANT LIGHT AND DEPENDENCE UPON THE SUPRACHIASMATIC NUCLEI. Vincent M. Cassone, Michael Chesworth* and Stuart M. Armstrong*. Department of Psychology, La Trobe University, Bundoora, Victoria, Australia 3083.

Although pinealectomy has little effect upon circadian rhythmicity among rodents, daily injections of the pineal hormone melatonin entrain free-running rats in constant darkness (Redman et al., 1983). This study investigated whether rats whose circadian rhythms were disrupted by (1) constant light (LL) or (2) lesions to the hypothalamic suprachiasmatic nuclei (SCN) could be synchronized by daily injections of melatonin. In the first set of experiments, rats were subjected to a paradigm of decreasing scotoperiod until they were unable to entrain, thereby free-running, becoming disrupted or arrhythmic in LL. After 3 weeks in LL, animals were injected every day with either 1 mg/kg melatonin (N=20) or saline-alcohol vehicle (N=10). While no effect of vehicle injections could be determined, melatonin injections entrained free-running rats and synchronized rhythmicity in those rats which became arrhythmic. In the second set of experiments, rats were entrained to an LD 12:12 cycle for 14 days before they either received bilateral lesions to the SCN (N=13) or sham-lesions to the area (N=4). All animals were allowed to recover for 2 weeks in LD before being placed in constant darkness (DD) for another 2 weeks. At 2 weeks, 1/2 of the rats received daily injections of 1 mg/kg melatonin and 1/2 received saline-alcohol vehicle for 60 days. Twelve of 13 lesioned rats became arrhythmic in DD, while no sham-lesioned rats showed long-term effects. Injections of melatonin entrained sham-lesioned rats and the 1 lesioned rat which received an incomplete lesion. Neither saline-alcohol vehicle nor melatonin injections had any effect on SCN-lesioned rats.

These data indicate that high doses of melatonin can synchronize components of activity in rats whose circadian rhythmicity had been disrupted by LL. These synchronizing and entraining effects of melatonin, moreover, appear to depend upon circadian oscillators within the SCN, suggesting that the SCN may be a site of melatonin's action in this experimental situation. Whether this reflects a physiological role for melatonin in circadian organization is as yet to be determined.

This research was supported by a La Trobe Research Fellowship to VMC while on leave from the Department of Neurology, S.U.N.Y @ Stony Brook, N.Y., U.S.A.

332.8 PHASE-SHIFTING EFFECT OF CARBACHOL ON THE CIRCADIAN ACTIVITY RHYTHM IN THE GOLDEN HAMSTER: DOSE-RESPONSE RELATIONSHIPS. Keith D. Anderson and Fred W. Turek. Dept. Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60201-3816.

Injection of the acetylcholine (ACh) agonist, carbachol, into the lateral ventricle of hamsters exposed to constant darkness (DD) mimics the phase-shifting effect of a light pulse on the freerunning circadian activity rhythm. The phase-response curve obtained for carbachol is similar to that for light pulses, and a daily carbachol injection can entrain the activity rhythm in a manner similar to a daily light pulse. As a basis for further studies on the role of ACh in mediating the effect of light on the circadian system, we investigated the relationship between the dose of carbachol injected and the magnitude of the resulting phase shift under different experimental conditions. A stainless steel cannula was stereotaxically implanted into the lateral ventricle of 3 groups of adult male hamsters exposed to 14 hr of light per day. Two groups were then transferred to DD and, 2 wk later, received 2 µl of a carbachol solution via the cannula at circadian time (CT) 22 or CT 14 (CT 12 = activity onset). One group was bilaterally enucleated and received carbachol at CT 22. Animals received an injection of a different concentration--between 0 and .03 molar--every 2 wk. Running-wheel activity was recorded throughout the study and plotted to determine the size of the phase shift induced by each injection. The table below shows the mean phase shift ± S.E.M., in hours, obtained at each dose. Injections at CT 22 induced phase advances and at CT 14 induced phase delays.

| | CONCENTRATION (moles/liter) | | | | | |
|---|---|---|---|---|---|---|
| | vehicle | .001 | .003 | .0056 | .01 | .03 |
| CT 22 | .2 ± .1 (N = 5) | .3 ± .1 (8) | .7 ± .2 (6) | 2.6 ± 1.0 (10) | 4.5 ± .5 (10) | 4.7 ± .8 (11) |
| CT 14 | | | .2 ± .1 (11) | .4 ± .1 (10) | .9 ± .2 (9) | |
| CT 22 (BL) | | | .1 ± .1 (9) | .1 ± .1 (9) | 1.0 ± .4 (8) | |

The magnitude of phase advance induced by a carbachol injection at CT 22 in hamsters exposed to DD appears to be dose-dependent, with a maximal response obtained at concentrations of .01 M or greater. However, the intermediate response obtained at .0056 M represents the mean of animals showing either a small or a large phase advance; only 2 of 10 animals actually showed an intermediate size phase advance. Although a complete dose-response curve for the other two groups has not yet been obtained, it appears that the magnitude of phase delay induced by carbachol at CT 14 is also dose-dependent, and that blind (BL) hamsters may be less sensitive to carbachol at CT 22 than sighted animals exposed to DD.

332.9 **DIAZEPAM BLOCKS LIGHT INDUCED PHASE ADVANCES OF THE CIRCADIAN LOCOMOTOR RHYTHM OF THE GOLDEN HAMSTER.** **M. R. Ralph and M. Menaker. Institute of Neuroscience, Dept. of Biol., University of Oregon, Eugene, OR 97403.**

**We have reported previously that light-induced phase delays but not phase advances of the circadian locomotor rhythm of hamsters can be blocked by the γ-aminobutyric acid (GABA) antagonist, bicuculline (Ralph and Menaker, 1985 Brain Res. 325:362). This suggested that GABA neurotransmission may be required for the processing of some, but not all light input to the clock. We have found that the benzodiazepine, diazepam, which can potentiate GABA transmission, blocks the effect of phase advancing light pulses on the hamster locomotor rhythm, but does not block the effect of phase delaying pulses.**

**Male golden hamsters (8-12 weeks of age), housed individually in running wheel cages in light tight boxes, were entrained to a 14:10 LD cycle for 7 days, and then released into constant darkness (DD). After 7 days in DD, each animal was given a 15 minute pulse of monochromatic light (515 nm; total fluence = 3.0 x $10^{14}$ photons·$cm^{-2}$·$sr^{-1}$) calculated to produce half maximal phase shifts at either phase advance (CT 18) or phase delay (CT 13.5) time points. At both time points, experimental animals received an i.p. injection of diazepam 30 minutes prior to the light pulse. Control animals received either saline or vehicle injections.**

**Diazepam blocked the effect of phase advancing light pulses (CT 18) but had no significant effect on phase delaying pulses (CT 13.5). The mean phase shifts induced by light in control groups were +1.02 ± .09 hr. and −.44 ± .10 hr. at CT 18 and CT 13.5, respectively. The blockade of light induced phase advances was dose dependent with an $ED_{50}$ of 7.5 mg/kg, and phase advances were completely blocked at doses above 12.5 mg/kg. Control injections of diazepam without light caused small phase delays (<0.2 hours), but these were not large enough to account for the reduction in the size of light-induced phase advances.**

**Taken together with the effects of bicuculline previously reported, these results suggest that GABA neurotransmission may be required for the processing of light-induced phase delays but may interfere with the processing of phase advances. Preliminary results indicate that bicuculline (2.5 mg/kg) may partly reverse the blocking effect of high doses (20 mg/kg) but not low doses (5 mg/kg) of diazepam. This raises the possibility that the effect of diazepam on phase advances may be mediated by more than one mechanism. Nonetheless, the data are consistent with the hypothesis that different neurochemical pathways may be involved in mediating light-induced phase advances and delays, and that GABA may be involved in one of those pathways.**

332.10 ULTRADIAN ACTIVITY RHYTHMS IN PREWEANLING RATS: ATTENUATED BY DESIPRAMINE BUT NOT ZIMELIDINE. Martin H. Teicher and Ross J. Baldessarini. Department of Psychiatry and Neuroscience Program, Harvard Medical School: Mailman Research Center, McLean Hospital, Belmont, MA 02178.

Richter (1927) first described 1-2 h activity rhythms in developing rats. These are maximal at 15 d and recede with maturation (Teicher & Flaum: Dev Psychobiol 12:411, 1979). Ultradian motility rhythms with 1-2 h periodicity also occur in human infants and in the young of most mammals. These rhythms can reemerge in adults under certain pathological conditions (in preparation). The present study acsertained if such rhythms are altered by antidepressants.

Developing rats reared in litters of 10-12 were studied at 15-16 d of age, after IP administration of desipramine (DMI) or zimelidine (ZMI), chosen as selective inhibitors of uptake of norepinephrine (NE) and serotonin (5HT), respectively. DMI was administered at 4 and 20 mg/kg, and ZMI given at equimolar doses (5.25 and 26.4 mg/kg). At 30 min after treatment, rats were placed alone in dark isolation chambers without food or water for 24 h. Activity was recorded continuously with a 6-channel, computer-interfaced electronic activity monitor, and individual activity scores were recorded on disks at 10 min intervals.

Time-series data were analyzed by low-resolution variance spectral analysis, as recommended by Kripke (Adv Sleep Res 1:374, 1974). This procedure yielded the percent of total spectral variance in harmonic bands from 0 to 72 cycles/day (cpd) at 1 cpd increments.

Saline-treated control rats (n=18) displayed a broad ultradian peak at about 7-15 cpd (31% of total spectral variance), as well as a moderate 1 cpd (circadian) peak (3.4% of variance). The low dose of DMI (n=9) diminished ultradian rhythmicity in the 9-16 cpd band (35% mean reduction, p<.0001) and enhanced the circadian peak by 39% (p<.05); the high dose diminished ultradian rhythmicity at 8-17 cpd even more, by 40% (p<.0001) and enhanced the circadian peak greatly (180%, p<.001). ZMI (n=6), in contrast, had only small and inconsistent effects on ultradian rhythmicity and tended to reduce the circadian component.

These results suggest that the balance between circadian and ultradian modulation of activity can be shifted by some antidepressants in a direction found with normal maturation. The selective NE-enhancer, DMI, increased circadian cyclicity at the expense of ultradian rhythms in young rats in a dose-dependent manner, while the 5HT-uptake inhibitor ZMI did not share this effect and may have had opposite actions to reduce circadian rhythmicity.

333.1 **Ontogeny of Thyrotropin-releasing hormone (TRH) metabolism in human cerebrospinal fluid (CSF).** **J.K. Rao*, E. Ponte *, A. Lopez*, A. Jayaraman and C. Prasad.** Departments of Medicine, Pediatrics, and Neurology, Louisiana State University Medical Center, New Orleans, La. 70112.

In tissue extracts, TRH is metabolized by two separate pathways, one intiated by an amidase (forming acid TRH, pGlu-His-Pro) and the other by pyroglutamate aminopeptidase (pGlu-peptidase). Cyclo (His-Pro), the product of the second pathway, has been shown to exhibit a variety of biologic activities in both man and animals. We have recently shown that TRH metabolism in human CSF is almost exclusively catalyzed by pGlu-peptidase. Since CSF is in constant exchange with the brain extracellular fluids, studies on the ontogeny of TRH metabolism in CSF might give insight into the functions of TRH in the brain.

[$^3$H-Pro]-TRH (20µM, 0.1µCi)was incubated at 37°C for 15, 30, 45 and 60 min. and the rates of synthesis of radioactive proline, acid TRH, and cyclo (His-Pro) was determined. Both amidase and pGlu-peptidase pathway activities were calculated by the rates of Pro + acid TRH and cyclo(His-Pro) formation respectively. The data presented below show that in CSF, TRH is exclusively metabolized via pGlu-peptidase pathway and the activity of this pathway in CSF from pre-term and newborn babies is considerabley lower($p<0.01$) than in adults.

| ONTOGENETIC STAGE | pmol / min / ml of CSF | |
|---|---|---|
| | pGlu-peptidase | amidase |
| Pre-term (29-36wks) | 2.29 ± 0.68(12) | < 1.0 (12) |
| Newborn (0-8days) | 4.05 ± 2.51 (8) | < 1.0 (8) |
| Adult (20-40years) | 19.20 ± 1.67 (7) | 1.02 ± 0.20(7) |

The observed low levels of pGlu-peptidase activity in pediatric CSF was not due to presence of enzyme inhibitors because, i) the enzyme activity did not increase following concentration by salt precipitation and dialysis (undialyzed: 2.62±1.02, n=5; dialized: 1.54 ± 0.47 pmol/min/ml, n=5; $p>0.2$), ii) the addition of increasing amounts of pediatric CSF in assay mixture did not affect the enzyme activity. Conclusions: 1) pGlu-peptidase is the major pathway of TRH metabolism in human CSF. 2) Very low activity of pGlu-peptidase in CSF from pre-term and newborn babies suggests a unique developmental role of this enzyme in brain TRH function(s).

333.2 ONTOGENY OF HYPOTHALAMIC CATECHOL AND INDOLEAMINES AS MEASURED BY HPLC. O. Khorram*, T.H. Le*, S.M. McCann, L. Krulich* (SPON: J. Lipton) Dept. of Physiology, Univ of Tex Hlth Sci Ctr, Dallas, TX.

The hypothalamic content of norepinephrine (NE), dopamine (DA), 5-hydroxyindoleacetic acid (5HIAA), 5-hydroxytryptamine (5HT), and 5-hydroxytryptophan (5HTP) were measured in rats starting on day 17 of prenatal life and continuing until day 34 of postnatal period. The amines were measured by HPLC with electrochemical detection. Prenatally, there was a steady increase in the NE levels reaching peak levels just prior to delivery. This increase was followed by a decline on the day of birth. Postnatally NE levels increased progressively with age, not reaching adult levels as late as day 34. Starting on day 20 of postnatal period a sex difference in NE levels was found with females having significantly higher levels than males. This sex difference was evident as late as day 34. Hypothalamic DA levels were low and showed no significant changes prenatally. The first increase in the levels of DA was seen on day 5. 20 day old females had significantly higher DA levels as compared to males. This sex difference was not evident on later days. α-methyl-p-tyrosine (α-MT)(150 mg/kg, i.p.) had no effect on NE levels in 10 day old rats, whereas it induced a significant decline in DA levels. The same results were obtained in 15 day old animals using a higher dose (200 mg) of α-MT, except that a slight decrease in NE levels was found 2 hours after the drug injection.

5-HT levels increased progressively pre and postnatally. 20 and 24 day old rats had higher 5-HT levels than males. High concentrations of 5-HIAA were measurable in fetal hypothalami with major increases before delivery, and on the day of birth. Postnatally no major changes in 5-HIAA levels were found, although 20 and 24 day old females had higher levels of 5-HIAA as compared to males. Contrary to the adult rat which has no detectable levels of 5-HTP, this indoleamine metabolite could be detected as early as day 17 of fetal period. 5-HTP concentrations peaked just prior to delivery and showed no significant changes postnatally. Injection of m-hydroxybenzyl hydrazine (100 mg/kg, i.p.) produced a significant increase in the levels of 5-HT and 5-HIAA in 15 day old rats, suggesting a high turnover of indoleamines is present early on in life.

Unknown peaks not corresponding to any known amine metabolite and absent from adult hypothalmi were found in both the fetal and postnatal period. Further investigation of amine metabolism during development and identification of these unknown peaks will be valuable in understanding hypothalamic regulation of pituitary function. Supported by NIH grants HD 09988, HD-07062.

333.3 **NEUROTRANSMITTER SYNTHESIS, STORAGE, AND TURNOVER IN NEONATALLY DEAFFERENTED SYMPATHETIC NEURONS.** A.J. Smolen and P. Beaston-Wimmer*. Dept. of Anatomy, Med. Coll. of Pa./E.P.P.I. Division, Philadelphia, PA. 19129.

Transsynaptic influences are thought to play a critical role in the developmental regulation of the expression of neurotransmitter related characteristics. In the superior cervical sympathetic ganglion (SCG) of rodents, tyrosine hydroxylase (TH), the rate limiting enzyme in catecholamine biosynthesis, undergoes a normal postnatal increase in activity, and this increase in activity fails to occur when the afferent input to the neurons of the SCG is removed at the time of birth. It is clear that the metabolism of neurotransmitter in a neuron does not depend solely on the activity of the synthetic machinery. Other factors which must be considered include the rate of release of the transmitter from the nerve terminals, the rate of reuptake, and the rate of degradation of transmitter within the cell. In the present study, we have begun to examine the metabolism of NE in sympathetic neurons and its regulation by transsynaptic influences by measuring the content and turnover of NE in SCG neurons. NE content was measured using high performance liquid chromatography with electrochemical detection, and the turnover of NE was determined by measuring NE content 3 hours after treatment with alpha-methyl- paratyrosine, which inhibits TH activity. NE content in the SCG underwent an 8 fold increase from the time of birth, and stabilized at adult levels at one month. Following neonatal deafferentation, there was a temporary stunting of NE accumulation. When regeneration of the afferents was permitted, there was a permanent reduction in TH activity, although the amount of NE increased to normal levels. Turnover of NE also reached normal levels. When regeneration of the afferents was prevented, TH activity was again permanently reduced, while the amount of stored NE increased to 70% of control levels. In this case, turnover of NE was significantly reduced. We conclude that the normal turnover of NE following reinnervation is most likely due to a return of synaptic activity impinging on the SCG neurons and a return of release of neurotransmitter from the nerve endings of these cells. These data suggest that there is a critical period during the first several postnatal weeks when afferent influences must be present in order for TH to undergo its normal increase in activity. By contrast, the amount of NE stored by sympathetic neurons and the rate of turnover of NE is not subject to the same critical period as is TH, but appears to be dependent on the activity of the neuron.

333.4 GLUCOCORTICOIDS AFFECT PROLIFERATION OF SMALL INTENSELY FLUORESCENT (SIF) CELLS IN SUPERIOR CERVICAL GANGLION (SCG). M.C. Bohn, Dept. of Neurobiology and Behavior, State University of New York, Stony Brook, New York 11794.

Dexamethasone (DEX) treatment of newborn rats increases the number of SIF cells in the SCG. These calls can be visualized by their intense catecholamine fluorescence and staining for tyrosine hydroxylase immunoreactivity (TH-IR). In addition, many SIF cells are stained for phenylethanolamine N-methyltransferase (PNMT) in DEX treated rats, but not in normal rats. Previous studies have shown that SIF cell responses to DEX are limited to the first postnatal week. The processes leading to an increased SIF cell number following DEX and loss of SIF cell responsiveness are presently unknown. This study was undertaken to determine whether SIF cell precursors are dividing in the postnatal rat and, if so, how DEX affects proliferation of these cells.

To determine whether division normally occurs in SIF cell precursors postnatally, rats were sacrificed two hours after an injection of 3H-thymidine (3H-T) on postnatal days 0,2,5,7,10,14 or 20. SCG sections were stained for TH-IR and processed for autoradiography. Many SIF-like cells were covered with silver grains in rats receiving 3H-T during the first postnatal week, but not thereafter.

The effect of DEX on SIF cell division was determined similarly by comparing the labeling index of SIF cells on postnatal day 6 in control and DEX (0.1µg/g; days 0-5) treated rats injected with 3H-T on days 0,2,4 or 6. The labeling index was markedly depressed in the DEX treated group even though many more SIF cells were observed. Labeled PNMT-IR cells were also observed.

These observations suggest that SIF cells are being generated during the first postnatal week in rat and that high levels of catecholamine phenotypic characters are present in dividing precursor cells. They also suggest that DEX inhibits proliferation of these precursors. Consequently, glucocorticoids appear to enhance the level of catecholamine characters in pre-existing cells, rather than stimulate proliferation of SIF cell precursors.

333.5 GLUCOCORTICOID HORMONE EFFECTS ON TRANSIENTLY CATECHOLAMINERGIC CELLS OF EMBRYONIC RAT INTESTINE STUDIED IN VIVO AND IN VITRO. G. Miller Jonakait and I.B. Black, Division of Developmental Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

Cells which transiently express catecholaminergic characteristics have been described in the embryonic rat intestine. Cells displaying immunoreactivity to tyrosine hydroxylase (T-OH) and formaldehyde-induced fluorescence (FIF) appear at 11.5 days of gestation (E11.5), but are no longer detected after E14. However, treatment of pregnant rats with reserpine on E11.5 results in 1) increased T-OH enzymatic activity in 13.5-day guts and 2) prolonged expression of T-OH and FIF in fetal gut perikarya (Jonakait et al., 1982). This paradoxical action of reserpine is probably mediated via maternal glucocorticoid hormones (GCH) since 1) maternal cortisol treatment mimics the effect of reserpine and 2) compromise of the maternal adrenal cortex with mitotane diminishes the effect of reserpine treatment. We now report that maternal drug regimens designed to suppress reserpine-induced increases in plasma GCH also block the reserpine-induced increases in fetal enteric T-OH activity. Thus, treatment of pregnant rats with either the synthetic GCH dexamethasone (dex; .1 mg/kg) or pargyline (25 mg/kg) 1 or 2 days prior to reserpine treatment blocked increased plasma GCH and also resulted in normal T-OH activity in E13.5 guts. These data confirm that the effects of reserpine on the fetal intestine involve increases in maternal GCH.

To determine whether GCH affect noradrenergic traits other than T-OH and FIF, we measured the high-affinity uptake of $^{3}$H-norepinephrine into T-OH-positive cells of the intestine at E13.5 (Jonakait, et al., 1985), but found it to be normal following reserpine treatment. This finding suggests that different characters of the noradrenergic phenotype are, in this instance, regulated differently.

We sought next to examine the site of GCH action. Dex, administered into the fetal environment via a transuterine injection at E11.5, had no demonstrable effect on T-OH activity measured at E13.5. However, to eliminate the possible confounding effects of placenta and fetus, we grew isolated E12.5 intestines in organotypic tissue culture. The medium contained Eagles' Minimum Essential Medium and 15% rat serum taken either from normal or adrenalectomized female rats. Growth in adrenalectomized rat serum or in medium supplemented by dex, cortisol, corticosterone, or cortexolone (0.1-10 uM) had no effect on T-OH activity measured after 4 days in vitro. Therefore, while the action of reserpine cannot occur without maternal GCH elevation, other factors or processes may be necessary for steroid action at the level of the fetal intestine. (Supported by NIH grant NS 17814).

333.6 DEPOLARIZING SIGNALS INCREASE TYROSINE HYDROXYLASE DEVELOPMENT IN CULTURED MOUSE SUBSTANTIA NIGRA. W.J. Friedman, C.F. Dreyfus, B.S. McEwen and I.B. Black. Rockefeller Univ. and Cornell Univ. Med. Coll., N.Y., N.Y. 10021.

While extracellular signals are well known to regulate neurotransmitter development in the peripheral nervous system, factors governing brain development remain to be characterized. Development of the dopaminergic phenotype in the mouse substantia nigra (SN) was studied by monitoring tyrosine hydroxylase (TH). This enzyme catalyzes the initial, and rate-limiting, step in catecholamine biosynthesis. Ventral mesencephalic explants were dissected from E15 mouse embryos and maintained in culture for one week. To define the effect of depolarizing influences on central neurons, cultures were grown with the pharmacologic depolarizing agent veratridine. This treatment elicited a significant increase in development of TH activity. Since the nigra receives an excitatory substance P innervation from the striatum, the effect of a stable analogue of the peptide (pGlu$^{5}$,MePhe$^{8}$,Sar$^{9}$) was examined. The presynaptic agonist elicited a significant increase in TH activity, reproducing the effects of pharmacologic stimulation.

To determine whether the rise in TH catalytic activity evoked by veratridine and substance P reflected elevation of enzyme protein, Western transfer analysis was employed. Immunoblots probed with anti-TH antiserum and analyzed densitometrically exhibited increased amounts of enzyme protein.

Our observations indicate that depolarization with a pharmacologic agent or with a presynaptic agonist elicit increased TH activity as well as enzyme molecule number. Studies are in progress to investigate underlying molecular genetic mechanisms governing these phenomena. Mellon Fdn. )

333.7 EXTRACELLULAR FACTORS REGULATE NEUROTRANSMITTER PLASTICITY IN MATURE SYMPATHETIC NEURONS. D.R. Kornack, J.E. Adler AND I.B. Black. Div. of Developmental Neurology, Cornell Univ. Med.Coll., New York, NY 10021.

Abundant evidence suggests that developing neurons are remarkably plastic, altering transmitter phenotypic expression in response to extracellular stimuli. To determine whether transmitter plasticity persists during maturity, we have examined mutability of peptidergic and catecholaminergic transmitter traits in adult rat superior cervical ganglia in vivo and in vitro.

Ganglionic decentralization (denervation) in adults increased substance P (SP) 4-fold in vivo. To examine mechanisms underlying this increase, adult ganglia were explanted to culture in the absence of added nerve growth factor (NGF). Explantation resulted in a 4-fold rise of SP in vitro, reproducing the results obtained in vivo. Veratridine prevented the increase in cultured adult ganglia, while tetrodotoxin blocked the veratridine effect, suggesting that membrane depolarization and sodium influx normally suppress SP content in mature ganglia, as in neonatal ganglia. Since NGF is well-known to govern sympathetic development, we examined the response of adult explants to the trophic agent. NGF exposure increased SP 15-fold in adult ganglia, suggesting that transmitter metabolism in mature sympathetic neurons remains responsive to the trophic protein. To determine whether peptidergic and catecholaminergic transmitter traits are differentially regulated in mature ganglia as in developing ganglia, we examined the activity of tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine biosynthesis. Explantation did not increase TH activity in adult ganglia, reproducing results previously obtained in the neonate.

Our observations suggest that remarkable plasticity persists in mature neurons in vivo and in culture. Further, adult sympathetic neurons remain responsive to NGF in vitro. Finally, mature neurons differentially regulate different transmitter phenotypic traits. (Supported by NIH Grants NS 10259, HD 12108 and aided by a Grant from the Hereditary Disease Foundation).

333.8 DEPOLARIZATION AND CALCIUM IONS REGULATE THE LEVEL OF ADRENAL PREPROENKEPHALIN mRNA. E.F. LaGamma, J.D. White, J.E. Adler, J.E. Krause, J.F. McKelvy, and I.B. Black. Cornell Univ. Med. Coll., N.Y. 10021 and SUNY, Stony Brook, N.Y. 11794.

To begin defining the molecular processes through which extracellular signals regulate co-localized transmitters, rat adrenal medullae were grown in explant culture. The (now denervated) explanted medullae exhibited a 10-fold increase in leucine-enkephalin (LEU) after 3 days in culture. Inhibition of protein synthesis with cycloheximide completely blocked the rise, whereas, inhibition of RNA synthesis with actinomycin-D, α-amanitin, or camptothecin inhibited the increase by 50%. To determine whether the rise in LEU was associated with an increase in specific mRNA coding for the opiate peptide precursor, northern blot analysis was performed using a $^{32}$P nick-translated cDNA probe complementary to human pheochromocytoma preproenkephalin mRNA (generosity of Dr. E. Herbert). A single species of preproenkephalin mRNA was detected after varying culture periods. The mRNA increased 34-fold after 2 days in culture and 74-fold after 4 days. Consequently, the rise in mRNA preceded the increase in LEU. Depolarization with either elevated potassium or veratridine, which prevents LEU accumulation, inhibited the increase in preproenkephalin mRNA as well. Moreover, the effect of veratridine was blocked by tetrodotoxin, suggesting that trans-membrane sodium ion influx affects elaboration of the message. To determine whether the depolarization effect was calcium ion-dependent, medullae were depolarized in the presence of EGTA or in the presence of a calcium ion "channel" blocker (D600). Inhibition of $Ca^{2+}$ influx prevented the effects of KCl-induced depolarization on LEU. Increasing intracellular $Ca^{2+}$ with the ionophore A23187, in the absence of depolarizing agents, reproduced the effects of depolarization, inhibiting the rise in LEU. Our studies suggest that depolarization, $Na^{+}$ and $Ca^{2+}$ influx affect levels of preproenkephalin mRNA. Further, in conjunction with the metabolic inhibitor data, our observations suggest that extracellular signals causing depolarization may alter gene read out. The effects of $Ca^{2+}$ on preproenkephalin mRNA is presently under investigation. (Supported by NIH Grants HL 00756, NS 10259, HD 12108 and NSF-BNS 8111475, NS 20372.

334.1 GENESIS OF CONCURRENT ASYNCHRONOUS PERIODIC RESPIRATORY PATTERNS. G.P. Moore and D. Hary*. Biomedical Engineering, University of Southern California, Los Angeles, California 90089-1451.

Under special circumstances, it is possible to induce a human subject to generate multiple, concurrent, asynchronous, periodic breathing patterns. Subjects were fitted with a face mask, allowing continuous recording of inspiratory and expiratory airflows and pressures. While testing the respiratory patterns of subjects who were instructed to breathe in synchrony with a visual pacing signal (whose rate, and inspiratory/expiratory duty cycle could be independently adjusted), we accidently discovered that after the subject successfully synchronizes for several minutes with the pacing signal, the parameters of that signal can be altered in such a way that, while he consciously follows the new pattern of the pacing signal, he may also unknowingly continue to breathe, concurrently, as if the previous pacing signal pattern were still present. Over a period of several minutes the subject continues to generate, although at a reduced amplitude, the periodic pattern of flow and pressure previously employed, while also generating a pressure-flow pattern conforming to the timing constraint of the new pacing signal. The initial, mutually asynchronous patterns eventually achieve an alternating phase-locked relationship, the previous pattern gradually shifting its timing to match the period of the current pacing signal. During the transition period, the onset-times of inspiration for the two generators may coincide. Yet, thereafter, the two patterns re-emerge and continue without interruption. When the onset-time of inspiration of one generator cycle drifts into the expiratory phase of the other generator cycle, monitored EMG signals of respiratory muscles show that the inspiratory generator immediately increases its output to compensate for, and effectively override, the expiratory effect of the other generator. This latter observation implies that a human can not only generate independent, concurrent respiratory patterns, but that these generators may ultimately compete at the level of the final common pathway. The flow and pressure patterns clearly indicate that, under these circumstances, what we might otherwise reasonably define as inspiration and expiration can occur simultaneously.

334.2 PHRENIC NERVE PERIODICITIES IN NEONATAL SWINE. H.L. Cohen, P.M. Gootman, A.M. Steele*, M.R. Gandhi*, L.P. Eberle* and P.P. Rao*. Dept of Physiology, Downstate Medical Center, SUNY, Brooklyn, N.Y. 11203 and Schneider Children's Hospital of Long Island Jewish-Medical Center, New Hyde Park, New York 11042.

Power spectral analyses of efferent phrenic (PHR) nerve discharge were used to assess maturational changes in the central respiratory oscillator of neonatal swine. Piglets from < 1 day to 39 days were anesthetized with Althesin ( 4 mg/kg/hr), immobilized with C10 (decamethonium Br), maintained on 100% 02 and artificially ventilated. Monophasic recordings were made on magnetic tape of left and/or right PHR activity (bandpass 3-10k Hz), integrated PHR activity, intratracheal pressure (ITP), blood pressure, EKG and markers indicating phases of the artificial ventilatory cycle. Power spectral analyses were performed on a PDP 11/45 computer. Sampling was triggered during inspiration (I = onset of PHR burst). Power spectral densities of PHR activity were investigated at a sampling interval of 244 μsec and 1024-2048 points/breath using the Fast Fourier Transform (FFT). Typically, two 1024 data points FFTs were computed per 500 msec epoch. The Nyquist foldover rate determined the low pass filter setting of 1 kHz. Average power was computed from 100-200 epochs sampled during I. Hanning windows were applied to reduce side lobe leakage. Results were plotted as average power per frequency interval (2 Hz). Examination of the power spectral peaks indicated that predominant activity occurred in two frequency bands: 1) a low frequency discharge from 15-35 Hz, which appeared to occur more frequently in younger piglets (< 2 weeks of age) apparently modulating a higher frequency discharge and 2) the higher frequency discharge, which ranged from 100-150 Hz and was an increasing function of age ($r = .88$). Two predominant peaks have also been reported for adult cats (Richardson, C.A. & Mitchell, R.A., Brain Res., 233: 317, 1982). Furthermore, we found that vagotomy did not produce a shift in peak power at the higher frequencies. Our results indicate that power spectral peaks in the range of 100-150 Hz can be used to monitor maturation of the central respiratory oscillator.

334.3 A PROJECTION FROM A DISCRETELY LOCALIZED CELL GROUP NEAR THE VENTRAL SURFACE OF THE ROSTRAL MEDULLA TO THE VENTRAL RESPIRATORY GROUP (VRG) IN THE CAT. H.H. Ellenberger*, J.C. Smith*, D.R. McCrimmon* and J.L. Feldman. (SPON: A. Gibson) Department of Physiology, Northwestern University , Chicago, IL 60611.

Neurons with somas in the VRG of the cat medulla provide the respiratory drive to phrenic motoneurons. The source of the phasic respiratory activity of VRG neurons has yet to be determined. It is possible that phasic inputs from a neural oscillator and inputs from central chemoreceptive structures arise from outside the VRG. To investigate these possibilities, projections to the VRG were examined using 1% wheat germ agglutinin conjugated horseradish peroxidase (HRP) as a retrograde tracer. Tissue was processed with a sensitive reaction using tetramethyl benzidine as the chromagen (Gibson et al, Brain Res., 298: 235, 1984). Pressure injections of (8-20nl) HRP solutions were made using a glass pipette fitted with a silver wire so that single-unit activity could be recorded prior to injection. Injections were centered within regions of phasic inspiratory cell activity in the VRG. In addition to observing projections described previously (Bystrzycka,Brain Res., 185: 59,1980), a novel projection to the VRG was identified. This group of cells is located near the rostral medullary ventral surface near the caudal end of the trapezoid nucleus. The cells of this compact group, termed here the retrotrapezoid nucleus (RTN) have small (~20um diameter), mostly fusiform somas positioned 200-300um deep to the ventral surface and about 3.5mm lateral to the midline. The rostrocaudal length of RTN is about 1.5mm. The RTN begins caudally as a small cluster of cells below the ventromedial tip of the most caudal portion of the facial nucleus, immediately ventrolateral to the nucleus paragigantocellularis lateralis. Further rostrally, cells of the RTN increase in number as the nucleus broadens in the lateral dimension beneath the facial nucleus. Rostrally, the RTN is bounded by the preolivary nucleus. The RTN projection to the region of the VRG appears to be exclusively ipsilateral. A respiratory function for the RTN remains speculative. Its superficial position in the rostral medulla suggests that these cells may be important in central chemosensitivity, perhaps providing the link between central chemosensitive structures and the inspiratory cells of the VRG. The RTN appears to lie in the rostral portion of the "intermediate chemosensitive area" of the ventral medullary surface, where cold block produces apnea in vagotomized cats (von Euler et al, in: Neurogenesis of Central Respiratory Rhythm,45,1985). An RTN projection to neurons in the VRG could mediate the effects of this chemosensitive region on phrenic nerve activity. Supported by NIH HL-23820 & T32-NS07243.

334.4 EFFECT OF NALOXONE ON THE CENTRAL RESPIRATORY CHEMOSENSITIVE ZONES OF THE CAT. J. A. Whittaker, D. G. Bernard, P. W. Archer, C. O. Trouth., Department of Physiology & Biophysics, Howard University, Washington, D. C. 20059.

Three chemosensitive zones on the ventrolateral surface of the medulla oblongata (VMS) are involved in the central chemical $CO_2$ regulation of respiration; a rostral, and intermediate and a caudal; the caudal area being the most sensitive to chemical and electrical stimulation. In spontaneously breathing cats anesthetized with alpha-chloralose (60 mg/kg), neuron in the caudal area were electrophysiologically tested for their responsiveness to topically applied acetylcholine (ACh), morphine, and naloxone, as well as to pH changes (7.4 - control, 7.0 - acid; 7.8 alkaline) following superfusion with mock cerebrospinal fluid (CSF). Topical application was by means of filter paper pledgets (1 mm $^2$) soaked in the test drugs that were prepared in mock cerebrospinal fluid (CSF) at pH 7.4. Units were also tested for their responsiveness to other modalities of sensation such as touch, pressure, joint manipulation and temperature. Non-phasic pH sensitive units increased their firing rate in response to increased inspired $CO_2$ (5% and 7%), CSF-pH 7.0, topical application of ACh (10 mg%) and the opiate antagonist naloxone (2 mg%). CSF-pH 7.8 and morphine (2 mg%) decreased neuronal firing rate from 23 to 6 Hz. Tidal volume and respiratory frequency which were recorded spirometrically in 3 cats also decreased following topical morphine application and/or superfusion with alkaline CSF. 2 mg% naloxone reversed the effects of alkaline (pH 7.8) superfusion as well as topical morphine application. Naloxone potentiated the effects of increased inspired $CO_2$ as well as topically applied ACh and acid superfusion (pH 7.1) causing marked increases in firing rate.

It appears that the endogenous opioids are involved in modulation or fine-tuning of the neuronal activity of non-phasic-pH sensitive neurons in the caudal chemosensitive areas of the cat.
Support: NIH - training grant 52 T 32 GM 07800 and NIH-MBRS Grant 2 S06RR08016.

334.5 ANTICHOLINESTERASE TOXICITY AT CENTRAL RESPIRATORY CHEMOSENSITIVE AREAS REDUCED BY OPIATE ANTAGONIST: P.W. Archer, R.M. Millis, J.A. Whittaker, D.G. Bernard, C.O. Trouth, Dept. Physiology & Biophysics College of Medicine, Howard Univ., Washington, D.C. 20059

Central respiratory chemosensitivity has been ascribed to neurons located within the marginal glia in caudal (Area L) and rostral (Area M) zones on the ventral medullary surface (VMS). In the present study the respiratory effects of cholinomimetics and opiates applied topically to the caudal area was investigated in cats anesthetized with α-chloralose (60 mg/kg). The drugs were topically applied by means of filter paper pledgets (1mm$^2$) soaked in the test drugs that were prepared in mock cerebrospinal fluid (CSF) at pH 7.4.Low concentrations of Acetylcholine (ACh) 2-8 mg% had no significant respiratory or cardiovascular effect. Graded increases in tidal volume (VT) and respiratory frequency (f) were observed at higher concentrations (8-25 mg%) however without cardiovascular effects.Nicotine (2-200 mg%) applied topically produced significant ($p<0.001$) increases in VT and f whereas mean arterial blood pressure (MABP) decreased significantly. Intravenous injections of Nicotine (200 mg) caused increases in VT, f and MABP. Physostigmine (2-20 mg%) potentiated the effects of ACh on respiration in dose-dependent manner, without cardiovascular effects. Larger concentrations of physostigmine (>25 mg%) produced systemic hypertension and tachycardia followed by apnea and hypotension. The cardiovascular effects of physostigmine were antagonized by atropine sulfate (AS) without affecting respiration. 8-25 mg% AS raised MABP and heart rate to control levels but apnea persisted. The opiate antagonist Naloxone (2-8 mg%) which caused marked increases in VT and f in spontaneously breathing cats, reversed the physostigmine induced apnea when topically applied. Morphine sulfate (2-20 mg%) at low concentrations decreased VT and f without significant vasomotor effects, however, at higher concentrations it caused apnea hypotension and bradycardia. Naloxone reversed the morphine induced respiratory depression and/or apnea whereas physostigmine at low doses (2-20 mg%) potentiated the respiratory effects of morphine.

Conclusion 1) Since acetylcholinesterase hydrolyzes not only ACh but also some Peptides - among them the endogenous opiates (EO)[1] it appears that the effect of topically applied physostigmine to the chemosensitive structures on the VMS may be partly due to its action on the EO system at this site. A modulatory role of the endogenous opiate system in the central chemosensitive drive to respiration is postulated. 2) The opiate antagonist Naloxone reduces the respiratory effects of reversible anticholinesterase toxicity of the central respiratory chemosensory apparatus.

334.6 INDUCED TRANSIENT HYPERTENSION INHIBITS LARYNGEAL ABDUCTOR ACTIVITY IN THE DRUG-FREE CAT. J.D. Marks, R.C. Frysinger, and R.M. Harper. Brain Research Institute and Department of Anatomy, UCLA, Los Angeles, CA 90024.

Cardiovascular dynamics affect diaphragmatic and upper airway muscle activity. Transient hypertension following pressor agent infusion is accompanied by decreases in respiratory rate and in peak integrated diaphragmatic EMG. Under anesthesia, the suppression of phasic respiratory activity is greater in certain upper airway muscles (e.g., genioglossus) over the diaphragm. We examined how transient hypertension affects the laryngeal abductors of the upper airway in the drug-free cat.
